The signal S occupies active timeslots along horizontal scan lines and is bordered by horizontal and vertical blanking signals as shown in Figs. 21.1.14, 21.1.16, and 21.1.17 which also show the timing signals: horizontal and vertical sync pulses as well as the color subcarrier burst. Video signal levels in NTSC are specified in IRE units. The peak of the sync pulses is at -40 IRE, the blanking level at 0 IRE, and the reference white level at 100 IRE. The black level “setup” is at +7.5 IRE. Figure 21.1.14 includes a table with specification of durations, levels, and tolerances for NTSC and most PAL standards. Figure 21.1.14 also shows that the composite signal “inversely” modulates the main carrier of a broadcast transmitter with zero carrier (0 percent) at the whiter-than-white level of 120 IRE and 75 percent at blanking level and 100 percent at -40 IRE (peak of sync).

Table 21.1.7 shows that the peak composite signal $Y' + C$ for saturated yellow, cyan, and green would exceed reference white level and overmodulate a broadcast transmitter. Similarly the lower level $Y' - C$ would drop significantly below blanking level, which may cause sync problems. To transmit the composite signal S within tolerable limits it must be reduced to $g_s S$, where g_s is a gain factor <1:

$$\text{NTSC video signal} = 7.5 + g_s \times 92.5 \times [Y' + C \sin(\omega_c t + c)] \quad \text{IRE units.} \tag{28}$$

In NTSC and PAL/BG the color bar signal as broadcast is at 75 percent amplitude ($g_s = 0.75$).

	NTSC	PAL/BDGHI
H	63.555 μ s	64 μ s
HBI	10.9 \pm .2 μ s	12 \pm .3 μ s
Sync pulse	4.7 \pm .2 μ s	4.7 \pm .2 μ s
Front porch	1.75 \pm .48 μ s	1.5 \pm .3* μ s
Burst	9 \pm 1 f_c -cycles	10 \pm 1 f_c -cycles
Burst level	40 IRE peak-peak	0.3 Volts peak-peak
Black level	7.5 \pm 2.5 IRE	.01 \pm .01 Volts ⁺

*1.65 \pm 0.1 in PAL/I.

+ In PAL 100 IRE = 0.7 Volts. Sync pulse is 0.3 Volts and modulation levels at white reference level are 10 percent in BDG and 20 percent in I.

FIGURE 21.1.14 Signal levels along a horizontal line in NTSC. Levels are shown in IRE video level units and in r.f. modulation levels. NTSC and PAL specifications are shown in the table. Modulation is negative in the sense that the white reference level is at a low carrier level and peak of sync is at peak r.f. power level.

Figure 21.1.16 shows a horizontal line signal in NTSC with color bars at 75 percent. The peak signal just about touches the 100 IRE white reference level, but drops to -16 IRE in blue and red (peak of sync is at -40 IRE). The figure also shows the vector diagram (vector scope) of the chrominance components and the burst. In PAL the color bar signals have ratio C/Y' as in NTSC but there is no 7.5 IRE black level setup. In PAL the phase is $+c^\circ$ and $-c^\circ$ on alternate lines. In PAL/BG the EBU-color bars at 75 percent are

$$\begin{aligned} \text{NTSC Color subcarrier signal} &= U \sin(\omega_c t) + V \cos(\omega_c t) = Q \sin(\omega_c t + 33^\circ) + I \cos(\omega_c t + 33^\circ) \\ &= C \sin(\omega_c t + c) \end{aligned}$$

FIGURE 21.1.15 Vector diagram showing quadrature modulation of the NTSC color subcarrier. With time the signal progresses in order $I, Q - I, -Q$.

0.3 + 0.7 × 0.75 × S volts, except that white is shown at 100 percent, i.e., at 1 V. In PAL/I they are at 100 percent amplitude and 95 percent saturation (V and U multiplied by 0.95). If saturated colors are avoided in programs, the gain g_s could be larger than 0.75, but this presents a risk for overmodulation, which causes noise in the received audio. In compatible black-and-white reception this gain reduction results in a 2.5-dB loss in signal-to-noise ratio.

The PAL Composite Video Signal

In NTSC a phase error with respect to the burst reference phase used to be a problem with early tape recorders. Adding a phase error φ to ω_ct in Eq. (24) causes the synchronously detected U and V outputs to be:

$$U(\phi) = U \cos \phi - V \sin \phi, \quad V(\phi) = V \cos \phi + U \sin \phi \tag{29}$$

This UV cross talk changes the tint because of the sin φ contributions. To abate this effect, the PAL system alternates the polarity of V and V(φ) on successive lines in a field (by switching during the HBI) and on the same line after two frames by choosing a subcarrier frequency that has an odd number of cycles in four frames = a PAL color cycle. Equation (29) shows that this is equivalent to altering the sign of the sin φ contribution to the error. These chroma errors may then be averaged and “canceled” in the HVS. However,

FIGURE 21.1.16 NTSC Color bars at 75 percent amplitude (EIA standard RS 189-A). See Table 21.1.8 for U , V , $B' - Y'$, $R' - Y'$, Y' , R' , G' , B' .

the alternating errors tend to be visible as crawling (“Hanover”) bars, partly due to the nonlinearity of the display. This problem is solved in “standard PAL” by canceling the $\sin\phi$ error with the use of a comb filter that averages luminance and chrominance signals on successive lines. The price is reduced vertical resolution. In PAL the phase c° of the chroma signal vector C shown in Fig. 21.1.15 alternates sign on every other line. To identify A-lines with chroma vector (U, V) and B-lines with chroma vector $(U, -V)$ the burst swings from a phase $c = 135^\circ$ on A-lines to -135° on B-lines. The reference phase $c = 180^\circ$ is derived by averaging burst on A and B lines. The color subcarrier progresses with time in the order $V, U, -V, -U$ on A-lines and in the order $U, V, -U, -V$ on B-lines.

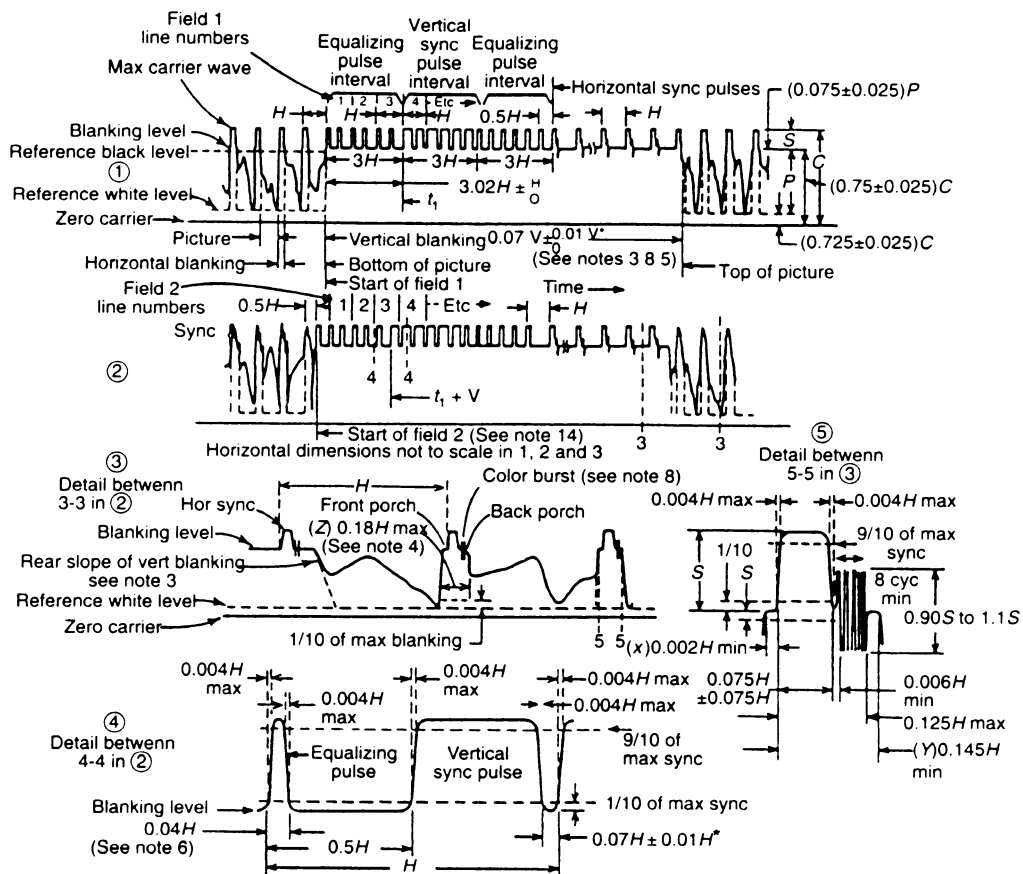

FIGURE 21.1.17 National Television System Committee color synchronizing-signal waveform (FCC Standard).

Notes: (1) H = time from start of one line to start of next line. (2) V = time from start of one field to start of next field. (3) Leading and trailing edges of vertical blanking should be complete in less than $0.1H$. (4) Leading and trailing slopes of horizontal blanking must be steep enough to preserve minimum and maximum values of $(x + y)$ and (z) under all conditions of picture content. (5) Dimensions marked with an asterisk indicate that tolerances are permitted only for long time variations and not for successive cycles. (6) Equalizing pulse area shall be between 0.45 and 0.5 of the area of a horizontal synchronizing pulse. (7) Color burst follows each horizontal pulse but is omitted following the equalizing pulses and during the broad vertical pulses. (8) Color burst to be omitted during monochrome transmission. (9) The burst frequency shall be 3.579545 MHz. The tolerance on the frequency shall be ± 10 Hz with a maximum rate of change not to exceed 0.1 Hz/s. (10) The horizontal scanning frequency shall be $2/455$ times the burst frequency. (11) The dimensions specified for the burst determine the times of starting and stopping the burst but not its phase. The color burst consists of amplitude modulation of a continuous sine wave. (12) Dimension P represents the peak excursion of the luminance signal from blanking level but does not include the chrominance signal. Dimension S is the synchronizing amplitude above blanking level. Dimension C is the peak carrier amplitude. (13) Start of field 1 is defined by a whole line between the first equalizing pulse and the preceding H sync pulses. (14) Start of field 2 is defined by a half line between the first equalizing pulse and the preceding H sync pulses. (15) Field 1 line numbers start with the first equalizing pulse in field 1. (16) Field 2 line numbers start with the second equalizing pulse in field 2.

Composite Signal Spectra: NTSC, PAL, and SECAM III

In NTSC the color subcarrier frequency is $f_c = 455 \times (F_H/2) \approx 3.58$ MHz. FCC rules specify f_c as $(63/88) \times 5$ MHz ± 10 Hz. This frequency is located exactly between two horizontal frequency components and exactly between vertical components $n = \pm (N - 1)/4 = \pm 131$ marked as $+F_H/2$ in the spectrum shown in Fig. 21.1.11.

In the vertical direction the subcarrier alternates phase on adjacent lines in a field and in the temporal direction it alternates phase on adjacent frames, completing a *color-cycle* in the duration of two frames (1/15 s or 238,875 cycles). In the picture the color subcarrier appears as an interference pattern of dots seen to move slowly upward with a velocity $v_T \cong 1/8$ ph/s, a phenomenon that can be seen on some black-and-white sets and in the green-magenta transition in color bars. For stationary pictures, spectral components of the modulated subcarrier interleave with the spectral components of the luminance, but the luminance and chrominance spectral components are now only $F_V/4$ apart as can be seen in Fig. 21.1.11. Luminance-chrominance cross talk is unavoidable and deteriorates with motion. High-frequency luminance components show up as low-frequency components in the synchronously detected chroma signals U and V or I and Q . Luminance cross talk into chrominance, referred to as *cross-color*, appears as undesirable color patterns. Chrominance cross talk into the luminance, referred to as *cross-luminance*, shows up as moving luminance high frequency patterns (dots, gratings, and so forth). Since the luminance energy is primarily concentrated at even multiples of $F_H/2$ and the chrominance energy is concentrated at odd multiples of $F_H/2$, the cross talk can be reduced by passing the frequency band with the shared spectrum through a 1H-delay comb filter. The comb filter partially separates luminance from chrominance, but also averages luminance and chrominance on successively transmitted lines, which are two lines apart in interlaced scan. The price is “tolerable” reduction of diagonal luminance resolution, tolerable reduction of vertical chrominance resolution, and *hanging dots*, which occurs when the chrominance information changes significantly from one line to the next, and some other artifacts. The picture quality is usually improved by a comb filter, particularly with some cooperative processing at the source. Chroma-luma separation can be significantly improved with more sophisticated techniques.

In PAL the color subcarrier has a frequency $f_c = (1135/4)F_H + F_V/2 = 4,433,618.75$ Hz (709,379 cycles in four frames). The PAL composite signal is

$$S = Y' + U\sin(\omega_c t) \pm V\cos(\omega_c t) = Y' + C\sin(\omega_c t \pm c) \quad (30)$$

The V -subcarrier is multiplied by a square wave with a frequency $F_H/2$. As a consequence, V modulates a number of subcarriers at frequencies $f_c \pm (2p + 1)(F_H/2)$ having amplitudes diminishing in proportion to $1/(2p + 1)$. The PAL color subcarriers appear as gratings which would move up slowly if it were not for the added 25 Hz. Shifting them all up in frequency by 25 Hz turn them into less visible gratings which appear to move three times faster downwards. A complete color cycle takes a duration of four frames = 0.16 s (709,379 cycles of the color subcarrier). An important feature of the PAL system is that the chrominance signals U and V can be partially separated with a comb filter.

In the SECAM III system (625/50) the chrominance signals U and V are conveyed on alternate lines (line sequential chroma). A 1H-delay line is used to make the U and V signals available simultaneously. Since there are an odd number of lines per frame, a line carrying U on one frame carries V in the next frame. The pre-emphasized U signal frequency modulates a subcarrier at a frequency $f_{ob} = 272 F_H = 4.25$ MHz and the pre-emphasized V signal frequency modulates a carrier at a frequency $f_{or} = 282 F_H = 4.40625$ MHz. The sidebands of the carriers are also pre-emphasized, and the polarity of the subcarriers (not the polarity of U and V) are altered in a sequence chosen to minimize their visibility. Flag signals are transmitted during vertical and horizontal blanking intervals to inform the receiver about parameters needed for proper detection. Specifications of the PAL and SECAM III systems are summarized in Fig. 21.1.18.

The Vertical Blanking Interval (VBI)

Figure 21.1.17 shows specifications for the vertical blanking interval in NTSC with the FCC designations of line numbers. The VBI occupies 21 lines on field 1 and 22 on field 2. Three lines of equalizing pulses are followed by three lines of vertical sync pulses and another three lines of equalizing pulses, all needed for reliable interlaced scan in adverse reception conditions. Synchronization pulses are followed by line 10 through line 22. Most of these lines can be used compatibly (without unblanking receivers) for transmission of auxiliary information including test signals, data transmission (teletext, ceefax, antiopie), and reference signals to improve reception. Each line is worth the equivalent of continuous transmission with 13-kHz bandwidth covering large areas with excellent signal-to-noise ratios. Most lines have been allocated for

FIGURE 21.1.18 Some r.f. transmission standards for NTSC, PAL, and SECAM.

specific purposes and with specified broadcast standards. In NTSC there is an FCC standard, *Teletext*, for broadcasting a digital ancillary signal with a payload of 33 bytes per line. Teletext can be used for many purposes, including captions.

One reference signal, a *ghost cancelling reference* (GCR) intended to correct for multipath distortion in television reception, has been adopted by the FCC as a standard in the United States. Basically the receiver adapts its r.f. transfer characteristics to correct detectable errors in the GCR. This system equalizes the transfer characteristic, not only for the effects of multipath but also for other transmission errors. The GCR adopted by the FCC appears as a frequency sweep (chirp) with carefully designed leading and trailing edge transients.

THE AUDIO SIGNALS

Monophonic Sound Broadcasting

In NTSC, PAL, and SECAM broadcasting, a “sound carrier” is modulated by an audio signal and added to the “picture carrier,” which is modulated by the composite video signals. The summation is usually done at a high power level in a passive linear hybrid circuit called a diplexer (Fig. 21.1.1). In NTSC and PAL the sound carrier is frequency modulated, in SECAM/L it is amplitude modulated. In NTSC the ratio of the peak picture carrier to the sound carrier is 7 to 10 dB (15 dB in CATV). As in FM radio broadcasting, the audio signals are pre-emphasized (75 μ s in NTSC, 50 μ s in all other systems) and limited to a bandwidth from 40 to 15,000 Hz. The frequency deviation in the NTSC monophonic standard is 25 kHz, ensuring excellent audio quality even when the picture is quite degraded by interference.

Stereophonic Sound Broadcasting

In the United States a standard (BTSC) was adopted by the FCC in 1984 for multiplexing two analog stereo signals, $L + R$ and $L - R$, to form a composite “stereo baseband signal.” The system is also referred to as MTS (multichannel television sound) and is described in the chapter on broadcasting.

In Germany (PAL/B,G) an additional r.f. carrier, 7 dB weaker than the main sound carrier, has been added at a frequency $15.5F_H \cong 242$ kHz above the main sound carrier, to transmit the right signal R . In this dual-sound-carrier system the compatible monophonic signal $M = L + R$ is transmitted on the main audio carrier.

In terrestrial broadcasting in Great Britain (PAL/I) an additional r.f. carrier, 10 dB weaker than the main sound carrier has been added at a frequency about 552 kHz above the main sound carrier, to convey digital stereophonic sound referred to as NICAM728 (*near instantaneous companding audio multiplex @ 728 kb/s*). To provide 15 kHz stereo the L and R signals are sampled at a 32-kHz rate with 14 bits per sample. Companding reduces the required number of bits per sample to be conveyed to 10. The 14 bits are restored in the receiver. In terrestrial broadcasting, bit-pairs, one bit from each channel, modulate the r.f. carrier in *differential quadrature phase shift keying* (DPSK) by shifting the phase of the carrier from the current phase by a multiple (0, 1, 2, 3) of 90°. NICAM was also the preferred digital format for D-MAC satellite broadcasting in Great Britain. Some SDTV television audio transmission standards are summarized in Fig. 21.1.18.

R.F. TRANSMISSION SIGNALS

Basics and Status

Video signals are transported to consumers by carriers having frequencies in various bands in the r.f. spectrum. A modulated carrier has the form

$$z(t) = x(t) \cos(\omega_c t) - y(t) \sin(\omega_c t) = E(t) \cos(\omega_c t + p(t)) \quad (31)$$

where x = in-phase signal
 y = quadrature signal
 $E = (x^2 + y^2)^{1/2}$ = envelope
 $p = \arctan (y/x)$ = phase
 $f = (1/2\pi)(dp/dt)$ = frequency deviation

In double sideband amplitude modulation (DSBAM) x is linearly related to the video signal while $y = 0$. In digital quadrature amplitude modulation (QAM) both x and y take a number of discrete levels. In phase shift keying (PSK), p takes discrete levels. In frequency modulation (FM) f carries the video information. In PSK and FM, E carries no information and is approximately constant. In orthogonal frequency division multiplex (OFDM), a vast number of carriers transport a video signal. In fiber optic transmission, the carrier is light, not always with a single frequency.

Television is broadcast to a large number of viewers by three transmission technologies: terrestrial broadcasting, cable, and satellite. Terrestrial broadcasting includes a microwave multipoint distribution system (wireless cable). Cable broadcasting includes all technologies that can deliver television into homes via some conduit. In satellite communication FM is used for analog video transmission and usually PSK (or differential PSK) for digital video transmission. While satellite broadcasting of digital television is rapidly becoming popular, open (i.e., not proprietary) signal standards are still under development. Detailed specifications of signals used in digital television satellite broadcast systems and in digital video disks (DVD) are proprietary at the time of this writing. A major effort to develop an international digital video broadcast standard is pursued by several standards organizations, in particular by the DVB group of the EBU. It is beyond this section to discuss various standards for point-to-point transmission of video, e.g., satellite and broadband digital networks (BISDN). In what follows the discussion is limited to standards for analog and digital terrestrial broadcasting in the VHF and UHF television broadcast bands (54 to 890 MHz in the United States), where the channel bandwidth constraints (6, 7, or 8 MHz) have had a major impact on video signal standards. Cable TV systems operate with essentially the same r.f. signals.

R.F. Signals in Analog Terrestrial and Cable TV Broadcasting

All high-power television stations radiate a signal consisting of a picture carrier that has a frequency close to the lower band limit of the channel and one or two sound carriers with frequencies close to the upper band limit of the channel as shown in Fig. 21.1.18. The picture carrier is amplitude modulated by the composite video signal, but only a part of the lower sideband is transmitted. This is referred to as a *vestigial sideband amplitude modulation*. VSBAM is usually generated by passing a DSBAM signal through a vestigial sideband filter. Figure 21.1.18 illustrates the bandpass characteristic of the radiated VSBAM picture signal. In the i.f. amplifiers of receivers, the signal is transferred through a “Nyquist” filter, which in theory is phase-linear and has an antisymmetric amplitude (not necessarily linear) response around the picture carrier frequency (Fig. 21.1.18). The output from the Nyquist filter consists of an in-phase signal x amplitude modulated by the desired video and a quadrature signal y amplitude modulated by a video frequency component delayed 90° (Hilbert transform of video). With a perfect Nyquist filter synchronous detection yields undistorted video, while envelope detection contains some quadrature distortion. Ghosts also contain the quadrature signal. For these reasons the Nyquist slope must not be too steep. VSBAM wastes almost half the transmitter power to reduce radiated bandwidth. In the United States some low-power TV stations are allowed to operate with DSBAM.

Figure 21.1.18 shows the radiated spectrum of the NTSC, PAL, and SECAM signals including the sound carrier(s). Also shown are a number of r.f. signal standards. The NTSC sound carrier frequency is 4.5 MHz ($286 F_H$) above the picture carrier frequency and is frequency modulated by the BTSC (MTS) stereo baseband signal. The power of the NTSC sound carrier is 7 to 10 dB weaker (in Cable TV 15 dB weaker) than the power of the picture carrier at peak of sync (peak power). The radiated power of an analog television signal is always specified by the peak power of the picture carrier. Modulation levels at peak of sync, blanking, and white level are shown in Fig. 21.1.14. Broadcast technology, recommended practices, and FCC rules are included in the section on broadcast transmitters.

Transmission Impairments of Analog Television Signals

Major impairments are:

- Random noise and man-made noise (including impulse noise)
- Linear distortion including multipath distortion (ghosts)
- Interference from other broadcast stations (including television co-channel interference, adjacent channel interference, and at UHF, interference from taboo channels)
- Jittery local oscillators
- Nonlinear distortion (including crossmodulation, triple beats)

Random noise (“snow”), caused primarily by receiver noise, is the principal impairment limiting the area, which can be covered by a broadcast station or the number of homes that can be reached from a cable television headend. Reception impaired by random noise is specified by the carrier-to-noise ratio (CNR) defined to be the ratio in dB of carrier peak power to total noise power in an r.f. bandwidth = B MHz. In NTSC terrestrial broadcasting the practice is to specify B = 6 MHz (TASO definition) and in cable television the practice is to specify B = 4 MHz (NCTA definition). Thus

$$\text{CNR(NCTA)} - \text{CNR(TASO)} = 1.76 \quad \text{dB} \quad (32)$$

Video signal-to-noise ratio, unweighted for subjective perception of noise, is defined as the ratio in dB of the white-minus blanking level to rms noise in the luminance bandwidth. In NTSC the unweighted SNR is related to the CNR as

$$\text{SNRU} = \text{CNR(TASO)} - 5.3 = \text{CNR(NCTA)} - 7.06 \quad \text{dB} \quad (33)$$

With noise weighted for subjective perception (CCIR), the NTSC weighted SNR is

$$\text{SNRW} = \text{SNRU} + 7.6 \quad \text{dB} \quad (34)$$

CNR(TASO) is related to the field strength E dB μ V/m (dBu) at the location of the receiving antenna:

$$\text{CNR(TASO)} = E + G - F - 20 \log_{10}(f \text{ MHz}) + 31.1 \quad \text{dB} \quad (35)$$

where G is the antenna gain minus cable losses and F is the system noise figure, both in dB.

The FCC has based determination of “grade B” noise-limited coverage on a just barely acceptable CNR(TASO) = 28.2 dB to be exceeded 90 percent of the time at 50 percent of the locations. To meet this performance with FCC “planning factors” (G, F, and a 90 to 50 percent time factor), the field strength on the grade B contour must exceed E(50/50) shown in Table 21.1.8 50 percent of the time at 50 percent of the locations.

Determination of E(50/50) and the 90 to 50 percent time factor (50/10) – E(50/50) is discussed in the section on broadcast transmitters.

The effects of an r.f. impulse (*impulse noise*) in the received composite video is a pulse with a shape, amplitude, and ringing which is determined by the video bandwidth of the receiver and the phase of the carrier at the instant of the impulse. Impulse responses are colorful, and chroma streaks can be long because of the narrow chrominance bandwidth.

Co-channel interference shows up as crawling venetian blinds. Their visibility for a given relative level of the interfering channel can vary by as much as 20 dB depending on the difference between the frequencies of

TABLE 21.1.8 Grade-B Field Strength at 50 Percent of the Locations 50 Percent of the Time 9 m Above Ground

	Low VHF (54–88 MHz)	High VHF (174–216 MHz)	UHF (470–806 MHz)
Grade-B E(50/50) dB μ V/m	47	56	64

the co-channels. A precise visual carrier frequency offset of ± 10010 Hz is cooperatively used by many NTSC broadcasters to minimize the visibility of co-channel interference.

Multipath transmission has two effects: (1) it changes the amplitude of the carrier which carries the desired signal and consequently the CNR and (2) it causes linear distortion of the video signal which can be characterized by an r.f. to video transfer function. Because VSBAM transmission also transmits the Hilbert transform of the video signal on a quadrature carrier, part of the ghost as it appears in the picture may consist of this quadrature signal. The transfer function varies rapidly with the relative carrier-phase of the ghosts. This is noticeable if a ghost is a reflection from an airplane (*airplane flutter*). The transfer characteristic can be equalized with a *deghoster* operating with a ghost cancelling reference signal (GCR) in the VBI. The standard GCR for NTSC is discussed in the sections on television transmitters and receivers. The carrier level, and consequently CNR, can be significantly affected by ghosts, not the least caused by reflections from nearby clutter, i.e., buildings, hills, trees, and so forth. A deghoster can straighten out the transfer characteristic, but it cannot improve degradation of CNR by ghosts.

There are numerous other impairments of the video signal, some caused in the r.f. path, some in the transmitter, and some in the receiver. Distortion, distortion specifications, measurement techniques, performance standards, and vertical interval test signals (VITS) for measurements of impairments are discussed in the chapter on broadcast transmitters.

Cable TV introduces impairments resulting from nonlinear distortion in broadband amplifiers. The most significant consequences of intermodulation between the many r.f. signals passed through a cascade of broadband amplifiers, are beats between three channels (triple beats), which primarily cause streaks in the picture, and cross-modulation, whereby a carrier is modulated by video conveyed by other carriers. Progress in amplifier design has made possible the distribution of the sum of more than 50 standard VSBAM television signals on a cable with imperceptible cross-modulation and triple beat interference levels in the video below -55 dB relative to 100 IRE. For a detailed discussion see the section on Cable TV.

DIGITAL VIDEO SIGNALS

Sampling and Quantizing Video Signals

In theory, a dynamic picture is sampled at lattice points in a three-dimensional space, two spatial and one temporal, and at each point (pixel or pel), three digital values specifying a color are sampled. In practice this process is often accomplished by sampling and quantizing analog component video signals. Conventional practice is to align samples along vertical lines ("rectangular" pels) in identical locations on successive frames.

Of key importance is where in the video transmission path, shown in Fig. 21.1.13, the A/D conversion takes place, what signals are sampled, and how noisy they are. Other key parameters are: sample rate, number of quantization levels, and anti-alias filtering preceding A/D conversion. A camera with CCD or CMOS sensors may be the first device to sample the image along a line. The number of reliably distinguishable levels is limited to a few hundreds by camera noise. Aliasing in CCD cameras in the spatial directions can be partially controlled by sensor size and defocusing, and in the temporal direction by the integration time. The data sampled on the faceplate of a CCD camera are, however, converted to analog signals, which are subject to very sophisticated signal processing. At the other extreme, digitization of the composite signal occurs far down the transmission path. While the sampled composite signal is free of horizontal aliasing, it is oversampled and impaired by luminance-chrominance cross talk, bandwidth limitations, and other artifacts that cannot be corrected. Composite digital signals may be useful and inexpensive for some NTSC and PAL applications, but repeated A/D and D/A conversion cause significant degradation of the signals.

Composite NTSC and PAL Signals

NTSC or PAL composite signals are almost always sampled at a sample rate equal to four times the color subcarrier frequency ($4 \times f_c$). Figure 21.1.15 shows that if the samples are taken at nulls of the in-phase and quadrature components of the color subcarrier, the sequence of sampled values in NTSC are $Y' + I$, $Y' + Q$, $Y' - I$, $Y' - Q$, . . . In PAL they are $Y' + V$, $Y' + U$, $Y' - V$, $Y' - U$, . . . on A-lines and $Y' - V$, $Y' + U$, $Y' + V$,

FIGURE 21.1.19 Digitized levels for composite NTSC and for components in CCIR601. Standard is for 8- and 10-bit quantization. 10-bit quantization levels are shown in italics.

- a. Composite NTSC
- b. Luminance component Y' in CCIR601
- c. Chrominance components in CCIR601

$Y' - U, \dots$ on B-lines. There are 910 samples on a NTSC line and 1135 on a PAL line. Chrominance and luminance can be separated in digital circuits with inputs from adjacent lines in a field.

A typical NTSC scale for 256 levels (8 bits) and 1024 levels (10 bits) is shown in Fig. 21.1.19a (SMPTE259M). According to this scale some levels are reserved for headroom and sync. In the 8-bit version, only a little more than 7 bits are available for 100 IRE units (blanking to white). Quantization causes distortion of the signal which sometimes appears in the picture as *quantization contours or puddles*. One way to reduce the visibility of contours is to “dither” the least significant bit with random noise. In busy picture quantization may have noiselike appearance. These artifacts are visible in 8-bit NTSC, so 10 bits per sample is commonly used in professional applications, implying a data rate of 143 Mb/s requiring a transmission bandwidth of about 80 MHz.

The adoption in 1982 of an international standard, ITU-R Recommendation 601 (CCIR601), for component digital television, was a major milestone in the development of digital television. The D1 tape format and numerous other applications are based on the CCIR601 standard. Television studio equipment is now almost all digital, and digital interfaces between equipments are almost always based on CCIR601.

TABLE 21.1.9 ATSC Format Interoperability Considerations

	Format		Aspect Ratio		Frame Rate		
	Resolution	Standard	TV	Film	60 I	30 P	24 P
TV	1920 x 1080 (square pixels)	16:9			60 I	30 P	24 P
	1280 x 720 (square pixels)	16:9		60 P		30 P	24 P
	704 x 480 (CCIR 601)	16:9	4:3	60 P	60 I	30 P	24 P
	640 x 480 (square pixels)		4:3	60 P	60 I	30 P	24 P
		Film	TV		TV		Film
	Computer			Computer		Computer	

Supported frame rates include both 60.0 and 59.94 Hz related rates

COMPONENT DIGITAL VIDEO SIGNALS

Digitization of composite analog signals is still common, e.g., in the D2 and D3 tape recording formats, in various production systems, e.g., for time base correction, frame synchronization, editing, as well as for video processing in consumer products. Advantages of digital technology: perfect multigeneration reproducibility; precise time and level controls, digital storage, and signal processing; data compression; easy manipulation by computers, multimedia; incorporation in digital data transport packets for packet switching (ATM), broadband digital communication (BISDN); error control; and so forth. Recently, international agreement has been reached on the use of 1920×1080 as a common image format for high-definition production and program exchange. The 1920×1080 format has its roots in the CCIR sampling standard, and brings international compatibility to a new level. Table 21.1.9 shows the picture sensing characteristics of the 1920×1080 format for a variety of frame rates.

HIGH-DEFINITION TELEVISION (HDTV)

Fundamentals and Picture Quality

The fundamentals of HDTV are the same as the fundamentals of television in general, which have been reviewed in the previous sections of this chapter. From the viewers point of view, HDTV differs from “standard” definition TV (SDTV) by a significantly improved viewing experience in many respects:

1. Sharper, higher resolution images. By design, HDTV is intended to be as good as the resolution of the human visual system at a viewing distance of four picture heights ($D = 4 \text{ ph}$). A large screen and a viewing distance of $D < 4$ stimulates viewer involvement in the scene. Compared to standard definition TV, HDTV increases horizontal luminance resolution by a factor of $\cong 3$, vertical luminance resolution by a factor of $\cong 2$, and horizontal chrominance resolution by a factor of $\cong 5$.
2. A wider, cinemalike picture with an aspect ratio of 16/9 instead of 4/3.
3. High-quality surround sound audio that produces an immersive, theaterlike experience.
4. A substantial reduction in picture artifacts, including the cross-luminance and cross-chrominance artifacts of analog color systems. In addition, digital HDTV eliminates the analog transmission impairments such as noise, ghosts, distortion, and interference from other stations.

Also, a digital HDTV channel has all the potentials of digital TV in general and can offer many information services to the consumer. A packetized data format with headers and descriptors provide flexibility, interoperability, and extensibility.

HDTV, however, suffers from some imperfections:

1. Although HDTV supports multiple raster formats, each one has certain trade-offs among spatial and temporal resolution. Interlaced scan formats at 30, 30/1.001, or 25 Hz and progressive scan formats at the film rates of 25 or 24 Hz continue to have the same motion-related artifacts as today’s analog TV systems and film. Also, in interlaced scan formats, line flicker may be visible at viewing distances $D < 3.3 \text{ ph}$. While HDTV progressive scan formats at 60, 60/1.001, and 50 Hz improve motion rendition, they do so at the expense of horizontal and vertical spatial resolution.
2. Large area flicker may be perceived at viewing distances $< 4 \text{ ph}$ at typical TV brightness. At $D = 4 \text{ ph}$ the width of the picture is sustained by a 25° viewing angle, which means that a part of the picture is seen by flicker-sensitive rod vision. While a 60-Hz flicker may be acceptable, 50 Hz may not be acceptable and may require frame doubling as in motion pictures.
3. In digital HDTV over narrowband channels, there may be some visible video compression and quantization artifacts.
4. In DTTB of HDTV, there is the “cliff effect”: Either a virtually perfect picture is received or no picture is received.

HDTV Production Standards

Efforts to establish national and international technical standards for production, distribution, and transmission of HDTV have been going on ever since Japan Broadcasting Corporation (NHK) started development of the analog 1125/60 HDTV system (MUSE) in the 1970s. In the mid-1980s the EBU proceeded with a project, referred to as “Eureka,” to develop European 1250/50/2:1 and 1250/50/1:1 production standards. In the United States, the Society of Motion Pictures and Television Engineers (SMPTE) has proposed production standards for an 1125/60 high-definition production system, referred to as the SMPTE274M and SMPTE296M, which have been adopted by ATSC, while SMPTE240M is used in Japan.

Analog HDTV Broadcast Standards

The first operational system was the analog 1125/60 MUSE system (“multiple sub-Nyquist sampling encoding”), which has been adopted in Japan as a standard for HDTV satellite direct broadcasting (DBS). In the MUSE system, video bandwidth requirements are reduced from 21 to 8.1 MHz by a technique of horizontal and temporal subsampling, whereby diagonal and motion resolution is traded off to improve horizontal luminance resolution. Four fields are required to complete a picture with all details. Some motion compensation is used. Chrominance is also subsampled and the chrominance signals C_r and C_b are time compressed by factors of 4 and 5, respectively, and transmitted on alternate lines in the horizontal blanking interval which occupies about 20 percent of the time. This “time compressed integrated” (TCI) signal is converted into an analog signal that modulates the satellite FM transmitter.

In Europe an analog DBS system, HD-MAC, was developed based on a 1250/50/2:1 production standard. HD-MAC has been abandoned in favor of digital television systems. HD-DIVINE developed by a Scandinavian consortium for DTTB was demonstrated in 1992.

In the United States and Canada, the Advanced Television Systems Committee (ATSC) was formed in 1982 by the television industry to coordinate standards for advanced television systems. In 1987 a number of committees were formed to study and tests proposed systems for DTTB of HDTV. Originally over a dozen analog systems were proposed and many transmission methods were considered. But in June of 1990, a landslide move toward digital television terrestrial broadcasting began when General Instrument Corporation announced its DigiCipher all digital system. Others soon proposed all digital systems and in 1992 and 1993, four digital systems and Narrow MUSE, were tested at the ACATS’ Advanced Television Test Center and by Cable Television Laboratories. Subjective tests were conducted in Canada by the Advanced Television Evaluation Laboratory (ATEL). The tests showed many advantages of the digital systems, which all performed better than Narrow-MUSE. In May 1993, the four proponents of digital systems formed a *Grand Alliance* which would develop a system combining the best features of each system. In 1994 and 1995, the Grand Alliance system was a subject of extensive tests (objective, subjective, and field tests), that validates its performance as a “best-of-the-best” digital system. The Grand Alliance system formed the basis for the ATSC standard (which added standard-definition formats) and the FCC transmission standard (which requires the use of the ATSC standard, with the exception that no picture format requirements whatsoever are specified by the FCC).

A better, but more expensive choice in terms of data rate, is A/D conversion of component video signals components. Usually the components are the pre-gamma corrected luminance signal Y' and the scaled chrominance signals $C_r = K_r(R' - Y')$ and $C_b = K_b(B' - Y')$ where $K_r = 0.5/(1 - T_R)$ and $K_b = 0.5/(1 - T_b)$. However, the choice can also be the pre-gamma corrected primaries R' , G' , and B' or the uncorrected primary signals R , G , and B . In the latter case the quantization must be at least 10 bits because of the high gain of the gamma-correcting circuit at low signal levels and the sensitivity of the HVS to contrast ratios. A quantum step at low luminance levels is more perceptible than at high luminance levels.

CCIR601 is a family of compatible international standards for component television. Figures 21.1.19b, 21.1.19c, and 21.1.20 summarize some key aspects of CCIR601. The common ground of 525/59.94 and 625/50 systems is that the duration of a TV line is about the same and that at a 13.5-MHz sample rate there is an integral number of sample points per line in all standard analog systems: $6 \times 143 = 858$ in 525/59.94 systems and $6 \times 144 = 864$ in 625/50 systems, as shown in Fig. 21.1.20. In both systems there are 720 *active samplepoint locations* per line. Along a line the active samples are preceded and followed by sequences of digital timing

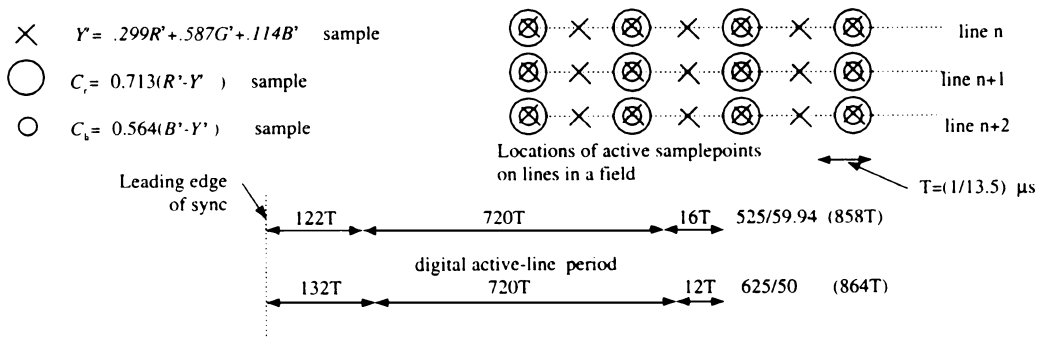

FIGURE 21.1.20 Sample point locations in 4:2:2 CCIR601 (ITU-R Rec. 601) for component SDTV digital television systems 525/59.94 and 625/50. Total samples per second = 27,000,000. In 4:2:0 the density of chrominance samples along a vertical line is reduced by a factor of 2 (see text). In 4:4:4 there are chrominance samples at every samplepoint location.

and ancillary data. This inactive period coincides with the horizontal blanking interval in all analog standard systems.

The CCIR601 4:2:2 format (family member) is summarized in Fig. 21.1.20. In a sequence of four Y' samples along a horizontal line there are two $C_r = K_R(R' - Y')$ samples and two $C_b = K_B(B' - Y')$ samples which are both co-located with every other Y' sample. The total number of active sampled values per line is thus 1440. The Nyquist bandwidths are 6.75 MHz for luminance and 3.875 MHz for chrominance. The CCIR601 standard specifies a 5.75 MHz low pass cutoff for luminance and a 2.75 MHz cutoff for chrominance. CCIR601 4:2:2 standard specifies either 8 or 10 bits per sampled value. The luminance and chrominance signal level as well as headroom and footroom are shown in Figs. 21.1.19b and 21.1.19c. The scale factors K_R and K_B (Table 21.1.6) are chosen to fit the chrominance signals C_r and C_b at 100 percent amplitude in the range 128 ± 112 (512 ± 448), which is about the same as the range of the luminance level.

In the CCIR601 4:4:4 format chrominance samples are co-located with every luminance sample. In the CCIR601 4:2:0 format the density of chrominance samples along a vertical line is reduced by a factor of 2 usually by taking some weighted average of 4:2:2 chrominance samples. In interlaced scan the so-derived 4:2:0 chroma samples appear to be uniformly interlaced in successive fields. The vertical chroma resolution in 4:2:0 is a factor of 2 less than in 4:2:2 or 4:4:4. The "raw" data rate of digitized video is high: 115 Mb/s for composite NTSC, up to 270 Mb/s for 4:2:2 CCIR601, and about 1 Gb/s for HDTV. By removing *statistical redundancy* and taking advantage of psychophysics to remove *irrelevant information*, the data rate of high quality HDTV has been reduced by a factor of 50 to about 20 Mb/s, which can be conveyed over a 6 MHz television broadcast channel.

With digitization of audio and video signals, television is becoming an integral part of a much broader field of digital information production and distribution. Digital standards strive to develop formats which provide high-quality data-compressed television and audio with considerations to *flexibility* of use and of receiver standards, *extensibility* to various formats, and *interoperability* with other applications, e.g., computers and data communications. In order to meet these objectives, a layered digital system architecture approach has been adopted as the basis for all DTV standards. This approach is loosely analogous to the ISO Open System Interconnect layered model for data communications. An international video compression standard, MPEG-2, provides the flexibility required to implement the three uppermost layers of the DTV system architecture. This standard was developed by the Motion Picture Expert Group of ITU and adopted by the International Standards Organization (ISO) and the International Electrotechnic Committee (IEC) in 1993. This accomplishment is the second major breakthrough toward international standards for digital television.

MPEG has a standard syntax (language) and protocol (rules) allowing for a great variety of inputs and for compatibility with many applications, i.e., not just one television standard or ancillary program. For example, there are "flags" specifying aspect ratio, samplepoint format, scanning standard, chromaticities, electro-optical transfer characteristics, sample rates, and so on. *Digital Television Standard* is referred to as the *ATSC*

TABLE 21.1.10 Picture Scanning Characteristics of the 1920 × 1080 High-Definition Common Image Format (ITU-R BT. 709-3)

Item	Parameter	System values									
		60/P	60/1	30/PsF	30/P	50/P	50/1	25/PsF	25/P	24/PsF	24/P
6.1	Order of sample presentation in a scanned system	Left to right, top to bottom For interlace and segmented frame systems, 1st active line of field 1 at top of picture									
6.2	Total number of lines	1125									
6.3	Field/frame/segment frequency (Hz)	60 (60/1.001)		30 (30/1.001)		50		25		24 (24/1.001)	
6.4	Interlace ratio	1:1	2:1	1:1	1:1	1:1	2:1	1:1	1:1	1:1	1:1
6.5	Picture rate (Hz)	60 (60/1.001)		30 (30/1.001)		50		25		24 (24/1.001)	
6.6	Line frequency* (Hz)	67500 (67500/1.001)		33750 (33750/1.001)		56250		28125		27000 (27000/1.001)	
6.7	Samples per full line -R, G, B, Y -C _B , C _R	2200 1100				2640 1320				2750 1375	
6.8	Nominal analog signal bandwidths† (MHz)	60		30		60		30			
6.9	Sampling frequency -R, G, B, Y (MHz)	148.5 (148.5/1.001)		74.25 (74.25/1.001)		148.5		74.25		74.25 (74.25/1.001)	
6.10	Sampling frequency‡ -C _B , C _R (MHz)	74.25 (74.25/1.001)		37.125 (37.125/1.001)		74.25		37.125		37.125 (37.125/1.001)	

*The tolerance on frequencies is ± 0.001 percent.

†Bandwidth is for all components.

‡C_B, C_R sampling frequency is half of luminance sampling frequency.

TABLE 21.1.11 Some Key Transmission Parameters of the ATSC System for DTTB of HDTV

Transmission parameters	Terrestrial mode
Modulation method	VSB
Channel bandwidth MHz	6
Symbol rate megasymbols/second	10.76
Excess bandwidth	11.5%
Bits per symbol	3
Reed-Solomon FEC	T = 10 (208, 188)
Trellis coding	2/3 rate
Segment length symbols	836
Sync symbols per segment	4
Frame sync	1 per 313 segments
Payload data rate Mb/s	19.3
CNR threshold dB	14.9
<i>Transport parameters</i>	
Multiplex technique	MPEG-2 systems layer
Packet size bytes	188
Packet header bytes	4 including sync

system for HDTV. The ATSC standards accommodate one interlaced and one proscan HDTV format, shown in Table 21.1.10. It accommodates a number of frame rates: 60, 30, and 24 frames per second as well as these rates divided by 1.001. The total samples per line shown in Table 21.1.10 are for 60 frames per second proscan (format 1) and for 30 frames per second interlaced (format 2) and imply a 74.25 MHz (74.25/1.001 MHz) sample rate in accord with the SMPTE274M and SMPTE296M production standards. The ATSC standard also accommodates two SDTV formats with 480V/704-H and 480V/640-H active luminance samples per frame and a standard 13.5 MHz sample rate for 60/1.001 field per second, as in CCIR601. The ATSC has adopted the Dolby AC-3 digital audio system, while European standards for digital TV may lean toward MPEG2 for audio. The ATSC system uses VSB for transmission.

Some of the key transmission parameters for the ATSC system are shown in Table 21.1.11. MPEG-2 has been rapidly and enthusiastically adopted for many applications besides DTTB, e.g., satellite broadcasting, digital video disc (DVD). Digital satellite systems (DSS) are in operation worldwide. In the United States DIRECTV, for home reception with an 18 in. dish, provides 150 television channels.

MPEG-2 Format for Video Compression

Source coding or compression of audiovisual data has two objectives: removal of redundancy (*entropy coding*) and reduction of irrelevancy (*perceptual coding*). The first objective is to take advantage of statistical correlation in the bit stream to increase the information (entropy) per transmitted bit. There is no redundancy in a picture if all samples are statistically independent as they are in random noise, while there is a lot of redundancy in a patch of blue sky. Statistical coding requires buffering to absorb a variable information rate. The second objective is to eliminate information which cannot be perceived by human observers. While a significant amount of information which is irrelevant to human observers has been removed in standard analog television (number of lines and fields, relative bandwidth of components, and so forth.), further elimination of imperceptible information is possible with digital techniques. Removal of redundancy and reduction of irrelevancy, while having different objectives, are not independent of each other or of the constraints imposed by the transmission channel.

Data compression obviously increases the information carried by remaining bits, which must be conveyed with a very low error rate. If at most one error per minute can be tolerated in a 20 Mb/s HDTV signal, the error rate must be less than one in a billion. A channel coder encodes the source coded bit-stream to minimize transmission errors given the characteristics of the channel.

FIGURE 21.1.21 Basic principles of video compression coding. I frames are intraframes coded only with DCT (see Fig. 21.1.23). In forward predicted frames *P* and bidirectionally predicted frames *B*, the difference between actual data and motion predicted data is DCT coded. Data in DCT “frequency” space are adaptively quantized and zig-zag scanned with run-length coding. From S. N. Baron and W. R. Wilson (1994).

Figure 21.1.21 illustrates the basic elements of the MPEG-2 compression format. A video sequence consists of a series of pictures. A picture is usually a progressively scanned or interlaced scanned frame, but it may also be a single interlaced field. The pictures are organized into groups of pictures (GoPs), which are a basic unit for compression (Fig. 21.1.22a). Within a GoP, the first picture is coded entirely with spatial, or intraframe coding, and is referred to as an I-picture (I-frame). Subsequent pictures in the GoP are predicted using block-based motion estimation techniques. P-pictures are predicted from preceding I- or P-pictures using forward motion compensation. B-pictures are bidirectionally predicted from adjacent I- and/or P-pictures.

All pictures are composed of Y, U, and V pixels in a 4:2:0 sampling grid organized as 8×8 blocks, as shown in Fig. 21.1.22b. A macroblock consists of the four luminance blocks and two chrominance blocks covering the same spatial area of the picture, and macroblocks are organized into slices. A macroblock is the basic unit for motion compensation, and each macroblock in a P- or B-picture may have motion vector information indicating its prediction in $1/2$ pixel components from the adjacent reference frames.

Within a Video Sequence...

a Group of Pictures (GOP) is composed of I- P- and B- pictures (frames)

FIGURE 21.1.22 (a) MPEG Group of Pictures.

Each 8×8 block is encoded with the DCT. DCT coefficients are quantized and scanned in zigzag order.

Two methods of data compression are used in MPEG-2: (1) intra-picture transform coding using discrete cosine transform (DCT), adaptive quantization, and variable length coding (VLC) and (2) motion compensation for prediction of P and B pictures. Motion vectors together with the intra-frame transform coded difference between predicted and actual picture is transmitted.

Pictures are composed of Slices

a Slice is a collection of adjacent Macroblocks

a Macroblock is a set of co-located luminance and chrominance blocks

(4 blocks of Y and 1 block each of Cr and Cb)

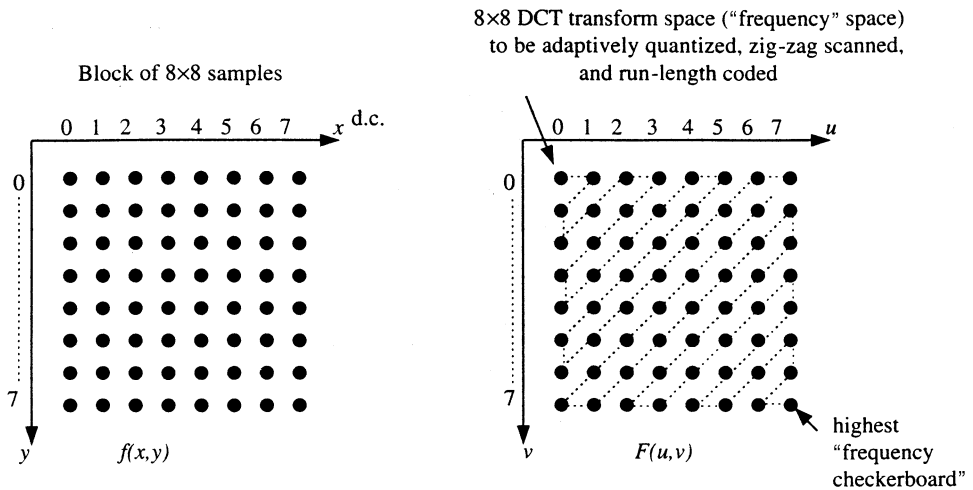

FIGURE 21.1.22 (b) Slices, Macroblocks, and Blocks.

The $N \times N$ two-dimensional discrete Fourier transform (DCT) is defined as:

$$F(u, v) = \frac{2}{N} C(u)C(v) \sum_{x=0}^{N-1} \sum_{y=0}^{N-1} f(x, y) \cos \frac{(2x+1)u\pi}{2N} \cos \frac{(2y+1)v\pi}{2N}$$

where $x, y = 0, 1, 2, \dots, N-1$ are discrete spatial coordinates in the pixel domain and $u, v = 0, 1, 2, \dots, N-1$ are discrete coordinates in the transform domain

and

$$C(u), C(v) = \begin{cases} 1 & \text{for } u, v = 0 \\ \sqrt{2} & \text{otherwise} \end{cases}$$

The inverse discrete Fourier transform (IDCT) is defined as:

$$f(x, y) = \frac{2}{N} \sum_{u=0}^{N-1} \sum_{v=0}^{N-1} C(u)C(v) F(u, v) \cos \frac{(2x+1)u\pi}{2N} \cos \frac{(2y+1)v\pi}{2N}$$

FIGURE 21.1.23 The discrete cosine transform (DCT). Many transform components have quantization level = zero. If x and y were continuous (which they are not) each transform component would be a product of a vertical and a horizontal cosine grating. From ISO/IEC 1.3818-2 Rec. H262.

The DCT transform is applied to an 8×8 block of samples $f(x,y)$ as shown in Fig. 21.1.23. In the transform domain the information is represented by an 8×8 array of real “frequency” components $F(u,v)$. A component $F(u,v)$ can be considered as the amplitude of an interference pattern consisting of the product of a horizontal and a vertical cosine wave (grating) forming a “checker-board” with soft-edged rectangular “squares.” The pattern with the smallest “squares” is represented by the component in the lower right corner in the frequency domain shown in Fig. 21.1.23, and the biggest “square” is represented by the dc component in the upper-left corner. The pels can be considered as samples of a superposition of these interference patterns. It must be kept in mind that the pixels $f(x,y)$ are *not* meant to represent a continuous function periodically mirrored in the x and y axis and band limited to the Nyquist bandwidth of the samplepoint lattice, and that a “frequency” component $F(u,v)$ does *not* specify a sine-wave grating. The DCT is strictly a transformation of an $N \times N$ array of numbers into another $N \times N$ array of numbers using Fourier techniques.

The DCT is remarkably effective in removing redundancy in typical pictures. When the pels $f(x,y)$ in a block are highly correlated, a large number of coefficients $F(u,v)$ in the transform domain are zero or very small, particularly the high-frequency components. The components in the transform domain are quantized. While the HVS is sensitive to quantization of low-frequency components, it tolerates large steps for high frequencies. An 8×8 *quant matrix* specifies the quantization steps to be associated with the array of $F(u,v)$ components. With quantum steps increasing with frequency, a large number of high-frequency components are quantized to level zero. MPEG allows for adapting the quant matrix for each block for an optimum trade-off between quality and available buffer memory. The quant matrix is specified in a header. The components are scanned in a zigzag pattern as shown in Fig. 21.1.23, generating a stream of symbols with bursts of zeros. The scanned data are subsequently variable length coded in run-amplitude pairs, specifying a non-zero component and an associated run length of zero coefficients. As in the Morse code, shorter codes are used for common pairs and longer for less common pairs. These symbols are delivered for transmission. DCT is the only technique used for I-picture data compression.

Motion compensation is used for P- and B-picture data compression. Before intra-frame coding (DCT), samples in blocks of P or B pictures are subtracted from predicted samples. The intra-frame encoded data of these “differential” pictures is transmitted together with data, *motion vectors*. Motion vectors are determined by matching a macroblock in the actual picture with macroblocks in a nearby area in the reference pictures (the reference picture for a P picture is the previous P or I picture and the reference pictures for B pictures are nearby I and P pictures). MPEG has standardized the vector range and how to specify macroblock motion vectors, but not how they are determined. After motion compensation, the pels of the P and B frames are highly decorrelated. This makes the subsequent DCT and quantization processes extremely efficient. In the atypical case where a predicted macroblock has higher entropy than the original image macroblock, intra-coding may still be used in P + B pictures. Given the capacity of the channel and the buffer memory, increased range and more accurate block prediction can reduce the call for quant matrices with coarse quantization. The consequence is compatible improvement of picture quality. Buffering the data for adaptive quantization is a sophisticated process. The outputs of video and audio data compression encoders are called program elementary streams (ES). MPEG classifies video ESs compression types, called *profiles*, intended for various applications. The profiles are called *simple, main, snr, spatial, and high*. MPEG also identifies various *levels* of video ESs characterized by the maximum number of active luminance samples per second. They are

Low:	352H \times 288V \times 30Hz	Main: 720H \times 576V \times 30Hz
High-1440:	1440H \times 1152V \times 60Hz	High: 1920H \times 1152V \times 60Hz

The two most important are main profile at main level (MP@ML) used in standard definition DTV system such as DVB and main profile at high level (MP@HL) and in high definition DN systems such as the ATSC standard.

Digital Audio for DTV

Just as analog video signals are digitized by sampling and quantization, analog audio signals are similarly converted into digital audio. A *de facto* international standard (AES/EBU) for high-quality digital audio is 48,000 samples per second and 16 bits per sample. Other standard sample rates are 44.1 kHz (compact disc) and 32 kHz. And just as digital video pels are compressed to discard redundant and imperceptible visual information, audio can also be compressed. By taking advantage of the psychophysics of the Human Aural System the data rate per audio channel can be reduced for transmission from $48 \times 16 = 768$ kb/s to substantially less than 128 kb/s with virtually imperceptible degradation. While there is an MPEG-2 audio standard, the Dolby AC-3 system, used in cinema theaters, has been adopted for the ATSC system for HDTV in North America. Both systems use *psychoacoustic coders* and deliver high-quality audio. The ATSC “Dolby Digital” system delivers five 20 kHz audio channels and a low-frequency (3 to 120 Hz) enhancement channel (LFE). This package of “5.1 channels” requires a maximum digital channel capacity of 384 kb/s.

Strings of digitized samples are converted from the time domain to the frequency domain, where spectra in 24 “critical bands” are processed. The basis for data compression is that in the vicinity of strong components, relatively weak components can be ignored without perceptible degradation (masking). The frequency components are coded and packetized. There are six levels of services including surround sound (complete main = CM, music and effects = CE), sound for visually impaired (VI) or hearing impaired (HI), as well as dialogue (D), emergency (E), and voice over (VO). Principles of *psychoacoustic coders* are discussed in the chapter on audio.

The ES data are put as payload in *packets*, like merchandise in freight cars to be assembled to form a train and referred to as *Packetized Elementary Streams (PES)*. A packet has a header including a label (packet ID, *PID*) and timing information. The packet also includes an *adaptation field*, including program clock, reference addresses, and descriptors for how the payload is to be used. In the MPEG-2 transport system a packet contains 188 bytes. Just as MPEG-2 compression is highly flexible, MPEG-s transport contains flags for local program insertion points, encryption for controlled access (CA), multimedia, interactive data, and many other descriptors.

It is one of the most important attributes of digital television that the information can be packetized and transmitted in a data communications format which is interoperable with other applications, and can be distributed not only by broadcasting (terrestrial, satellite, cable), but over various data communication networks, for example, as *Asynchronous Transfer Mode (ATM)* using communication over BISDN. BISDN includes fiber optics transmission. ATM uses fixed length packets (53 bytes) with a header containing descriptors as well as addresses for switching. The convergence of broadcasting, multimedia, telecommunications, data communications, and computer applications presents complex compatibility and standardization problems which at present are addressed by a number of international standardization committees. Digital television is now part of the broader industry of information production and distribution. MPEG is part of this activity, and the various adaptation layers have been designed to provide interoperability, so that MPEG-2 transport streams may be easily layered on top of other digital communication systems.

Digital Television Terrestrial Broadcasting (DTTB)

Considerations driving the selection of digital modulation approaches for DTTB include striking an appropriate balance among *quality, coverage, and compatibility* as determined by public policy priorities of various countries:

- Reception of high-quality HDTV and audio
- Good coverage of population and area with acceptable reliability
- Acceptable levels of DTTB interference into reception of existing services, particularly reception of standard analog television signals (NTSC, PAL, SECAM) (Fig. 21.1.18)

In the United States the FCC has only made available the existing TV broadcast bands for DTTB of HDTV, allocating an additional 6-MHz TV channel for DTV to every existing broadcast station to be radiated from an antenna which is close to the NTSC antenna of the associated station. The consequence is that current rules for station allocations, including so-called UHF taboos, must be changed to accommodate about 1700 new DTTB channels in the TV broadcast bands, primarily at UHF, with tolerable interference from NTSC transmitters and acceptable DTTB interference into existing NTSC reception. The FCC’s channel allocation plan is based on extensive measurements, field tests, and computer modelling. Thus DTV coverage is primarily limited by interference into existing NTSC service, so achieving the required data rate (approximately 20 Mb/s) at the lowest possible power is paramount.

CNR in DTTB is defined as the ratio in dB of *average power* to total noise power in the channel. With the USB modulation used in the ATSC standard, the threshold of visibility of errors caused by random noise occurs at $\text{CNR} \cong 15$ dB. At about 1 dB below this threshold the picture is not useable. Random noise is only one of a number of possible transmission impairments (see previous section). In contrast with broadcasting of analog video, impairments in proposed DTTB systems add up toward a threshold at which reception abruptly changes from perfect to useless. This abrupt coverage limit in DTTB is referred to as the “cliff effect,” and is similar to the effect in FM radios.

The radiated DTTB signal is noiselike and has a peak-to-average power ratio of 8 to 10 dB. Co-channel DTTB interference into NTSC appears essentially as random noise. Comparing DTTB coverage with NTSC grade-B coverage on the same channel and with the same receiving antenna, transmission line and receiver noise figure as in NTSC reception, the required effective radiated *peak power* in DTTB of HDTV could be 3 to 5 dB less than NTSC *peak power* radiating from the same antenna. While HDTV quality of DTTB is far better than NTSC grade-B quality, statistics of field strength variability with time and location is critical considering the “cliff effect” in DTTB. DTTB reception reliability can, however, be improved by as much as 10 dB with a better receiving antenna and an antenna amplifier.

Modulation Methods for Digital TV

Four modulation methods (see Eq. 31) widely used for r.f. transmission of digital television:

- PSK: Phase shift keying may be preferred in digital TV satellite broadcasting
- QAM: Quadrature amplitude modulation in digital cable television system
- VSB: Vestigial sideband is used in the ATSC standard for terrestrial DTV broadcasting
- COFDM: Coded orthogonal frequency division multiplex is used in the DVB-T standard for terrestrial DTV broadcasting

In QAM, a carrier in the middle of the channel is amplitude modulated double sideband in-phase by one sequence of digital symbols and in quadrature by another sequence of symbols. In a 2.5-MHz Nyquist bandwidth 5 megasymbols per second can be transmitted in the I channel as well as in the Q channel. Thus, a 5-MHz channel can convey 10 megasymbols per second. To reduce extended ringing and intersymbol interference, the spectrum is rolled off antisymmetrically around the Nyquist band edges. This calls for some extra bandwidth. Figure 21.1.24 illustrates typical roll-off for transmission of about 10 megasymbols per second over a 6-MHz television channel.

The quantized symbols in the I and Q channels are coincident, and consequently the amplitude and phase of the carrier at symbol detection time can be represented by a point in a constellation of points in the *xy-plane* representing all possible transmitted vectors as shown in Fig. 21.1.24. If the number of constellation points is K , the signal is referred to as K -QAM ($K = 64$ for 3 bits/symbol and 16 for 2 bits/symbol). Figure 21.1.24 shows that each constellation point is associated with a “decision” cell. An error occurs if transmission impairments at decision time moves a signal vector into the wrong cell. The distance from a constellation point to the border of its cell represents the allowed “budget” for transmission impairments. Figure 21.1.24 shows an approximate relation between the error rate and the rms level σ of Gaussian noise (expressed in terms of the distance from a constellation point to the border of its box). For a typical error rate of 10^{-3} , $\sigma = 0.35$ or -11 dB. The figure also shows the carrier level for $(2N)^2$ -QAM. For 16QAM the required CNR for an error rate of 10^{-3} is seen to be about 18 dB. Channel coding (see below) can improve this relation to an error rate of 10^{-9} out of the channel decoder for a CNR of 15 dB at the input of the demodulator. However, other impairments leave only a part of the error budget to random noise. Phase jitters are particularly damaging to the peripheral vectors. Carrier phase and symbol phase recovery in the demodulator are also critical and complex functions.

VSB is quite similar to QAM. In fact if I and Q symbols in QAM are interleaved in time rather than coincident, they can be detected with a synchronous carrier at the Nyquist band-edges as well as in the center of the band. In VSB detection, the symbols arrive in a sequence $I, Q, -I, -Q, I, Q, \dots$, i.e., at twice the QAM rate but with half the number of bits per symbol. Thus, for a given data rate, the required CNR for a given error rate is about the same as in QAM. As in standard analog television VSB transmits a quadrature signal that eliminates a sideband but doubles the average power. Peaks in the transmitted signal are caused by the quadrature signal. The peak-to-rms ratio is, however, about the same as in QAM (8 to 10 dB). The antisymmetric roll-off around the carrier reduces peaks, ringing, and intersymbol interference. A residual carrier pilot tone is also used. ATSC standard has to improve robustness and reduce lock-in time.

While VSBAM is an extreme time division multiplex system, OFDM is an extreme frequency division multiplex system. OFDM is an entirely different approach to over-the-air transmission of digital data. OFDM uses hundreds of narrowband channels equally spaced along the frequency axis. Each carrier is modulated (QAM)

FIGURE 21.1.24 QAM signal vector constellation points and CNR. Spectra VSBAM, DTTB broadcasting in the United States in the presence of co-channel NTSC radiation.

by digital symbols in such a way that the spectrum of the channel has a sinc/x response with nulls at the carrier frequencies of the other channels, as illustrated in Fig. 21.1.25. As a consequence these channels are "orthogonal" along the frequency axis and do not interfere with each other. Figure 21.1.25 shows that each QAM symbol occupies a long period of time T . In the frequency domain the symbols are spaced $F = 1/T$ Hz. There is a period D between symbols in the time domain to guard against intersymbol interference due to ghosts.

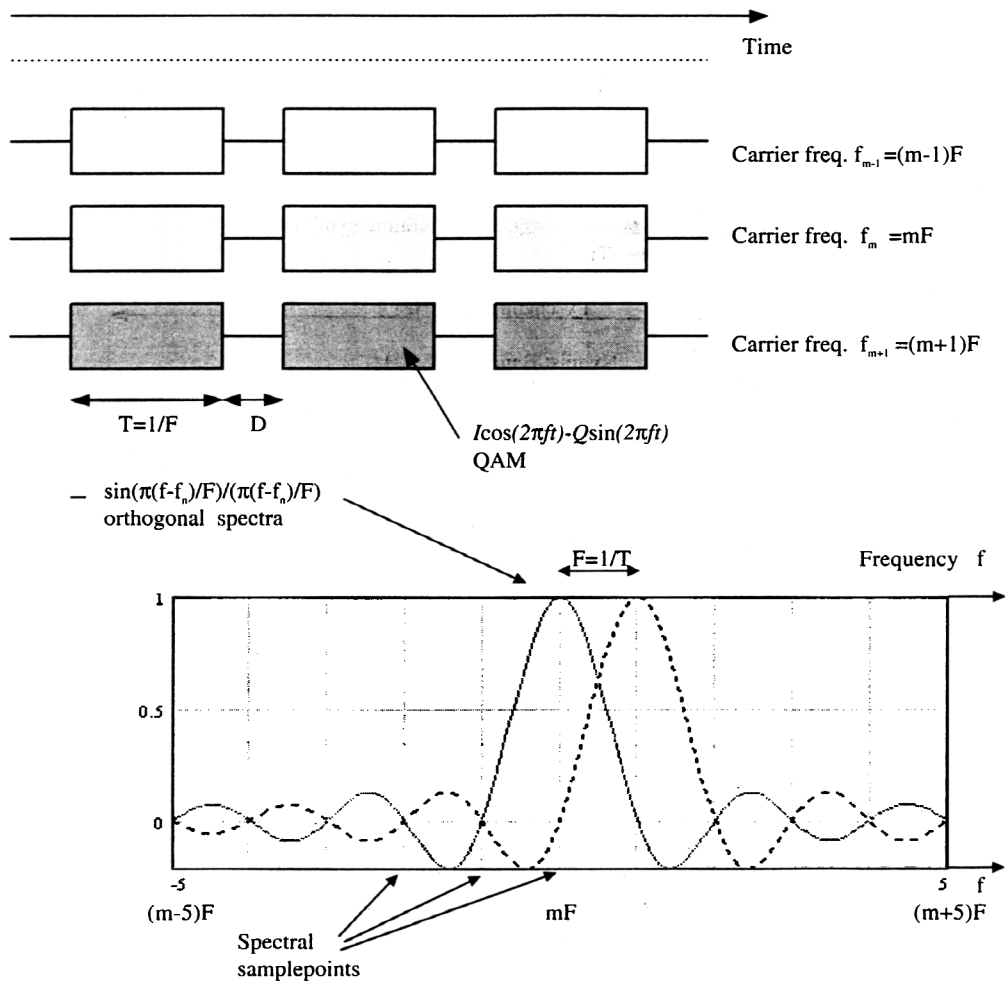

FIGURE 21.1.25 OFDM (orthogonal frequency division multiplex) time-frequency representations. Temporal guardband D is chosen to minimize intersymbol interference due to multipath.

Each symbol is not distorted by a ghost, but the level of the symbol is affected by ghosts. With an equalizer, the CNR of different channels may be different. The terrestrial DVB standard (D1 3-T) includes two OFDM formats: 2k with 1705 carriers and 8k with 6817 carriers. In the 8k format the guard interval D is scalable.

With coded OFDM (COFDM) lost information in different channels can be managed. While OFDM is tolerant of impulse noise, a disturbance occupying a part of the spectrum may wipe out a number of channels. For broadcasting in the presence of strong interference from standard analog television transmitters, it has been proposed that OFDM channels coinciding with bands around the picture, sound, and color subcarrier of an analog TV co-channel signal be left vacant (Fig. 21.1.24). Other methods using error correction designed for this type of interference are also possible. COFDM can be used for same channel cellular digital broadcasting of identical information. Co-channel interference is then equivalent to a ghost. The time guard D has a significant impact on the geographic spacing of the cell. In detection of OFDM, the symbols transmitted during a period T are derived by a spectral analysis of a fast Fourier transform of the temporal signal received during the period.

All transmission systems used for DTTB take the packetized bitstream through a channel coder before it is delivered to a modulator. Since the source coders have eliminated a large amount of redundancy in the video and audio programs, the bitstream feeding the *channel coder* is extremely intolerant to errors. The channel coder adds redundancy in the form of *forward error correction* (FEC) and possibly by *trellis coding* as illustrated in Fig. 21.1.2. The purpose of FEC is to correct transmission errors at the receiver. The Reed-Solomon block FEC can very effectively correct random errors. In the Grand Alliance system 20 parity bytes are added to the 188 byte packet to correct for up to 10 errors ($t = 10$ R-S code). The price is a 10 percent increase in required channel capacity (code rate $R = 188/208$). However, since errors induced by RF interference are generally burst errors, the data interleaving technique is used to regroup data, so that a burst error in transmission is dispersed to appear as random errors spread across many Reed-Solomon FEC blocks, each of which can correct the random error. The purpose of trellis-coding is to prevent errors from occurring, particularly errors caused by random noise, or conversely, to reduce the required CNR for a given error rate. In trellis-coded transmission, fewer symbols are used than the number of symbols that the modulator can generate, i.e., more bits per symbols are available than are transmitted. In the decoder, hard decisions are not made on a symbol by symbol basis, but detected levels of a number of symbols in a sequence form a vector (soft data) which is compared with vectors which possibly could have been transmitted (allowed vectors). Using “soft” data from several symbols and cleverly selected allowed vectors, the required CNR for a given error rate can be reduced.

CHAPTER 21.2

VIDEO SIGNAL SYNCHRONIZING SYSTEMS

Richard A. Kupnicki

TYPES OF SYNCHRONIZATION DEVICES

Video synchronization is the process of aligning or matching two or more dissimilar signals with respect to their timing relationship. In order to fulfill this function, it is first necessary to have a reference video signal such as that produced by a master or a slave sync generator. Then it is necessary to perform the actual signal synchronization using a frame synchronizer.

The three types of synchronization devices which will be discussed herein are the master sync generator, the slave sync generator, and the frame synchronizer. Each fulfills a specific, independent function within the television facility. For each, there are often subgroups which relate to the different video signal formats.

The master sync generator is usually free running and is used as a lock source for all other devices within the facility. The master generator is further characterized by its own high-stability internal oscillator. Frequently two master sync generators will be used together in conjunction with an automatic change over unit in order to minimize the impact of equipment failure. A master sync generator does not need to lock a reference input signal. Sometimes a high stability frequency source may be used as a reference in critical applications.

A slave sync generator will have all the attributes of the master with the addition of circuits to allow the generator to lock to an incoming reference sync signal (generated by a master). Some design savings are generally achieved in the slave generator by relaxing the specifications of the local oscillator circuits. The main purpose of the slave generator is to produce a local sync reference, with timing capability, thus permitting timing offsets with respect to the master generator. Note that as a good practice, color black should be used as the reference video signal due to its constant average picture level (APL) in order to minimize jitter introduced into the phase lock loop.

A video frame synchronizer is used whenever it is necessary to bring an unrelated video source back into timing relationship within a facility. A typical example of this requirement would be a satellite feed or other external source. As well as providing the necessary timing controls, the majority of frame synchronizers will also provide some measure of video conditioning (processing amplifier functions) such as video level control and hue control.

A modern television studio processes audio along with video. Use of frame synchronizers in the signal paths adds considerable delay to the video signal, to the point where video gets delayed more than audio. A human finds it objectionable when audio is more than one video frame ahead or two frames behind its associated video signal. To avoid this problem, audio must be delayed to the same degree as video. To aid in audio synchronization process a suitable reference signal, digital audio reference signal (DARS) needs to be generated by the master or slave sync generators. SMPTE time code is also generated to aid in editing of audio and video streams.

MULTI-STANDARD SLAVE SYNCHRONIZING GENERATOR

Slave sync generators are generally used to provide a local color black reference signal which is locked to a master sync generator system, either directly or via a distribution system.

The use of slave sync generators is an integral part of any television or related facility. They provide a means for timing local devices or groups of devices to a common master reference. Modern slave sync generators will generally always provide an infinite phasing capability, thus allowing the timing outputs of the slave generator to be located anywhere in time relative to the master generator. *Infinite phasing* refers to the capability to adjust vertical phase anywhere within a color frame. "H" phasing refers to adjustments within a line and "fine" phasing refers to adjustment within a subcarrier cycle.

A complete block functional diagram of a slave synchronizing generator (Fig. 21.2.1) should be used as a reference for the following description. The figure shows a multi-standard generator capable of locking to and generating reference NTSC and PAL signals. The implementation differences are summarized in Table 21.2.1, as it is practical to build one piece of hardware with programmable registers to satisfy the requirements of both television systems. In general practice, analog NTSC is used as a reference for all 29.97-frame-per-second-based systems and analog PAL as reference for 25-frame-per-second-based systems.

The reference signal's color burst component is separated using a bandpass filter. The stripped color burst signal is then fed to the complex multiplier. The subcarrier generator block generates two other signals referred to as Sin and Cos since they have a quadrature relationship. The subcarrier generator is composed of an accumulator feeding a set of Sin and Cos ROM look up tables. The ROM outputs are converted to analog via a DAC before feeding the multipliers. The multiplier output is low-pass filtered to retain the difference frequencies, i.e., the frequency error between the crystal oscillator and the input signal. In PAL applications,

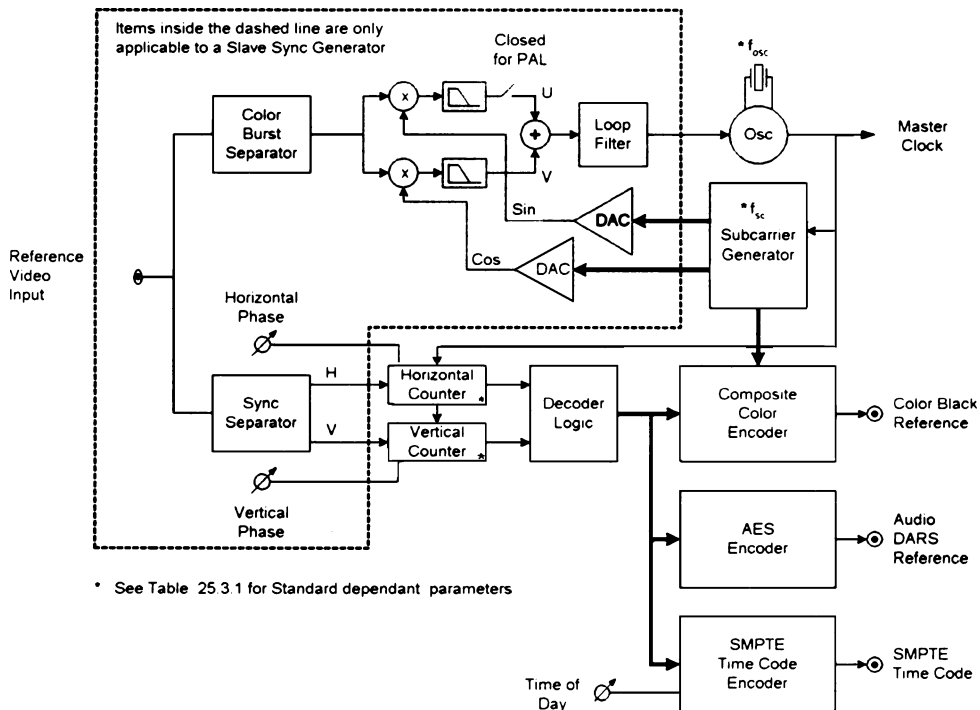

FIGURE 21.2.1 Multi-Standard Sync generator.

TABLE 21.2.1 Standard Related Parameters

Reference video standard	f_{osc} (MHz)	f_{sc} (MHz)	Horizontal counter counts	Vertical counter counts
NTSC	13.5	3.579545	858	525
PAL	13.5	4.43361875	864	625

both filtered axis (U and V) are summed together in order to average the swinging color burst. The resultant error is further filtered by a loop filter before it is applied to the voltage controlled crystal oscillator (VCXO). The oscillator output drives the subcarrier generator as previously described, thus closing the loop. Fine phasing can be implemented by placing an adder between the accumulator and ROM tables in the subcarrier generator. Adding a constant has the effect of statically rotating the sinusoids, thus achieving a phase offset between the input and output and a phasing resolution in the subnanosecond range.

The generation of the blanking interval pulses is performed by two very similar circuits running at horizontal (H) and vertical (V) rates, respectively. The H logic is composed of 858 counter counts for NTSC and 864 counter counts for PAL, which is clocked by the local crystal oscillator running at 13.5 MHz. The output of the counter function is a 10-bit address to a look up table. The H counter is itself synchronized by using the horizontal sync from the reference video input and using the leading edge to preload the counter. The instantaneous load value at the time of initiation of the load defines the relative H timing output to input.

Generation of the vertical pulses is almost identical to the horizontal except that the counter length is 525 for NTSC and 625 for PAL and the clock used is twice the horizontal rate (31.5 kHz) derived from the horizontal counter and look up table decoder.

The respective outputs of both the horizontal and vertical decoders are gated together in a decoder logic block to produce the required final composite outputs of sync, burst flag, and blanking.

Having derived the ingredient signals, the remaining task is to generate the actual output reference signals. In the past, up to the mid-1990s, a reference synchronization generator would generate the basic drive signals (color subcarrier, sync, burst flag, composite blanking), since the process of encoding and decoding was expensive and cumbersome. At the same time one had to deal with routing and timing of multiple signals. With the advancements in silicon, encoding of the drive signals into one composite signal became the norm. When encoding video it is important to remember to transfer the color frame relationship of the input reference signal to the generated reference signal. In addition, generation of audio DARS reference and SMPTE time code are considered to be important functions performed by a sync generator.

The following standards best described the parameters associated with the reference signals mentioned previously.

Reference signal	Associated standard
Video	SMPTE 170M and SMPTE 318M
Audio (DARS)	AES 3, AES 5, and AES 11
Time code	SMPTE 12M

MULTI-STANDARD MASTER SYNCHRONIZING GENERATOR

Master sync generators are generally used in pairs, via an automatic change over device, as the primary reference for a facility. The design of a master generator is in some ways much simpler than a slave since sections of circuitry are simply removed, as can be seen from Fig. 21.2.1. However, the remaining circuits are usually upgraded to meet the tight tolerances required for a master generator, particularly in the case of the crystal oscillator.

Referring to Fig. 21.2.1, it can be seen that the phase lock loop and associated circuit are deleted and the oscillators left to free run. In television plants where interchange of program material extends beyond the plant

boundaries and the production is a live event (e.g., the Olympics), it is desirable to lock the oscillator to an external high stability reference, like an atomic standard or GPS. In this case the internal oscillator is placed in a PLL configuration with an external input. The dividers need to be selected so the comparator sees the same frequency from the forward the feedback paths.

The internal crystal oscillator of a master sync generator is generally of very high quality to maintain the required specification of $3.579545 \text{ MHz} \pm 10 \text{ Hz}$ maximum variation over the operating temperature range and in conjunction with the aging of the crystal.

Two methods are used to maintain a consistent environment for the internal crystal oscillator. The first method has the crystal enclosed in an oven, which is maintained at a constant temperature, typically 66°C (high enough such that the ambient temperature is not a factor). This has the associated drawbacks of considerable power consumption and being able to achieve this temperature instantaneously upon power up. The second method uses a temperature compensation network where the temperature is sensed and a control voltage for the VCO is offset.

There is an interesting derivative of the oven approach, which relies on operation of the crystal closer to the ambient room temperature. In this scenario, if the ambient temperature is above the set crystal temperature, cooling is required and vice versa. This is accomplished using a device based on the Peltier Effect for both heating and cooling under closed loop control.

VIDEO FRAME SYNCHRONIZER

A frame synchronizer is a device that accepts video information at one rate and provides an output that is “in time” with respect to a reference. Synchronization is achieved by writing the incoming video into memory at one rate, and then reading it out at a rate locked to the facility reference (master sync generator). The memory, therefore, acts as a buffer, allowing the data to accumulate prior to discharge.

A mechanical example to illustrate this buffering action of memory would be a stream flowing downhill into a reservoir contained by a dam. At the bottom of the dam the water is discharged at a constant rate. The volume of water the stream is supplying can increase or decrease, but the water discharged at the bottom of the dam will remain constant due to the buffering action of the accumulating water in the reservoir.

A complete functional block diagram of a typical frame synchronizer (Fig. 21.2.2) should be used as a reference for the following description.

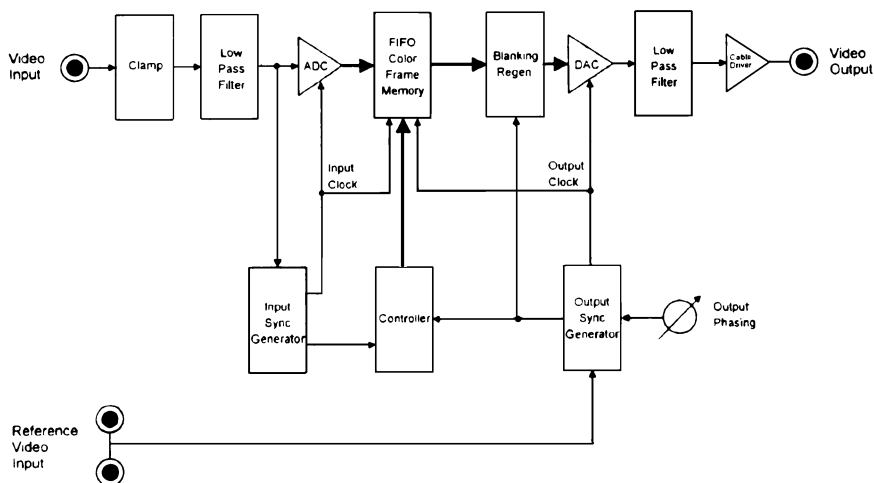

FIGURE 21.2.2 Typical video frame synchronizer.

The input video is first clamped in order to establish a known dc level, which is within the window of the analog-to-digital converter. This is followed by a low-pass filter that prevents any harmonics above one-half the sampling frequency (14.31818 MHz in the case of NTSC) from passing through, thus satisfying the Nyquist sampling criteria.

The signal is then digitized using either an 8- or 10-bit converter. The choice of 8 or 10 bits is the determining factor in frame synchronizer classes. Higher end applications will use 10-bit quantization. However, this is a cost versus performance function.

The digital video data are then stored in a FIFO memory where, after a period of time, it is read back out. New blanking is inserted into the signal and the information is then converted back into the analog domain and low-pass filtered.

Information is required for both the input and output processing sections for the purposes of timing. This is produced by the input and output sync generator sections, as illustrated in Fig. 21.2.2.

The input sync generator samples the incoming video signal and locks a local oscillator to the incoming subcarrier at a 4 fsc rate (fsc = the frequency of the subcarrier). The horizontal and vertical portions of the incoming signal are decoded to provide the information required by the controller and subsequent memory.

The output sync generator performs a similar function except that it samples an external video reference in order to establish a timing reference and clock for the output video. The output sync generator also provides phasing capability which permits the positioning of the output video signal anywhere in time with respect to the reference video signal.

MEMORY

The quantity of memory used must be enough to store one complete color frame of video. This is the smallest unit of video, which can be deleted or repeated while still maintaining the proper color relationship. This means four fields of video in the case of NTSC and eight fields in the case of PAL video signals. It is worthwhile to note that some video frame synchronizers store the complete video line, blanking included, while others store only the active portion of the line.

The most common type of memory used is DRAM where the controller provides read and write addressing. The latest trend is to use FRAM (Field RAM) which employs a FIFO structure and only read and write pointer resets need be provided by the controller.

It is necessary to provide a mechanism such that memory addressing is synchronized to the sync structure of the video signal. For example, if pixel 1 of line 1 is written into location X of the memory, at the time that location X is read back, that information must be placed back on line 1, pixel 1 of the output sync structure. In the case where FRAM is used, this is accomplished by generating a write/reset pulse coincident with the leading edge of sync of the first full line in the vertical interval of field 1 in the color frame sequence based on the input sync generator. Similarly, the read/reset is generated in the same manner, except it is based on the output sync generator. In the case of DRAM memory, the controller will contain read and write address counters that are reset with pulses as described in the FRAM implementation.

FRAME SYNCHRONIZERS WITH DIGITAL I/O

The emergence of digital video standards has increased the importance of frame synchronizers because of the increased processing throughout delays associated with digital equipment. The structure of the frame synchronizer is easily adapted to digital interface in either the parallel or serial video domains.

The analog-to-digital and digital-to-analog converter sections are replaced with the appropriate digital interface, and the input sampling clock is derived directly from the incoming video signal rather than having to extract this information (these codes are embedded directly as part of the digital signal's structure). The output sync generator remains the same since the majority of house reference signals are still analog color black. The change over to a digital house reference will likely happen in the future. Once this does happen, the output sync generator will shift in appearance to that of the input sync generator just described.

CHAPTER 21.3

DIGITAL VIDEO RECORDING SYSTEMS

Peter H. N. de With, M. van der Schaar

INTRODUCTION TO MAGNETIC RECORDING

Historical Development

Recording of video signals has established itself as a continuously growing and indispensable technique in video communication services and the video entertainment area. The currently available video recorders for professional and consumer applications have evolved from the early experiments in magnetic tape recording, which were focused on analog voice and audio recording. In the 50s, a number of companies experimented and succeeded to record video signals for broadcasting purposes, however, using rather diverging technical approaches, as the optimal concept for video recording was still being explored. The discrepancies in the applied techniques were due to a new technical hurdle that had to be taken: the required video bandwidth is roughly 300 times the bandwidth of audio signals. It is therefore not surprising that a number of system proposals were based on extending the traditional longitudinal audio recording technique by using a plurality of longitudinal tracks that are registered simultaneously, and, in order to further cope with the demanding bandwidth, a very high tape speed.

In 1956, Ampex announced a system (Quadruplex, or simply Quad) that enabled a substantially lower tape speed, by applying a rotary drum containing a head wheel that turns around at a much higher speed than the tape is transported. Another technique, which had a major impact on further developments in video recording, was the frequency modulation of the video signal prior to storage. This principle, in which a carrier having a relatively low frequency, e.g., 5 MHz, is frequency modulated by the wideband video signal, is still being applied in the current analog video recorders for registration of the luminance signal. The major drawback of the Quad system was its segmented storage of television fields on tape caused by relatively short tracks, which demanded accurate time-base correction for picture reconstruction. The short tracks resulted from the applied transversal recording technique, in which the tracks were written perpendicular to the tape length, so that several rotations, and thus tracks, were required to cover one complete television field.

The segmentation problem was solved a few years later (1959) by other companies, which realized a helical-scan video tape recorder (VTR) that formed the basis of the currently available VHS format. In the 1960s, emphasis was put on the implementation of consumer video cassette recorders (VCRs)—a logical successor of audio cassette recording—that allowed a much simpler tape loading mechanism. One of the first VCRs for professional use is the U-matic system, introduced by Sony in 1970. Since then, many systems have been realized and passed through the consumer's horizon,¹ among which a VCR by Philips in 1970, called the N-1500 (the first consumer VCR), Betamax by Sony in 1975, the VHS system by JVC in 1976, V-2000 again by Philips in 1979, and 8 mm by a company consortium in 1984.

FIGURE 21.3.1 Helical-scan tape recorder with two heads.

FIGURE 21.3.2 Azimuth recording track pattern and reading with a magnetic head having corresponding azimuth.

As a result of the fast progress, video recording has even started to influence audio recording by means of the introduction in 1987 of the digital R-DAT format, which is fundamentally a miniaturized video recorder.² The generation of video recorders from the past two decades is based on helical-scan recording, which is depicted in Fig. 21.3.1. In such a system,³ the magnetic heads are mounted on a rotary head wheel inside a cylindrical drum, which has the tape wrapped helically around it. The tracks written on tape have a shallow angle with respect to the tape direction and are gradually crossing the tape width, so that a single track can be long enough to store an entire television field.

The continuous drive for higher quality and the demand for more compact mechanics have been satisfied by an increased recording density with each new generation of video recorders. The enormous augmentation in information density is mainly a result of better recording media and heads.⁴ The linear-density improvement resulted from better magnetic tapes, offering higher signal-to-noise ratio (SNR) and more high-frequency output, thereby enabling more flux reversals per unit of length. This is expressed by the decrease in the minimum wavelength.⁵ The track density improves with the higher SNR and better tracking systems, enabling a further reduction of the track pitch, i.e., the distance between the centers of two adjacent tracks.

Another technique, introduced by Sony in the Betamax system (1975), which significantly contributed to a higher track density, is azimuth recording, in which the tracks are recorded without guardband (the empty space between tracks) and with alternating azimuth (Fig. 21.3.2). Azimuth is the angle between the actual gapline of the magnetic head and the direction perpendicular to the track length. Azimuth recording, which reduces the effects of “sidereading” on adjacent tracks, is now a universally applied technique in consumer video recorders.

The areal recording density improves considerably from higher track densities than from higher linear densities. Although for the consumer the volume density is the most important—a parameter in which magnetic recording clearly outperforms optical disk recording, one of its key parameters, the tape thickness, has not decreased very rapidly. In the future, it is therefore expected that tape manufacturers will work toward tapes with thinner base films, which further contributes to a higher volume density. In recent years, the mass production of optical disks, which was initiated by the success of the compact disc for audio and the CD-ROM for data, has become the leading technology for video recording systems. This has resulted in the DVD recorder and playback-only systems, which are available for various home and personal computer systems.

Analog Consumer Video Recording

From the systems mentioned above, two analog recorders are still in use in the home today: VHS and the 8 mm system. From both standards, camcorders are available as well. The 8 mm cassette is smaller than that of the VHS system, therefore a special compact VHS-C cassette was later introduced for camcorder use only.

The small cassette needs an adaptor for playback in the desktop VHS recorder. With respect to the tape format, the following characteristics apply.

Video. Video fields originating from the odd and even lines of complete pictures (frames) are recorded line by line in individual tracks, thus one field per track. This holds both for most professional systems and the consumer VHS and 8 mm system. This recording allows access to each field individually, for trick modes, such as still picture or fast search (also called picture shuttle).

Audio. VHS has two audio tracks in the direction of the tape travel, while 8 mm uses audio recording inside the slanted tracks.

Mechanics. All home recorders use 180° wrap angle with two video heads diametrically opposed, such as in Fig. 21.3.3. The heads are mounted on a wheel inside a rotating drum. The scan speed, i.e., the actual speed of reading or writing over the tape surface varies between 25 m/s for professional recorders and about

4 m/s for consumer recorders. The tape travel speed is only a fraction of this. Furthermore, the systems are usually cassette based. Some professional recorders use an omega wrap that covers nearly a full circle.

Recording density. The consumer recorders apply relatively narrow tracks of, say, 20 μm . The consumer recorders apply azimuth recording for high recording density, whereas professional recorders use guard bands between two succeeding slanted tracks. The tracks in professional systems are less narrow.

Tape format. Figure 21.3.4 shows a typical footprint of a tape format. VHS uses longitudinal tracks for the audio signal. The video tracks are slanted. The 8 mm system uses an audio slanted track with an edit gap between the video and the audio part, thereby enabling separate editing of video and audio. The control track at the bottom allows the insertion of markers and time code on tape for programming and fast searching to a specific point. The place and location of control and audio tracks may vary from standard to standard, especially for professional analog video recorders such as the B- and C-type recorders and the Betacam and M-machines (see, e.g., Ref. 6).

FIGURE 21.3.3 Headwheel with two head pairs and 180° wrap angle used in consumer recorders.

Comparison of VHS and 8 mm Systems

Table 21.3.1 depicts the key parameters of VHS and 8 mm systems. The numbers of the Betamax system have been added for comparison. Table 21.3.1 shows that Betamax and VHS are comparable and are nearly equal systems. The picture quality of Betamax was slightly better, because the drum was larger and more tape was consumed, allowing a broader recording frequency band. For home recorders, VHS finally won the battle because more prerecorded movies were available in the market, and it offered a longer playing time. The 8 mm system was introduced later and offers a higher picture quality than VHS, merely as a result of using newer, thinner tapes with an improved magnetic layer. Consequently, the system size could be reduced (drum, cassette), combined

FIGURE 21.3.4 Tape format as used in consumer recorders.

TABLE 21.3.1 Key Parameters of Betamax, VHS, and 8 mm Helical-Scan Cassette Recorders

	Betamax	VHS	8 mm
Tape width	12.65 mm (0.5 in.)	12.65 mm (0.5 in.)	8 mm
Tape thickness	20/16.5 μm	20/16.5 μm	13 (10 Hi-8) μm
Tape material		Co γ Fe oxide	Metal particle
Head drum diameter	75 mm	62 mm	40 mm
Tape wrap angle	180°	180°	180°
Head-tape speed	7.0 m/s	5.8 m/s	3.76 m/s
Linear tape speed	4.0/2.0/1.33 cm/s	3.34/1.67/1.12 cm/s	1.43 cm/s
Video track width	58.6/29.2/19.5 μm	58.6/29.2/19.5 μm	20.5 μm
Audio track width	1.05 mm	1.0 mm	0.65 mm
Track length		97 mm	62.6 mm
Track angle		6°	4° 53'
Azimuth angle		+/-6°	+/-10°
Video modulation	FM composite	FM composite	FM composite
Color modulation	color under	color under	color under
FM carrier, sync tip	3.5 MHz	3.4 MHz	4.2 MHz
P.White in spectrum	4.8 MHz	4.4 MHz	5.4 MHz
		7 MHz (SVHS)	7.7 MHz (Hi-8)
Chrominance carrier	688 kHz	629 kHz	743 kHz
Cassette size	156 \times 96 \times 25 mm	162 \times 104 \times 25 mm	95 \times 62.5 \times 15 mm
Playing time	60/120/180/240 min	120/240/360/480 min	90 min

with a smaller track width. The carrier frequencies were raised to a higher level. Because of its smaller size, the 8 mm camcorder products became an almost immediate success and they have gradually pushed VHS camcorders out of the consumer market.

Nowadays, the VHS and VHS-C camcorders are being used less often, and camcorders are typically based on either the analog 8 mm format or the digital DV system discussed later. The success of the DV system has also resulted in the reintroduction of the 8 mm format, but now based on digital recording using the video compression technique that was developed for the DV system. This product was introduced at the end of the 1990s by Sony and is called "Digital 8." Camcorders are basically video tape recorders in small form with a lens, optical pickup device based on a CCD sensor (resolution 250,000 pixels or higher), a viewfinder using a color liquid crystal display (LCD), and a microphone for capturing audio signals.

Color Modulation in Analog Recorders

The video signal recording on VHS and 8 mm is such that the color is modulated with a specific technique, called "color under." This will be explained now, starting from the limitation of the magnetic recording channel properties. The television signal contains about 5 MHz bandwidth. The magnetic recording channel is bandlimited, that is, it cannot record either zero frequency or very high frequencies. Analog professional and consumer recorders therefore modulate the signal to a bandpass signal. The modulation is based on frequency modulation (FM).

Professional analog recorders such as the type C machines apply direct recording, in which the frequency carrier is modulated by the composite video signal. The composite video signal contains the baseband luminance (Y) signal with a 5-MHz spectrum onto which the chrominance or color (C) signal is added with amplitude modulation using a specific carrier frequency. For PAL this is 4.43 MHz and for NTSC it is 3.58 MHz. With direct recording, the sync tip (lowest voltage) of the video signal has a carrier frequency of 7.06 MHz, the blanking signal (zero video) is modulated with 7.8 MHz and the peak white signal (full video) with 9.3 and 10 MHz, for PAL/Secam and NTSC, respectively. These numbers refer to the analog type C recorder. This type

FIGURE 21.3.5 Spectrum of a full color video signal after applying the “color under” system.

consumer recorders such as VHS, the modulation spectrum looks typically like Fig. 21.3.5. Figure 21.3.5 shows the resulting spectrum with the modulation carrier frequencies and Fig. 21.3.6 depicts an example of an encoder block diagram required for modulation. The required bandwidth for the modulated video signal is well below 10 MHz. However, owing to the bandwidth restrictions, the color bandwidth is in practice limited to about 300 kHz for the VHS system.

Digital Video Recording and the Growth of Bit-Rate Reduction

The advent of digital signal processing techniques and its subsequent rapid development has resulted in a reconsideration of the current concepts for video recording. Digital processing and recording not only outperforms analog recording with respect to time stability, robust picture reconstruction, and (flawless) reproduction after multiple copying, but also allows for advanced image manipulation techniques that were impossible with the conventional analog technology. In the past decade, we have witnessed a transition from analog recording to digital recording systems. As always, at the introduction stage of a new technology where costs are still critical, the first systems are targeted for professional (broadcast) applications. The first full-digital video recorder brought to the market was the D-1,⁷ which was introduced around 1985. It was a YUV-component video recorder, capable of recording a CCIR-601 video signal. Soon thereafter, a digital recorder, referred to as D-2, was agreed upon, for composite NTSC⁸ and PAL video signals. From 1995 onwards, the gradual introduction of a digital format for consumer applications took place, called the DV system. The DV system established itself as a compact camcorder format, initially for semiprofessional and ENG applications but recently also for the consumer. Principal manufacturers are Sony, JVC, and Matsushita. From a technological viewpoint, a small-sized digital video recorder became feasible and the IEEE-1394 digital interface to computers for off-line digital editing has proven its value.

In addition to the developments in consumer magnetic recording, video recording has further broadened its scope of application by new video (image) storage equipment based on optical disc recording. One of the first systems was the compact disc interactive (CD-i) system of Philips⁹ from about 1990, of which the video-coding technique was standardized for multimedia applications MPEG-1,^{10,11} electronic photography using magnetic and optical storage equipment, or even solid-state memory. The CD-i was soon succeeded by the

FIGURE 21.3.6 Modulation block diagram for the “color under” system.

of modulation requires a total bandwidth of 15 MHz, which is too expensive for consumer systems. The advantage of direct recording is the excellent quality.

Consumer analog recorders have a different system for adding the color signal to the modulated spectrum. In order to save bandwidth, the luminance signal is modulated with a lower carrier frequency. The color signal is then modulated with a carrier frequency residing at the low-frequency part of the luminance spectrum, so that the color signal is located close to zero frequency and below the luminance signal. This approach is therefore called the “color under” system. The principle is visualized in Fig. 21.3.5 and Fig. 21.3.6. In analog consumer recorders such as VHS, the modulation spectrum looks typically like Fig. 21.3.5.

video-CD (VCD) format, offering straightforward MPEG-1 compressed video¹⁰ on 1.2 Mb/s on a compact disc. The system is still being used in Asia. Both CD-i and VCD are discussed later in this chapter. In the past years, the optical recording density was improved to a quad-fold of the audio CD, and the new video compression standard MPEG-2^{12,13} was used to store video in strongly compressed form. The disk format was standardized as the Digital Versatile Disc (DVD). The high density of the DVD and the compression factor of 25 of MPEG-2 for broadcast video enables recording of a full movie on a single disk. This format has resulted in a number of recordable DVD formats¹⁴ of which DVD – RW and DVD + RW are most known. Other DVD formats are DVD-ROM and DVD-RAM. Details of the above-cited systems are disclosed in the subsequent sections.

The importance of video bit-rate reduction techniques (data compression) cannot be underestimated. The implementation of this technology in various forms combined with the implementation in cost-efficient silicon chips has fueled the realization of many new products in consumer electronics as described above. Video compression has been widely studied, which is proven by the excellent introductory textbooks on digital image processing and associated video coding,^{15–17} which are available for the interested reader. More details about the algorithms video data compression for recording can be found in reviews, see e.g. Ref. 18. From this literature, it can be deduced that transform coding¹⁵ has proven its merits for efficient coding of video signals. During the 90s, advanced video compression has become an emerging and enabling technology for new systems in digital transmission and storage. An example of successful video compression supporting digital video broadcasting in the MPEG standard,^{10–13} which will be discussed in a succeeding section.

From Composite to YUV-Component Video

Except for the video cassette recorders such as VHS and 8 mm systems, which store the video signal in composite form, all modern recording systems are based on YUV- or YCrCb-component recording. Composite recording means that the video signal is basically one signal with the color signal modulated into it around the color subcarrier frequency. With component recording, the input video signal, which is mostly generated by a camera in three color components—red, green, and blue (RGB), is also recorded in three separate signals, mostly YCrCb. The three RGB components are converted to YCrCb components at the input of the recorder (e.g., with camcorders) or the signal is already ordered in YCrCb format (with, e.g., DVD playback). The conversion is a 3×3 matrix multiplication with a RGB sample triplet at the input and the new YCrCb triplet at the output. The Y-signal refers to the luminance portion (black and white) of the full-color signal, the UV or CrCb to the color-difference signals, i.e., B-Y and R-Y. The CrCb components are shifted and centered around the value 128 in an 8-bit format between 0 and 255, in accordance with the Y component, whereas U and V signals are centered around zero. Since the color-difference signals contain less energy than the Y-component, they are usually sampled with a lower frequency than the Y sample frequency, e.g., with half or a quarter of the Y sample frequency.

TABLE 21.3.2 Key Parameters of Typical YCrCb Sampling Standards Used in Digital Video Products.

Sampling standard	4:1:1	4:2:0	4:2:2
Sample frequency Y	13.5 MHz	13.5 MHz	13.5 MHz
Y samples/line active	720 (704)	720 (704)	720
Y lines active (50/60)	576/480	576/480	576/480
Cr/Cb sample frequency	3.375 MHz	6.75 MHz	6.75 MHz
C samples/line active	180 (176)	360 (352)	360
C lines active	576/480	288/240	576/480
Active bit rate (8-bit)	124 Mb/s	124 Mb/s	166 Mb/s

Note: When interlacing is used, the number of lines per picture splits into two groups (fields) of odd and even lines.

Table 21.3.2 summarizes the most important properties of common sampling standards. The 4:2:2 sampling standard is mostly found in professional recorders, such as the D-1. The DV format applies 4:2:0 in Europe and 4:1:1 in the United States and Japan. The DVD standards are all based on 4:2:0 sampling in both 50 and 60 Hz countries. Older products such as VCD use 4:2:0, albeit at halved horizontal and vertical resolution of the input signal, also known as SIF or CIF resolution (standard or common intermediate format). The halved resolution at the input is required to obtain the low bit rate on CD. It should be noted that the conversion from RGB to YUV or YCrCb signals reduces the quality of the full-color signal, because the difference signals are sampled at reduced frequencies. The advantage is a smaller input bit rate (see Table 21.3.2) at the expense of some loss of sharpness in color transients.

PROFESSIONAL DIGITAL VIDEO RECORDING

The Lossless D-1, D-2, and D-3 Systems

The gradual introduction of digital signal processing in the studio and an increased use of computer graphics in video signals resulted in the introduction of various digital video tape recorders for professional use. The advantages of digital signal storage in a studio environment are, apart from conventional issues such as increased robustness, that multiple editing generations (copy of copy) are allowed. The deterioration in quality is much less than that with analog recorders. In the early 1990s, both composite (D-2, D-3) and component digital studio recorders (D-1) were used. D-1 is the oldest one (introduced in the mid-1980s), but due to its robustness for editing it is still being used actively. All systems are cassette recorders, based on helical-scan recording and use 8 bits for video sampling.^{6,19} The recording mechanics are constructed in such a way that three different types of cassettes can be inserted without adaptors, leading to various playing times. Another common property is that they do not use video compression in order to offer maximum quality for studio applications. For further comparison, see Table 21.3.3.

When uncompressed video is used, the bit rates after sampling with sufficiently high frequency are too high (e.g., about 100 Mb/s at minimum) for using a single recording head. Therefore, a head *pair* is used for recording two tracks simultaneously. Professional recorders sometimes use a plurality of heads to offer high picture quality during special modes such as “still picture,” slow motion, and fast forward or backward search. The picture quality of digital VTRs in such modes is further improved by *shuffling* the pixels in a special way prior to recording on tape.⁷ The shuffling balances and smoothes the effect on the picture quality of crossing various tracks that inevitably lead to data discontinuities.¹⁸ D-1 can search up to 64 times the normal speed and

TABLE 21.3.3 Key Parameters of Digital Professional Video Recorders (f_{sc} = Color Subcarrier Frequency, 3.58 MHz for NTSC and 4.43 MHz for PAL)

	D-1	D-2	D-3
Video recording type	Component	Composite	Composite
Tape width	19 mm (3/4 in.)	19 mm (3/4 in.)	12.65 mm (0.5 in.)
Tape magnetic layer	Fe oxide	Metal	Metal particle
Tape speed	28.6 cm/s	13.2 cm/s	8.4 cm/s
Track width	40 μm	39 μm	20 μm
Bit length	0.45 μm	0.43 μm	0.38 μm
Recording density	55 kb/mm ²	59 kb/mm ²	130 kb/mm ²
Video sample freq. (Y/C)	13.5/6.75 MHz	$4f_{sc}$	$4f_{sc}$
Video sampling	8 bits	8 bits	8 bits
Audio sampling	20 bits	20 bits	20 bits
Audio recording	4 tracks	4 tracks	4 tracks
Recording bit rate	216 Mb/s	105 Mb/s	105 Mb/s
Playing time	76/34/11 min	208/94/32 min	240/125 min

still show a complete—though noisy—picture. The noise is caused by a picture that is constituted from data blocks of pixels originating from various pictures with different time origin. The data shuffling redistributes the pixels over the image leading to an effect perceived as pixel “noise.” The noise increases with the search speed.

The recording density continuously improves because of the introduction of better magnetic tapes, using special magnetic materials for higher density. The D-3 that was introduced in 1990 by Panasonic uses a higher recording density than the D-1 and D-2 machines. It is based on the small size of Betacam of Sony and a format called M-II of Panasonic, but now designed for digital recording. Another difference is that the D-3 cassettes contain half-inch tapes, whereas D-1 and D-2 use $\frac{3}{4}$ -in. tapes. The high recording density reduces the robustness against channel errors, such as scratches and dirt, but this is combated by *error correction codes*. The aforementioned recorders apply Reed-Solomon (R-S) block codes for error protection. A group of pixels is mapped into a data block onto which a string of parity check symbols is appended. These codes can reduce a fluctuating Byte Error Rate (BER) in the order of 10^{-4} 10^{-5} to as low as 10^{-10} 10^{-12} . This extra coding step is also an aid in achieving sufficient robustness for multiple editing iterations to, e.g., 100 times.

D-5 Recorder

The D-5 of Panasonic is an extension of the D-3 machine and is backward compatible to D-3. The unique feature of D-5 is the recording of 16:9 aspect ratio television signals, using three video components of 10-bit resolution. For wide screen, an 18-MHz sampling frequency is used. Additionally, an adapter can be used with 4:1 video compression for recording HDTV signals of 1.2 Gb/s.

Professional Recorders with Compression

The DV format that is being discussed later in the chapter has resulted in three different formats:

- **DVCAM** (Sony) is very similar to DV, using 25 Mb/s video with DV compression, 8-bit sampling on 4:1:1, and the 6.35-mm DV tape with a metal evaporated layer. However, 15 μm tracks are used, giving higher robustness. It is DV backwards compatible. Audio is done with 2-track recording, 16-bit sampling, and 738 kb/s subcode can be added.
- **DVCPRO** (Panasonic) is also compatible with DV and even DVCAM. The major differences are the use of two longitudinal tracks for improved editing (cue and control). The track pitch is 18 μm for robustness. This system was later extended to 50 Mb/s recording, called DVCPRO50, offering 4:2:2 broadcast quality recording with less compression (slightly more than 3:1) than DV (5:1).
- **Digital-S** (JVC) uses 0.5-in. tape based on S-VHS recording mechanics and a twin DV compression system for high-quality 4:2:2 broadcast recording. This system also records with a compression of 3:1:1. The 50 Mb/s machines have 4-track audio and the double subcode capacity of DVCAM, i.e., 1.47 Mb/s.

The Betacam SX recorder has also 8-bit video with compression using a 0.5-in. tape. The compression is higher—about 10:1—than DV, since it applies the MPEG 4:2:2 Studio Profile. This was chosen for compatibility reasons with emerging MPEG-based DVB standards. The video data rate is 18 Mb/s.

Finally, a number of digital high-definition recorders were introduced with the first experimental transmissions of digitally compressed HDTV in the United States. Examples are HDCAM, HDD-1000, and HDD-2700 machines. Typical resolutions are 1440 through 1920 samples by 720 progressive, 1035 or 1080 interlaced lines, using 10-bit video sampling. Audio is performed with 20-bit sampling and recorded with 4 or 8 tracks.

D-VHS

D-VHS (or Data-VHS) is the latest development of the VHS video format developed by JVC that enables digital recording of high-definition broadcasts and multichannel broadcasts. Three different D-VHS modes have been

standardized: the STD (standard) mode, the HS (high speed) mode which is compatible with high-definition (HD) digital images and multichannel broadcasts, and the LS (low speed) mode which enables a maximum recording time of 49 h (Fig. 21.3.7 and Table 21.3.4). The technical format specifications of D-VHS were standardized in April 1996. D-VHS is compatible with all types of digital broadcasts in the world including new digital high-definition broadcasts.

FIGURE 21.3.7 Various D-VHS formats.

Main Characteristics of D-VHS

D-VHS³⁹ enables bit-stream recording of digital broadcasts, in addition to analog recording of conventional broadcasts. D-VHS takes advantage of the characteristics of tape as a medium to provide extremely large

21.70 VIDEO AND FACSIMILE SYSTEMS

capacity digital data storage. D-VHS maintains compatibility with conventional VHS by allowing recording and playback of the enormous amount of VHS software available as well as stored around the world. D-VHS can readily evolve and spread as a household device owing to the possibility of using current VHS technologies, parts, and manufacturing facilities.

The data that are recorded from digital video broadcasts are actually an MPEG-compressed video and audio program, as standardized by, e.g., the DVB standard. This standard is based on MPEG-2 compression and so-called MPEG-2 transport stream (TS) packets of 188 bytes. The DVB standard has adopted most of the MPEG-2 standard as the basis for transmission of digital programs. The MPEG standard is explained later in this chapter. The recording of digital data on a basically analog machine is not without problems because the required media such as magnetic heads and tape for digital data differ from heads and tape that are optimal for analog signals. Fortunately, the size of the VHS headwheel (62 mm) is large enough to contain additional heads and transformers for constituting a compatible recording system.

DV RECORDING SYSTEM

Introduction

The design of the DV format has shown that for digital TV recording (and HDTV), small-sized recording mechanics giving sufficient playing time can only be achieved if the recording bit rate is reduced substantially. The initial bandwidth expansion due to the digitization of the video signal, combined with binary recording instead of the analog multilevel recording, must be compensated to a large extent by bit-rate reduction.⁴³ The relation between recording mechanics and video compression has played an important role in setting the DV standard so that both will be addressed.

For consumer recording,¹⁹ the trend is toward small recording mechanics, especially for portable applications, and digital recording of compressed digital video signals. These aspects have been combined into the DV system, which was first announced in 1993²⁰ and which has been further developed by a substantial group of companies. The main focus of the standard was to introduce attractive small camcorder products in the mid-90s. Experimental digital video recording systems were initiated at the end of the 80s.^{21–25} Since September 1995, a number of companies have introduced DV camcorders into the market. Based on the DV technology employing also new tapes,^{26–30} the professional systems DVCPRO and DVCAM have emerged, which are increasingly popular.

Despite the acceptance of the MPEG and JPEG standards in numerous applications, the development of the DV video compression standard was largely guided and justified by the targeted product and cassette size, power consumption, and the consumer price level. Irrespective of the previous issues, a number of recording system constraints have to be satisfied in any case and are rather typical, namely:

- Editing, preferably on picture basis
- Robust for repeated (de-)compression, resulting from analog video dubbing
- Multitrack format, using a set of tracks for one frame (see Fig. 21.3.9)
- Forward and backward search on tape, from small data bursts pictures have to be recovered (see Fig. 21.3.9)
- Very high robustness
- High picture quality

DV System Architecture

Figure 21.3.8 from Ref. 31 portrays the block diagram of the recording system. Signal processing is divided into two main classes:

- Source coding employing video compression and source data formatting
- Channel coding using error-correcting codes and modulation codes for spectrum shaping of the bit stream

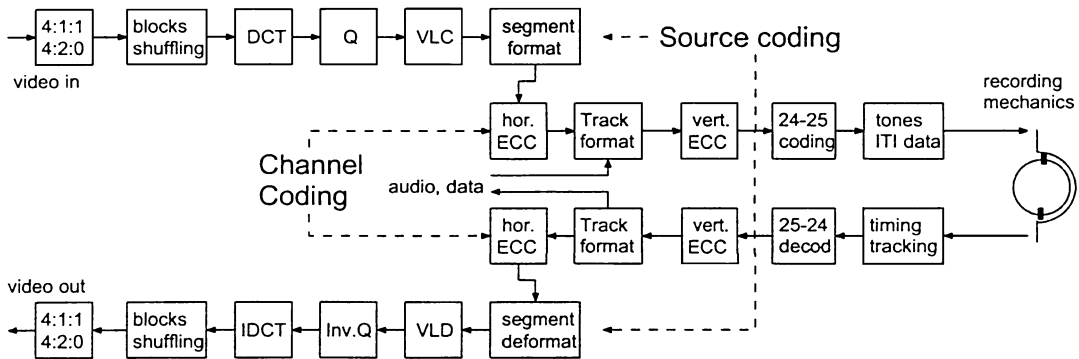

FIGURE 21.3.8 Block diagram of complete processing of consumer DV recording system.

FIGURE 21.3.9 Multitrack format and trick play.

color-difference signals (Cr and Cb) are subsampled either horizontally with a factor 2 (4:1:1) for 60 Hz or vertically with a factor 2 (4:2:0) for 50 Hz systems.

For error-correction coding (ECC), the DV recording format employs the obligatory Reed-Solomon (R-S) product codes, of which the error-correcting properties are defined within a track. After compression, the data are organized in small packets, called sync blocks. Each sync block gets some parity bytes (HECC) assigned to it for random byte errors and for error detection of burst errors. Subsequently, the complete video data block (or audio) is extended with extra sync blocks containing vertical parity bytes (VECC). The performance of these codes is very good for removing random errors and general burst errors. As a second step in channel coding,⁴⁰ a high-efficiency DC-free 24-25 channel code was adopted, described in Refs. 32, 33, to constitute pilot tones for tracking, which are embedded in the data.

TABLE 21.3.5 Key Parameters of Digital Consumer DV Recorder

Scanner	2 heads
Scanner diameter	21.7 mm
Scanner speed	9000 rpm
Tape width	6.35 mm

Recording rate	41.85 Mb/s
Tracking	Embedded tracking tones
Channel modulation	24-25 code
Error correction code	R-S product code
Video bit rate	25 Mb/s
Video coding	8 \times 8 intraframe DCT
Trick mode implementation	Video macroblock shuffling

The video compression is based on the discrete cosine transform (DCT), and subsequent quantization and variable-length coding (VLC) of the transformed video data. Since the operations are performed on blocks of 8 \times 8 samples, the video input signal is stored for line-to-block conversion. Shuffling of data blocks is performed for improving the picture quality under normal and trick play. The sampling of the video signal is derived from the CCIR-601 standard (4:2:2) with 13.5 MHz sampling frequency for the luminance (Y) signal. The

recording mechanism is based on a small drum of 21.7 mm, which rotates at 9000 rpm. The basic recording mode (2 \times 1 head) has a capacity of 41.85 Mb/s (equivalent to 25 Mb/s video), but the system can be upgraded mechanically and electronically to 83.7 Mbit/s (50 Mbit/s net video rate) for HDTV recording.³¹ Possibilities to go to 12.5 Mbit/s video rate or lower, required for recording of MPEG signals (MP@ML SDTV), have been indicated earlier.³² Table 21.3.5 portrays the key parameters of the experimental recording system.

FIGURE 21.3.10 Important 8-mm tape parameters.

DV Cassette Size and Capacity

Cassette Size Related to the 8 mm System. The well-known analog 8 mm cassette was the reference and the starting point for establishing the cassette parameters in relation to the playing time. The largest tape length in the 8 mm system is about 125 m. Some relevant parameters of the 8 mm tape format are depicted in Fig. 21.3.10. The effective width w of the tape area for analog video and PCM audio ($221 \pm$ wrap) equals 6.6 mm, which is somewhat lower than the tape width of 8 mm. The edges cannot be used for the helical tracks because of the limited head-tape contact. The product of L and w results in 0.83 m^2 maximum usable tape area A_t . The cassette capacity C in bits is the ratio of A_t to the bit area A_b ; it was estimated from experiments on ME tape that a track width of $10 \mu\text{m}$ with a bit length of $0.25 \mu\text{m}$ would result in sufficient SNR and robustness for the DV system. The gross 8 mm cassette capacity is therefore 330 Gb.

To derive the net capacity for compressed video, the estimated practical contributions for overhead are tabulated in the left column of Table 21.3.6. The estimations are educated guesses of the expected overhead, assuming a sync block size of around 1000 bits and a not usable track margin of $\pm 5 - 6$. For clarification, the real values of the DV system have been added in the right columns of Table 21.3.6. The overhead for channel modulation and digital audio is now briefly clarified. A well-known block code such as 8-10 modulation needs an overhead of 20 percent. Some form of channel modulation is a must, primarily for tracking and robustness reasons, but the overhead should be limited. The sophisticated 24-25 modulation from Ref. 33 with only 4 percent overhead has proven to be an attractive candidate. The overhead for digital audio is in principle more an absolute value in bit rate and less a relative overhead. However, we have assumed that the

TABLE 21.3.6 Contributions to Recording Rate

Topic	Estim. (%)	DV (kbit)	DV fraction (%)
Channel modulation	4	5.4	3

Video	61	83.2	62
Total one track	100	134.9	100

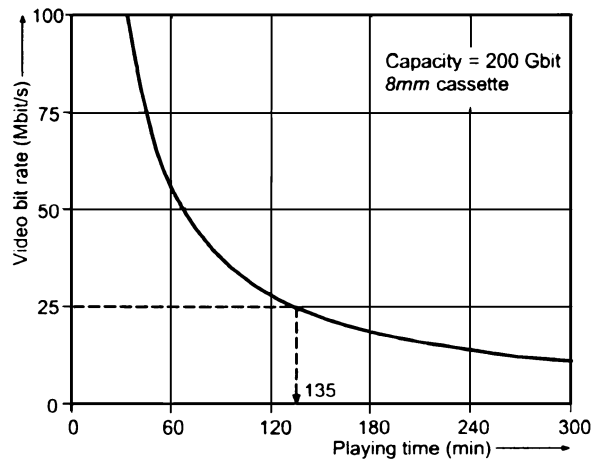

FIGURE 21.3.11 Video bit rate and playing time.

bits needed for digital audio are a reasonable 10 percent fraction of the bits for compressed video, hence 6 percent of the total.

From the previously discussed overhead inventory it is clear that, even with an economical solution for channel modulation, only around 60 percent of the gross capacity is available for compressed video. The net cassette capacity for the 8 mm system is therefore 200 Gb. From this number a simple relation is obtained between the compressed video bit rate and the playing time, which is graphically presented in Fig. 21.3.11. This curve explains why the video bit rate of 25 Mb/s was chosen.

Requirements of the DV System. Prior to discussing the principal DV system parameters, we list the basic aims and assumptions for defining the recording system:

- Pocketable camcorders, which are substantially more compact than the analog 8 mm system. Playing time is less important; 60 min is regarded as sufficient. Picture quality and editability are of utmost importance.
- Home-use recording of HDTV signals with a minimum playing time of 135 min needed to record almost all movies in one piece. At the time of standardization, HDTV systems such as MUSE in Japan, HDMAC in Europe, and ATV in the United States were seen as very important for the near future.
- Home recording of SDTV signals, with the same compression as for the camcorder. Ratio of HDTV to SDTV bit rate of 2:1, resulting in a minimum playing time of 270 min for SDTV.
- Preferably, a one-cassette system has to be adopted.

It will be clear that the last point can be conflicting with the first two, owing to the significantly higher bit rate and playing time demands of the HDTV system, when compared to the camcorder application. This will become more apparent from a further evaluation of Fig. 21.3.11. At a playing time of 135 min for HDTV, the available video bit rate for an 8 mm cassette equals 25 Mb/s, and consequently 12.5 Mb/s for SDTV. It is elucidated later that this bit rate is considered too low for an economical, well editable, and high-quality compression scheme for the camcorder. In fact, the double of this bit rate was regarded as realistic. This inevitably leads to a two-cassette system with a larger cassette for home use and a compact cassette with less playing time for the camcorder. Currently, the camcorder cassette has proven to be the main cassette in practical use.

Cassette Sizes for DV System. The net cassette capacity for home use was planned to be 400 Gb, requiring a substantially larger cassette compared to the analog 8 mm system. The required capacity of the small

FIGURE 21.3.12 Preferably, a one-cassette system has to be adopted.

camcorder cassette is roughly one quarter of the standard cassette, owing to the playing time ratio, and has therefore half its size. This is substantially smaller than the 8 mm cassette. The relative sizes of the final DV cassettes are depicted in Fig. 21.3.12.

Thus far the thickness of the cassettes was assumed identical to the 8 mm cassette. This is suitable for the larger standard cassette, but a small camcorder cassette with this thickness is not very elegant. Additionally, the compactness of the camcorder is influenced by this parameter, which was therefore reduced as far as possible to the well-known quarter inch (6.35 mm) owing to the camcorder application. The final thicknesses for the standard and small cassettes are 14.6 and 12.2 mm, respectively.

Drum Diameter and Speed

For a camcorder the focus is on an economical drum for the camcorder, which is the well-known drum concept having two heads of different azimuth on opposite sides and using a wrap angle of 180° . This not only leads to the lowest drum complexity, but also minimizes the required read/write electronics and therefore power dissipation, because only single recording channel electronics are needed. Alternative drum configurations do exist and their relations to other applications will be elucidated briefly.

The relation between the drum and video signals asks for a single worldwide recording system with identical rates and drum speeds everywhere. Furthermore, an integer number of tracks/frame was realized to support editing, combined with a small drum size for compactness. The results are given in Table 21.3.7. A comparison between Table 21.3.7 and the wish list at the beginning of this section shows that 10/12 tracks/frame is a well-balanced choice, taking into account a few additional considerations. First, an even number of tracks/frame is preferred for both systems, owing to azimuth recording. Second, higher drum speeds generally yield a higher power dissipation of the drum motor, but too small drum diameters pose problems with mounting internal electronics. Fine-tuning of the tape format resulted in 41.85 Mb/s channel rate, 34.024 mm track length, 21.7 mm drum size, and 9.1668° track angle for the DV system. The effective track length is 32.890 mm, which corresponds to an effective wrap of 174° .

Alternative drum concepts are important for possible extensions toward HDTV, using a doubled recording rate. This is at best achieved with a drum containing two head pairs that are mounted diametrically. The second double head requires continuous two-channel recording, allowing for an HD mode with two times the bit rate of SD. Full compatibility to the SD and even longplay (LP) modes is realized by using only one head pair. If the second double head is mounted with a slightly modified height position, it can also be used for read after write in generic data recording applications (see Ref. 31 for further details).

DV Video Blocks and Sync Block Format

In the DV system, video data is mapped onto the tracks, where each track consists of data packets, called sync blocks. Video data in the form of images is divided into macroblocks, i.e., a 16×16 pixel area from an image.

TABLE 21.3.7 Various Drum Configurations

Tracks/ frame (30/25)	Track rate (tr/s)	Drum speed (rpm)	Track length (mm)	Drum diam. (mm)	Track angle (deg.)
5/6	150	4500	67	42	5
10/12	300	9000	33	21	10
15/18	450	13500	22	14	15
20/24	600	18000	17	11	20

FIGURE 21.3.13 Macroblocks (MBs) taken from 525/30 and 625/25 frames and corresponding MB structure.

This section addresses the mapping of those macroblocks (MBs) on the sync blocks in the tracks, under the assumptions of 10/12 tracks/frame and 25 Mbit/s for compressed video. After sampling of the analog signal, the effective area of the video frame consists of 720 pixels horizontally by 480 or 576 lines vertically for the 525/30 and 625/25 systems, respectively. This is depicted in Fig. 21.3.13. The pixels are grouped in DCT blocks of 8×8 pixels, resulting in 5400 or 6480 luminance DCT blocks/frame. With 10/12 tracks/frame, this leads to an identical number of 540 luminance DCT blocks/track for both systems. Although the subsampling of the chrominance signals is different for 525/30 and 625/25, the ratio of luminance to chrominance is 4:2 in both cases. Macroblocks are formed, consisting of four luminance and two chrominance DCT blocks, resulting in 135 MBs per track.

There are restrictions on sync block (SB) mapping. For reasons of convenience in hardware implementation, robustness, and trick-play performance, a fixed mapping of a limited number of MBs (a unit) onto an integer number of SBs has been adopted. Moreover, a multiple of such mapping units should exactly fit into one track for obvious reasons. As a result, the number of MBs per unit is a divider of 135. Possibilities are 1, 3, 5, 9, 15, . . . Similarly, the same units, in the sequel called segments, will be used as independent coding units for the video compression. The video segment size was fixed to 5 MBs, because it was found from simulations that no essential improvement in picture quality could be obtained for larger segments (see Fig. 21.3.20) in the subsection on DV video compression). This results in 27 video segments per track.

The remaining key parameter in the mapping is the number of SBs per segment. It is clear that this number will vary the total amount of video SBs in a track, which, as a consequence of the previous result, should be a multiple of 27.

For determining the last parameter of the format, the highest possible trick-play speed was a decisive factor (thereby adopting a constant bit-rate concept). Assuming a reasonable positioning of the head for reading (mapped into a "quality factor" $Q = 1/2$) and relative tape speed $n > 1$, the recovered data burst length D during fast reading can be approximated by $D = T_L/n$. The track length is denoted T_L . Naturally, as the speed increases, the amount of data read becomes smaller. Figure 21.3.14 portrays the data recovered as a function from the search speed (relative to the reference playback speed). Because the position of the track crossings with respect to the SBs is arbitrary at high speeds, the data burst must be at least two SBs in order to retrieve one correctable SB from tape. The maximum trick-play speed n_{\max} is then given by

$$n_{\max} = \frac{T_L}{D_{\min}} = \frac{T_L}{2} \quad (1)$$

with T_L expressed in SBs being the total length of a track for 180° wrap. The total overhead in a 180° track is assumed to be 40 percent, of which 15 percent is SB-based. The remaining 25 percent of the overhead can be expressed as SBs on top of the video SBs. Therefore, the total number of SBs in a track (T_L) is $4/3$ times the

FIGURE 21.3.14 Data burst length vs. search speed.

number of video SBs. Results for T_L and n_{\max} are given in Table 21.3.8. In practice, the value of n_{\max} will be somewhat lower.

Table 21.3.8 shows why the 5-5 mapping has been chosen in the DV standard. First, this mapping leads to the highest possible trick-play speed. Second, note that with this mapping, in contrast to the other possible mappings, one MB is stored in one SB, thereby enabling a fixed allocation of the most important data. For trick play, this enables the decoding on SB basis, which was assumed implicitly for the calculation of n_{\max} . Third, as a bonus, the 5-5 mapping results in the shortest SB length. This property, combined with the fixed data allocation, proves to be very beneficial for the robustness of the system. With the chosen 5-5 mapping, the size of an SB can be determined. With 83 kbit and 135 MBs in a track for video, a 77-byte data area is required to store one macroblock. The addition of a 2-byte Sync pattern, a 3-byte ID, and 8-byte parity for the inner (horizontal) ECC results in a total SB length of 90 bytes. For completeness, it is mentioned that this number must be a multiple of 3 bytes, because of the 24-25 channel coding. The SB structure of the DV system is given in Fig. 21.3.15.

DV Video Compression

It has been explained that video compression is required to establish a low bit rate and sufficient playing time. For this reason, an intraframe coding system was adopted. Intraframe coding means that each picture is compressed independent of other pictures. However, to support the high-speed search the system goes one step further and concentrates on coding segments of a picture as independent units. This will be elaborated in this section. We consider a feedforward-buffered bit-rate reduction scheme, based on DCT coding, in which the pictorial data are analyzed prior to coding. The aim is to define a compression system with fixed-length coding of a relatively small group of MBs because this is beneficial for recording applications such as trick play and robustness. Given the system constraints from previous sections, the target system is based on frame-based DCT coding with VLC. Such a system operates well using compression factors 5 to 8. This results globally in a bit rate after compression of 20 to 25 Mb/s. Numerous subjective quality experiments during development

TABLE 21.3.8 Various Mappings of MBs to SBs

MB's per segment	SB's per segment	Video SB's per track	Total SB's per track	n_{\max}

5	4	108	144	72
5	5	135	180	90

FIGURE 21.3.15 Format of a single sync block (SB).

of the DV standard provided evidence that about 25 Mb/s yielded the desired picture quality, which is well above analog consumer recorders such as VHS and 8 mm.

DV Feedforward Coding Concept. In most transform coding systems using VLC techniques, the variable-rate output is buffered and monitored by feedback quantizer control to obtain—on the average—a constant bit rate, although the bit rate is locally varying. With feedback compression systems having a locally varying output bit rate, the relation between the recovered data bits and the location of the data in the picture is lost. The major advantage of the feedforward coding system is that relatively small groups of DCT blocks, henceforth termed segments, are coded independently and, in contrast with a feedback system, as a fixed entity. This property makes the segments independently accessible on the tape, while the fixed code length ensures a unique relation between the segment location on tape and its location in the reconstructed picture. The latter property, in combination with the 1 macroblock-per-SB data allocation (see previous section on mapping), is exploited for optimizing the picture quality during trick modes (see later).

In the feedforward coding system (see Fig. 21.3.16), video is first organized into blocks and subsequently in groups of blocks, called segments. Each segment is then compressed with DCT coding techniques into a fixed code length (bit cost), despite the application of VLCs. Fixed-length coding of a small group of DCT blocks (several tenths only) can only be realized if the transformed data are analyzed prior to coding, requiring temporal data storage. During the storage of a segment, several coding strategies are carried out simultaneously, from which only one is chosen for final quantization and coding. This “analysis of the limited future” explains the term feedforward buffering. Feedforward coding has two important advantages: a fixed relation between the data on tape and the reconstructed image, and a high-intrinsic robustness as the channel error propagation is principally limited within a video segment.

DV Motion-Adaptive DCT. The DCT has become the most popular transform in picture compression, since it has proven to be the most efficient transform for energy compaction, whereas the implementation has limited complexity. The definition of the DCT used in the DV system is

$$F(u, v) = C(u)C(v) \sum_{i=0}^{N-1} \sum_{j=0}^{N-1} f(i, j) \cos \frac{(2i+1)u\pi}{2N} \cos \frac{(2j+1)v\pi}{2N} \quad (2)$$

where a block of samples $f(i, j)$ has size $N \times N$. The two constants $C(u)$ and $C(v)$ are defined by $C(w) = \frac{1}{2}$, for $w = 0$ and $C(0) = \frac{1}{2}\sqrt{2}$. The DV standard applies a block size of 8×8 samples because it provides the best compromise between compression efficiency and complexity and robustness.

One of the first main parameters for coding efficiency is to choose between intrafield and intraframe coding. In the latter system, the odd and even fields are first combined into a complete image frame prior to block

FIGURE 21.3.16 Architecture of feedforward video compression system.

FIGURE 21.3.17 Architecture of a motion-adaptive DCT transformer.

coding. It has been found that intraframe coding is about 20 to 30 percent more efficient than intrafield coding, or, for the available 25 Mb/s bit rate, it offers a considerable better quality. For this reason, intraframe coding was adopted in the standard. However, it was found in earlier investigations that local motion in sample blocks leads to complicated data structures after DCT transformation, which usually are particularly difficult to code. The solution for this problem is to split the vertical transform into two field-based transforms

of length $N/2$. Hence, first an N -point horizontal transform (HDCT) is performed yielding intermediate data $F_h(I, v)$, and subsequently, two vertical $(N/2)$ -point transforms (VDCT), specified by

$$F(u, v) = C(u)C(v) \sum_{i=0}^{N/2-1} \sum_{j=0}^{N-1} g_s(i, j) \cos \frac{(2i+1)u\pi}{N} \cos \frac{(2j+1)v\pi}{2N} \quad (3)$$

$$F(u+4, v) = C(u)C(v) \sum_{i=0}^{N/2-1} \sum_{j=0}^{N-1} g_d(i, j) \cos \frac{(2i+1)u\pi}{N} \cos \frac{(2j+1)v\pi}{2N} \quad (4)$$

$$g_s(i, j) = [f(2i, j) + f(2i + 1, j)]$$

$$g_d(i, j) = [f(2i, j) - f(2i + 1, j)]$$

Note that in the first field-based output coefficient block, the sum of the two fields is taken as an input, while in the second coefficient block the difference of the two fields is considered. Hence, this corresponds to a two-point transform in the temporal domain.

The required DCT processor architecture is depicted in Fig. 21.3.17.

DV Adaptive Quantization

The primary elements for quantization of the coefficients $F(u, v)$ are frequency-dependent weighting, adaptivity to local image statistics, and global bit-rate control. These elements are individually addressed briefly. The weighting is based on the decaying sensitivity of the transfer function H of the human visual system (HVS). As an example, as HVS model from the literature has been plotted in Fig. 21.3.18, in which the transfer function of the HVS has been normalized.

When using that model the image is divided in 8×8 blocks, in Fig. 21.3.18 we find that the HVS decreases exponentially, is multiplicative in nature, and hence $F_w(u, v) = W(u, v)F(u, v)$. The weighting function can be simplified using special multiplying factors (see Table 21.3.10). For simplicity, the matrix of factors $W(u, v)$

FIGURE 21.3.18 HVS function of radial frequency f_r .

	2	2	3	3	3	3	3	3		1	2	2	3	3	3	3	3	
																	difference	

are not different for each (u, v) combination. Instead, groups of (u, v) combinations apply the same weighting factor, according to Table 21.3.9.

The second element of quantization is the adaptivity to local image statistics. The adaptivity is to be worked out by measuring the contents of the DCT coefficient block. One of the most well-known metrics for local activity is the “ac energy” of the block, $\sum_{u,v} F(u, v)^2$. However, simpler metrics, such as the maximum of all $F(u, v)$ within a block, perform satisfactorily as well. The DV system allows that any metric in the encoder is acceptable: the decoder simply follows the two decision bits reserved for the quantizer classification. This freedom also allows different quantization of luminance

(Y) and color (Cr, Cb) blocks. Generally, more activity or information content results in more coarse quantization. The third element in the quantizer is a final block quantization by a linear division with a step size S . The advantage of this approach is its simplicity and it leads to uniform quantization. The variable S defines the accuracy of the global block quantization. When taking into account the elements previously discussed, the overall quantization is specified by $F_Q(u, v) = W(u, v)F(u, v)/S$. For camcording, low implementation cost is of utmost importance. A particular simple system is obtained by taking $W(u, v) = S = 2^{-p}$ with p being an integer that is controlled by all three elements discussed in this subsection. The final quantization table is shown in Table 21.3.10. The weighting area numbers in Table 21.3.10 refer to Table 21.3.9.

FIGURE 21.3.19 Diagonal zigzag scanning in 8×8 and $2 \times (4 \times 8)$ mode for clustering of zeros.

DV Variable-Length Coding

A bit-assignment using one coding table only was chosen for simplicity. The coding algorithm is fundamentally the same as in MPEG compression and is based on runlength counting of zeros only and the use of an end-of-block (EOB) codeword.

The principle of the algorithm is that first the block of quantized coefficients is scanned using diagonal zigzag scanning in order to create a one-dimensional stream of numbers. The scanning is adapted to motion. The purpose of the scanning is to cluster zero coefficients (see Fig. 21.3.19), so that they can be coded efficiently. Second, from the start of the string, zeros are counted until a nonzero coefficient is noticed. The magnitude of this nonzero coefficient is combined with the preceding length of zeros into a single event (run, amplitude), which is jointly coded with a single codeword. The sign of the coefficient is appended at the end of the codeword. An excerpt of the encoding table showing the variable wordlengths and codewords is given in Table 21.3.11. The coding table is optimized to prevent large codewords and low implementation cost.

Total DV Video Performance

The control and overall performance of the compression system is now indicated. The system optimizes the picture quality by testing a number of quantizer settings in parallel. The optimal quantization strategy m_{opt} is the quantizer setting (strategy) that yields a bit rate just below or equal to the desired bit rate. The choice of m_{opt} can vary between 0 and $M - 1$ when M different quantization strategies are used. The picture quality of the compression system for various segment sizes K and number of quantization strategies M was measured. The resulting picture quality is expressed in SNR (dB), which refers to the mean squared error (MSE) with the original picture compared to squared peak white (255^2). The results of the measurements are shown in Fig. 21.3.20.

The optimal choice of the segment size K and the number of strategies M can be derived from Fig. 21.3.20. Evidently, the recording system designer opts for the smallest possible value of K (small segments), because it yields a high robustness and it enables higher search speeds. However, Fig. 21.3.20 shows that if the size becomes too small, i.e., $K < 30$, the picture quality deteriorates rapidly. For $K = 30$ to 60 DCT blocks, the resulting SNR remains nearly constant. Therefore, a segment size of $K = 30$ was adopted as being the best compromise. The 30 DCT blocks are not arbitrarily chosen from the picture, but clustered in groups, called MBs. An MB (see Fig. 21.3.13) is a group consisting of 2×2 DCT blocks of 8×8 Y samples each and the two corresponding 8×8 color blocks Cr and Cb. In order to improve the picture quality of the compression system, MBs are selected from different areas of the picture, so that the influence of local image statistics is smoothed. The result is a stable and high picture quality for a large class of images. However, after compression, the MBs are redistributed in order to improve the visual performance during search (see later in this DV section). A second conclusion is that $M = 16$ gives a substantial improvement in picture quality, compared to $M = 8$. The quality improvement can be fully explained by a more efficient use of the available bit rate, which becomes particularly important for small segment sizes.

FIGURE 21.3.20 SNR of DV compression system for various segment sizes K and number of strategies M (CCIR-601 images, 4:2:0 sampling, 25 Mb/s).

The subjective picture quality of the system is known as excellent and regarded as very close to levels for professional use. For regular input pictures, the SNR approaches 40 dB, and the resulting subjective image quality of the system comes rather close to the quality of existing professional recording systems. For complex and detailed imagery, the SNR is a few dBs lower.

Macroblock-Based SB Format

The DV format uses a special compressed data format inside a sync block (SB) to improve robustness for high-speed search, where a part of the error-correction coding (ECC) cannot be applied, because only data portions of a track are recovered. This considerably multiplies the chance of having errors in the signal. Second, at higher tape speeds, the head-to-tape contact is reduced and less stable, which also leads to a lower robustness. The special data format enables the compression decoder to cope with residual errors in the video data. In order to construct a robust format, it is absolutely essential to limit the propagation of errors that emerge from erroneous variable-length decoding. The propagation of errors is limited in three ways, which are briefly discussed.

First, *fixed-length coding of segments* is realized by the choice of a feedforward coding scheme. Every segment is compressed into a fixed bit cost, so that the decoder should periodically reset itself at a segment border. A proper numbering of SBs allows to identify the start of a new segment without using the compressed data. Error propagation from segment to segment is therefore impossible. Second, *identification of individual macroblocks* is enabled. A segment consists of five full-color MBs as indicated in the previous section. For robustness, a single MB is put into a single SB. Note that the MB is sometimes smaller than a SB and sometimes larger. Furthermore, every SB has a fixed unique location on tape. As a result, each MB—at least the low-frequency information—can be addressed. Third, *identification of individual DCT blocks* is possible. Within an SB (thus one MB) six DCT blocks are located. Each compressed DCT block is of variable length. Similarly, to the MBs, by putting the low-frequency data of each DCT block on a fixed position, each DCT block can be addressed and partially decoded, and error propagation is limited to high-frequency components of DCT blocks only.

The internal SB format is depicted in Fig. 21.3.21. A group of five SBs forms a fixed-length segment, preventing error propagation. As a bonus, the fixed-length segment compression allows replacement of individual segments for post editing or error concealment in the compressed domain, without decoding the full picture. The individual segments can also easily be transmitted over a digital interface (IEEE-1394) to other equipment. Figure 21.3.21 also shows the fixed positions of the start of each DCT block.

DV Data Shuffling for Trick Play

The DV standard applies special data shuffling techniques to optimize the picture quality both for normal playback and for high-speed search on tape. It was elucidated in preceding subsections that a coding unit, called video segment, consists of five MBs only. When considering MBs for shuffling, the following general statement applies. For smoothing statistics, a regular distribution over the picture area of the MBs for one segment results in the highest average picture quality for all practical video material. This subsection describes MB shuffling in more detail, taking the 625/25 system as an example.

FIGURE 21.3.21 Inner SB data format showing the fixed predetermined positions of low-frequency DCT coefficients of each block and the construction of segments using these sync blocks.

FIGURE 21.3.22 Selection of MBs for segment construction and assignment of picture areas on tracks.

Data Ordering for Optimal Picture Quality at Normal Speed. As depicted in Fig. 21.3.13, a picture consists of 480/576 lines of 720 pixels wide. With 10/12 tracks per frame, it is clear that the data of 48 lines or 135 MBs is stored in one track. In the case of the 625/25 video system, the picture of 36 by 45 MBs is divided into 12 horizontal rows of three MBs high and 45 MBs wide, where each row corresponds to one track. On the other hand, one segment consists of five MBs, which should originate from distributed parts of the picture, preferably with the highest distance. A maximum horizontal distance is achieved when they are distributed regularly, leading to a horizontal pitch of nine MBs. Consequently, the picture is divided into five columns of nine MBs wide. The row-column structure is depicted in Fig. 21.3.22. Despite the difference in video lines, the 525/30 picture is divided similarly in 10 rows and five columns. In the vertical direction, a regular distribution with maximum distance is also the optimal for a good picture quality. Taking into account the 10/12 rows for both systems and a universal algorithm, a distance of two rows is the best option.

A unit of 3 by 9 MBs is called a superblock. A picture consists of superblocks $S_{i,j}$ with i, j being the row and column number, respectively. The numbering of the MBs within the superblock can be found in Fig. 21.3.23. The construction of a superblock for the 525/30 system is somewhat different because of modified MB dimensions (see Fig. 21.3.13). Since the distances are known now, a suitable algorithm has to be defined such that the five MBs forming one segment are spread out over the picture area. The following algorithm has been adopted:

$$V_{i,k} = \sum_{p=0}^4 MB[(i + 2p) \bmod n, 2p \bmod 5, k] \tag{5}$$

with $0 \leq i < n - 1, 0 \leq k \leq 26$, and $n = 10$ or 12 . Furthermore, $M[i, j, k]$ denotes the macroblock number k in superblock $S_{i,j}$. The MBs forming segment $V_{0,0}$ are indicated in Fig. 21.3.22.

FIGURE 21.3.23 Ordering of macroblocks in repetitive clusters called superblocks.

Macroblock Mapping for Trick Play. Editing and picture reconstruction in normal play are performed on a picture basis, so that the mapping can be optimized for trick play. Consequently, the data of one picture is recorded in an alternative order within the boundaries of the set of tracks assigned to the complete picture. The following aspects are used in the mapping: *Coherency and speed adaptivity*. Coherency means that the best subjective trick-play picture quality is obtained if the largest possible coherent picture parts are refreshed in one piece.¹⁸ The picture quality should be adaptive to the speed, meaning that the highest quality is achieved for the lowest search speeds. At the introduction of the MBs, it was shown that the recovered data burst length from tape increases for lower speeds (see Fig. 21.3.14). Consequently, neighboring pictorial information should be recorded side by side in a track.

The previous insight contradicts with the MB shuffling for efficient video encoding at normal speed requiring that the pictorial information should be spread out over the picture. As indicated in Fig. 21.3.21, the majority of the information for one MB is stored in one SB. This is an attractive property for trick play. It enables decoding on a SB rather than on a segment basis, resulting in a slightly reduced but still adequate picture quality for trick play. This feature allows for a block mapping on MB basis instead of segments, thereby solving the paradox between MB shuffling and actual mapping on tape.

The selection of the optimal mapping for a large set of trick-play speeds is a difficult issue, especially if the possibilities for alternative scanners have to be considered simultaneously. The highest flexibility in all situations is achieved by a more or less direct projection of the picture on the tape. This is realized by recording the superblocks in one row of Fig. 21.3.22 one after the other in a track, with the row number equal to the track number. MBs within a superblock are stored in the order indicated in Fig. 21.3.23. A schematic representation of the final mapping is given in Fig. 21.3.24. On top of this mapping, trick-play speeds are chosen carefully at special fractional noninteger values, leading to sufficient refresh of data over time. More details can be found in Ref. 18. In general, it can be concluded that the search speed should be such that all other picture parts are refreshed between the updates of a specific part.

Conclusion on DV System

It has been clarified that the adopted cassette size and tape thickness have determined the required compression factor and the resulting bit rate of 25 Mb/s after compression. At this bit rate, sufficient playing time can be obtained, both for an ultrasmall camcorder cassette and the larger desktop cassette. For desktop video recording, the trend is clearly to disk-based recording, which is discussed later in this chapter. The compression system has been optimized for low-cost intraframe coding because of the use in portable equipment. The feedforward coding architecture is different from MPEG-based recording in DVD, but it offers high robustness for high-speed search and error concealment. The compression in fixed-length segments offers besides robustness also easy packet transmission over digital links. The system yields a high picture quality, even in the case of motion, owing to a special motion adaptivity.

The independent compression and coding of segments, based on five macroblocks only, allows for high search speeds during trick play and provides a very robust tape format. In normal play, the powerful R-S product ECC ensures an error-free and flawless reproduction of the recorded images. A special macroblock format mapped

FIGURE 21.3.24 Reorganization of macroblocks on tape for trick play so that the picture is stored in coherent form on tape.

onto single channel sync blocks enables data recovery at very high search speeds. Even at high search speeds, the format limits error propagation severely and shows only errors in high-frequency information. Moreover, the special data shuffling scheme enables a relatively high perceptual performance during trick-play modes.

CD-I AND VIDEO CD

Introduction to Optical Recording

Optical recording can support much higher packing densities than magnetic recording. A typical optical recorder has a $1.6 \mu\text{m}$ track spacing, and a minimum recorded wavelength of $1.2 \mu\text{m}$. A single side of a 30-cm optical disc can record as much as 60 min of video. Several systems are in use since the early 90s.

The first system is designed for mass replication. An expensive master produces numerous very cheap copies, in a similar manner to phonograph discs. However, the process is more refined because of the smaller dimensions involved. This system is highlighted subsequently in more detail. The second system uses an irreversible change produced by laser heating selected spots in the medium. The change may be melting, bubble formation, a dye change, or a chemical change. The systems in which writing is irreversible are termed *write once* or WORM (write once, read many times) systems. A typical example is the Panasonic 20-cm optical recorder that stores nearly 14 min of an NTSC signal. The disc rotates at 1800 rpm and the system can either record a single spiral track, or 24,000 concentric tracks.

The third method uses laser heating to define the small recorded area, but the recording is magnetic and therefore erasable. The system is similar to WORM systems except that the disc is coated with a thin magnetic layer. Like any magnetic recording, the signal can be erased or it can be overwritten. Such a system using analog recording can store over 30 min of NTSC television per side of a 30-cm disc. If digital recording is used, 50 s on each side of the 13-cm disc can be recorded.

We describe herein briefly a type of system that is suited for mass replication. There have been several approaches to the home optical disc system, including one pioneered by Philips, named Laservision. The Philips video disc consists of a transparent plastic material with a diameter of 30 cm and a thickness of 2.5 mm for a double-sided recording. The audio disc has grooves, whose walls move a transducer to reproduce the audio signals. The video disc must meet a requirement of much higher information density. It has no grooves and has tracks with a much finer structure. The track spacing is about one-sixtieth of that of an audio disc. The rotational speed is synchronous with the vertical frame rate to enable recording of one complete frame per revolution (1800 rpm for NTSC, 1500 rpm for PAL and SECAM). A longer-playing version of the Philips system maintains a constant track-to-pickup velocity, allowing approximately 1 h per side of recording.

Let us now briefly look into the basic optical readout technology. In both Laservision and the CD-based system, the signal is recorded in the form of a long spiral track, consisting of pits of about $0.5 \mu\text{m}$ width (see Fig. 21.3.25 (a)). The pits have been pressed into a plastic type of substrate

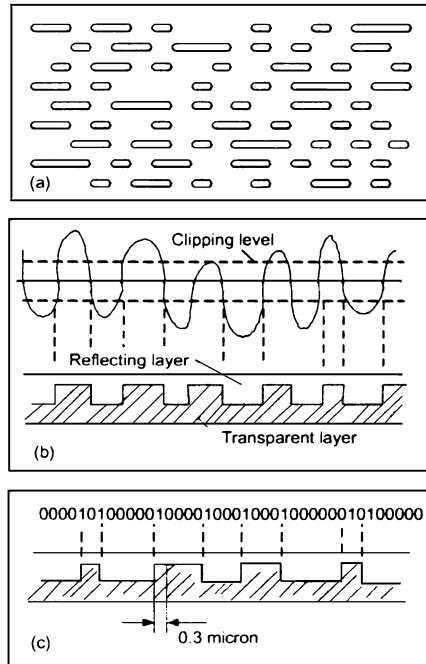

FIGURE 21.3.25 (a) The pits in an optical disk of Laservision or CD with tracks of about $0.5 \mu\text{m}$ width, (b) the analog waveform in Laservision is clipped and the transitions defining pits and walls on the disc, (c) the conversion of a binary string into pits and walls in reflective layer on the compact disc where each transition corresponds with a "1" in the binary signal. Between each binary 1, every flat distance of $0.3 \mu\text{m}$ represents a binary 0. The reflective layer is the backside of the optical disc.

with a special stamp. The stamp originates from a parent disc that was generated by a real laser-burned disc. The recorded layer is protected by a transparent coating. Since the coating is much thicker than the recorded layer, scratches and dirt on the surface of the disc are outside the focal plane of the optical pickup that reads out the data.

An essential difference between Laservision and all CD successors is that Laservision registers analog and CD holds digital information. Figure 21.3.25(b) depicts how the analog signal is recorded on a Laservision disc. The video signal is frequency modulated (FM) and an analog sound signal is superimposed on the FM-modulated video signal. The resulting signal is clipped for not exceeding maximum positive and negative signal values. The transitions of the signal coincide with the pits and walls on the disc. A predecessor of the video-CD was a system called *CD-Video* of Philips that recorded a digital audio signal in special modulation area on top of the FM-video signal.

Figure 21.3.25(c) portrays the recording of digital data on the CD. The length of each pit or wall is $0.3 \mu\text{m}$ or a multitude of this length with a certain maximum. With a special coding algorithm, called *eight-to-fourteen modulation* (EFM), the number of zeros between two ones is kept between a pre-defined minimum and maximum value. Such a code is often referred to as a *run-length-limited* (RLL) code. The bounding of zeros helps in robustness by avoiding DC energy and it helps with synchronization. As can be noticed, each transition corresponds with the bit value 1 and the intermediate bits get the bit value 0. These bits are called *channel bits* and they originate via a coding procedure from the data bits. The data bits for digital audio (CD-DA) are resulting from 16-bit audio samples that represent a stream of binary numbers, called *pulse code modulation* (PCM). An illustration of the focus motor and detection optics is illustrated in Fig. 21.3.26. To track the line of very narrow pits by a closed-circuit servo like the one depicted in the illustration, two auxiliary light beams are formed, which are slightly displaced from the centerline of the track, one on each side of the correct position. Two photodiodes are introduced into the optical paths on either side of the quadrant detectors, as portrayed in Fig. 21.3.26. The error signal generated by the difference in output of these diodes, after appropriate filtering, is used to deflect a galvanometer mirror and thus move the beam laterally to correct the error. Similar techniques can be used for optical tracking, where the signal envelope of recovered waveform after opto-electrical transformation by receiving photodiodes can be kept as high as possible.

Figure 21.3.27 depicts an outline of the signal path of the compact disc. Assuming correct servo control and focus of the laser beam, the electrical signal coming from photodiodes is amplitude controlled by a gain amplifier.

FIGURE 21.3.26 Example construction for focusing the laser beam on the optical disc.

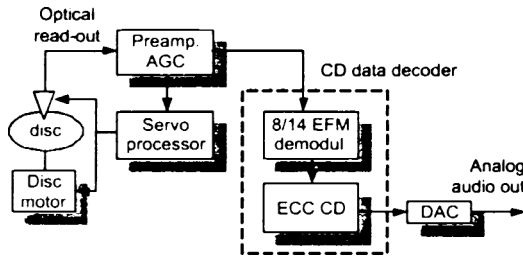

FIGURE 21.3.27 Block diagram of signal path in compact disc.

Solomon decoder. After the complete ECC decoding, the audio samples come available as PCM data and are available for digital-to-analog conversion (DAC).

The output in the form of a digital string of channel bits is buffered and demodulated by the EFM demodulator. This involves a mapping of groups of 14 channel bits and three merging bits into consecutive bytes. Subsequently, these bytes are buffered in the error-correction decoder (ECC). This ECC decoder recomputes data packets and corrects possible errors. The decoder consists of a Reed-Solomon block decoder combined with a so-called *cyclic interleaved redundancy check* (CIRC). The latter step involves data interleaving to spread out errors and cut the length of long burst errors into shorter pieces that can be handled by the Reed-

History and CD-i Concept

The CD format was invented in 1980 and was introduced in Europe and Japan in 1982 and in the United States in 1983. This originally introduced format was CD-audio (CD-A, CD-DA, or “Red Book” CD, as specified in the International Electrotechnical Commission IEC-908 standard available from the American National Standards Institute). Additional CD formats were subsequently introduced: CD-ROM (1984), CD-i (1986), CD-WO [CD-R] (1988), Video-CD (1994), and CD-RW (1996).

The primary focus in this section is on the compact disc interactive (CD-i). Even if CD-i is not very much used anymore, its importance to the evolution of the digital multimedia recording systems aimed at applications such as home entertainment, education, and training has been fundamental. It should be noted that the strong development of the CD-based formats was the fundament for the recent success of the DVD,⁵ which is discussed later in this chapter. Furthermore, the CD-i format resembles very much the video-CD format that is currently very popular in Asia. CD-i combines audio, video, text, graphics, and animation, while providing features such as interactivity.

At the time of its introduction, CD-i provided several advantages over PC-based interactive systems, some of which still hold today:

- *Cost* compared with that of building a PC with the same audiovisual performance and functionality.
- *Compatibility*, since each CD-i disc is compatible with every CD-i player. There are no “system requirements,” such as a type of display adapter, sound card, version of the operating system, screen resolution, CD-ROM drive speeds, drivers, hardware conflicts, and so forth, like in the PC-based scenario.
- *Ease-of-use*. A CD-i player and software are very easy to use and do not require software setup, adjusting the hardware or other complex installation procedures. Moreover, CD-i can be connected to a variety of devices, such as TV sets and stereosystems. As an additional advantage, the user interfaces resemble those of CE devices, making it a far more comfortable system for many people to use over a PC.
- *Worldwide standard*. CD-i is a worldwide standard, crossing the borders of various manufacturers and TV systems. Every disc is compatible with every player, regardless of its manufacturer or the TV system (PAL, NTSC, or SECAM) that is being used.

CD-i System Specification

The CD-i players are based on a 68000 CPU running at least at 15 MHz, with at least 1 Mbyte of RAM, a single speed CD-drive, dedicated audio and video decoding chips, at least 8 kbyte of nonvolatile storage memory, and a dedicated operating system called CD-RTOS, which stands for *compact disc real-time operating system*. CD-RTOS is based on version 2.4 of Microware’s OS-9/68K operating system that is very similar to the Unix operating system, and supports multitasking and multiuser operation. The operating system as well as other player-specific software such as the player’s start-up shell are hard coded in a ROM of at least 512 kbyte.

CD-i Sector Format

CD-i is able to retrieve in real time the audiovisual data stored on the disc and send this information to the appropriate decoder ICs, without putting a heavy load on the overall system performance. Hence, a CD-i player does not need much RAM or processing power, since all audio and video decoding is performed in real time without storing large amounts in RAM for later decoding. To enable the simultaneous retrieval of both audio and video information, data are interleaved on the CD-i disc.

Since a CD-i disc is read at a constant continuing speed, the designer needs to be aware of the audio or video bit-stream quality. For instance, when a lower audio quality is used, fewer sectors will be occupied than with a higher quality. Alternatively, it is also possible to read only the sectors belonging to one audio channel at a time, and then move back to the beginning of the disc and read the sectors of another audio channel. Since a CD-i disc lasts for 74 min and the lowest audio quality only uses one out of every 16 sectors, the audio can be digitally recorded for $(16 \times 74 \text{ min})$ over 19 h.

Because of this real-time reading of sectors, every CD-i player reads data at the same speed, sometimes referred to as normal speed or single speed. It would be unnecessary to make a CD-i player running at a higher speed CD-drive, since data are to be read in real-time according to the specifications (thus single speed) and audio, video, and animation would be out of sync when being read at a higher speed. Special attention has been paid to the development of encoding techniques that enable high-quality audio and video within the single data speed and hence resulting in a longer playing time, instead of using a high-speed drive and by such reducing the playing time.

For CD-ROM, the mode 1 sector format is defined that allows for 2048 bytes of user data in every sector, with an accompanying 280 bytes of error correction information in each sector. When data are read at 75 sectors per second (the normal CD speed), this results in a data rate of 150 kbytes per second. For CD-i, it is not always necessary to have error correction in each sector. For example, audio and video need a much lower degree of correction than data. Instead, the 280 bytes used for error correction in mode 1 could be added to the 2048 of user bytes, resulting in 2324 bytes of user data per sector. This larger sector size results in an improved data rate of about 170 kbyte per second, which is referred to as mode 2. Within mode 2, two forms were defined: form 1 does incorporate the original error correction and is used for data and form 2 which lacks the error correction is used for multimedia. Mode 2 added an additional header to the header of mode 1, which holds information about the type of data that are contained in a sector (audio, video, data, and so forth), the way it is coded (for example, which audio level is used), and an indication of the used sector form. This header is interpreted by the CD-i system for each sector, which is then processed by the appropriate decoders. Both forms of mode 2 sectors can be interleaved, so that program data and audio and video can be read instantaneously from the disc.

Note that when all sectors are form 1, the disc holds 648 Mbyte. When all sectors are form 2, the capacity is 744 Mbyte. CD-i's disc capacity can hence be between 648 and 744 Mbyte. Although a CD-i disc consists of only mode 2 sectors, a CD-i system must be able to read mode 1 sectors on CD-ROM discs, and of course the audio sectors that are defined for CD audio.

Physical Dimensions and Specifications

A CD disc is 120 mm in diameter (60 mm radius), with a hole 15 mm diameter (7.5 mm radius) and a thickness of 1.2 mm. Starting at the hole edge at 7.5 mm radius, there is a clamping area extending from 7.5 to 23 mm radius (this area is partly clear and partly metalized, and may include a visible inscription stamped by the manufacturer), then a 2 mm wide lead-in area extending from radius 23 to 25 mm (containing information used to control the player), then the 33 or 33.5 mm wide data area (program area) extending from radius 25 to a maximum of c. 58 mm, a lead-out area (which contains digital silence or zero data) of width 0.5 to 1 mm from radius starting maximally at c. 58 mm, and finally at c. 1 mm unused area extending to the outer edge.

CD-i Disc Structure

A CD-i disc is divided into tracks. A CD-i disc contains at least one CD-i track, and may also optionally contain additional CD-Audio tracks that may also be played on a standard CD-Audio player. The first 166 sectors

of the CD-i track are message sectors, followed by the disc label. Subsequently, an additional 2250 message sectors follow that contain a spoken message in CD-Audio format, which informs users who put the disc in a regular CD-Audio player about the possible damage to equipment or speakers when the disc is not taken out immediately. Usually, a modern CD-Audio player will recognize the CD-i track as a data track and will not play it, so you won't hear the message. The disc label contains some specified fields that offer a lot of information about the disc, such as the title and creator, but also the name of the CD-i application file that needs to be run at start-up. Furthermore, the disc label contains the file structure volume descriptor, which is loaded into RAM at start-up. This allows the system to find a certain file on a CD-i disc in only one stroke. After these message sectors and disc label, the actual CD-i data start.

CD-i Audio

A minimal configuration (denominated also "Base Case") of a CD-i player should be able to decode standard PCM audio as specified for CD-Audio, as well as a dedicated audio coding scheme called *adaptive delta pulse code modulation* (ADPCM). The difference with PCM is that audio is not stored individually per time segment, but that only the difference (delta) to the previous sample is recorded. Owing to the existing correlation between adjacent samples, a significant decrease in the used storage space on the disc can be achieved, and hence in the bit stream being read from the disc. When normal PCM CD-Audio would be used (which occupies all successive sectors), this would not leave room for video or animations to be read without interrupting the audio playback.

CD-i provides three levels of ADPCM audio, all of which can be used either in mono or stereo, as shown in Table 21.3.12. Note that level A provides Hifi quality, Level B gives FM radio quality, while Level C is for voice quality. Level C mono can be used for up to 16 voice channels, e.g., in different languages. The sector structure facilitates switching between languages on the fly, as the sectors are interleaved on the disc.

Thus, when ADPCM Level C is used, only 1 out of every 16 sectors needs to be used for audio, leaving all other sectors for other data such as video or animation. It is also possible to record different audio channels at once, allowing for the seamless switching between, e.g., various languages. The disc may also be read from the beginning while decoding a different audio channel, allowing for increased audio-playing times, as indicated in Table 21.3.12.

A CD-i player equipped with a digital video cartridge is also able to decode MPEG-1 Layer I and II audio. MPEG is far more efficient in coding audio, resulting in an even longer playing time while providing a highly increased audio quality when compared to ADPCM. This is because of the fact that MPEG audio is based on precision adaptive subband coding (PASC),³⁵ which uses perceptual coding to only store those audio signals that are audible, while filtering out other signals. Note that CD-i offers a very flexible way of using MPEG audio (for example, at various bit rates and quality levels), but cannot decode MPEG-1 Level III, or MP3 files.

CD-i Video

The video image of a CD-i player consist of four "planes," which are overlaid on top of each other. The first plane is used by a cursor and its size is limited to 16×16 pixels. The second and third planes are shown

TABLE 21.3.12 Different ADPCM Formats

Format	Frequency (kHz)	Numbers of	Used sectors	Recording time
CD-audio PCM	44.1	bits per sample 16	all sectors	up to 74 min
ADPCM Level A stereo	37.8	8	1 in 2 sectors	up to 2.4 h
ADPCM Level A mono	37.8	8	1 in 4 sectors	up to 4.8 h
ADPCM Level B stereo	37.8	4	1 in 4 sectors	up to 4.8 h
ADPCM Level B mono	37.8	4	1 in 8 sectors	up to 9.6 h
ADPCM Level C stereo	18.9	4	1 in 8 sectors	up to 9.6 h
ADPCM Level C mono	18.9	4	1 in 16 sectors	up to 19.2 h

underneath the cursor and are used for full screen images. The fourth plane is used for a single-colored background or for MPEG full motion video (or to display video from an external source on some players). Parts of an image on one of the middle two planes can be transparent, so that the underlying plane becomes visible. This can be used, for example, to show subtitles or menus on an image. Both planes can also be used for blending and fading effects.

There are various encoding techniques for video that can be used in CD-i, which are indicated below.

DYUV. DYUV or Delta YUV is used for the encoding of high-quality photographs and other natural images. It is based on the fact that the human eye is more sensible to differences in brightness than to differences in color. Therefore, it stores one color for a set of pixels, and a brightness value for each pixel. The result is an image of slightly more than 100 kbyte. Owing to the complexity of a DYUV image, the storage on the disc must take place in advance, and it cannot be created nor modified in the player. DYUV is used mostly in CD-i titles because of its high quality and efficient storage.

RGB555. RGB555 is a compression format that allows only 5 bits per *R*, *G*, and *B* value, resulting in a picture with a maximum of over 32,000 colors. Since RGB555 uses both planes to display the image, it cannot be used in combination with other graphics. An RGB555 image is roughly 200 kbyte in size. The image can be altered by the player at run time. RGB555 is actually never used in regular CD-i titles because of its inefficiency and limitations in usage.

CLUT. CLUT, or color look-up table, is a compression method aimed at coding simple graphics. The colors used in a certain picture are stored in a CLUT-table, which reduces the size of the image dramatically, because color values refer to the appropriate CLUT-entry instead of indicating, for example, a 24-bit color value. In CD-i, a CLUT image can have an 8-bit (256 colors), 7-bit (128 colors), 4-bit (16 colors), or 3-bit (8 colors) resolution.

Run Length Encoding (RLE). RLE is a variation of the CLUT compression method that besides storing the CLUT-color table in an image, further reduces the image size by storing certain “run lengths” of repeating horizontal pixels with the same color. The results are usually pictures between 10 and 30 kbyte in size. This makes RLE ideal for compressing animations that contain large continuous areas with similar colors.

QHY. QHY, or quantized high Y, is an encoding technique that combines DYUV and RLE, resulting in a very sharp high-quality natural image, that is displayed in CD-i’s high-resolution mode. A QHY image is usually about 130 kbyte in size. Since it consists of a DYUV component, it cannot be modified by the player. QHY is, for example, used to display the images of a photo-CD in high resolution on a CD-i player.

CD-i can display both main planes in either normal, double, or high resolution, which are 384×280 , 768 times a DYUV image is always standard resolutions. It is possible for the images on each of the planes to be displayed 280 and 768×560 pixels, respectively. Some encoding techniques are limited to a single resolution, for example at once, even if they are in different resolutions. For example, a double-resolution CLUT4 menu bar can be overlaid on a standard resolution DYUV image. CD-i highest resolution (768×560 pixels), used for QHY images, is the highest resolution that can be made visible on a normal TV set.

To enable audiovisual data to be coded at CD-i bit-rates, MPEG-1 compression has been employed. This standard allows CD-i to display 384×280 progressive video sequences, at a video quality roughly comparable to standard VHS.

Full Motion CD-i Players

The quality of the “Base Case” CD-i players can be further extended to “Full Motion” audiovisual quality.⁹ For this, two coding formats are defined for video sectors: “MPEG video” and “MPEG still picture” for storage of MPEG-coded progressive video and interlaced still picture data. One new coding format is defined for audio sectors: “MPEG audio” for storage of coded MPEG audio data. All these video, still picture, and audio sectors are a form 2 sector with a usable datafield of 2324 bytes, while the Full Motion application program is stored in a normal data sector.

To code audio, CD-i applies MPEG layer I and layer II. Audio can be coded in stereo and in mono, at varying bit rates. For instance, for speech and other audio not requiring a high quality, the lowest bit rate for mono

of 32 kbit/s can be used. For high-quality audio, a bit rate of 192 kbit/s in stereo is necessary to achieve similar quality to the compact disc. Audio can be coded in stereo, joint stereo (i.e., intensity stereo), dual channel, or single channel. All bit rates allowed by MPEG for these layers are supported. The applied audio sampling frequency is 44.1 kHz. The bit rates can vary from 32 to 448 kbit/s for layer I and from 32 to 384 kbit/s for layer II. For more information, see Ref. 9.

The Full Motion system in CD-i⁴¹ supports the video parameters defined in the video part of the MPEG standard, but some parameters have a larger range in the CD-i system. For instance, while in the MPEG-1 specification the bit rate should not exceed 1.856 Mb/s; in the Full Motion system a maximum bit rate of about 5 Mb/s is allowed. Also, in the Full Motion system, video coding with a variable bit rate is allowed, leading to a higher visual quality. The maximum picture width is 768 pixels and the maximum height is 576 lines. The supported picture rates are 23.976, 24, 25, 29.97, and 30 Hz. The maximum size of the VBV buffer is 40 kbyte. More information on the specific video parameters employed for CD-i Full Motion video can be found in Ref. 9. Digital video is displayed on the background plane and can be overlaid with images coded in CLUT or RLE format.

The system part of the MPEG standard applies a multiplex structure consisting of packs and packets. In each MPEG video sector, still picture sector, and audio sector, one pack is stored. Each pack consists of a pack header and one or more packets containing a packet header followed by data from one audiovisual stream. More information can be found in Ref. 9.

The authoring system provided by the CD-i⁴¹ allows to optimize the audiovisual compression parameters to the requirements of the application. On a CD-i disc multiple MPEG audio and video streams can be recorded in parallel, e.g., for applications requiring audio in different languages. Moreover, during the authoring process, trade-offs can be made between the number of streams, the bit rate, the audio or picture quality of each stream, and, in the case of video, the picture size.

Compatibility to Other Formats

A CD-i player only plays discs that incorporate a dedicated application program that was designed for CD-i's operating system and hardware components. For some disc types, such as video-CDs, photo-CDs, and CD-BGM, this CD-i application is a mandatory part of the disc's specification. Next to this, the CD-i standard requires the player to be able to play back standard CD-Audio discs.

Differences between Video-CD and CD-i. A video-CD is a compact disc with up to 75 min of VHS quality video with accompanying sound in CD quality. Audio and video are coded according to the MPEG-1 standard and the disc layout (see Fig. 21.3.28) is based on the CD-i Bridge (see Fig. 21.3.29) specification to allow for the playback on a variety of playback devices such as CD-i players and dedicated video-CD players.

Video-CD became very popular mainly in Asia, while elsewhere, it is mainly used as a prototype tool. Although video-CD compatibility is not required for DVD-video players, it is very likely that video-CD playback

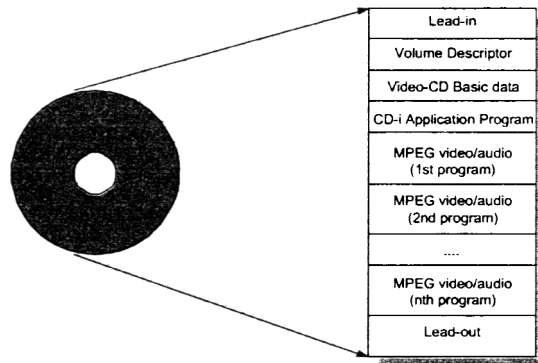

FIGURE 21.3.28 Video CD—disc data allocation.

FIGURE 21.3.29 CD-i bridge.

functionality is included since every DVD-video player must be able to decode MPEG-1 as well. Another difference is that the resolution of the MPEG video on a CD-i movie disc is slightly higher than the defined resolution of a video-CD disc (384×280 for the CD-i “Base Case” players instead of 352×240 for video-CD). This also prevents extracting the video from a CD-i disc in order to burn a video-CD. To do this, reencoding of the video according to the White Book (video-CD) specification is necessary, leading to a decreased picture quality.

BRIEF DESCRIPTION OF MPEG VIDEO CODING STANDARD

The Meaning of I, P, and B Pictures

MPEG video coding is described here because it applies both to VCD (and CD-i) and the DVD system that will be described next. Many good overviews of the MPEG video coding standards can be found in a variety of books¹³ and articles.¹¹ The MPEG video compression algorithm relies on two basic techniques: block-based motion compensation for the reduction of the temporal redundancy and DCT-based compression for reducing spatial correlations. The DCT-based compression has been described in detail in the section on DV recording. The intraframe DCT coder of DV comes close to the MPEG video processing with respect to DCT, quantization, and VLC coding. Therefore, the focus is in this section on exploiting the temporal redundancy.

In MPEG, three picture types are considered: intra pictures (I), predicted pictures (P), and bidirectional prediction pictures (B). Intra pictures are intraframe coded, i.e., temporal correlation is not exploited for the compression of these frames. I pictures provide access points for random access but achieve only moderate compression, because as their name indicates, compression is limited within the same picture. Predicted pictures, or P pictures, are coded with reference to a past I or P picture and will in general be used as a reference for a future frame. Note that only I and P pictures can be used as a reference for temporal prediction. Bidirectional pictures provide the highest level of compression by temporally predicting the current frame with respect to both a previous and current reference frame. B pictures can achieve higher compression since they can handle effectively uncovered areas, since an area just uncovered cannot be predicted from the past reference, but can be properly predicted from the future reference. They also have the additional benefit that they decouple prediction and coding (no error propagation is incurred from the prediction errors of B pictures).

In all cases, when a picture is coded with respect to a reference, motion compensation is applied to improve the prediction and the resulting coding efficiency. The relationship with respect to the three picture types is illustrated in Fig. 21.3.30. The I pictures and the B and P pictures predicted based on it form a group-of pictures (GOP). The GOP forms an information layer in MPEG video and is from the data point of view buildup as shown at the lower side of Fig. 21.3.30. First, the I picture is coded at the start and kept in a memory in the encoder. These memories are indicated at the bottom in Fig. 21.3.31. Second, the next

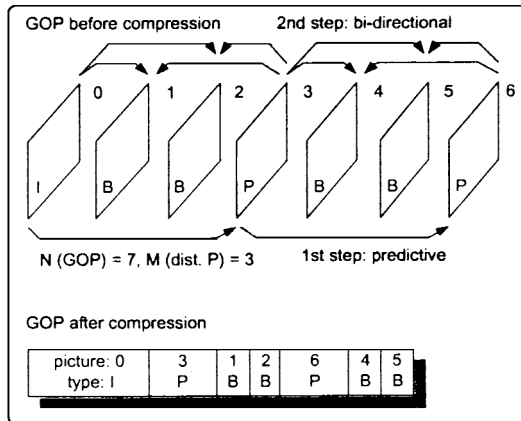

FIGURE 21.3.30 A group-of-pictures (GOP) divided in I, P, and B pictures.

P picture is selected and coded with reference to the I picture. The pictorial result after local decoding is also stored in a second memory. Third, the two B pictures in between are processed in sequential order. Each B picture is coded depending on the past I picture and the near P picture in future. This explains the term *bidirectional*. When the B pictures in between have been processed, the process repeats itself and the next P picture is first coded and stored as reference, and so on. Note that MPEG video coding as a result changes the transmission order of pictures over the channel (see bottom of Fig. 21.3.30 for the modified order).

MPEG Coding and Motion Compensation

Coding and processing with reference to a past and future picture involves motion compensation (MC). This means that the motion of objects is taken into account and predicted and only the difference between

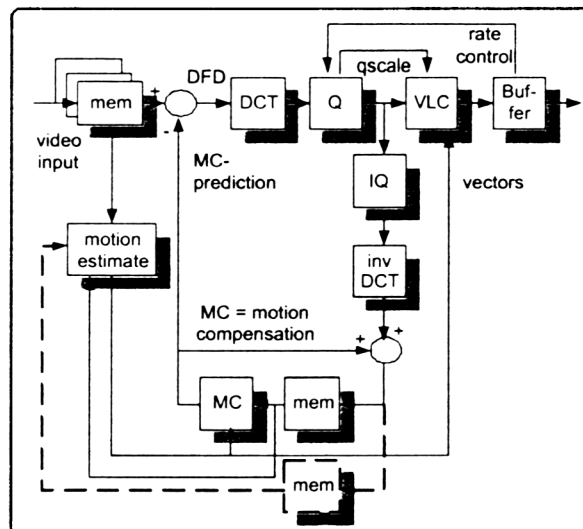

FIGURE 21.3.31 MPEG video encoder block diagram.

the temporal prediction and the actual video data is coded (see Fig. 21.3.31). In order to predict the motion of video data, it is first measured in an initial step, called *motion estimation* (ME). Motion compensation and estimation in MPEG are based on block-based processing. Hence, the blocks of video samples in actual and reference picture are compared. The typical block size for comparison in MPEG is a macroblock of 16×16 pixels.

There is a trade-off between the coding gain due to motion compensation and the cost of coding the necessary motion information (prediction type, motion vectors relative to the reference pictures, and so forth). Hence, in MPEG, the choice of 16×16 macroblocks for the motion compensation unit is the result of such a trade-off. The motion information is coded differentially with respect to the motion information of the previous adjacent macroblock. The differential motion information is likely to be small, except at object boundaries, and it is coded using a variable-length code to provide greater efficiency.

To reduce the spatial correlation in I, P, and B pictures, DCT-based coding is employed. After the computation of the transform coefficients, they are quantized using a visually weighted quantization matrix. Subsequently, after quantization the coefficients are zigzag scanned and grouped into (run, amplitude) pairs. To further improve the coding efficiency, a Huffman-like table for the DCT coefficients is used to code (run, amplitude) pairs. Only those pairs with a high probability of occurrence are coded with a VLC, while less likely pairs are coded with an escape symbol followed by fixed-length codes, in order to avoid extremely long codewords and reduce the cost of implementation. All these steps are indicated in Fig. 21.3.31.

The quality of video compressed with the MPEG-1 algorithm at rates about 1.2 Mb/s is comparable to VHS quality recording. The quality of MPEG-2 video is higher, but it is also operated at a higher bit rate between 3 to 5 Mb/s. This is discussed further in the next section about DVD.

THE DVD SYSTEM

Introduction and History

The DVD system was introduced in 1996¹⁴ and has experienced a strong growth of interest and sales in the consumer area. The key factors of its success are the very high quality of the reproduced video and audio signals and the fact that the storage is based on a high-capacity optical disc medium. The latter factor builds clearly on the success of the compact disc technology, albeit with strongly improved densities to boost the total storage capacity of the disc.

The success of DVD results also from the perfect fit with the trends that are taking place in the consumer and computer industry. In the 90s, computer applications have been expanding continuously toward high-quality audio and video recording and playback functions. For example, video compression of MPEG-1¹⁰ and MPEG-2¹² have been adopted gradually and the CD audio playback function evolved to CD-ROM and later CD-R/CD-RW recording subsystems in the multimedia computers. Nowadays, DVD-ROM has become an integral part of the modern multimedia computer, thereby solving (temporarily) the ever increasing request for more storage capacity on a removable medium. DVD-video players share most of the same physical and mechanical components with DVD-ROM drives in the computer. In the coming years, DVD recording (R/RW), which is already introduced, will occupy a significant part of consumer and general computing applications.

A DVD holds 4.4 to 15.9 GB (gigabytes), which is the same as 4.7 to 17 billion bytes. The capacity improvement of the typical DVD of 4.7 GB compared to CD (of 0.65 GB) results from different factors, which are shown in Table 21.3.13. The expansion to larger capacities results from extra bit layers, which will be elucidated in the next subsection. The DVD capacity was tuned to satisfy one of the main applications: storing a full-length and full-quality movie on a single disc. Over 95 percent of the Hollywood movies are shorter than 2 h 15 min, so that 135 min was taken as a guideline for the design of a digital video disc system. Uncompressed movies, e.g., with 4:2:2 10-bit sampling, run at 270 Mb/s and consume more than 32 Mbyte/s, requiring more than 250 gigabytes storage capacity. With resampling on a somewhat lower resolution to 124 Mb/s and MPEG-2 video coding offering a compression factor of 30, the average bit rate is reduced to 3.5 Mb/s for the video signal. Additionally, on the average, three tracks of audio consuming 384 kb/s each are added to come to 4.4 Mb/s average bit rate.

TABLE 21.3.13 Key Parameters of CD and DVD Standard Where Improvement Factors in Both Density and Channel Coding Lead to an Improvement of a Factor of 7 in Capacity

	CD	DVD	Factor
Pit length	0.83 μm	0.40 μm	2.08
Track pitch	1.6 μm	0.74 μm	2.16
Data area surface	8605 mm^2	8759 mm^2	1.02
Channel modulation ratio	8/17 EFM	8/16 EFM+	1.06
Error correction ratio	1064/3124 (34%)	308/2366 (13%)	1.32
Sector overhead ratio	278/3390 (8.2%)	62/2418 (2.6%)	1.06

Unlike the DV format, almost everything in the DVD standard is variable. The previous discussion on playing time was entirely based on average numbers. Let us consider some variations on the application. If the movie producer skips two audio tracks, the playing time increases to a near 160 min. The difference can, e.g., be used to increase the picture quality. The maximum bit rate can be as high as 9.8 Mb/s for the video and the total bit rate including audio is limited to 10.08 Mb/s. This maximum rate can be sustained and would lead to a playing time of 62 min. On the other side of the spectrum, if a movie is recorded in MPEG-1 at about 1.2 Mb/s, the playing time becomes more than 9 h. This discussion applies to DVD-video. When considering DVD-ROM, the flexibility in usage and the recorded data is infinite. If a new video coding technique is found in the future, the disc may be used to store more than 3 h of high-quality film.

Bit Layers in DVD

The increase in storage capacity from 4.7 to 15.9 gigabytes results from a new technology that was applied in the DVD system, where information bits can be stored in more than one layer. The laser that reads the disc can be focused at two different levels. Hence it can read the top layer or it can look through the top layer and read the layer beneath. This process is enabled by a special coating on the top layer, which is semireflective, thereby allowing the laser wavelengths to pass through. The reading process of a disc starts at the inside edge and gradually moves toward the outer edge, following a spiral curve. The length of this curve is about 11.8 km. If the laser reaches the end of the first layer, it quickly refocuses on the second layer and starts reading backwards. The switch to the second layer takes place in the order of 100 ms, which is fast enough to match this electronically with data buffering in order to prevent hiccups in presentation of the video or audio data. The reading process of bits from the disc is faster than the decoding of it to compensate for time losses from refocusing. Possibilities for various forms of reading and layering are shown in Fig. 21.3.32. First, DVDs can be single-sided or double-sided. Second, each side can have one or two information layers, indicated with the tiny square waves in Figs. 21.3.32(a) through 21.3.32(e). The information layers are in the middle of the disc for protection and enabling the double-sided options. A double-sided disc is constructed by binding two

FIGURE 21.3.32 Various configurations of bit layers and sides: SS = single side, DS = double side, SL = single layer, DL = double layer.

TABLE 21.3.14 DVD Capacities Resulting from the Various Combinations of Layers, Sides, and Disc Sizes. The Triangles Represent the Focused Laser Beam. CD-ROM is Added for Reference (Assuming Four Times the Speed)

Type	Diam.	Sides	Layers	Gigabytes	Pl.-time/(h)
DVD-5	12 cm	SS	SL	4.70	2.25
DVD-9	12 cm	SS	DL	8.54	4.0
DVD-10	12 cm	DS	SL	9.40	4.50
DVD-18	12 cm	DS	DL	17.08	8.0
	8 cm	SS	SL	1.46	0.75
	8 cm	SS	DL	2.66	1.25
	8 cm	DS	SL	2.92	1.5
	8 cm	DS	DL	5.32	2.5
CD-ROM	12 cm	SS	SL	0.68	0.25

stamped substrates back to back. Single-sided discs have a blank substrate on one side. There are even more possibilities, since DVDs can also vary in size, i.e., by using 8 cm or 12 cm diameter for the disc. The most important options are shown in Table 21.3.14. Physically, each substrate has a thickness of 0.6 mm. The thickness of a DVD is thus 1.2 mm so that it equals the thickness of a CD. The glued construction of the DVD makes them more rigid than a CD, thereby enabling more accurate tracking by the laser and thus a higher density.

A special topic is backward compatibility to the CD-ROM format. Although this is not required, the key manufacturers see this point of vital importance, because of large market presence of CD formats. One of the problems is that with CD, the data are within a stamped metal layer deep inside the disc (virtually at the back-side), whereas in DVD it is in the middle. The focusing is therefore different. This leads to a player with three focusing levels. Another problem is that CD discs do not well reflect the 635 to 650 nm wavelength transmitted by a DVD player. This sometimes leads to extra lasers or optical devices. A last aspect is the compatibility with data formats (VCD, CD-i, photo CD, and so forth) requiring extra electronics inside data decoding circuitry. In practice, most DVD players have backward compatibility with VCD and sometimes with one or more CD-R/RW formats.

The DVD Disc

The disc is read from the bottom, starting with data layer 0. The second layer, called layer 1, is further from the readout surface. The layers are actually very close, spaced about $55 \mu\text{m}$ from each other. The backside coating of the deepest layer is made from metal (such as aluminium) and is thus fully reflective, while it has a semitransparent coating on top. Layer 1 has a semireflective coating to enable reading of layer 0. The first layer is about 20 percent reflective and the second layer 70 percent. The substrate is transparent. The laser light has a wavelength of 650 or 635 nm (red laser). The lens has a numerical aperture of 0.60 and the optical spot diameter is 0.58 to $0.60 \mu\text{m}$.

FIGURE 21.3.33 Physical 12 cm DVD disc area parameters.

Figure 21.3.33 portrays the key areas of the disc. The burst cutting area is for unique identification of a disc via a 188-byte code and can be used for automatic machines with multiple disc storage capacity (e.g., a juke box). Table 21.3.15 shows relevant parameters for recovering bits from a DVD-ROM or DVD-video. What strikes the eye here is the robustness: a scratch of 6 mm can be covered by the ECCs, which clearly outperforms the CD channel coding.

TABLE 21.3.15 Key Physical Bit Reading Parameters for DVD-ROM

Pit length SL	0.40–1.87 μm
Pit length DL	0.44–2.05 μm
Track pitch	0.74 μm
Average data bit length	0.267 (SL)/0.293 μm (DL)
Average channel bit length	0.133 (SL)/0.147 μm (DL)
Velocity	570–1630 rpm (574–1528 rpm data)
Scanning speed	3.49 m/s (SL), 3.84 m/s (DL)

DVD Data Format

The logical data format of DVD is indicated in Table 21.3.16. A key parameter is the easy to use sector size of user data of 2048 bytes that nicely fits with computer applications. The modulation code is called EFMPlus, a more efficient successor of the EFM code that was applied for the CD. This code enables a high density of bits on the disc, by limiting the number of zeros between two transitions. In this case, the code bounds the number of zeros between 2 and 8, between each group of ones. The modulation also helps keep DC energy low and provides synchronization in the channel. The ECC is a powerful R-S product code having considerably less overhead than in the CD. By using row-column processing of the rectangular data sector block of 192 by 172 bytes, it is well suited for removing burst errors resulting from scratches and dirt and so on. Note that the gross number of user data here is 11.08 Mb/s, instead of the 10 Mb/s earlier. The extra 1 Mb/s is available for extra insertion of user data such as subpictures and the like. The following figures explain the data sector construction in more detail.

The construction of a DVD data sector is portrayed by Fig. 21.3.34. The sector consists of 12 rows of 172 bytes each. The first sector starts with identification bytes (sector number with error detection on it) and copy protection bytes and the last sector ends with four EDC bytes for a payload ECC. Figure 21.3.35 depicts the conversion from data sectors into ECC blocks. All data sectors together then form a block of 192 rows of 172 bytes each. The rows of the ECC block are interleaved to spread out possible burst errors, thereby enhancing the removal of those errors. Looking vertically in Fig. 21.3.35 each of the 172 columns of the ECC block gets an outer parity check data of 16 bytes assigned to it. This extra data forms the outer parity block. Similarly, for each of the 208 rows (192 + 16 bytes), a 10-byte inner parity check is computed and appended. The power of the R-S product code is such that a (random) error rate of 2 percent is reduced to less than one error out of 10^{15} bits (million-billion). The product code works on relatively small blocks of data, resulting in a maximum correctable burst error of approximately 2800 bytes, which corresponds to about 6 mm scratch length protection.

To come to recording sectors, each group of 12 rows of the complete ECC block gets one row of parity added to it, leading to a spread of parity codes as well. Thus, a recording sector consists of 13 (12 + 1) rows

TABLE 21.3.16 Data Format Parameters of DVD

Data sector (user data)	2048 bytes
Logical data sector size	2064 bytes (2048 + 12 header + 4 EDC)
Recording sector size	2366 bytes (2064 + 302 ECC bytes)
Unmodulated physical sector	2418 bytes (2366 + 52 sync bytes)
Modulated physical sector	4836 bytes (2418 \times 2 bytes)
Modulation code	8–16 (EFMPlus)
Error correction code	R-S product code (208,192,17) \times (182,172,11)
ECC block size	16 sectors (32,768 bytes user data)
ECC overhead	15% (13% of recording sector)
Format overhead	16% (37,856 bytes for 32,768 user B)
User/Channel data rate	11.08/26.16 Mb/s

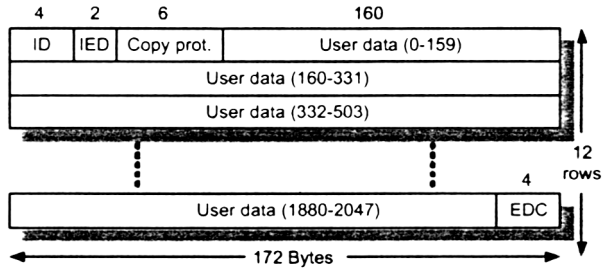

FIGURE 21.3.34 Construction of a DVD data sector.

of 182 (172 + 10) bytes. A recording sector is split in the middle and 2 bytes are inserted for synchronization and 2 sync bytes are added at the beginning of the first half. This leads to two parts of 2 + 91 bytes (total 186 bytes) and 13 rows, which form 2418 bytes together. This block is modulated to 4836 bytes by the EFMPPlus code.

DVD-Video

The DVD-video system is an application of the DVD-ROM standard and aims at playback of high-quality movies together with multichannel audio. Presently, this is one of the mostly accepted standards of the DVD products. DVD-video consists of one stream of MPEG-2 video coded at variable rate, up to eight channels of Dolby digital multichannel audio or MPEG-2-coded multichannel audio or linear PCM audio, and up to 32 streams of subpicture graphics with navigation menus, stills pictures, and control for jumping forward and backward through the video program. With respect to video resolution, the format intends to serve and output both analog standard resolution TV as well as high-quality digital TV and possibly in future digital HDTV. Many multimedia computers can playback DVD-video as well.

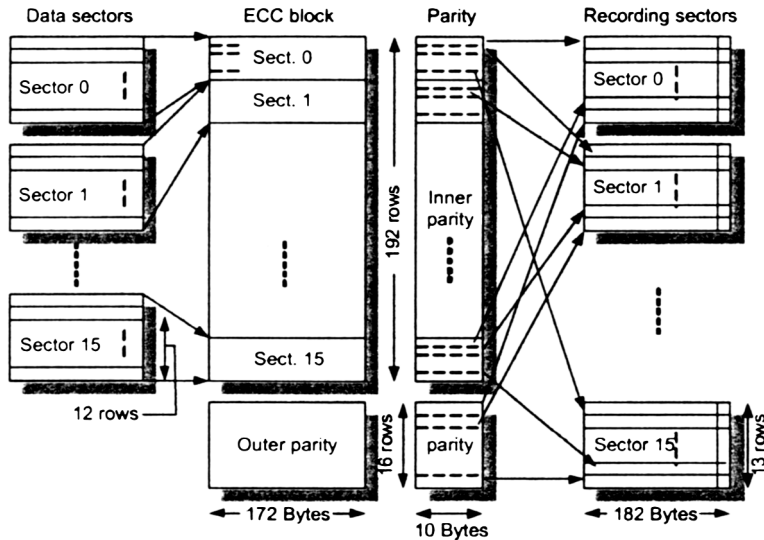

FIGURE 21.3.35 Data sectors mapped into DVD ECC blocks that are subsequently converted into recording sectors.

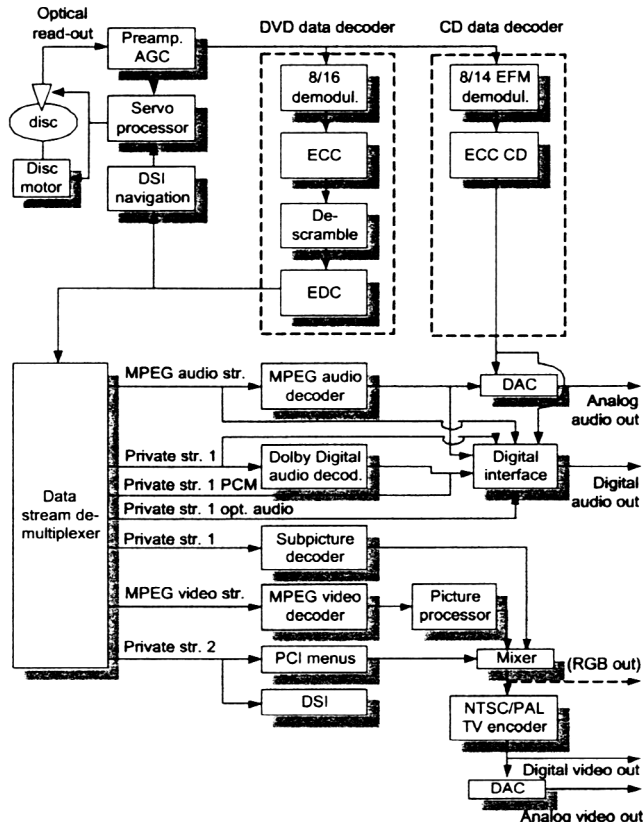

FIGURE 21.3.36 Block diagram of DVD player with CD compatibility.

The system diagram of DVD-video is depicted in Fig. 21.3.36. The diagram depicts audio data reading on disc with either CD audio data decoding or via the DVD demultiplexing of audio streams. The video results from demultiplexing the DVD data into the various data streams. Audio is decoded with MPEG or Dolby digital decoders. The amount of postprocessing is growing continuously and may involve noise reduction, sharpness improvement, and even 100 Hz conversion (Europe). The NTSC/PAL encoder ensures seamless connection to existing TV receivers.

The data flow and buffering operates as follows. The channel bits from disc are read in a constant 26.16 Mb/s rate. The EFMPlus 8-16 demodulator halves this to 13.08 Mb/s and this is reduced after ECC to a constant user data stream of 11.08 Mb/s. Data search information (DSI) is copied from this stream prior to writing this in a track buffer. A so-called MPEG program stream of variable rate is recovered at 10.08 Mb/s, which contains five different packetized elementary streams (PES): video, audio, subpicture, presentation control information (PCI), and the data search information (DSI). The latter two streams are system overhead data. The 10.08 Mb/s data rate is the maximum rate of the video and audio stream together. Video may be coded as MPEG-1 or MPEG-2 streams and has the form of a PES stream; audio, if coded as MPEG, is also a PES stream. The PCI and DSI streams are mapped as MPEG private streams. Another private stream contains the subpicture data and alternative audio data. Since audio consumes data rate, the video is limited to either 9.8 Mb/s for MPEG-2 and 1.85 Mb/s for MPEG-1. The pulse code modulation (PCM) audio stream is maximally 6.14 Mb/s, which can consist of eight channels audio sampled at 16 to 48 kHz. Note that each AV

decoder has its own buffers for keeping data at the input. The buffer sizes for video, audio, subpicture, and PCI are 232, 8, 52, and 3 kbyte, respectively.

DVD Audio and Data

Audio streams in DVD are based on three different possibilities as follows:

- *PCM audio*. This is a straightforward stream of digital samples of audio without compression, referred to as LPCM. The minimum bit rate is 768 kb/s and for multiple channels, it can be maximally 6.144 Mb/s. The typical bit-rate is 1.536 Mb/s for 48 kHz sampling frequency.
- *Dolby digital*. This is based on the Dolby digital coding scheme, having a minimum, typical, and maximum bit rate of 64, 384, and 448 kb/s, respectively. The coding scheme is also known as AC-3. There can be one, two, three, four, or five channels with an optional subwoofer channel (all together indicated as Dolby 5.1). All Dolby digital decoders are required to downmix 5.1 channels to two channels stereo PCM and analog output.
- *MPEG audio*. MPEG-1 audio layer II is based on coding the audio spectrum in individual subbands. It is limited to 384 kb/s bit rate, the typical rate is 192 kb/s. MPEG-2 audio can extend this from 64 kb/s to maximally 912 kb/s. The typical rate is 384 kb/s. At maximum, seven channels can be used (7.1 with subwoofer). The advanced audio coding (AAC) mode is optimized for perception and is part of MPEG-2 audio coding. The primary audio track of DVD is always MPEG-1 compatible.

The subpicture data of 10 kb/s may grow to 3.36 Mb/s maximally, whereas the DTS data can have a rate up to 1.536 Mb/s. Typically, the rates for this type of data are rather limited in capacity. Various coding types and parameters can be used in the above options. Coding algorithms can be besides the MPEG equal to LPCM, AC-3, DTS, and SDDS. The last two modes involve optional multichannel formats (e.g., 5.1) using compression on PCM-based channels. Audio sampling can be performed at 16, 20, or 24-bit resolution. Sampling rate is 48 or 96 kHz and the dynamic range compensation (DRC) of the audio signals can be switched on and off. Along with certain applications, a code can be used, such as surround (multichannel HQ audio), karaoke (for singing with supporting subtitling), or an unspecified code.

The data are organized in files. Each side of the disk contains one logical volume, using one partition and one set of files. Each file is a contiguous area of data bytes to support easy transfer and decoding. The complete list of constraints applies to the normal DVD-video application that are used at playback. However, the format allows to record special data files that do not satisfy the above constraints. This is allowed if they are formatted into the DVD-video "Data" stream, behind the regular data that are required for playback. Then a specially designed player can access the extra data. This option allows many special applications in the future.

DVD Conclusions

DVD is an evolutionary product that successfully builds further on the widely accepted and distributed optical recording technology of the CD. The principal advantage is the excellent video and audio quality recorded on a single disc. Table 21.3.17 provides the main system parameters of DVD compared with DV and D-VHS. The table clearly shows that VHS is lagging behind in picture quality and that the digital formats of DV and DVD are comparable with each other.

The compression factor of DVD is high but the quality is approaching the DV quality in spatial resolution. The MPEG compression relies heavily on the motion compensation, which is not used in DV. Thus the temporal quality of DV clearly outperforms that of DVD and this explains why there are semiprofessional DV systems (e.g., DVCPRO) for portable studio applications.

The coming years will show further penetration of recordable DVD formats in the market (DVD-RW, DVD + RW, DVD-R³⁶ with the above-mentioned resolution and quality. Meanwhile, even higher capacity optical discs are being developed to pave the way for HDTV and to stay comparable with computer hard disks.

TABLE 21.3.17 DVD Compared to Other Existing Recording Systems

	DV	D-VHS	DVD
Video	Component digital	Composite analog or digital bit stream	Component digital
Playing time	0.5–1 h (mini) 4.5 h (standard)	2–6 h (VHS) 4–40 h (D-VHS)	2.25 h (1 layer) 4.5 h (2 layers)
Data capacity	5–50 Gbytes	32–40 Gbytes (300–400 m tape)	4.7–17 Gbytes
Compression	Intraframe DV factor 5	External (MPEG-2)	MPEG-1/MPEG-2 factor 30
Data rate	25.146 Mb/s video 1.536 Mb/s audio	28.2 Mb/s HD, 14.1 Mb/s STD, 2–7 Mb/s LP	Up to 9.8 Mb/s combined VBR or CBR V + A
Error correction	R-S product code + track interleave	R-S (inner/outer)	R-S product code
Channel modulation	24-25 code	NA	EFMPlus (8–16 block)
TV video systems	525/60/2:1 29.97 Hz 625/50/2:1 25 Hz	NA NA	525/60, 1:1 24 Hz/ 2:129.97 Hz 625/50/2:1 25 Hz 1:1/24 Hz
V 525 resolution	720 × 480 (346 kpixels)	320 × 480 (154 kpixels) VHS	720 × 480 (346 kpixels)
V 625 resolution	720 × 576 (415 kpixels)	320 × 580 (187 kpixels) VHS	720 × 480 (415 kpixels)
Audio	2 tracks of 2 channels (32 kHz, 12-bit nonlinear PCM) or 1 track of channels (32/44.1/48 kHz 16-bit PCM)	Analog VHS stereo HiFi or digital bit stream (MPEG/Dolby like)	8 tracks of up to 8 channels each (LPCM/ Dolby digital/MPEG-2)
Audio SNR	72 dB (12-bit), 96 dB (16-bit)	40 dB(mono), 90 dB HiFi	96–144 dB
Trick play, searching	Up to 70–90 times, with complete picture	Up to 10–20 times, with distorted picture (VHS)	Jumping to I pictures several speeds, stills

NETWORKED AND COMPUTER-BASED RECORDING SYSTEMS

Personal Video Recorder (PVR)

The final part of the chapter is devoted to new emerging technologies and products in recording of which most are related to further applying the computer technology into consumer systems. The personal video recorder (PVR) is a TV recorder that records on a computer hard disk as opposed to tape. The PVR is also called personal digital recorder, digital video recorder, digital network recorder, smart TV, video recording computer, time-shifted television, hard disk recorder, personal television receiver, television portal, or on-demand TV. PVR has evolved as a direct consequence of digital recording and low-cost hard disk storage. The advantages of hard-disk-based recording are:

- Allowing random access to content
- Metadata can be stored along with the content (allowing easier searching, selection and management of content, segmentation of content, richer interaction, and so forth)
- Easier transfer and redistribution of content

Some of the features provided by the PVR justify its popularity in first product trials.

Simultaneous record and replay, allowing “trick” modes such as pausing and rewinding live TV. This allows pausing of a live TV program when the phone rings, later viewing of a program that has already started but is not yet finished, “fast-forward” through parts of programs when watching a time-shifted program, and so forth.

Sophisticated interactive multimedia information services, regular program and news updates that are instantly available to consumers. For instance, downloads of electronic program guides (EPGs) with the TV signal or via the phone network simplify program selection, browsing (by time, by channel, and so forth), and recording.

Automatic indexing of recorded programs allowing easy retrieval and manipulation of content.

“Intelligent” agents that can automatically record or recommend TV programs that they think the viewer might want to watch. For instance, the EPG can also include metadata describing the programs (e.g., the actors, the genre) or a brief text summary, that can be used by the PVR to manage the recording process. Consequently, the PVR can use this metadata to automatically record or recommend similar types of programs the users have recorded in the past or preferences they have entered as part of the set-up procedure.

Nonlinear viewing of programs that were recorded in a linear manner. The viewing is performed by, e.g., skipping certain segments.

Several brands of PVRs exist—TiVo, Replay TV, Ultimate TV, Xcent, and so on. Subsequently, we will explain some of the technology and issues behind the PVR, by giving some implementation examples.

Content-Format I/O and Storage. The various PVR brands use different formats for the I/O and for the storage format. This choice is very important since it influences the overall PVR architecture, the necessity for content protection as well as the resulting quality of the stored content. For instance, TiVo’s I/O interfaces are analog, even for the digital services, thereby eliminating issues such as conditional access and scrambling. For storage, the analog signals are converted to digital and then compressed using MPEG-2 coding. This implies that in the case digitally broadcasted content is stored using TiVo, the audiovisual quality can potentially be decreased by the cascaded encoding/decoding process. To solve this problem, other PVR configurations store the original broadcast digital signal in scrambled form on its hard disk, giving the potential for better audiovisual quality and the possibility for the conditional access operator to control the replay of stored programs. On the positive side, however, because TiVo compresses the content, easy trade-offs between quality and storage capacity can be made. For example, if a TiVo has 40 Gigabytes of hard disk capacity, this represents about 40 h storage at “basic” quality or about 12 h at “best” quality. It should be noted, however, that the “best” quality is limited by the incoming audiovisual content quality.

Event- Versus Time-Driven Programming. To better understand the differences between these types of programming, let us consider two different implementations. For the TiVo PVR, data are downloaded daily via the telephone network, and depending on the availability of the data, TiVo can have program details for up to two weeks in advance. The TiVo data are entirely time-driven, such that the program is stored based on the a priori available time information. Alternatively, other PVRs are event-driven, i.e., detect the program junctions. For instance, Xcent PVR uses a 64 kb/s channel on the satellite transponder to which the PVR tunes by default to keep recording when a program runs late.

Software Downloading to Existing PVRs for Enabling New Services. Different services can be enabled using the PVR functionality. For instance, “trailer selection” services are expected to appear enabling the viewer to simply press a button when a trailer for a program is presented, and the PVR will automatically record the program whenever this is broadcast. This can be done using the program metadata (see next paragraph). Furthermore, other e-commerce services can also be enabled via similar mechanisms, as described below.

Metadata. Since the introduction of the PVR, it was argued that the scheduling of the programs at attractive hours will lose its power to attract viewers, because the PVR can present desired video programs that were already stored on its hard disk on-demand. If scheduling will indeed lose its power to attract the viewers, its place will probably be taken by the metadata and services that support PVR functions. Consequently, the battle for the attention of the viewers will be won by the provider that can describe programs and services most

fully and attractively using metadata. Moreover, with a PVR it is possible for the viewer to skip all advertisements. Nevertheless, the content still has to be paid for, such that new mechanisms are necessary to encourage the viewers to watch commercials. To enable this, ubiquitous metadata can be employed to target advertisements at specific interest groups. Furthermore, PVR's combination of storage, processing power, and supporting metadata offers potential for new kinds of programs (e.g., educational), where the viewer interactively navigates around the stored program.

Note that standards are necessary for describing multimedia content, i.e., metadata, which is required by these services. MPEG-7 provides such a standard³⁷ (see the "MPEG-7" section). Furthermore, while many PVRs are already existing on the market, proprietary solutions restrict the user to a single service or content provider and lock together the broadcaster, service provider, and the PVR manufacturer. Consequently, to enable PVR proliferation, standards are necessary for metadata to choose programs, for finding the programs in a multi-channel, web-connected broadcasting environment, for management of the rights that must be paid for in order to support the services, and so forth. These standards are generated in a new worldwide body, the TV-Anytime forum (see "TV-Anytime" section).

Brief MPEG-7 Overview

As mentioned in the PVR section, digital audiovisual recorded material is increasingly available to users in a variety of formats. For instance, persistent large-volume storage that allows nonlinear access to audiovisual content, such as hard-disk storage in powerful PC platforms and personal video recorders (PVR), is becoming available in many consumer devices. Consequently, there is a need for rapid navigation and browsing capabilities to enable users to efficiently discover and consume the contents of the stored audiovisual programs. Users will also benefit from having nonlinear access to different views of a particular program, adapted to the user's personal preferences, interests, or usage conditions such as the amount of time the user wants to spend in consuming the content or the resources available to the user's terminal. Such adaptability will enhance the value provided by the multimedia content. The MPEG-7 standard,³⁸ formally named *Multimedia Content Description Interface*, provides a rich set of standardized tools to describe such multimedia content (see Fig. 21.3.37). A good description of the MPEG-7 standard can be found in Refs. 37 and 38. In this section, we will summarize only those MPEG-7 components that can be useful in finding, retrieving, accessing, filtering, and managing digitally recorded audiovisual content.

The main elements of the MPEG-7 standard^{37,38} are presented below.

- *Descriptor (D)* is a representation of a feature. A descriptor defines the syntax and the semantics of the feature representation.
- *Description Scheme (DS)* specifies the structure and semantics of the relationships between its components, which may be both Ds and DSs.

FIGURE 21.3.37 MPEG-7 standardization role.

- *Description Definition Language (DDL)* is a language to specify description schemes. It also allows the extension and modification of existing DS. MPEG-7 decided to adopt XML Schema Language as the MPEG-7 DDL. However, DDL requires some specific extensions to XML Schema Language to satisfy all MPEG-7 requirements.
- *Binary representation* provides one or more ways (e.g., textual, binary) to encode descriptions. A coded description is a description that has been encoded to fulfill relevant requirements such as compression efficiency, error resilience, random access, and so forth.

MPEG-7 offers a comprehensive set of audiovisual description tools that can be used for effective and efficient access (search, filtering, and browsing) to multimedia content. For instance, MPEG-7 description tools allows the creation of descriptions of content that may include:³⁷

- Information describing the creation and production processes of the content (director, title, short feature movie)
- Information related to the usage of the content (copyright pointers, usage history, broadcast schedule)
- Information of the storage features of the content (storage format, encoding)
- Structural information on spatial, temporal, or spatio-temporal components of the content (scene cuts, segmentation in regions, region motion tracking)
- Information about low-level features in the content (colors, textures, sound timbres, melody description)
- Conceptual information of the reality captured by the content (objects and events, interactions among objects)
- Information about how to browse the content in an efficient way (summaries, variations, spatial and frequency subbands, and so forth)
- Information about collections of objects
- Information about the interaction of the user with the content (user preferences, usage history)

The process of generating metadata for content description that can later be used for retrieving, accessing, filtering, and managing digitally recorded audiovisual content is portrayed in Fig. 21.3.38. Note that the MPEG-7 metadata can be either physically co-located on the same storage system with the associated audiovisual content or could also be stored elsewhere. In the latter case, mechanisms that link multimedia and its MPEG-7 descriptions are needed.

Example: MPEG-7 Usage in PVR Applications

For a better understanding of the MPEG-7 importance to the field of digital recording, let us consider its benefits in a PVR application. In this application, content descriptions could be generated by a service provider,

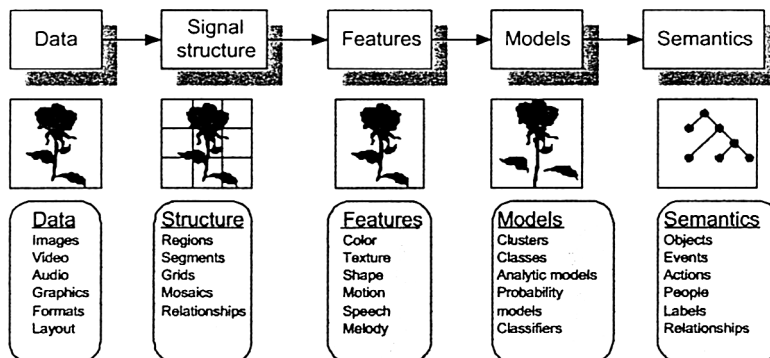

FIGURE 21.3.38 Generating metadata for content description.

separate from the original content provider or broadcaster. Certain high-level content descriptors, such as the program name and channel name, can be downloaded by the PVR in advance to provide an on-screen electronic program guide (EPG). This EPG enables the user to efficiently navigate at the program level and record programs easily. Moreover, summary descriptions can be made available in advance as well (e.g., in the case of movies), or downloaded at the end of a program (e.g., in the case of sports events). Furthermore, low-level descriptions that describes the various features of the content can also be provided. These descriptions can include information for video transcoding (i.e., transcoding hints), that can be used by the PVRs or transcoding proxies whenever transcoding from the “source” (service provider) content quality to a lower quality that can be used for local storage is desired.

Additionally, other descriptions may be generated by the user, e.g., by marking highly entertaining segments for later review. Such a feature can be simply provided by the PVR by copying the XML-fragment associated with the selected segment, including its name and locators and storing this element separately, along with some high-level elements that will allow its easy identification at a later time. Such fragments can be exchanged with friends or relatives. MPEG-7 is also developing description schemes that can capture the user’s preferences with respect to a specific content, and store them on the PVR under the user’s control. These schemes support personalized navigation and browsing, by allowing the user to indicate the preferred type of view or browsing, and automatic filtering of content based on the user’s preferences.

TV Anytime

The *TV Anytime Forum*⁴² is an international consortium of companies dedicated to producing standards for PVRs. TV Anytime aims at developing a generic framework that incorporates standards, tools, and technologies for an integrated system providing a multitude of services such as movies on demand, broadcast recording, broadcast searching and filtering, retrieving associated information from web pages, home banking, e-commerce, home shopping, and remote education. To enable this vision, TV Anytime will define specifications

- That will enable applications to exploit local persistent storage in consumer electronics platforms
- That are network independent with regard to the means for content delivery to consumer electronics equipment, including various delivery mechanisms (e.g., ATSC, DVB, DBS, and others) and the Internet and enhanced TV
- For interoperable and integrated systems, from content creators/providers, through service providers, to the consumers
- That provide the necessary security structures to protect the interests of all parties involved

Two important components in the TV Anytime framework are the digital storage and recording and the metadata, because they allow consumers to access the content they want, whenever they want it and how they

FIGURE 21.3.39 Various digital storage models: (a) in-home consumer storage—personal digital recorder (PDR), (b) remote consumer storage—network digital recorder (NDR), (c) PDR + NDR combination.

want it (i.e., presented and tailored according to the user preferences/requests). Metadata can be easily stored along with the content to enable searching, selection, and management of the content in a much easier fashion as compared to the current analog VCRs, and also allow a richer interaction with the stored content. Other benefits of local digital storage are that the TV viewers can order a program to be recorded using a single button during a trailer, making available intelligent agents that based on the stored user preferences can record TV programs that they think a viewer might want to watch and consuming a program in a nonlinear rather than linear manner (e.g., a news program). Note also that the digital recording process can be performed within the TV Anytime framework locally, remotely, or in a combined manner (see Fig. 21.3.39).

Hence, digital recording of content on local storage and digital broadcasting together with the framework provided by TV Anytime for content referencing and location resolution, metadata and rights management and protection, are providing significant benefits as compared with alternative forms of content delivery such as analog broadcasting, Internet, and broadband networks.

CHAPTER 21.4

TELEVISION BROADCAST RECEIVERS

Lee H. Hoke, Jr.

GENERAL CONSIDERATIONS

Television receivers are designed to receive signals in two VHF bands and one UHF band, and optionally a complement of the cable-TV channels, according to the United States and Canadian standards. The lower VHF band (channels 2 to 6) extends from 54 to 88 MHz in 6-MHz channels, with the exception of a gap between 72 and 76 MHz. The higher VHF band (channels 7 to 13) extends from 174 to 216 MHz in 6-MHz channels. The UHF channels are spaced 254 MHz above the highest VHF channels, comprising 56 6-MHz channels extending from 470 to 806 MHz. Cable channels extend continuously from 54 to approximately 1000 MHz, also with 6-MHz spacing. Figure 21.4.1¹ shows the CATV channelization plan adopted jointly by the NCTA and EIA in 1983 and revised in 1994. The television tuner is thus required to cover a frequency range of more than 15:1. TV tuners of past generations use separate units to cover the UHF and VHF bands. Current design practice includes the circuitry to receive all bands in a single unit.

The signal coverage of TV transmitters is generally limited to line-of-sight propagation, with coverage extending from 30 to 100 mi depending on antenna height and radiated power. The coverage area is divided into two classes of service, depending on the signal level. The service area labeled class A is intended to provide essentially noise-free service and specifies the signal levels shown.

Channels	Peak signal level, $\mu\text{V}/\text{m}$	Peak open-circuit antenna voltage, μV
<i>Class A service</i>		
2-6	2500	3500
7-13	3500	1800
14-69	5000	800
<i>Class B service</i>		
2-6	225	300
7-13	630	300
14-69	1600	250

For the limiting area of fringe service the signal levels are defined as shown for class B service. The typical level of the sound signal is from 3 to 20 dB below the picture level, due to radiated sound power and antenna gain. The block diagram of a monochrome TV receiver for analog signal reception is shown in Fig. 21.4.2.

FIGURE 21.4.1 Frequency spectrum and channel designation for broadcast and cable television. (From EIA IS-6, Revised Aug./1992)

RECEIVERS FOR DIGITAL TELEVISION TRANSMISSIONS

From Analog to Digital—the Contrast

When comparing a block diagram of the typical receiver for digital transmission to that of a current analog receiver, the first impression is the difference in complexity. A digital receiver (Fig. 21.4.3) contains more functional blocks, several of which differ greatly and have a high degree of complexity while still containing others that are similar to those of an analog set. The digital set contains more silicon ICs, as both memory and signal processor devices, many of which are custom designs at this date, a factor that may increase the set cost by \$200 to \$300 compared to a baseline NTSC set having a similar display size.

One basic advantage of the digital format is the increase in information that can be transmitted in a standard channel (6 MHz for the United States). This leads to packing three to four programs into a channel, or in the case of the U.S. Advanced Television System Committee (ATSC) Standard, a single HDTV signal or a group of up to four standard definition (SD) TV programs. Complexity here involves comparing the nearly 150,000 picture elements in an NTSC picture display to the 2 million picture elements of an HDTV display, an increase of 13 to 1. This equates to an RGB studio signal having 3×1080 active lines \times 1920 samples per line \times 8 bits per sample \times 30 pictures per second, which equals approximately 1.5 Gb/s.³ By using video compression, especially MPEG-2, this can be reduced to a more reasonable value of 20 Mb/s for transmission as a TV signal.

Many private concerns (broadcast and cable) within the United States as well as other countries are not interested in using digital transmission as a carrier for HDTV pictures. Instead their involvement with digital transmission is for satellite direct-to-home broadcast and for program coverage throughout the country, including a more robust signal throughout all areas for mobile and personal portable use. These diverse requirements have led to differing, optimized, digital RF modulation schemes. For example, the ATSC system uses a vestigial sideband system (VSB), quadrature phase-shift keying (QPSK) has been selected for satellite-to-home, quadrature-amplitude modulation (QAM) is the method chosen for digital cable (D-CATV), and for terrestrial area coverage in several countries outside the United States the orthogonal frequency division multiplex (OFDM) multicarrier modulation scheme has been selected. Each of these leads to differences in the receiver configuration as will be described later.

With current analog TV signal transmission, as the distance from the transmitter to the receiver increases, the picture becomes progressively noisier (snowy), until it is judged as “unwatchable,” although the sound might still be acceptable. With the digital signals and the high degree of data compression, however, the picture remains crystal clear and noise-free until a certain distance from the transmitter (deteriorating signal-to-noise ratio by 1 to 2 dB) at which point the picture suddenly breaks up and is completely lost (brick wall effect,

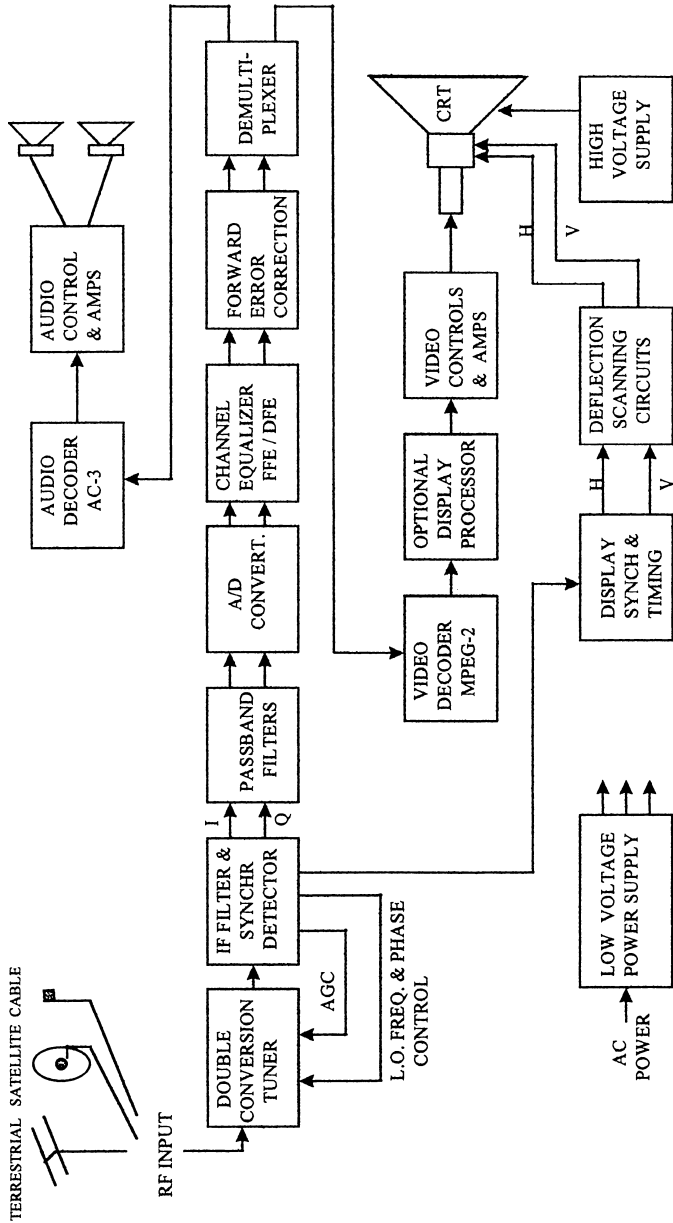

FIGURE 21.4.3 Block diagram of typical receiver for digital TV transmissions.

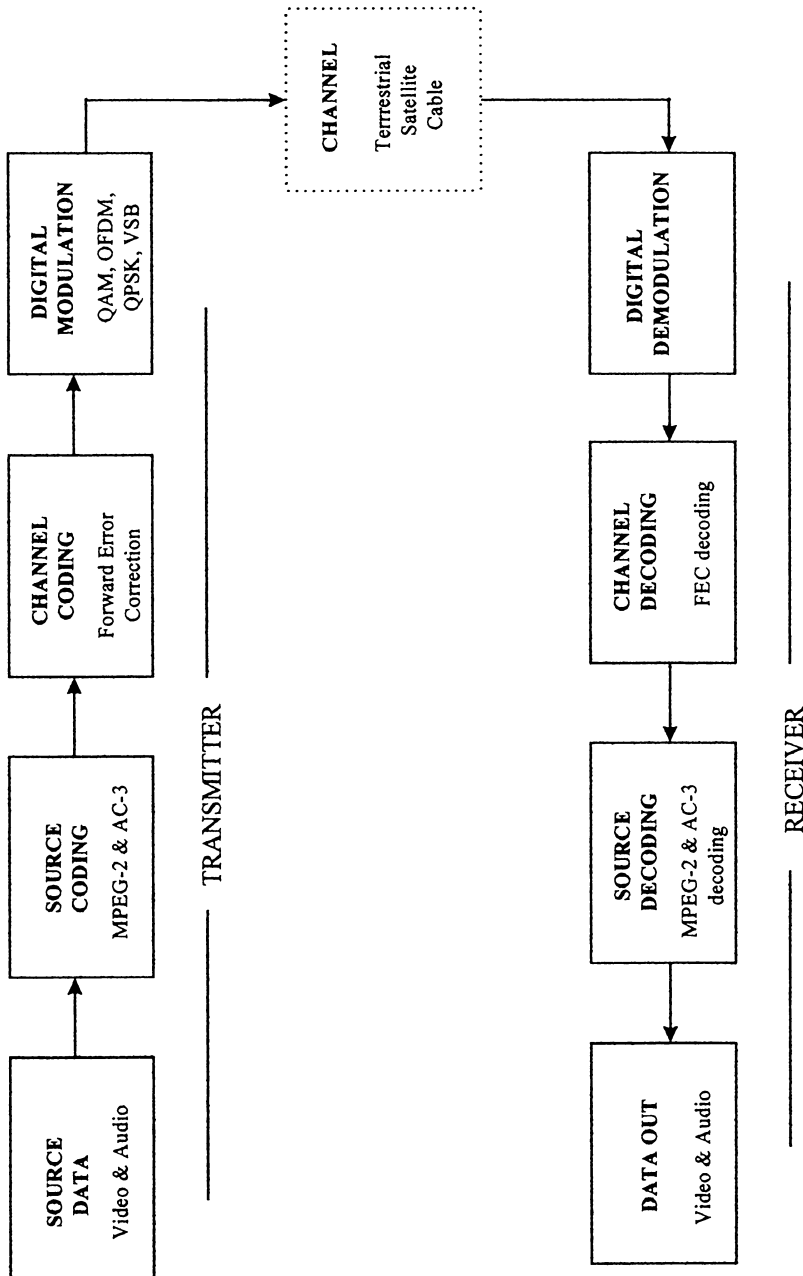

FIGURE 21.4.4 Basic elements of a digital TV system.

sometimes referred to as the waterfall effect) as compared to the gradual deterioration of an analog TV signal. A similar phenomenon can be observed in a satellite-to-home system. A storm cloud or leaves on trees can reduce the signal level just below the threshold at which point the received picture is lost completely, again a change of only 1 to 2 dB. In an effort to overcome the deficiencies of the transmission channel such as ghosts, noise, fades, and co-channel interference, the digital signal is encoded with forward error correction (FEC), often called channel coding, at the transmitter end. This necessitates complementary decoding at the receiving end, as shown in Fig. 21.4.4. The various types of encoding used with current digital TV systems are Reed-Solomon, Viterbi, trellis, interleaving, and convolutional, or a combination of these (concatenated coding system), depending on the robustness of the channel (cable, satellite or terrestrial).⁴ For a cable system, this additional signal processing ensures high-quality service throughout the entire system with no signal deterioration at the extremities.

The final difference to be discussed is the mapping of the demodulated video signal onto the display means (CRT, LCD, and so forth). Typically, this will be one-to-one, that is, the display system will be designed to match the specification (scan lines and pixels or samples per line) of the decoded video. This is true except for the ATSC system where five distinctively different video formats have been allowed for transmission. In the receiver, these must be converted to the natural parameters of the display device (display field rate, interlaced or progressive display, lines per field, and samples per line). Details will be covered in a later section.

Set-top boxes and high-definition (HD) or digital-ready TV sets will be the mechanism that brings digital technology to the consumer for the next several years as the transition from analog to digital takes place. Currently within the United States three of the modulation techniques to be discussed later have become “standards” in a particular application, i.e., VSB for terrestrial, QAM for cable, and QPSK for direct-to-home satellite. Although the ability to design a TV set that can accommodate all three exists, the cost to the consumer would be prohibitive. To include a range of sets in the retail product line to handle each individual application might be cost effective, but would be prohibitive to the retailer as well as very confusing to the customer. In order to achieve flexibility needed by customers who have changed their TV delivery service frequently over the years, a set-top box that is unique to the service has become the answer. Not only does this solve the input signal demodulation problem in an economic way, the output of each box connects to a standard, existing NTSC receiver, thereby allowing the customer to use his old set with the new service. Typically, for cable and satellite, these boxes are rented from the local cable provider or the retail outlet that sells and installs the satellite system hardware. Recent set-top boxes from at least two manufacturers have included the dual function of being a terrestrial HDTV decoder as well as a satellite decoder for the DirecTV system. This eases the “Which box should I buy?” decision for the consumer. Signals available from these boxes include composite video (CVBS), S-video (Y/C) for standard TV receivers, and high-resolution component video (Y, P_b, P_r) and RGB to drive HDTV-ready monitor receivers.

Although new fully integrated digital HDTV sets are available on the market, their price is still considerably above the standard market level for a TV set. The most popular designs currently available are the “HD Ready TVs,” which have upgraded display capability consisting of wider bandwidth video, up to 30 MHz, progressive scan, a higher-resolution CRT or projection display mechanism, and input connectors and wide-band circuitry which accepts progressive ($2f_H$) video signals or interlaced signals ($1f_H$) and convert them to progressive. A block diagram of an HD-ready receiver design is shown in Fig. 21.4.5.

QAM DIGITAL MODULATION

QAM digital modulation has been found to be advantageous for cable systems because of its simplicity, robustness, and its ability to deliver high-quality video signals in a 6-MHz channel over a hybrid fiber/coaxial network to subscriber homes where the signals are received via set-top boxes. The QAM signal can be considered to be a double-sideband suppressed carrier amplitude-modulated scheme. The input data bit stream is split into two independent data streams with one modulating the in-phase carrier while the other modulates the quadrature carrier component. Higher-order systems (M), e.g., $M = 16, 64, \dots$, contain additional sets of carriers that are evenly phase spaced from the others.⁵ Figure 21.4.6 shows a block diagram of a QAM receiver that can decode either the usual 64-QAM (20 Mbit/s) or the higher information density 256-QAM signal (40 Mbit/s).⁶

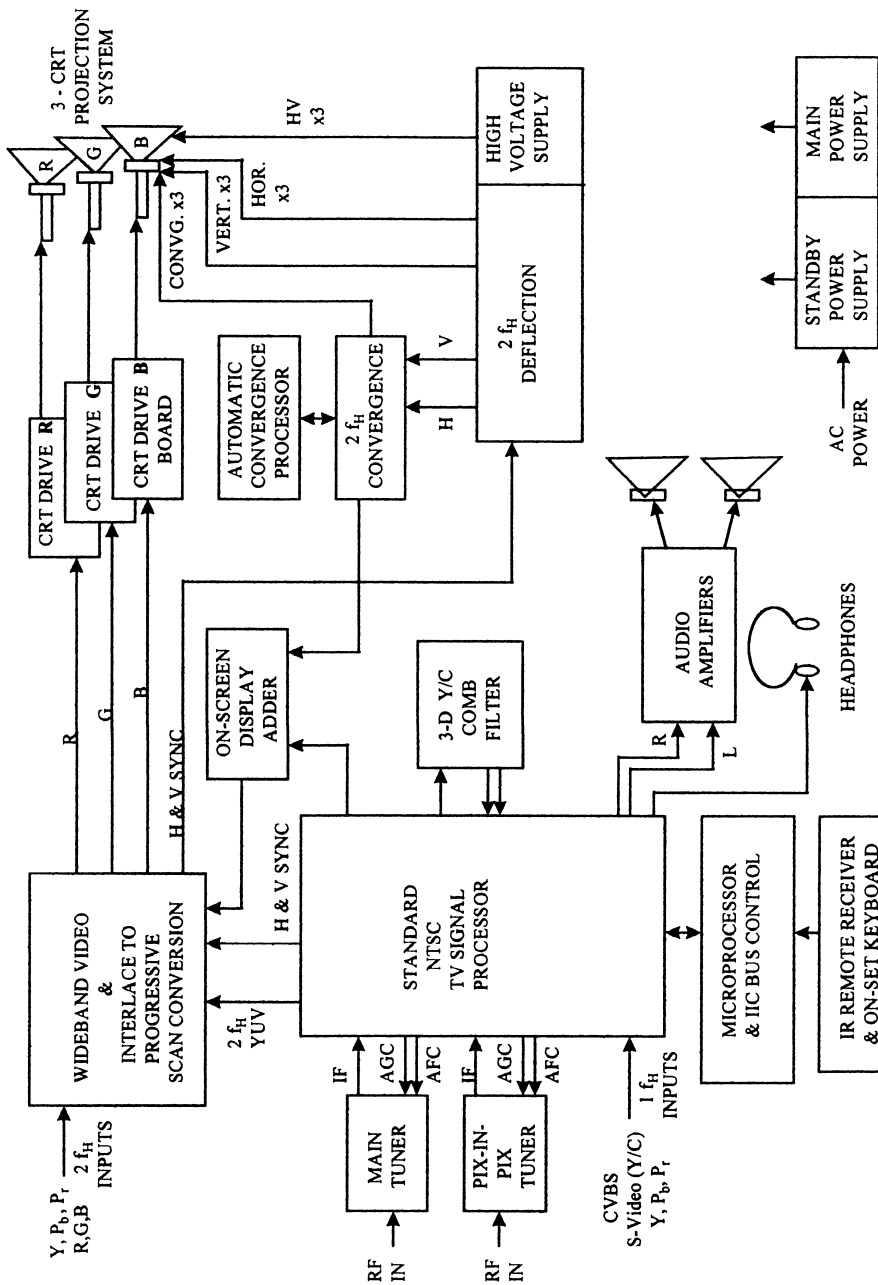

FIGURE 21.4.5 HD-ready TV receiver block diagram.

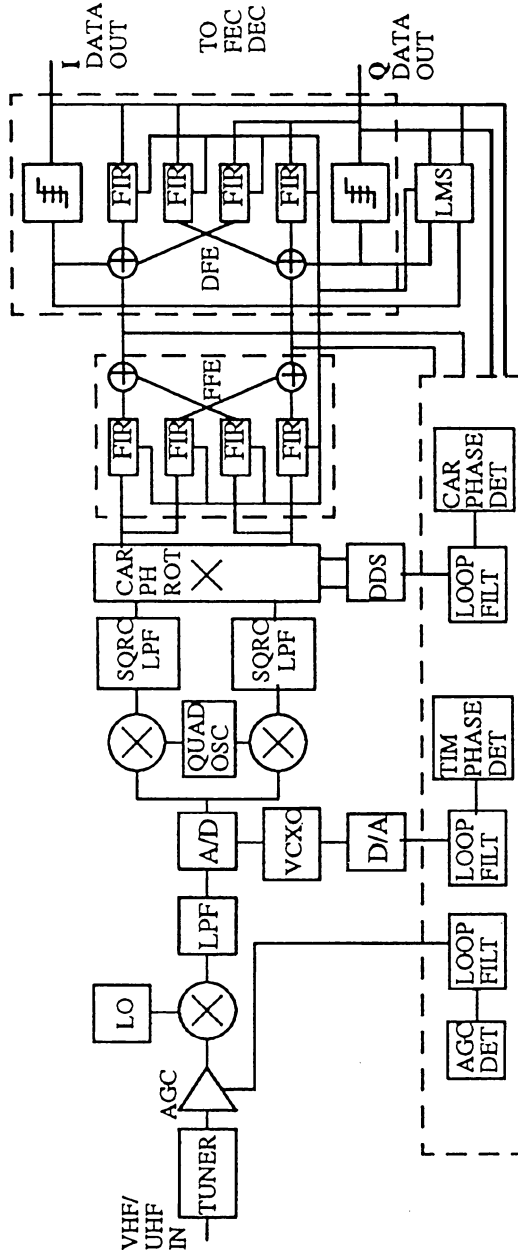

FIGURE 21.4.6 Block diagram of a QAM receiver. (From Ref. 6)

(a) Receivers for QPSK transmission: (a) demodulation after A/D conversion; (b) demodulation prior to A/D conversion. (From Refs. 9 and 10)

The tuner is of conventional TV tuner design with somewhat tighter specs for local oscillator phase noise and hum modulation. An AGC amplifier maintains a constant signal level to the second mixer that transposes the IF signal to baseband where it is low-pass filtered to remove all frequencies that would cause aliasing in the analog-to-digital A/D converter. The signal is then demodulated into in-phase I and quadrature Q components and again low-pass filtered. Because free-running oscillators were used in earlier stages, a carrier phase rotation corrector stage is needed to realign the amplitudes of the I and Q components. This stage is part of a feedback loop that uses equalized I and Q as inputs. An adaptive equalizer consisting of a feed-forward section and a decision-feedback section removes amplitude and phase distortion caused by reflections and imperfections in the previous filters and the transmitter upconverter. These equalizer stages are made up of sections of programmable-tap FIR filter sections. Following equalization and symbol quantization, the forward error correction takes place. The data are then fed to MPEG-2 and AC-3 source decoders (not shown) for final processing. Two somewhat modified implementations of QAM demodulators for cable TV application are given in recent literature.^{7,8} In the first, the QAM waveform is sampled at a low IF instead of baseband. This has led to simplified hardware implementation, whereby QAM decoding, including equalization, is achieved on one IC chip. The second design, also intended for use in a set-top cable box, describes two ICs; one performing as downconverter, containing the IF amplifier, local oscillator, quadrature demodulator, and AGC. The second IC contains antialias filters, A/D converters, digital I/Q demodulators, frequency and time domain equalizers, symbol-to-byte mapping, and Reed-Solomon forward error correction.

QPSK QUADRATURE-PHASE-SHIFT KEYING

QPSK quadrature-phase-shift keying is the accepted digital modulation for satellite-to-home application. This technique is used in direct broadcast satellite (DBS) systems in the United States (DirecTV and others), the European direct video broadcast (DVB) Eureka system, and the Japanese 8-PSK system. *M*-PSK is similar to *M*-QAM in that multiple phases of the carrier ($M = 4$ for QPSK, 8 for 8-PSK) are modulated by split bit streams. The modulation, however, is only phase, thereby leading to a constant amplitude RF signal. At the receiver, the process is similar to that for QAM, except that the decision leading to reconstruction of the transmitted bit stream is made only on phase information.⁵ A receiver block diagram and circuitry, therefore, is very similar to that shown earlier for the QAM case. Circuits that convert the signal to a baseband digital signal before demodulating the QPSK signal as well as the alternate process of demodulating QPSK as an analog signal at IF, then doing the remaining signal processing, have been built.^{9,10} In the former, extensive analog circuitry is used after the tuner to accomplish antialias band filtering, AGC and A/D conversion. A block diagram is shown in Fig. 21.4.7a. The block diagram of the second approach, Fig. 21.4.7b, is similar to that shown for a QAM receiver in Ref. 7, except that the QPSK demodulator consisting of a quadrature demodulator with $4f_{if}$ local oscillator is located in the first IC with outputs to the A/D converters being baseband analog I and Q signals. In both cases, the QPSK demodulation is followed by channel decoding, which includes filtering, deinterleaving and FEC, usually Reed-Solomon type. Synchronizing either to the carrier or to the recovered I and Q signals, Fig. 21.4.8, is also an important feedback loop that is contained in most receiver designs of this type.¹¹

ORTHOGONAL FREQUENCY DIVISION MULTIPLEX

Orthogonal frequency division multiplex (OFDM) can be thought of as a multiple carrier version of QAM in which the individual carriers are equally spaced in frequency across the channel bandwidth. The input data stream is split into parallel blocks of symbols, each of which modulates a separate carrier. The carriers are then summed and transmitted. Owing the orthogonality of the carriers, the sampled output is effectively the inverse discrete Fourier transform of the input sequence. This parallel transmission or multiple carrier modulation (MCM) technique avoids several problems such as fading and impulse noise, which affect single carrier modulation (SCM) systems. At the receiver end, the signal is down-converted and sampled at the appropriate frequency, locked to the transmitted signal, then passed to the discrete Fourier transform demodulator where the

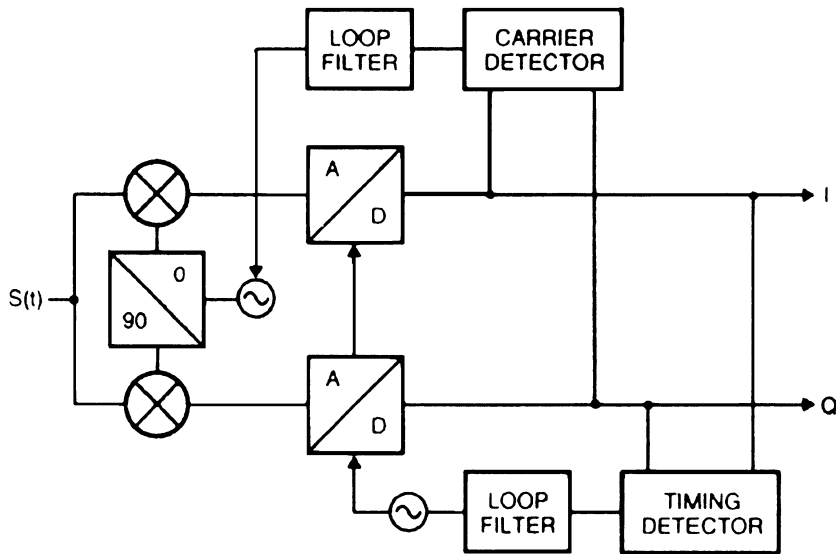

FIGURE 21.4.8 Demodulator concept having both carrier and clock recovery. (From Ref. 11)

symbols are recovered.⁵ Figure 21.4.9 shows a block diagram of the classical OFDM system for television, including transmitter and receiver. At the transmitter the processes that occur prior to the IFFT are done in the frequency domain, while those after the IFFT are in the time domain. At the receiver, the process is complementary with those processes ahead of the FFT being in the time domain and those after the FFT being in the frequency domain.¹²

OFDM modulation has been selected for digital terrestrial TV broadcast (dTTb) in Europe not only for fixed location reception but also for mobile and portable applications. In the United States, some factions have vigorously pushed for OFDM as opposed to the Grand Alliance vestigial-sideband system, which will be covered later in this section.

An OFDM receiver that follows the block diagram shown previously is shown in Fig. 21.4.10. This design features a single IC chip that contains both analog and digital circuits for implementing much of the OFDM demodulation. The analog part contains an antialiasing filter, AGC stage, and A/D converter, which outputs 8 bit resolution to the digital part of the IC. The digital part of the chip contains a signal detection unit that aids in start-up, channel change and provides AGC; an I/Q mixer for down-converting the signal to baseband; and an I/Q resampler where carrier and sampling clock frequency adjustments are made. The FFT unit can perform either 2k or 8k demodulation. The parallel symbols are then converted to serial bit stream and sent through the Viterbi plus Reed-Solomon error decoding. The output of the chip then consists of a bit stream that is sent to the MPEG-2 decoder for source decoding.

VESTIGIAL SIDE-BAND MODULATION

Eight-level vestigial side-band modulation (8-VSB) was proposed by the Grand Alliance in 1993. A testing phase was completed and the FCC accepted the system in 1995 as the standard for terrestrial digital television including both high and standard definition for the United States. The tests showed that the proposed system was robust to not only in-channel noise, ghosts, or reflections, but also the coexistent NTSC stations which would be broadcasting on the same and adjacent channels during the years of transition from analog to digital. In extensive field tests made in the Charlotte, N.C. area in 1994, the VSB system using 12 dB lower radiated signal than

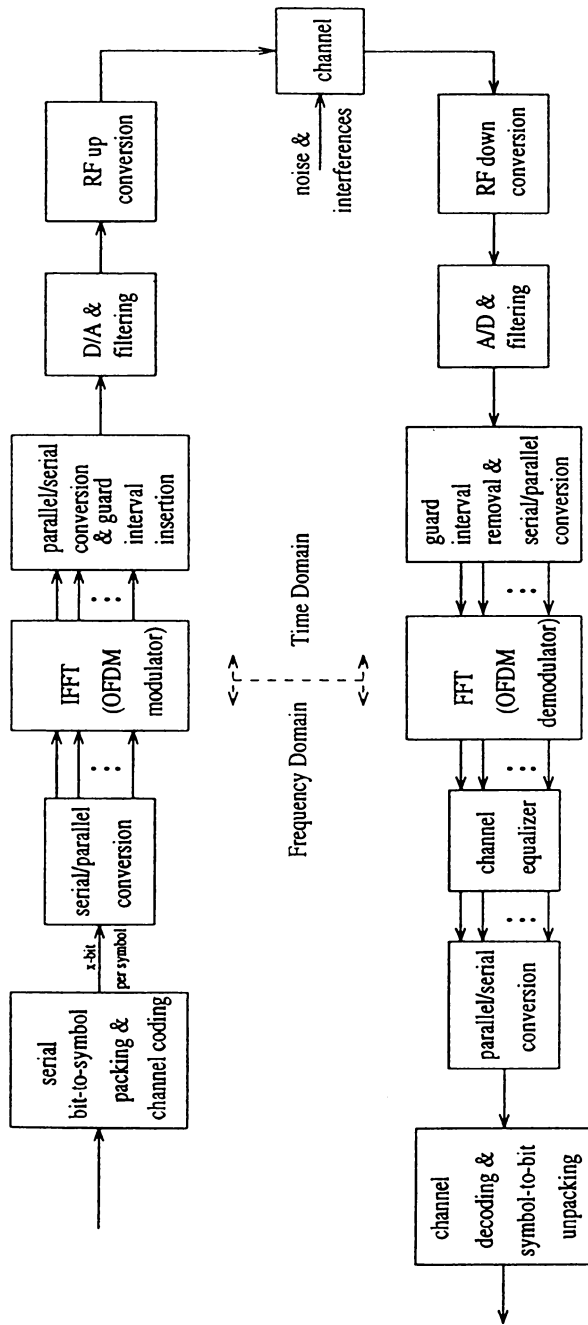

FIGURE 21.4.9 OFDM system diagram. (From Ref. 12)

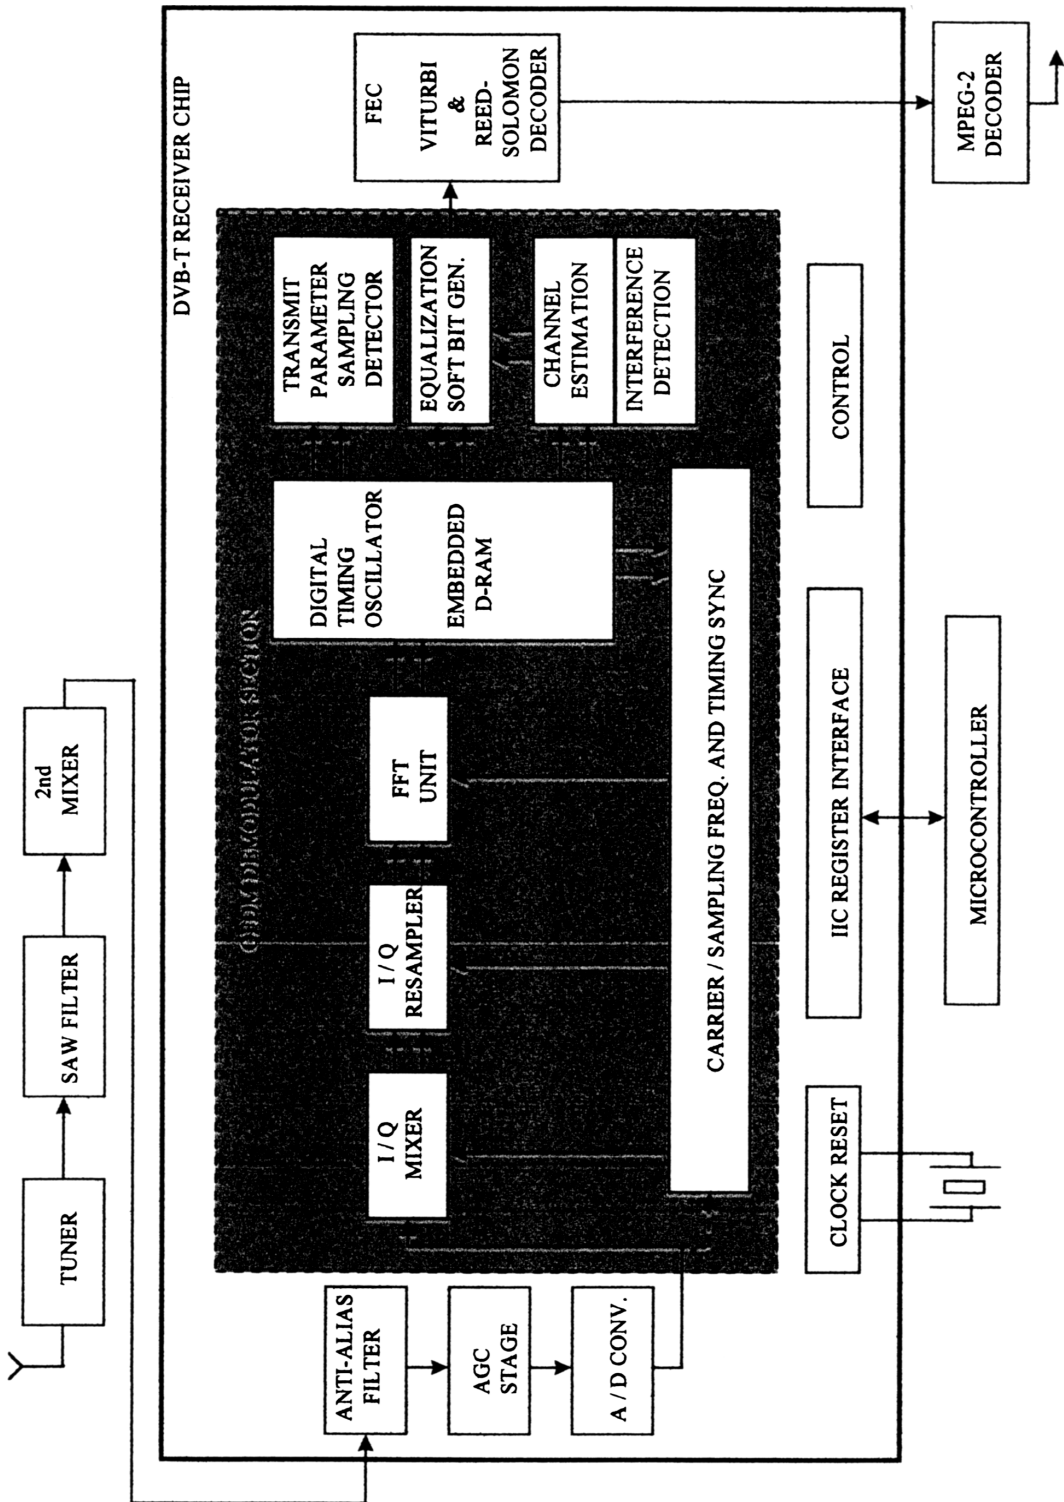

FIGURE 21.4.10 DVB-T OFDM receiver block diagram. (Redrawn from Ref. 13)

FIGURE 21.4.11 VSB and NTSC RF spectra. (From Ref. 14)

the NTSC broadcast outperformed NTSC by a significant margin.¹⁴ The actual calculated and measured margin at which picture or sound deterioration takes place in the presence of white noise favors 8-VSB over NTSC by 19 dB. The spectrum of VSB and NTSC are similar in that both completely fill the 6-MHz channel and that both use a carrier that is located near the lower channel edge. In VSB, however, the spectrum of the modulation within the channel is nearly flat and uniform, as compared to NTSC's chroma subcarrier and sidebands and the FM modulated sound carrier at the upper end of the channel. A comparison is shown in Fig. 21.4.11. Much testing has also been done on cable systems of a 16-VSB modulation system that has a throughput of nearly 40 Mbit/s, double that of the 8-VSB system.¹⁵ The discussions between the Advanced Television Systems Committee and the cable industry to set one standard for HDTV transmission appear to be nearing the consensus stage.

To date, most TV manufacturers have developed and marketed digital TV sets having capability to decode the full HDTV 8-VSB standard. The blueprint for the system and prototype hardware has been reported in numerous technical publications.¹⁴⁻¹⁷ A simple block diagram of the receiver is shown in Fig. 21.4.12.

A similarity can be seen between these major blocks and those shown for the digital TV receivers described earlier, especially the OFDM receiver. Trellis decoding by Viterbi means and Reed-Solomon FEC is a dominant part of each of the receivers. Each has some means to equalize the channel to correct for ghosts and bursts. The VSB system, however, uses only the I component for data recovery and therefore needs only a single A/D converter and channel equalizer instead of the two matched units used in other systems. While the other systems synchronize by using the demodulated data symbols and therefore need quadrature correction circuitry, the VSB system has three transmitted mechanisms for synchronizing the receiver to transmitter. The first is the pilot carrier located 0.31 MHz in from the lower band edge. A frequency/phase-locked loop (FPLL) in the receiver, Fig. 21.4.13, establishes synchronization to this carrier. A noncoherent AGC feedback adjusts the gain of the IF amplifier and tuner to bring the signal into range of the A/D converter. Repetitive data segment syncs consisting of four symbols per segment provide the second synchronizing means. These sync pulses are detected from among the synchronously detected random data by a narrow bandwidth filter. A feedback loop, Fig. 21.4.14a, then creates a properly phased 10.76 MHz symbol clock along with a coherent AGC control voltage that locks the proper demodulated signal level to the A/D converter. A third mechanism is to compare the received data field segment with a set of ideal segments (field 1 and field 2) contained in a frame sync recovery circuit within the receiver. This circuit is shown in Fig. 21.4.14b.

Following this, a circuit determines if there is a co-channel NTSC signal. If so, the NTSC interference rejection comb filter, a one-tap linear feed-forward filter that has nulls nearly corresponding to the frequencies of the NTSC video carrier, chroma subcarrier, and aural carrier, is switched in Fig. 21.4.15. This filter degrades white noise performance by 3 dB and will not be included in receivers after all NTSC transmitters are silent.

FIGURE 21.4.12 VSB Receiver. (From Ref. 15)

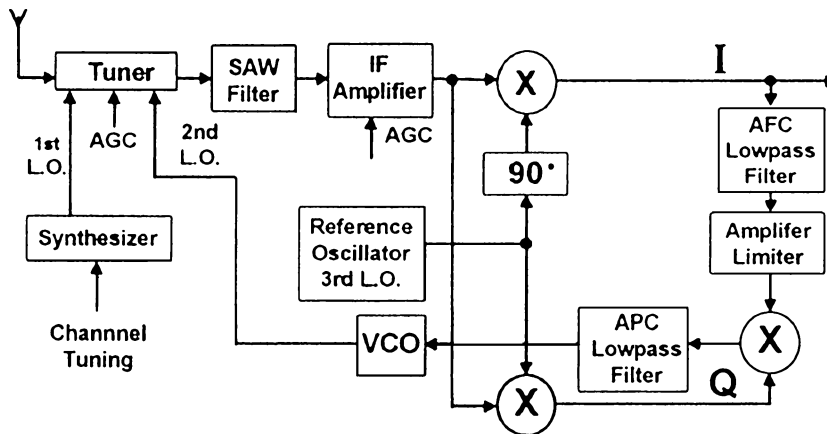

FIGURE 21.4.13 Tuner—IF frequency/phase lock loop. (From Ref. 15)

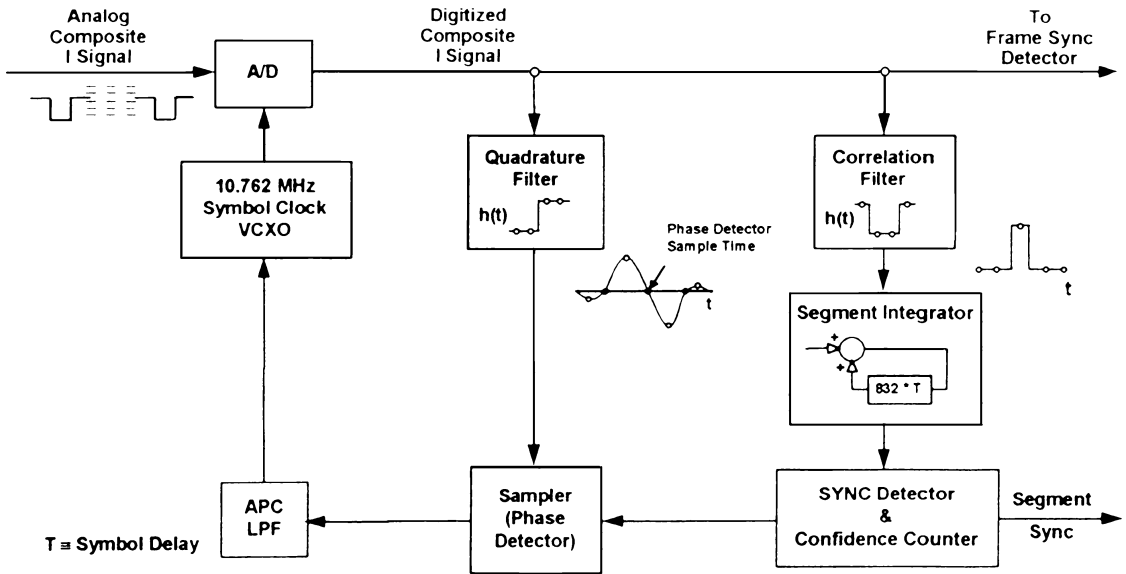

Following the NTSC interference rejection filter is a channel equalizer that compensates for linear channel distortions such as tilt and ghosts. The prototype system used a 64 tap feed-forward transversal filter followed by a 192 tap decision feedback filter. A least-mean-square algorithm was used to compare the transmitted training signal, pseudo-noise sequences which are a part of the data filed sync, to a stored image of the training signal with the error being feed-back to set the tap coefficients. Once equalization is achieved at this level, the circuit can lock on to either data symbols throughout the frame or the data itself for further fine-tuning of the ghost canceling. Airplane flutter is usually too rapid for a full tap evaluation and is therefore handled by the latter technique. A block diagram of the equalizer is shown in Fig. 21.4.16.

The next block in the receiver chain is a phase tracking loop, Fig. 21.4.17, which tracks out phase noise that had not been removed by the Tuner-IF PLL operating on the pilot carrier. This circuit consists of a digital filter that constructs a Q signal from the existing I signal. These signals are then used to control a complex multiplier or phase derotator. It has been reported that the 8-VSB receiver system consisting of the front-end FPLL and the phase-tracking circuit can compensate for phase errors up to -77 dBc/Hz at a 20 kHz offset from the carrier.

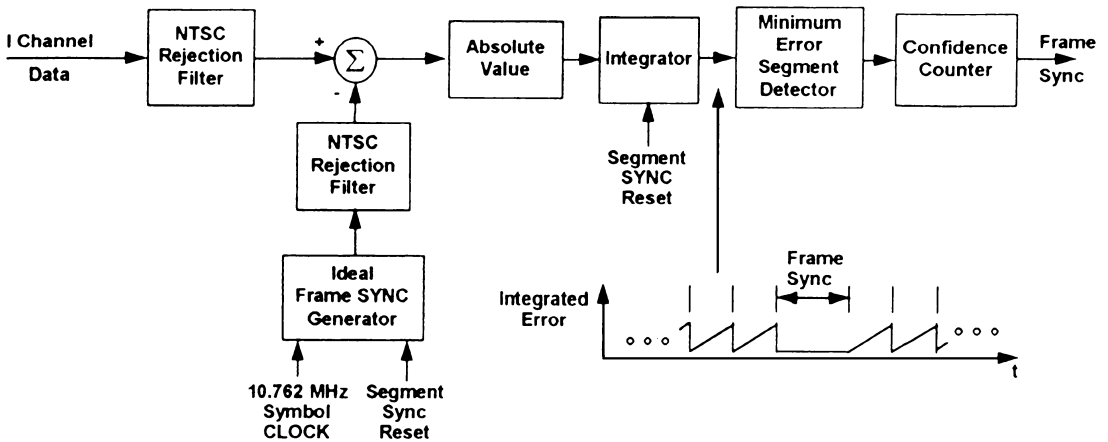

The next block provides deinterleaving of the 12 symbol intersegment code interleaving which was applied in the transmitter. At the same time, trellis decoding takes place in a structure shown in Fig. 21.4.18. Here, one trellis decoder is provided for each branch although in more recent designs, a single trellis decoder is used in a time-multiplexed fashion to reduce IC complexity.^{18,19} Following trellis decoding, Reed-Solomon decoding takes place. At this point, channel decoding is complete and the data are ready to be split into the appropriate audio and video packets and sent to the source-decoding circuitry.

The receiver-to-transmitter lock-up and signal-decoding process takes place in the following sequence:¹⁶

1. Tuner first local oscillator synthesizer acquisition
2. Noncoherent AGC reduces unlocked signal to within A/D range
3. Carrier acquisition (FPLL)
4. Data segment sync and clock acquisition
5. Coherent AGC of signal (IF and RF gains properly set)
6. Data field sync acquisition
7. NTSC rejection filter insertion decision made
8. Equalizer completes tap adjustment algorithm
9. Trellis and RS data decoding begins

a. Segment sync and symbol clock recovery.

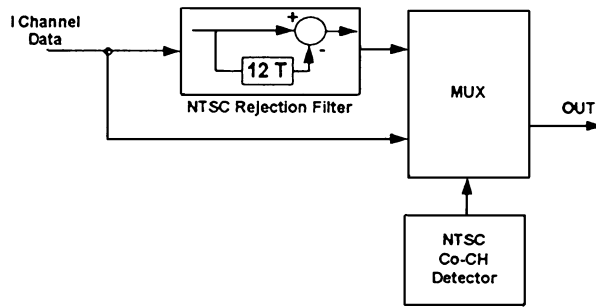

b. Data frame sync detection.

FIGURE 21.4.14 (a) Segment sync and symbol clock recovery; (b) data frame sync recovery. (From Ref. 14)

SOURCE DECODING

Source decoding consists of decoding the AC-3 audio and the MPEG-2 video which had been encoded at the transmitter using the main profile at high level (MP@HL) specification.^{3,16,20} A block diagram of an MPEG-2 decoder is shown in Fig. 21.4.19. Here video frames are created from the compressed packet data and stored

(a)

(b)

FIGURE 21.4.15 (a) NTSC interference rejection filter; (b) comb filter spectrum. (From Ref. 14)

in frame memory. The decoded video is then read out and passed on to the display circuitry of the receiver in whatever format is required by that display.

The final piece of the TV receiver system is the display. The drive requirements of the display do not necessarily match the format of the decoded video signal. In fact, the ATSC Standard permits the transmission of any one of numerous video formats (Table 21.4.1).¹⁶

The requirement for this section of the receiver, therefore, is to scan convert or format convert the decoded video from the MPEG-2 decoder into the form needed by the display. Typically, this is accomplished by loading the video into RAM-type memory (frame buffer) and clocking the video out at a rate and in a format needed for the display (pixels per line, lines per frame/field, progressive or interlaced fields).²¹ In the case where there is not a 1:1 match between the total number of video pixels in a frame and the display pixels, e.g., displaying an HDTV

FIGURE 21.4.16 VSB receiver equalizer. (From Ref. 3)

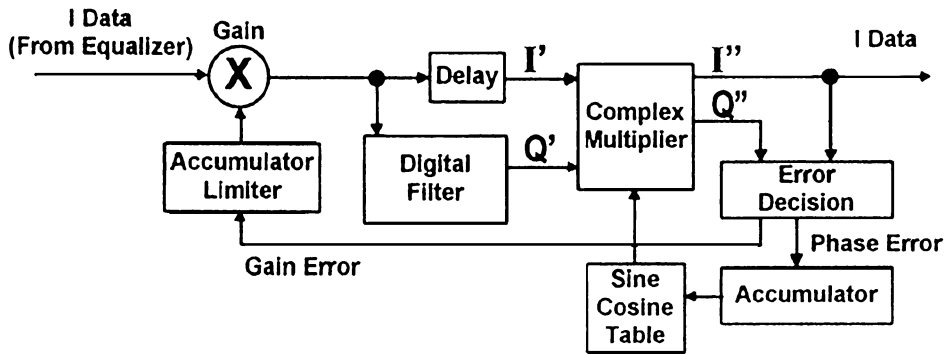

FIGURE 21.4.17 Phase-tracking loop block diagram. (From Ref. 15)

signal on a standard NTSC-type SDTV display, an intermediate step of data interpolation, frame storage, and smoothing is needed (Fig. 21.4.20). Often, noise reduction and motion compensation is included in this step. In some newer designs a considerable saving in memory requirements can be achieved when the downconversion of the video information is accomplished within the MPEG-2 decoding process^{22,23} (Fig. 21.4.21).

The video signals in the display section are usually in the Y/C format, then converted to Y, P_b, P_r format and finally to analog R, G, B format, especially if driving a direct-view CRT or CRT projection display. The parameters of the final video signals for several of the more popular ATSC display formats of Table 21.4.1 is shown in Table 21.4.2.

Figure 21.4.22 gives a comparison of bandwidth requirements for various values of horizontal picture resolution. It is interesting to note that although the video channel bandwidth requirements are identical for the

TABLE 21.4.2 Picture Parameters, Video Bandwidth Requirements and Scan Frequencies for Several Display Systems

System	Type	Active picture elements	Total elements	Rate per second	Video bandwidth* (MHz)	Horizontal frequency (kHz)
HDTV	1080i	H pixels V lines	1920 1080	2200 30 frames (60 fields)	37.125	33.57
HDTV	720p	H pixels V lines	1280 720	1650 60 frames	37.125	45
NTSC (16:9) (SDTV)	525i	H pixels V lines	704 480	858 30 frames (60 fields)	13.5	15.75
VGA (16:9) [†]	480p	H pixels V lines	704 480	858 60 frames	27	31.5

*Similar to ITU-R BT.601-4 which uses only 704 of 720 pixels and only 480 of 483 lines.

[†]Video bandwidth values are for the Nyquist criterion.

1080i and 720p systems, the picture resolution of the two systems differs by a factor of 1.5. Discussion of how much resolution is really necessary to sell HDTV to the public has been going on for the past 10 years, and may continue. Figure 21.4.23 shows the results of a study made on several integrated HD and HD-Ready TV sets now available in the marketplace. These sets were driven at the video inputs with a 1080i signal and each

HD Resolution vs Bandwidth**FIGURE 21.4.22** High-definition picture resolution vs. video bandwidth.

FIGURE 21.4.23 Picture resolution performance of several HD and HD-Ready TV sets.

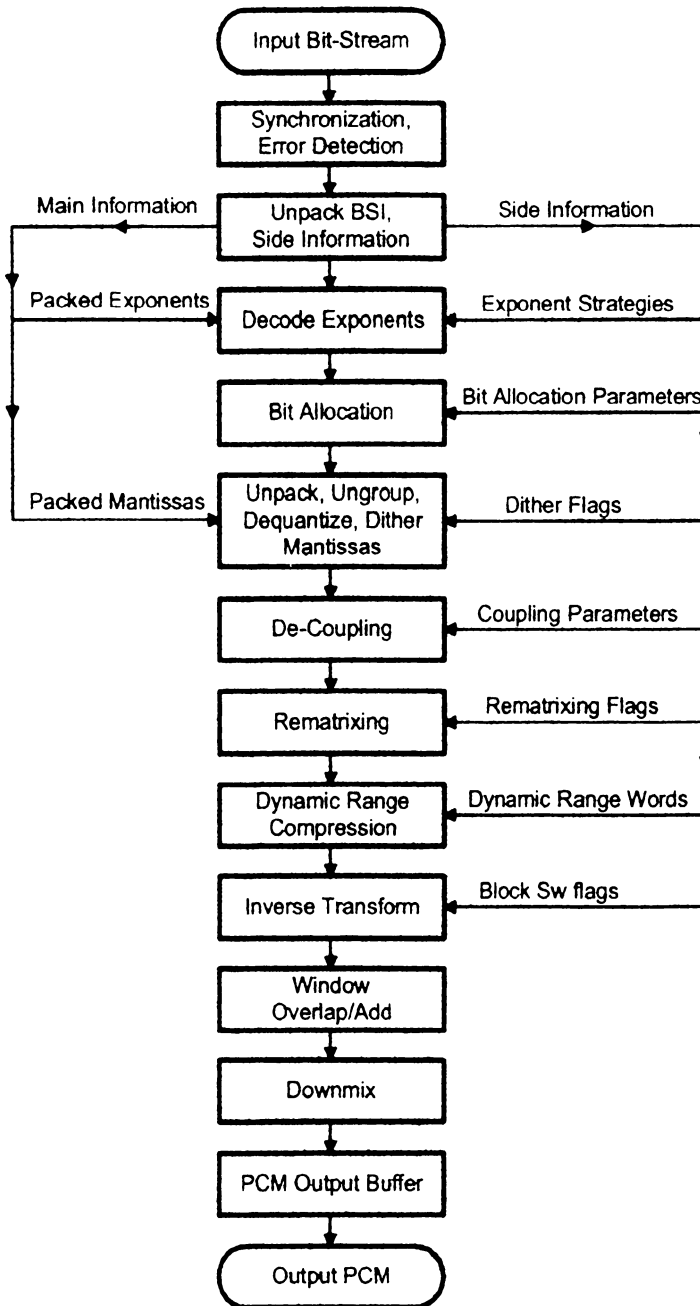

FIGURE 21.4.24 Flow diagram of the AC-3 decoding process. (From Ref. 25)

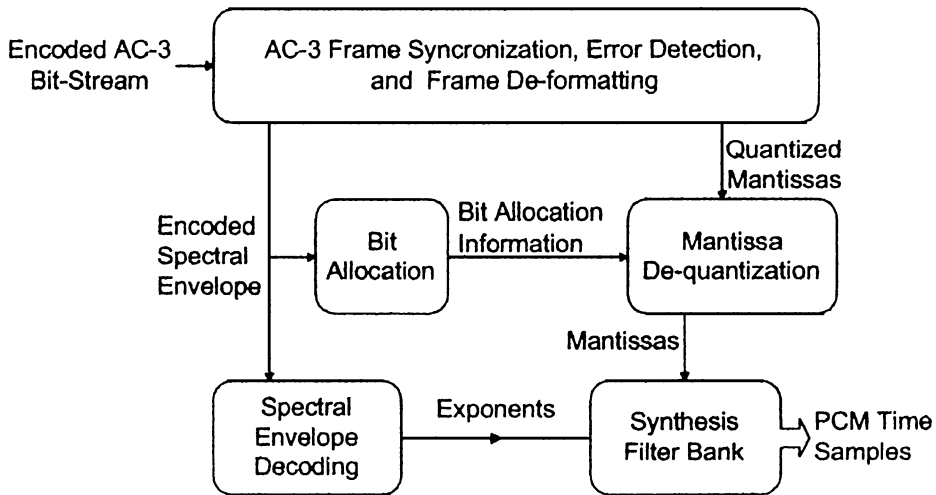

FIGURE 21.4.25 AC-3 audio decoder. (From Ref. 25)

either displayed full resolution or down-converted to the native scan/video capability of the receiver. The major diagonal line on the chart represents the 1080i locus with full HD resolution at one end and NTSC at the other. In the case of several receivers, severe aliasing of the multiburst pattern caused the observed picture to be judged to have a lower frequency value than the design intent. Second generation designs will most likely correct these deficiencies.

The audio that had been encoded at the transmitter using the AC-3 specifications is decoded into one to six audio channels, all at line level (left, center, right; left surround, right surround, and low-frequency enhancement sub woofer²⁵). Since the low-frequency enhancement channel has an upper bandwidth limit of 120 Hz, it is usually not counted as a complete channel, but only as 0.1 channel, leading to the designation of AC-3 as having 5.1 channels. It is not necessary for a receiver to decode all the available channels. A monophonic receiver will need to provide only one output audio signal. In this case, the receiver's decoder will down-mix the six channels into one. A popular decoder design will provide a down-mix of six into two audio outputs for use in lower cost stereo TV sets.

The AC-3 bit stream is composed of frames each containing sync, encoding/decoding information, and six blocks of audio data. These frames are decoded using the process shown in Figs. 21.4.24 and 21.4.25. Each frame can be decoded as a series of nested loops in which each channel can be handled independently. This process can be accomplished in an audio DSP IC. One such implementation for the full 5.1 channel output uses 6.6K RAM, 5.4K ROM, and 27.3 MIPS. A lower-cost 2 channel implementation requires the same amount of ROM and nearly the same MIPS, but only 3.1K RAM.²⁴ PCM to analog (D/A) converters, amplifiers, level and balance controls, and speakers complete the audio system.

DISPLAYS

Liquid-Crystal Displays (LCDs)

Use of both monochrome and color LCDs has become popular, especially in small personal portable television receivers. The operation of these devices is not limited by the high-voltage requirements of conventional CRTs. Instead, the picture raster is constructed of a rectangular MOS switching matrix of from 240 to 600 horizontal elements and from 200 to 400 vertical elements.²⁶ The gates of all the thin-film transistors (TFTs) in a given

FIGURE 21.4.26 LCD television picture display. (From Benson & Whitaker, Ref. 2)

horizontal row are connected to a common bus (Fig. 21.4.26). Likewise the drains of all transistors in a vertical column are connected to a common bus. Vertical scan (row addressing) is produced by sequentially driving the gate buses from the shift register. Horizontal scan, which contains the video information (column addressing), is somewhat more difficult because of the stray capacitance and cross-under resistance associated with drain bus. A given line of video is broken into the same number of pieces as there are pixels in the horizontal row, and stored in the sample-and-hold (S/H) stages, which all drive their respective drain bus lines simultaneously, thus creating a line sequential display. The information on a drain is, therefore, changed only once for each horizontal period ($63.5 \mu\text{s}$).

A color LCD contains a repeating sequence of red, green, and blue filters covering adjacent pixels of a horizontal row.²⁷ The sequence is offset by one pixel in adjacent rows. The video and chroma signals are decoded and matrixed in the conventional manner. The *R-G-B* signals are then clocked into the line S/H stages in the appropriate sequence.

LARGE-SCREEN PROJECTION SYSTEMS

The display for picture sizes of up to 36 in. diagonal usually consists of a direct-view CRT. For pictures above 36 in., a relatively new technology has emerged and a number of projection technologies have become popular for domestic use.

Plasma display panel (PDP) systems are a relatively new type of direct view display. Typical sizes have been 40 in. with 4:3 length-to-height ratio, 42 and 60 in. diagonal with a 16:9 length-to-height ratio. The major advantage to a PDP is that it has a depth of only a few inches. This product has been touted as the "picture on the wall." The structure consists of two pieces of glass separated by an insulating structure in the form of small pockets, cells, or stripes. Each cell is filled with an ionizing gas such as neon and xenon. On the facing sides of the glass plates are metal electrodes, vertical (column) on one and horizontal (row) on the other (Fig. 21.4.27).

FIGURE 24.4.27 Cross-section of one pixel of an AC plasma display panel. (From Ref. 28)

When a voltage of several hundred volts is applied to a given row and column electrodes, the gas in the appropriate cell ionizes giving off ultraviolet light, thus exciting the color phosphor deposited on the glass plate. Since a cell is either on or off, pulse modulation is used to obtain a shade of gray or a desaturated color. This is accomplished in the driving circuitry by slicing each video field into 8 to 10 subfields and then driving all cells at the subfield rate. The 60-in. unit possesses a resolution of 1280×720 (HDTV quality) and has a 500-to-1 contrast ratio in a dark room. The 42-in. units have 852×480 or 1024×1024 pixel counts. Light output over 500 cd/m^2 has been measured. Although this technology has been shown to produce bright, outstanding pictures, the consumer price is still somewhat higher than any of the other display systems at this time.

CRT projection systems consisting of three cathode-ray tubes, with a typical raster diagonal of 3 to 5 in., produce three rasters in red, green, and blue, being driven by the respective *R*, *G*, and *B* drive signals. These images are projected through three wide-aperture lenses to either a highly reflective screen having a diagonal dimension of 50 in. to 8 or 10 ft (front projection) or to the back of a diffused translucent screen having diagonal dimension of 40 to 70 in. (rear projection) (Fig. 21.4.28). By careful adjustment of the deflection and orientation of the CRTs and lenses, the rasters are brought into precise registry and geometric congruence.^{29,30} Various surfaces (typically two or four) of the rear projection screen are impressed with patterns of fine-pitch grooves that form lens elements to “focus” or control the direction of the light as it leaves the screen. Medium screen gains (three to six) are preferred and can be designed for more uniform image brightness over a wider viewing angle. Currently, brightness levels of 600 cd/m^2 can be achieved with rear projection systems having a picture size of 35 to 50 in. measured diagonally. Since the projection system has no shadow mask in its electrooptical path, the system can achieve better resolution than a conventional large-screen direct-view color CRT. At this time, CRT projection is the preferred display system for large screen HDTV.

FIGURE 21.4.28 Mechanical arrangement of large-screen rear-projection receiver.

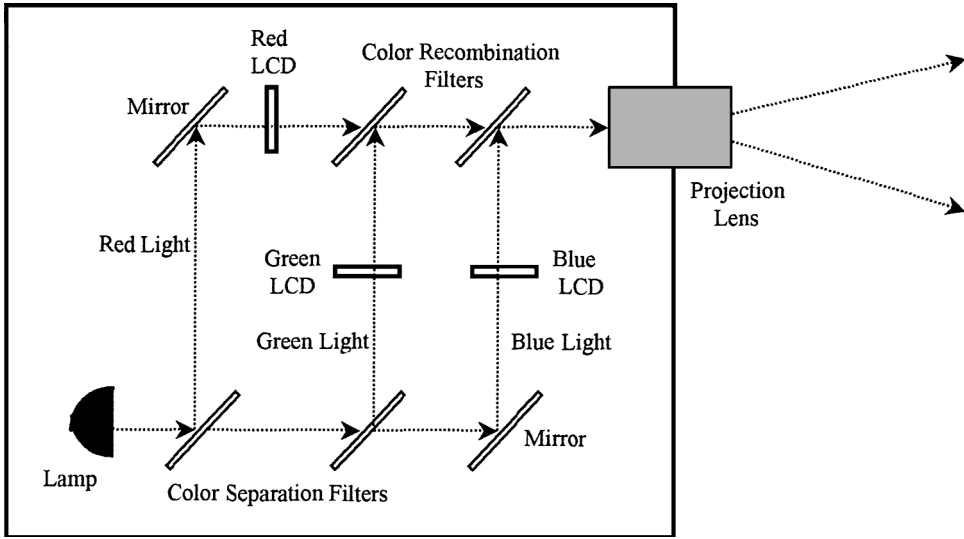

FIGURE 21.4.29 Typical LCD projection system.

6-segment Color Disk

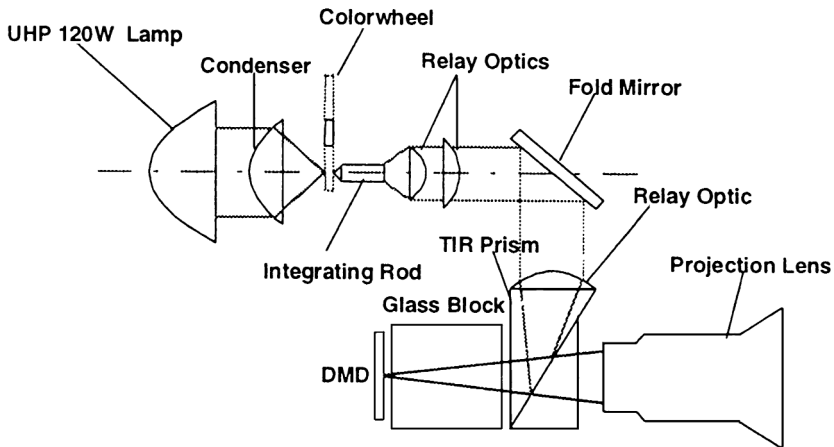

FIGURE 21.4.30 Optical system using a digital micromirror device. (From Ref. 33)

LCD projection systems use three LCD panels each measuring 1 to 2 in. diagonal. A single high-intensity light bulb illuminates a series of color-selective dichroic mirrors that split the light into three paths. Each light path passes through its respective LCD panel (red, green, and blue). The three light paths are then combined into one by another series of dichroic mirrors and passed through a lens that projects the image onto either a front or a rear screen (Fig. 21.4.29). Light output of the unit can be improved by adding a collimating element consisting of several microlenses just in front of the illuminating lamp.³¹ As in the case of CRT projection, the precise alignment of LCD panels and mirrors is essential to register the three color images. Another novel design that has not yet been universally adopted uses only two LC panels, one black and white (B/W) and one three-color unit. This simplifies the mechanical design, uses fewer components, and has simpler convergence alignment. The B/W panel supplies the brightness to make up for the low transparency of the color panel. Video signals to the two panels are matrixed in a unique manner to yield correct color performance.³²

LCD projectors currently exist in home theater size (front projection), rear projection self-contained large-screen TV sets, and small portable units having weight of 5 to 10 lb and light output of 500 lm to greater than 1000 lm for use in classroom.

Digital micromirror device (DMD™) display systems also called digital light processing (DLP™) use a semiconductor IC that contains an array of small mirror elements mounted on its surface, one for each pixel. When an electrical charge is applied to the substrate under a mirror, it will tilt by $+10^\circ$ (ON) and -10° (OFF). In the $+10^\circ$ configuration, the light from a high-intensity light is reflected through a lens and projected onto the viewing surface. In order to obtain shades of gray, the electrical charge to the mirrors is pulse modulated. Two configurations of this basic architecture have been developed. In the first, three DMD ICs, one for each color, are used. The light splitting, combining, and convergence of the three images is similar to that described for the LCD projector. The second configuration, now becoming more popular, uses a small six-segmented color wheel in the light path (Fig. 21.4.30).³³ The video signal sent to the DMD is that of a field sequential format in which the DMD is activated to the red picture image when the light is passing through the red portion of the color filter wheel; likewise for blue and green. Currently DMDs having picture definition of 1280×720 pixels are being used in HDTV applications.^{34,35} Because of the light weight of the mechanism, DLP projectors are also becoming popular as portable units for classroom and traveling use. (DMD and DLP are trademarks of Texas Instruments.)

CHAPTER 21.5

FACSIMILE SYSTEMS

Stephen J. Urban

INTRODUCTION

Facsimile is one of the original electrical arts, having been invented by Alexander Bain in 1842. In its long history it has prompted or helped accelerate the development of a variety of devices and methods, including the photocell, linear phase filters, adaptive equalizers, image compression, television, and the application of transform theory of signals and images. Facsimile systems have been used for a variety of services.¹ *The Wall Street Journal*, *USA Today*, and other newspapers have used facsimile to distribute their newspapers electronically, so that they can be printed locally. Weathermaps and satellite images are transmitted by other facsimile systems. Associated Press uses a form of facsimile to send photographs to newspapers. The most well-known facsimile system is the familiar one used in businesses and homes called simply “fax”—short for the Group 3 facsimile machine. The following discussion concentrates on Group 3, since it embodies techniques found in most other systems.

GROUP 3 FACSIMILE STANDARDS

Facsimile standards have been developed with international cooperation by the Telecommunication Standardization Sector of the International Telecommunication Union (ITU-T, formerly the CCITT). The ITU-T is made up of a number of study groups, each working on a particular aspect of telecommunications standardization. Study Group 16 (SG16) develops facsimile standards (called “Recommendations” by the ITU-T). National bodies may have their own slightly different version of the international standard. In the United States, the Telecommunications Industry Association TR-29 Committee was responsible for the development of standards for facsimile terminals and facsimile systems. TR-29, organized in the early 1960s, was a major contributor to the 1980 Group 3 Recommendation. Facsimile and modem standardization efforts have now been combined in the TIA-30 committee.

The ITU-T produced the first international facsimile standard in 1968, Recommendation T.2 for Group 1 facsimile. In North America a facsimile standard was used that was similar to Rec. T.2, but with enough of a difference so that North American machines were not interoperable with the rest of the world. The Group 1 standard provided for a 6-min transmission of a nominal 210 mm by 297 mm page at a scanning density of 3.85 lines per mm. In 1976 the first truly international facsimile standard, T.3 for Group 2 facsimile, was published. A Group 2 facsimile machine transmitted a page in half the time of a Group 1 machine with about the same quality. Both of these machines were analog, and neither used image compression.

In 1980, the Group 3 standards were published. Group 3 provided significantly better quality and shorter transmission time than Group 2, accomplished primarily by digital image compression. The Group 4 standard followed in 1984, with the intent to provide higher quality (twice the resolution of Group 3), higher speed (via digital networks), and more functionality. Since 1984 work has continued on both the Group 3 and Group 4

standards, with most of the advances being made in Group 3. Although Group 4 was intended to be the next generation facsimile terminal, it is clear that Group 3 has equaled or surpassed Group 4 in terms of performance and functionality. Group 3 can now use the same compression algorithm as Group 4, can provide the same image quality, and can operate on digital networks, thereby matching the short transmission times of Group 4. Actually Group 3 may be a little faster, because its protocol overhead is less.

Both Group 1 and Group 2 facsimile are now obsolete; neither are included in most new facsimile terminal implementations. The following discussion concentrates on Group 3 facsimile, which represents the vast majority of facsimile machines in current use.

The Group 3 facsimile recommendations, ITU-T Recommendations T.4² and T.30,³ were first published in 1980. Recommendation T.4 covered the compression algorithm and modulation specifications, and Recommendation T.30 described the protocol. Group 3 originally was designed to operate on the general switched telephone network (GSTN) in half-duplex mode. The protocol specifies a standard basic operation that all Group 3 terminals must provide, plus a number of standard options. The various parameters and options that may be used are negotiated at 300 b/s, before the compressed image is transmitted at higher speed. *All* Group 3 machines must provide the following minimum set of capabilities: a pel density of 204 pels/in. horizontally and 98 pels/in. vertically; one-dimensional compression using the modified Huffman code; a transmission speed of 4800 b/s with a fallback to 2400 b/s; and a minimum time per coded scan line of 20 ms (to allow real time printer operation without extensive buffering). This requirement ensures that even the newest Group 3 facsimile machines can communicate with those designed to the 1980 Recommendations.

The standards options defined in the 1980 Recommendations are the following: use of the modified READ code to achieve two-dimensional compression; a vertical pel density of 196 pels/in. to provide higher image quality; a higher transmission speed of 9600 b/s with a fall back to 7200 b/s; and a minimum coded scan line time of zero to 40 ms. Many new options have been added over time. These are described in the following pages.

RESOLUTION AND PICTURE ELEMENT (PEL) DENSITY

The resolution of the scanners and printers used in facsimile apparatus (and the associated transmitted pel density) has a direct effect on the resulting output image quality. The highest pel density specified for the original Group 3 terminal was approximately 204 by 98 pels per 25.4 mm. The actual specification is 1728 pels per 215 mm by 7.7 lines/mm. This is referred to as “metric based” pel density. The Group 4 recommendations support the following standard and optional pel densities: 200 × 200, 240 × 240, 300 × 300, and 400 × 400 pels per 25.4 mm (referred to as “inch based” pel density). Note that the pel densities specified for Group 3 are “unsquare,” that is, not equal horizontally and vertically. Group 4 pel densities are “square.” This difference causes a compatibility problem. If the Group 3 pel densities were to be extended in multiples of their current pel densities, for example to 408 × 392, then a distortion of approximately 2 percent horizontally and vertically occurs when communicating with a 400 × 400 “square” machine. The ITU-T has decided to accept this distortion and encourage a gradual migration to the square pel densities. Accordingly, Group 3 has been

TABLE 21.5.1 Metric Based Pel Densities

Pel density (approximate) (pels/25.4 mm)	Tolerance	Number of picture elements along a scan line		
		ISO A4	ISO B4	ISO A3
Horizontal 204	±1%	1728/215 mm	2048/225 mm	2432/303 mm
Vertical 98				
Horizontal 204	±1%	1728/215 mm	2048/225 mm	2432/303 mm
Vertical 196				
Horizontal 408	±1%	3456/215 mm	4096/225 mm	4864/303 mm
Vertical 392				

TABLE 21.5.2 Inch Based Pel Densities

Pel density (pels/25.4 mm)	Tolerance	Number of picture elements along a scan line		
		ISO A4	ISO B4	ISO A3
Horizontal 200	± 1%	1728/219.45 mm	2048/260.10 mm	2432/308.86 mm
Vertical 100				
Horizontal 200	± 1%	1728/219.45 mm	2048/260.10 mm	2432/308.86 mm
Vertical 200				
Horizontal 300	± 1%	2592/219.45 mm	3072/260.10 mm	3648/308.86 mm
Vertical 300				
Horizontal 400	± 1%	3456/219.45 mm	4096/260.10 mm	4864/308.86 mm
Vertical 400				

enhanced to include higher pel densities, including both multiples of the original Group 3 pel densities and "square pel densities." Specifically, optional Group 3 pel densities of 408 × 196, 408 × 392, 200 × 200, 300 × 300, and 400 × 400 pels per 25.4 mm have been added. These are summarized in Tables 21.5.1 and 21.5.2.

The metric-based pel densities and their picture elements are given in Table 21.5.1. Specific values for the number of pels per line are given in Table 21.5.1 for all the Group 3 pel densities for ISO A4, ISO B4, and ISO A3.

The optional inch-based pel densities and their picture elements are shown in Table 21.5.2. Specific values for the number of pels per line are given in Table 21.5.2 for all the Group 3 pel densities for ISO A4, ISO B4, and ISO A3.

NOTE: An alternative standard pel density of 200 pels/25.4 mm horizontally × 100 lines/25.4 mm vertically may be implemented provided that one or more of 200 × 200 pels/25.4 mm, 300 × 300 pels/25.4 mm, and 400 × 400 pels/25.4 mm are included.

PROTOCOL

A facsimile call is made up of five phases, as shown in Fig. 21.5.1. In phase A (call establishment) the telephone call is placed, either manually or automatically by the facsimile terminal(s). In phase B (premessage procedure) the call station responds with signals identifying its capabilities. The calling station then sends signals to indicate the mode of operation to be used during the call (e.g., transmission speed, resolution, page size,

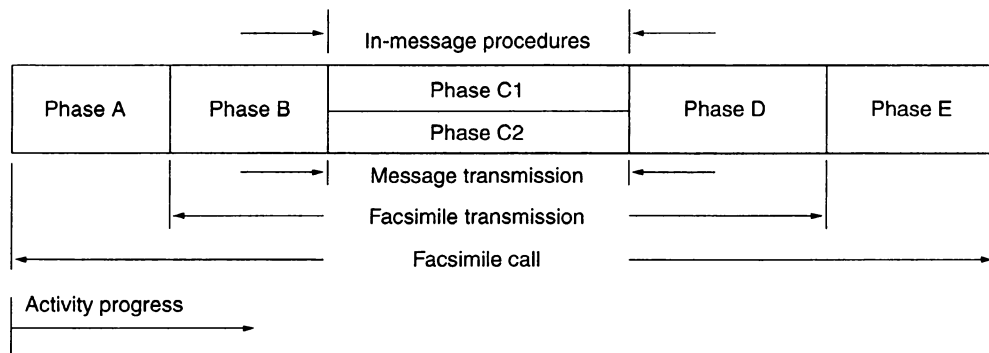

FIGURE 21.5.1 The five phases of a facsimile call.

image coding method). The option selection must be consistent with the capability set received from the called station. Phase C (in-message procedure and message transmission) includes both procedural signaling and the transmission of the facsimile image. Procedural signaling includes, for example, a modem training sequence from the sending station that allows the receiving station to adapt its modem to the telephone line characteristics. If the receiving station trains successfully and is ready, it responds with a confirmation to receive (CFR) signal. Upon receipt of the CFR, the sending station sends the facsimile image at the negotiated higher speed. As in phases B and D, all signaling is communicated at 300 b/s using high-level data link control (HDLC), before the compressed image is transmitted at higher speed. Phase D (postmessage procedure) includes information of end-of-message, confirmation of the reception of the message, and transmission of further message information. In phase E the call is disconnected.

DIGITAL IMAGE COMPRESSION

One-Dimensional Coding Scheme—Modified Huffman Code (MHC)

A digital image to be transmitted by facsimile is formed by scanning a page from left to right and top to bottom, producing a bit map of picture elements. A scan line is made up of runs of black and white pels. Instead of sending bits corresponding to black and white pels, coding efficiency can be gained by sending codes corresponding to the lengths of the black and white runs. A Huffman procedure⁴ uses variable length codes to represent the run lengths; the shortest codes are assigned to those run lengths that occur most frequently. Run-length frequencies are tabulated from a number of “typical” documents, and are then used to construct the code tables. True Huffman coding would require twice 1729 code words to cover a scan line of 1728 pels. To shorten the table, the Huffman technique was modified for Group 3 facsimile to include two sets of code words, one for lengths of 0 to 63 (terminating code table), and one for multiples of 64 (make-up code table). Run lengths in the range of 0 to 63 pels use terminating codes. Run lengths of 64 pels or greater are coded first by the appropriate make-up code word specifying the multiple of 64 less than or equal to the run length, followed by a terminating code representing the difference. For example, a 1728-pel white line would be encoded with a make-up code of length 9 representing a run of length 1728, plus a terminating code of length 8 representing a run of length zero, resulting in a total code length of 17 bits (without the synchronizing code). When the code tables for Group 3 were constructed, images containing halftones were deliberately *excluded*, so as not to skew the code tables and degrade the compression performance for character-based documents.

The modified Huffman code is mandatory for all Group 3 machines, providing a basis for interoperability. It is relatively simple to implement, and produces acceptable results on noisy telephone lines. In order to ensure that the receiver maintains color synchronization, all coded lines begin with a white run length code word. If the actual scan line begins with a black run, a white run length of zero is sent. Black or white run lengths, up to a maximum length of one scan line (1728 picture elements or pels) are defined by the code word in Tables 21.5.3 and 21.5.4. Note that there is a different list of code words for black and white run lengths.

Each coded line begins with an End-of-Line (EOL) code. It is a unique code word that can never be found within a valid coded scan line; therefore, resynchronization after an error burst is possible.

A pause may be placed in the message flow by transmitting FILL. FILL is a variable length string of 0s that can only be placed after a coded line and just before an EOL, but never within a coded line. Fill must be added to ensure that the transmission time of the total coded scan line is not less than the minimum transmission time established in the premessage control procedure. The end of a document transmission is indicated by sending six consecutive EOLs.

Two-Dimensional Coding Scheme—Modified READ (MR)

The MR coding method makes use of the vertical correlation between black (or white) runs from one scan line to the next (called vertical mode). In vertical mode, transitions from white to black (or black to white) are coded relative to the line above. If the transition is directly under (zero offset), the code is only one bit. Only fixed

offsets of zero and ± 1 , ± 2 , and ± 3 are allowed. If vertical mode is not possible (for example, when a nonwhite line follows an all-white line) then horizontal mode is used. Horizontal mode is simply an extension of MHC; that is, two consecutive runs are coded by MHC and preceded by a code indicating horizontal mode. To avoid the vertical propagation of transmission errors to the end of the page, a one-dimensional (MHC) line is sent every K th line. The factor K is typically set to 2 or 4, depending on whether the vertical scanning density is 100 or 200 lines per inch. The K -factor is resettable, which means that a one-dimensional line may be sent more frequently (than 2 or 4) when considered necessary by the transmitter. The synchronization code (EOL) consists of eleven 0s followed by a 1, followed by a tag bit to indicate whether the following line is coded one-dimensionally or two-dimensionally.

The two-dimensional coding scheme is an optional extension of the one-dimensional coding scheme. It is defined in terms of changing picture elements (see Fig. 21.5.2).

A changing element is defined as an element whose color (i.e., black or white) is different from that of the previous element along the same scan line.

- a_0 The reference or starting changing element on the coding line. At the start of the coding line a_0 is set on an imaginary white changing element situated just before the first element on the line. During the coding of the coding line, the position of a_0 is defined by the previous coding mode.
- a_1 The next changing element to the right of a_0 on the coding line.
- a_2 The next changing element to the right of a_1 on the coding line.
- b_1 The first changing element on the reference line to the right of a_0 and of opposite color to a_0
- b_2 The next changing element to the right of b_1 on the reference line.

Code words for the two-dimensional coding scheme are given in Table 21.5.5.

Extended Two-Dimensional Coding Scheme—Modified Modified READ (MMR)

The basic facsimile coding scheme specified for Group 4 facsimile (MMR) may be used as an option in Group 3 facsimile. This coding scheme must be used with the Error Correction Mode (ECM) option, described below. This coding scheme, described in ITU-T Recommendation T.6,⁵ is very similar to that of Group 3 (Rec. T.4). The same modified READ code is used, but only two-dimensional lines are transmitted with no EOL codes for synchronization. An error-free communication link makes this possible. A white line is assumed before the first actual line in the image. No fill is used; adequate buffering is assumed to provide a memory to memory transfer.

TABLE 21.5.4 Make Up Codes

White run lengths	Code word	Black run lengths	Code word
64	11011	64	0000001111
128	10010	128	000011001000

448	01100100	448	000000110101
512	01100101	512	0000001101100
576	01101000	576	0000001101101
640	01100111	640	0000001001010
704	011001100	704	0000001001011
768	011001101	768	0000001001100
832	011010010	832	0000001001101
896	011010011	896	0000001110010
960	011010100	960	0000001110011
1024	011010101	1024	0000001110100
1088	011010110	1088	0000001110101
1152	011010111	1152	0000001110110
1216	011011000	1216	0000001110111
1280	011011001	1280	0000001010010
1344	011011010	1344	0000001010011
1408	011011011	1408	0000001010100
1472	010011000	1472	0000001010101
1536	010011001	1536	0000001011010
1600	010011010	1600	0000001011011
1664	011000	1664	0000001100100
1728	010011011	1728	0000001100101
EOL	000000000001	EOL	000000000001

Note: For those machines that choose to accommodate larger paper widths or higher pel densities, the following Make Up Code Set may be used:

Run length (black and white)	Make up codes
1792	0000001000
1856	00000001100
1920	00000001101
1984	000000010010
2048	000000010011
2112	000000010100
2176	000000010101
2240	000000010110
2304	000000010111
2368	000000011100
2432	000000011101
2496	000000011110
2560	000000011111

Note: Run lengths in the range of lengths longer than or equal to 2624 pels are coded first by the make-up code of 2560. If the remaining part of the run (after the first make-up code of 2560) is 2560 pels or greater, additional make-up codes(s) of 2560 are issued until the remaining part of the run becomes less than 2560 pels. Then the remaining part of the run is encoded by terminating code or by make-up code plus terminating code according to the range as mentioned above.

FIGURE 21.5.2 Changing picture elements.

The objective of each of the image compression schemes is to reduce the number of bits transmitted and thus the transmission time (and cost). The more aggressive schemes provide the most compression, at a cost of increased implementation complexity. In general, T.6 coding outperforms T.4 two-dimensional coding which outperforms T.4 one-dimensional coding. The differences tend to be smaller on “busy” images and greater on images containing more white space. On dithered images and halftones the compression is very poor (or even negative), and one-dimensional coding outperforms the other methods in some cases.

MODULATION AND DEMODULATION METHODS (MODEMS)

Every Group 3 facsimile machine must be able to operate at the standard modem speeds of 4.8 and 2.4 kb/s according to ITU-T Recommendation V.27ter. The receive modem has an automatic equalizer to compensate for the telephone line amplitude distortion and envelope-delay distortion, improving the accuracy of the delivered digital facsimile signal. Optional modems are V.29 (9.6 and 7.2 kb/s), and V.17 with Trellis coding for improved error immunity (14.4, 12, 9.6, and 7.2 kb/s) and V.34 for speeds up to 33.6 kb/s.

Group 3 facsimile modems adapt to the transmission characteristics of the telephone connection. Before sending fax data, the modem sends a standard training signal. The receiver uses this signal to “adapt” to the electrical characteristics of the connection. The highest rate available in both facsimile machines is tried first. If this speed would give too many errors, the next lower speed is tried by the transmitter. If this fails, the modem rate again steps down to the next lower speed. This system assures transmission at the highest rate consistent with the quality of the telephone line connection.

Standard Operation—V.27ter (4.8 and 2.4 kb/s)

At 4.8 kb/s, the modulation rate (or baud rate) is 1600 baud or 1.6 kB. The data stream to be transmitted is divided into groups of three consecutive bits (tribits). Each is encoded as a phase change relative to the phase

TABLE 21.5.5 Two-Dimensional Code Table

Mode	Elements to be coded	Notation	Code word	
PASS	b_1, b_2	P	0001	
HORIZONTAL	$a_0 a_1 a_2$	H	$001 + M(a_0 a_1) + M(a_1 a_2)$ _{Note}	
VERTICAL	a_1 just under b_1	$a_1 b_1 = 0$	$V(0)$	1
	a_1 to the right of b_1	$a_1 b_1 = 1$	$V_R(1)$	011
		$a_1 b_2 = 2$	$V_R(2)$	000011
		$a_1 b_1 = 3$	$V_R(3)$	0000011
	a_1 to the left of b_1	$a_1 b_1 = 1$	$V_L(1)$	010
		$a_1 b_1 = 2$	$V_L(2)$	000010
	$a_1 b_1 = 3$	$V_L(3)$	0000010	

Note: Code M() of Horizontal mode represents the code words in Tables 21.5.3 and 21.5.4.

TABLE 21.5.6 Tribit Values and Phase Changes

Tribit values	Phase change
0 0 1	0°
0 0 0	45°
0 1 0	90°
0 1 1	135°
1 1 1	180°
1 1 0	225°
1 0 0	270°
1 0 1	315°

TABLE 21.5.7 Dibit Values and Phase Changes

Dibit values	Phase change
00	0°
01	90°
11	180°
10	270°

of the preceding signal tribit element (see Table 21.5.6). At the receiver, the tribits are decoded and the bits are reassembled in correct order.

At 2.4 kb/s, the modulation rate is 1200 baud or 1.2 kB. The data stream to be transmitted is divided into groups of two bits (dibits). Each dibit is encoded as a phase change relative to the phase of the immediately preceding signal element (see Table 21.5.7). At the receiver the dibits are decoded and reassembled in the correct order.

Optional Operation A—V.29 (9.6 and 7.2 kb/s)

For optional higher speed operation, such as may be possible on high-quality circuits, the optional mode may be used.

At all speeds, the modulation rate is 2.4 kB. At 14.4 kb/s the scrambled data stream to be transmitted is divided into groups of six consecutive data bits and mapped onto a signal space of 128 elements. At 12 kb/s the scrambled data stream is divided into groups of five consecutive data bits and mapped onto a signal space of 64 elements. At 9.6 kb/s the data are divided into groups of four consecutive data bits and mapped onto a signal space of 32 elements. At 7.2 kb/s the data are divided into groups of three consecutive data bits and mapped onto a signal space of 16 elements. The V.17 modem is more robust than V.29, due to its trellis coding method; e.g., V.17 can operate at 9.6 kb/s on telephone lines where V.29 cannot.

Higher data rates are theoretically possible, and are highly desirable for transmission of continuous tone color. The V.34 modem standard approved in 1994 provides speeds to 33 kb/s.

The use of this modem is described in Annex F of Recommendation T.30. This modem also uses trellis coding and a number of symbol rates from 2400 to 3429 symbols/per second. It requires the use of ECM and runs in half-duplex for facsimile. An unusual feature of this modem is the use of Recommendation V.8 for the modem start-up procedures. V.8 provides the means to determine the best mode of operation *before* the initiation of the handshake.

INTERNET FACSIMILE

The availability of the Internet for international communication provides the potential for using this transmission medium in the transfer of Group 3 facsimile messages between terminals. Since the characteristics of IP networks differ from those provided by the PSTN, some additional provisions need to be standardized to maintain successful facsimile operation. Service requirements for Internet facsimile are defined in Recommendation F.185. Two methods have been defined to meet these service requirements: a store-and-forward method akin to email and a real-time method that is largely transparent as far as the end-points are concerned.

Store-and-Forward Facsimile

Store-and-forward Internet facsimile occurs when the sending and receiving terminal are not in direct communication with each other. The transmission and reception takes place via the store-and-forward mode on the Internet using Internet email. In store-and-forward mode the facsimile protocol “stops” at the gateway to the Internet. It is reestablished at the gateway leaving the Internet.

Two modes of store-and-forward facsimile are defined. In “Simple” mode store-and forward only the coded image is transmitted. In “Full” mode store-and-forward facsimile over the Internet three requirements must be satisfied:

1. The capabilities of the terminals are exchanged.
2. An acknowledgement of receipt is exchanged between gateways and may be transferred from the receiving terminal to the sending terminal.
3. The contents of standard messages used by the transmitting terminal are preserved.

ITU-T Recommendation T.37, *procedures for the transfer of facsimile data via store-and-forward on the Internet*, approved in 1998, standardized the Simple mode. It references a set of IETF documents called “Request for Comment” documents (RFCs) that define the procedures for facsimile communication over the Internet using email. Full mode was added in 1999 with Addendum 1. The intention is that Full mode should support, to the greatest extent possible, the standard and optional features of Group 3 facsimile. This would include, among others, delivery notification, capabilities exchange, color and other optional coding mechanisms, and file transfer.

Real-Time Internet Facsimile

Recommendation T.38, *procedures for real-time Group 3 facsimile communication between terminals over IP networks*, was approved by the ITU-T in 2002. This standard describes how facsimile transmission takes place between Internet gateways. Communication between the facsimile machine and the gateway is by means of T.30. The T.38 procedures work in conjunction with Rec. H.323 and Rec. H.225.

The transmission method in T.38 may be described as a demodulation/remodulation (demod/remod) procedure. The facsimile transmission arrives at the gateway as a data stream modulated by the facsimile modem into an analog signal. At the gateway the signal is demodulated. It is then packaged into data packets to be conveyed over the Internet by the emitting gateway. The receiving gateway reassembles the packets and modulates them into a modem signal that continues on to the receiving facsimile terminal. Neither facsimile terminal is aware that part of the transmission was over the PSTN and part over the Internet. Once the PSTN calls are established on both ends, the two Group 3 terminals are virtually linked. All T.30 session establishment and capabilities negotiation is carried out between the terminals. An alternate scenario would be a connection to a facsimile-enabled device (for example, a PC), which is connected directly to an IP network. In this case, there is a virtual-receiving gateway as part of the device’s facsimile-enabling software and/or hardware.

Transmission Protocols. There are two types of transmission protocols over the Internet: TCP and UDP. The TCP protocol is error free (via retransmission) so that errors translate into delay. UDP has no error control. Errors manifest themselves as lost packets. T.30 is very sensitive to delay, since there are a number of timers active in the protocol, which, if they expire, would cause transmission to fail. Lost packets could have serious consequences. If a packet is lost in the image transmission phase, it could cause lost scan lines in the image, unless ECM error control was in effect.

Modem Rate Alignment. When the TCP protocol method is selected, each gateway independently provides rate negotiation with the facsimile modems and training is carried out independently. It would therefore be possible to have each end of the connection negotiate to a different data rate, which would be a problem. To prevent this from occurring, a set of messages is provided to align the modem speeds. Because of the lower delays experienced with using UDP, the modems can negotiate data rates without relying on gateways. The V.34 modem is not used with Internet facsimile because of the added complexity.

Error Correction Mode

The optional error correction mode applies to one-dimensional and two-dimensional coding, and provides true error correction. The primary objective of ECM is to perform well against burst errors. Additional objectives included backwards compatibility with existing facsimile machines, and minimizing the transmission overhead in channels with low error rates.

The error-correction scheme is known as page selective repeat ARQ (automatic repeat request). The compressed image data are embedded in high-level data link control (HDLC) frames of length 256 octets or 64 octets, and transmitted in blocks of 256 frames. The communication link operates in a half-duplex mode; that is, the transmission of image data and the acknowledgment of the data are not sent at the same time. The technique can be thought of as an extension to the Group 3 protocol. The protocol information is also embedded in HDLC frames, but does not use selective repeat for error control. Every Group 3 facsimile machine must have the mechanism to transmit and receive the basic HDLC frame structure, including flags, address, control, and frame check sequence. Thus the use of an extended HDLC scheme helped to minimize changes to existing facsimile designs.

The transmitting terminal divides the compressed image data into 256-octet or 64-octet frames and sends a 256-octet block of frames to the receiving terminal. (The receiving terminal must be able to receive both frame sizes). Each transmitted frame has a unique frame number. The receiver requests retransmission of bad frames by frame number. The transmitter retransmits the requested frames. After four requests for retransmission for the same block, the transmitter may stop or continue, with optional modem speed fall back.

The page selective repeat ARQ is a good compromise⁶ that balances complexity and throughput. A continuous selective repeat ARQ provides slightly higher throughput, but requires a modem back channel. Forward error correction (FEC) schemes typically have higher overhead on good connections, can be more complex, and may break down in the presence of burst errors. In addition to providing the capability of higher throughput on noisy lines, the error correction mode option supports an error-free environment that has enabled many new features. Examples of these are T.6 encoding, color fax, and secure operation.

COLOR FACSIMILE

Group 3 facsimile is capable of transmitting color, including color or gray scale photographs and colored text and line art. Much research has been devoted to the development of a “universal” compression technique that would apply to both photographs and text, but the best approach to achieve high compression ratios and retain quality is to compress the different image types according to their individual attributes. Photographs are compressed using an approach that puts a high emphasis on maintaining the smoothness and accuracy of the colors. Text and line art are compressed with an approach that puts high emphasis on maintaining the detail and structure of the input.

The method to transmit continuous tone color was added to Group 3 facsimile in 1994, with the approval of Recommendation T.42. This method is based on the popular Joint Photographic Experts Group (JPEG) standard. Although this was a good first step toward a color facsimile capability, it was not an efficient solution for text or line art. To correct this problem, Recommendation T.43, based on JBIG, was developed to accommodate text and line art with some limited color capability. The Mixed Raster Content (MRC) option was added to correct a weakness of the color facsimile options that use JPEG and JBIG; that is, before MRC there was no standard way of efficiently coding a page that contained *both* text and color photographic content. The MRC option, as implemented by ITU-T Recommendation T.44, is a way of describing documents with both bi-level and multilevel data within a page. These methods are outlined in the following paragraphs.

Coding Continuous Tone Color and Gray Scale Images

The facsimile standards include an option for the transmission of continuous-tone color and gray-scale images, based on an ISO/ITU-T standard⁷ commonly known as JPEG. As a result of diverse requirements, the JPEG compression algorithm is not a single algorithm but a collection of techniques that are often referred to as a *toolkit*. The intent is that applications, such as facsimile, will have a “customized” subset of the JPEG components. A detailed description of JPEG with a comprehensive bibliography is given in Ref. 8.

JPEG specifies two classes of coding processes: lossy and lossless processes. The lossy processes are all based on the discrete cosine transform (DCT), and the lossless are based on a predictive technique. There are four modes of operation under which the various processes are defined: the sequential DCT-based mode, the progressive DCT-based mode, the sequential lossless mode, and the hierarchical mode.

In the sequential DCT-based mode, 8×8 blocks of pixels are transformed, the resulting coefficients are quantized and then entropy coded (losslessly) by Huffman or arithmetic coding. The pixel blocks are typically formed by scanning the image (or image component) from left to right, and then block row by block row from top to bottom. The allowed sample precisions are 8 and 12 bits per component sample. All decoders that include any DCT-based mode of operation must provide a default decoding capability, referred to as the baseline sequential DCT process. This is a restricted form of the sequential DCT-based mode, using Huffman coding and 8 bits per sample precision for the source image. The application of JPEG to facsimile is based on the baseline sequential DCT process.

Continuous tone color was added to Group 3 facsimile with the approval of Recommendation T.42. In order to represent continuous tone color data accurately and uniquely, a device-independent interchange color space is required. This color image space must be able to encode the range of hard copy image data when viewed under specified conditions. In addition to the basic color space, the reference white point, illuminant type, and gamut range must also be specified. The image pixel values are represented in the CIE 1976 ($L^* a^* b^*$) color space, often referred to as CIELAB. This color space, defined by the CIE (Commission Internationale de l'Éclairage), has approximately equal visually perceptible difference between equispaced points throughout the space. The three components are L^* , or luminance, and a^* and b^* in chrominance. The luminance-chromaticity spaces offer gray-scale compatibility and higher DCT-based compression than other spaces. The human eye is much more sensitive to luminance than chrominance; thus it is easier to optimize the quantization matrix where luminance and chrominance are separate components. Subsampling the chrominance components provides further compression.

The basic resolution is 200 pels/25.4 mm. Allowed values include 200, 300, and 400 pels/25.4 mm, with square (or equivalent) pels. At 200×200 pels/25.4 mm, a color photograph (A4 paper size) compressed to 1 bit per pixel and transmitted at 64 kb/s would require about 1 min to send. The selection of 8-bit or 12-bit data precision can also have an effect on the data compression. Subsampling and data precision, as well as the ability to send color, are negotiated in Phase B.

Lossless Coding of Color and Gray Scale Images

Recommendation T.43 was developed to accommodate text and line art with some limited color capability. Recommendation T.43 defines a lossless color data representation method using Recommendation T.82, which was prepared by the Joint Bi-level Image Experts Group (JBIG). In this recommendation, three types of images are treated: the first type is a one-bit-per-color CMY(K) or RGB image; the second type is a palletized color image in which palette tables are specified with the CIELAB color space defined in Recommendation T.42; and the last type is a continuous-tone color and gray-scale image also specified with the CIELAB color space. Images can be created in a variety of ways, including conventional scanning, computer generation, or by image processing techniques such as one of the dither methods. Recommendation T.43 was approved in July 1997. The following section presents an overview of JBIG compression, followed by a description of the three image types treated by Recommendation T.43.

JBIG overview (ITU-T T.82/ISO11544). The progressive bi-level coding technique consists of repeatedly reducing the resolution of a bi-level image, creating subimages each having one-half the number of pels per line and one-half the number of lines of the previous image. The lowest-resolution image, called the base layer, is transmitted losslessly (free of distortion) by binary arithmetic coding. The next higher resolution image is transmitted losslessly, using its own pels and previously transmitted (causal) pels as predictors in an attempt to predict the next pel to be transmitted. If prediction is possible (both transmitter and receiver are equipped with rules to tell whether this is the case), the predicted pel value is not transmitted. This progressive build-up is repeated until the final image has been losslessly transmitted (the process stopped at the receiver's request). A sequential mode of transmission also exists. It consists of performing the entire progressive transmission on

successive horizontal stripes of the original image. The algorithm performs image reduction, typical prediction, deterministic prediction, and binary arithmetic encoding and decoding.

Recommendation T.43. The one-bit-per-color mode was intended to represent images with primary colors using the CMY(K) or RGB color space. Each bit-plane indicates the existence of one of the primary colors. The image is encoded with JBIG and transmitted. The receiver represents the image on a CRT (soft-copy) or a printed (hard copy) using its own primary colors. The colors of the document may not be represented accurately at the receiver in the one-bit-per-color mode since neither RGB nor CMY(K) are device-independent color spaces. A typical application of the mode is to transmit business correspondence containing a colored logo.

The palletized color mode expands the possible number of colors that may be used to characterize an image, and in addition provides the capability for accurate color reproduction. Both of these features are achieved by using color palette table data as specified by the device-independent interchange color space (CIELAB) defined in Recommendation T.42. The price for this added capability is coding (and transmission) efficiency, that is, the compression is less so the facsimile transmission takes longer.

The continuous-tone color mode provides the highest color accuracy of the three modes in Recommendation T.43 and the lowest compression efficiency. In this mode, an original continuous-tone color or gray-scale image is generated in the color space defined in Recommendation T.42 (CIELAB). This mode provides lossless encoding using JBIG bit-plane compression. Gray-code conversion on the bit planes is used to improve the compression efficiency.

Coding Images with Mixed Raster Content

The MRC option, as implemented by ITU-T Recommendation T.44, is a way of describing raster-oriented (scanned or synthetic) documents with both bi-level and multilevel, continuous-tone or palletized colors (contone) usually associated with naturally occurring images: bi-level detail associated with text and line art and multilevel colors associated with the text and line art. The goal of MRC is to make the exchange of raster-oriented mixed content color documents possible with higher speed, higher image quality, and modest computing resources. This efficiency is realized through segmentation of the image into multiple layers (planes) as determined by image type, and applying image specific encoding and spatial and color resolution processing. The MRC method defines no new image compression methods, but does require that all previously defined compression methods used in Group 3 facsimile be supported.

SECURE FACSIMILE

Group 3 secure facsimile, including new Annexes to T.30 and a new Recommendation T.36, was approved by the ITU-T in July 1997. The new and amended recommendations accommodate two methods—one based on a public-key cryptosystem and one based on a secret-key cryptosystem. The public-key management system is based on the method devised by Ron Rivest, Adi Shamir, and Leonard Adleman. It is called RSA after the initials of its inventors. The secret-key method is based on the Hawthorne Key Management (HKM) system, the Hawthorne Facsimile Cipher (HFX40), and the HFX40-I message integrity system, hereafter referred to as the HKM/HFX cryptosystem. Both systems are incorporated into the Group 3 facsimile protocol, and either may be used independently.

Procedures Using the RSA Security System

The procedures for the RSA security system are defined in Annex H of ITU-T Recommendation T.30. The RSA security system uses one pair of keys (encipherment public key and encipherment secret key) for document encryption.

The registration mode permits the sender and receiver to register and store the public keys of the other party prior to secure facsimile transmission. Two parties wishing to communicate can register their public keys with

another user in two steps. First, the sender and receiver each hash their identities and public key(s) and the hash results are exchanged out of band (directly, by mail, by phone, and so forth) and stored in the terminals. Then the identities and public keys of the two parties are exchanged and stored in the registration mode of the T.30 protocol. The validity of the identity and public key(s) of the other party is assessed by hashing these values and comparing them with the hash result that was exchanged out of band.

An optional security page follows the last page of the transmitted document. The security page contains the following parameters: security page indicator, identity of the sender, public key of the sender, identity of the recipient, random number created by the recipient, time stamp, length of the document, digital signature of the entity in brackets, certificate of the public key of the sender, and security-page-type identification.

One other significant issue is the key length. Because of varying regulations of different governments, it was agreed to limit the session key length for the RSA secure facsimile system to 40 bits. The amendment also adds a redundancy mechanism that repeats the 40-bit session key to fit the length of the various encipherment algorithms whose key lengths are required to be longer than 40 bits.

Procedures Using the HKM/HFX Cryptosystem

The secret-key method consists of the Hawthorne Key Management system, the HFX40 carrier cipher (encryption algorithm), and the HFX40-I message integrity system (hashing algorithm). The HKM key management algorithm includes a registration procedure, and a secure transmission of a secret key that enables subsequent transmission to be provided securely. These procedures are defined as ITU-T Recommendation T.36.

In the registration mode, the two terminals exchange information that enables them to uniquely identify each other. This is based on the agreement between the users of a secret one-time key that must be exchanged securely (not defined by the Recommendations). Each terminal stores a 16-digit number that is uniquely associated with the terminal with which it has carried out registration. This number is used together with a challenge procedure to provide mutual authentication and document confirmation. The procedure is also used to transmit the session key to be used for document encryption and hashing.

An override mode is also provided that bypasses the exchange of security signals between two terminals. Just as in the classic secret-key cryptosystem approach, this mode depends on the secure exchange of a secret key outside the system. This key is used by the transmitting terminal to encrypt the document and by the receiving terminal to decrypt the document.

SECTION 22

BROADCAST AND CABLE SYSTEMS

Coded orthogonal frequency multiplex (COFDM) is used in new audio transmission systems so that numerous low-power broadcast transmitters spaced over a wide area can broadcast the identical signal on the same identical frequency. As an automobile travels around the region, CD quality reception is obtained continuously with no interference or receiver retuning required.

Radio broadcast data systems have digital subcarriers superimposed or added to the existing channel spectrum. These subcarriers transmit such information to the receivers as station call letters, road conditions, program or music names, and other data believed to be useful in a moving automobile.

One of digital technology's main advantages is the applicability of computer processing power and features so that the challenges of scrambling and signal security can be approached with new techniques. Unfortunately, with cable television systems, this advanced digital technology also provides new means of attack for the would-be cable television pirate. To counter this problem, it must be possible to respond to a security attack by replacing the breached security element. If the cable operator owns the set-top boxes, they can be replaced. If the set-top boxes were sold to the subscriber, a plug-in card or module, called the point of deployment module, is used. It remains the property of the cable operator and can be disabled electronically. The subscriber would then be given a new POD device based on a system not yet breached. R.J.

CHAPTER 22.1

BROADCAST TRANSMISSION PRACTICE

Earl F. Arbuckle, III

INTRODUCTION

Broadcasting refers to those wireless services, such as standard broadcast, FM, television, and short-wave, which are intended for free reception by the general public. Point-to-point communications links (i.e., two-way radio) and point-to-multipoint private or subscription-based transmission systems (i.e., MMDS, ITFS, and DBS satellite) are not included in this definition and are therefore not discussed in this section.

In the United States, broadcasting activities are regulated by the Federal Communications Commission (FCC). The FCC is empowered by the Communications Act of 1934 (as amended) to administratively control the use of radio frequency (RF) spectrum by means of licensing users within an allocations framework developed through international consensus at various World Administrative Radio Conferences (WARC). Potential licensees must demonstrate by formal application and engineering studies that a license grant would conform to spectrum allocation, technical performance, and public service criteria spelled out in the FCC Rules. In the following paragraphs, reference is made, when appropriate, to the specific section of the FCC Rules relevant to the paragraph. Because technology is developing rapidly and the FCC Rules are dynamic, the reader is warned to consult them directly whenever specific compliance must be determined. For the same reason, this handbook will state only the fundamental tenets of those rules which are likely to remain immutable.

ALLOCATIONS

Standard Broadcast (AM)

An amplitude-modulated (AM) standard broadcast channel is that band of frequencies occupied by the carrier and the upper and lower sidebands with the carrier frequency at the center. Channels are designated by their assigned carrier frequencies. The AM broadcast band consists of 117 carrier frequencies which begin at 540 kHz and progress in 10 kHz steps to 1700 kHz. (FCC Rules 73.14)

Classes of AM broadcast channels and stations are:

Clear channel. One on which stations are assigned to serve wide areas. These stations are protected from objectionable interference within their primary service areas and, depending on the class of station, their secondary service areas. Stations operating on these channels are classified as follows:

Class A station. An unlimited time station that operates on a clear channel and is designed to render primary and secondary service over an extended area and at relatively long distances from its transmitter. Its primary service area is protected from objectionable interference from other stations on the same and

adjacent channels, and its secondary service area is protected from interference from other stations on the same channel. The operating power shall not be less than 10 kW nor more than 50 kW.

Class B station. An unlimited time station, which is designed to render service only over a primary service area. Class B stations are authorized to operate with a minimum power of 0.25 kW (or, if less than 0.25 kW, an equivalent of RMS antenna field of at least 141 mV/m at 1 km) and a maximum power of 50 kW, or 10 kW for stations that are authorized to operate in the 1605–1705 kHz band.

Class D station. Operates either daytime, limited time, or unlimited time with nighttime power less than 0.25 kW and an equivalent RMS antenna field of less than 141 mV/m at 1 km. Class D stations shall operate with daytime powers not less than 0.25 kW nor more than 50 kW. Nighttime operations of Class D stations are not afforded protection and must protect all Class A and Class B operations during nighttime hours. New Class D stations that had not been previously licensed as Class B will not be authorized.

Regional channel. One on which Class B and Class D stations may operate and serve primarily a principal center of population and the rural area contiguous thereto.

Local channel. One on which stations operate unlimited time and serve primarily a community and the suburban and rural areas immediately contiguous thereto.

Class C station. Operates on a local channel that is designed to render services only over a primary service area that may be reduced as a consequence of interference. The power shall not be less than 0.25 kW, nor more than 1 kW. Class C stations that are licensed to operate with 0.1 kW may continue to do so. (FCC Rules 73.21)

Frequency Modulation Broadcast (FM)

The FM broadcast band consists of that portion of the radio frequency spectrum between 88 and 108 MHz. It is divided into 100 channels of 200 kHz each. For convenience, the frequencies available for FM broadcasting (including those assigned to noncommercial educational broadcasting) are given numerical designations that are shown in the accompanying CD-ROM.

Different classes of FM station are provided so as to best serve the intended coverage area. Class A stations, for example, are authorized to serve a single community of limited geographic size. Class B stations have increased capability, which is suitable for metropolitan area coverage. Class C stations, on the other hand, are considered regional services and are granted increased power and antenna height accordingly. The maximum effective radiated power (ERP) in any direction, reference height above average terrain (HAAT), and distance to the class contour for each FM station class are listed in Table 22.1.1.

TABLE 22.1.1 Maximum ERP, HAAT, and Distance to the Class Contour for Each FM station Class

Station class	Maximum ERP	Reference HAAT in meters (ft)	Class contour distance in kilometers (mi)
A	6 kW (7.8 dBk)	100 (328)	28 (17)
B1	25 kW (14.0 dBk)	100 (328)	39 (24)
B	50 kW (17.0 dBk)	150 (492)	52 (32)
C3	25 kW (14.0 dBk)	100 (328)	39 (24)
C2	50 kW (17.0 dBk)	150 (492)	52 (32)
C1	100 kW (20.0 dBk)	299 (981)	72 (45)
C	100 kW (20.0 dBk)	600 (1968)	92 (57)
D*	0.01 kW (−20.0 dBk)	N/A	N/A

*Secondary

Analog NTSC Television Broadcast (TV)

A television channel is a band of frequencies 6 MHz wide in one of the television broadcast bands (VHF or UHF) and designated either by number or by the extreme lower and upper frequencies. Numerical designation of channels is given on the CD-ROM. Channels 2 through 13 are considered very high frequency (VHF), while channels 14 through 69 are considered ultrahigh frequency (UHF). The FCC Rules provide specific channel allocations to cities and towns so as to maximize spectrum reuse and efficiency.

Unlike radio stations, television stations are not actually described by a class designation, but rather by channel number and service level; namely, a station would be considered low-band VHF if assigned to a channel from 2 through 6, high-band VHF if assigned to a channel from 7 through 13, or UHF if assigned to a channel from 14 through 69. A station is considered either full power or low power. The following shows the allowable effective radiated power and antenna height for full power stations, which also vary by geographic zone (see Zone Descriptions on the CD-ROM).

Minimum power requirements require at least -10 dBk (100 W) horizontally polarized visual effective radiated power in any horizontal direction. No minimum antenna height above average terrain is specified. Maximum power may not exceed the permitted boundaries specified in the following formulas:

1. Channels 2 to 6 in Zone I:

$$\text{ERP}_{\text{Max}} = 102.57 - 33.24 * \text{Log}_{10}(\text{HAAT}), \text{ and } -10 \text{ dBk} \leq \text{ERP}_{\text{Max}} \leq 20 \text{ dBk}$$

2. Channels 2 to 6 in Zones II and III:

$$\text{ERP}_{\text{Max}} = 67.57 - 17.08 * \text{Log}_{10}(\text{HAAT}) \text{ and } 10 \text{ dBk} \leq \text{ERP}_{\text{Max}} \leq 20 \text{ dBk}$$

3. Channels 7 to 13 in Zone I:

$$\text{ERP}_{\text{Max}} = 107.57 - 33.24 * \text{Log}_{10}(\text{HAAT}), \text{ and } -4.0 \text{ dBk} \leq \text{ERP}_{\text{Max}} \leq 25 \text{ dBk}$$

4. Channels 7 to 13 in Zones II and III:

$$\text{ERP}_{\text{Max}} = 72.57 - 17.08 * \text{Log}_{10}(\text{HAAT}), \text{ and } 15 \text{ dBk} \leq \text{ERP}_{\text{Max}} \leq 25 \text{ dBk}$$

5. Channels 14 to 69 in Zones I, II, and III:

$$\text{ERP}_{\text{Max}} = 84.57 - 17.08 * \text{Log}_{10}(\text{HAAT}), \text{ and } 27 \text{ dBk} \leq \text{ERP}_{\text{Max}} \leq 37 \text{ dBk}$$

*Where ERP_{Max} = maximum effective radiated power in decibels above 1 kW (dBk) and HAAT = height above average terrain in meters.

The boundaries specified are to be used to determine the maximum possible combination of antenna height and ERP_{dBk} . When specifying an ERP less than that permitted by the lower boundary, any antenna HAAT can be used. Also, for values of antenna HAAT greater than 2300 m the maximum ERP is the lower limit specified for each equation.

Service Levels and Coverage Prediction

In general, AM broadcast service is determined by field strength and interference protection levels. Interference protection is necessary since AM medium wave frequencies have the potential to travel great distances. FM and TV broadcast service, on the other hand, is determined mainly by field strength, since interference protection is typically not provided in the FCC Rules. FM and TV operate on frequencies that can be characterized as having “line-of-sight” propagation.

Standard broadcast (AM) service levels are as follows:

Mainland U.S. Class A stations operate with a power of 50 kW. These stations are afforded protection as follows (stations in Alaska are subject to slightly different standards). In the daytime, protection is provided to the 0.1 mV/m groundwave contour from stations on the same channel, and to the 0.5 mV/m groundwave contour from stations on adjacent channels. In the nighttime, such protection extends to the 0.5 mV/m—50 percent skywave contour from stations on the same channel.

Class B stations are stations that operate on clear and regional channels with powers not less than 0.25 kW nor more than 50 kW. Class B stations should be located so that the interference received from other stations will not limit the service area to a groundwave contour value greater than 2.0 mV/m nighttime and to the 0.5 mV/m groundwave contour daytime, which are the values for the mutual protection between this class of stations and other stations of the same class.

Class C stations operate on local channels with powers not less than 0.25 kW, nor more than 1 kW. Such stations are normally protected to the daytime 0.5 mV/m contour. On local channels the separation required for the daytime protection shall also determine the nighttime separation.

Class D stations operate on clear and regional channels with daytime powers of not less than 0.25 kW (or equivalent RMS field of 141 mV/m at 1 km if less than 0.25 kW) and not more than 50 kW. Class D stations that have previously received nighttime authority operate with powers of less than 0.25 kW (or equivalent RMS fields of less than 141 mV/m at 1 km) are not required to provide nighttime coverage and are not protected from interference during nighttime hours.

When a station is already limited by interference from other stations to a contour value greater than that normally protected for its class, the individual received limits shall be the established standard for such station with respect to interference from each other station.

The four classes of AM broadcast stations have in general three types of service area, i.e., primary, secondary, and intermittent. Class A stations render service to all three areas. Class B stations render service to a primary area but the secondary and intermittent service areas may be materially limited or destroyed due to interference from other stations, depending on the station assignments involved. Class C and Class D stations usually have only primary service areas. Interference from other stations may limit intermittent service areas and generally prevents any secondary service to those stations which operate at night. Consistent intermittent service may still be obtained in many cases depending on the station assignments involved.

The groundwave signal strength required to render primary service is 2 mV/m for communities with populations of 2500 or more and 0.5 mV/m for communities with populations of less than 2500. (See FCC Rules Part 73.184 for curves showing distance to various groundwave field strength contours for different frequencies and ground conductivities.)

A Class C station may be authorized to operate with a directional antenna during daytime hours provided the power is at least 0.25 kW. In computing the degrees of protection which such antenna will afford, the radiation produced by the directional antenna system must be assumed to be no less, in any direction, than that which would result from nondirectional operation using a single element of the directional array, with 0.25 kW.

All classes of AM broadcast stations have primary service areas subject to limitation by fading and noise, and interference from other stations to the contours set out for each class of station.

Secondary service is provided during nighttime hours in areas where the skywave field strength, 50 percent or more of the time, is 0.5 mV/m or greater. Satisfactory secondary service to cities is not considered possible unless the field strength of the skywave signal approaches or exceeds the value of the groundwave field strength that is required for primary service. Secondary service is subject to some interference and extensive fading whereas the primary service area of a station is subject to no objectionable interference or fading. Only Class A stations are assigned on the basis of rendering secondary service. (Standards have not been established for objectionable fading because of the relationship to receiver characteristics. Selective fading causes audio distortion and signal strength reduction below the noise level, objectionable characteristics inherent in many modern receivers. The automatic volume control circuits in the better designed receivers generally maintain the audio output at a sufficiently constant level to permit satisfactory reception during most fading conditions.)

Intermittent service is rendered by the groundwave and begins at the outer boundary of the primary service area and extends to a distance where the signal strength decreases to a value that is too low to provide any service. This may be as low as a few $\mu\text{V/m}$ in certain areas and as high as several millivolts per meter in other areas of high noise level, interference from other stations, or objectionable fading at night. The intermittent service area may vary widely from day to night and generally varies over shorter intervals of time. Only Class A stations are protected from interference from other stations to the intermittent service area.

Broadcast stations are licensed to operate unlimited time, limited time, daytime, share time, and specified hours. New stations may be licensed only for unlimited time operation. Unlimited time stations may operate 24 h per day. Limited time stations (Class B only) may operate only during daytime hours until local sunset or

sunset at the nearest Class A station on the same frequency, whichever is easternmost. Daytime stations may operate only between local sunrise and local sunset. Share time stations, of which there are very few, operate on a frequency that is shared by another station in the same service area in accordance with a mutually agreed upon schedule which the FCC incorporates into the stations' licenses. Stations authorized to operate during specified hours will have those hours enumerated in their FCC license.

FM Broadcast Service Levels

FM broadcast service levels are determined by the class of FCC authorization. Within any class, coverage will be a function of effective radiated power (ERP) and antenna height above average terrain (HAAT). In general, higher ERP and higher HAAT result in larger coverage areas. The FCC table of allotments takes these factors into consideration to minimize the potential for interference or coverage overlap. Thus, FM broadcast stations are not generally protected from interference caused by the operation of other FM stations, so long as those stations operate in compliance with the FCC Rules. Class D (secondary) stations may not cause interference to primary stations.

The primary protection against interference is based on a minimum allowable spacing between FM broadcast transmitter sites (see accompanying CD-ROM).

Determination of predicted field strengths for FM broadcast stations is made using the FCC F(50/50) graphs. (Refer to FCC Rules 73.699 for the current graphs.) The 50 percent field strength is defined as that value exceeded for 50 percent of the time. The procedure to be used is as follows:

The F(50/50) chart gives the estimated 50 percent field strengths exceeded at 50 percent of the locations in dB above $1 \mu\text{V/m}$. The chart is based on an effective power radiated from a half-wave dipole antenna in free space, that produces an unattenuated field strength at 1 km of about 107 dB above $1 \mu\text{V/m}$ (221.4 mV/m).

To use the chart for other ERP values, convert the ordinate scale by the appropriate adjustment in dB. For example, the ordinate scale for an ERP of 50 kW (17 dBk) should be adjusted by 17 dB and, therefore, a field strength of 40 dBu would be converted to 57 dBu. When predicting the distance to field strength contours, use the maximum ERP of the main radiated lobe in the pertinent azimuthal direction. When predicting field strengths over areas not in the plane of the maximum main lobe, use the ERP in the direction of such areas, determined by considering the appropriate vertical radiation pattern.

The antenna height to be used with this chart is the height of the radiation center of the antenna above the average terrain along the radial in question. In determining the average elevation of the terrain, the elevations between 3 and 16 km from the antenna site are used.

Profile graphs are drawn for eight radials beginning at the antenna site and extending out 16 km. The radials should be drawn for each 45° of azimuth starting with True North. At least one radial must include the principal community to be served even though it may be more than 16 km from the antenna site. However, in the event none of the evenly spaced radials include the principal community to be served, and one or more such radials are drawn in addition, these radials must not be used in computing the antenna height above average terrain.

The profile graph for each radial is then plotted by contour intervals from 12 to 30 m, and, where the data permit, at least 50 points of elevation (generally uniformly spaced) should be used for each radial. In instances of very rugged terrain where the use of contour intervals of 30 m would result in several points in a short distance, 60- or 12-m contour intervals may be used for such distances. On the other hand, where the terrain is uniform or gently sloping, the smallest contour interval indicated on the topographic map should be used, although only relatively few points may be available. The profile graph should indicate the topography accurately for each radial, and the graphs should be plotted with the distance in kilometers as the abscissa and the elevation in meters above mean sea level as the ordinate. The profile graphs should indicate the source of the topographical data used. The graph should also show the elevation of the center of the radiating system. The graph may be plotted either on rectangular coordinate paper or on special paper that shows the curvature of the earth (commonly called 4/3 radius paper). It is not necessary to take the curvature of the earth into consideration in this procedure, as this factor is taken care of in the charts showing signal strengths. The average elevation of the 13 km distance between 3 and 16 km from the antenna site should then be determined from the profile graph for each radial. This may be obtained by averaging a large number of equally spaced points, by using a planimeter, or by obtaining the median elevation (that exceeded for 50 percent of the distance) in sectors and averaging those values. In the event that any of the radials encompass large amounts of water or non-U.S. territory, slightly different rules are applied.

22.8 BROADCAST AND CABLE SYSTEMS

Here is an example calculation of HAAT where all of the radials are over land within the United States and the heights above average terrain on the eight radials are as follows:

Radial	Meters
0°	120
45°	255
90°	185
135°	90
180°	-10
225°	-85
270°	40
315°	85

The antenna height above terrain is computed as follows:

$$(120 + 255 + 185 + 90 - 10 - 85 + 40 + 85)/8 = 85 \text{ m}$$

In cases where the terrain in one or more directions from the antenna site departs widely from the average elevation of the 3- to 16-km sector, the prediction method may indicate contour distances that are different from what may be expected in practice. For example, a mountain ridge may indicate the practical limit of service although the prediction method may indicate otherwise. In such cases, the prediction method should be followed, but a supplemental showing may be made concerning the contour distances as determined by other means. Such supplemental showings should describe the procedure used and should include sample calculations. Maps of predicted coverage should include both the coverage as predicted by the regular method and as predicted by a supplemental method. When measurements of an area are required, these should include the area obtained by the regular prediction method and the area obtained by the supplemental method. In directions where the terrain is such that antenna heights less than 30 m for the 3- to 16-km sector are obtained, an assumed height of 30 m should be used for the prediction of coverage. However, where the actual contour distances are critical factors, a supplemental showing of expected coverage must be included together with a description of the method used in predicting such coverage. In special cases, the FCC may require additional information as to terrain and coverage.

The effect of terrain roughness on the predicted field strength of a signal at points distant from an FM transmitting antenna is assumed to depend on the magnitude of a terrain roughness factor which is a measure of the number of points along a profile segment where the elevations are exceeded by all points on the profile for 10 and 90 percent, respectively, of the length of the profile segment. This factor is simply added to the profile average height. No terrain roughness correction need be applied when all field strength values of interest are predicted to occur 10 km or less from the transmitting antenna. The FCC F(50/50) field strength charts were developed assuming a terrain roughness factor of 50 m, which is considered to be representative of average terrain in the United States. Where the roughness factor for a particular propagation path is found to depart appreciably from this value, a terrain roughness correction should be applied.

Television Broadcast Service Levels

In the authorization of TV stations, two field strength contours are represented in the FCC F(50,50) coverage chart. These are specified as Grade A and Grade B and indicate the approximate extent of coverage over average terrain in the absence of interference from other television stations. Under actual conditions, the true coverage may vary greatly from these estimates because the terrain over any specific path is likely to be different from the average terrain on which the field strength charts were based. The required field strength in decibels above 1 $\mu\text{V}/\text{m}$ (dBu) for the Grade A and Grade B contours is as follows:

	Grade A (dBu)	Grade B (dBu)
Channels 2-6	68	47
Channels 7-13	71	56
Channels 14-69	74	64

It should be realized that the F(50/50) curves when used for Channels 14 to 69 are not based on measured data at distances beyond about 48.3 km (30 mi). Theory would indicate that the field strengths for Channels 14 to 69 should decrease more rapidly with distance beyond the horizon than for Channels 2 to 6. For this reason, the curves should be used with appreciation of their limitations in estimating levels of field strength. Further, the actual extent of service will usually be less than indicated by these estimates due to interference from other stations. Because of these factors, the predicted field strength contours give no assurance of service to any specific percentage of receiver locations within the distances indicated.

As in the case of FM broadcast stations, television stations are not guaranteed any protection from interference except for that arising out of minimum spacing requirements. In the special case of channel 6 television stations, additional protection is afforded by restrictions on the operation of noncommercial educational stations on the adjacent lower end of the FM broadcast band (FCC Rules 73.525).

Technical Standards

In the United States, the Federal Communications Commission (FCC) establishes the technical standards with which all broadcast facilities must comply. Such standards have the goal of providing maximum service to the public and, therefore, address issues such as transmitter emissions purity, frequency, power, and modulation. These standards help ensure that each broadcaster radiates a signal that is compatible with the intended receivers without causing undo interference to other stations.

Medium wave AM standard broadcasting definitions are included on the accompanying CD-ROM.

Amplitude Modulation Broadcasting

The emissions of AM broadcast stations must not cause harmful interference. Such emissions may be measured using a properly operated and suitable swept-frequency RF spectrum analyzer using a peak hold duration of 10 min, no video filtering, and a 300-Hz resolution bandwidth, except that a wider resolution bandwidth may be employed above 11.5 kHz to detect transient emissions. Alternatively, other specialized receivers or monitors with appropriate characteristics may be used to determine compliance with the FCC Rules. Measurements made of the emissions of an operating station are to be made at ground level approximately 1 km from the center of the antenna system.

FCC Rules require that emissions 10.2 to 20 kHz removed from the carrier must be attenuated at least 25 dB below the unmodulated carrier level, emissions 20 to 30 kHz removed from the carrier must be attenuated at least 35 dB below the unmodulated carrier level, emissions 30 to 60 kHz removed from the carrier must be attenuated at least $[5 + 1 \text{ dB/kHz}]$ below the unmodulated carrier level, and emissions between 60 and 75 kHz of the carrier frequency must be attenuated at least 65 dB below the unmodulated carrier level. Emissions removed by more than 75 kHz must be attenuated at least $43 + 10 \text{ Log (Power in watts)}$ or 80 dB below the unmodulated carrier level, whichever is the lesser attenuation, except for transmitters having power less than 158 W, where the attenuation must be at least 65 dB below carrier level.

The percentage of modulation is to be maintained at as high as is consistent with good quality of transmission and good broadcast service. Generally, the modulation should not be less than 85 percent on peaks of frequency recurrence, but where lower modulation levels may be required to avoid objectionable loudness or to maintain the dynamic range of the program material, the degree of modulation may be reduced to whatever level is necessary for this purpose, even though under such circumstances, the level may be substantially less than the level that produces peaks of frequency recurrence at a level of 85 percent.

Maximum modulation levels for AM stations must not exceed 100 percent on negative peaks of frequent recurrence, or 125 percent on positive peaks at any time. AM stations transmitting stereophonic programs must not exceed the AM maximum stereophonic transmission signal modulation specifications of the stereophonic system in use. For AM stations transmitting telemetry signals for remote control or automatic transmission system operations, the amplitude of modulation of the carrier by the use of subaudible tones must not be higher than necessary to effect reliable and accurate data transmission and may not, in any case, exceed 6 percent. If a limiting or compression amplifier is employed to maintain modulation levels, precaution must be taken so as not to substantially alter the dynamic characteristics of programs.

AM Stereophonic Transmission

The FCC has never issued a technical standard for AM stereo transmission, but rather chose to adapt a market-driven approach wherein several competing systems were allowed to coexist. Only two systems survived this competition, Motorola's C-Quam and Kahn's ISB (independent sideband). The systems are incompatible, but both are mono compatible.

C-Quam uses a quadrature phase modulation scheme wherein the main amplitude modulated carrier contains the left plus right channel information, thus insuring monaural receiver compatibility. The left minus right stereo information is transmitted on two subcarriers, phase modulated in quadrature, which are recovered in the C-Quam receiver and combined with the main carrier modulation in a matrix, resulting in separate left and right channels that are then amplified and fed to speakers.

The ISB system essentially uses the redundant characteristics of normal full carrier, double sideband amplitude modulation to provide left and right channels. All of the information being transmitted by such a system can be recovered, using a suitable receiver, from either the upper or the lower sideband, with or without the carrier. So the ISB system simply transmits the left channel on the lower sideband and the right channel on the upper sideband. The carrier is not suppressed, so as to ensure compatibility with monaural receivers, which recover both channels additively to produce monaural audio. ISB receivers recover the sidebands independently, routing left and right channels to the corresponding amplifiers. However, AM stereo failed in the marketplace.

Frequency Modulation Broadcasting

Definitions are given on the accompanying CD-ROM.

FM broadcast stations must maintain the bandwidth occupied by their emissions in accordance with the FCC specification detailed below. If harmful interference to other authorized stations occurs, the problem must be corrected promptly or the station may be forced to cease operation.

1. Any emission appearing on a frequency removed from the carrier by between 120 kHz and 240 kHz inclusive must be attenuated at least 25 dB below the level of the unmodulated carrier. Compliance with this requirement will be deemed to show the occupied bandwidth to be 240 kHz or less.
2. Any emission appearing on a frequency removed from the carrier by more than 240 kHz and up to and including 600 kHz must be attenuated at least 35 dB below the level of the unmodulated carrier.
3. Any emission appearing on a frequency removed from the carrier by more than 600 kHz must be attenuated at least $43 + 10 \text{ Log } 10$ (power, in watts) dB below the level of the unmodulated carrier, or 80 dB, whichever is the lesser attenuation.

Preemphasis shall not be greater than the impedance-frequency characteristics of a series inductance resistance network having a time constant of $75 \mu\text{s}$.

The percentage of modulation is to be maintained at as high a level as is consistent with good quality of transmission and good broadcast service. Generally, the modulation should not be less than 85 percent on peaks of frequent recurrence, but where lower modulation levels may be required to avoid objectionable loudness or to maintain the dynamic range of the program material, the degree of modulation may be reduced to whatever level is necessary for this purpose, even though under such circumstances the level may be substantially less than the level that produces peaks of frequent recurrence at a level of 85 percent.

Maximum modulation levels must not exceed 100 percent on peaks of frequent recurrence referenced to 75-kHz deviation. However, stations providing subsidiary communications services using subcarriers concurrently with the broadcasting of stereophonic or monophonic programs may increase the peak modulation deviation as follows:

1. The total peak modulation may be increased 0.5 percent for each 1.0 percent subcarrier injection modulation.
2. In no event may the modulation of the carrier exceed 110 percent (92.5-kHz peak deviation).

If a limiting or compression amplifier is employed to maintain modulation levels, precaution must be taken so as not to substantially alter the dynamic characteristics of programs. Modern audio processing, often using digital circuitry, is able to significantly increase the density of modulation without adverse impairment to the audio.

Multiplex Stereo

FM broadcast stations may transmit stereophonic programming via a compatible multiplex system. This system uses a matrix to derive sum (left + right) and difference (left – right) signals from the applied audio. The monaural and stereophonic frequency response is 50–15,000 Hz.

The sum signal is used to frequency modulate the main carrier. A monaural receiver will demodulate this main carrier into an audio signal containing both left and right signals, so no information will be lost. The difference signal is used to modulate a double-sideband stereo subcarrier operating at 38 kHz. This subcarrier, which must be suppressed to a level of less than 1 percent of the main carrier, is developed as a phase-locked second harmonic of the $19,000 \pm 2$ Hz stereo “pilot” signal, which frequency modulates the main carrier between the limits of 8 and 10 percent. This pilot signal is used by stereophonic receivers to enable stereo demodulating circuits and, almost always, some kind of stereo mode indicator. The stereo demodulator will provide a difference signal that can then be combined with the sum signal to regenerate the original left and right audio signals at the receiver output.

Because of the “triangular” shape of the noise spectrum, the effective noise floor of the 38 kHz difference subcarrier is higher than that of the baseband audio frequencies. The result is that signal-to-noise ratios are somewhat poorer for a stereo transmission system than for a monaural system. (This is the reason for the use of a companded difference channel in the BTSC television stereo system.)

Subsidiary Communications Authorization (SCA)

The FCC may issue a subsidiary communications authorization to an FM broadcast station so that station may provide limited types of subsidiary services on a multiplex basis. Permissible uses fall within the following categories:

1. Transmission of programs or data which are of a broadcast nature but which are of interest primarily to limited segments of the public wishing to subscribe thereto. Examples include background music, storecasting, detailed weather forecasting, real-time stock quotations, special time signals, and other material of a broadcast nature expressly designed and intended for business, professional, educational, religious, trade, labor, agricultural, or other groups.
2. Transmission of signals which are directly related to the operation of FM broadcast stations, i.e., relaying broadcast material to other FM and standard broadcast stations, remote cueing and order circuits, remote control telemetry, and similar uses. SCA operations may be conducted without time restriction so long as the main channel is programmed simultaneously.

SCA subcarriers must be frequency modulated and are restricted to the range of 20 to 75 kHz, unless the station is also broadcasting stereophonically in which case the restriction is 53 to 75 kHz.

Digital Audio Radio Service (DARS)

In 1997, the FCC finally awarded spectrum after a long rule-making process for DARS to two winners in an auction. XM Satellite Radio and Sirius Radio each inaugurated pay-to-listen subscription satellite-delivered services in 2001 with no free-to-air component, so they do not fit the definition of broadcasting and will not be discussed here.

Currently there is no free digital radio broadcasting available in the United States. The FCC continues to consider various approaches to an analog-to-digital transition for the incumbent terrestrial radio broadcasters. However, no system has yet been deployed as of 2002.

Analog NTSC Television Broadcasting

The accompanying CD-ROM includes definitions.

Note: not drawn to scale

FIGURE 22.1.1 Visual amplitude characteristic.

Visual Transmission Systems

Transmission standards are:

1. The width of the television broadcast channel is 6 MHz.
2. The visual carrier frequency is nominally 1.25 MHz above the lower boundary of the channel.
3. The aural center frequency is 4.5 MHz higher than the visual carrier frequency.
4. The visual transmission amplitude characteristic is generally required to conform to that shown in Fig. 22.1.1.
5. The chrominance subcarrier frequency is $63/88$ times precisely 5 MHz ($3.57954545 \dots$ MHz). The tolerance is ± 10 Hz, and the rate of frequency drift must not exceed 0.1 Hz per second (cycles per second squared).
6. For monochrome and color transmissions the number of scanning lines per frame is 525, interlaced two to one in successive fields. The horizontal scanning frequency is $2/455$ times the chrominance subcarrier frequency; this corresponds nominally to 15,750 Hz (with an actual value of $15,734.264 \pm 0.044$ Hz). The vertical scanning frequency is $2/525$ times the horizontal scanning frequency; this corresponds nominally to 60 Hz (the actual value is 59.95 Hz). For monochrome transmissions only, the nominal values of line and field frequencies may be used.
7. The aspect ratio of the transmitter television picture is four units horizontally to three units vertically.
8. During active scanning intervals, the televised scene is scanned from left to right horizontally and from top to bottom vertically, at uniform velocities.
9. A carrier is modulated within a single television channel for both picture and synchronizing signals.
10. A decrease in initial light intensity will cause an increase in radiated power (negative transmission).
11. The reference black level is always represented by a definite carrier level.

12. The blanking level is transmitted at 75 ± 2.5 percent of the peak carrier level.
13. The reference white level of the luminance signal is 12.5 ± 2.5 percent of the peak carrier level.
14. It is customary to employ horizontal antenna polarization. However, circular or elliptical polarization may be employed if desired, in which case clockwise (right-hand) rotation, as defined in the IEEE Standard Definition. 42A65-3E2, and transmission of the horizontal and vertical components in time and space quadrature shall be used. For either omnidirectional or directional antennas the licensed effective radiated power of the vertically polarized component may not exceed the licensed effective radiated power of the horizontally polarized component. For directional antennas, the maximum effective radiated power of the vertically polarized component must not exceed the maximum effective radiated power of the horizontally polarized component in any specified horizontal or vertical direction.
15. The effective radiated power of the aural transmitter must not exceed 22 percent of the peak radiated power of the visual transmitter, but may be less. Typically, 10 percent aural power is used.
16. The peak-to-peak variation of transmitter output within one frame of video signal due to all causes including hum, noise, and low-frequency response, measured at both scanning synchronizing peak and blanking level, must not exceed 5 percent of the average scanning synchronizing peak signal amplitude.
17. The reference black level must be separated from the blanking level by setup interval, which shall be 7.5 ± 2.5 percent of the video range from blanking level to the reference white level.
18. For monochrome transmission, the transmitter output should vary in substantially inverse logarithmic relation to the brightness of the subject.
19. The color picture signal consists of a luminance component transmitted as amplitude modulation of the picture carrier and a simultaneous pair of chrominance components transmitted as the amplitude modulation sidebands of a pair of suppressed subcarriers in quadrature.
20. The radiated chrominance subcarrier must vanish on the reference white of a transmitted scene.

Visual transmitter performance:

1. The field strength or voltage of the lower sideband must not be greater than 20 dB for a modulating frequency of 1.25 MHz or greater and in addition, for color, shall not be greater than -42 dB for a modulating frequency of 3.579545 MHz (the color subcarrier frequency). For both monochrome and color, the field strength or voltage of the upper sideband shall not be greater than -20 dB for a modulating frequency of 4.75 MHz or greater. For stations operating on Channels 15 to 69 and employing a transmitter delivering maximum peak visual power output of 1 kW or less, the field strength or voltage of the upper and lower sidebands may depart from the visual amplitude characteristic by no more than the following amounts:
 - 2 dB at 0.5 MHz below visual carrier frequency
 - 2 dB at 0.5 MHz above visual carrier frequency
 - 2 dB at 1.25 MHz above visual carrier frequency
 - 3 dB at 2.0 MHz above visual carrier frequency
 - 6 dB at 3.0 MHz above visual carrier frequency
 - 12 dB at 3.5 MHz above visual carrier frequency
 - 8 dB at 3.58 MHz above visual carrier frequency (for color transmission only)

The field strength or voltage of the upper and lower sidebands must not exceed a level of -20 dB for a modulating frequency of 4.75 MHz or greater. If interference to the reception of other stations is caused by out-of-channel lower sideband emission, the technical requirements applicable to stations operating on Channels 2 to 13 must be met.

2. The attenuation characteristics of the visual transmitter must be measured by application of a modulating signal to the transmitter input terminals in place of the normal composite television video signal. The signal applied will ordinarily be a composite signal composed of a synchronizing signal to establish peak output voltage plus a variable frequency sine wave voltage occupying the interval between synchronizing pulses. (The "synchronizing signal" referred to in this section means either a standard synchronizing wave form or

22.14 BROADCAST AND CABLE SYSTEMS

any pulse that will properly set the peak.) The axis of the sine wave in the composite signal observed in the output monitor should be maintained at an amplitude 0.5 of the voltage at synchronizing peaks. The amplitude of the sine wave input must be held at a constant value. This constant value should be such that at no modulating frequency does the maximum excursion of the sine wave, observed in the composite output signal monitor, exceed the value 0.75 of peak output voltage. The amplitude of the 200-kHz sideband should be measured and designated 0 dB as a basis for comparison. The modulation signal frequency is then varied over the desired range and the field strength or signal voltage of the corresponding sidebands measured. As an alternate method of measuring in those cases in which the automatic d-c insertion can be replaced by manual control, the above characteristic may be taken by the use of a video sweep generator and without the use of pedestal synchronizing pulses. The d-c level should be set for midcharacteristic operation.

3. A sine wave, introduced at those terminals of the transmitter which are normally fed the composite color picture signal, should produce a radiated signal having an envelope delay, relative to the average envelope delay between 0.05 and 0.20 MHz, of 0 microsecond (μs) up to a frequency of 3.0 MHz; and then linearly decreasing to 4.18 MHz so as to be equal to 0.17 μs at 3.58 MHz. The tolerance on the envelope delay is $\pm 0.05 \mu\text{s}$ at 3.58 MHz. The tolerance increases linearly to $\pm 0.1 \mu\text{s}$ down to 2.1 MHz, and remains at $\pm 0.1 \mu\text{s}$ down to 0.2 MHz. (Tolerances for the interval of 0.0 to 0.2 MHz are not specified at the present time.) The tolerance should also increase linearly to $\pm 0.1 \mu\text{s}$ at 4.18 MHz.
4. The change rate of the frequency of recurrence of the leading edges of the horizontal synchronizing signals should not be greater than 0.15 percent per second, the frequency to be determined by an averaging process carried out over a period of not less than 20, nor more than 100 lines, such lines not to include any portion of the blanking interval.

Requirements applicable to both visual and aural transmitters are:

1. Automatic means must be provided in the visual transmitter to maintain the carrier frequency within ± 1 kHz of the authorized frequency; automatic means must also be provided in the aural transmitter to maintain the carrier frequency 4.5 MHz above the actual visual carrier frequency within ± 1 kHz.
2. The transmitters should be equipped with suitable indicating instruments for the determination of operating power and with other instruments necessary for proper adjustment, operation, and maintenance of the equipment.
3. Adequate provision must be made for varying the output power of the transmitters to compensate for excessive variations in line voltage or for other factors affecting the output power.
4. Adequate provisions should be provided in all component parts to avoid overheating at the rated maximum output powers.
5. The construction, installation, and operation of broadcast equipment is expected to conform with all applicable local, state, and federally imposed safety regulations and standards, enforcement of which is the responsibility of the issuing regulatory agency.
6. Spurious emissions, including radio frequency harmonics, must be maintained at as low a level as the state of the art permits. As measured at the output terminals of the transmitter (including harmonic filters, if required), all emissions removed in frequency in excess of a 3 MHz above or below the respective channel edge shall be attenuated no less than 60 dB below the visual transmitter power.
7. If a limiting or compression amplifier is used in conjunction with the aural transmitter, due care should be exercised because of the preemphasis in the transmitting system.
8. TV broadcast stations operating on Channel 14 and Channel 69 must take special precautions to avoid interference to adjacent spectrum land mobile radio service facilities.

Vertical Interval Signals

The interval beginning with line 17 and continuing through line 20 of the vertical blanking interval of each field may be used for the transmission of test signals, cue and control signals, and identification signals. Test signals may include signals designed to check the performance of the overall transmission system or its individual components. Cue and control signals shall be related to the operation of the TV broadcast station. Identification signals may be transmitted to identify the broadcast material for its source, and the date and time of its origination.

Modulation of the television transmitter by such signals must be confined to the area between the reference white level and the blanking level, except where test signals include chrominance subcarrier frequencies, in which case positive excursions of chrominance components may exceed reference white, and negative excursions may extend into the synchronizing area. In no case may the modulation excursions produced by test signals extend beyond peak-of-sync, or to zero carrier level.

The use of such signals must not result in significant degradation of the program transmission of the television broadcast station, nor produce emission outside of the frequency band occupied for normal program transmissions.

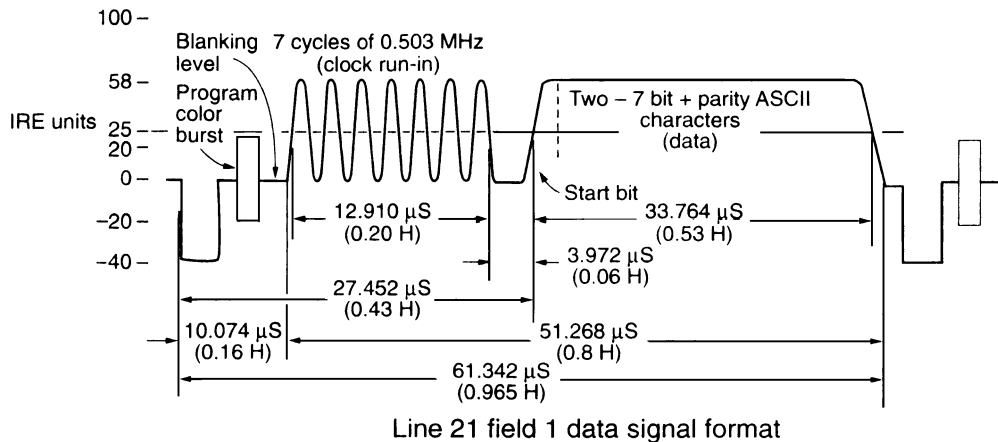

Vertical interval signals may not be transmitted during the portion of each line devoted to horizontal blanking.

Closed Captioning

Line 21, in each field, may be used for the transmission of a program related data signal, which, when decoded, provides a visual depiction of information simultaneously being presented on the aural channel (closed captions). Such data signal shall conform to the format described in Fig. 22.1.2 and may be transmitted during all periods of regular operation. On a space available basis, Line 21 in field 2 may also be used for text-mode data and extended data service information.

The signals on fields 1 and 2 would ordinarily be distinct data streams, for example, to supply captions in different languages or at different reading levels. The data signal shall be coded using a non-return-to-zero (NRZ) format and shall employ standard ASCII 7 bit plus parity character codes. (Note: For more information on data formats and specific data packets, see EIA-608, "Line 21 Data Services for NTSC" available from the Electronics Industries Association.)

At times when Line 21 is not being used to transmit a program-related data signal, data signals that are not program related may be transmitted, provided the same data format is used and the information to be displayed is of a broadcast nature.

Horizontal dimensions not to scale

1. Data "1" = 50 IRE units, data "0" = 0.
2. Data pulse rise time = 2 T bar rise time.
3. Data time base = $32 f_H$ (0.50349650 MHz.)
4. Data bit interval = $H/32$ (1.986 μ S.)
5. Negative going zero crossings of clock are coherent with data transitions.
6. Data and clock run-in coherent with H.

FIGURE 22.1.2 Line 21 (closed captioning) data format.

Test Signals

Vertical interval test signals include the following:

Composite: Includes white bar to detect the line time distortions (such as over- or underdamped response) and 12.5 “T” pulse, which enables measurement of group (envelope) delay.

Multiburst: Contains packets of various frequencies, which give an indication of amplitude versus frequency response.

Modulated stairstep: Used to determine differential gain and phase response of a transmission system.

Line 19, in each field, may be used only for the transmission of the Ghost-Cancelling Reference (GCR) signal described in OET Bulletin No. 68. The vertical interval reference (VIR) signal formerly permitted on Line 19 and described in Fig. 22.1.3, may be transmitted on any of Lines 10 to 16.

The GCR signal, shown in Fig. 22.1.4, serves as a reference for adaptive filter delay networks in receivers and demodulators (see also Fig. 22.1.5). By correcting the network response to reconstitute a proper GCR in the receiver, active picture area is also corrected to reduce the effects of multipath reception and “ghosts.”

Aural Transmission Systems

Transmission Standards are as follows:

1. The modulating signal for the main channel shall consist of the sum of the stereophonic (biphonic, quadraphonic, and the like) input signals.
2. The instantaneous frequency of the baseband stereophonic subcarrier must at all times be within the range of 15 to 120 kHz. Either amplitude or frequency modulation of the stereophonic subcarrier may be used.

Note: the chrominance reference and the program color burst have the same phase.

FIGURE 22.1.3 Vertical interval reference signal.

FIGURE 22.1.4 The 525-line system ghost canceling reference signal (A).
The spectrum of the 525-line system GCR (B).

3. One or more pilot subcarriers between 16 and 120 kHz may be used to switch a TV receiver between the stereophonic and monophonic reception modes or to activate a stereophonic audio indicator light, and one or more subcarriers between 15 and 120 kHz may be used for any other authorized purpose; except that stations employing the BTSC system of stereophonic sound transmission and audio processing may transmit a pilot subcarrier at 15,734 Hz \pm 2 Hz. Other methods of multiplex subcarrier or stereophonic aural transmission systems must limit energy at 15,734 Hz \pm 20 Hz, to no more than \pm 0.125 kHz aural carrier deviation.

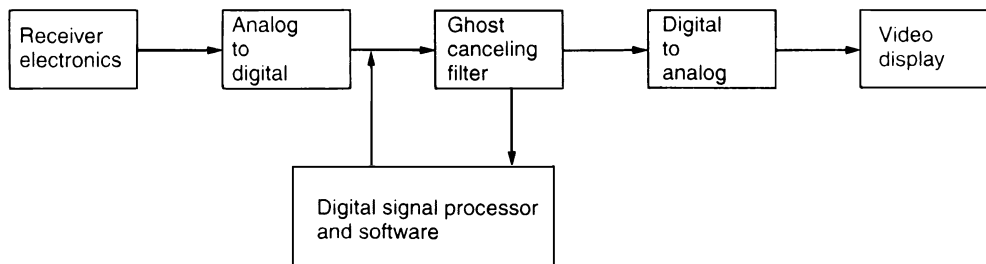

FIGURE 22.1.5 Ghost canceling reference block diagram.

22.18 BROADCAST AND CABLE SYSTEMS

4. Aural baseband information above 120 kHz must be attenuated 40 dB referenced to 25 kHz main channel deviation of the aural carrier.
5. Multiplex subcarrier or stereophonic aural transmission systems must be capable of producing and must not exceed ± 25 kHz main channel deviation of the aural carrier.
6. The arithmetic sum of nonmultiphonic baseband signals between 15 and 120 kHz must not exceed ± 50 kHz deviation of the aural carrier.
7. Total modulation of the aural carrier must not exceed ± 75 kHz.

Aural transmitter performance:

1. Preemphasis should be employed as closely as practicable in accordance with the impedance-frequency characteristics of a series inductance-resistance network having a time constant of $75 \mu\text{s}$.
2. If a limiting or compression amplifier is employed, care should be exercised in its connection in the circuit due to the use of preemphasis in the transmitting system.
3. For the aural transmitter of TV broadcast stations, a frequency deviation of ± 25 kHz is defined as 100 percent modulation (except in the case of BTSC MTS).

BTSC MTS (Stereo)

The Broadcast Television Systems Committee (BTSC) Multichannel Television Sound (MTS) system was developed by the broadcast industry to provide a standardized approach to the addition of aural subcarriers to the television broadcast sound carrier for the purpose of transmitting multiple sound channels. The system provides for stereo, second audio program (SAP), and a professional cueing (PRO) channel. While the FCC has not enacted MTS as an absolute standard, it has promulgated regulations that protect the technical parameters so that the manufacturers, broadcasters, and the public can expect a consistent multichannel television sound service.

The objectives of the BTSC system, which was adopted in 1984, are as follows:

1. Compatibility with existing monophonic television receivers
2. Simultaneous stereo and SAP capability
3. Provision for other professional or station use subcarriers
4. Noise reduction in both the stereo and SAP channels
5. Increased aural carrier deviation to accommodate the new subcarriers

The BTSC MTS baseband spectrum is shown in Fig. 22.1.6.

The BTSC monophonic (L + R sum) channel is identical to the normal non-BTSC baseband aural signal, ensuring compatibility with existing nonstereo television receivers. The stereo subcarrier is very similar to that

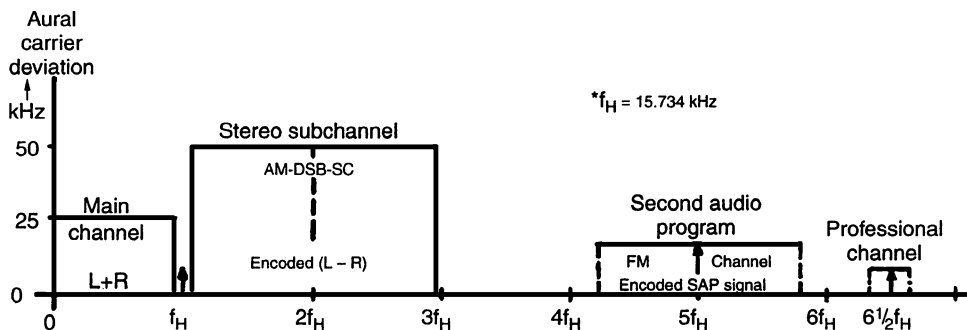

FIGURE 22.1.6 BTSC baseband spectrum.

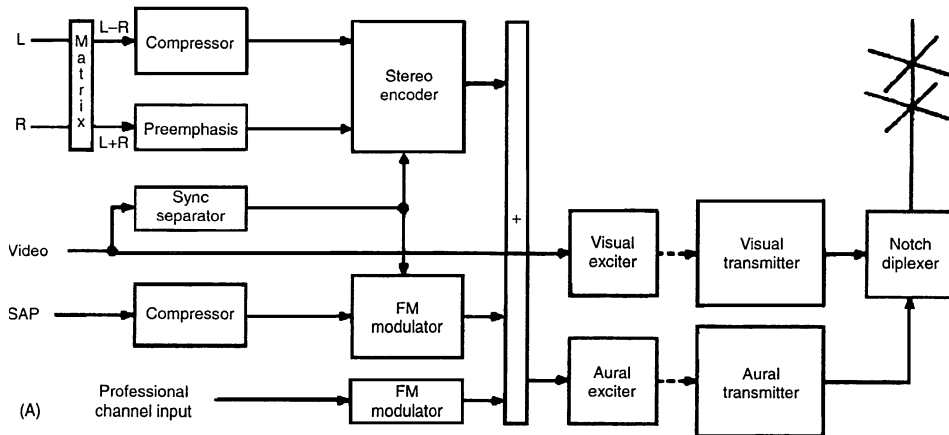

FIGURE 22.1.7 BTSC transmission block diagram.

used in FM broadcasting, except that it operates at a frequency of 31,468 Hz (twice the NTSC horizontal scanning rate of 15,734 Hz, or “H”). This subcarrier is a double-sideband, suppressed-carrier, amplitude modulated signal. An unmodulated pilot signal at 15,734 Hz, derived from the associated video horizontal synchronizing (H), is also transmitted, which is used by the receiver to reinsert, at its second harmonic (2H), the reference carrier for the stereo subcarrier. Special provisions are made in transmitting and receiving equipment to ensure that the H components from the visual signal do not interfere with the H sound pilot. In addition, the BTSC stereo subcarrier is modulated with a difference signal (L-R) that is companded, unlike FM broadcast, to provide improved signal-to-noise performance amidst the noise, multipath distortion, and intercarrier “buzz” often generated by television transmitting and receiving systems. The compander circuits employ a combination of fixed preemphasis, “spectral” compression, and amplitude compression. Expander circuits found in BTSC-compatible receivers restore the proper dynamic range and stereo image while reducing undesirable artifacts of the transmission process.

The Second Audio Program (SAP) channel is located at 5H (78,670 Hz) in the aural baseband. It is frequency modulated with audio, which may or may not be related to the main program. SAP audio is companded using the same system as the stereo subcarrier, which results in fairly good fidelity at the receiver. Typical uses include the simulcasting of a second language version of the main program, aural “captioning” of the main program to benefit the visually impaired, or transmission of other services, such as local weather information.

The remaining BTSC subcarrier is called the Professional (PRO) channel and is centered at 6.5 H (102,271 Hz). It is frequency modulated with a very narrow deviation of only ± 3 kHz. It may be used to transmit voice or data.

A typical BTSC transmission block diagram is shown in Fig. 22.1.7 and a typical BTSC receiver-decoder is shown in Fig. 22.1.8.

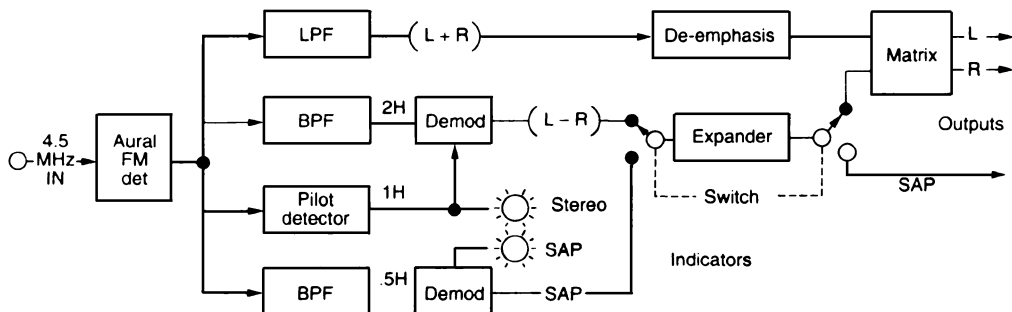

FIGURE 22.1.8 BTSC receiver-decoder block diagram.

22.20 BROADCAST AND CABLE SYSTEMS

Because BTSC specifications are protected, but not mandated, by the FCC, other subcarriers are permitted to be transmitted in the aural baseband between 16 and 120 kHz. The only restriction is that they must not interfere with BTSC or monophonic receiver operation. Amplitude or frequency modulation carrying analog or digital signals may be used.

BTSC stereo has several significant advantages over the simpler FM broadcast stereo system in that there is no “stereo noise penalty,” owing to the use of companding, and there is no required reduction in the allowable deviation of the monophonic signal. The FCC does not require stations transmitting BTSC MTS to meet any particular audio performance standards. Rather, a market-driven approach has been taken. Nevertheless, BTSC MTS is capable of excellent performance.

The most significant impairments to BTSC performance result from crosstalk and incidental carrier pulse modulation (ICPM) in the transmission system. Crosstalk can occur due to nonlinearities in the TV aural exciter, high-power RF amplifier stages, combining networks, or the antenna system. ICPM results from phase modulation of the visual carrier which is independent of the aural carrier. Since most receivers employ intercarrier detection of the sound carrier, ICPM will cause a “buzz” in the sound unless kept to levels below 3° to 5° . Excessive ICPM will show up in the demodulated video as differential phase shift.

ATSC Digital Television Systems

ATSC digital transmission systems definitions are included on the accompanying CD-ROM.

The ATSC Digital Television Standard is intended to provide a system capable of transmitting high-quality video and audio and ancillary data over a single 6-MHz channel. The system is specified to deliver 19.39 Mbps of throughput in a 6-MHz terrestrial broadcasting channel. This means that encoding a high-resolution video source containing about four times as much detail as that of conventional television (NTSC) resolution requires a bit-rate reduction by a factor of up to 50. To achieve this bit-rate reduction, the system is designed to exploit complex video and audio compression technology so that the resultant payload may be transmitted in a standard 6-MHz-wide television channel. The video encoding relies on MPEG-2 compression and audio is encoded using multichannel Dolby AC-3. Figure 22.1.9 depicts a typical ATSC encoder. The resultant transport stream is then randomized and transmitted using 8VSB (8 level, vestigial sideband) modulation. The transport specifications are shown in Table 22.1.2. Figure 22.1.10 shows the basic arrangement of an ATSC decoder. Figures 22.1.11 and 22.1.12 depict block diagrams of an 8VSB transmitter and receiver, respectively.

The objective is to minimize the amount of data required to represent the video image sequence and its associated audio. The goal is to represent the video, audio, and data sources with as few bits as possible while preserving sufficient quality to recreate those sources as accurately as required for the particular application. While the transmission subsystems described in the ATSC Standard are designed specifically for terrestrial transmission, the objective is that the video, audio, and service multiplex/transport subsystems be useful in

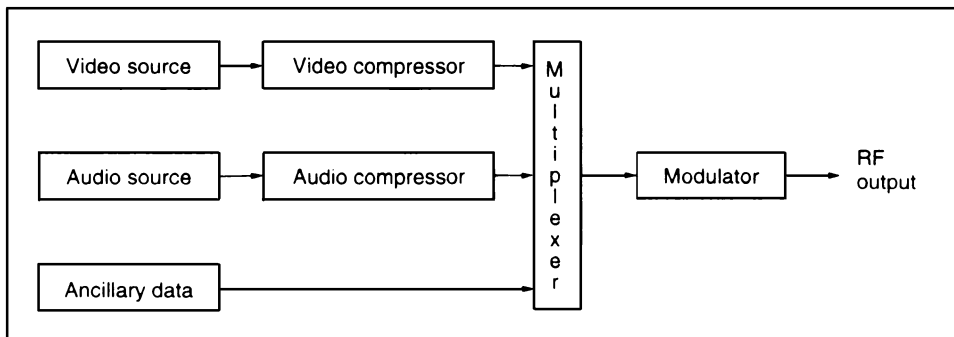

FIGURE 22.1.9 Grand Alliance encoder.

TABLE 22.1.2 ATSC Transmission Specifications

Transmission parameter	Terrestrial mode
Channel bandwidth	6 MHz
Excess bandwidth	11.5 percent
Symbol rate	10.76 Msymbols/s
Bits per symbol	3
Trellis FEC	2/3 rate
Reed-Solomon FEC	(208,188) T = 10
Segmented length	836 symbols
Segmented sync	4 symbols per segment
Frame sync	1 per 313 segments
Payload data rate	19.3 Mbit/s
NTSC co-channel rejection	NTSC rejection filter in receiver
Pilot power contribution	0.3 dB
C/N threshold	14.9 dB

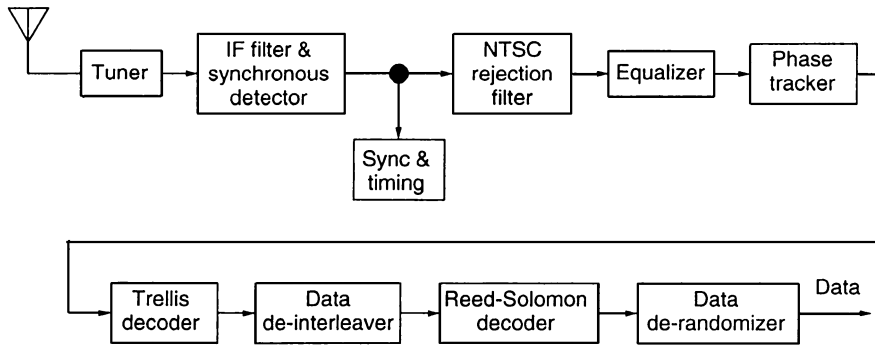

FIGURE 22.1.12 ATSC VSB receiver.

other applications, including those not presently identified. Conditional access provisions are included in the standard, to allow future subscription and data services.

The entire process is so efficient that once the conversion of broadcast television from NTSC analog to ATSC digital is complete, part of the present television spectrum will be reallocated away from broadcast service. UHF television channels 52 to 69 will ultimately be assigned to other nonbroadcast services. While the FCC anticipates that this will occur in 2006, the roll out of ATSC digital television in the United States currently underway is not progressing as fast as originally forecast. Some pundits predict the transition will continue at least through 2015.

Figure 22.1.9 shows a block diagram of the video encoder, while Fig. 22.1.10 shows the corresponding decoder. Figure 22.1.11 shows a block diagram of an ATSC VSB transmitter. Figure 22.1.12 shows a diagram of the ATSC VSB receiver. (See also Table 22.1.3.)

Short Wave Broadcasting

Definitions are given on the accompanying CD-ROM.

Transmission system performance: The construction, installation, and performance of an international broadcasting transmitter system shall be in accordance with good engineering practice.

Spurious emissions must be effectively limited.

1. Any emission appearing on a frequency removed from the carrier frequency by between 6.4 kHz and 10 kHz inclusively, must be attenuated at least 25 dB below the level of the unmodulated carrier.

TABLE 22.1.3 ATSC Transport Specifications

Transport parameter	
Multiplex technique	MPEG-2 systems layer
Packet size	188 bytes
Packet header	4 bytes including sync
Number of services	
Conditional access	Payload scrambled on service basis
Error handling	4-bit continuity counter
Prioritization	1 bit/packet
System multiplex	Multiple program capability described in PSI stream

2. Any emission appearing on a frequency removed from the carrier frequency by more than 10 kHz and up to and including 25 kHz must be attenuated at least 35 dB below the level of the unmodulated carrier.
3. Any emission appearing on a frequency removed from the carrier frequency by more than 25 kHz must be attenuated at least 80 dB below the level of the unmodulated carrier.
4. In the event spurious emissions from an international shortwave broadcasting transmitter cause harmful interference to other stations or services, additional steps may be required to eliminate the interference.

The transmitter must be equipped with automatic frequency control apparatus so designed and constructed that it is capable of maintaining the operating frequency within 0.0015 percent of the assigned frequency.

No international broadcast station will be authorized to install or be licensed for operation of transmitter equipment with a rated carrier power of less than 50 kW.

The percentage of modulation should be maintained as high as possible consistent with good quality of transmission and good broadcast practice. In no case should it exceed 100 percent on positive or negative peaks of frequent recurrence. It also should not be less than 85 percent on peaks of frequency recurrence. The highest allowable modulating frequency is 5 kHz.

BROADCASTING EQUIPMENT

In the following sections, general characteristics and typical examples of some current broadcasting equipment are presented. A brief theory of operation and a block diagram are provided.

Medium Wave AM Transmission Systems

Medium wave transmitters are now generally solid state up to about 10 kW. Higher power transmitters may still employ one or more vacuum tube stages to achieve power levels of 100 kW or more. The maximum power level allowed in the United States is 50 kW, but other jurisdictions may authorize power levels exceeding 1000 kW. Such transmitters are usually fixed-tuned to operate on only one frequency.

Figure 22.1.13 shows a block diagram of a Continental Electronics 419F 250 kW power tube transmitter. This transmitter employs low-level solid-state audio and RF stages which drive an unmodulated intermediate-level tube RF power amplifier (IPA). The output of this IPA then drives a pair of large power amplifier tubes, arranged in the efficient "Doherty" configuration where modulation is applied with a 90° phase shift to the screens. One tube is considered to be the "carrier" tube and contributes most of the unmodulated power output. The other tube is called the "peak" tube and produces no power in the absence of modulation. On 100 percent negative modulation peaks, the carrier tube cuts off, reducing the transmitter output to zero. On 100 percent (or greater) positive peaks, the carrier tube and the peak tube both contribute approximately equal amounts of power. Efficiency of this design exceeds 60 percent.

Figure 22.1.14 shows a block diagram for the Nautel AMPFET 5 W and AMPFET 10 kW solid-state transmitters. They employ a high-efficiency MOSFET pulse width modulation system which collector-modulates MOSFET RF amplifiers operating in class D to achieve an overall transmitter efficiency exceeding 72 percent. The transmitters differ mainly in the number of RF amplifier modules necessary to achieve rated power.

Modern medium wave broadcast stations typically employ one or more vertical radiators operating over a ground system (counterpoise) comprised of multiple copper radials to provide either nondirectional or directional coverage patterns over the service area of interest. Directional arrays, consisting of one or more individual towers, are normally specified to protect the service areas of other stations by producing nulls in the directions to be protected. Antenna towers are normally at least one quarter wavelength in height, though shorter towers may be electrically lengthened by means of capacitive or inductive loading. Towers may be self-supporting or guyed. Each tower normally has an antenna tuning unit at its base, which serves to match the tower's feed point impedance to that of the transmission line. Directional antenna systems will also have a phasing network that delivers power with the appropriate amplitude and phase shift to each tower so as to achieve the desired coverage pattern (Fig. 22.1.15).

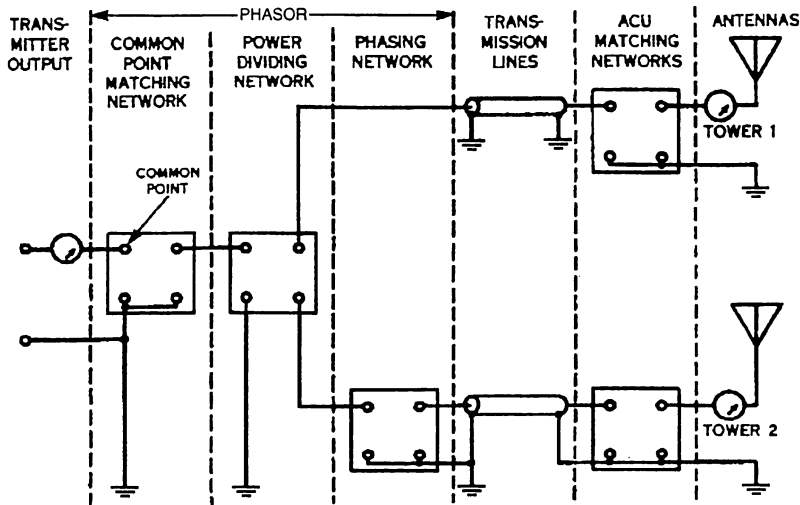

FIGURE 22.1.15 Directional antenna system block diagram.

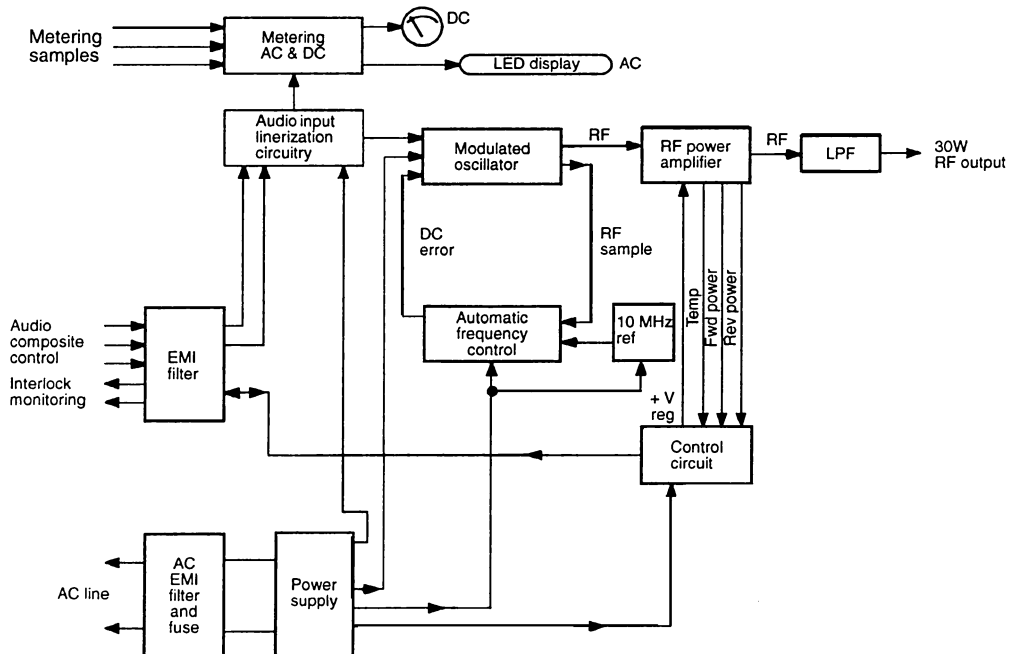

FIGURE 22.1.16 FM exciter.

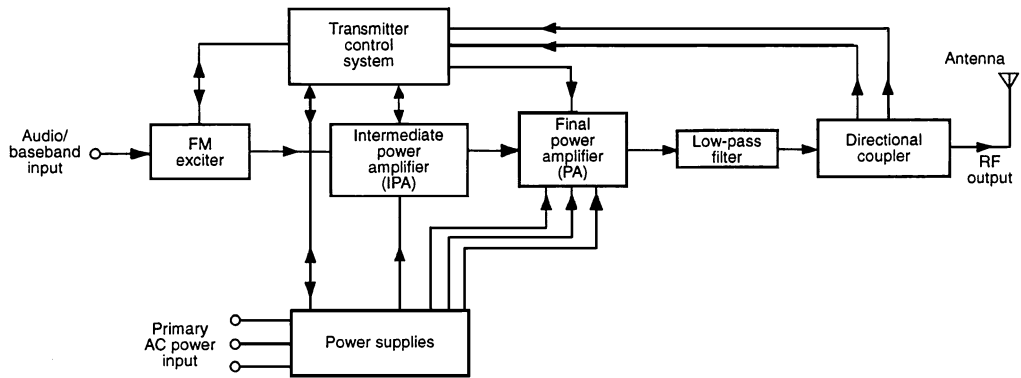

FIGURE 22.1.17 FM amplifier and control circuits.

Wire antennas, such as the flat tops and dipoles used in the early days of medium wave broadcasting, are not favored today, principally because of their high angles of radiation and poor ground wave efficiency. Such characteristics result in inferior local coverage and increased interference to distant stations, especially at night.

Frequency Modulation Transmission Systems

FM transmitters consist of several main components, namely:

1. An exciter, Fig. 22.1.16, which converts the audio baseband to frequency-modulated RF. The exciter determines the key qualities of the transmitted signal. All modern exciters employ direct modulation.
2. Power amplifier stages, Fig. 22.1.17, which boost the output of the exciter to the full rated output of the transmitter. Such stages usually operate class C, a nonlinear though highly efficient mode.
3. Power supplies, which provide the necessary ac and dc voltages to operate the transmitter.
4. Control circuits, Fig. 22.1.17, which allow the transmitter to be turned on and off, the power to be adjusted, and protect the transmitter against damage from overload.
5. Low-pass filtering to suppress undesired harmonic frequencies.

FM broadcast stations may use antennas with either horizontal or circular polarization. The advantage of circular polarization is that twice as much power may be used as compared to the horizontal polarization case, since the FCC allows the vertical component of radiated power to be equal to or less than the horizontal component. Most FM antennas are based on dipole or loop designs. Two or more elements are usually stacked to obtain increased gain at the expense of vertical bandwidth. Since it is possible to make very wide-band antennas relative to the width of a single FM channel, it is common in some areas to combine (or multiplex) several FM stations onto one physical antenna. This is done using large networks of three- or four-port combiners.

Analog NTSC Television Transmission Systems

Modern VHF Television transmitters are solid state at all power levels to 60 kW and more. Reliability and performance have been enhanced by the elimination of heat-producing tubes and high voltage in the amplifier stages of the transmitter. Instead, large amounts of RF power are produced by combining many

TABLE 22.1.4 Typical Solid-State VHF Transmitter Specifications

VISUAL	
Type of emission	5M45C3F
Frequency range (channels 2 to 6)	54 to 88 MHz

smaller stages, each of which operates on low voltage and comparatively high current. The Larcan 30-kW transmitter shown in Fig. 22.1.18 is typical. The transmitter has been designed to operate conservatively at 30 kW peak sync visual power and 3 kW average aural power.

Typical solid-state VHF transmitter specifications are given in Table 22.1.4.

Ruggedly constructed, this transmitter is modular in format. Many of the modules are standard, thereby providing a very high degree of commonality in systems using transmitters of various power ratings and frequencies. The simplicity of design and use of standard, readily available components enhances serviceability.

All important parameters are monitored and can be displayed on the meters built into the exciter and amplifier. This equipment is suitable for automatic or remote-control operation.

The exciter-modulator provides a fully processed, precorrected, on-channel signal. Low-level IF modulation and surface acoustic wave (SAW) filter technology are employed to ensure superior color performance and simplicity of operation.

The exciter (model TEC-3V) is modular in construction and BTSC stereo compatible. In addition to the normal audio input, the exciter also has two wideband inputs to accept the signals from stereo, separate audio program (SAP), and pro-channel generators. A built-in incidental carrier phase modulation (ICPM) corrector ensures optimum performance when transmitting multichannel sound or teletext. All routine on-air adjustments are screwdriver adjustable from the front panel, with an extender module provided for servicing and more extensive adjustments. The precorrection circuits, aural preemphasis, and SAW filters can be switched out of circuit by front panel locking-type toggle switches. These circuits are all unity-gain, thus no level adjustments are required when switching in and out of circuit. Each IF and RF module has a BNC test point located on the front panel. These test points are fed from a directional coupler at the module output, and have no effect on the module output when connected to a 50- Ω load.

The visual output of the exciter is fed to four broadband solid-state 9 kW amplifiers that require no tuning or adjustment. All of the modules in each amplifier are operated well below their maximum ratings.

It can be seen from the RF flow diagram that there are four stages of amplification. The preamplification stages are high gain, broadband, thin-film integrated circuit amplifiers operating class A. The IPA stages also operate class A and consist of two transistors whose outputs are combined by 3-dB quadrature couplers. The driver stage consists of two amplifiers operating class A, again with their outputs combined by a 3-dB quadrature coupler. Each device is a pair of push-pull FETs in a single case.

The four visual final stages each consist of six modules whose outputs are combined in a six-way stripline combiner. This method of combining provides excellent isolation between modules and the failure of one or more modules will not affect the performance or reliability of the others. To combine the four final stages, 3-dB couplers are used with the output fed to an external diplexer. Each output module has AGC control, VSWR protection, and a test jack for monitoring purposes. The aural chain of the transmitter operates in a similar manner.

The control circuitry in this transmitter is extremely simple because no interlocking or sequential starting of power supplies is required. The transmitter is basically built as two parallel halves; i.e., amplifiers 1-1A and 1-1B, complete with their own power supplies and protection circuits, can be operated independently or together with amplifiers 1-2A and 1-2B. The transmitter control panel, situated below the visual and aural IPA units in cabinet 2, enables single or joint control to be made.

All control, status, and telemetry signals are brought out on a 25-pin D connector.

For UHF broadcasters, transmitters have been the subject of ongoing development work ever since the inception of UHF stations in the 1950s. When the UHF band was initially allocated for television service, most stations signed on-the-air with lower power tetrode and traveling wave tube transmitters. Later, klystrons were developed that allowed generation of much higher power at UHF frequencies. Klystrons have the advantage of no delicate grid or large anode structure, while providing extremely high gain. The problem was, as stations increased power with klystrons, very complex and expensive transmitters were required. Power efficiency, while better than a tetrode, was fairly low. In the late 1970s, as oil prices rose and cost of energy became an important factor, stations began to employ klystron pulsers, which boosted efficiency somewhat, to cut their electrical usage. At the same time, many development projects were undertaken to improve the klystron's fundamental efficiency. The MSDC (multistage, depressed collector) klystron was one result. By using multiple collectors, operating at graduated voltages, more electrons could be collected and efficiency increased. Sometime later, tube manufacturer Eimac developed a new type of gridded klystron, which they called a *Klystrode inductive output tube* (IOT). The IOT achieved even better efficiency than the MSDC klystron without the complication of multiple high-voltage power supplies. Almost all modern high-power UHF transmitters employ IOT power amplifiers.

Figure 22.1.19 shows the block diagram of a typical UHF transmitter. Table 22.1.5 gives typical UHF TV transmitter characteristics.

Antenna designs vary depending on whether the intended use is VHF or UHF television. It is generally not possible to use one antenna to cover both UHF and VHF bands, nor even to cover the entirety of any one band with a single antenna. Antennas for television broadcast usually provide an omnidirectional antenna pattern, but directional antennas are sometimes employed at UHF stations.

VHF antennas will use designs similar to those shown in Fig. 22.1.20. Antennas similar to those shown in Fig. 22.1.21 are often used in UHF applications.

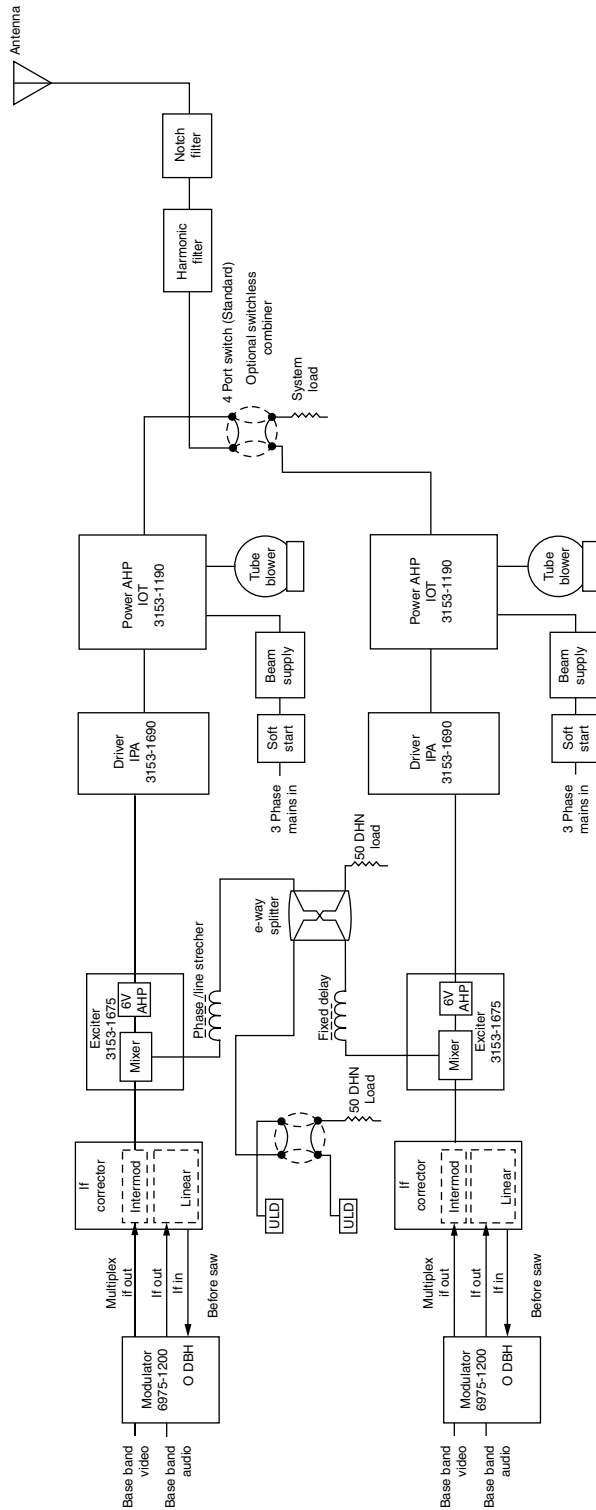

FIGURE 22.1.19 Larcan/TTC redundant UHF transmitter.

TABLE 22.1.5 Typical UHF TV Transmitter Characteristics

Vision performance	Sound performance
Frequency range: 470–806 MHz	Intercarrier (+4.5 MHz)
Output impedance: 50 or 75 Ω	Frequency stability: ± 15 Hz, phase locked to video line
Video output: 75 Ω , 36 dB return loss	Monaural input: 600 Ω , balanced
Sideband response: –3.58 MHz –42 dB or better –1.25 MHz and below –20 dB or better Carrier to –0.5 MHz +0.5 dB, –1.0 dB Carrier to +4.0 MHz ± 0.5 dB +4.00 to +4.18 MHz +0.5 dB, –2.0 dB +4.75 MHz and above –40 dB or better	Broadband input (2): 75 Ω , unbalanced
Variation in response with brightness: ± 0.75 dB	Monaural performance (± 25 kHz deviation) Frequency response: ± 0.5 dB, 50 Hz to 15 kHz Preemphasis: 75 μ S or flat
Frequency stability: ± 250 Hz (maximum—30 days)	Distortion (with deemphasis): 0.5%
Modulation capability: 100%	FM noise: –60 dB
Differential gain: 0.5 dB	AM noise: –55 dB
Differential phase: 3°	AM synchronous noise: –40 dB
Low frequency nonlinearity: 1.0 dB	Stereo performance Frequency response: ± 0.5 dB, 50 Hz to 120 KHz
Envelope delay: 0.2–2.0 MHz ± 40 nS 3.58 MHz ± 30 nS 4.18 MHz ± 60 nS	FM noise: –70 dB, ± 75 KHz reference
Regulation of output: 3%	Distortion (THD): 0.5%
Variation of output: 2%	Distortion (IMD): 0.5%
AM noise (RMS): –55 dB	Stereo separation (equivalent mode): 40 dB
K-factors: 2T—2% 12.5T—3%	BTSC pilot protection: –45 dB or better
Spurious and harmonics: –60 dB	(<i>Note:</i> Patent pending noise reduction circuit required in common amplification systems.)
Incidental carrier phase modulation: $\pm 1.5^\circ$	General performance Operating ambient temperature: 0 to 50°C
Common amplification applications in band intermodulation: –60 dB	Altitude: Sea level to 7,500 FT: Consult factor for other altitudes.
Stereo pilot carrier protection: Full compliance with FCC specification 73.682(c)(3)	Relative humidity: 0 to 95% noncondensing

ATSC Digital Television Transmission Systems

Digital television transmitters are similar to combined-amplification analog transmitters, except that the modulator/exciter accepts a single 19.39 Mbps digital bit stream, usually via a SMPTE 310 interface. The following stages of amplification are tuned to pass the 6-MHz wide, broadband noise-like spectrum of the ATSC 8VSB-modulated signal. Following the final stage(s) of amplification, a constant-impedance mask filter is normally employed to provide the stringent band-edge rejection levels required by the FCC Rules.

Digital television transmitters are typically rated by average power, instead of the peak power ratings normally ascribed to analog transmitters. Solid-state ATSC transmitters on either VHF or UHF channels may achieve power levels of up to 30 kW. UHF digital stations may require higher transmitter output power levels, up to 100 kW or more, which may currently only be economically produced by IOT transmitters, in the same manner as is done for high-power NTSC UHF transmitters. Such transmitters are typically assembled from multiple IOT amplifiers, each producing up to 25 kW of average digital power, which are electrically connected by “magic tee” combiners. Figure 22.1.22 shows a block diagram of the Harris CD3200P2 two-IOT ATSC digital transmitter, capable of 42 kW average power.

The broadband nature of the ATSC signal means that the venerable klystron, still used in some analog UHF television transmitters, is not suitable because of its relatively narrow bandwidth capability. However, that same broadband characteristic has enabled tube manufacturers to apply the multistage depressed-collector (MSDC) technology, originally developed around the klystron, to the IOT. This technology, which consists of multiple electron collectors operating at progressively lower beam voltages, results in a substantial increase in the efficiency of the conventional IOT. Figure 22.1.23 shows the internal structure of a typical MSDC IOT manufactured by L-3 communications.

CHAPTER 22.2

AM AND FM BROADCAST RECEIVERS

Lee H. Hoke, Jr.

AM RECEIVERS: GENERAL CONSIDERATIONS

AM broadcast receivers are designed to receive amplitude-modulated signals between 530 and 1700 kHz (566 to 177 m wavelength), with channel assignments spaced 10 kHz. To enhance ground-wave propagation the radiated signals are transmitted with the electric field vertically polarized.

AM broadcast transmitters are classified, according to the input power supplied to the power amplifier, from a few hundred watts up to 50 kW. The operating range of the ground-wave signal, in areas where the ground conductivity is high, is up to 200 mi for 50-kW transmitters. During the day the operating range is limited to the ground-wave coverage. At night, refraction of the radiated waves by the ionosphere causes the waves to be channeled between the ionosphere and the earth, resulting in sporadic coverage over many thousands of miles. The nighttime interference levels thus produced impose a restriction on the number of operating channels that can be used at night.

The signal-selection system is required to have a constant bandwidth (approximately 10 kHz), continuously adjustable over a 3:1 range of carrier frequencies. The difficulty of designing cascaded tuned rf amplifiers of this type has resulted in the universal use of the superheterodyne principle in broadcast receivers.

A block diagram of a typical design is shown in Fig. 22.2.1. In this figure the signal is supplied by a vertical monopole (whip) antenna in automobile radio receivers or by a ferrite-rod loop antenna in portable and console receivers. An rf amplifier is used in most automobile designs but not in small portable models.

In some receivers the local oscillator is combined with the mixer, which simplifies the rf portion of the receiver. An intermediate frequency of 455 kHz is used in portable and console receivers, while 262.5 kHz is common in automobile radio designs. Diode detectors have been used in discrete component designs for detection of the i.f. signal. Push-pull class B audio-power amplifiers are used to minimize current drain. A moving coil permanent-magnet speaker is used as the output transducer.

A potential major improvement in AM radio sound quality occurred in 1990 with the adoption of the *Amax* voluntary standard by the National Radio Systems Committee (NRSC)¹ and implementation by most radio stations. This standard established a receiver audio frequency response of not less than 50 to 7500 Hz, with limits of +1.5 dB, -3.0 dB referenced to 0 dB at 400 Hz. The receiver shall have less than 2 percent total harmonic distortion plus noise (THD+N) and shall have a deemphasis curve that complements the preemphasis now added to the AM broadcast modulation. Attenuation at the 10-kHz adjacent frequencies shall be at least 20 dB. In addition, the receiver must be equipped with a noise blanker circuit (impulse noise suppressor) and have means for connecting an external antenna. To many listeners, AM and AM-stereo receivers designed to these specifications gave performance rivaling FM receivers of equivalent class in tests conducted at the 1992 NAB convention.

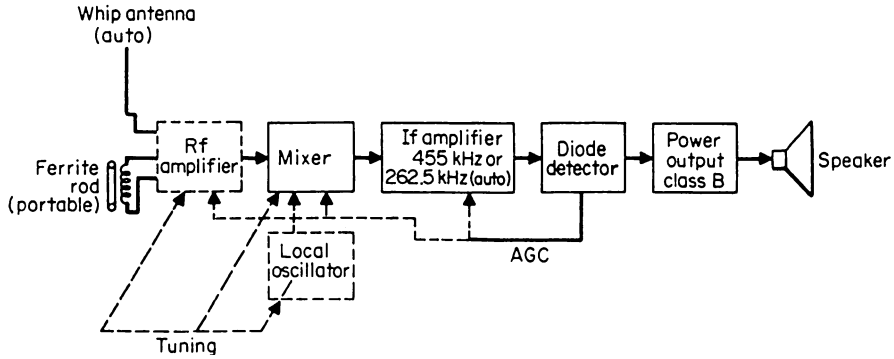

FIGURE 22.2.1 Block diagram typical of AM receivers.

Design Categories

AM receiver designs currently fall into three categories:

Portable Battery-Powered Receivers without External Power Supply. These units vary in size from small pocket radios operating on penlite cells to larger hand-carried units using D cells for power. The power output in the larger portable units is about 250 mW.

Console and Component Type AM Receivers Powered by the Power Line. These units are usually a part of an AM-FM receiver, with high audio-power output capability. The power output ranges from several watts to more than 100 W. Most audio systems use push-pull class B operation. Most such systems are equipped with two amplifier systems for FM stereo operation.

Automotive Receivers Operated on the 12-V Battery-Generator System of the Automobile. The primary current used in transistorized receivers usually does not exceed 1 A. Because of operation in the high ambient noise of the vehicle, the power output is relatively high (2 to 20 W).

Sensitivity and Service Areas

The required sensitivity is governed by the expected operating field strengths. Typical field strengths for primary (ground-wave) and secondary (sky-wave) service are as follows:

Field strength, mV/m	
Primary service:	
Central urban areas (factory areas)	10–50
Residential urban areas	2–10
Rural areas	0.1–1.0
Secondary service	Areas where sky-wave signals > 0.5 mV/m at least 50 percent of the time

Co-channel protection is provided for signals exceeding 0.5 mV/m. The receiver sensitivity and antenna system should be adjusted to provide usable outputs with signals of the order of 0.1 mV/m if the receiver is to be used over the maximum coverage area of the transmitter.

The required circuit sensitivity is controlled by the efficiency of the antenna system. A car-radio receiver vertical antenna is adjustable to about 1 m in length. Since the shortest wavelengths are of the order of 200 m, the antenna can be treated as a nonresonant short-capacitive antenna. The open-circuit voltage of such a short monopole antenna is

$$E_a = 0.5l_{\text{eff}}E_f \quad \text{mV}$$

where l_{eff} is the effective length of antenna (m) and E_f is the field strength (mV/m).

The radiation resistance of the short monopole is small compared with the circuit resistance of the receiver input circuit, but the antenna is not matched to the input impedance since matching is not critical, adequate antenna voltage being available at the minimum field strength (0.1 mV/m) needed to override noise. The car-radio antenna is coupled to the receiver by shielded cable. This, with the receiver input capacitance, forms a capacitive divider, reducing the antenna voltage applied to the receiver. To ensure adequate operation the receiver should offer 20 dB signal-to-noise ratio when 10 to 15 μV is applied to the input terminals.

Portable and console receivers use much shorter built-in antennas, usually horizontally polarized coils wound on ferrite rods. The magnetic antenna can be shielded from electric field interference. Although the effective length of a ferrite rod is shorter than that of a whip antenna, the higher Q of the ferrite rod and coil could provide approximately the same voltage to the receiver. The unloaded Q of a typical ferrite-rod antenna coil is of the order of 200. The voltage at the terminals of the antenna coils is QE_a .

Selectivity

Channels are assigned in the broadcast band at intervals of 10 kHz, but adjacent channels are not assigned in the same service area. In superheterodyne receivers, selectivity is required not only against interference from adjacent channels but also to protect against image and direct i.f. signal interference.

FIGURE 22.2.2 Typical selectivity curve of an AM receiver using a ferrite-rod antenna without rf amplifier.

Figure 22.2.2 shows the overall response of a typical portable receiver using a ferrite rod without an rf amplifier.

The primary adjacent-channel selectivity is provided by the i.f. stages, whereas image and direct i.f. selectivity must be provided by the rf circuits. In receivers using a ferrite-rod antenna and no rf stage, the rf selectivity is provided by the antenna. High Q in the antenna coil thus not only provides adequate signal to override the mixer noise but also protects against image and i.f. interference. With a Q of 200 the image rejection at 1400 kHz is about 40 dB, while the direct i.f. rejection at 600 kHz is about 24 dB. With an rf stage added, the image rejection is about 50 dB and the i.f. rejection about 46 dB.

Since car-radio receivers are subjected to an extreme dynamic range of signal levels, the selectivity must be slightly greater to accommodate strong signal conditions. The image rejection at 1400 kHz is typically 58 dB in spite of the lower i.f. frequency; the i.f. rejection is typically 50 dB, and the adjacent-channel selectivity is about 20 dB.

High-Signal Interference

When strong signals are present, the distortion in the rf and i.f. amplification stages can generate additional interfering signals. The transfer characteristic of an amplifier system can be expressed in a power series as

$$E_{\text{out}} = G_1 E_{\text{in}} + G_2(E_{\text{in}})^2 + G_3(E_{\text{in}})^3 + \cdots + G_n(E_{\text{in}})^n$$

where E_{out} = output voltage

E_{in} = input voltage (same units)

G_1, G_2, \dots, G_n = voltage gains of successive amplifier stages

22.40 BROADCAST AND CABLE SYSTEMS

When the input signal consists of two or more modulated rf signals, E_{in} becomes

$$E_{in} = e_1 \cos \omega_1 t + e_2 \cos \omega_2 t$$

where

$$e_1 = E_1[1 + Ea_1(t)/E_1], \quad e_2 = E_2[1 + Ea_2(t)/E_2]$$

where E_1 = signal 1 carrier

E_2 = signal 2 carrier

$Ea_1(t)$ = audio modulation first signal

$Ea_2(t)$ = audio modulation second signal

I.F. Beat. When two strong signals are applied to the amplifier with carrier frequencies separated by a difference equal to the intermediate frequency, a difference-frequency signal appears, which is independent of the local oscillator frequency. Because of the wide frequency spacing, interference of this kind can take place only in the mixer or rf amplifier and only with strong signals (signal strengths of several volts per meter). These signals are derived from the G_2 term:

$$E_{i.f.beat} = G_2 e_1 e_2 \cos (\omega_1 - \omega_2)t$$

where $e_1 e_2$ and $\omega_1 \omega_2$ are the respective amplitude and angular frequencies.

Cross Modulation. When a strong interfering signal is present, the modulation on the interfering signal can be transferred to the desired signal by third-order distortion components. This type of interference does not occur at a critical frequency of the interfering signal, provided that it is close enough to the desired signal frequency not to be attenuated by the selectivity of the receiver. This type of distortion can take place in the rf, mixer, or i.f. stages of the receiver. These signals are derived from the G_3 terms:

$$E_{crossmod} = G_3 (e_2)^2 e_1 / 4 \cos \omega_1 t$$

The cross modulation is proportional to the square of the strength e_2 of the interfering signal.

Intermodulation. Another type of interference due to third-order distortion is caused by two interfering carriers. When these signals are so spaced from the desired signal that the first signal is arbitrarily spaced by Δf and the second signal is $2\Delta f$, third-order distortion can create a signal on the desired carrier frequency. These signals are derived from the G_3 terms:

$$E_{intermod} = G_3 e_1^2 e_2 / 4 \cos (2\omega_1 - \omega_2)t$$

The interference is proportional to the square of the amplitude of the closer carrier times the amplitude of the farther carrier. Intermodulation is sometimes masked by cross modulation; it occurs only when the e_2 signal is stronger than the desired carrier after attenuation by the rf selectivity of the receiver.

Harmonic Distortion. Harmonic-distortion interference usually arises from harmonics generated by the detector following the i.f. amplifier, which radiated back to the tuner input.

Choice of Intermediate Frequency

Two intermediate frequencies are used in broadcast receivers: 455 kHz and 262.5 kHz. The 455-kHz i.f. has an image at 1450 kHz when the receiver is tuned to 540 kHz, thus allowing good image rejection with simple selective circuits in the rf stage. At 540 kHz the selectivity must be sufficient to prevent i.f. feedthrough since the receiver is particularly sensitive at i.f. frequencies because converter circuits typically have higher gain at

i.f. than at the converted carrier frequency. The choice of the higher i.f. frequency also makes i.f. beat interference less likely. The second harmonic falls at 910 kHz and the third harmonic at 1365 kHz.

The 262.5 kHz i.f. has a lower limit of image frequency at 1065 kHz, which requires somewhat more rf selectivity than is needed when the higher i.f. is used. The second harmonic of the 262.5-kHz frequency falls below the broadcast band (at 525 kHz) and hence does not interfere. On the other hand, there are more higher-order responses in the passband (787.5, 1050, 1312.5, and 1575 kHz). Sensitivity to i.f. feedthrough when the receiver is tuned to 540 kHz is greatly reduced by the use of the lower i.f. frequency.

Circuit Implementation

Although hobbyists still build AM broadcast receivers using multiple stages of discrete components as described in previous editions of this handbook, all present-day commercially built receivers are designed with ICs which require only a handful of additional components to complete their function. Figure 22.2.3 shows one such implementation with its associated peripheral components.

This circuit is intended for shirt-pocket use and drives audio earphones.^{2,3} In other applications, a simple mono audio amplifier IC can be added to provide table-top or clock-radio application. The design follows the classic superheterodyne block diagram of mixer, oscillator, intermediate frequency amplifier, detector, and audio amplifier. In designs intended for automotive radio, an RF amplifier stage precedes the mixer and a much higher power amplifier is included. Station selection is provided by an RF L-C tank circuit and an oscillator L-C tank circuit.

Differential amplifiers, in single or multiple dc-coupled stages, are generally used for rf and i.f. amplification. This configuration gives excellent high-frequency stability, extremely low distortion (low generation of both cross-modulation and intermodulation spurious responses), and has wide AGC range capability (typically 30-dB gain reduction for a single stage, 55 dB for a dual stage).

Double-balanced mixers are typically used to achieve a high degree of isolation between the rf and local oscillator and between the local oscillator and i.f. In some applications the rf stage can be dc-coupled to the mixer with no need for an interstage frequency-selection network. When compared to classical single transistor mixer, the spurious response level of a double-balanced mixer is considerably lower, thereby reducing the stop-band filter requirement.

The *local oscillator* typically employs internal control circuitry to stabilize the amplitude of the waveform and maintain low distortion. This is particularly important in varactor-diode tuning applications where a change in amplitude will tend to shift the bias voltage of the oscillator tank circuit, thereby causing mistracking with the other varactor-tuned circuits.

Selectivity is achieved more often by the use of the block filter-block gain configuration rather than the conventional distributed filter, cascade stage design approach. Mechanically vibrating elements can be designed with Q 's much higher than electric circuits. Piezoelectric vibrator plates made of quartz or (for low and medium frequencies) barium titanate form the equivalent of a high- Q coil-and-capacitor combination which can be used singly or in combination to form i.f. filters with steep band-edge selectivity characteristics. The piezoelectric vibrator converts energy from electric to mechanical and back to electric with relatively little loss.

Barium titanate resonators have been used in some broadcast receiver designs. While they have the advantage of small size (at 455 kHz), the disadvantage is the numerous spurious responses caused by multiple modes of vibration. Hence those resonators must be used in combination with coils and capacitors to suppress the spurious responses. Three configurations of block filter networks are shown in Fig. 22.2.4. The main frequency selection element is the piezoelectric ceramic filter.⁴

Both single-ended and full-wave balanced *envelope detectors* are used, depending on the intended application. The full-wave detector produces a lower level of distortion in the recovered audio over a very wide range, including lower absolute level, of input carrier levels.

An *AGC amplifier* provides a control voltage to the i.f. and rf stages. This voltage is proportional to the carrier amplitude. Second-order filtering is often incorporated to reduce audio distortion, even at low audio frequencies, and to give fast settling time which is advantageous with electronic tuning systems when operated in the "station search" mode.

Some IC designs contain an *audio preamplifier* that provides additional filtering to remove residual carrier from the audio signal. Preamplifier output levels are typically 0.25 to 0.3 V for a 30 percent modulated medium-level carrier input to the i.f.

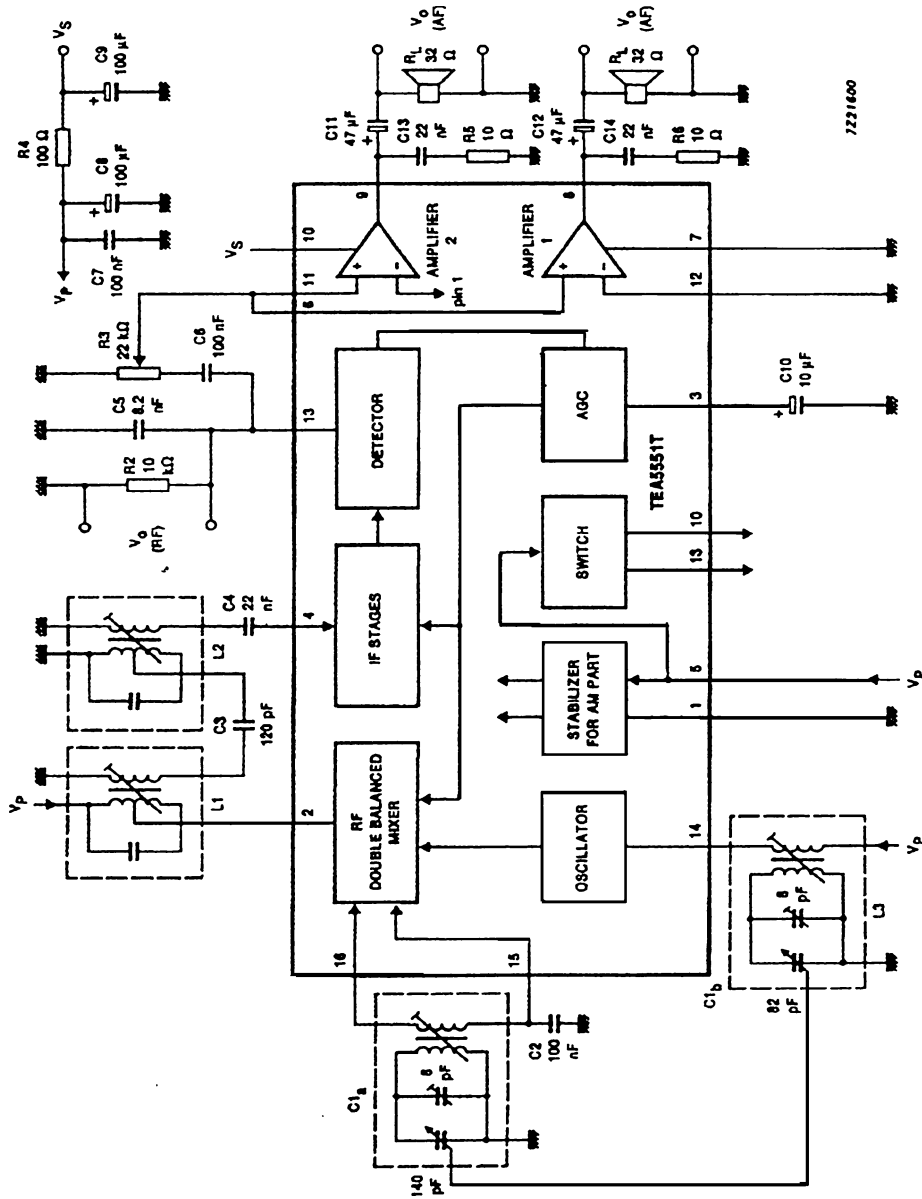

FIGURE 22.2.3 Typical AM receiver integrated circuit. (From Philips Semiconductor)

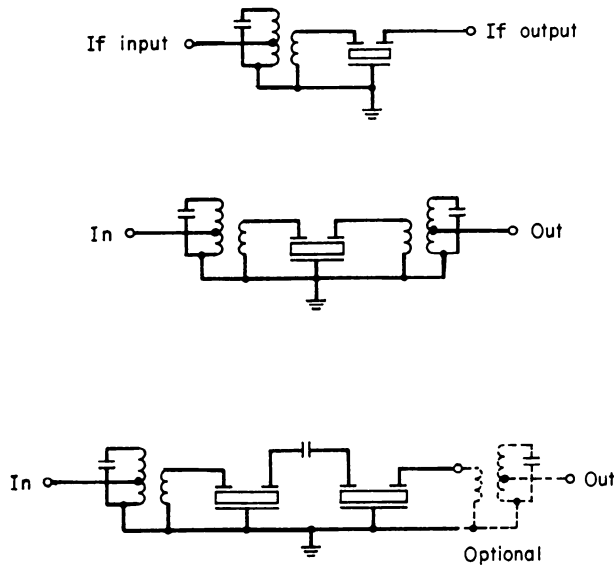

FIGURE 22.2.4 Three configurations of i.f. block filter networks.

IC *audio power amplifiers* fall into four major categories. Both monaural and two-channel (stereo) versions are available in each category.

1. Fifty to 500 mW, 1.5 to 9 V supply, intended for personal applications with 1.5- to 2-in. loudspeaker or earphone.
2. One-half to 2 W for table model, power-line-connected applications.
3. Two to 20 W, 12 to 16 V supply, for car radios.
4. Ten to 100 W for high-fidelity systems. The higher-powered designs in this category are typically a hybrid of IC's mounted on a ceramic thick-film substrate.

AM Stereo

In March 1982, after many months of testing and evaluation by the National AM Stereo Radio Committee, the FCC ruled that it could not select a single system for AM stereo and therefore made a “free marketplace” ruling. Of the five systems under consideration at that time, three were put into operation throughout the United States. These were

1. Compatible quadrature amplitude modulation (C-QUAM)
2. Amplitude and phase modulation (AM/PM)
3. Independent sideband modulation (ISB)

By 1993, the C-QUAM system was recognized as the overwhelming marketplace leader and was given full endorsement by the FCC.

QUAM can be thought of as the addition of two carriers having the same frequency in phase quadrature (separated by 90°), one being modulated by the left audio signal (L), the other by the right audio signal (R). In practice, this is achieved by amplitude-modulating a single carrier with the sum of L and R , and deviating the carrier phase according to a function made up of the sum of quadrature sidebands of $L + R$ and $L - R$. At the transmitter a correction factor is added to have the envelope truly represent $L + R$ and therefore maintain compatibility (low distortion in recovered audio) with existing monophonic AM receivers (C-QUAM).⁵ Stereo identification is provided by a 25-Hz tone phase-modulating the carrier.

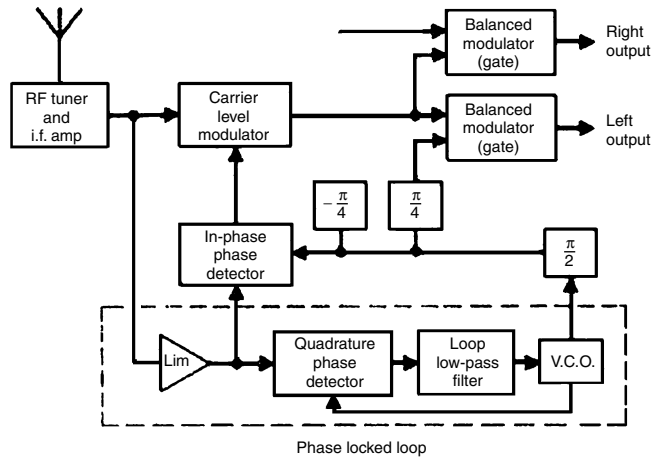

FIGURE 22.2.5 Block diagram of a C-QUAM AM-stereo receiver. (From Parker et al., Ref. 6)

The block diagram of a stereo receiver designed to receive C-QUAM is shown in Fig. 22.2.5. The PLL is locked to the carrier frequency and supplies the cw reference for demodulation. The complementary correction to transform the C-QUAM signal to QUAM is performed by multiplying the carrier in the receiver by a function of the angle between the transmitted sidebands. Recovery of the L and R audio signals is accomplished by conventional quadrature demodulation. The receiver front end must be designed to a higher-quality level than that of a conventional monophonic AM receiver. Since phase components of the signal are now important, the local oscillator noise and tuning system flutter must be kept to a minimum.⁶ Incidental carrier phase modulation (ICPM) caused by tuned circuit misalignment must also be minimized.

FM BROADCAST RECEIVERS: GENERAL CONSIDERATIONS

Broadcast FM receivers are designed to receive signals between 88 and 108 MHz (3.5 to 2.8 m wavelength). The broadcast carrier is frequency-modulated with audio signals up to 15 kHz, and the channel assignments are spaced 200 kHz. The FM band is primarily intended to provide a relatively noise-free radio service with wide-range audio capability for the transmission of high-quality music and speech. The service range in the FM band is generally less than that obtainable in the AM band, especially when sky-wave signals are relied on for extending the AM coverage area.

VHF signals are limited to usable service ranges of less than 70 mi. Since sky-wave signals do not materially affect the transmission of FM signals, there is no equivalent night effect and licenses are not limited to daylight hours only, as with many AM operations. In the past, all FM signals in the United States were horizontally polarized. However, the rules have been changed to allow maximum power to be radiated in both the horizontal and vertical planes.

Unlike AM broadcasting, where the station power is measured by the power supplied to the highest-power rf stage, FM transmitters are rated in *effective radiated power* (ERP), i.e., the power radiated in the direction of maximum power gain. This method of power measurement is used since the transmitting antenna has significant power gain, resulting in an ERP many times the input power supplied to the rf output stage of the transmitter.

Although FM receivers have been principally used in high-fidelity audio installations, more recently small pocket-sized FM receivers have been designed with limited audio-output capabilities. Also, an increasing number of FM receivers are being included in automobile installations.

In 1960 the FCC amended the broadcast rules to allow the transmission of stereophonic signals on FM stations. This transmission is equivalent to the transmission of two audio signals, each having 15 kHz bandwidth, transmitted on the same carrier as used for monophonic FM signals. Since the FM signal was initially designed to have sufficient additional bandwidth to achieve improved signal-to-noise ratio at the receiver, there is room to multiplex the second component of the stereophonic signal with no increase in the radiated bandwidth. However, the signal-to-noise ratio is reduced when the multiplexing technique is employed.

Sensitivity

The field strength for satisfactory FM reception in urban and factory areas is about 1 mV/m. For rural areas, 50 $\mu\text{V/m}$ is adequate signal strength. These signal levels are considerably lower than the equivalent levels for AM reception in the standard broadcast bands. These effects make satisfactory reception with these lower signal levels possible: (1) the effects of lightning and atmospheric interference (static) are negligible at 100 MHz, compared with the interference levels typical of the standard broadcast band; (2) the antenna system at 100 MHz can be matched to the radio-receiver input impedance, providing more efficient coupling between the signal power incident on the antenna and receiver, and (3) the use of the wide-band FM method of modulation reduces the effects of noise and interference on the audio output of the receiver.

The open-circuit voltage of a dipole for any length up to one-half wavelength is given by

$$E_{oc} = E_f (5.59 \sqrt{R_r}) / F_s \quad \text{mV}$$

where E_{oc} = open-circuit antenna voltage

E_f = field strength at antenna (mV/m)

F_s = received signal frequency (MHz)

R_r = antenna radiation resistance (Ω)

For a half-wave dipole $R_r = 72 \Omega$; for a folded dipole R_r is 300 Ω . For antennas substantially shorter than one-half wavelength, $R_r = 8.75l^2F_s^2 \times 10^{-3}$, where l is the total length of the dipole in meters. For a folded dipole one-half wavelength long operating at 100 MHz, the open-circuit voltage is $E_{oc} = 0.97E_f$. The voltage delivered to a matched transmission and receiver input is one-half of this value, $0.48E_f$.

The noise in the receiver output is caused by the antenna noise plus the equivalent thermal noise at the receiver input. The input impedance generates an excess of noise compared with the noise generated by an equivalent resistor at room temperature. The noise generated is given by

$$E_{nr} = E_n \sqrt{2NF - 1} \quad \text{V}$$

where E_{nr} = equivalent noise generated in receiver input

E_n = equivalent thermal noise (V) = $(\sqrt{4R_{in}kT\Delta f})$

R_{in} = receiver input resistance

k = Boltzmann's constant = 1.38×10^{-23} J/K

T = absolute temperature = 290 K

Δf = half-power bandwidth of receiver response taken at discriminator

NF = receiver noise figure. (If the noise figure is given in decibels, $NF_{dB} = 10 \log NF$.)

The generator noise and receiver noise add as the square root of the sum of the squares. Figure 22.2.6 shows that the equivalent receiver input noise is $0.707E_n\sqrt{NF}$. For a receiver with 300- Ω input resistance and 200-kHz noise bandwidth, $E_n = 0.984 \mu\text{V}$. A typical noise factor for a well-designed receiver is 3 dB, or two times power ($\sqrt{2}$ voltage) increase, giving an equivalent noise input of $1.39 \mu\text{V}$.

In an AM receiver the signal-to-noise (S/N) ratio at the receiver input is a direct measure of the S/N ratio to be expected in the audio output. In an FM receiver using frequency deviation greater than the audio frequencies transmitted, the S/N ratio in the output may greatly exceed that at the rf input. Figure 22.2.7 shows typical output S/N ratios obtained with receiver bandwidths adjusted to accommodate transmitted signals with modulation indexes of 1.6 and 5.0, compared with the audio S/N ratio when AM modulation is used and the bandwidth of the receiver is adjusted to accommodate the AM sidebands only. As shown in this figure, the S/N

FIGURE 22.2.6 Equivalent sources of receiver noise; (a) with resistive generator; (b) with galactic noise source included.

FIGURE 22.2.7 Typical signal-to-noise ratios for FM and AM for deviation ratios of 1.6 and 5.

ratio for a properly designed receiver operating with a modulation index of 5 is 18.8 dB higher than that of an AM receiver with the same rf S/N ratio.

For rf S/N ratios in FM higher than 12 dB, the audio S/N ratio increases 1 dB for each 1-dB increase in rf S/N ratio. For FM S/N ratios lower than 12 dB, the S/N ratio in the audio drops rapidly and falls below the AM S/N ratio at about 9 dB. The point at which the ratio begins to fall rapidly is called the *threshold signal level*. It occurs where the carrier level at the discriminator is equal to the noise level. The threshold level increases directly as the square root of the receiver bandwidth, i.e., approximately the square root of the modulation index. The equation for S/N improvement using FM is

$$\frac{(S/N)_{FM}}{(S/N)_{AM}} = \sqrt{3}\Delta$$

where Δ is the deviation ratio. Since broadcast standards in the United States for FM call for a modulation index of 5 for the highest audio frequency, the direct S/N improvement factor is 18.8 dB for rf S/N ratios exceeding 12 dB.

In the FM system a second source of noise improvement is provided by pre-emphasis of the high frequencies at the transmitter and corresponding de-emphasis at the receiver. The pre-emphasis network raises the audio level at a rate of 6 dB/octave above a critical frequency, and a complementary circuit at the receiver decreases the audio output at 6 dB/octave, thus producing a flat overall audio response. Figure 22.2.8 shows simple RC networks for pre-emphasis and de-emphasis.

The additional S/N improvement using de-emphasis in an FM receiver is

$$\frac{(S/N)_{out}}{(S/N)_{in}} = \frac{f_a^3}{3[f_a f_0^2 - f_0^3 \tan^{-1}(f_a/f_0)]}$$

where $(S/N)_{out}$ = signal-to-noise at de-emphasis output

$(S/N)_{in}$ = signal-to-noise ratio at de-emphasis input

f_a = maximum audio frequency

f_0 = frequency at which de-emphasis network response is down 3 dB

For $f_a = 15$ kHz and a 75- μ s time constant ($f_0 = 2.125$ kHz), the S/N improvement is 13.2 dB. The total S/N improvement over AM is 32 dB when the carrier is high enough to override noise plus 12 dB for the 75-kHz deviation used in U.S. broadcast stations. The minimum coherent S/N ratio is therefore 44 dB.

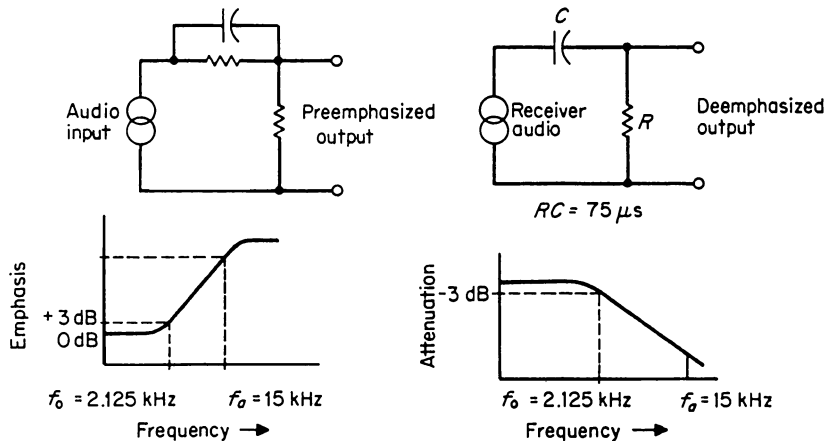

FIGURE 22.2.8 Pre-emphasis and de-emphasis circuits and characteristics.

When a dipole receiving antenna is used, an additional noise component is produced by *galactic noise*, because the dipole pattern does not discriminate against sky signals. The ratio of signal to galactic noise can be improved by using an antenna array with gain in the horizontal direction, i.e., one that discriminates against sky-wave signals. The additional noise is shown in Fig. 22.2.6. Using the calculated value of E_n and assuming a 3-dB noise factor in the receiver gives an equivalent noise input to the receiver of $1.39 \mu\text{V}$. The required field strength to produce a 12-dB S/N ratio at the receiver and a 44-dB S/N ratio at the audio output when using a half-wave dipole is $11.5 \mu\text{V/m}$.

Selectivity

When the FM system uses a high-modulation index, the system is not only capable of improving the S/N ratio but will reject an interfering co-channel signal. The FM signal modulation involves very wide phase excursions, and since the phase excursion that can be imparted to the carrier by an interfering signal is less than 1 rad, the effect of the interference is markedly reduced. The co-channel-interference-suppression effect requires that the interfering signal be smaller than the desired signal, since the larger signal acts as the desired carrier, suppressing the modulation of the smaller signal. This phenomenon is called the *capture* effect since the larger signal takes over the audio output of the receiver.

The capture effect produces well-defined service areas, since signal-level differences of less than 20 dB provide adequate signal separation. Although it is useful in suppressing undesired signals of a level less than the desired signal, the capture effect can also produce an annoying tendency for the receiver to jump between co-channel signals when fading, for example, caused by airplanes makes the desired signal drop below the interfering signal by only a few decibels. This effect also occurs in FM radios used in automobiles when motion of the antenna causes the relative signal levels to change.

Tuners

The FM tuner is matched to the antenna input. An rf amplifier is used to override the mixer noise. The mixer provides a 10.7-MHz i.f. signal. Most FM tuners contain a single stage of rf amplification. The mixer may be self-oscillating or employ a separate oscillator. The rf stage must have a low noise figure to reach the minimum threshold-signal level, but its most important requirement is to provide the mixer and i.f. amplifier with signals free of distortion.

When the rf amplifier is overloaded, the signal supplied to the i.f. amplifier may be distorted or suppressed. For single interfering signals there are three significant sources of difficulty: (1) image signals may

capture the receiver, suppressing the desired signal; (2) strong signals at one-half the i.f. frequency (5.35 MHz) above the desired signal may capture the receiver; or (3) a strong signal outside the range of the i.f. beat but strong enough to cause limiting in the rf stage may drastically reduce the output of the rf amplifier at the carrier frequency.

When two strong signals are present, three conditions may produce unsatisfactory operation: (1) cross modulation of two adjacent upper- or lower-channel signals may produce an on-channel carrier; (2) two strong signals spaced 10.7 MHz in the rf passband may produce an i.f. beat, or (3) submultiple i.f. beats may be produced by strong signals spaced at i.f. submultiple spacings in the rf band. To minimize the effects of distortion and provide a low noise figure, many FM tuners employ an FET type transistor rf stage.

I. F. Amplifiers

To provide sufficient image separation, a higher intermediate frequency (10.7 MHz) is used in FM than in standard broadcast AM. The i.f. amplifier must provide sufficient gain for the noise generated by the rf amplifier to saturate the limiting stages fully if the benefits of wide-band FM are to be obtained at low signal levels. The high gain should be supplied with a low noise figure in the first i.f. amplifier stage, so that the noise introduced by the i.f. is small compared with the noise from the rf amplifier.

One of the most important characteristics of the i.f. amplifier is phase linearity, since envelope-delay distortion in the passband is a principal cause of distortion in FM receivers. Care must also be taken to avoid regeneration since this would cause phase distortion and hence audio distortion in the detected signal.

Although AGC is theoretically unnecessary, it is sometimes used in the rf stage to avoid overload. Such overload, coming before sufficient selectivity is present, could produce cross modulation, causing capture by an out-of-band signal. In the classical cascade amplifier design the requirements of high gain and good phase linearity are generally met by using amplifiers with double-tuned circuits adjusted to operate at critical coupling.

Limiters

The design of the limiter is critical in determining the operating characteristics of an FM receiver. The limiter should provide complete limiting with constant-amplitude signal output on the lowest signal levels that override the noise. In addition, the limiting should be symmetrical, so that the carrier is never lost at low signal levels. This is essential if the receiver is to capture on the strongest signal when there is little difference in signal strengths between the weaker and the stronger signals. Finally, the bandwidth in the output must be wide enough to pass all the significant sideband terms associated with the carrier, to prevent spurious amplitude modulation due to the lack of sufficient bandwidth to provide the constant-amplitude FM signals. The differential amplifier with dc coupling can be made to provide highly symmetrical limiting.

FM Detectors

There are five well-known types of FM detectors: (1) the balanced-diode discriminator (Foster-Seeley circuit); (2) the ratio detector using balanced diodes; (3) the slope-detector-pulse-counter circuit using a single diode with an RC network to convert FM to AM; (4) the locked-oscillator or PLL circuit, which uses a variation in current as the frequency is varied to convert the output of an oscillator (locked to the carrier frequency) to a voltage varying with the modulation; and (5) the quadrature detector circuit that produces the electrical product of the two voltages, the first derived from the limiter, the second from a tuned circuit that converts frequency variations into phase variations. The output of the product device is a voltage that varies directly with modulation.

Circuit Implementation

Integrated circuits designed for use in audio broadcast receivers in many parts of the world contain functional combinations of AM/FM and AM/FM stereo circuitry.

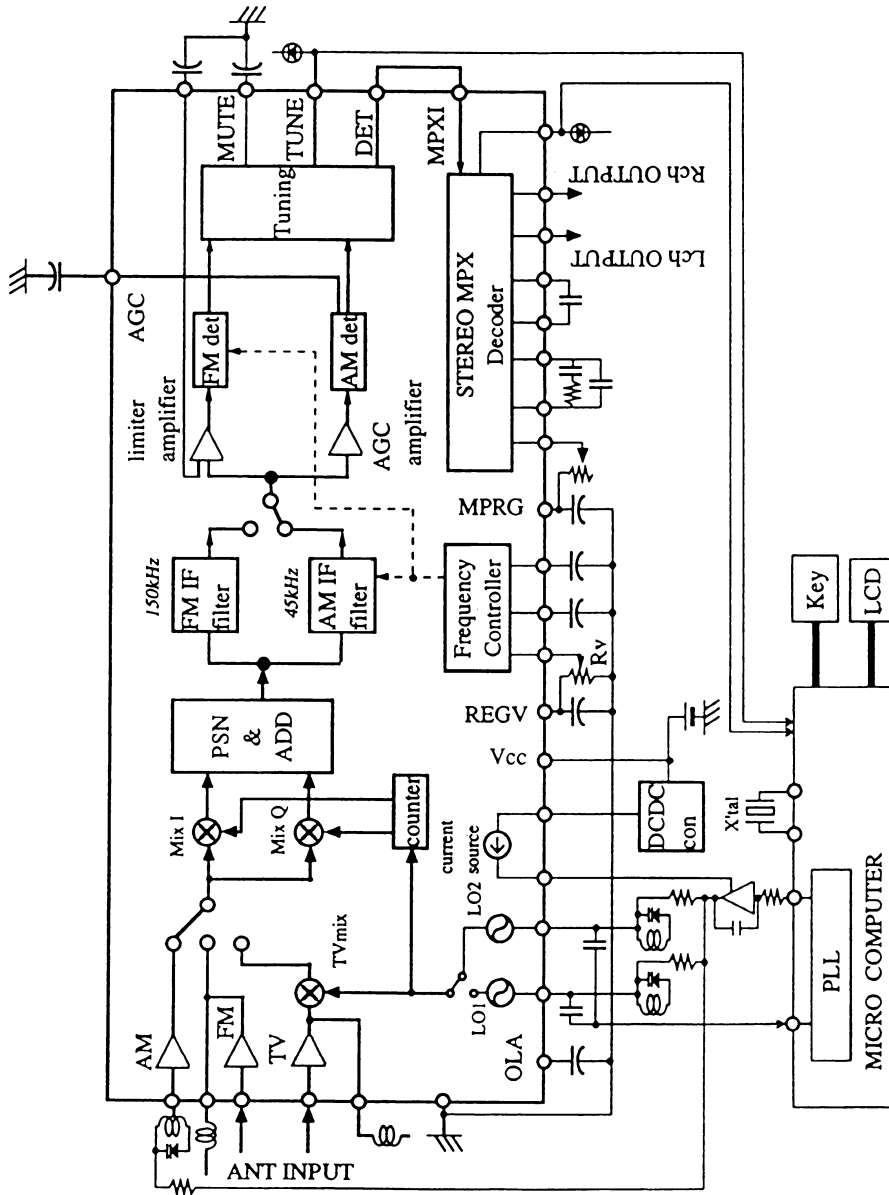

FIGURE 22.2.9 Block diagram of AM/FM/TV sound receiver having a digital tuning system. (From Ref. 9)

Differing classes of these ICs find use in battery operated shirt-pocket radios, portable boom-boxes, line-connected table radios, component stereo audio systems, and automobile radio receivers. In recent years, designs have been developed to provide broadcast audio reception in personal computers.⁷ Most ICs contain all the functions from antenna through low-level audio for both AM and FM reception.^{8–10} A block diagram of one such unit is shown in Fig. 22.2.9.

FM Stereo and SCA Systems

Since FM broadcasting uses a bandwidth of 200 kHz and a modulation index of 5 for the highest audio frequency transmitted, it is possible by using lower modulation indexes to transmit information in the frequency range above the audio. This method of using a supersonic carrier to carry additional information is used in FM broadcasting for a number of purposes, most notably in FM stereo broadcasting.

In broadcasting stereo the main-channel signal must be compatible with monophonic broadcasting. This is accomplished by placing the sum of the left- and right-hand signals ($L + R$) on the main channel and their difference ($L - R$) on the subcarrier. The subcarrier is a suppressed-carrier AM signal carrying the $L - R$ signal.

The suppressed-carrier method causes the carrier to disappear when L and R vary simultaneously in identical fashion. This occurs when the $L - R$ signal goes to zero and allows the peak deviation in the monophonic channel to be unaffected by the presence of the stereo subcarrier.

In the receiver it is necessary to restore the subcarrier. In the U.S. Standards, the technique used provides a pilot signal at 19 kHz, one-half the suppressed carrier. The frequency subcarrier is restored by doubling the pilot-signal frequency and using the resulting 38-kHz signal to demodulate the suppressed-carrier ($L - R$) signal. The suppressed carrier has a peak deviation of less than 2, and the subcarrier is amplitude-modulated. The composite stereo signal thus has a S/N ratio 23 dB below that of monophonic FM broadcasting. The main ($L + R$) channel is not affected by the stereo subcarrier ($L - R$) signal.

The stereo signal can be decoded in two different ways. In the first, the subcarrier is separately demodulated to obtain the $L - R$ signal. The $L + R$ and $L - R$ signals are then combined in a matrix circuit to obtain the individual L and R signals. In the second method, more widely used, the composite signal is gated to obtain the individual L and R signals directly. The circuit uses a doubler circuit to obtain the 38-kHz reference signal. The latter signal is added to the composite signal, and the signal is decoded in a pair of full-wave peak rectifiers to obtain the L and R signals directly. This type of demodulation is also performed in present-day ICs by use of a synchronous demodulator circuit. The 38-kHz reference signal is derived from a 76-kHz oscillator, which is synchronized to the incoming 19-kHz pilot via a PLL and the necessary dividers. This configuration yields a simple circuit consisting of an IC and relatively few simple, i.e., no coils, resistor and capacitor networks.¹¹

In the SCA system an additional subcarrier is placed well above the stereo sidebands at 67 kHz. This subcarrier is used for auxiliary communication services (SCA—subsidiary communications authorization).

DIGITAL RADIO RECEIVERS

Since about 1985 the European Broadcast Commission has been evaluating proposals for a digital audio service to include both terrestrial and satellite delivery. In 1987 the Eureka 147 Consortium was established to develop a novel system based on coded orthogonal frequency division multiplex (COFDM) approach and the advanced audio compression scheme now known as MUSICAM. In late 1994, following extensive testing, this proposal became the accepted digital method for Europe. In 1995, it was accepted as the Canadian standard and was well on its way to being a global standard. The advantage of COFDM modulation is that it allows for numerous low-power broadcast transmitters spaced over a wide area to each broadcast the identical signal on the same identical frequency. As an automobile travels around the region, the reception will continue to have CD quality with no interference or receiver retuning required. A more detailed description of the Eureka 147 system is contained in Ref. 12.

A typical DAB (Eureka 147) receiver block diagram is shown in Fig. 22.2.10. Several IC manufacturers make chip sets for this type receiver. Typically two large-scale ICs are used in the design, one for channel decoding and the other for audio source decoding.

LSB = lower sideband USB = upper sideband IBOC = in-band/on-channel

FIGURE 22.2.11 The digital signal is included in the spectrum of the analog channel. The digital radio signals fall within the frequencies allocated to stations, the so-called FCC FM or AM masks, indicated by the cross-hatched area. For FM [top], IBOC digital sidebands are placed on either side of the analog host signal. For AM [bottom], the setup is similar except that, in addition, some digital carriers are also co-located in the region of the AM host itself. (From Ref. 13)

U.S. IBOC Digital Broadcast Systems for AM and FM

In the United States the Eureka 147 system has not been accepted because of the wide bandwidth, 1.5 MHz, needed for each transmission system and the large number of independent broadcasters who would need this bandwidth for each station. There exists no available unused spectrum in the United States for additional services.

A current proposal, which occupies the same channel space as present AM and FM stations, is being field tested by the Digital Audio Broadcast Subcommittee of the National Radio Systems Committee (NRSC). This system and the staffing belongs to iBiquity Digital Corporation, which was formed as a merger of several other proposals and proponents over the period from the early 1990s through 2001.¹³ The system provides a digital signal on the upper and lower edges of the main analog (AM or FM) channel from which derives the name in-band-on-channel (IBOC) (Fig. 22.2.11). The digital signal will have the same identical program material (simulcast) as the analog transmission. A time delay will exist between the analog and the digital signals in order to provide diversity. In the receiver, this will lead to a more robust reception quality. It is anticipated that sometime in the future as the transition from analog to digital occurs that the analog signal will disappear and the digital signal will occupy the entire channel.

This technology will enhance both the AM and FM band's audio fidelity. AM will sound like FM does today and FM will have compact-disc-like audio. Multipath, noise, and interfering signals that cause the static, hiss, pops, and fades heard on today's analog radios will be virtually eliminated, thus ensuring crystal clear reception. Additionally, the technologies will allow for new wireless data services to be received from AM and FM stations, such as station information, artist and song identification, traffic, weather, and news and sports scores.¹⁴

A receiver design for the IBOC service would have a similar block diagram as present AM or FM receivers with the addition of two blocks: (1) an OFDM decoder IC and time delay memory and control to handle the diversity provided by the two carriers and (2) a decoder IC to restore the audio perceptual audio coder (PAC) compression provided at the transmitter. Several major broadcast manufacturers and radio receiver manufacturers have already signed license agreements with the technology owner. At least 20 broadcast stations situated in major market areas of the United States were involved in the field testing phase. The service was launched in 2003 and receivers are now available.

Radio Broadcast Data Systems

Unlike the two systems described earlier (DAB and IBOC), which were "totally digital," this section will deal with the existing analog FM systems that have digital subcarriers superimposed or added into the existing channel spectrum. These subcarriers would transmit to the receiver information such as station call letters, road conditions, program or music name, and other data believed to be useful to a moving automobile. In Europe the system has been called *radio data system* (RDS) and has been in operation for several years, whereas in the United States it is known as *radio broadcast data system* (RBDS). In Japan a similar system called *data radio channel* (DARC) is being implemented. Currently in the United States numerous FM radio stations are broadcasting RBDS signals and receivers which make some use of RBDS number in the hundreds of thousands.¹⁵

Superimposed subcarriers in the United States system exist at 57 kHz (third harmonic of the 19 kHz stereo pilot tone) with injection level of 2 to 3 percent. ICs to decode this signal from the main FM stereo multiplex have been developed by several companies and have been used in receiver design for several years for both RDS and RBDS service.

The Japanese DARC system employs a 76 kHz level-controlled minimum shift keying (L-MSK) modulation. The level being controlled by the level of the $R - L$ signal to reduce interference in the $L - R$ channel and therefore reduce noise and interference in the recovered stereo signals. Most of the circuitry added to an FM receiver to handle this service is contained in one LSI-IC.¹⁶

Satellite Radio

Numerous satellite digital audio radio service (SDARS) proposals have been on the table both internationally and in the United States during the 1990s. At the present time, only four appear to be viable. The WorldSpace system covers Africa (AfriStar launched in October 1999) and Asia (AsiaStar launched in March 2000). A third satellite will cover Central and South America.¹⁷ Development of the Japanese Communication Satellite System operated by Mobile Broadcasting Corporation dates from the early 1990s.^{18,19} Two U.S. services are the XM system (launched in 2001) and the Sirius system (launched in 2002). Both are aimed at auto radio application and are subscription services (XM at \$9.95 per month and Sirius at \$12.95 per month).

Receivers for the WorldSpace system are available from several major radio receiver manufacturers and are on sale in the intended countries. Over 50 channels of low noise, interference-free audio and multimedia programming are available in the 1467–1492 MHz (L-band) spectrum. The system is primarily intended for direct-to-home broadcast. RF modulation is digital QPSK combined with convolutional and Reed-Solomon forward error correction. Ninety-six channels of 16 kbit/s each are combined using time-division multiplex (TDM). High-quality audio is ensured by encoding the audio using the MPEG 2.5 layer 3 compression scheme. The basic diagram of a typical receiver using two ICs is shown in Fig. 22.2.12.²⁰

Several other semiconductor manufacturers have either two IC or three IC solutions for WorldSpace radios. Functional block diagrams for all are very similar.

The Japanese system receivers are being developed to handle both satellite and terrestrial signals with automatic switching and antenna diversity. Reception of the signals in the 2.6 GHz band will be by an antenna assembly consisting of two microstrip antennas, i.e., a high gain with a low-noise amplifier for satellite reception and a low-gain unit for the terrestrial pickup. Multimedia signals containing up to 50 programs will be available from the satellite. These include MPEG-4 video, CD-quality audio, and digital information services to mobile receivers.¹⁸

The two U.S. SDARS differ from each other in several ways. XM employs two geostationary satellites, while Sirius has three satellites covering the western hemisphere in an elliptical pattern. A technical comparison of the two U.S. satellite radio services is shown in Table 22.2.1.¹³ Both systems employ three degrees of diversity in order to guarantee uninterrupted service to the receiver. These three are:

1. Spatial. Use of two widely separated satellites and numerous terrestrial repeaters to fill in the holes created by building shadows, tunnels, and other obstructions to the satellite signal in metropolitan areas.
2. Frequency. The two satellites will transmit the same signal but in different frequency bands.
3. Time. A time delay of several seconds will exist between the transmissions of the same signal from each satellite.

At the receiver, these diversity situations can be resolved with the strongest and cleanest signal at the moment taking command of the circuitry. The receiving antenna will be of a simple omnidirectional design mounted on the roof or side window of the car.

The XM receiver uses two custom-integrated circuits that are fabricated by using CMOS and proprietary high-speed bipolar technology.²¹ A block diagram of the receiver is shown in Fig. 22.2.13.

TABLE 22.2.1. The U.S. Satellite Digital Audio Radio Services (SDARS)

Parameter	Satellite radio		Comments
	Sirius	XM	
IN ORBIT			
No. of satellites (longitude)	3 (nominal 100° W)	2 (85° and 115° W)	Sirius satellites are in a highly elliptical orbit, rising and setting every 16 h: XM types are geostationary
Uplink frequencies	7060–7072.5 MHz	7050–7075 MHz	Sirius also uses Ku-band (14–12 GHz) uplink to feed repeaters
Downlink frequencies	2320.0–2324.0 MHz and 2328.5–2332.5 MHz	2332.5–2336.5 MHz and 2341.0–2345.0	Redundant downlink signals are for spatial/frequency/time diversity
Satellite elevation angle	60°	45°	Typical
ON LAND			
Location	New York City	Washington, D.C	
No. of studios	75	82	In main facility
No. of terrestrial repeaters	105 (46 markets)	1500 (70 markets)	Approximate numbers
Repeater EIRP	Up to 40 kW	90% are 2 kW	
OTHER CHARACTERISTICS			
No. of CD-quality (64-kb/s) channels	50		Lower-quality services use 0.5–64 k/s
No. of news-talk-sports channels	50		System is reconfigurable on the fly
Satellite modulation	TDM-QPSK		Each carrier is about 4 MHz wide
Terrestrial repeater modulation	TDM-COFDM		Carrier ensemble is about 4 MHz wide
Channel coding scheme	Concatenated		Error-correcting Reed-Solomon outer code and rate 1/2 convolutional inner code
Source coding scheme	Lucent PAC		Nominal rate for top-quality music: 64 k/s
Transmission rate	4.4 M/s	4.0 M/s	Before channel coding

COFDM = coded orthogonal frequency-division multiplexing; EIRP = equivalent isotropic radiated power; PAC = Perceptual Audio Coder; QPSK = quadrature phase shift keying; TDM = time-division multiplexing.

CHAPTER 22.3

CABLE TELEVISION SYSTEMS

Walter S. Ciciora

INTRODUCTION

Cable television service is enjoyed by almost 70 million U.S. households. This is a market penetration of over 68 percent. Cable systems have expanded capacity and added digital signal capability. High-speed cable modems and telephony are important growth areas. Video on demand (VOD) is offered to ever more subscribers. Interactive television is beginning to gain acceptance. It is expected that these growth trends will continue.

HISTORICAL PERSPECTIVE

The original purpose for cable television was to deliver broadcast signals in areas where they were not received in an acceptable manner with an antenna. These systems were called Community Antenna Television, or CATV. In 1948, Ed Parson of Astoria Oregon, built the first CATV system consisting of twin-lead transmission wire strung from housetop to housetop. In 1950, Bob Tarlton built a system in Landsford, Pennsylvania, using coaxial cable on utility poles under a franchise from the city.

In the mid-1970s, an embryonic technology breathed new life into cable television. This technology was satellite delivery of signals to cable systems, which added more channels than were available from terrestrial broadcasters. While satellites and earth stations were very expensive investments, these programming pioneers understood that the costs could be spread over many cable operators who, in turn, serve many subscribers.

Subscribers are offered a variety of video services. The foundation service taken by most subscribers is called *basic*. Off-air channels, some distant channels, and some satellite-delivered programs are included. The satellite programs include the super stations and some of the specialty channels. *Pay television* constitutes premium channels, usually with movies and some special events, which are offered as optional channels for an extra monthly fee. Some cable systems offer *Pay-Per-View* (PPV) programming which is marketed on a program-by-program basis. Recent movies and special sport events are the mainstay of PPV programming. *Impulse Pay Per View* (IPPV) allows the subscribers to order the program spontaneously, even after it has begun. The ordering mechanism usually involves an automated telephone link or, occasionally, two-way cable.

Ways of providing conditional access to allow for a limited selection of service packages at differing price points are often included in the cable system. Simple filters remove the unsubscribed channels in some systems, while elaborate video and audio scrambling mechanisms involving encryption are used in other cable systems.

Since cable television systems must use the public right-of-way to install their cables, they, like power, telephone, and gas companies, must obtain a franchise from the local governmental authorities. This is a nonexclusive

Note: This overview is based on a CableLabs publication, "Cable Television in the United States."

franchise. However, experience with multiple cable systems has shown that the economics of the business generally only support one system per community.

The decade of the 1990s introduced major changes into the cable industry. From a technical perspective, the addition of optical fiber improved signal quality, increased bandwidth, enhanced reliability, and reduced operating costs while making two-way cable practical. The second major technical advance was the introduction of digital television signals. Digital video multiplied the program capacity dramatically. These two technical advances enabled significant new service opportunities. Near video on demand (NVOD) took advantage of increased signal capacity. True VOD was made possible by the dramatic performance increases and cost reductions on hard drive storage systems. High-speed cable modem services and telephony became possible as cable operators learned to send digital signals reliably. Cable systems changed from entertainment-only systems into general-purpose, comprehensive communications facilities.

SPECTRUM REUSE

For NTSC, each television channel consumes 6 MHz because of vestigial side-band amplitude modulation, VSB-AM. Compared with double side-band amplitude modulation's need for 8.4 MHz, VSB-AM transmits one complete side-band and only a vestige of the other. At the time the standard was created, the design requirements of practical filters determined the amount of side-band included. The consumer's receiver selects the channel to be watched by tuning a 6-MHz portion of the assigned spectrum. In the terrestrial broadcast environment, channels must be carefully assigned to prevent interference with each other. The result of this process is that most of the terrestrial broadcast television spectrum is vacant. Better television antennas and better television circuits allow more of the spectrum to be used. However, with nearly 300 million receivers and more than 100 million VCRs in consumers' hands, the changeover process to upgraded systems would be difficult, costly, and require something like 20 years.

The rest of the terrestrial spectrum that is not assigned to broadcast has other important uses. These include aircraft navigation and communications, emergency communication, and commercial and military applications. The terrestrial spectrum is too limited to supply the video needs of the U.S. viewer.

Cable television is made possible by the technology of coaxial cable. Rigid coaxial cable has a solid aluminum outer tube and a center conductor of copper-clad aluminum. Flexible coaxial cable's outer conductor is a combination of metal foil and braided wire, with a copper-clad steel center conductor. The characteristic impedance of the coaxial cable used in cable television practice is 75 Ω . The well-known principles of transmission line theory apply fully to cable television technology.

The most important characteristic of coaxial cable is its ability to contain a separate frequency spectrum and respect the properties of that separate spectrum so that it behaves like over-the-air spectrum. This means that a television receiver connected to a cable signal will behave as it does when connected to an antenna. A television set owner can become a cable subscriber without an additional expenditure on consumer electronics equipment. The subscriber can also cancel the subscription and not be left with useless hardware. This ease of entry and exit from an optional video service is a fundamental part of cable's appeal to subscribers.

Since the cable spectrum is tightly sealed inside an aluminum environment (the coax cable), a properly installed and maintained cable system can use frequencies assigned for other purposes in the over-the-air environment. This usage takes place without causing interference to these other applications or without having them cause interference to the cable service. New spectrum is "created" inside the cable by the "reuse" of spectrum. In some cable systems, dual cables bring two of these sealed spectra into the subscriber's home, with each cable containing different signals.

The principal negative of coaxial cable is its relatively high loss. Coaxial cable signal loss is a function of its diameter, dielectric construction, temperature, and operating frequency. A ballpark figure is 1 dB of loss per 100 ft.

CABLE NETWORK DESIGN

Since cable television is not a general-purpose communication mechanism, but rather a specialized system for transmitting numerous television channels in a sealed spectrum, the topology or layout of the network can be

customized for maximum efficiency. The topology that has evolved over the years is called tree-and-branch architecture.

There are five major parts to a cable system: (1) the headend, (2) the trunk cable, (3) the distribution (or feeder) cable in the neighborhood, (4) the drop cable to the home and in-house wiring, and (5) the terminal equipment (consumer electronics).

Flexible coaxial cable is used to bring the signal to the terminal equipment in the home. In the simplest cases, the terminal equipment is the television set or VCR. If the TV or VCR does not tune all the channels of interest because it is not “cable compatible,” a converter is placed between the cable and the TV or VCR tuner.

The home is connected to the cable system by the flexible drop cable, typically 150 ft long.

The distribution cable in the neighborhood runs past the homes of subscribers. This cable is tapped so that flexible drop cable can be connected to it and routed to the residence. The distribution cable interfaces with the trunk cable through an amplifier called a bridge amplifier, which increases the signal level for delivery to multiple homes. One or two specialized amplifiers called line extenders are included in each distribution cable. Approximately 40 percent of the system’s cable footage is in the distribution portion of the plant and 45 percent is in the flexible drops to the home.

The trunk part of the cable system transports the signals to the neighborhood. Its primary goal is to cover distance while preserving the quality of the signal in a cost-effective manner. Broadband amplifiers are required about every 2000 ft depending on the bandwidth of the system. The maximum number of amplifiers that can be placed in a run or *cascade* is limited by the buildup of noise and distortion. Twenty or 30 amplifiers may be cascaded in relatively high-bandwidth applications. Older cable systems with fewer channels may have as many as 50 or 60 amplifiers in cascade. Approximately 14 percent of a cable system’s footage is in the trunk part of the system.

The headend is the origination point for signals in the cable system.

When the whole picture is assembled, the tree shape of the topology is evident. The trunk and its branches become visible.

The cable industry had an early interest in fiber optics. Since signal losses in optical fiber are orders of magnitude lower than signal losses in coaxial cable, power-consuming amplifiers in the trunk became unnecessary.

Initially, laser technology was the most significant challenge to implementing fiber optics in cable systems. The laser had to have extreme linearity in order to avoid distortions of the broadband analog signal. This degree of linearity is not necessary in a digital transmission system. Once the process of producing sufficiently linear lasers were mastered, the rapid roll out of optical fiber in cable systems began.

Coaxial cable design had become an optimized, well-understood process prior to the introduction of fiber. Optical fiber offered a wide variety of options that caused cable system design to become much more complex. Many approaches were tried and as the cost of the various components came down, new approaches became possible. The technique had generally become known as *hybrid fiber coax* (HFC). Optical fiber is relatively inexpensive. It is supplied in a plastic protective sheath that is a bit more expensive on a per foot basis. But the most expensive element is the cost of installation. As a result, when optical fiber is installed, multiple strands of unused fiber are included in anticipation of future needs. These fibers are called “dark fiber” since they have not yet had lasers installed. As future growth in subscribers and services leads to demands for more bandwidth, these fibers are activated.

The point where the optical fiber ends and the coaxial distribution begins is called a “node.” The node serves a group of subscribers. The size of the group depends on the demographics and the philosophy of the system designer. The size ranges from a few hundred to a few thousand homes. “Node splitting” is the process of activating dark fibers to create additional smaller nodes out of a larger node. This is done when additional upstream signal return capacity is required or when additional downstream frequency reuse is needed.

Downstream frequency reuse is an important concept, giving rise to one of cable’s most sustainable competitive advantages against other communications systems. Since cable trunks or fibers extend from the cable head end into neighborhoods, different programming can be placed on the same frequencies. This technique greatly expands the reach of cable’s spectrum. There are services that dedicate signals to groups of subscribers or individual subscribers. These services include VOD high-speed cable modem services and telephony. These services do not comply with the broadcast model and require directed signals to individual locations. Nodalization, the process of splitting larger nodes into smaller groups, makes this possible with limited spectrum capacity. As these services increase in penetration, they burden the assigned frequencies that are shared among the subscribers connected to a node. Two choices are possible: assign more channels to the service or split the node. So nodalization is a means of creating additional capacity when more spectra are unavailable.

SIGNAL QUALITY

The ultimate goal of the cable system is to deliver pictures of adequate quality at an acceptable price while satisfying stockholders, investors, and holders of the debt generated by the huge capital expenses of building the cable system plant. This is a difficult balancing act. It would be a simple matter to deliver very high-quality video if cost were not a consideration. Experience teaches that subscriber satisfaction is a complex function of a variety of factors led by program quality, and variety, reliability of service, video and sound quality, and the amount of the subscriber's cable bill.

The principal picture impairments can be divided into two categories—coherent and noncoherent. Coherent impairments result in a recognizable interfering pattern or picture. They tend to be more objectionable than noncoherent impairments of equal strength.

The principal noncoherent picture impairment is noise. Random noise behavior is a well-understood part of general communication theory. The familiar Boltzmann relationship, noise figure concepts, and the like apply fully to cable television technology. Random noise is the consequence of the statistical nature of the movement of electric charges in conductors. This creates a signal of its own. This noise is inescapable. If the intended analog signal is ever allowed to become weak enough to be comparable to the noise signal, it will be polluted by it yielding a snowy pattern in pictures and a seashore sounding background to audio.

Noise levels are expressed in cable system practice as ratios of the video carrier to the noise in a television channel. This measure is called the carrier-to-noise ratio (CNR) and is given in decibels (dB). The target value for CNR is 45 to 46 dB. Noise in the picture, called snow, is just visible when CNR is 42 to 44 dB. Snow is objectionable at CNRs of 40 to 41 dB.

Coherent interference includes ingress of video signals into the cable system, reflections of the signal from transmission-line impedance discontinuities, cross modulation of video, and cross modulation of the carriers in the video signal. This latter phenomenon gives rise to patterns on the screen, which are called *beats*. These patterns often look like moving diagonal bars or heringbones.

The evaluation of signal quality takes place on two planes, objective and subjective. In the objective arena, measurements of electrical parameters are used. These measurements are repeatable. Standardized, automated test equipment has been developed and accepted by the video industries. Table 22.3.1 lists the parameters usually considered important and the values of good, current practice.

TABLE 22.3.1 Signal Quality Parameters

Parameter	Symbol	Value
Carrier/noise (CNR)	C/N	46 dB
Composite second-order	CSO	-53 dB
Composite triple beat	CTB	-53 dB
Signal level at TV		0 to +3 dBmV

Signal Quality Target Values

The ultimate performance evaluation involves the subjective reaction of viewers. One example of the difficulties experienced is the fact that different frequencies of noise have differing levels of irritation. High-frequency noise tends to become invisible, while low-frequency noise creates large moving blobs, which are highly objectionable. Subjective reactions to these phenomena are influenced by such factors as the age, gender, health, and attitude of the viewer. The nature of the video program, the characteristics of the viewing equipment, and the viewing conditions also impact the result.

As time progresses, the level of performance of consumer electronics will continue to increase. As ATV and HDTV are introduced, still more demands will be made on cable system performance. The trend to larger screen sizes also makes video impairments more evident.

DIGITAL VIDEO

In the 1980s, the over-the-air broadcast industry attempted to upgrade its services by proposing high-definition television (HDTV).

The HDTV baseband analog signal coming from a television camera has substantially greater bandwidth than the NTSC baseband signal. Digitizing the signal results in even greater bandwidth requirements. This made

complying with the FCC's 6-MHz channel requirement impossible without further signal processing. Fortunately, the digital nature of the signal enabled massive data compressing. The principle feature of digital signal processing, which enables these data compressions, is inexpensive large-scale memory. Such memory does not exist in analog implementations. Since video consists of a series of 30 complete still pictures every second, which usually have only small portions of the image change from picture to picture, the unchanging portions can be stored in digital memory. Only the differences need to be transmitted. This saves a tremendous amount of bandwidth. For example, if the image is a "talking head" against a stationary background, once the background is transmitted, it can be stored and further retransmission minimized or avoided. Only the relatively small fraction of the picture that changes needs to be transmitted. Also, the motion of much of the images consists of the horizontal or vertical translation of elements of the picture. So rather than resending those elements, an instruction to relocate them will suffice. Even more compression is possible by taking advantage of the human visual perception mechanism. Humans are more sensitive to luminance detail than color detail. Perception of detail diminishes if the object is in motion. Such factors enable still more compression of the visual data. The overall consequence is that only about 2 percent of the data generated by digitizing the analog signal is required for excellent reconstruction of the video at the receiver.

The observation was made that if an HDTV signal could be compressed with digital means to fit into a 6-MHz spectral slot, multiple standard-definition TV (SDTV) signals could be placed in that same spectral slot. This development has become commercially much more important than HDTV. The multiplication of capacity by digital compression made direct broadcast satellite (DBS) practical. DBS with a few dozen analog channels simply didn't have enough variety to be a realistic competitor to 50, 70, or 100 cable channels. However, digital compression enabled DBS to have several hundred channels, much more than cable in analog format. DBS could offer NVOD. The stagger starting of movies on multiple channels reduced the waiting time for a movie. A 2-h movie assigned eight program streams would require a maximum wait time of just 15 min, averaging to 7.5. Several tens of movie titles are offered at various stagger starts yielded a compelling service. The need to launch the digital DBS service in a timely manner prevented waiting for the complete resolution of the details of the broadcast digital television standard. Consequently, the digital broadcast compression standard and the DBS compression system are very similar, but not completely identical.

The competitive threat of DBS forced a response from cable that had to be implemented before the broadcast standard was complete. This resulted in yet a third digital approach that was mostly, but not completely, the same as the broadcast standard. The broadcast signal environment is more difficult than that found in cable and both are very different from the satellite system. Thus there are three different, incompatible modulation techniques. The satellite transmitter is a saturation device that is either on or off and transmits only one digital bit per symbol, i.e., time element. The broadcast signal must deal with multipath and low signal strengths at great distances from the transmitter. The broadcast modulation scheme is called 8-VSB (vestigial side band) and transmits three digital bits per symbol. Cable's signal environment has essentially no multipath and only modest signal strength differences between channels. Consequently, the cable signal can transmit many more digital bits per symbol. Two modulation schemes are common: 64 QAM (quadrature amplitude modulation) carrying five digital bits per symbol and 256 QAM conveying seven digital bits per symbol. QAM is very bandwidth efficient. All of these methods include extensive error detection and error correction methods with the broadcast signal the most protected. These powerful techniques allow for the recovery of transmission errors.

An important trade-off exists between image quality and program quantity. The more of the data capacity in a 6-MHz channel that is assigned to one program, the better its image quality. Five or six Mb/s (million bits per second) yields essentially perfect video under nearly all circumstances. But some types of video provide acceptable results with just 1.5 to 2 Mb/s. The decoder at the receiver that converts the bits to the analog signals necessary to drive the display device can accommodate any of these bit rates. So the choice is made at the point of origination of the video. A 256 QAM system has a payload of data of about 38 Mb/s. Thus six program streams of 6 Mb/s can be carried or double that for 3 Mb/s. The bit rate does not have to be the same for all streams or for all times. The data capacity can be allocated based on the type of programming and changed as needed. A further efficiency technique called *statistical multiplexing* can be employed. Statistical multiplexing averages out the bit capacity assignments depending on the needs of the multiple program streams sent in a 6-MHz channel. Thus when one program has high detail or high action or both, it is temporarily assigned the bits it needs while other less demanding channels make a contribution. This allotment changes from moment to moment depending on the needs of the program streams. Statistically, better quality and perhaps an additional program stream can be accommodated in this manner. The same techniques can be applied in satellite and broadcast. Because of the

more difficult signal conditions in broadcast, only four to six program streams can be accommodated in the broadcast 6 MHz.

The video compression method used by broadcast, cable, and satellite is called MPEG after the committee that standardized it, the Moving Pictures Expert Group. MPEG is actually a collection of standards that can be applied to fit a variety of applications. The standard is unsymmetrical in that the equipment necessary to encode the signal is much more complex than the hardware needed to decode it. This makes very good economic sense since there will be many more receiving devices than transmitters. A further important feature is that improvements in the encoder result in better video reception without the need to modify the decoder. So as more processing power becomes affordable in encoders and as the techniques evolve, improved results are obtained in the system with previously installed receivers. In some cases, the bit rate can be reduced as well.

While the United States has selected 8-VSB as its broadcast modulation scheme, much of the rest of the world has selected versions of QAM. Frustratingly, the opportunity for much more signal commonality was not achieved. Signal differences prevent a worldwide receiver that can function on cable, broadcast, and satellite anywhere in the world. Multiple subsystems are required. Fortunately, the digital portion of the signal allows relatively easy interconversion between standards.

Techniques for delivering 3 to 6 Mb/s of data in the analog television signal without significant interference to the analog television signal have been developed. These developments might have made the original FCC's hope of a compatible system possible, at least in cable. But the standards are now too entrenched. However, these methods can be used to add either data or encoded video to an analog signal.

The auxiliary service of transmitting data in either an analog or a digital television signal has been called datacasting. A wide variety of services are proposed for this technique including data to computers, additional video signals, downloading to hard drives, and other services.

CABLE SYSTEM TRADE-OFFS

The experienced cable system designer has learned how to balance noise, nonlinear distortions, and cost to find a near optimal balance.

Signals in cable systems are measured in decibels relative to 1 mV across 75 Ω . This measure is called dBmV. Applying the well-known Boltzmann noise equation to 75- Ω cable systems yields an open-circuit voltage of 2.2 μ V in 4 MHz at room temperature. When terminated in a matched load, the result is 1.1 μ V. Expressed in dBmV, the minimum room-temperature noise in a perfect cable system is -59.17 dBmV.

Starting at the home, the objective is to deliver at least 0 dBmV, but no more than 10 dBmV to the terminal on the television receiver. Lower numbers produce snowy pictures and higher numbers overload the television receiver's tuner, resulting in cross modulation of the channels. If a converter or descrambler is used, its noise figure must be taken into account. There are two reasons for staying toward the low side of the signal range: cost and the minimization of interference in the event of a signal leak caused by a faulty connector, damaged piece of cable, or defect in the television receiver. Low signal levels may cause poor pictures for the subscriber who insists on splitting in the home to serve multiple receivers. Working our way back up the plant, we need a signal level of 10 dBmV to 15 dBmV at the tap to compensate for losses in the drop cable.

The design objectives of the distribution part of the cable system involve an adequate level of power not only to support the attenuation characteristics of the cable but to allow energy to be diverted to subscribers' premises. Energy diverted to the subscriber is lost from the distribution cable. This loss is called *flat loss* because it is independent of frequency. Loss in the cable itself is a square-root function of frequency and is therefore contrasted to flat loss. Because of flat losses, relatively high power levels are required in the distribution part of the plant, typically 48 dBmV at the input to the distribution plant. These levels force the amplifiers in the distribution part of the plant to reach into regions of their transfer characteristics that are slightly nonlinear. As a result, only one or two amplifiers, called line extenders, can be cascaded in the distribution part of the plant. These amplifiers are spaced 300 to 900 ft apart depending on the number of taps required by the density of homes.

Because the distribution part of the plant is operated at higher power levels, nonlinear effects become important. The television signal has three principal carriers—the video carrier, the audio carrier, and the color subcarrier. These concentrations of energy in the frequency domain give rise to a wide range of “beats” when passed through nonlinearities. To minimize these effects, the audio carrier is attenuated about 15 dB below the video carrier.

When cable systems only carried the 12 VHF channels, second-order distortions created spectrum products that fell out of the frequency band of interest. As channels were added to fill the spectrum from 54 MHz to as much as 650 MHz, second-order effects were minimized through the use of balanced, *push-pull* output circuits in amplifiers. The third-order component of the transfer characteristic dominates in many of these designs. The total effect of all the carriers beating against each other gives rise to an interference called *composite triple beat* (CTB). In an older 35-channel cable system, about 10,000 beat products are created. More channels create more beats. Channel 11 suffers the most with 350 of these products falling in its video. Third-order distortions increase about 6 dB for each doubling of the number of amplifiers in cascade. A 1-dB reduction in amplifier output level will generally improve CTB by 2 dB. If these products build to visible levels, diagonal lines will be seen moving through the picture. When these components fall in the part of the spectrum that conveys color information, spurious rainbows appear.

The design objective of the trunk part of the cable system is to move the signal over substantial distances with minimal degradation. Because distances are significant, lower-loss cables are used. One inch and 0.75 in. diameter cable is common in the trunk, while 0.5 in. cable is found in the distribution. Signal levels in the trunk at an amplifier's output are 30 to 32 dBmV, depending on the equipment used. Cable trunk is rapidly being replaced by fiber. No new cable systems are being built with coax in the trunk.

It has been determined through analysis and confirmed through experience that optimum noise performance is obtained when the signal is not allowed to be attenuated more than about 20 to 22 dB before being amplified again. Amplifiers are said to be "spaced" by 20 dB. The actual distance in feet is a function of maximum frequency carried and the cable's attenuation characteristic. Modern high-bandwidth cable systems have their amplifiers fewer feet apart than older systems with fewer channels. Since attenuation varies with frequency, the spectrum in coaxial cable develops a *slope*. This is compensated with equalization networks in the amplifier housings.

Since the signal is not repeatedly tapped off in the trunk part of the system, high-power levels are not required to feed splitting losses. As a result, signal levels are lower than in the distribution portion of the plant. Typical levels are about 30 dBmV. For the most part, the amplifiers of the trunk are operated within their linear regions. The principal challenge of trunk design is keeping noise under control. Each doubling of the number of amplifiers in the cascade results in a 3-dB decrease in the CNR at the end of the cascade and a 6-dB increase in the amount of CTB.

If the noise at the end of the cascade is unacceptable, the choices are to employ lower noise amplifiers, shorter cascades, or a different technology such as microwave links or fiber optic links.

TECHNICAL DETAIL

The balance of this chapter concentrates in more detail on issues relating to the technical performance of cable systems. Some generalizations have been made in order to group explanations. This section is intended to serve as a briefing, so selective trade-offs were made on the amount of detail given. There are always exceptions, for cable systems do not neatly fall into clear types. A reading list is provided. The following topics will be covered: channel capacities and system layouts, FCC spectrum regulation, means of increasing channel capacity, scrambling methods, the interface between the cable and the customer's equipment, and fiber in cable television practice.

Channel Carriage Capacity

Channel carriage capacity is based on radio frequency (RF) bandwidth. It is a useful characteristic for classifying cable systems. There are three types of system (Table 22.3.2). Systems are categorized by their highest operating frequency. Downstream signals are transmitted to the customers' homes.

A cable system configuration consists of: (1) the headend (the signal reception, origination, and modulation point), (2) main trunk (or tree) cable, which is coaxial in older systems and fiber in new and upgraded systems and runs through the central streets in communities, (3) coaxial distribution (branch) cable to the customer's neighborhood, including distribution taps, (4) subscriber drops to the house, and (5) subscriber terminal equipment (television sets, converter/descramblers, VCRs, and so forth). Distribution plant is sometimes called *feeder* plant. Programming comes to the headend by satellite signals, off-air signals from

TABLE 22.3.2 Classification of Cable Systems

	Bandwidth (MHz)	Operating frequencies (MHz)	Number of channels
Small	170	50–220	12–22 (single coax)
Medium	220	50–270	30 (single coax)
	280	50–330	40 (single coax)
Large	350	50–400	52 (single coax)/104 (dual coax)
	400	50–450	60 (single coax)/120 (dual coax)
	500	50–550	80 (single coax)
	700	50–750	116 (single coax)
	950	50–1 GHz	158 (single coax)

broadcast stations, and signals imported via terrestrial microwave. Signals originating from the headend are from a co-located studio facility, VCRs, character generators, or commercial insertion equipment.

Plant mileage is calculated using the combined miles of strand that support the coaxial cables in the air and the footage of trenches where cables are installed in the ground. There are about a million miles of plant in more than 11,000 U.S. cable systems.

Extension cables, or drops, interconnect main coaxial plant lines to customers' homes. 220 MHz systems built 15 or more years ago are found in rural areas or in areas with clusters of smaller established communities. Some of these systems operate trunk lines running over 20 mi with 50 or more amplifiers in cascade. Total plant mileage for an average 220 MHz systems extends from 50 to 500 mi and services up to 15,000 cable customers. New construction of 220 MHz systems occur only where there are small numbers of potential customers (no more than 300) and where plant mileage does not exceed 10 mi.

Medium capacity cable systems operate with upper frequencies at 270 and 300 MHz, and total bandwidths of 220 and 280 MHz, respectively. 270 MHz systems deliver 30 channels, while 330 MHz systems deliver 40. Although new cable systems are seldom built with 40-channel capacity, plant extensions to existing 270-, 300-, and 330-MHz systems occur. Electronic upgrade is frequently employed to increase 270 MHz systems to 330 MHz. Some 220 MHz systems are upgrading to 300 MHz.

Medium capacity systems account for about 75 percent of total plant mileage. They serve a wide range of communities, from rural areas (population of 5000 to 50,000) to some of the largest systems built in the late '70s.

Large capacity cable systems achieve high channel capacities through extended operating frequencies and through the installation of dual, co-located, coaxial cable. Single coaxial cable systems range from 54-channel 400 MHz to 80-channel 550 MHz. With dual cable, it is not unusual to find 120 channels.

Large capacity cable systems account for about 15 percent of total cable plant miles. They are primarily high-tech systems designed for large urban areas previously not cabled. Recently, cable systems extending to 750 MHz have been built. Three cable systems with 1 GHz bandwidths have been constructed to date, the first in Queens, New York. That system, called Quantum, introduced NVOD for the first time to U.S. subscribers. Many cable systems are now constructed so that they can easily be upgraded to 750 MHz or 1 GHz. It is not uncommon to use GHz-rated passive components and amplifier housings to facilitate a later upgrade.

Large capacity systems are designed, and some operate, as two-way cable plant. In addition to the downstream signals to the customers (50 MHz to upper band edge), upstream signals are carried from customers to the cable central headend, or hub node. They are transmitted using frequencies between 5 and 30 MHz.

Channelization

There are three channelization plans to standardize the frequencies of channels. The first plan has evolved from the frequency assignments that the Federal Communications Commission (FCC) issued to VHF television broadcast stations. This plan is called the standard assignment plan.

The second channelization plan is achieved by phase locking the television channel carriers. It is called the incrementally related carriers (IRC) plan. The IRC plan was developed to minimize the effects of third-order

distortions generated by repeated amplification of the television signals as they pass through the cable plant. As channel capacities increased beyond 36 channels, composite, third-order distortions became the limiting distortion.

The third channelization type is the harmonically related carriers (HRC) plan. It differs from the standard and IRC plan by lowering carrier frequencies by 1.25 MHz. With HRC, carriers are phase locked and fall on integer multiples of 6 MHz starting with channel 2 at 54 MHz. This plan was created to further reduce the visible impact of amplifier distortions.

FM radio services are carried at an amplitude that is 15 to 17 dB below Channel 6's video carrier level. The services are carried on cable in the FM band slot of 88 to 108 MHz. In an IRC channel plan, Channel 6's aural carrier falls at 89.75 MHz, which reduces the available FM band to 90 to 108 MHz.

Low-speed data carriers are transmitted in the FM band or in the guard band between Channels 4 and 5 in a standard frequency plan. The amplitude of these carriers is at least 15 dB below the closest video carrier level.

Frequencies Under Regulation

FCC rules and regulations govern the downstream cable frequencies that overlap with the over-the-air frequencies used by the Federal Aviation Administration (FAA). The frequencies are from 108 to 137 MHz and from 225 to 400 MHz. They are used by the FAA for aeronautical voice communications and navigational information. Since cable plant is not a perfectly sealed system, the FCC and FAA want to maintain a frequency separation between signals carried on cable and frequencies used by airports near the cable system boundaries. In 400-MHz systems, over 30 channels are affected by the FCC rules on frequency offset and related operating conditions.

Effects of the FCC Rules

The maximum, unregulated, carrier power level rule has been reassessed and changed. The previous limit of 1×10^{-5} W (28.75 dBmV) has been raised to 1×10^{-4} W (38.75 dBmV). Carriers with power levels below 38.75 dBmV are not required to follow the frequency separation and stability criteria. Carriers within ± 50 kHz of 156.8 MHz, ± 50 kHz of 243 MHz, or ± 100 kHz of 121.5 MHz, which are emergency distress frequencies, must be operated at levels no greater than 28.75 dBmV at any point in the cable system.

Increasing Channel Capacity

There are several ways to increase channel capacity. If the actual cable is in good condition, channel capacity is upgraded by modifying or replacing the trunk and distribution amplifiers. If the cable has seriously deteriorated, the cable plant is completely rebuilt.

Upgrades (Retrofitting) and Rebuilds

An upgrade is defined as a plant rehabilitation process that results in the exchange or modification of amplifiers and passive devices (such as line splitters, directional couplers, and customer multitaps). A simple upgrade requires new amplifier circuit units called hybrids. A full upgrade replaces all devices in the system. In an upgrade project, most of the cable is retained. Goals of an upgrade project include increasing the plant's channel capacity and system expansion to outlying geographic areas. New amplifier technology such as feedforward and/or power doubling circuitry and advances in amplifier performance have greatly enhanced the technical and financial viability of upgrades. Upgrades are often the least expensive solution to providing expanded service.

In a rebuild, the outside plant is replaced.

System Distortion and System Maintenance

Constraints on the design and implementation of cable systems are imposed by each device used to transport or otherwise process the television signal. Each active device adds small distortions and noise to the signal.

Even passive devices contribute noise. The distortions and noise compound so that with each additional device the signal becomes less perfect.

Any nonlinear device, even bimetallic junctions, cause distortions. The primary contributors are the slight nonlinearities of amplifiers. Because the amplifiers are connected in cascade, the slight damage to the signal accumulates.

Noise in any electronic system can come from many sources. The major source is the random thermal movement of electrons in resistive components. For a cable system at 20°C or 68°F, the thermal noise voltage in a 4-MHz bandwidth will be 1.1 μV or -59.1 dBmV. This is the minimum noise level, or noise floor. Noise contributions from amplifiers add on a power basis, with the noise level increasing 3 dB for each doubling of the number of identical amplifiers in cascade. Eventually, the noise will increase to objectionable levels. The difference between the RF peak level and the noise level is measured to quantify the degree of interference of the noise power. The power levels in watts are compared as a ratio. This is called the signal-to-noise ratio, or SNR. In a cable system, the apparent effect of noise is its interference with the video portion of the TV channel. This level is compared to the video carrier and called the carrier-to-noise ratio (CNR).

As the CNR value decreases, the interference of noise with the signal becomes visible as a random fuzziness, called *snow*, that can overwhelm the picture resolution and contrast. The point where the picture becomes objectionably noisy to viewers is at a CNR = 40 dB. In well-designed systems, the CNR is maintained at 46 dB. While an increase in signal level would improve the CNR, unfortunately, there can be no level increase without increases in distortions.

The distortion products of solid-state devices used in cable amplifiers are a function of the output levels and bandwidths. The higher the signal level, the greater the distortion products produced. Modern amplifiers use balanced configurations, which almost completely cancel the distortion caused by the squared term of the amplifier's transfer characteristic. The dominant remaining distortions are called triple beats. They are caused by the cubed term. Because distortion products add on a voltage basis, the composite triple beat (CTB) to carrier ratio changes by 6 dB for each doubling of the number of amplifiers in cascade, whereas the CNR decreases by 3 dB for each doubling.

As signal levels are increased in the distribution sections, additional allowances must be made in the system design. As a rule of thumb, CNR is determined primarily by the conditions of trunk operation and signal-to-distortion ratio (SDR) primarily by the conditions of distribution operation.

Two other factors limit the geography of a cable system. Cable attenuation rises with increasing frequency. More equal gain amplifiers are required to transmit the signal a given distance. But noise limits the maximum number of amplifiers used. The second factor is that amplifier distortion is a function of channel loading. The more channels carried, the greater the distortions.

System Reflections

Signal reflections occur throughout the cable plant and are called *microreflections*. They are caused by the individual slight errors in impedance match. The severity of the mismatch is measured by the magnitude of the return-loss ratio. The larger the return loss, the better. Perfection is infinite. Mismatches include connectors, splices, and even damage to the cable itself.

Microreflections are likely to be a serious problem for ATV transmission because of their digital nature.

Phase Noise

Phase noise is added to the original signal through modulation and frequency conversion processes. A significant amount of phase noise must be added to the video carrier before generated impairments become perceptible. Narrowband phase noise (measured 20 kHz from the video carrier) in a TV channel produces variations in the luminance and chrominance levels that appear as an extremely grainy pattern within the picture. The perceptibility level of phase noise on the video carrier is 53 dB below the carrier at 20 kHz. If the frequency conversion or modulation processes are operating close to specification, phase noise impairments should not be perceptible on the customer's TV unless the converter/descrambler is malfunctioning or is of poor quality.

Amplifier Distortions and Their Effects

New amplifier technology based on feedforward and power-doubling techniques increases power levels with fewer distortions. However, additional sources of minutely delayed signals have been created. The signal delays produced in these amplifiers have similar end results in picture degradation as the delayed signals generated by reflected signals in the cable plant. But they are caused by a different mechanism. These amplifiers use parallel amplification technology. The signals are split, separately amplified, and then recombined.

With a feedforward amplifier, the signals are purposely processed with delay lines. If the propagation time is not identical through each of the amplifiers' parallel circuits, signals will be recombined that are delayed by different amounts of time. In most circumstances, the amount of differential delay is small and will not produce a visible ghost, but it may cause loss of picture crispness. Since the hybrids used in these amplifiers are normally provided in matched pairs or in a single hybrid package, these delays are only a problem when the hybrids are not replaced as a matched set.

In systems that carry more than 30 channels, CTB is the limiting distortion. However, cross modulation (X-MOD) distortions, which is often the limiting factor in systems with less than 30 channels, can reappear as the controlling factor in dictating system design. The HRC and the IRC channelization plans discussed in the first section were developed to minimize the visible degradation in picture quality that is caused by CTB.

X-MOD is one of the easiest distortions to identify visually. Moderate X-MOD appears as horizontal and vertical synchronizing bars that move across the screen. In severe cases, the video of multiple channels is visible in the background.

Moderate CTB is the most misleading distortion since it appears as slightly noisy pictures. Most technicians conclude that there are low signal levels and CNR problems. CTB becomes visible as amplifier operating levels exceed the design parameters. Once CTB reaches a severe stage, it becomes more readily identifiable because it causes considerable streaking in the picture.

Composite second order (CSO) beats can become a limiting factor in systems that carry 60 or more channels and use the HRC or IRC channelization plans. This distortion appears as a fuzzy herringbone pattern on the television screen. The CSO beats fall approximately 0.75 and 1.25 MHz above the video carrier in a television channel. An IRC channelization will frequency-lock these beats together while increasing their amplitude relative to the carrier level.

Hum modulation caused by the 60-Hz amplifier powering is identified by its characteristic horizontal bar that rolls through the picture. If the hum modulation is caused by the lack of ripple filtering in the amplifier power supply, it will appear as two equally spaced horizontal bars that roll through the picture.

Frequency Bands Affected by Radio Frequency Interference

Discrete beat products can be difficult to identify by the displayed picture impairment. Radio frequency interference that leaks into the cable system from nearby RF transmitters causes spurious carriers to fall in the cable spectrum. Common sources of signal leakage are cracked cables and poor quality connections. When either of these situations happen, strong off-air television and FM radio broadcast signals interfere.

If television stations are carried at the same frequency on cable as broadcast and the headend channel processing equipment is phase locked to the off-air signal, the effects of this interference will be ghosting. The ghost appears before (to the left of) the cable signal since propagation time through the air is less than through cable. If the signals are not phase locked together, lines and beats appear in the picture.

Often there is interference from off-air signals due to consumer electronics hardware design. If the internal shielding of the equipment is inadequate, the internal circuits will directly pick up the signal. This phenomenon is called DPU for *direct pick-up interference*. This is the original motivation for cable converters. Those early set-top boxes tuned no more channels than the TV set, but they protected against DPU by incorporating superior shielding and connecting to the TV set through a channel not occupied off-air.

DPU can be misleading. When the subscriber switches to an antenna, he might receive better pictures than from the cable connection. He concludes that his TV receiver is operating correctly and the cable system is faulty. The only convincing argument is a demonstration with a receiver, which does not suffer from DPU. Viacom Cable has measured off-air field intensities of eight volts per meter. The German specification for immunity to DPU is 4 v/m. VCR tuners are generally inferior to TV tuners because the VCR market is even

more price competitive. The Electronic Industries Association (EIA) and NCTA Joint Engineering Committee are studying this issue.

The second most likely source of radio frequency interference is created by business band radios, paging systems, and amateur radio operators. These signals leak into the cable system and interfere with cable Channels 18 through 22 and Channels 23 and 24 (145 to 175 and 220 to 225 MHz). It is easy to determine that these signals are caused by an RF transmitter because of the duration of the interference and, sometimes, by hearing the broadcast audio. Since the signals are broadcast intermittently, it is almost impossible to determine the exact location(s) of ingress. Cable systems that operate above 450 MHz may find severe forms of interference. They are subjected to high-power UHF television stations, mobile radio units and repeaters, as well as a group of amateur radio operators signals in the top 10 to 12 channels. The extreme variation of shortwave signals in time and intensity makes location of the point(s) of infiltration of these signals difficult.

The upstream 5 to 30-MHz spectrum is a problem for operators who have two-way cable systems. There are many sources of interference and these signals accumulate upstream. In a two-way plant, a single leak in the system can make that portion of the upstream spectrum unusable throughout the entire plant; whereas in the downstream spectrum a leak may only affect a single customer's reception.

Signal Security Systems

Means of securing services from unauthorized viewership of individual channels range from simple filtering schemes to remote controlled converter/descramblers. The filtering method is the commonly used method of signal security and is the least expensive.

Trapping Systems

There are two types of filtering or trapping schemes: positive trapping and negative trapping. In the positive trapping method, an interfering jamming carrier(s) is inserted into the video channel at the headend. If the customer subscribes to the secured service, a positive trap is installed at the customer's house to remove the interfering carrier. The positive trapping scheme is the least expensive means of securing a channel where less than half the customers subscribe.

A drawback to positive trap technology is its defeatability by customers who obtain their own filters through theft, illegal purchase, or construction. Another drawback is the loss of resolution in the secured channel's video caused by the filter's effect in the center of the video passband. Pre-emphasis is added at the headend to correct for the filter's response, but loss of picture content in the 2- to 3-MHz region of the baseband video signal remains.

Negative trapping removes signals from the cable drop to the customer's home. The trap is needed for customers who do not subscribe. This is the least expensive means of securing a channel when over half the customers subscribe. The negative trap is ideal. There is no picture degradation of the secured channel because the trap is not in the line for customers who take the service. A drawback occurs for customers who do not subscribe to the secured service but want to view adjacent channels. These customers may find a slightly degraded picture on the adjacent channels due to the filter trapping out more than just the secured channel. This problem becomes more significant at higher frequencies, owing to the higher Q (efficiency) required of the filter circuitry. From a security standpoint, it is necessary for the customer to remove the negative trap from the line to receive an unauthorized service. Maintaining signal security in negative trapped systems depends on ensuring that the traps remain in the drop lines.

Scrambling and Addressability

There are two classes of scrambling technologies: (1) RF synchronization suppression systems and (2) base-band scrambling systems.

The concept of addressability should be considered separately from the scrambling method. Non-addressable converter/descramblers are programmed via internal jumpers or a semiconductor memory chip called a

programmable read only memory (PROM) to decode the authorized channels. These boxes' authorization must be physically changed by the cable operator. Addressable converters are controlled by a computer-generated data signal originating at the headend either in the vertical blanking interval (VBI) or by an RF carrier. This signal remotely configures the viewing capabilities of the converter. Impulse-pay-per-view (IPPV) technology is supported by addressable converter/descrambler systems.

RF Synchronization Suppression Systems. Converter-based scrambling systems that perform encoding and decoding of a secured channel in an RF format comprise the commonly used scrambling technology. The more common is known as *gated* or *pulsed* synchronization suppression. With this method, the horizontal synchronizing pulses (and with some manufacturers, the vertical synchronization pulses) are suppressed by 6 dB and/or 10 MHz dB. This is done in the channel's video modulator at the IF frequency. The descrambling process in the converter/descrambler occurs at its channel output frequency. This is accomplished by restoring the RF carrier level to its original point during the horizontal synchronization period. Variations of this method pseudorandomly change the depth of suppression from 6 to 10 dB or only randomly perform suppression.

A phase-modulated RF scrambling technique based on precision matching of SAW filters constructed on the same substrate has been introduced. This low-cost system is extending operators' interest in RF scrambling techniques for use within addressable plants.

Baseband Scrambling Systems. Baseband converter/descrambler technology provides a more secure scrambling technology for delivering video services. The encoding format is a combination of random or pseudorandom synchronization suppression and/or video inversion. Because the encoding and decoding are performed at baseband, these converter/descramblers are complex and expensive.

Maintenance of the system's video quality is an ongoing issue. The encoders are modified video processing amplifiers. They provide controls to uniquely adjust different facets of the video signal. The potential for setup error in the encoder, in addition to the tight tolerances that must be maintained in the decoders, has presented challenges to the cable operator.

Off-Premises Systems

The off-premises approach is compatible with recent industry trends to become more consumer electronics friendly and to remove security-sensitive electronics from the customer's house. This method controls the signals at the pole rather than at a decoder in the home. This increases consumer electronics compatibility since authorized signals are present in a descrambled format on the customer's drop. Customers with cable-compatible equipment can connect directly to the cable drop without the need for converter/descramblers. This allows the use of all VCR and TV features.

Interdiction technology involves a scheme similar to that of positive trap technology. In this format, the pay television channels to be secured are transported through the cable plant in the clear (not scrambled). The security is generated on the pole at the subscriber module by adding interference carrier(s) to the unauthorized channels. An electronic switch is incorporated allowing all signals to be turned off. While this method of signal access control has generated a lot of interest, practical problems and its incompatibility with advanced services and digital signals has precluded any wide-spread application.

Digital Encryption

One of digital technology's main advantages is the applicability of computer-processing power and features. As a result, the old challenges of scrambling and signal security can be approached with new techniques.

However, the advanced digital technology that makes better security possible also provides new means of attack for the would-be pirate. The microprocessors that are the heart of personal computers are available in ever-faster speeds. More memory, more hard disk speed and capacity, and high-speed cable modems make these more potent means of attack. Additionally, the high-speed cable modem makes it possible to combine the processing power of multiple personal computers. Consequently, it must be possible to respond to a security attack by replacing the breached security element. This can be done in two ways. If the cable operator owns

the set-top boxes, the cable operator can replace the set-top boxes when it is judged that the security breach is excessive. This occurs when the breach is relatively accessible to a significant fraction of the subscriber base, not just a handful of experimenters. However, if the set-top boxes were sold to subscribers, this option is not readily available. In the case of set-top boxes sold to subscribers, the security element must be replaceable in the event of significant breach. A plug-in card or module called the point of deployment (POD) module is used. The POD remains the property of the cable operator and can be electronically disabled. The subscriber would then be given a new POD device based on a system not yet breached.

Signal Splitting at the Customer's Premises

The common devices at the cable drop to the customer's home are grounding safety devices called *ground blocks* and a two-way signal splitter that sometimes has a built-in grounding terminal.

Splitters or ground blocks should have little effect on picture quality provided there is adequate signal to handle the splitter's loss. The signal strength may be below specifications because of an excessively long drop or more activated cable outlets in the house than the cable design anticipated. To compensate, some systems use an AC-powered drop amplifier. These amplifiers can create problems—a reduced CNR or increased distortions.

Consumer electronics switching devices, designed to allow convenient control and routing of signals between customer products and cable systems' converters/descramblers, have built-in amplification stages to overcome the losses associated with the internal splitters. These amplifiers add distortions or noise. When cable systems were designed, consumer electronics switching devices were not taken into account because they did not exist.

Signal splitting in VCRs can be a problem. To compensate for recording SNR deficiencies, inexpensive VCRs sometimes split the signal unequally between the by-pass route and the VCR tuner. This gives the VCR a stronger signal than the TV receiver to improve VCR performance. In addition, this strategy reduces the quality of the signal routed to the TV. When it is compared with VCR playback, the disparity in performance is reduced.

Consumer Electronics Compatibility

Cable systems are becoming more consumer friendly by trapping popular secured services. More cable-ready television sets are appearing in the customer's home. With VCRs that are also cable ready, some of the interface issues are becoming simpler. Some television sets have built-in A/B selector switches and video input ports that allow signal source switchings to be performed through the television's remote control. Up to three A/B switches, two splitters, and two converter/descramblers have been wired into configuration allowing the consumer to watch and record the programming desired. Even with this configuration, consumers lose the ability to preprogram the VCR to record more than one channel.

Hopefully, the days of complex interfaces will soon be over. A positive step in this direction is the EIA Decoder Interface Interim Standard, IS-105. This connection system is oriented toward supporting external, low cost, descramblers. If a descrambler is connected to the TV set or VCR via this technique, the user regains use of the advanced features precluded by converters.

PROJECTIONS FOR DIGITAL CABLE

The advent of digital television has created new complexities for the interface between cable and consumer electronics, as well as exciting new opportunities. What can or may transpire is governed not only by technical developments but by rules and regulations imposed by Congress and the FCC, as well as by consumer preferences and the marketing objectives of the cable industry, broadcasters, and consumer electronics manufacturers. Many of these factors are related and are discussed at length on the accompanying CD-ROM, in the section on Projections for Digital Cable. Also discussed therein are Digital Must Carry, Cable Modems and Telephone, and Interactive Television.

NAVIGATION AND DETECTION SYSTEMS

Electromagnetic wave theory is fundamental to all navigation and detection systems. Global positioning system (GPS) applications have brought an added dimension to this area and in many applications works with radar systems in more sophisticated applications. The basic operation of the radar system has not changed in years; however, computers and digital technology have significantly enhanced the way data are processed.

Underwater sound systems are nothing more than radar systems at lower frequencies. We can work with underwater systems like we do for the higher-frequency electromagnetic systems to communicate, navigate, detect, track, classify, and so on. We are just working with substantially longer wavelengths. C.A.

RADAR PRINCIPLES

David K. Barton

THE RADAR SYSTEM AND ITS ENVIRONMENT

Radar is an acronym for radio detection and ranging, and is defined⁷ as a device for transmitting electromagnetic signals and receiving echoes from objects of interest (targets) within its volume of coverage. The signals may be in the frequency range from the high-frequency radio band (3 to 30 MHz) to light (10^{15} Hz), although most systems operate between 300 MHz and 40 GHz. The target is a passive reflecting object in primary radar, while in secondary radar a beacon (transponder) is used to reinforce and identify the echo signal.

A radar system in its environment is shown in Fig. 23.1.1. Transmission is typically through a directional antenna, whose beam can either scan a coverage volume (search radar) or follow the echo from a previously detected target (tracking radar). Transmission is over a line-of-sight path through the atmosphere or space, except for over-the-horizon radar using ionospheric bounce paths. The target can be a man-made object (e.g., an aircraft or missile) or a natural surface or atmospheric feature (land formation, ocean wave structure, or precipitation cloud). The target echo is often received with the same antenna used for transmission, from which it is routed to the receiver by a duplexer. Environmental factors that influence radar performance include the characteristics of the propagation path (attenuation, refraction, and reflection) and reception of noise and interference from objects both within and beyond the radar beam (thermal radiation, accidental or intentional radio interference, and echoes from unwanted target objects, called clutter). The radar information may be used locally by an operator, or may be transmitted as analog or digital data to a remote site or network.

Radar Frequencies

Radar can be operated at any frequency at which electromagnetic energy can be generated and radiated, but the primary bands used are identified in Table 23.1.1. The band letter designations provide the radar engineer with a convenient way of specifying radar frequency with sufficient accuracy to indicate the environmental and antenna problems, but without disclosing potentially secret tuning limitations. The International Telecommunications Union (ITU) defines no specific service for radar, and the assignments listed are derived from those radio services which use radar: radiolocation, radionavigation, meteorological aids, earth exploration satellite, and space research. Where the ITU defines UHF as extending from 300 to 3000 MHz, radar engineers use L and S bands to refer to frequencies above 1000 MHz.

The applications of the several frequency bands are discussed in the following section.

Radar Functions and Applications

The basic functions performed by the radar are implicit in the definition: target detection, and measurement of target position (not only range but angles and often radial velocity). Other measured data may include target amplitude, size and shape, and rate of rotation. The major fields of applications are listed in Table 23.1.2.

FIGURE 23.1.1 Radar system in its environment.

Radar Subsystems. A block diagram of a simple, coherent pulsed radar is shown in Fig. 23.1.2. The dashed lines divide the equipment into seven subsystems, according to the technology used in implementation (see the following chapter on radar technology). In this radar, operation is controlled by a synchronizer, which initiates the pulsing of the transmitter and the gates and triggers that control the receiver, signal processor, and display. The synchronizer may also serve as the frequency reference used in the exciter to generate the r.f. drive signal, at carrier frequency f_0 , to the transmitter and the local oscillator signals used for downconversion of the signal to intermediate frequency f_c in the superheterodyne receiver. The system is termed coherent because the exciter maintains the transmission (carrier) frequency at a consistent phase with respect to the local oscillator signals.

The transmitted pulse is generated by amplification of the exciter r.f. drive, during the pulse supplied by the modulator and triggered by the synchronizer. This pulse is passed to the antenna through the duplexer, an r.f. switch that connects the transmitter to the antenna, with low loss, during the pulse transmission. During transmission, the duplexer protects the sensitive receiver from damage by establishing a short circuit across the receiver input

TABLE 23.1.1 Radar Frequency Bands (IEEE Standard 521-1984)

Band designation	Nominal frequency range	Specific frequency range for radar based on ITU assignments for region 2 (N. and S. America)
HF	3–30 MHz	No specific assignment for radar
VHF	30–300 MHz	138–144 and 216–225 MHz
UHF	300–1000 MHz	420–450 and 890–942 MHz
L	1–2 GHz	1.215–1.4 GHz
S	2–4 GHz	2.3–2.5 and 2.7–3.7 GHz
C	4–8 GHz	5.25–5.925 GHz
X	8–12 GHz	8.5–10.68 GHz
K_u	12–18 GHz	13.4–14 and 15.7–17.7 GHz
K	18–27 GHz	24.05–24.25 GHz
K_a	27–40 GHz	33.4–36 GHz
V	40–75 GHz	59–64 GHz
W	75–110 GHz	76–81 and 92–100 GHz
mm	110–300 GHz	126–142, 144–149, 231–235, and 238–248 GHz

TABLE 23.1.2 Radar Applications

Type of application	Specific applications	Usual bands
Air surveillance	Long-range early warning	UHF, L
	Ground-controlled intercept, air-route surveillance	L
	Acquisition for weapon system, height finding and three-dimensional radar, air collision avoidance	S
Space and missile surveillance	Ballistic missile early warning, missile acquisition, satellite surveillance	VHF, UHF
Surface search and battlefield surveillance	Sea search, navigation and collision avoidance, ground mapping	X, K _u , K _a
	Mortar and artillery location	C, X
	Airport taxiway control, intrusion detection, land vehicle collision avoidance	K _u , K _a
Weather radar	Observation and prediction, weather avoidance (aircraft), cloud-visibility indicators	S, C
Tracking and guidance	Antiaircraft fire control, surface fire control, missile guidance, range instrumentation, satellite instrumentation, precision approach and landing	C, X, K _u
	Smart weapons, projectiles, bombs	K _a , V, W
Astronomy and geodesy	Planetary observation, earth survey, ionospheric sounding	VHF, UHF, L

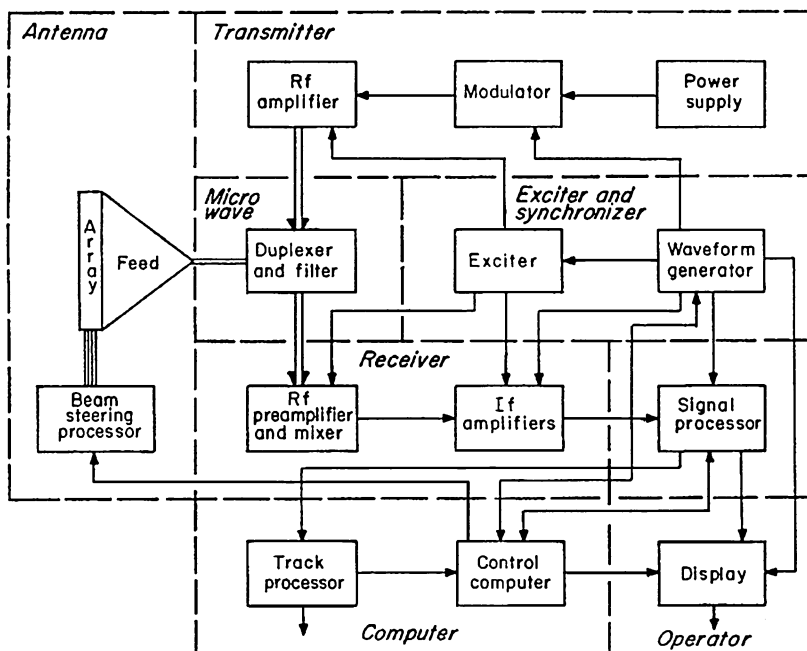

FIGURE 23.1.3 Block diagram of phased-array radar (Ref. 2).

terminal. The antenna shown is a parabolic reflector, steered mechanically in one or two axes by servomechanisms. The received signal passes from the antenna to the receiver through the duplexer, which has disconnected the transmitter and established a low-loss path to the receiver terminal. A low-noise r.f. amplifier is used at the receiver input, followed by a mixer for conversion to intermediate frequency (i.f.). Following amplification of several tens of decibels, the signal passes to the signal processor, which is designed to optimize the ratio of signal to noise and clutter. Outputs to the display will consist, ideally, of target echoes, appearing at locations on the display corresponding to the target range and angles. In a tracking radar, the signal outputs are fed back to control the antenna steering and the position of the range gate in the receiver.

A more advanced radar, using a computer-controlled phased-array antenna, is shown in Fig. 23.1.3. An eighth subsystem has been added, consisting of the control computer and a track processor, both implemented digitally. Beam steering is also controlled digitally by the beam steering processor. The simple synchronizer has been replaced by a digitally controlled waveform generator. Digital control is also applied to the receiver, signal processor and display. The phased-array radar may be programmed to perform a variety of functions in rapid sequence, including search, target tracking, and tracking and guidance of interceptor missiles. Such a radar is known as a multifunction array radar (MFAR), favored in modern U.S. weapon systems. Phased-array radar may be used solely for search (usually as a three-dimensional, or 3D radar, scanning in elevation as well as in azimuth), or solely for tracking, in which case multiple-target tracking is possible through rapid sequencing among several targets.

RADAR-RANGE EQUATIONS

A radar range equation is a relationship by which the detection range expected on a given target by a given radar may be calculated. Different equations may be derived, depending on whether the radar and its mode of operation can be specified in detail or only in a more general way, and on the complexity of the environment to which the calculation is applicable.

Basic Radar Range Equation

The basic radar range equation applies to a radar for which the known parameters include observation time (the time during which the beam lies on the target), and which operates in a benign environment (thermal noise only). The peak signal power S received by the radar antenna over a free-space path is calculated from the transmitted peak power P_t and a series of factors that describe, basically, the geometry of the radar beam relative to the target:

$$S = \frac{P_t G_t A_r \sigma}{(4\pi)^2 R^4} \quad (1)$$

where G_t = transmit antenna gain

A_r = effective receive antenna aperture area

σ = target cross section

R = target range

Since the receive aperture and gain are related by

$$A_r = \frac{G_r \lambda^2}{4\pi} \quad (2)$$

where λ is the carrier wavelength, the signal power can also be given as

$$S = \frac{P_t G_t G_r \lambda^2 \sigma}{(4\pi)^3 R^4} \quad (3)$$

Thermal noise in a radar receiver is a combination of receiver-generated and environmental noise, extending over the entire radar frequency band with a power density N_0 given by

$$N_0 = kT_s \quad (4)$$

where k is the Boltzmann's constant = 1.38×10^{-23} W/(Hz · K) and T_s is the system noise temperature referred to the antenna terminal. The system noise temperature⁸ is calculated from the receiver noise factor F_n , line losses L_r , and antenna temperature T_a :

$$T_s = T_a + T_r + L_r T_e \quad (5)$$

$$T_a = \frac{0.88T'_a - 254}{L_a} + 290 \quad (6)$$

$$T_r = T_{lr}(L_r - 1) \quad (7)$$

$$T_e = T_0(F_n - 1) \quad (8)$$

where T_r = temperature contribution of loss L_r

T'_a = sky temperature from Fig. 23.1.4

L_a = antenna ohmic loss

T_{lr} = physical temperature of the receiving line

T_e = temperature contribution of the receiver

T_0 = standard temperature (290 K) used in measuring noise factor

It can be seen that low noise factor and low losses can lead to $T_s < 290$ K when the antenna is looking upward into space.

FIGURE 23.1.4 Sky temperature for an idealized antenna (lossless, no earth-directed sidelobes) located at the earth's surface, as a function of frequency, for a number of beam elevation angles. Solid curves are for geometric-mean galactic temperature, sun noise 10 times quiet level, sun in unity-gain side lobe, cool-temperature-zone troposphere, 2.7-K cosmic black-body radiation, zero ground noise. Upper dashed curve is for maximum galactic noise (center of galaxy, narrow-beam antenna), sun noise 100 times quiet level, zero elevation angle, other factors the same as the solid curves. Lower dashed curve is for the minimum galactic noise, zero sun noise, 90° elevation angle.⁸

The noise power at the i.f. output of the receiver will depend on receiver bandwidth and gain, but this noise power is equivalent to an input power at the antenna terminal of

$$N = N_0 B_n = kT_s B_n \tag{9}$$

where B_n is the noise bandwidth of the i.f. filter. For a wideband filter and a simple pulse ($B_n \gg 1/\tau$, where τ = pulse width) the signal peak is not affected by the filter, and $S/N = S/kT_s B_n$. In general, however, the SNR at the receiver i.f. output is calculated from the ratio of received pulse energy $S\tau$ to noise density:

Ideal energy ratio for single pulse:

$$\frac{E_1}{N_0} = \frac{P_t \tau G_t G_r \lambda^2 \sigma}{(4\pi)^3 R^4 kT_s} \tag{10}$$

Intermediate-frequency power ratio for single pulse:

$$\frac{S}{N} = \frac{E_1}{N_0 L_m} = \frac{P_t \tau G_t G_r \lambda^2 \sigma}{(4\pi)^3 R^4 kT_s L_m} \tag{11}$$

where L_m = i.f. filter matching loss. For a rectangular pulse, this loss is shown in Fig. 23.1.5a, as a function of the product $B_n \tau$ for different filter shapes. For a system using linear-fm pulse compression (chirp), the loss will be a function of the weighting applied to achieve the desired time-sidelobe level, as shown in Fig. 23.1.5b.

The expression of i.f. output SNR in terms of transmitted pulse energy $P_t \tau$ permits the range equation to be used with any type of pulse modulation, without in-depth knowledge of that modulation and its processing

FIGURE 23.1.5 Intermediate-frequency filter matching loss: (a) rectangular pulse with different filter shapes; (b) linear-fm pulse compression with weighting for different sidelobe levels.

in the receiving system. Most systems will be characterized by i.f. matching loss L_m between 0.7 and 1.5 dB, and little error will result from assuming $L_m = 1$ dB even if the actual modulation and processing are completely unknown.

When the radar maintains coherence and processes the target echo over a coherent processing interval t_f , the output of the i.f. processor will be

$$\frac{S}{N} = \frac{E}{N_0 L_m} = \frac{P_{av} t_f G_t G_r \lambda^2 \sigma}{(4\pi)^3 R^4 k T_s L_m} \tag{12}$$

where P_{av} = average transmitter power = $P_t \tau f_r$ for pulsed radar operating at pulse repetition frequency f_r , and L_m = matching loss of the filter to the entire waveform received over t_f s. In this form, the equation can be applied directly to a radar using any type of waveform (and processing): pulsed (noncoherent processing), by setting $t_f = t_r$, the pulse repetition interval; pulsed (coherent doppler processing) or CW, where $t_f = 1/B_f$ is the integration time of the doppler filter with bandwidth B_f . In the limit, for systems with coherent processing, $t_f = t_o$, the total observation time during which the target lies within the radar beam, and there will be only one output sample from the doppler filter. In most cases, however, $t_f < t_o$, and there will be $n' = t_o/t_f$ independent output samples available for subsequent noncoherent integration.

RF Loss Factors

Equations (10) to (12) consider free-space transmission conditions and idealized radar operation (except for a possible matching loss). In practice, a number of other factors must be included in expressing the energy ratio of the received signal.

- a. *Signal attenuation prior to receiver:* Transmission line loss L_t ; antenna losses (to the extent they are not included in G_t, G_r, T_s); receiving line and circuit losses at r.f. (to the extent they are not included in T_s); atmospheric attenuation L_a (see Figs. 23.1.20 to 23.1.22); and atmospheric noise (included in T_s through T'_a , Fig. 23.1.4, for clear air, and using Eq. (54) when precipitation is present).
- b. *Surface reflection and diffraction effects:* Pattern-propagation factor F , calculated from Eq. (57) with data from Figs. 23.1.24 and 23.1.25, appears as F^4 in the numerator of the radar equation ($F > 1$ implies extra gain from the surface interaction).
- c. *Antenna pattern and scanning:* The gains G_t and G_r are defined on the beam axis, and apply directly for tracking radar, with signal energy calculated for arbitrarily chosen observation time t_o ; for one-coordinate scan at ω rad/s, the observation time is calculated using $t_o = \theta_3/\omega$, where θ_3 is the one-way half-power beamwidth (in radians) in the scan coordinate, and signal energy is calculated using gains G_t and G_r , evaluated at the point of the scan nearest the target; for two-coordinate scan, the observation time is $t_o = t_s \theta_a \theta_e / \psi_s$, where θ_a and θ_e are azimuth and elevation beamwidths, and ψ_s is the solid angle searched in time t_s , and signal energy is calculated using maximum gains. The variation in actual antenna gains brought to bear on the target, as a function of target position in the beam, is included as a beamshape loss in calculation of the *deductibility factor*, which is the energy ratio required to achieve given detection performance.
- d. *Signal-processing losses:* A number of losses resulting from nonideal signal processing are discussed in Radar Functions and Applications, and included in the deductibility factor.

When the r.f. losses are included, the equations for energy ratio become

$$\frac{E_t}{N_0} = \frac{P_t \tau G_t G_r \lambda^2 \sigma F^4}{(4\pi)^3 R^4 k T_s L_t L_\alpha} \quad (13)$$

$$\frac{E}{N_0} = \frac{P_{av} t_f G_t G_r \lambda^2 \sigma F^4}{(4\pi)^3 R^4 k T_s L_t L_\alpha} \quad (14)$$

Calculation of Detection Range in Noise

The deductibility factor for noncoherent integration is denoted by $D_x(n, n_e)$, where n is the number of noncoherently integrated pulses and $n_e \leq n$ is the number of independent target samples included in the integration. By setting $E_t/N_0 = D_x(n, n_e)$, we may solve for the maximum range at which the given detection performance is achieved, for a noncoherent system:

$$R_m^4 = \frac{P_t \tau G_t G_r \lambda^2 \bar{\sigma} F^4}{(4\pi)^3 k T_s D_x(n, n_e) L_t L_\alpha} \quad (15)$$

The average target cross section $\bar{\sigma}$ is used in this equation, and any target fluctuation effects are included in the deductibility factor. When coherent integration is used, the deductibility factor becomes $D_x(n', n_e)$ where n' is the number of independent noise samples available from a doppler filter. By setting $E/N_0 = D_x(n', n_e)$, we may solve for the maximum range at which the given detection performance is achieved, for any system (including the noncoherent system, for which $t_f = t_r$, $P_{av} t_f = P_t \tau$, and $n' = n$):

$$R_m^4 = \frac{P_{av} t_f G_t G_r \lambda^2 \bar{\sigma} F^4}{(4\pi)^3 k T_s D_x(n', n_e) L_t L_\alpha} \quad (16)$$

It should be noted that Eqs. (15) and (16) are transcendental, since the atmospheric loss L_α depends on range R_m . It may be necessary to use an iterative calculation, in which an initial estimate of R_{m1} is made with $L_{\alpha 1} = 1$, followed by one or two refinements in which $L_{\alpha 2}$ is evaluated at R_{m1} to calculate R_{m2} , and $L_{\alpha 3}$ is evaluated at R_{m2} to calculate the final R_m . Another method is to apply Eq. (13) or (14) repeatedly with varying range until the resulting energy ratio equals the required D_x , or to perform such calculations at fixed range intervals and interpolate to find the range giving the required D_x . If the factor F^4 shows oscillatory behavior with target range, as it may when surface reflections are present, there may be several values of range at which the equation is satisfied, corresponding to the beginnings and endings of detection regions.

The deductibility factor D_x used in the range equations will be found from the theoretical value derived in Radar Functions and Applications for the various fluctuating target cases, increased by the filter matching loss L_m (Fig. 23.1.5), the beamshape loss L_p , and the miscellaneous signal processing loss L_x .

Search-Radar Equation

The potential performance of a search radar, or of a tracking radar during acquisition scan, can be determined from its average power, receiving aperture, and system temperature, without regard to its frequency or waveform. The steps in deriving optimum search performance from Eq. (16) are as follows:

a. Group all r.f. and other losses into a combined search loss given by

$$L_s = \frac{L_m L_t L_\alpha L_p^2 L_f L_c L_x L_n}{F^4} \quad (17)$$

where L_p^2 = two-coordinate beamshape loss
 L_i = integration loss
 L_c = collapsing loss
 L_f = fluctuation loss
 L_x = miscellaneous signal processing loss
 L_n = a beamwidth factor

b. Assume uniform search, without overlap, of an assigned solid angle ψ_s in a time t_s using a rectangular beam whose solid angle is

$$\psi_b = \theta_a \theta_e = \frac{4\pi}{G_i L_n} \ll \psi_s = A_m (\sin \theta_m - \sin \theta_0) \tag{18}$$

where θ_a and θ_e = 3-dB beamwidths
 L_n = beamwidth factor relating gain to solid angle of the beam
 A_m = azimuth sector searched
 θ_m and θ_0 = upper and lower elevation search limits

c. Express the observation time t_o for a target as

$$t_o = \frac{t_s \psi_b}{\psi_s} = \frac{4\pi t_s}{G_i \psi_s L_n} \tag{19}$$

and assume that all signal energy reaching A_r during t_o is integrated for one detection decision. The definition of two-coordinate beamshape loss, which is included in L_s , is consistent with Eq. (19).

d. Substitute Eqs. (2), (17), (18), and (19) into (16) to obtain the search radar equation:

$$R_m^4 = \frac{P_{av} A_r t_s \bar{\sigma}}{4\pi \psi_s k T_s D_0(1) L_s} \tag{20}$$

Neither wavelength nor waveform appears directly in Eq. (20) although wavelength and aperture size must permit Eq. (18) to be satisfied in such a way as to concentrate energy within ψ_s , and the loss terms may vary with wavelength, waveform, and scan procedure. The new loss term L_n appearing in Eq. (19) is an antenna beam loss that accounts for energy outside the main lobe and not available for integration. The often used gain expression $G = 25,000/\theta_a \theta_e$, with θ in degrees, corresponds to a 40 percent loss of useful energy, or $L_n = 2.0$ dB. Reduced directivity caused by illumination taper does not appear in L_n but enters the search radar equation through A_r . Practical minimum values for L_s are between 11 and 13 dB for $P_d = 0.9$ with optimum diversity and scan procedure.

Beacon-Range Equations

One-way transmission from a radar to a beacon gives the interrogation power level S_b at the beacon receiver:

$$S_b = \frac{P_t G_t G_r \lambda^2}{(4\pi)^2 R^2 L_{\alpha 1} L_b} \tag{21}$$

where G_b = beacon antenna gain in the radar direction
 $L_{\alpha 1}$ = one-way atmospheric loss
 L_b = loss between the beacon antenna and receiver

On the return link, a beacon peak power P_b determines the signal power S at the radar antenna terminal:

$$S = \frac{P_b G_b G_r \lambda^2}{(4\pi)^2 R^2 k T_s L_m L_{\alpha 1}} \quad (22)$$

DETECTION

The term *detection* in radar can refer to either of two steps in signal processing. First, it may refer to the process by which the signal envelope is extracted from the sinusoidal i.f. waveform (i.e., envelope *detection*). Second, it may refer to the determination that a target signal is present at the output of the processor (i.e., threshold *detection*). Both processes are discussed in this section. The meaning will usually be apparent from the context.

Signal and Noise Statistics

Most radar signals are sinusoids with narrowband modulation (in amplitude or phase) superimposed by the transmitter, antenna, and target. Random noise is also constrained approximately to the signal bandwidth when it reaches the detection circuits after passage through the receiver. The instantaneous i.f. output noise voltage can be described in terms of in-phase and quadrature components

$$V = V_i \cos(2\pi f_c t) + V_q \sin(2\pi f_c t) \quad (23)$$

Either component of V can be described by a gaussian probability distribution

$$dP_v = \frac{1}{\sqrt{2\pi N}} \exp\left(\frac{-V^2}{2N}\right) dV \quad (24)$$

where dP_v = probability that voltage lies between V and $V + dV$, and N = mean-square noise voltage (average noise power). The video noise voltage E_n out of a linear envelope detector, corresponding to $E_n = \sqrt{V_i^2 + V_q^2}$ has a Rayleigh distribution

$$dP_e = \frac{E_n}{N} \exp\left(\frac{-E_n^2}{2N}\right) dE_n \quad (25)$$

These noise distributions are shown in Fig. 23.1.6. The probability P_f that the noise envelope will exceed a given threshold level E_t is the shaded area to the right of E_t in Fig. 23.1.6b.

$$P_f = \int_{E_t}^{\infty} \frac{E_n}{N} \exp\left(\frac{-E_n^2}{2N}\right) dE_n = \exp\left(\frac{-E_t^2}{2N}\right) \quad (26)$$

If a sinusoidal signal of peak amplitude E_s is present with the noise, the distribution of envelope voltage E_s is Rician

$$dP_s = \frac{E_n}{N} \exp\left(\frac{-E_n^2 + E_s^2}{2N}\right) I_0\left(\frac{E_n E_s}{N}\right) dE_n \quad (27)$$

where I_0 is the Bessel function with imaginary argument. The probability of detection P_d for a sample taken at the peak of the signal is the area under this curve and above the threshold E_p , as shown in Fig. 23.1.7 for different signal-to-noise power ratios $S/N = E_s^2/2N$.

FIGURE 23.1.6 Probability distributions of noise: (a) Gaussian distribution of I and Q components of i.f. noise voltage; (b) Rayleigh distribution of detected envelope.²

FIGURE 23.1.7 Probability distributions of envelope of signal plus noise.²

Single-Sample Detection Probability

When a single sample is available for detection, the threshold is set to give the desired false-alarm probability according to Eq. (26), and the detection probability follows from the integral of Eq. (27). The results are plotted in Fig. 23.1.8, where each curve gives P_d versus S/N for the threshold setting corresponding to the P_f value shown. The value of S/N required to achieve given P_d with fixed P_f is denoted by $D_0(1)$, the single-pulse deductibility factor for the steady-signal case. For example, for $P_d = 0.90$, $P_f = 10^{-6}$, we find $D_0(1) = +13.2$ dB. Although steady signals are seldom encountered in radar, data from this figure are used as the basis for establishing deductibility factors for fluctuating targets in systems using single or multiple pulses.

Filters and Signal Spectra

Detection performance for a single sample has been shown to depend on the S/N ratio at the i.f. output. Noise power at this point is a function of the receiver gain, the bandwidth, and the noise spectral density in the early stages of the receiver, before bandwidth is established. It is customary in detection analysis to assume an ideal (noise-free) receiver of unity gain and to replace all actual noise sources with an equivalent broadband source of spectral density N_0 , given by Eq. (4), added to the input signal. The output noise power will then be $N = N_0 B_n$, where B_n is the equivalent noise bandwidth of the receiver. The signal output power will also depend on the receiver bandpass characteristics, and on the input signal energy.

The maximum possible output S/N will be

$$(S/N)_{\max} = E/N_0 \tag{28}$$

where E is the total signal energy and $(S/N)_{\max}$ is measured at the maximum of the signal envelope out of a matched filter. Practical filters can approach, but never exceed, the performance of a matched filter.

The matched filter for a single, uncoded pulse of duration τ and energy E_1 can be approximated by a conventional bandpass filter whose bandwidth is $B \approx 1/\tau$. A matching loss is defined for this case as

$$L_m = \frac{E_1/N_0}{S/N} \tag{29}$$

(see Fig. 23.1.5). Pulses with internal coding or modulation require more complex filters.

A train of pulses transmitted coherently (with controlled phase) produces a spectrum consisting of many separate lines (Fig. 23.1.9), and requires a *comb filter* with a matched series of response bands properly phased

FIGURE 23.1.8 Detection probability versus signal-to-noise ratio of steady signal.

to add all signal components into one output. Although such a filter is readily synthesized for a selected point in the time-frequency domain, using a range gate and narrowband filter, it is difficult to match to signals of unknown time delay and doppler shift. Hence the integration of pulse trains is often carried out at video (after phase has been removed by an envelope detector). The IF filter is matched approximately to a single pulse, giving $S/N = (E_1/N_0)L_m$ at the envelope detector. Successive video pulses are added (integrated) on the radar display or in some other range-ordered storage device, prior to threshold detection.

Video Integration

Pulse train integration at video reduces the required energy of each pulse but introduces a loss in performance relative to predetection (matched-filter) integration in a comb filter. This integration loss $L_i(n)$ is defined as the increase in total signal energy required for a given P_d and P_f , relative to that needed with predetection integration. The deductibility factor $D_0(n)$ for n -pulse video integration as defined by Blake⁸ and the IEEE⁷ is

$$D_0(n) = \frac{L_i D_0(1)}{n} \tag{30}$$

where $D_0(1)$ is the detectability factor for the single-sample case, from Fig. 23.1.8. Curves of integration loss L_i versus n are shown in Fig. 23.1.10, with $D_0(1)$ as a parameter. From these two figures, the steady-target

data originally derived by Marcum¹⁴ may be reproduced with an accuracy of about 0.1 dB. For example, if $P_d = 0.90$ and $P_f = 10^{-6}$ are needed, $D_0(1) = +13.2$ dB from Fig. 23.1.8, and $L_i = 5.7$ dB for $n = 100$ pulses, giving a total energy ratio requirement $100 \times D_0(100) = +18.9$ dB and a single-pulse requirement $D_0(100) = -1.1$ dB.

False-Alarm Time

The D_0 curves of Fig. 23.1.8 correspond to a given probability P_f of a false alarm from each independent sample applied to the threshold. If the detection circuits are operative for $t < t_r$ seconds in each repetition interval t_r , there will be $\eta = t_g B_n$ independent samples applied to the threshold during the integration interval nt_r , producing an average of ηP_f false alarms. The ratio of total time to average number of alarms is the false-alarm time t_{fa} . In some discussions, following Marcum's usage,⁶ the false-alarm time t_{fa} is defined as the interval in which the probability of at least one false alarm is 0.5, and a false-alarm number n' is defined as the number of independent samples applied to the threshold during t_{fa} . Since $t_{fa} = 0.69 t_{fa}$, Marcum's false-alarm number is related to false-alarm probability by

FIGURE 23.1.9 Waveform and spectrum of coherent pulse train.⁵

$$n' = \frac{0.69 B_n t_g \overline{t_{fa}}}{nt_r} = \frac{0.69}{P_f} \tag{31}$$

Collapsing Loss

Practical radars seldom preserve their full r.f. signal resolution through the integration and thresholding processes, where use of insufficient video bandwidth or broadened range gates may prove economical. The n video samples of signal plus noise are then integrated along with m extra samples of noise, a process described in terms of collapsing ratio

$$\rho = 1 + \frac{m}{n} \tag{32}$$

The effect, when using a square-law detector, is the same as if the signal energy were redistributed over $\rho n = m + n$ pulses, leading to a larger L_i value (Fig. 23.1.10) associated with the integration of ρn pulses. The additional loss is referred to as the collapsing loss L_c :

$$L_c(\rho, n) = \frac{L_i(\rho n)}{L_i(n)} \tag{33}$$

Formulas for ρ in different cases are given in Table 23.1.3. In cases for which the number of independent threshold samples varies inversely with ρ , P_f may be permitted to increase, and the energy added to overcome collapsing will not be as great as in other cases.

Detection of Fluctuating Signals

Swerling Case 1 (Rayleigh Target Fluctuation). Essentially all actual radar targets fluctuate in amplitude, as a function of aspect angle and hence of time, following the Rayleigh distribution. The correlation time t_c of this fluctuation can be estimated, for a target of width L_x rotating at rate ω_a relative to the radar line of sight, from

$$t_c = \frac{\lambda}{2\omega_a L_x} \tag{34}$$

FIGURE 23.1.10 Integration loss versus number of pulses (Ref. 10).

Since this time is generally much greater than the observation time t_o , the target amplitude remains correlated over the n pulses are integrated, meeting the definition of the Swerling Case 1 (slowly fluctuating) target.¹¹ In order to ensure high probability of detection, it is necessary to increase the average signal power to provide a margin for fading, and this increase is called fluctuation loss. This loss is primarily a function of required detection probability, as shown in Fig. 23.1.11. The Rayleigh distribution is a chi-square distribution with two

TABLE 23.1.3 Equations for Collapsing Ratio $\rho = (m + n)/n$

Cases for which P_{fd}/ρ remains constant	
1. Restricted CRT sweep speed s , where d = spot diameter and τ = pulse width	$\rho = 1 + \frac{d}{s\tau}$
2. Restricted video bandwidth B_v , where $B = 1/\tau$ = i.f. signal bandwidth	$\rho = 1 + \frac{1}{2B_v\tau} = 1 + \frac{B}{2B_v}$
3. Collapsing of coordinates onto the display, where $2\Delta_r/c$ = time-delay interval displayed per display cell, $\omega_e t_v$, $\omega_a t_v$ = elevation and azimuth scans during integration time t_v , and θ_e and θ_a = beamwidths	$\rho = \frac{2\Delta_r}{c\tau}$ or $\rho = \pi = \frac{\omega_e t_v}{\theta_e}$ or $\rho = \frac{\omega_a t_v}{\theta_a}$
Cases for which P_{fa} remains constant	
4. Excessive i.f. bandwidth $B_n > 1/\tau$, followed by matched video $2B_v = 1/\tau$	$\rho = 1 + B_n\tau$ (use L_c in place of L_m)
5. Receiver outputs mixed at video, where M = number of receivers	$\rho = M$
6. i.f. filter followed by gate of width τ_g and by video integration	$\rho = B_n\tau \left(1 + \frac{\tau_g}{\tau} \right)$

FIGURE 23.1.11 Fluctuation loss versus detection probability for Rayleigh fluctuating target (Swerling Case 1).

degrees of freedom, corresponding to the I and Q components of the reflected signal, each of which has a gaussian distribution. The figure gives data for $1 < n < 10$, and the loss will be a few tenths of a decibel higher for integration of tens or hundreds of pulses.

Having calculated the detectability factor for a steady target, we can now adjust this to find the detectability factor $D_1(n)$ for the Rayleigh fluctuating target:

$$D_1(n) = D_0(n)L_f(1) = \frac{D_0(1)L_i(n)L_f(1)}{n} \tag{35}$$

For example, for $P_d = 0.90$, $P_f = 10^{-6}$, $n = 100$, we can estimate $L_f = 8.6$ dB, from which the total energy requirement will be $100 \times D_1(100) = +27.5$ dB and the single-pulse requirement $D_1(100) = +7.5$ dB.

Reduction of Fluctuation Loss with Diversity

As in communications, the application of diversity can reduce the required fade margin (fluctuation loss). When the number of diversity samples (independent samples of target amplitude) available for integration is n_e , the fluctuation loss becomes¹⁰

$$L_f(n_e) = [L_f(1)]^{1/n_e} \tag{36}$$

or, in decibels,

$$[L_f(n_e)]_{\text{dB}} = \frac{1}{n_e} [L_f(1)]_{\text{dB}} \tag{37}$$

Since diversity samples must be integrated noncoherently, the integration loss will increase as n_e increases. The optimum number of diversity samples, when coherent integration would otherwise be available, depends on the required P_d , and for $P_d = 0.90$ there is a broad optimum between four and eight samples. Diversity is available in time, frequency, polarization, or aspect angle.

Time Diversity. The number of independent target samples available in an observation time t_o is

$$n_e = 1 + t_o/t_c \leq n \tag{38}$$

In the limit, when $t_c < t_r$, $n_e = n$, the detectability factor is that given by Swerling for the Case 2 (rapidly fluctuating) target. Coherent integration cannot be carried out on the Case 2 target, but such rapid fluctuation is not normally seen for stable targets.

Frequency Diversity. The number of independent target samples available when the n pulses are distributed uniformly over a frequency interval Δf is

$$n_e = 1 + \Delta f/f_c \tag{39}$$

where $f_c = c/2L_r$ and L_r is the radial dimension of the target (along the radar line of sight). For example, a target of length $L_r = 15$ m will provide an independent target sample for each 10 MHz of frequency shift. A dual-diversity radar system, with two fixed frequencies separated by any amount greater than f_c , will provide $n_e = 2$, regardless of the number of pulse transmitted. There are two degrees of freedom for each channel, and hence the signal available for integration at the combined output of the two channels will have four degrees of freedom, corresponding to the statistics of the Swerling Case 3 model. Use of pulse-to-pulse frequency agility with adequate total bandwidth can provide $n_e = n$, giving Swerling Case 2 statistics.

Polarization Diversity. Use of two orthogonal polarizations can also provide $n_e = 2$. A system operating with pulse-to-pulse frequency agility on two orthogonal polarizations can provide Swerling Case 4 statistics, $n_e = 2n$. It is not necessary to have separate L_f curves for each Swerling case, since Eq. (.37) permits all data to be calculated with sufficient accuracy from Fig. 23.1.11.

Aspect Angle (Space) Diversity. Radar systems using more than one site can observe a target over spatially diverse paths, obtaining independent samples on each path. If the echo signals are then combined for integration at a central point, diversity gain can be achieved. This mode of operation leads to complexity and high cost, because of the need to duplicate equipment and supporting facilities and the need to compensate for differing signal delays and doppler shifts before combining the signals. Hence, it is not usually a practical option for the system designer.

Detectability Factor with Diversity. The final value of theoretical detectability factor with diversity, $D_e(n, n_e)$, will be found using $L_f(n_e)$ in place of $L_f(1)$ in Eq. (35). The value $D_x(n, n_e)$ used in the radar equation will be this theoretical value increased by filter mismatch, beamshape, and miscellaneous signal processing losses.

Cumulative Probability of Detection

It is not always possible to combine successive signals from a given target through integration. For example, if the signals are obtained from more than one scan across the target position, or if the repetition interval is long and the target velocity high, the target may have moved in range by an amount greater than the radar resolution, and successive signals will not remain in the same integration cell. The conventional means of using all the signal information in such cases is to accumulate the probabilities of detection resulting from each observation, rather than the energy of the observations. If the probability of detection on each observation (or scan) is P_d , the probability of obtaining at least one detection on k observations is the cumulative probability of detection,

$$P_c = 1 - (1 - P_d)^k \tag{40}$$

The cumulative probability of detection will build up quite rapidly over several scans, even when the single-scan probability is below 50 percent. Large fluctuation loss can be avoided by scanning the search region several times with low P_d . However, such a process is less efficient than integration of energy from all scans with adequate diversity.

TARGETS AND CLUTTER

Target Cross Section

The primary parameter used to describe a radar target is its radar cross section, defined as 4π times the ratio of the reflected power per unit solid angle in the direction of the source to the power per unit area of the incident wave. A large sphere (whose radius $a \gg \lambda$) captures power from an area πa^2 , scattering it uniformly in solid angle, and hence has a radar cross section $\sigma = \pi a^2$ equal to its projected area.

FIGURE 23.1.12 Normalized cross section of a sphere (Ref. 1).

The variation of sphere cross section with wavelength (Fig. 23.1.12) illustrates the division into three regions of the spectrum:

- a. The optical region, $a \gg \lambda$, where cross section is essentially constant with wavelength.
- b. The resonant region, $a \approx \lambda/2\pi$, where the cross section oscillates about its optical value due to interference of the direct reflection with a creeping wave, propagated around the circumference of the object.
- c. The Rayleigh region, $a \ll \lambda/2\pi$, where the cross section drops rapidly below its optical value, varying as $1/\lambda^4$.

Although the sphere cross section varies with wavelength, it is constant over all aspect angles, and hence can serve as a reference for radar testing and evaluation. The cross section of all other objects vary with aspect angle, requiring more complex descriptions: amplitude probability distributions, fluctuation frequency spectra (or time correlation functions), and radar frequency correlation functions. For a few simple shapes, it is possible to write expressions for maximum cross section as a function of size and wavelength:

$$\sigma = 0.88\lambda^2 \text{ resonant dipole viewed normal to axis}$$

$$\sigma(0) = 2\pi aL^2/\lambda \text{ cylinder viewed normal to axis}$$

where a is the radius and L is the length, both assumed $\gg \lambda$,

$$\sigma(0) = 4\pi A^2/\lambda^2 \text{ flat plate viewed normal to surface}$$

where $A = wL$ is the plate area, assumed $\gg \lambda^2$. The cross section of a cylinder or a rectangular plate varies with aspect angle, with a pattern in the plane that includes dimension L given by

$$\sigma(\theta) = \sigma(0) \left[\frac{\sin\left(\frac{2\pi L}{\lambda} \sin\theta\right)}{\frac{2\pi L}{\lambda} \sin\theta} \cos\theta \right]^2 \tag{41}$$

For most other shapes, it is necessary to calculate cross section from complex equations or computer codes, or to measure it with a calibrated radar.

Amplitude Distributions

The cross section of a complex object is best described statistically by its probability density function, examples of which are shown in Fig. 23.1.13. These functions represent the Swerling fluctuation models

$$\text{Cases 1 and 2: } dP = \frac{1}{\bar{\sigma}} \exp\left(\frac{-\sigma}{\bar{\sigma}}\right) d\sigma \quad \sigma \geq 0 \tag{42}$$

$$\text{Cases 3 and 4: } dP = \frac{4\sigma}{\bar{\sigma}^2} \exp\left(\frac{-2\sigma}{\bar{\sigma}}\right) d\sigma \quad \sigma \geq 0 \tag{43}$$

where $\bar{\sigma}$ is arithmetic mean of the distribution. The median value σ_{50} is used as the center of each plot.

Spectra and Correlation Intervals. Swerling Cases 1 and 3 describe slowly fluctuating targets, for which the correlation time t_c is such that all pulses integrated in the time t_o within a single scan are correlated but successive

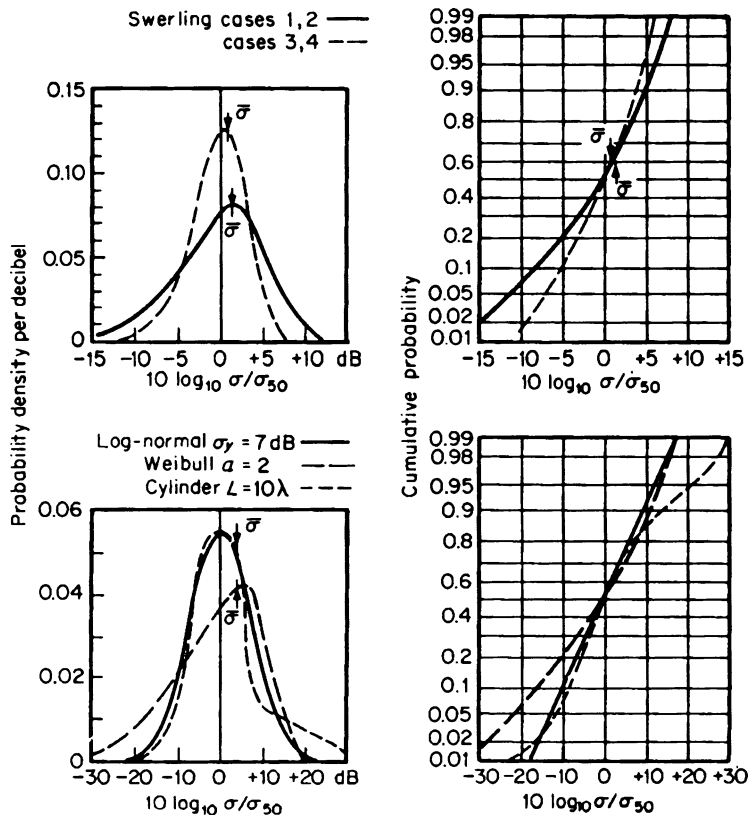

FIGURE 23.1.13 Amplitude distributions of cross section. Upper plots: Cases 1 and 2; lower plots: Cases 3 and 4.

scans separated by t_s give uncorrelated values:

$$t_o \ll t_c < t_s \tag{44}$$

Cases 2 and 4 describe fast (pulse-to-pulse) fluctuations, $t_c < t_r$.

Target Glint and Scintillation. Targets composed of multiple scattering elements whose phase variations cause fluctuations in signal amplitude are subject to errors in radar position measurement. The apparent source of the composite echo signal wanders back and forth across the target, and at times the signal appears to originate from points well beyond the physical spread of the target itself. In principle, the variance in position estimate is infinite, for a measuring system with unlimited dynamic range and measurement bandwidth. However, for practical reasons this *glint error* is closely approximated by a gaussian distribution with standard deviation $\sigma_r = 0.35L_r$ (in range), or $\sigma_\theta = 0.35L_x/R$ rad (in angle), where L_r is the spread of the target scattering elements along the radar beam and L_x that normal to the beam. On typical aircraft targets, the distribution of significant scattering elements produces values of L between one-third and two-thirds of the maximum target dimensions, leading to glint errors from 0.1 to 0.25 the aircraft dimensions.

Measurement systems using sequential samples of target echo amplitude (conical-scanning and sector-scanning systems) are subject to additional *scintillation errors* caused by interaction of the target amplitude fluctuations with the measurement process. Typical values of this error are about $\sigma_\theta = 0.03\theta_3$ for conical-scanning trackers and $\sigma_\theta = 0.1\theta_3$ for sector scanning search radar.

Clutter Echoes

Unwanted radar echoes (clutter) may originate from land or sea surfaces (characterized by a dimensionless surface reflectivity σ^0), from precipitation or chaff occupying a volume of space (with a volume reflectivity η_v), or from discrete objects such as birds (described by cross sections in square meters). The cross section of distributed clutter can be found by multiplying the area or volume of the radar resolution cell by the appropriate reflectivity parameter:

For surface clutter,

$$\sigma_c = A_c \sigma^0 = \left(\frac{R\theta_a}{L_p} \right) \left(\frac{\tau_n c}{2} \sec \psi \right) \sigma^0 \tag{45}$$

For volume clutter,

$$\sigma_c = V_c \eta_v = \left(\frac{R\theta_a}{L_p} \right) \left(\frac{R\theta_e}{L_p} \right) \left(\frac{\tau_n c}{2} \right) \eta_v \tag{46}$$

where τ_n is the processed pulse width, $L_p = 1.33$ is beamshape loss, and ψ is the grazing angle between the radar beam and the surface.

Models for surface clutter reflectivity can be very complex, taking into account grazing angle, terrain type and vegetation or sea state, wind speed and direction, polarization, and other parameters. However, a simple approximate model uses a parameter γ to characterize the surface, and accounts for a broad region in grazing angle using

$$\sigma^0 = \gamma \sin \psi, \quad \psi_c < \psi < \pi/3 \tag{47}$$

$$\psi_c = \frac{\lambda}{4\pi\sigma_h} \tag{48}$$

where the surface roughness parameter σ_h is the rms deviation of surface heights from the average. For grazing angles below ψ_c , interference or reflected and direct rays reduces the illumination of the surface scatterers,

FIGURE 23.1.14 Sea clutter reflectivity versus grazing angle.²

FIGURE 23.1.15 Land clutter reflectivity versus grazing angle.²

FIGURE 23.1.16 Radar reflectivity of rain and snow.²

causing the clutter propagation factor to drop below unity: $F_c = \psi/\psi_c$. The effective surface reflectivity, seen by the radar, becomes $\sigma^0 F_c^4$. At angles near vertical incidence, σ^0 increases steeply as a result of quasispecular reflection. Typical variation in the reflectivity is shown in Fig. 23.1.14 for the medium-rough sea and Fig. 23.1.15 for land surfaces. Sea clutter has an inherent frequency sensitivity, but for land clutter the effect of frequency is primarily in the propagation factor.

Reflectivity of precipitation clutter depends on the rate r in the mm/h of water content, and on wavelength:

$$\text{Rain: } \eta_v = 5.7 \times 10^{-14} r^{1.6} / \lambda^4, \quad \lambda > 0.02 \text{ m} \tag{49}$$

$$\text{Snow: } \eta_v = 1.2 \times 10^{-13} r^2 / \lambda^4 \tag{50}$$

These values are plotted in Fig. 23.2.16, with rain values extended into the millimeter-wave bands, based on measurements.¹²

RESOLUTION

Definition of Resolution

A target is said to be resolved if its signal is separated by the radar from those of other targets in at least one of the coordinates used to describe it. For example, a tracking radar may describe a target by two angles, time delay, and frequency (or doppler shift). A second target signal from the same angle and at the same frequency, but with different time delay, may be resolved if the separation is greater than the delay resolution (processed pulse width) of the radar.

Resolution, then, is determined by the relative response of the radar to targets separated from the target to which the radar is matched. The antenna and receiver are configured to match a target signal at a particular angle, delay, and frequency. The radar will respond with reduced gain to targets at other angles, delays, and frequencies. This *response function* can be expressed as a surface in a five-dimensional coordinate system, the fifth coordinate representing amplitude of response. Because five-dimensional surfaces are impossible to plot,

and because angle response is almost always independent of delay-frequency response, these pairs of coordinates are usually separated, requiring only two three-coordinate plots.

Antenna Resolution

In angle, the response function $\chi(\theta, \phi)$ is simply the antenna voltage pattern. It is found by measuring the system response as a function of angles from the beam center. It has a main lobe in the direction to which the

FIGURE 23.1.17 Efficiency and beamwidth constant for antennas with tapered illumination: (a) efficiency versus sidelobe level; (b) beamwidth constant versus sidelobe level.

antenna is scanned, and sidelobes extending over all visible space. Angular resolution, i.e., the main-lobe width in the θ and ϕ coordinates, is generally taken to be the distance between the -3 -dB points of the pattern. The width, amplitude, and location of the lobes are determined by the aperture illumination (weighting) functions in the two coordinates across the aperture.

Because the matched antenna is uniformly illuminated, its response has relatively high sidelobes which are objectionable in most radar applications. To avoid these, the antenna illumination may be mismatched (tapered), with resulting loss in gain and broadening of the main lobe. Figure 23.1.17 shows the effects of tapering for sidelobe control on the gain and beamwidth of a rectangular antenna. As the sidelobe level is reduced, aperture efficiency η (the ratio of gain to that of the uniformly illuminated antenna having the same dimensions) falls below unity. At the same time, the beamwidth (which would have been $\theta_3 = 0.886\lambda/w$ for uniform illumination) increases.

Waveform Resolution

Time delay and frequency can also be viewed as if they were two angular coordinates, i.e., as a two-dimensional plane above which the response can be plotted to describe the filter response to a given signal as a function of the time delay t_d and the frequency shift f_d of the signal relative to some reference point to which the radar is matched. Points on the surface are found by recording the receiver output voltage while varying these two target coordinates. The response function $\chi(t_d, f_d)$ is given, for any filter and signal, by

$$\chi(t_d, f_d) = \int_{-\infty}^{\infty} H(f)A(f - f_d) \exp(j2\pi f t_d) df \quad (51)$$

or

$$\chi(t_d, f_d) = \int_{-\infty}^{\infty} h(t_d - t)a(t) \exp(j2\pi f_d t) dt \quad (52)$$

where the functions $A(f)$ and $a(t)$, $H(f)$ and $h(t)$, are Fourier transform pairs describing the signal and filter, respectively.

The transform relationship, Eqs. (50) and (51), governing the time-frequency response function are similar to those which relate the far-field antenna patterns to aperture illumination functions. Hence, data derived for waveforms can be applied to antennas, and vice versa, by interchanging analogous quantities between the two cases. There is a significant difference between waveform and antenna response functions and constraints, however, because the two waveform functions (in time delay and frequency) are dependent on each other through the Fourier transform. The two antenna patterns (in θ and ϕ coordinates) are essentially independent of each other, depending on aperture illuminations in the two aperture coordinates x and y . Further differences arise from the two-way pattern and gain functions applicable to the antenna case.

Ambiguity Function of a Single Pulse

When the filter response is matched to the waveform, $H(f) = A^*(f)$, $h(t) = a^*(t_d - t)$, the magnitude of the squared response function $|\chi(t_d, f_d)|^2$ is called the *ambiguity function* of the waveform. Figure 23.1.18 shows the square root of this function (the voltage response of the matched filter) for three pulses with different modulations. For a simple pulse with constant carrier frequency and phase (Fig. 23.1.18a), there is a single main lobe whose time response is a triangle extending over $\pm\tau$ in time with zero amplitude outside that region. In frequency, the function has the $(\sin^2 x)/x^2$ shape, with sidelobes extending over infinite bandwidth.

Introduction of phase modulation during the transmission of the pulse broadens the frequency spread of the response and narrows the response along the time axis. This is the principle of pulse compression, of which the most common form is linear fm (chirp), shown in Fig. 23.1.18b. With the linear-fm function, very low sidelobes can be obtained in region on both sides of the main, diagonal response ridge. Along this ridge, however, the response falls very slowly from its central value, and targets separated by almost one transmitted pulse width will be detected if they are offset in frequency by the correct amount. Pseudorandom phase coding can generate a single narrow spike in the center of the ambiguity surface (Fig. 23.1.18c), at the expense of large-amplitude sidelobes elsewhere on the ambiguity surface.

FIGURE 23.1.18 Ambiguity functions for single pulses: (a) response for a constant carrier pulse with rectangular envelope; (b) chirp response for Hamming weighting on transmit and receive; (c) response for the 13-element Barker code (Ref. 4).

The plots of Fig. 23.1.18 illustrate an important property of the ambiguity function: the total volume under the surface is equal to the signal energy (or to unity, when normalized) for all waveforms. Compression of the response along the time axis must be accompanied by an increase in response elsewhere in the time-frequency plane, either along a well-defined ambiguity ridge (for linear fm) or in numerous random lobes (for random-phase codes). For mismatched filters, the response function (cross-ambiguity function) has similar properties, although the central peak will be reduced in amplitude.

Mismatched filters are often used to reduce sidelobe levels in linear-fm pulse compression. The matching efficiency and pulse broadening factors have the same relationship to sidelobe levels as were illustrated in Fig. 23.1.17 for aperture efficiency and beam broadening for tapered aperture illuminations.

Ambiguity Functions of Pulse Trains

The principle of constant volume under the ambiguity function is also applicable to pulse trains. A train of coherent pulses of width τ , with pulse repetition interval $t_r = 1/f_r \gg \tau$, merely generates a repeating set of surfaces similar to Fig. 23.1.18a at intervals t_r in time. The added volume equals the energy of the additional pulses, and if the energy is normalized to unity (by division among the several pulses), the amplitude of each response peak is reduced proportionately. The location of peaks and associated sidelobes is shown in Fig. 23.1.19a. The result is to form a series of responses spaced in range by the *unambiguous range interval* R_u . When the signal is coherent over an observation time $t_o = nt_r$, the time response of the matched filter stretches the ambiguity function to $\pm t_o$ along the time axis. At the same time, there is formed a series of ambiguous responses spaced in radial velocity by the *blind speed* v_b , as shown in Fig. 23.1.19b, c.

Within the central lobes, this response is concentrated in spectral lines separated by f_r and approximately $1/t_o = f_r/n$ wide in frequency (Fig. 23.1.19b). Near the ends of the ambiguity function, where the matched-filter impulse response overlaps $n' < n$ pulses of the received train, the lines broaden to width f_r/n' , and at the end of the ambiguity function, where $n' = 1$, no line structure remains. If the repetition rate is increased, holding constant the pulse width and number of pulses in the train, t_o is decreased and the ambiguity volume is redistributed into a smaller number of broader lines. A decrease in pulse width, such that t_o is restored to its original value and n is increased, leads to a broader overall ambiguity function, with the original number of lines in frequency but with narrower and more numerous response bands along the time axis (Fig. 23.1.19c).

The coherent pulse train is thus characterized by a pattern of ambiguities in range and velocity, where the *unambiguous range* is $R_u = c/2f_r$, and the *unambiguous velocity* (or blind speed interval) is $v_b = \lambda f_r/2$. The product of these two quantities (the unambiguous area in the range-velocity plane) depends only on wavelength: $R_u v_b = \lambda c/4$.

Resolution of Targets in Clutter

The choice of the waveform is often dictated by the need to resolve small targets (aircraft, buoys, or projectiles) from surrounding clutter. The clutter power at the filter output is found by integrating the response function over the clutter region, with appropriate factors for variable clutter density, antenna response, and the inverse fourth-power range dependence included in the integrand. Signal-to-clutter ratio S/C for a target on the peak of the radar response is then given by

$$\frac{S}{C} = \frac{\sigma G_t(0)G_r(0)|\chi(0,0)|^2}{\int_v \eta_v(\theta, \phi, f_d t_d) G_t(\theta, \phi) G_r(\theta, \phi) \chi(f_d, t_d)^2 (R/R_c)^4 dv} \tag{53}$$

where σ = target cross section

η_v = clutter reflectivity

R/R_c = target-to-clutter range ratio

v = four-dimensional volume containing clutter

The usual equations for S/C ratio are simplifications of Eq. (53) for various special cases (e.g., surface clutter, homogeneous clutter filling the beam, and so forth). Clearly, the S/C ratio is improved by choosing a waveform

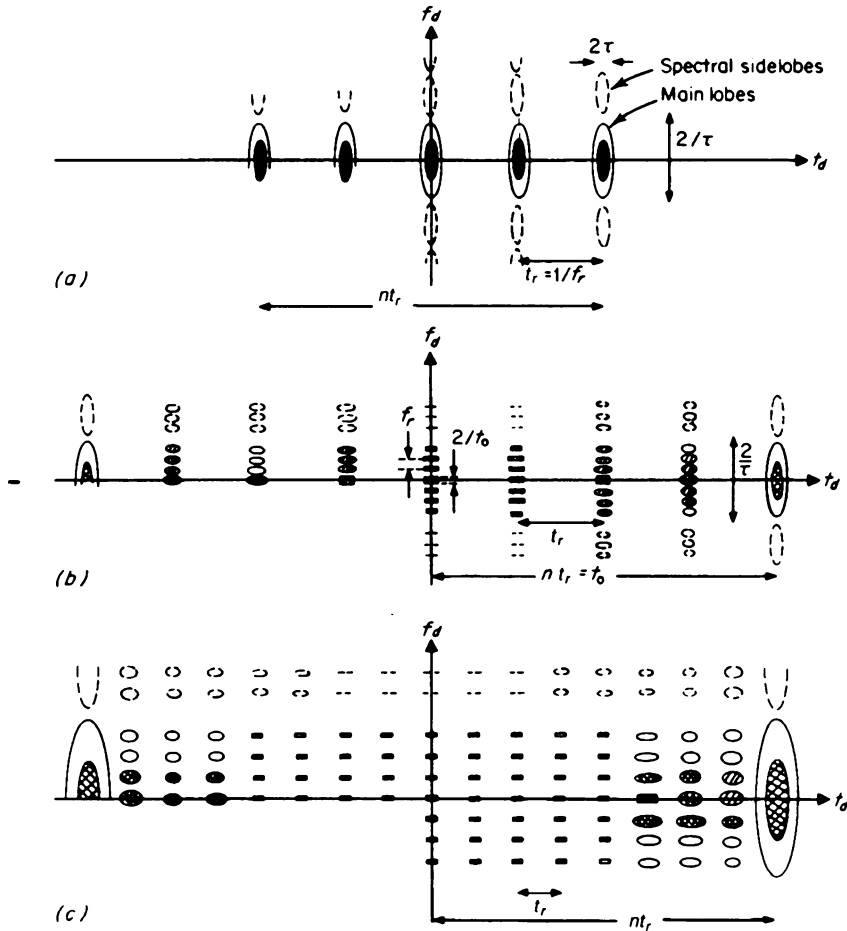

FIGURE 23.1.19 Ambiguity functions of uniform pulse trains: (a) noncoherent pulse train; (b) coherent pulse train; (c) coherent pulse train with reduced pulsewidth τ , increased f_r .

and filter such that $\chi(f_d, t_d)$ is minimized in clutter regions while maintaining a high value $\chi(0,0)$ for all potential target positions. In a search radar, a two-dimensional bank of filters and range gates would be constructed to cover the intervals in doppler and delay occupied by targets, and the clutter power for each of these filters would then be evaluated using Eq. (53).

RADAR PROPAGATION

In the radar equation (15), the echo signal power is seen to be proportional to pattern-propagation factor F^4 , which is the product of F_t^2 for the transmit path and F_r^2 for the receive path, and inversely proportional to L_{α} , the two-way path attenuation. The attenuation depends on the length of the path in which molecules of the

atmosphere and of clouds or precipitation are encountered, and the wavelength of the radar wave. The pattern-propagation factor depends on the interaction of the wave with the underlying surface, and the antenna gains in the directions of the target and the reflected wave from the surface.

Apart from the issue of echo signal strength, propagation will affect the accuracy of target position measurements. Errors will be introduced by refraction of the wave as it passes from the target to the radar, and by the multiple signal components which may reach the radar from the underlying surface as a result of reflection and diffraction.

Atmospheric Attenuation. The frequency bands used for radar were selected to minimize the effects of the atmosphere while achieving adequate bandwidth, antenna gain, and angular resolution. Attenuation is introduced by air and water vapor, by rain and snow, by clouds and fog, and (at some frequencies) by electronics in the ionosphere.

Clear-Air Attenuation. Attenuation in the clear atmosphere is seldom a serious problem at frequencies below 16 GHz (Fig. 23.1.20). The initial slope of the curves shows the sea-level attenuation coefficient k_α in decibels per kilometer, and this coefficient is reduced as the path reaches higher altitude. Above 16 GHz, atmospheric attenuation is a major factor in system design (Fig. 23.1.21). The absorption lines of water vapor (at 22 GHz) and oxygen (near 60 GHz) are broad enough to restrict radar operations above 16 GHz in the lower troposphere to relatively short range, even under clear-sky conditions. Attenuation versus frequency for two-way paths through the entire atmosphere is shown in Fig. 23.1.22.

Precipitation, Cloud, and Fog Effects. Above 2 GHz, rain causes significant attenuation, with k_α roughly proportional to rainfall rate r and to the 2.5 power of frequency. The classical data on rain attenuation^{13,14} were based on drop-size distributions given by Ryde and Ryde,¹⁵ which gave generally accurate results, except for a 40 percent underestimate of the loss between 8 and 16 GHz, at low rainfall rates. Later data were derived by Wexler and Atlas¹⁶ from a modified Marshall-Palmer distribution.¹⁷ At high rates (100 mm/h) the loss coefficient k_α/r is doubled between 8 and 16 GHz, giving better agreement with measurements and matching the measurements of Medhurst¹⁸ above 16 GHz. The Wexler and Atlas data provide the most satisfactory estimates for general use, and these were used in preparing Fig. 23.1.23.

Very small water droplets, suspended as clouds or fog, can also cause serious attenuation, especially since the affected portion of the transmission path can be tens or hundreds of kilometers. Attenuation is greatest at 0°C (Fig. 23.1.24). Transmissions below 2 GHz are affected more seriously by heavy clouds and fog than by rain of downpour intensity.

Water films that form on antenna components and radomes are also sources of loss. However, such surfaces can be specially treated to prevent the formation of continuous films.^{19,20}

Apparent Sky Temperature. Associated with the atmospheric loss is a temperature term, which must be added to the radar receiver input temperature. Figure 23.1.4 showed this loss temperature T'_a as a function of frequency, for clear-air conditions. When precipitation is present, there will be additional loss along the atmospheric path, generating additional loss temperature into the antenna. For this situation, the sky temperature is calculated from total atmospheric loss L_α using

$$T'_a = 290 \left(1 - \frac{1}{\sqrt{L_\alpha}} \right) + T_g \quad (54)$$

where T_g is the galactic background noise, a significant component for $f \leq 1$ GHz.

Ionospheric Attenuation. In the lowest radar bands, the daytime ionosphere may introduce noticeable attenuation.²¹ However, above the 100 MHz, this attenuation seldom exceeds 1 dB.

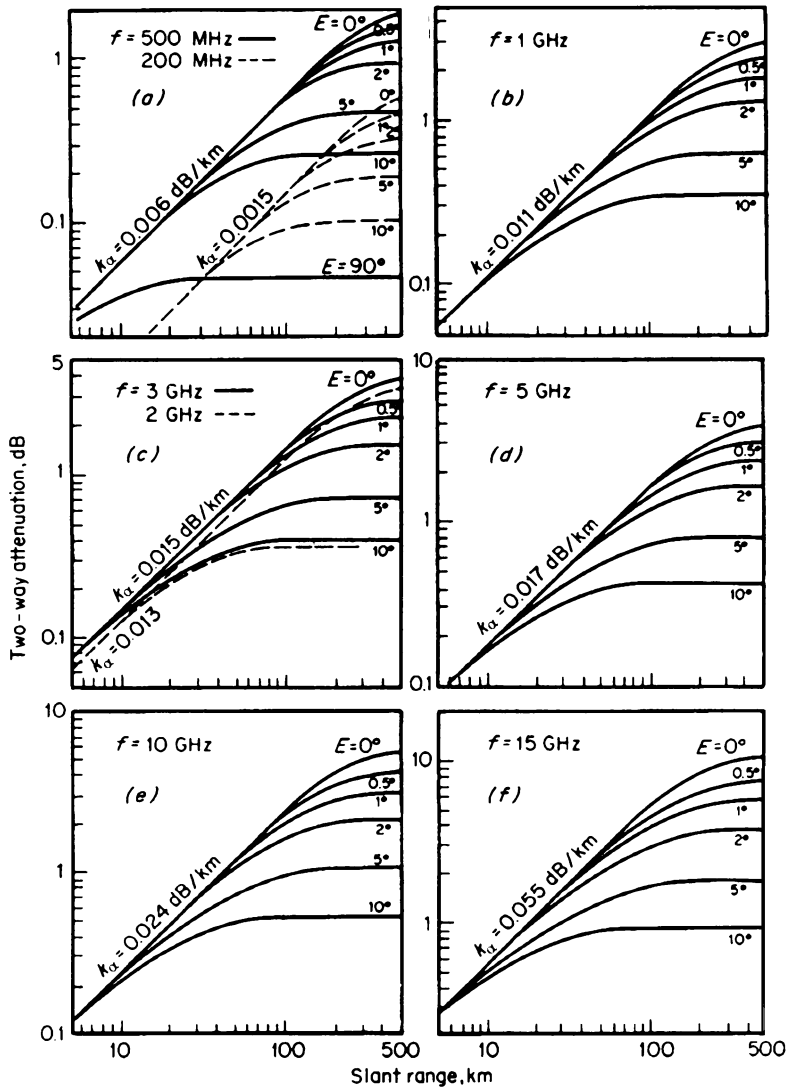

FIGURE 23.1.20 Atmospheric attenuation (0.2 to 15 GHz) versus range and elevation angle E . (Data from Ref. 8)

Surface Reflections

The radar target scatters power in all directions, and some of this power arrives at the radar antenna via reflection from the surface. If the radar receiving antenna pattern has significant response in the direction from which these reflections arrive, the receiver will be presented with a composite (multipath) signal, in which the reflected components interfere with the direct signal, alternately adding to and subtracting from the direct signal magnitude. This will affect the detectability of the signal, and will introduce multipath error in the measurement of target position. On the transmit path, the same phenomenon will modulate the illumination of the target, affecting the magnitude of the echo but not its arrival angle.

FIGURE 23.1.21 Atmospheric attenuation (20 to 100 GHz) versus range and elevation angle E . (Data from Ref. 8)

Specular Reflection. The simple model for surface reflection applies to a flat, smooth surface (Fig. 23.1.25). Ignoring curvature of the earth, the specular reflection from this surface arrives at the radar from a negative elevation angle θ_r , approximately equal to the positive elevation angle θ_t , of the direct ray from the target:

$$\text{Target elevation} = \theta_t = \sin^{-1} \left(\frac{h_t - h_r}{R} \right) \approx \frac{h_t - h_r}{R} \tag{55}$$

$$\text{Depression angle of reflection} = \theta_r = \psi = \sin^{-1} \left(\frac{h_t + h_r}{R} \right) \approx \frac{h_t + h_r}{R} \tag{56}$$

The depression angle from the radar is equal to the grazing angle ψ at the surface. The extra pathlength for the reflected ray will be

$$\delta_0 \approx R (\cos \theta_r - \cos \theta_t) \approx \frac{2h_t h_r}{R} = 2h_r \theta_t \tag{57}$$

For a radar beam pointed at elevation angle θ_b , the voltage gain for the direct ray will be $f(\theta_t - \theta_b)$, and for the reflected ray will be $f(\theta_t + \theta_b)$. The reflected ray will arrive at the antenna with a relative amplitude equal

FIGURE 23.1.22 Absorption loss for two-way transit of the entire troposphere, at various elevation angles (Ref. 8).

to the surface reflection coefficient ρ , resulting in an apparent antenna gain for the composite signal given by

$$f_r'(\theta_i) = f_r(\theta_i - \theta_b) + \rho f_r(-\theta_r - \theta_b) \exp \left[-j \left(\frac{2\pi\delta_0}{\lambda} + \phi \right) \right] = F_r(\theta_i) f(0) \tag{58}$$

where ϕ is the phase angle of the reflection coefficient and F_r is the pattern-propagation factor for the receive path. A similar expression involving the transmit pattern $f_t(\theta)$ will give the transmit pattern-propagation factor F_t . A two-way pattern-propagation factor $F^4 = F_t^2 F_r^2$ is used in the radar equation, and the detection range will be directly proportional to F .

As a result of the reflected signal, the coverage pattern of a search radar that has a broad elevation pattern will appear as in Fig. 23.1.25b. Near the horizon, where $f(\theta_i - \theta_b) \approx f(-\theta_r - \theta_b)$, $\rho \approx 1$, and $\phi \approx \pi$, the reflection lobes extend the coverage to twice the free-space value, while the nulls give zero signal. The nulls will appear at angles such that

$$\sin \theta_n = i \left(\frac{\lambda}{4h_r} \right) \approx \theta_n, \quad i = 0, 1, 2, \dots \tag{59}$$

FIGURE 23.1.23 Attenuation in rain.

FIGURE 23.1.24 Attenuation in clouds or fog (values of k_a are halved at $T = 18^\circ\text{C}$).

For elevated radars or long-range targets, curvature of the earth cannot be ignored, and equations that correct for curvature must be used [Ref. 3, p. 553]. However, flat earth approximations are adequate for radars up to 100 m from the surface viewing targets at ranges of a few tens of km.

The Fresnel reflection coefficient ρ_0 as a function of grazing angle ψ , for various surface materials, is plotted in Fig. 23.1.26. For horizontal polarization, the reflection coefficient remains near -1 for grazing angles below about 10° . For vertical polarization, the coefficient goes from -1 at low angles, through a minimum near zero amplitude, and to a positive value at high angles. The angle at which the real part of the coefficient goes through zero is known as the Brewster angle, and at this angle most of the power is absorbed by the surface.

Reflection from Rough Surface. Actual land and water surfaces are irregular, reducing the magnitude of the specular reflection to a value $\rho_0\rho_s$, where the specular scattering factor ρ_s is a function of the rms surface height deviation σ_h , the wavelength, and the grazing angle:

$$\rho_s = \exp \left[-2 \left(\frac{2\pi\sigma_h \sin \psi}{\lambda} \right)^2 \right] \tag{60}$$

The specular scattering factor is plotted in Fig. 23.1.27 as a function of normalized surface roughness.

As the specular scattering coefficient decreases, diffuse reflections appear, containing the power which has been lost to the specular component. These diffuse components arrive from a broad elevation region surrounding the point of specular reflection, and much of their power may fall outside the beamwidth of the antenna. They have random fluctuations in amplitude and phase, and produce little effect on detection range. However, they are important sources of tracking error.

FIGURE 23.1.25 Effect of surface reflections: (a) geometry of specular reflection; (b) lobing pattern produced by reflections (Ref. 2).

FIGURE 23.1.26 Fresnel reflection coefficient, as a function of grazing angle, for different surfaces: (a) horizontal polarization; (b) vertical polarization.

Diffraction at the Surface. Rays that pass close to the curved earth surface, or to an obstacle rising from the surface, are affected by diffraction. Smooth-sphere diffraction modifies the pattern-propagation factor at elevation angles less than $\theta_n/2$, where the pathlength difference between direct and reflected rays is less than $\lambda/4$. The calculation of F for such paths is described in [Ref. 3, pp. 297–302] and in Sec. 12 of this handbook.

Diffraction over obstacles such as trees, ridges, or fences will follow the knife-edge diffraction theory. Figure 23.1.28 shows curves for smooth-sphere and knife-edge diffraction.

Tropospheric Refraction

The refraction index of the troposphere, for all radar frequencies, can be expressed in terms of a deviation from unity in parts per million, or *refractivity*

$$N \equiv (n - 1) \times 10^6 = \frac{77.6}{T} \left(P + \frac{4810p}{T} \right) \tag{61}$$

FIGURE 23.1.27 Specular scattering factor versus normalized surface roughness.

where T = temperature in kelvins
 P = total pressure in millibars
 p = partial pressure of water-vapor component
 n = refractive index

Dry air at sea level can have a value as low as $N = 270$, but normal values lie between 300 and 320.

The Central Radio Propagation Laboratory (CRPL) of the National Bureau of Standards (now the National Oceanic and Atmospheric Administration) established a family of exponential approximations to the variation in refractivity with altitude for the normal atmosphere, in which the average U.S. conditions are represented by

$$N(h) = 313.0 \exp(-0.14386h) \tag{62}$$

FIGURE 23.1.28 Diffraction for paths near surface: (a) smooth-sphere diffraction; (b) diffraction over obstacle.

where h is the altitude in km above sea level. The velocity of wave propagation is $1/n$ times the vacuum velocity, including an extra time delay in radar ranging and causing radar rays to bend downward relative to the angle at which they are transmitted. Figure 23.1.29 shows, on an exaggerated scale, the geometry of tropospheric refraction.

For surveillance radars, the effects of refraction are adequately expressed by plotting ray paths as straight lines above a curved earth whose radius k_a is $4/3$ times the true earth's radius: $a = 6.5 \times 10^6$ m, $ka = 8.5 \times 10^6$ m.

FIGURE 23.1.29 Geometry of tropospheric refraction.

FIGURE 23.1.30 Low-angle ducting effect (Ref. 2).

FIGURE 23.131 Ionospheric errors in range and elevation angle, for different target altitudes: (a) range error versus frequency; (b) elevation angle error versus frequency.

A special problem can arise when the ray is transmitted at E_i an elevation below 0.5° into an atmosphere whose refractivity has a rapid drop, several times greater than the standard 45 N -units per km. Under those conditions, the ray can be trapped in a surface duct (Fig. 23.1.30) or in an elevated duct bounded by layers of rapidly decreasing N . The result is a great increase in radar detection range for targets within the duct (and for clutter) at the expense of coverage just above the ducting layer. Although there is some leakage of energy through the top of the duct, increasing at lower frequencies, the duct will usually trap all radar frequencies sufficiently to create a gap just above the horizon, through which targets can pass undetected.

Ionospheric Refraction

The refractivity of the ionospheric at radar frequencies is given by

$$N_i = (n - 1) \times 10^6 = -\frac{40N_e}{f^2} \times 10^6 = \frac{-1}{2} \left(\frac{f_c}{f} \right)^2 \times 10^6 \tag{63}$$

where N_e is the electron density per m^3 and f_c is the critical frequency in hertz ($f_c \approx 9\sqrt{N_e}$). Since f_c seldom exceeds 14 MHz, the refractivity at 100 MHz is less than 10^4 N -units, and above 1 GHz it does not exceed 100 N -units. Figure 23.1.31 plots the errors in range end elevation angle for normal ionospheric conditions for targets at different altitudes. Ionospheric errors are not generally significant for radars operating in the gigahertz region, but can dominate the analysis of tracking error in the 200- and 400-MHz bands.

SEARCH-RADAR TECHNIQUES

A *search radar* is one that is used primarily for the detection of targets in a particular volume of interest. A *surveillance radar* is used to maintain cognizance of selected traffic within a selected area, such as an airport terminal area or air route.⁷ The difference in terminology implies that the surveillance radar provides for the maintenance of track files on the selected traffic, while the search radar output may be simply a warning or one-time designation of each target for acquisition by a tracker. There is no significant difference in radar characteristics between the two uses, but the requirements for detection probability and search frame time may lead to different operating modes, scan patterns, and maximum ranges. The following discussions of search radar are equally applicable to surveillance systems.

Search Beams and Scan Patterns

Search radars are described as two-dimensional (2D) when resolution and measurement takes place in range and azimuth coordinates, or three-dimensional (3D) when the elevation coordinate is also measured. Beam shapes and scan patterns for the two types are shown in Fig. 23.1.32. The first four parts of this figure represent 2D radars that scan only in azimuth:

- (a) Horizon scan, using a narrow beam, fixed in elevation at the horizon
- (b) Fan beam, using a broad beam whose lower edge is at the horizon

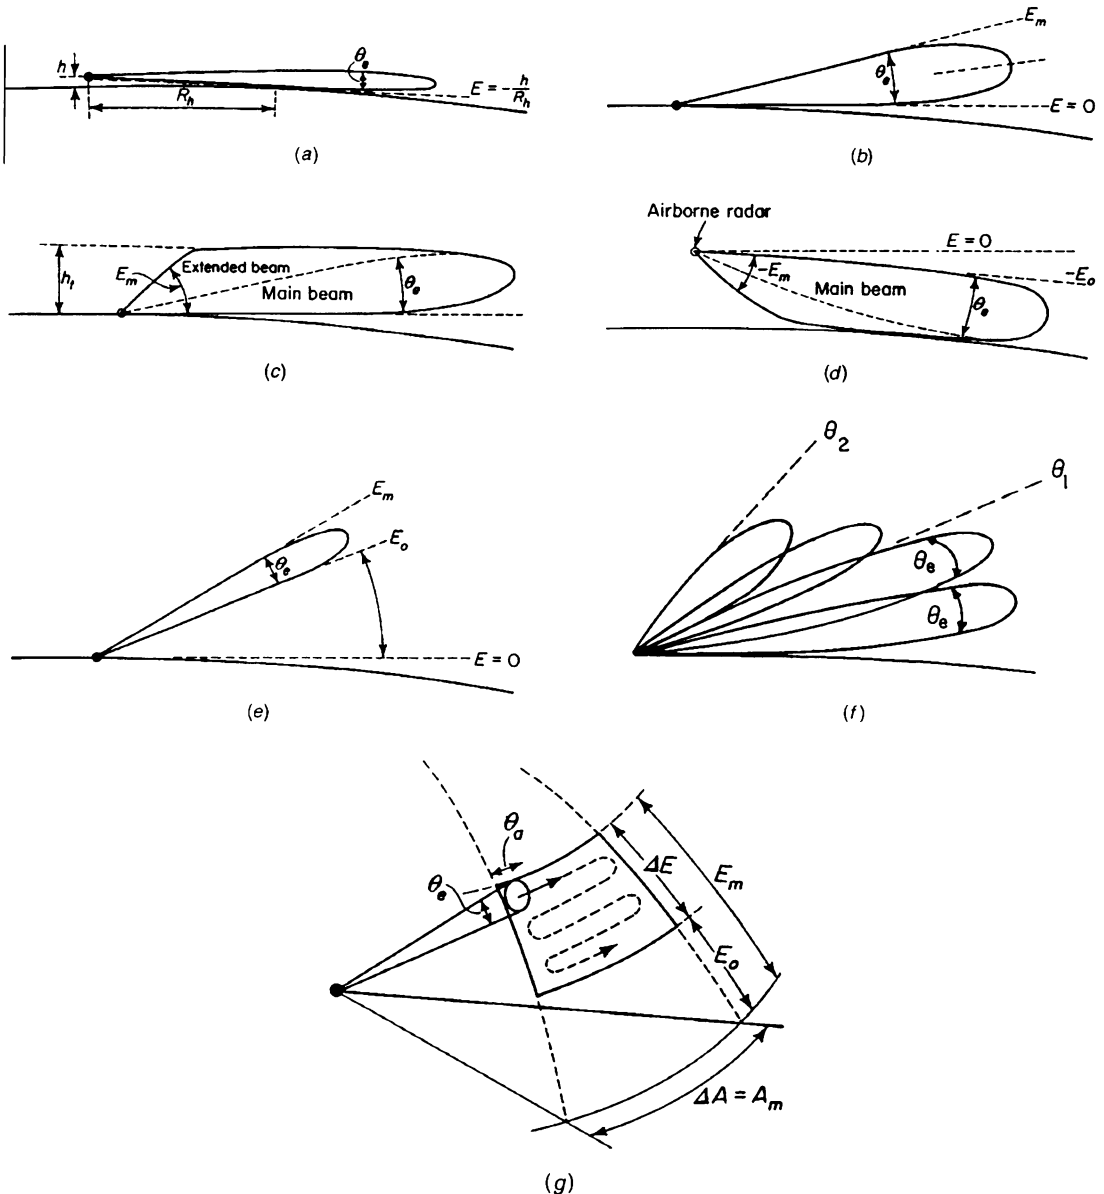

FIGURE 23.1.32 Basic types of search beams and scans.

- (c) Coscant-squared beam, similar to the fan beam but with extended coverage in elevation above the main beam, at reduced range
- (d) Inverted csc^2 beam, for coverage to the surface from an airborne radar

The last three parts of the figure represent 3D radars:

- (e) Elevation-scanning pencil beam, used at fixed azimuth for height-finding radar and combined with azimuth scan for volume 3D coverage;
- (f) Stacked beams in elevation, scanning in azimuth for volume 3D coverage;
- (g) Raster scan of a sector in both azimuth and elevation, often used in the search mode of a multifunction array radar.

Whatever the type of scan, the pulsed search radar will resolve and measure in range, for each beam position, and may also use doppler processing to resolve in radial velocity. The CW search radar may or may not resolve in range, as well as in radial velocity, depending on the modulation applied to the carrier.

Search-Radar Detection Process

Early search radars depended entirely on cathode-ray-tube displays with human operations for target detection, and this process remains one of the most efficient and adaptable. The curves for detection probability (Fig. 23.1.8) may be applied to the human operator if a suitable miscellaneous signal processing loss component for the operator, $L_{xo} \approx 4$ dB, is included in calculation of D_x for use in the radar equation. When the operator is fatigued or distracted, even larger losses will be encountered.

Electronic and digital integrators and automatic target detector circuits are included in many modern search radars to ensure more consistent performance than can be provided by human operators. The performance of such systems is not necessarily better than that of an alert operator, especially in the presence of clutter and interference or jamming. In order to hold the number of false alarms below the level which would overload the subsequent data processing and tracking, it is essential that the automatic detector system include constant-false-alarm-rate (CFAR) circuits to adapt the threshold to actual interference levels at the receiver-processor output. Typical CFAR techniques are shown in Fig. 23.1.33. The circuits (a) and (b) provide averaging of surrounding resolution cells in the frequency-domain; (c) averages in the time domain, over range cells surrounding the detection cell; (d) averages in the angle domain, over sectors each side of the antenna main lobe.

Use of CFAR detection processing leads to a loss, which must be included as a component of miscellaneous signal processing loss L_x . This loss may be estimated from Fig. 23.1.34. The CFAR ratio is defined as the ratio of the negative exponent x of false-alarm probability (e.g., $x = 6$ for $P_f = 10^{-6}$) to the number of independent interference samples, m_e , averaged in setting the threshold.

Moving-Target Indication

A moving-target indicator (MTI) is a device that limits the display of radar information primarily to moving targets. The sensitivity to target motion is usually provided through their doppler shifts, although *area MTI* systems have been built, which cancel targets on the basis of overlap of their signal envelopes in both range and angle.

In the usual pulse-amplifier coherent MTI system (Fig. 23.1.35), two cw oscillators in the radar are used to produce a phase and frequency reference for both transmitting and receiving, so that echoes from fixed targets have a constant phase at the detector, over the train of pulses received during a scan. These echoes will be canceled, leaving at the output only those signals whose phase varies from pulse to pulse as a result of target motion.

Coherent MTI can also be implemented with a pulsed oscillator transmitter (Fig. 23.1.36), in which the coherent oscillator at i.f. is locked in phase to a downconverted sample of each transmitted pulse. Although the transmitted and received signals are noncoherent, the phase-detected output is coherent and clutter components can be canceled. Both systems attenuate targets in a band centered on zero radial velocity, the depth and width of the rejection notch depending on the design of the canceler and the stability of the received signals.

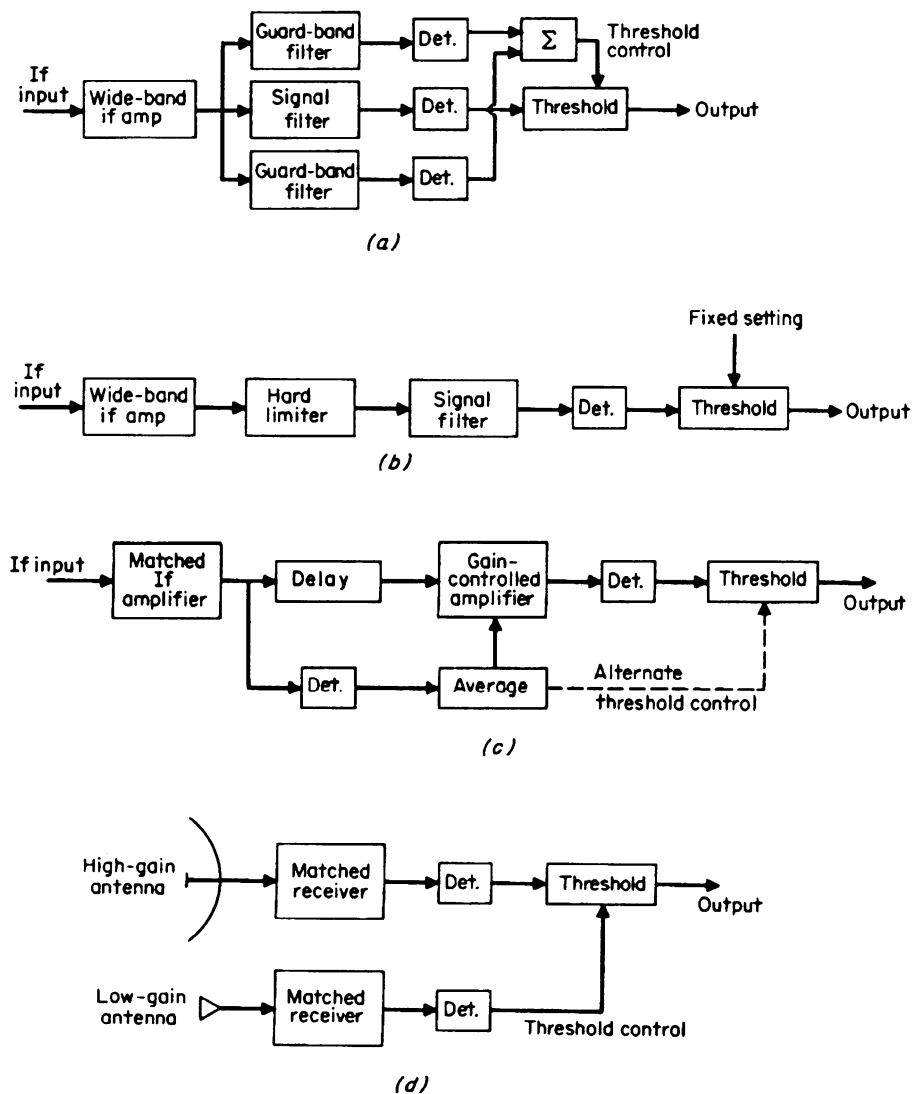

FIGURE 23.1.33 CFAR techniques: (a) guard-band system; (b) Dicke fix system; (c) range-averaged AGC; (d) sidelobe blanker.

Two variations on the coherent MTI are available for rejection of clutter with nonzero radial velocity. In the clutter-locked MTI, the average doppler shift of a given volume of clutter is measured and used to control an offset frequency oscillator in the receiver, shifting the received clutter components into the rejection notch. Short- or long-term averages may be used to obtain rapid adaptation to varying clutter velocity (as in weather clutter) or better rejection of selected parts of a complex clutter background. The alternative is *non-coherent MTI*, in which the clutter surrounding a target provides the phase reference with which the target signal is mixed to produce a baseband signal having target doppler shift. Although simpler to implement,

FIGURE 23.1.34 Universal curve for CFAR loss (Ref. 23).

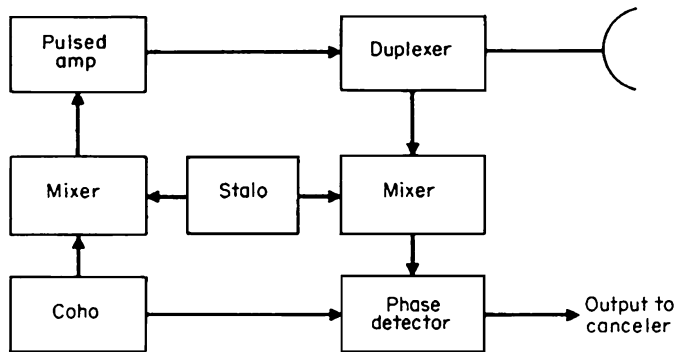

FIGURE 23.1.35 Coherent MTI system.

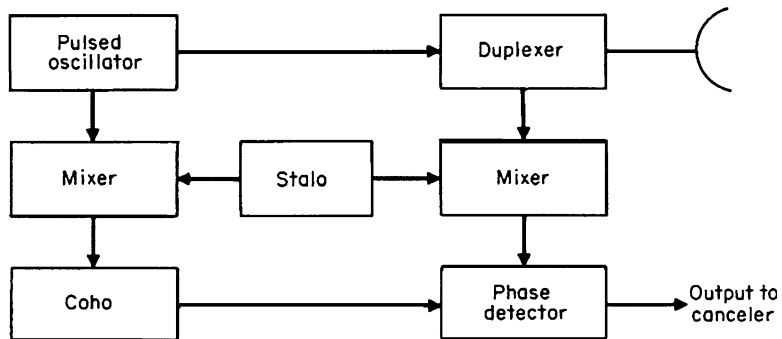

FIGURE 23.1.36 Coherent-on-receive MTI system.

23.42 NAVIGATION AND DETECTION SYSTEMS

noncoherent MTI does not cancel as completely and may lose target signals when the clutter is too small to provide a reference.

The MTI canceler is designed to pass as much of the target spectrum as possible while rejecting clutter. Since search-radar MTI must cover many range cells without loss of resolution, canceling filters are implemented with delay lines, with multiple range gates feeding bandpass filters, or with range-sampled digital filters which perform these functions. The response of several typical cancelers is shown in Fig. 23.1.37. A wide variety of response shapes is available through the use of feedback and multiple, staggered repetition rates.²⁴ In particular, through proper use of stagger (Fig. 23.1.37c), it is possible to maintain detection of most targets with nonzero radial velocities, even those which would fall in one of the blind speeds v_{bj} (ambiguous rejection notches) of an MTI with a single repetition rate:

$$v_{bj} = j \frac{\lambda f_r}{2} \quad j = \pm 0, 1, 2, \dots \quad (64)$$

The MTI radar system must transmit, in each beam position, at least two pulses (for a single-delay canceler), and when feedback is used the pulses in each beam must extend for the duration of significant impulse response of the filter.

Performance of MTI

The basic measure of MTI performance is the *MTI improvement factor I*, defined by

$$I = \frac{(S/N)_{out}}{(S/N)_{in}} \Big|_{all v_r}$$

This is equal to the *clutter attenuation* when the targets are distributed uniformly over one or more blind-speed intervals. The basic relationships between *I* and parameters of the radar and clutter can be expressed in terms of the ratio of rms clutter spread to repetition frequency or blind speed:

$$z = \frac{2\pi\sigma_f}{f_r} = \frac{2\pi\sigma_v}{v_{bl}} = \frac{2\pi\sigma_v}{\lambda f_r} \quad (65)$$

- where σ_f = standard deviation of clutter power spectrum in hertz
- f_r = repetition rate
- σ_v = standard deviation in m/s
- v_{bl} = first blind speed from Eq. (64)

For a scanning beam viewing motionless clutter, motion of the beam induces a velocity spread such that

$$z = 2\sqrt{\ln 2} \frac{\omega}{f_r \theta_3} \frac{1.665}{n} \quad (66)$$

In general, the rms spread must be calculated using the rms sum of components due to scanning, internal motion of clutter, radar platform motion, and instabilities in the radar.

Another term describing MTI radar performance is *subclutter visibility (SCV)*, which is the maximum input clutter-to-signal ratio at which target detection can be obtained:

$$SCV = \frac{I}{D_{xc}} \quad (67)$$

where D_{xc} is the clutter detectability factor (output signal-to-clutter ratio required for detection). Depending on the integration gain that follows the MTI, D_{xc} may be as large as 100 (or 20 dB), or as small as unity (0 dB).

FIGURE 23.1.37 Frequency response of MTI filters: (a) single- and double-delay without feedback; (b) double-delay with feedback; (c) double- and triple-delay with staggered prf and feedback (Ref. 24).

In phased array radar, the beam may be scanned in discrete steps over the coverage volume without spreading the clutter spectrum. The duration of each beam dwell then limits the allowable impulse response time of the filter. In many such cases, three-pulse bursts are used to support a double-delay canceler without feedback. Stagger to avoid blind speeds may be applied within each dwell, on a pulse-to-pulse or burst-to-burst basis, or on a dwell-to-dwell basis.

An important consideration in step-scanning systems is the possible presence of clutter beyond the unambiguous range of the waveform. Such clutter cannot be canceled unless extra pulses (*fill pulses*) are included in the dwell to produce identical clutter inputs on those pulse repetition intervals processed in the MTI filter. Pulse-to-pulse stagger may not be used when clutter beyond the unambiguous range is to be canceled, and burst-to-burst stagger waveforms must include fill pulses in each burst, increasing the required dwell time.

When an average is taken over all target velocities, the MTI system does not change the signal-to-noise ratio (SNR). However, for given average SNR, the probability of detection may be severely degraded by several factors. First, the number of independent noise samples available for integration is reduced because successive outputs on successive are not independent at the canceler output. The effective number of samples integrated is $(2/3)n$ for a single-delay canceler, and $(1/2)n$ for double-delay, where n is the number of pulses per beamwidth. The number is further reduced by the number of fill pulses and the necessity to gate the canceler output after each step in scanning and each change in PRF, when burst-to-burst stagger is used. If the quadrature canceler channel is not implemented, the number of target samples is reduced by a factor of 2. For a Case 1 target viewed over a short dwell, the Rayleigh distribution is reduced to a single-sided gaussian distribution, with twice the decibel value of fluctuation loss. Finally, the clutter rejection notches in the velocity response curve present some targets from being detected, making it difficult to achieve high probabilities of detection regardless of SNR. These losses in information, expressed in terms of required increases in SNR to maintain a given detection performance, constitute MTI loss components of miscellaneous signal processing loss, often totaling 6 to 12 dB.

Pulsed Doppler Radar Systems

A *pulsed doppler radar* is a system in which targets are selected in one or more narrowband filters. For search radar, these filters must cover the velocity band occupied by targets, omitting or desensitizing filters containing clutter.

FIGURE 23.1.38 Frequency response of filter bank in pulsed doppler radar.

As a result, the envelope of filter response will have a shape similar to that of an optimized MTI canceler (Fig. 23.1.38). To generate the narrow filter responses, a pulsed doppler radar must transmit, receive, and process a train of pulses considerably longer than required for MTI. Coherent integration is inherent in the narrow doppler filters used in pulsed doppler systems, and hence these systems may operate with greater energy efficiency than MTI radars.

Pulsed doppler radar can operate in any of three modes:

1. *Low-PRF mode*, in which target detections are intended only within the unambiguous range of the waveform ($R_{tmax} < R_u$). In most cases, this mode has multiple ambiguities within the band of target velocities.
2. *Medium-PRF mode*, in which target detections are required at ranges and velocities beyond the unambiguous values ($R_{max} > R_u$, $v_{max} > v_b$).
3. *High-PRF mode*, in which target detections are intended only within the unambiguous velocity interval ($v_{max} < \omega_b$). In most cases, this mode has multiple range ambiguities within the range interval occupied by targets. When the radar platform is moving at velocity v_p , high-PRF operation requires $(v_{max} + 2v_p) < v_b$, to avoid aliasing of sidelobe clutter into the target filter. Thus, airborne radars operating at X-band must typically use PRFs in excess of 100 kHz.

An example of low-PRF pulsed doppler processing is the *moving target detector* (MTD), shown in Fig. 23.1.39. Designed for application to conventional airport surveillance radars, this processor accepts digitized baseband signals from in-phase and quadrature phase detectors. The radar transmits 24 pulses per beam position, in two 12-pulse

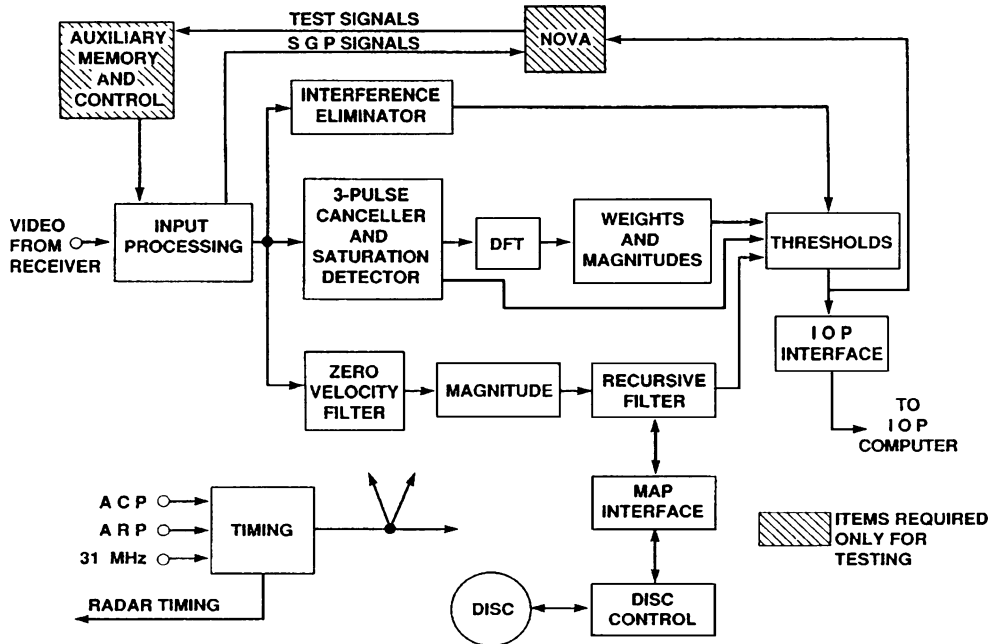

FIGURE 23.1.39 Block diagram of moving target detector system (Ref. 25).

coherent processing intervals (CPIs). In each CPI, after two fill pulses, a 10-pulse burst is applied to the triple-delay cancelers, producing an eight-pulse burst for subsequent doppler filtering in the discrete Fourier transform. A parallel zero-velocity channel feeds a clutter map through a recursive filter, averaging over several scans of the antenna. The eight filter channels are passed to range-cell averaging CFAR thresholds that desensitize those filters having range-extensive clutter.

Blind speeds can be eliminated by the burst-to-burst PRF diversity used in the MTD, provided that the clutter spectrum is not excessively wide. The two sets of filter response curves are shown in Fig. 23.1.40, along with a typical rain clutter spectrum. In this example, the rain clutter will desensitize filters 6, 7, and 0 at both PRFs. The target aliased into filters 6 and 7 at one PRF, appears in filter 5 at the other PRF, ensuring detection. If the clutter spectrum expands to cover more than about 20 percent of the blind speed interval, loss of targets may be expected.

An airborne high-PRF doppler processor is shown in Fig. 23.1.41. The mainlobe clutter in this example appears just below the platform velocity, corresponding to a beam position displaced from the velocity vector. Sidelobe clutter extends from $+v_p$ to $-v_p$, with enhancement at zero velocity where the clutter is viewed at vertical incidence (the *altitude line*). To reduce the dynamic range of digital processing, analog filters pass only velocities between v_p and $v_b - v_p$. Within the passband of the analog filters, many doppler filters are formed, usually through FFT processing.

Because the high-PRF radar normally has only a few range cells within the pulse repetition interval, CFAR will be based on doppler filter averaging. If a medium-PRF mode is included in the airborne radar, a combination of doppler and range cell averaging may be used.

The requirement for fill pulses is the same in pulsed doppler radar as in MTI, to ensure that the clutter input has reached steady state before coherent processing begins. However, as PRF increases into the medium- or high-PRF region, the number of such pulses may become very large. The basic requirements is that the time during which the initial transient must be gated out of the processor, after each change in PRF or beam position, is the delay time for the most distant significant clutter sources.

FIGURE 23.1.40 MTD filter responses and clutter spectrum (Ref. 25).

CW Radar

A cw transmissions has no velocity ambiguity, and so cw radar equipment can be designed with a broad clutter notch, providing up to 130 dB rejection of fixed and moving clutter. Coherent integration of target signals in selected doppler bands is also provided by a single set of narrowband filters, rather than the multiple sets required

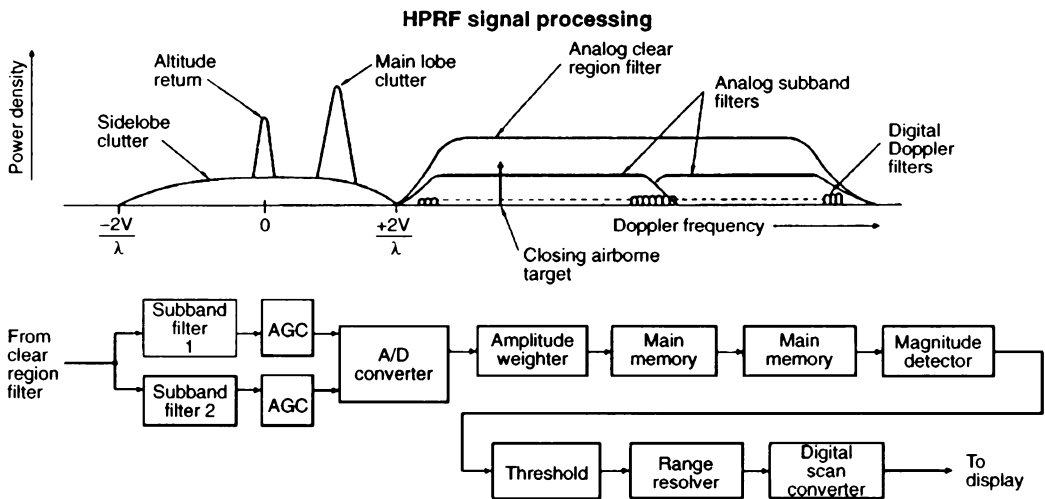

FIGURE 23.1.41 High-PRF airborne radar spectrum and processor (Ref. 26).

for range-gated operation in pulsed systems. Three problems, however, restrict the usefulness of cw radar for search:

1. *Isolation of receiver from transmitter.* Direct feed-through of transmitter power to the receiver must be minimized, requiring separate antennas in high-power systems and careful design in all systems to avoid receiver saturation.
2. *Magnitude of short-range clutter echo.* The echo power received from clutter in a cw radar is proportional to the integrated product of the reflectivity, antenna gain factors, and $(\text{range})^{-4}$ over the common volume of the transmitting and receiving beams. In both volume and surface clutter, the echo power is dominated by the clutter at the shortest range in the common volume, and the effective clutter cross section is a function of beamwidth and range R_c to the point where the beams substantially overlap. The required clutter improvement for a cw radar may therefore be very high because of the $(R/R_c)^4$ term, where R is target range.
3. *Transmitter noise.* Both the direct feed-through from transmitter to receiver and the echoes from short-range clutter will contain random noise components from the transmitter. Special circuits may be designed to cancel the direct feed-through and low-frequency components of reflected noise, but the higher-frequency components will appear with phase shift from the range delay and cannot be canceled completely. Subclutter visibility in cw systems is generally controlled by these noise components.

TRACKING AND MEASUREMENT

Detection of a target within a given resolution cell implies at least coarse measurement of target coordinates, to the value describing the center of the cell in each coordinate. However, measurements can be made with much greater accuracy by interpolating target position within the resolution cell. This process is normally carried out in both search and tracking radars, with emphasis on high accuracy in the tracking case.

The Basic Process of Measurement

The basic process by which target position is interpolated within a resolution cell involves the formation of two offset response channels in the coordinate of interest (Fig. 23.1.42). The difference Δ and sum Σ of these two channels are formed, and the ratio Δ/Σ provides a measure of the target displacement from the equisignal axis.

The two channels may be formed either simultaneously or sequentially. Simultaneous channel formation is usual in range and doppler measurement, as well as in monopulse angle measurement. Sequential channel formation is often used for angle measurement, where a second antenna beam and receiving channel would be relatively expensive. The two outputs are stored over one or more switching cycles, permitting the Δ and Σ channels to be generated (Fig. 23.1.43a). A convenient implementation of the ratio process is to apply slow automatic gain control (AGC) to the common receiving channel (Fig. 23.1.43b). In the case of simultaneous channel formation (Fig. 23.1.43c), the AGC operates as a closed loop in the Σ channel, and open-loop in the Δ channel. Whichever method is used, the normalized output ratio Δ/Σ can be calibrated in terms of target position and used either to correct the output data relative to the axis position or to close a tracking loop.

Measurement Accuracy

The rms error in measurement σ_z , caused by thermal noise, can be expressed in terms of the half-power width z_3 of the resolution cell, the slope constant k_z for the measurement system, and the signal-to-noise energy ratio E/N_0 in the Σ channel of the system:

$$\sigma_\theta = \frac{\theta_3}{k_m \sqrt{2E/N_0}} \quad (68)$$

When other types of interference are present, the ratio E/N_0 may be replaced by $E/I_{0\Delta}$, where $I_{0\Delta}$ is the spectral density of interference in the Δ channel.

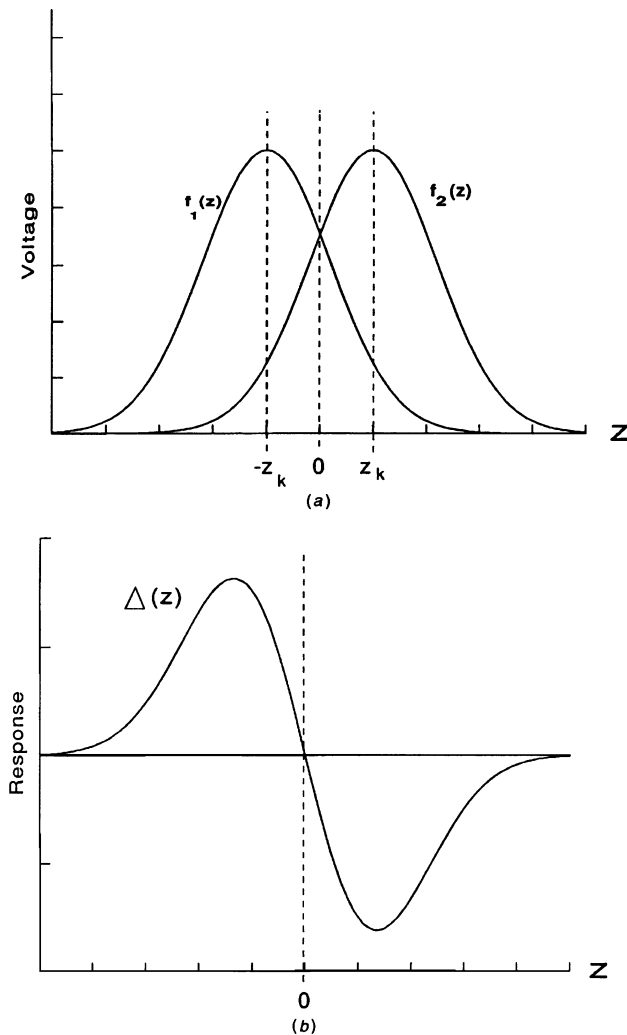

FIGURE 23.1.42 Basic process of measurement: (a) two displaced response channels in coordinate z ; (b) difference Δ of two channels; (c) sum Σ of two channels; (d) normalized ratio Δ/Σ . (Continued)

Ideal estimators can be characterized⁸ in terms of their slope constants:

Angle measurement: $k_m = L\theta_3/\lambda = 1.61$ (for uniform illumination of aperture)

Time delay measurement: $k_t = \beta\tau_3 = 1.61$ (for rectangular spectrum)

Frequency measurement: $k_f = \alpha B_3 = 1.61$ (for rectangular pulse)

Coherent frequency measurement: $k_f = \alpha_f B_{3f} = 1.61$

Here L = rms aperture with $= (\pi/\sqrt{3})w$ for rectangular aperture of width w , β = rms spectral width $= (\pi/\sqrt{3})B$ for rectangular spectrum of width B , α = rms time duration $= (\pi/\sqrt{3})\tau$ for rectangular pulse of width τ and α_f = rms time duration $= (\pi/\sqrt{3})t_f$ for coherent pulse train received with uniform amplitude over time t_f . The half-power resolution cell widths are θ_3 in angle, τ_3 in time, and B_3 or B_{3f} in frequency.

FIGURE 23.1.42 (Continued)

The ideal estimators are implemented using a Σ channel derived from uniform aperture illumination, uniform spectral weighting, or uniform weighting in time, giving $(\sin x)/x$ response (sidelobe levels -13.5 dB). This is combined with a Δ channel derived from linear-odd illumination or weighting. The linear-odd function generates a response, which is the derivative of the Σ response (sidelobe levels -11 dB relative to Σ mainlobe).

Practical Estimators. In most practical cases, the need for sidelobe control dictates use of tapered or weighted functions for aperture illumination, signal spectrum, and pulse train amplitude. The weighting tends to increase the half-power width of the resolution cell and decrease the rms width in the transform coordinate, leaving the slope constant near 1.6.

In a tracker that observes the target continuously, the received signal energy E will increase without limit. For purposes of evaluating tracking error, it must be assumed that the tracker averages over a number of pulses $n = f_r t_o = f_r / 2\beta_n$, where t_o is the time constant of the tracking loop and β_n is its (one-sided) noise bandwidth. For multiple-target phased arrays, t_o is the dwell time on the target of interest.

Angle Tracking

In a tracking radar, the antenna pattern is usually a narrow, circular beam, directed at the selected target either continuously, with a mechanically steered antenna, or with a time-shared phased array beam. The electro-mechanical or electronic servo loop is controlled to minimize the angle errors, as measured by an error-sensing antenna and receiver system. In early tracking radars, the beam was scanned about the tracking axis in a narrow cone, producing amplitude modulation on signals from targets displaced from the axis. The conical-scanning radar has been largely replaced by monopulse radar, which forms the sum and difference beams simultaneously. The normalized error is formed on a single pulse (or a few pulses received within the AGC time constant),

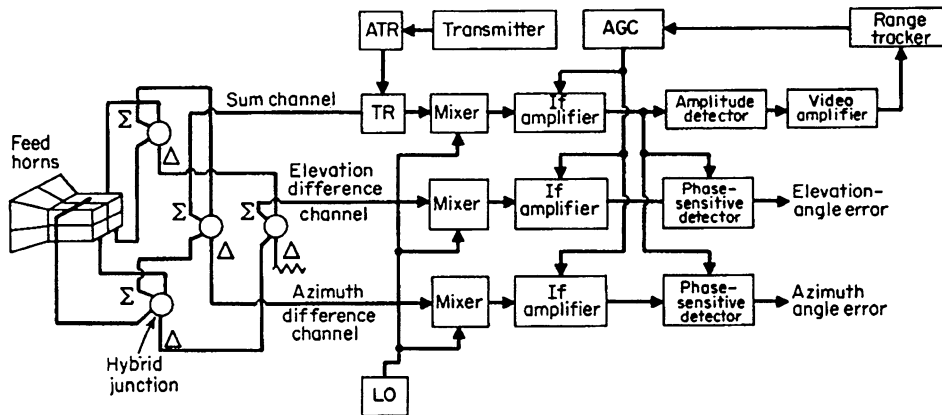

FIGURE 23.1.44 Block diagram of conventional monopulse tracking radar (Ref. 6).

eliminating errors caused in conical scanning radar by target amplitude scintillation. A block diagram of a typical monopulse tracker is shown in Fig. 23.1.44.

The conventional system illustrated uses three identical receiver channels to process the Σ and two Δ signals. The Σ channel is used for transmitting, and on receiving its output provides target detection, ranging, and AGC. It also serves as a phase reference for detection of the Δ signals. These detected error signals, appearing as bipolar video pulses at the phase detector output, are smoothed to DC and applied as inputs to the angle servo channels, causing the antenna to follow the target in azimuth and elevation.

Monopulse Antennas. The patterns required from a monopulse antenna consist of the Σ pattern, generally a circular pencil beam with sidelobes controlled by tapering of the aperture illumination, and a pair of Δ patterns. A typical Δ pattern may approximate that of Fig. 23.1.45a, calculated for a cosine illumination taper. The azimuth Δ pattern will have two azimuth lobes of opposite polarity (0° and 180° phase), approximating that of

FIGURE 23.1.45 Typical monopulse antenna patterns, using cosine taper.

FIGURE 23.1.46 Normalized measurement slope versus sidelobe ratio for monopulse antenna in which Δ pattern is derivative of Σ pattern.

Fig. 23.1.45*b*. This pattern was calculated for an illumination given by a linear-odd function multiplied by the cosine taper. The azimuth Δ pattern in the elevation coordinate will reproduce the Σ elevation pattern. The elevation Δ pattern will have the two lobes in elevation, and will reproduce the Σ pattern in azimuth.

For an antenna with a Δ pattern following the derivative of the Σ pattern, the beam broadening is more rapid than the decrease in slope, and the normalized slope k_m actually increases as sidelobe levels are reduced (Fig. 23.1.46). In most practical antennas, however, departure from the derivative Δ pattern and various losses restrict the normalized slope to values near 1.6.

The rms error of the angle estimate in the presence of thermal noise will be given by

$$\sigma_\theta = \frac{\theta_3}{k_m \sqrt{2E/N_0}} \tag{69}$$

where θ_3 is the half-power beamwidth of the Σ pattern, k_m is the normalized slope constant ≈ 1.6 , and E/N_0 is assumed large. This slope is the derivative of the normalized Δ pattern, as shown in Fig. 23.1.45:

$$k_m \equiv \left[\frac{d(\Delta/\Sigma)}{d(\theta/\theta_3)} \right]_{\theta=0} \tag{70}$$

When the Σ signal-to-noise ratio presented to the phase-sensitive detectors of Fig. 23.1.44 is not high ($S/N < 4$), estimation error will be increased by detector loss, and monopulse tracking performance will be degraded. Detailed analysis of this effect is given in Ref. 3, pp. 467–472.

When a reflector or lens as the radiating aperture, monopulse patterns are generated by a cluster of horns in the focal plane. The early four-horn feed clusters have given way to more advanced horn structures, using additional horns or multiple modes to generate efficient, low-sidelobe illumination functions.²⁷ Table 23.1.4 shows the performance of five types of horn cluster, in terms of sum-channel aperture efficiency η_a , measurement slopes k_m in both coordinates, and sidelobe ratios G_s (mainlobe-to-sidelobe power) in sum and difference patterns. These values were derived by Hannan²⁷ for rectangular apertures, but the absolute levels of performance are unchanged when an elliptical aperture having the same maximum dimensions is used. The efficiency will be higher for the elliptical aperture because it is referred to the smaller area of the ellipse.

Monopulse array systems using constrained feeds can be designed to have arbitrary Σ and Δ illumination functions (e.g., Taylor functions for Σ and Bayliss functions²⁸ for Δ), independently controlled in the feed networks. Such systems will have their efficiencies reduced by feed and phase shifter losses, as well as by the selected taper functions. Phased array systems using horn-fed reflectors or lenses can be described by the parameters of Table 23.1.4, with efficiencies reduced by losses in the phase shifter. Introduction of more complex

TABLE 23.1.4 Monopulse Feed Horn Performance

Type of horn	η_a	H -plane		E -plane		G_{sr} dB	G_{se} dB	Feed shape
		$K_r\sqrt{\eta_y}$	K_m	$K_r\sqrt{\eta_x}$	K_m			
Simple four-horn	0.58	0.52	1.2	0.48	1.2	19	10	
Two-horn dual-mode	0.75	0.68	1.6	0.55	1.2	19	10	
Two-horn triple-mode	0.75	0.81	1.6	0.55	1.2	19	10	
Twelve-horn	0.56	0.71	1.7	0.67	1.6	19	19	
Four horn triple-mode	0.75	0.81	1.6	0.75	1.6	19	19

horn structures having additional modes can produce illumination functions having low sidelobes and spillover, with gain and slope approximating those of constrained-feed arrays but with higher efficiencies due to decreased feed losses.

Range Tracking

Measurement of target range is carried out by estimating the time delay t_d between transmission and reception of each pulse, and calculating range as

$$R = \frac{t_d}{c} \tag{71}$$

where c is the velocity of light ($c = 2.997925 \times 10^8$ m/s in vacuum, somewhat less in the atmosphere). The time delay is estimated by counting clock pulse between the times of transmission and reception of the centroid of the pulse, and correcting for any fixed delays within the radar components (transmission line, filters, and the like). The accuracy of the measurement is dependent on the accuracy with which the centroid of the received pulse, contaminated by noise and other interference, can be determined.

The ideal estimation process is to identify the centroid of the received pulse by passing the signal through a matched filter, differentiating with respect to time, and stopping the counter when the derivative passes

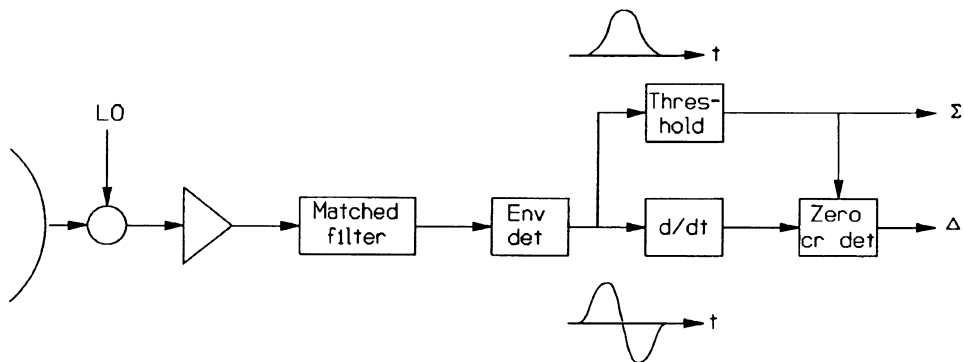

FIGURE 23.1.47 Block diagram of optimum pulse centroid estimator.

through zero. A block diagram of this process is shown in Fig. 23.1.47. The resulting time-delay accuracy is then given by Eq. (68) with parameters appropriate to the time coordinate:

$$\sigma_1 = \frac{1}{\beta\sqrt{2E/N_0}} = \frac{\tau_3}{k_t\sqrt{2E/N_0}} \quad (72)$$

where β = rms signal bandwidth
 τ_3 = half-power width of processed pulse
 k_t = slope constant ≈ 1.61

In order for the circuit of Fig. 23.1.47 to produce centroid estimates without gross error from false zero crossings on noise, the signal energy ratio E/N_0 must be high enough to avoid the occurrence of false alarms at the Σ threshold prior to reception of the target pulse.

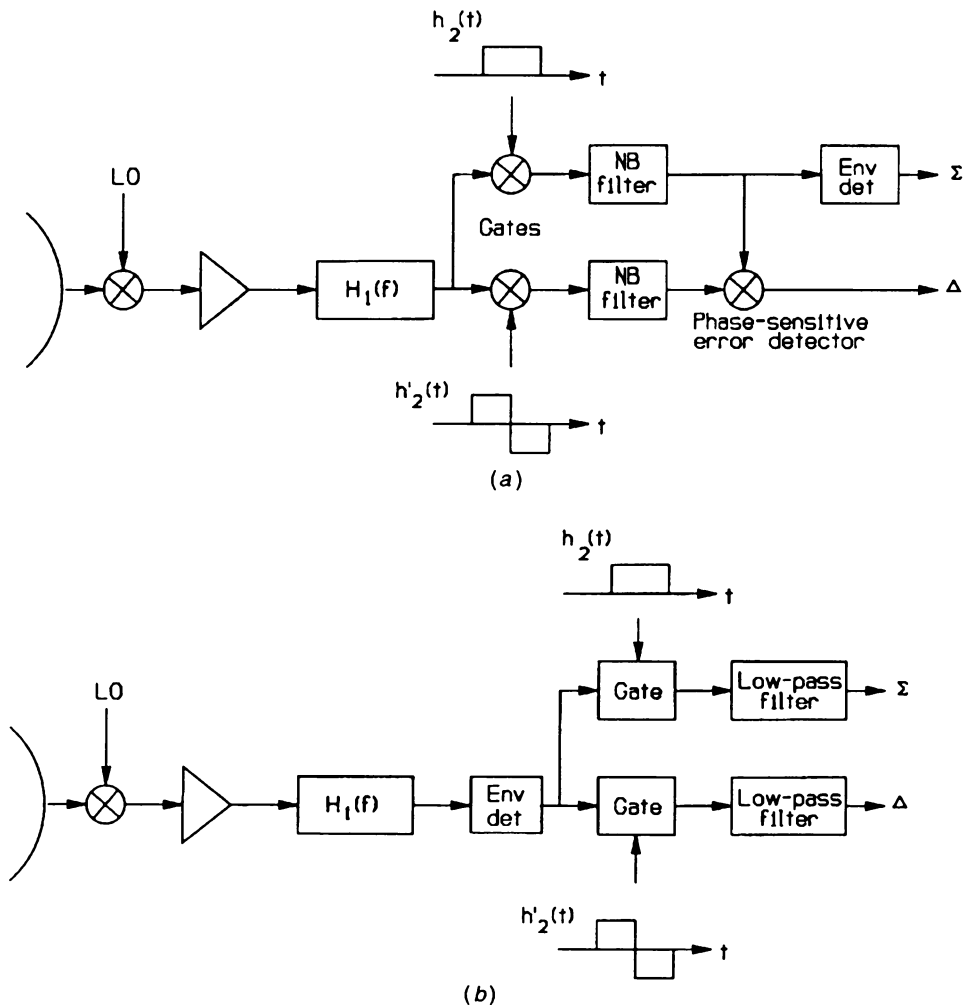

FIGURE 23.1.48 Centroid estimators for pulses in a train: (a) coherent processing; (b) noncoherent processing.

When the energy ratio of the individual pulse in a pulse train is low, time-delay estimation will normally be carried out using a tracking correlator, as shown in Fig. 23.1.48. Reception of a coherent pulse train permits the correlation to be performed prior to envelope detection (Fig. 23.1.48a). The i.f. filter $H_1(f)$ has a broad bandwidth passing the complete spectrum of the individual pulse, providing pulse compression if that pulse contains phase modulation. The locally generated reference signals labeled $h_2(t)$ and $h'_2(t)$ are approximately matched to the pulse width, and often take the form of rectangular gate and split-gate functions as shown. The Δ output of this system is a DC voltage proportional to the time difference between the center of the gate function and the received pulse centroid. This voltage is then normalized to the Σ amplitude and used as input to the variable time-delay generator that initiates the gates. The noise error in coherent processing is given by Eq. (72), using the energy ratio of the pulse train as integrated in the narrowband filters.

When the pulse train is not coherent, the individual pulses must be passed through envelope detectors prior to narrowband filtering, as shown in Fig. 23.1.48b. The performance of the noncoherent processor, when the energy ratio of the individual pulse is low, is reduced by loss (small-signal suppression) in the envelope detector, in a way similar to that of the angle tracker.

Doppler Tracking

Doppler tracking is used in coherent radars for two purposes: (1) It permits the signal to pass a narrowband filter, providing coherent integration and rejecting clutter; and (2) It provides accurate radial velocity data on the target. A transmission at frequency f_0 , reflected from a target moving with radial velocity $v_t = R$, will be received at $f_0 + f_d$. The change in frequency f_d is known as the doppler shift:

$$f_d = f_0 \left(\frac{c - v_t}{c + v_t} - 1 \right) = \frac{-2f_0 v_t}{c} \left(1 - \frac{v_t}{c} + \frac{v_t^2}{c^2} - \dots \right) \approx \frac{2f_0 v_t}{c} = -\frac{2v_t}{\lambda} \quad (73)$$

Target velocity is calculated from the measured doppler shift as

$$v_t = -\frac{f_d c}{2f_0} \left(1 - \frac{f_d}{2f_0} + \frac{f_d^2}{4f_0^2} - \dots \right) \approx \frac{f_d c}{2f_0} = -\frac{f_d \lambda}{2} \quad (74)$$

In most cases, the signal bandwidth is small enough relative to f_0 so that the doppler shift can be regarded as a simple displacement of the spectrum relative to that transmitted, and the target velocity will be small enough relative to c that the approximations in Eqs. (73) and (74) are valid.

The frequency accuracy of an ideal estimator is given by Eq. (68) with parameters appropriate to the frequency coordinate:

$$\sigma_f = \frac{1}{\alpha \sqrt{2E/N_0}} = \frac{B_3}{k_f \sqrt{2E/N_0}} \quad (75)$$

When a coherent pulse train is measured, the applicable bandwidth B_3 in Eq. (75) is the bandwidth of each spectral line shown in Fig. 23.1.9. Figure 23.1.49 shows a block diagram of a range-gated doppler centroid estimator for use with a coherent pulse train. Two narrowband filters, displaced each side of the tracking frequency f_c , are used to form Σ and Δ channels in the frequency coordinate. The Σ i.f. signal is used as a reference to phase detect the Δ signal, providing a DC error value that can be used to control an oscillator shifting the LO to center the signal at the frequency f_c .

Before measurements can be made with the accuracy implied by Eq. (75), the central line of the received spectrum must be placed in the narrowband i.f. filter-discriminator of Fig. 23.1.50. When the waveform duty factor is small, or when pulse compression is used, there will be many spectral lines present ($2B/f_r$ lines within

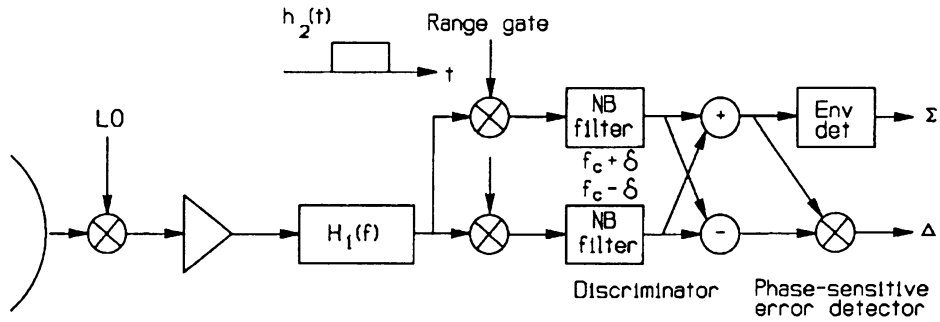

FIGURE 23.1.49 Block diagram of frequency centroid estimator for use with coherent pulse train.

the main lobe of the spectrum, for a signal bandwidth B at repetition frequency f_r). The frequency ambiguity can be resolved in one of several ways:

1. A discriminator operating at i.f. on the spectral envelope may obtain coarse frequency data adequate to place the central line in the fine discriminator bandwidth, if duty factor is not too small;
2. For systems with adequate range resolution, range data may be differentiated to obtain an estimate of v_r and hence of f_d ;
3. Observation of the correlation at two or more PRFs may resolve the ambiguity.

Search-Radar Measurements

As the search radar beams scans (usually in azimuth), measurements can be made of target range and angle (and sometimes of radial velocity). The equations given above for tracking radar can be applied to the range and velocity measurements, using the energy ratio E/N_0L_p obtained during the scan across the target. Measurements of azimuth angle are made by estimating the time (and hence the antenna angle) of the centroid of the pulse train envelope received by the radar. This time measurement may be performed with a split-gate tracker similar to that used in ranging, but operating on a time-scale matched to observation time t_o rather than pulse width. The target to be measured is selected by a range gate or equivalent channel of the detection processor. Alternatively, the signal may be integrated, differentiated, and the centroid estimated as the point where the derivative passes through zero.

FIGURE 23.1.50 Scintillation error in a scanning radar.⁵

Measurements of azimuth angle are made by estimating the time (and hence the antenna angle) of the centroid of the pulse train envelope received by the radar. This time measurement may be performed with a split-gate tracker similar to that used in ranging, but operating on a time-scale matched to observation time t_o rather than pulse width. The target to be measured is selected by a range gate or equivalent channel of the detection processor. Alternatively, the signal may be integrated, differentiated, and the centroid estimated as the point where the derivative passes through zero.

The azimuth angle error due to thermal noise will be

$$\sigma_\theta = \frac{\theta_3}{2\sqrt{E/N_0}} \tag{76}$$

where the constant 2 in the denominator includes the slope constant, the doubling of energy ratio normally appearing in error equations, and the beamshape loss effect. This factor is essentially constant for all beam shapes and for one-way and two-way beam patterns,⁸ where θ_3 is the one-way, half-power beamwidth.

Thermal noise and other interference are not the only factors affecting search radar angle accuracy. Fluctuating targets will induce a *scintillation error* in the estimate, independent of SNR. This error depends on

the relationship between the target amplitude correlation time t_c and the observation time t_o of the beam. The number of independent samples obtained is

$$n_e = 1 + \frac{t_o}{t_c} \quad (77)$$

Figure 23.1.50 shows the dependence of scintillation error on the quantity $(n_e - 1) = t_o/t_c$. When this ratio is between 0.1 and 10, the error will exceed $0.05\theta_3$.

Error Analysis

The total error in estimating a target coordinate is found by evaluating each of several error components, and forming the rss sum

$$\sigma = \sqrt{\sigma_1^2 + \sigma_2^2 + \dots} \quad (78)$$

The individual error components include the thermal noise error from Eqs. (68) to (76), errors from other interference components, the scintillation error for a scanning radar, and other components due to dynamic lags in tracking, target glint, atmospheric refraction, multipath reflections, and imperfections in the radar components and circuits.

Random Interference Components. In addition to thermal noise, the following interference components will cause random errors, which are estimated by substitution of E/I_Δ for E/N_0 in Eqs. (68) to (76):

1. Clutter, for which I_Δ is estimated from the power spectral density of clutter within $\pm\beta_n$ of the target spectral lines; additional error may result when the clutter in the Σ and Δ channels is correlated (Ref. 3, pp. 531–533);
2. Jamming, in the case of stand-off and escort jammers, using the jamming spectral density J_Δ ; in the case of a self-screening noise jammer, the jamming constitutes a beacon signal and J_0/N_0 is the energy ratio;
3. Multipath reflections, for which the energy ratio can be equated with the power ratio S/M_Δ , determined by integration of the reflected power over the Δ pattern (Ref. 2, pp. 512–531);
4. Cross-polarized signal, using the ratio $(\sigma/\sigma_c)(\Delta_c/\Sigma)^2$, where σ_c is the cross-polarized target cross section and Δ_c is the cross-polarized difference channel voltage on the tracking axis (Ref. 3, pp. 415–416).

Target-Induced Error Components. The error components induced by target characteristics are glint, dynamic lag, and scintillation errors (the latter in angle estimates of scanning radars only, as discussed above).

Target glint results from interaction of the several scatterers of the target, changing the phase pattern of the echo in space and time. Where the scatterers are distributed uniformly over a target span L , the rms error will be approximately $L/3$ in that coordinate (producing an angle error $L/3R$ radians).

Dynamic lag results primarily from target accelerations, which can be followed only imperfectly by the tracking loops. The error for an acceleration a_t in any coordinate will be

$$\epsilon_a = \frac{a_t}{K_a} = \frac{a_t}{2.5\beta_n^2} \quad (79)$$

where K_a is the acceleration error constant of the tracking loop and β_n is (one-sided) loop bandwidth. It is the requirement for adequate bandwidth to follow the accelerations that prevents the tracking radar from operating with heavy smoothing of random errors.

FIGURE 23.1.51 Elevation angle error versus target range, for different elevation angles and altitudes.

FIGURE 23.1.52 Range error versus target range, for different elevation angles and altitudes.

Atmospheric Refraction. Major errors in elevation angle and range result from the change in refractive index of the atmosphere with altitude. The beam tends to bend downwards as it leaves the earth, causing the angle of arrival measured by the radar to be higher than the actual target elevation. The reduced velocity of propagation in the atmosphere also makes the time delay somewhat greater than would be measured in a vacuum. These bias errors in elevation and range, for a radar at sea level, are plotted in Figs. 23.1.51 and 23.1.52 as a function of target range R and elevation angle E_e .

Other Sources of Error. The remaining error components that must be evaluated in order to estimate radar accuracy consist of instrumental errors in the design and construction of the radar. These are both mechanical and electrical in origin, and must be evaluated for each particular radar using detailed data on design parameter and construction or circuit tolerances.

CHAPTER 23.2

RADAR TECHNOLOGY

Harold R. Ward

Radar development, since its beginning during World War II, has been paced by component technology. As better rf tubes and solid-state devices have been developed, radar technology has advanced in all its applications. This subsection presents a brief overview of radar technology. It emphasizes the components used in radar systems that have been developed specifically for the radar application. Since there are far too many devices for us to mention, we have selected only the most fundamental to illustrate our discussion.

In this subsection, the sequence in which each subsystem is discussed parallels the block diagram of a radar system. Pictures of various radar components give an appreciation for their physical size, while block diagrams and tabular data describe their characteristics. The material for this subsection was taken by permission largely from Ref. 1, to which we refer the reader for more detail and references.

RADAR TRANSMITTERS

The requirements of radar transmitters have led to the development of a technology quite different from that of communication systems. Pulse radar transmitters must generate very high power, pulsed with a relatively low duty ratio.

The recent development of high-power rf transistors capable of producing a few hundred watts of peak output power at S band has made solid-state radar transmitters feasible. See Ref. 2a. A corporate combiner is needed to sum the outputs of many devices to obtain the power levels required of medium- and long-range search radars. Such solid-state transmitters offer the following advantages over tube transmitters: low-voltage operation (typically 36 V), no modulator required, and reliable operation through the redundant architecture. While the solid-state transmitter still costs more than its tube equivalent, the solid-state technology is developing more rapidly.

Tube-type power oscillators and power-amplifier stages consist of three basic components: a power supply, a modulator, and a tube. The power supply converts the line voltage into dc voltage of from a few hundred to a few thousand volts. The modulator supplies power to the tube during the time the rf pulse is being generated. Although the modulation function can be applied in many different ways, it must be designed to avoid wasting power in the time between pulses. The third component, the rf tube, converts the dc voltage and current to rf power. The devices and techniques used in the three transmitter components are discussed in the following paragraphs.

RF Tubes

The tubes used in radar transmitters are classified as *crossed-field*, *linear-beam*, or *gridded* (see Sec. 7). The crossed-field and linear-beam tubes are of primary interest because they are capable of higher peak

TABLE 23.2.1 Comparison of Modulators

Modulator	Fig.	Flexibility		Pulse-length capability		Pulse flatness	Crowbar required		Modulator voltage level
		Duty cycle	Mixed pulse lengths	Long	Short		Load arc	Switch arc	
Line-type: Thyatron/SCR	25-50	Limited by charging circuit	No	Large PFN	Good	Ripples	No		Medium/Low
Magnetic modulator	25-52	Limited by reset and charging time	No	Large C's and PFN	Good	Ripples	No		Low
Hybrid SCR-magnetic modulator	...	Limited by reset and charging time	No	Large C's and PFN	Good	Ripples	No		Low
Active switch: Series switch	25-51a	No limit	Yes	Excellent; large capacitor bank	Good	Good	Maybe	Yes	High
Capacitor-coupled	25-51b	Limited	Yes	Large coupling capacitor	Good	Good	Maybe	Yes	High
Transformer-coupled	25-51c	Limited	Yes	Difficult; XF gets big; large capacitor bank	Good	Fair	Maybe	Yes	Medium-high
Modulator anode	...	No limit	Yes	Excellent; large capacitor bank	OK, but efficiency low*	Excellent	Yes	Yes	High
Grid	...	No limit	Yes	Excellent; large capacitor bank	Excellent	Excellent	Yes	...	Low

*Unless ON and OFF tubes carry very high peak current or unless modulator anode has high mu. After Weil, Ref. 2.

powers at microwave frequencies. Gridded tubes such as triodes and tetrodes are sometimes used at UHF and below. Since these applications are relatively few, gridded tubes will not be described here (see Sec. 7).

Modulators

If a pulsed radar transmitter is to obtain high efficiency, the current in the output tube must be turned off between pulses. The modulator performs this function by acting as a switch, usually in series with the anode current path. Some rf tubes have control electrodes that can also be used to provide the modulation function. There are three kinds of modulators in common use today: the line-type modulator, magnetic modulator, and active-switch modulator. Their characteristics are compared in Table 23.2.1.

The *line-type modulator* is the most common and is often used to pulse a magnetron transmitter. A typical circuit including the high-voltage power supply and magnetron is shown in Fig. 23.2.1. Between pulses, the pulse-forming network (PFN) is charged. A trigger fires the thyatron V_1 , shorting the input to the PFN, which causes a voltage pulse to appear at the transformer T_1 . The PFN is designed to produce a rectangular pulse at the magnetron cathode, with the proper voltage and current to cause the magnetron to oscillate. The line-type modulator is relatively simple but has an inflexible pulse width.

Active-switch modulators are capable of varying their pulse width within the limitation of the energy stored in the high-voltage power supply. A variety of active-switch cathode pulse modulators is shown in Fig. 23.2.2.

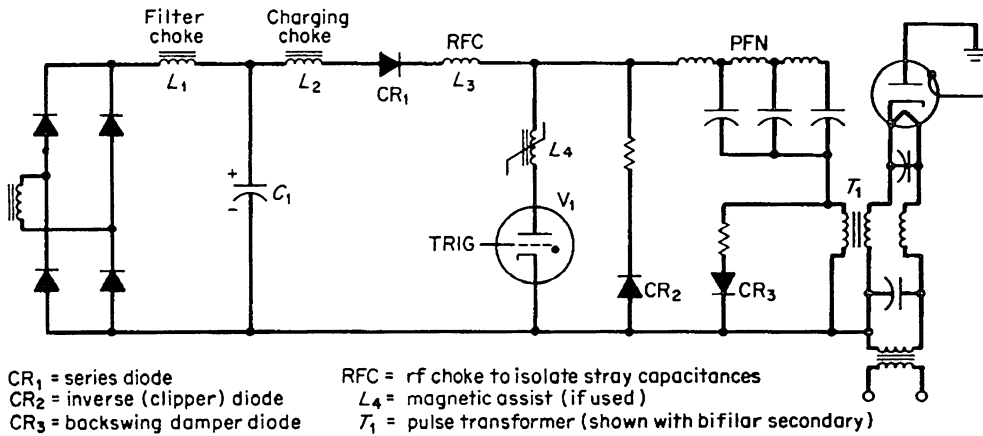

FIGURE 23.2.1 Line-type modulator.¹²

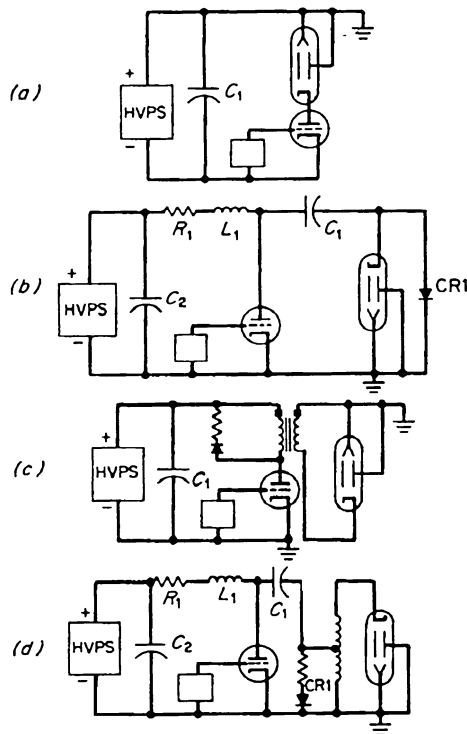

FIGURE 23.2.2 Active-switch cathode pulser: (a) direct-coupled; (b) capacitor coupled; (c) transformer coupled; (d) capacitor- and transformer-coupled.²

FIGURE 23.2.3 Magnetic modulator.²

Active-switch modulators using a vacuum tube free of gas but capable of passing high current and holding off high voltage are called *hard-tube modulators*.

The *magnetic modulator*, a third type of cathode pulse modulator (Fig. 23.2.3) has the advantage that no thyatron or switching device is required. Its operation is based on the saturation characteristics of inductors L_2 , L_3 , and L_4 . A long, low-amplitude pulse is applied to L_1 to charge C_1 . When C_1 is nearly charged, L_2 saturates, and the energy in C_1 is transferred resonantly to C_2 . The process is continued to the next stage, where the transfer time is about one-tenth that of the stage before. The energy in the pulse is nearly maintained so that at the end of the chain a short-duration high-amplitude pulse is generated.

Power Supplies and Regulators

The power supply converts prime power from the ac line to dc power, usually at a high voltage. The dc power must be regulated to remove the effects of line-voltage and load variation.

Protective circuitry is usually included with the high-voltage power supply to prevent the rf tube from being damaged in the event of a fault. Improper triggers and tube arcs are detected and used to trigger a crowbar circuit that discharges the energy stored in the high-voltage power supply. The crowbar is a triggered spark gap capable of dissipating the full energy of the power supply. Thyratrons, ignitrons, ball gaps, and triggered vacuum gaps are used.

Stability. Radar systems with moving-target-indicator (MTI) place unusually tight stability requirements on their transmitters. Small changes in the amplitude, phase, or frequency from one pulse to the next can degrade MTI performance. In the transmitter, the MTI requirements appear as constraints on voltage, current, and timing variations from pulse to pulse. The relation between voltage variations and variation in amplitude and phase shift differs with the tube type used. Table 23.2.2 lists stability factors for the various tube types used with a high-voltage power supply (HVPS).

RADAR ANTENNAS

The great variety of radar applications has produced an equally great variety of radar antennas. These vary in size from less than a foot to hundreds of feet in diameter. Since it is not feasible even to mention each of the types here, we shall discuss the three basic antenna categories, search antennas, track antennas, and multifunction antennas, after first reviewing some basic antenna principles.

FIGURE 23.2.4 Three-dimensional pencil-beam pattern of the AN/FPQ-6 radar antenna. (Courtesy of D. D. Howard, Naval Research Laboratory)

A radar antenna directs the radiated power and receiver sensitivity to the azimuth and elevation coordinates of the target. The ability of an antenna to direct the radiated power is described by its antenna pattern. A typical antenna pattern is shown in Fig. 23.2.4. It is a plot of radiated field intensity measured in the far field (a distance greater than twice the diameter squared divided by the wavelength from the antenna) and is plotted as a function of azimuth and elevation angle. Single cuts through the two-dimensional pattern, as shown in Fig. 23.2.5, are more often used to describe the pattern. The principle of reciprocity assures that the antenna pattern describes its gain as a receiver as well as transmitter. The gain is defined relative to an isotropic radiator.

TABLE 23.2.2 Stability Factors

	Frequency- or phase-modulation sensitivity	Impedance, ratio Dynamic static	Current or voltage change for 1% change in HVPS voltage	
			Line-type modulator	Low-impedance* hard-tube modulator, or dc operation
Magnetron	$\frac{\Delta f}{f} = \left(\begin{matrix} 0.001 \\ \text{to} \\ 0.003 \end{matrix} \right) \frac{\Delta I}{I}$	0.05–0.1	$\Delta I = 2\%$	$\Delta I = 10\text{--}20\%$
Stabilotron or stabilized magnetron	$\frac{\Delta f}{f} = \left(\begin{matrix} 0.002 \\ \text{to} \\ 0.0005 \end{matrix} \right) \frac{\Delta I}{I}$	0.05–0.1	$\Delta I = 2\%$	$\Delta I = 10\text{--}20\%$
Backward-wave CFA	$\Delta\phi = 0.4 \text{ to } 1^\circ$ for 1% ΔIII	0.05–0.1	$\Delta I = 2\%$	$\Delta I = 10\text{--}20\%$
Forward-wave CFA	$\Delta\phi = 1.0 \text{ to } 3.0^\circ$ for 1% ΔIII	0.1–0.2	$\Delta I = 2\%$	$\Delta I = 5\text{--}10\%$
Klystron	$\frac{\Delta\phi}{\phi} = \frac{1}{2} \frac{\Delta E}{E} \quad \phi \approx 5\lambda$ $\Delta\phi \approx 10^\circ$ for 1% $\Delta E/E$	0.67	$\Delta E = 0.8\%$	$\Delta E = 1\%$
TWT	$\frac{\Delta\phi}{\phi} \approx \frac{1}{3} \frac{\Delta E}{E} \quad \phi \approx 15\lambda$ $\Delta\phi \approx 20\%$ for 1% $\Delta E/E$	0.67	$\Delta E = 0.8\%$	$\Delta E = 1\%$
Triode or tetrode	$\Delta\phi = 0 \text{ to } 0.5^\circ$ for 1% ΔIII	1.0	$\Delta I = 1\%$	$\Delta I = 1\%$

*A high-impedance modulator is not listed because its output would (ideally) be independent of HVPS voltage.

FIGURE 23.2.5 Radiation pattern for a particular paraboloid reflector antenna illustrating the main-lobe and side-lobe radiation.³

The gain used as a defining parameter is the gain at the peak of the beam or main lobe (see Fig. 23.2.5). This is the one-way power gain of the antenna

$$G_p = 4\pi A \eta_a / \lambda^2$$

where A = area of antenna aperture (reflector area for a horn-fed reflector antenna)

λ = radar wavelength in units of A

η_a = aperture efficiency, which accounts for all losses inherent in the process of illuminating the aperture

Tapered-aperture-illumination functions designed to produce low side lobes also result in lower aperture efficiency η_a and larger beamwidth θ_3 , as shown in Fig. 23.2.6. A second gain definition sometimes used is directive gain. This is defined as a maximum radiation intensity, in watts per square meter, divided by the average radiation intensity, where the average is taken over all azimuth and elevation angles.

Directive gain can be inferred from the product of the main-lobe widths in azimuth and elevation, over a wide range of tapers (including uniform). For example, an array antenna, with no spillover of illumination

FIGURE 23.2.6 Aperture efficiency and beamwidth as a function of highest side-lobe level for a circular aperture: (a) aperture efficiency; (b) normalized beamwidth.⁵

power, gives

$$G_d = 36,000/\theta_{3a}\theta_{3e} \tag{80a}$$

where θ_{3a} = 3-dB width of the main lobe in the azimuth coordinate (degrees) and θ_{3e} = 3-dB main-lobe width in the elevation coordinate (degrees). For horn-fed antennas the constant in Eq. (80a) is about 25,000.

Search Antennas

Conventional surface and airborne search radars generally use mechanically scanned horn-fed reflectors for their antennas. The horn radiates a spherical wavefront that illuminates the reflector. The shape of the reflector is designed to cause the reflected wave to be in phase at any point on a plane in front of the reflector. This focuses the radiated energy at infinity. Mechanically scanning search radars generally have fan-shaped beams that are narrow in azimuth and wide in the elevation coordinate. In a typical surface-based air-search radar the upper edge of the beam is shaped to follow a cosecant-squared function. This provides coverage up to a fixed altitude. Figure 23.2.7 illustrates the effect of cosecant-squared beam shaping on the coverage diagram as well as on the antenna pattern. In the horn-fed reflector the shaping can be achieved by either the reflector or the feed, and the gain constant in Eq. (80a) is reduced to about 20,000.

Tracking-Radar Antennas

The primary function of a tracking radar is to make accurate range and angle measurements of a selected target's position. Generally, only a single target position is measured at a time, as the antenna is directed to follow the target by tracking servos. These servos smooth the errors measured from beam center to make pointing corrections. The measured errors, along with the measured position of the antenna, provide the target-angle information.

Tracking antennas like that of the AN/FPS-16 use circular apertures to form a pencil beam about 1° wide in each coordinate. The higher radar frequencies (S, C, and X band) are preferred because they allow a smaller aperture for the same beamwidth. The physically smaller antenna can be more accurately pointed. In this section we discuss aperture configurations, feeds, and pedestals.

One of the simplest methods of producing an equiphase wavefront in front of a circular aperture uses a parabolic reflector. A feed located at the focus directs its energy to illuminate the reflector. The reflected energy is then directed into space focused at infinity. The antenna is inherently broadband because the electrical path length from the feed to the reflector to the plane wavefront is the same for all points on the wavefront.

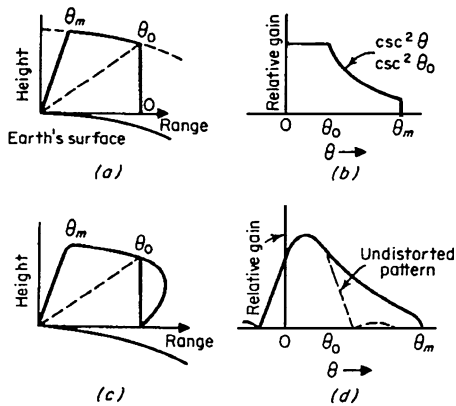

FIGURE 23.2.7 Elevation coverage of a cosecant-squared antenna: (a) desired elevation coverage; (b) corresponding antenna pattern desired; (c) realizable elevation coverage with pattern shown in (d); (d) actual cosecant-squared antenna pattern.⁸

FIGURE 23.2.8 Schematic diagram of a Cassegrain reflector antenna.⁹

Locating the feed in front of the aperture is sometimes inconvenient mechanically. It also produces spillover lobes where the feed pattern misses the reflector. The Cassegrain antenna shown in Fig. 23.2.8 avoids these difficulties by placing a hyperbolic subreflector between the parabolic reflector and its focus. The feed now illuminates the subreflector, which in turn illuminates the parabola and produces a plane wavefront in front of the aperture.

Lenses can also convert the spherical wavefront emanating from the feed to a plane wavefront over a larger aperture. As the electromagnetic energy passes through the lens, it is focused at infinity (see Fig. 23.2.9).

FIGURE 23.2.9 Geometry of simple converging lenses: (a) $n > 1$; (b) $n < 1$.⁹

Depending on the index of refraction n_g of the lens, a concave or convex lens may be required. Lenses are typically heavier than reflectors, but they avoid the blockage caused by the feed or subreflector.

A single feed providing a single beam is unable to supply the angle-error information necessary for tracking. To obtain azimuth and elevation-error information, feeds have been developed that scan the beam in a small circle about the target (conical scan) or that form multiple beams about the target (monopulse). Conical scanning may be caused by rotating a reflector behind a dipole feed or rotating the feed itself. It has the advantage compared with monopulse that less hardware is required in the receiver, but at the expense of somewhat less accuracy.

Modern trackers more often use a monopulse feed with multiple receivers. Early monopulse feeds used four separate horns to produce four contiguous beams that were combined to form a reference beam and azimuth and elevation-difference beams. More recently, multimode feeds have been developed to perform this function more efficiently with fewer components (see Fig. 23.1.44).

Shaft angle encoders quantize radar pointing angles through mechanical connections to azimuth and elevation axes. The output indicates the angular position of the mechanical bore-site axis relative to a fixed angular coordinate system. Because these encoders make an absolute measurement, their outputs contain 10 to 20 bits of information. A variety of techniques is used, the complexity increasing with the accuracy required. Atmospheric errors ultimately limit the number of useful bits to about 20, or 0.006 mrad. In less

precise tracking applications, synchros attached to the azimuth and elevation axes indicate angular position within a fraction of a degree.

Multifunction Arrays

Array antennas form a plane wavefront in front of the antenna aperture. These points are individual radiating elements which, when driven together, constitute the array. The elements are usually spaced about 0.6 wavelength apart. Most applications use planar arrays, although arrays conformal to cylinders and other surfaces have been built.

Phased arrays are steered by tilting the phase front independently in two orthogonal directions called the *array coordinates*. Scanning in either array coordinate causes the beam to move along a cone whose center is at the center of the array. The paths the beam follows when steered in the the array coordinates are illustrated in Fig. 23.2.10, where the *z* axis is normal to the array. As the beam is steered away from the array normal, the projected aperture in the beam's direction varies, causing the beamwidth to vary proportionately.

Arrays can be classified as either active or passive. *Active arrays* contain duplexers and amplifiers behind every element or group of elements; *passive arrays* are driven from a single feed point. Only the active arrays are capable of higher power than conventional antennas.

Both passive and active arrays must divide the signal from a single transmission line among all the elements of the array. This can be done by an optical feed, a corporate feed, or a multiple-beam-forming network. The *optical feed* is illustrated in Fig. 23.2.11. A single feed, usually a monopulse horn, illuminates the array with a spherical phase front. Power collected by the rear elements of the array is transmitted through the phase shifters that produce a planar front and steer the array. The energy may then be radiated from the other side of the array, as in the lens, or be reflected and reradiated through the collecting elements, where the array acts as a steerable reflector.

Corporate feeds can take many forms, as illustrated by the series-feed networks shown in Fig. 23.2.12 and the parallel-feed networks shown in Fig. 23.2.13. All use transmission-line components to divide the signal among the elements. Phase shifters can be located at the elements or within the dividing network.

FIGURE 23.2.10 Beam-steering contours for a planar array.

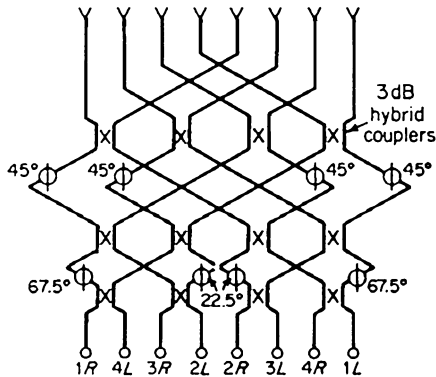

FIGURE 23.2.14 Butler beam-forming network.¹¹

FIGURE 23.2.15 Typical Reggia-Spencer phase shifter.¹²

Multiple-beam networks are capable of forming simultaneous beams with the array. The Butler matrix shown in Fig. 23.2.14 is one such technique. It connects the N elements of a linear array to N feed points corresponding to N beam outputs. It can be applied to two-dimensional arrays by dividing the array into rows and columns.

The phase shifter is one of the most critical components of the array. It produces controllable phase shift over the operating band of the array. Digital and analog phase shifters have been developed using both ferrites and *pin* diodes. Phase shifter designs always strive for a low-cost, low-loss, and high-power-handling capability.

FIGURE 23.2.16 Switched-line phase bit.¹²

The Reggia-Spencer phase shifter consists of a ferrite inside a waveguide, as illustrated in Fig. 23.2.15. It delays the rf signal passing through the waveguide. The amount of phase shift can be controlled by the current in the solenoid, through its effect on the permeability of the ferrite. This is a reciprocal phase shifter that has the same phase shift for signals passing in either direction. Nonreciprocal phase shifters (where phase-shift polarity reverses with the direction of propagation) are also available. Either reciprocal or nonreciprocal phase shifters can be locked or latched in many states by using the permanent magnetism of the ferrite.

Phase shifters have also been developed using *pin* diodes in transmission-line networks. One configuration, shown in Fig. 23.2.16, uses diodes as switches to change the signal path length of the network. A second type uses *pin* diodes as switches to connect reactive loads across a transmission line. When equal loads are connected with a quarter-wave separation, a pure phase shift results.

When digital phase shifters are used, a phase error occurs at every element due to phase quantization. The error in turn causes reduced gain, higher side lobes, and greater pointing errors. Gain reduction is tabulated in Table 23.2.3 for typical quantizations. Figure 23.2.17 shows the rms side-lobe levels caused by phase quantization in an array of N elements. The rms pointing error relative to 3-dB beamwidth is given by

$$\sigma_{\theta}/\theta_3 \approx 1.12 / 2^m \sqrt{N}$$

TABLE 23.2.3 Gain Loss in a Phased Array with m -Bit Digital Phase Shifters

Number of Bits, m	Gain Loss, dB
3	0.228
4	0.057
5	0.0142
6	0.00356
7	0.00089
8	0.0022

where m is the number of bits of phase quantization and N is the number of elements in array.⁵

Frequency scan is a simple array-scanning technique that does not require phase shifters, drivers, or beam-steering computers. Element signals are coupled from points along a transmission line as shown in Fig. 23.2.18. The electrical path length between elements is much longer than the physical separation, so that a small frequency change will cause a phase change between elements large enough to steer the beam. The technique can be applied only to one array coordinate, so that in two-dimensional arrays, phase shifters are usually required to scan the other coordinate.

MICROWAVE COMPONENTS

The radar transmitter, antenna, and receiver are all connected through rf transmission lines to a duplexer. The duplexer acts as a switch connecting the transmitter to the antenna while radiating and the receiver to the antenna while listening for echoes. Filters, receiver protectors, and rotary joints may also be located in the various paths. See Section 7 for a description of microwave devices and transmission lines.

A variety of other transmission-line components are used in a typical radar. Waveguide bends, flexible waveguide, and rotary joints are generally necessary to route the path to the feed of a rotating antenna. Waveguide windows provide a boundary for pressurization while allowing the microwave energy to pass through. Directional couplers sample forward and reverse power for monitoring, test, and alignment of the radar system.

Duplexers

The duplexer acts as a switch connecting the antenna and transmitter during transmission and the antenna and receiver during reception. Various circuits are used that depend on gas tubes, ferrite circulators, or *pin* diodes as the basic switching element. The duplexers using gas tubes are most common. A typical gas-filled TR tube is shown in Fig. 23.2.19. Low-power rf signals pass through the tube with very little attenuation. Higher power causes the gas to ionize and present a short circuit to the rf energy.

Figure 23.2.20 shows a balanced duplexer using hybrid junctions and TR tubes. When the transmitter is on, the TR tubes fire and reflect the rf power to the antenna port of the input hybrid. On reception, signals received by the antenna are passed through the TR tubes and to the receiver port of the output hybrid.

FIGURE 23.2.17 RMS side lobes due to phase quantization.¹¹

FIGURE 23.2.18 Simple types of frequency-scanned antennas: (a) broad-wall coupling to dipole radiators; (b) narrow-wall coupling with slot radiators.¹⁴

FIGURE 23.2.19 Typical TR tube.³

Circulators and Diode Duplexers

Newer radars often use a ferrite circulator as the duplexer. A TR tube is required in the receiver line to protect the receiver from the transmitter power reflected by the antenna due to an imperfect match. A four-port circulator is generally used with a load between the transmitter and receiver ports so that the power reflected by the TR tube is properly terminated.

In place of the TR tube *pin* diode switches have been used in duplexers. These are more easily applied in coaxial circuitry and at lower microwave frequencies. Multiple diodes are used when a single diode cannot withstand the required voltage or current.

Receiver Protectors. TR tubes with a lower power rating are usually required in the receive line to prevent transmitter leakage from damaging mixer diodes or rf amplifiers in the receiver. A keep-alive ensures rapid ionization, minimizing spike leakage. The keep-alive may be either a probe in the TR tube maintained at a high dc potential or a piece of radioactive material. Diode limiters are also used after TR tubes to further reduce the leakage.

FIGURE 23.2.20 Balanced duplexer using dual TR tubes and two short-slot hybrid junctions: (a) transmit condition; (b) receive condition.³

FIGURE 23.2.21 Typical construction of a dissipative waveguide filter.¹⁵

Filters

Microwave filters are sometimes used in the transmit path to suppress spurious radiation or in the receiver signal path to suppress spurious interference. Because the transmit filters must handle high power, they are larger and more difficult to design.

Narrow-band filters in the receive path, often called *preselectors*, are built using mechanically tuned cavity resonators or electrically tuned YIG resonators. Preselectors can provide up to 80 dB suppression of signals from other radar transmitters in the same rf band but at a different operating frequency.

Harmonic filters are the most common transmitting filter. They absorb the harmonic energy to prevent it from being radiated or reflected. Since the transmission path may provide a high standing-wave ratio at the harmonic frequencies, the presence of harmonics can increase the voltage gradient in the transmission line and cause breakdown. Figure 23.2.21 shows a harmonic filter where the harmonic energy is coupled out through holes in the walls of the waveguide to matched loads.

RADAR RECEIVERS

The radar receiver amplifies weak target returns so that they can be detected and displayed. The input amplifier must add little noise to the received signal, for this noise competes with the smallest target return that can be detected. A mixer in the receiver converts the received signal to an intermediate frequency where filtering and signal decoding can be accomplished. Finally, the signals are detected for processing and display.

Low-Noise Amplifiers

Because long-range radars require large transmitters and antennas, these radars can also afford the expense of a low-noise receiver. Considerable effort has been expended to develop more sensitive receivers. Some of the devices in use will be described here after a brief review of noise-figure and noise-temperature definitions.

FIGURE 23.2.22 Contribution to system noise temperature.

Noise figure and noise temperature measure the quality of a sensitive receiver. Noise figure is the older of the two conventions and is defined as

$$F_n = \frac{S/N \text{ at output}}{S/N \text{ at input}}$$

where S is the signal power, N is the noise power, and the receiver input terminates is at room temperature. Before low-noise amplifiers were available, a radar's noise figure was determined by the first mixer, which would be typically 5 to 10 dB. For these values of F_n it was approximately correct to add the loss of the waveguide to the noise figure when calculating signal-to-noise ratio. As better receivers were developed with lower noise figures, these approximations were no longer accurate, and the noise-temperature convention was developed.

Noise temperature is proportional to noise-power spectral density through the relation

$$T = N/kB$$

where k is Boltzmann's constant and B is the bandwidth in which the noise power is measured. The noise temperature of an rf amplifier is defined as the noise temperature added at the input of the amplifier required to account for the increase in noise due to the amplifier. It is related to noise figure through the equation

$$T = T_0(F_n - 1)$$

where $T_0 = \text{standard room temperature} = 290 \text{ K}$.

The receiver is only one of the noise sources in the radar system. Figure 23.2.22 shows the receiver in its relation to the other important noise sources. Losses, whether in the rf transmission line, antenna, or the atmosphere, reduce the signal level and also generate thermal noise. The load presented to the rf transmission line by the antenna is its radiation resistance. The temperature of this resistance T_a depends on where the antenna beam is pointed. When the beam is pointed into space, this temperature may be as low as 50 K. However, when the beam is pointed toward the sun or a radio star, the temperature can be much higher. All these sources can be combined to find the system noise temperature T_s , according to the equation

$$T_s = T_a + (L_r - 1)T_{tr} + T_e L_r$$

where T_a = temperature of the antenna
 L_r = transmission-line loss defined as ratio of power in the to power out
 T_{tr} = temperature of transmission line
 T_e = receiver noise temperature

FIGURE 23.2.23 Noise characteristics of radar front ends.

Figure 23.2.23 shows the noise temperature as a function of frequency for radar-receiver front ends. All are noisier at higher frequencies. Transistor amplifiers and uncooled

parametric amplifiers are finding increased use in radar receivers. *Transistor amplifiers* have been improved steadily, with emphasis on increased operating frequency. Although the transistor amplifier is a much simpler circuit than the parametric amplifier, it does not achieve the parametric amplifier's low noise temperature.

A balanced mixer is often used to convert from rf to i.f. Balanced operation affords about 20 dB immunity to amplitude noise on the local-oscillator signal. Intermediate frequencies of 30 and 60 MHz are typical, as are 1.5 to 2 dB intermediate-frequency noise figures for the i.f. preamplifier. Double conversion is sometimes used with a first i.f. at a few hundred megahertz. This gives better image and spurious suppression.

The *matched filter* is usually instrumented at the second i.f. frequency. This filter is an approximation to the matched filter and therefore does not achieve the highest possible signal-to-noise ratio. This deficiency is expressed as mismatch loss. Table 23.2.4 lists the mismatch loss for various signal-filter combinations when the optimum bandwidth is used.

Pulse Compression

Pulse compression is a technique in which a rectangular pulse containing phase modulation is transmitted. When the echo is received, the matched-filter output is a pulse of much shorter duration. This duration approximately equals the reciprocal of the bandwidth of the phase modulation. The compression ratio (ratio of transmitted to compressed pulse lengths) equals the product of the time duration and bandwidth of the transmitted pulse. The technique is used when greater pulse energy or range resolution are required than can be achieved with a simple uncoded pulse.

Linear FM (chirp) is the phase modulation that has received the widest application. The carrier frequency is swept linearly during the transmitted pulse. The wide application has both caused and resulted from the development of a variety of dispersive analog delay lines. Delay-lines techniques covering a wide range of bandwidths and time durations are available. Table 23.2.5 lists the characteristics of a number of these dispersive delay lines.

Range lobes are a property of pulse-compression systems not found in radar using simple cw pulses. These are responses leading and trailing the principal response and resembling antenna side lobes; hence the name range lobes. These lobes can be reduced by carefully designing the phase modulation or by slightly mismatching the compression network. The mismatch can be described as a weighting function applied to the spectrum.

Detectors

Although bandpass signals on an i.f. carrier are easily amplified and filtered, they must be detected before they can be displayed, recorded, or processed. When only the signal amplitude is desired, square-law characteristics may be obtained with a semiconductor diode detector, and this provides the best sensitivity for detecting pulses in noise when integrating the signals returned from a fluctuating target. Larger i.f. signal amplitudes derive

TABLE 23.2.5 Characteristics of Passive Linear-fm Devices

	B , MHz	T , μ s	BT	f_0 , MHz	Typical loss, dB	Typical spurious, dB
Aluminum strip delay line	1	500	200	5	15	-60

the diode detector into the linear range, providing a linear detector. The linear detector has a greater dynamic range with somewhat less sensitivity. When still greater dynamic range (up to 80 dB) is required, log detectors are often used. Figure 23.2.24 shows the functional diagram of a log detector. The detected outputs of cascaded amplifiers are summed. As the signal level increases, stages saturate, reducing the rate of increase of the output voltage.

Some signal-processing techniques require detecting both phase and amplitude to obtain the complete information available in the i.f. signal. The phase detector requires an i.f. reference signal. A phase detector can be constructed by passing the signal through an amplitude limiter and then to a product detector, where it is combined with the reference signal, as shown in Fig. 23.2.25. An alternative to detecting the amplitude and phase is to detect the in-phase and quadrature components of the i.f. signal. The product detector shown in Fig. 23.2.25 can also provide this function when the input signal is not amplitude-limited. Quadrature detector circuits differ only in that the reference signal is shifted by 90° in one detector relative to the other.

Analog-to-Digital Converters

Digital signal processors require that the detected i.f. signals be encoded by an analog-to-digital converter. A typical converter may sample the detected signal at a 1-MHz rate and encode the sampled value into a 12-bit

FIGURE 23.2.24 Logarithmic detector.¹⁶

FIGURE 23.2.25 Balanced-diode detector.¹⁶

binary word. Encoders operating at higher rates have been built, but with fewer bits in their output. Encoders typically have errors that about equal the least significant bit.

EXCITERS AND SYNCHRONIZERS

Exciters

Two necessary parts of any radar system are an *exciter* to generate rf and local-oscillator frequencies and a *synchronizer* to generate the necessary triggers and timing pulses.

The components used in exciters are oscillators, frequency multipliers, and mixers. These can be arranged in various ways to provide the cw signals needed in the radar. The signals required depend on whether the transmitter is an oscillator or a power amplifier.

Transmitters using power oscillators such as magnetrons determine the rf frequency by the magnetron tuning. In a noncoherent radar, the only other frequency required is that of the local oscillator. It differs from the magnetron frequency by the i.f. frequency, and this difference is usually maintained with an automatic frequency control (AFC) loop. Figure 23.2.26 shows the circuit of a simple magnetron radar, illustrating the two alternative methods of tuning the magnetron to follow the *stable local oscillator (stalo)* or tuning the stalo to follow the magnetron.

If the radar must use coherent detection (as in MTI or pulse doppler applications), a second oscillator, called a *coherent oscillator (coho)*, is required. This operates at the i.f. frequency and provides the reference for the product detector. Because an oscillator transmitter starts with random phase on every pulse, it is necessary to quench the coho and lock its phase with that of the transmitter on each pulse. This is accomplished by the circuit shown in Fig. 23.2.27.

FIGURE 23.2.26 Alternative methods for AFC control.¹⁶

FIGURE 23.2.27 Keyed coho.¹⁶

When an amplifier transmitter is used, coho locking is not required. The transmit frequency can be obtained by mixing the stalo and coho frequencies, as shown in Fig. 23.2.28. The stalo and coho are not always oscillators operating at their output frequency. Figure 23.2.29 shows an exciter using crystal oscillators and multipliers to produce the rf and local-oscillator frequencies. Crystals may be changed to select the rf frequency without changing the i.f. frequencies.

The stability required of the frequencies produced by the exciter depends on the radar application. In a simple noncoherent radar a stalo frequency error shifts the signal spectrum in the i.f. passband, and an error which is a fraction of the i.f. bandwidth can be allowed. In MTI or pulse doppler radars, phase changes from pulse to pulse must be less than a few degrees. This requirement can be met with crystal oscillators driving frequency multipliers or fundamental oscillators with high-*Q* cavities when sufficiently isolated from electrical and mechanical perturbation. Instability is often expressed in terms of the phase spectrum about the center frequency.

Crystal oscillators driving frequency multipliers are finding increased use as stalos. A typical multiplier might multiply a 90-MHz crystal oscillator frequency by 32 to obtain an S-band signal. This source has the long-term stability of the crystal oscillators, but with degraded short-term stability. This is because the multiplier increases the phase modulation on the oscillator signal in proportion to the multiplication factor; i.e., each doubler stage raises the oscillator sideband 6 dB. Frequency may be varied by tuning the crystal oscillator (about 0.25 percent) or by changing crystals.

Synchronizers

The synchronizer delivers timing pulses to the various radar subsystems. In a simple marine radar this may consist of a single multivibrator that triggers the transmitter, while in a larger radar 20 to 30 timing pulses may

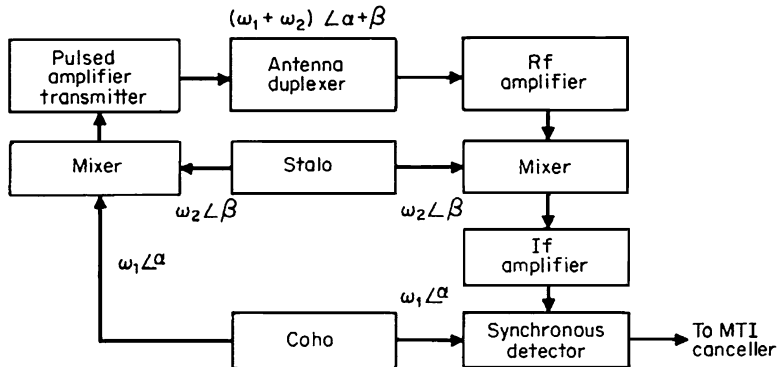

FIGURE 23.2.28 Coherent radar.¹⁶

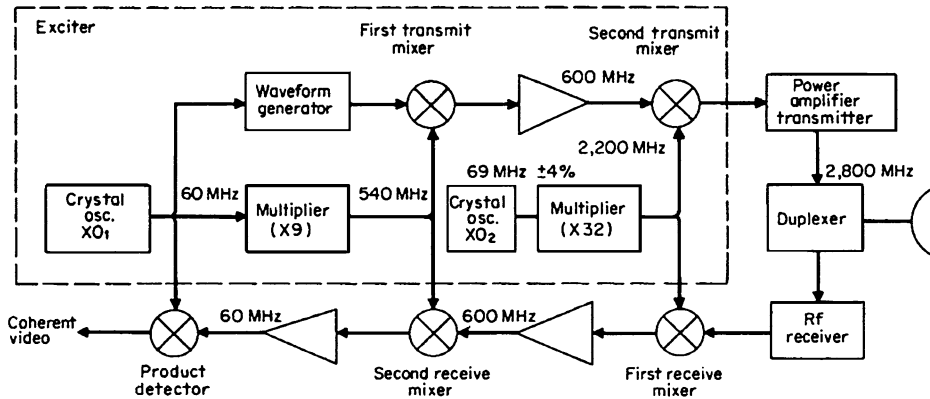

FIGURE 23.2.29 Coherent-radar exciter.

be needed. These may turn on and off the beam current in various transmitter stages; start and stop the rf pulse time attenuators; start display sweeps; etc.

Timing pulses or triggers are often generated by delaying a pretrigger with delays that may be either analog or digital. New radars are tending toward digital techniques, with the synchronizer incorporated into a digital signal processor. A diagram of the delay structure in a digital synchronizer is shown in Fig. 23.2.30. A 10-MHz clock moves the initial timing pulse through shift registers. The number of stages in each register is determined by the delay required. Additional analog delays provide a fine delay adjustment to any point in the 100-ns interval between clock pulses.

The synchronizer will also contain a range encoder, in radars where accurate range tracking is required or where range data will be processed or transmitted in digital form. Range is usually quantized by counting

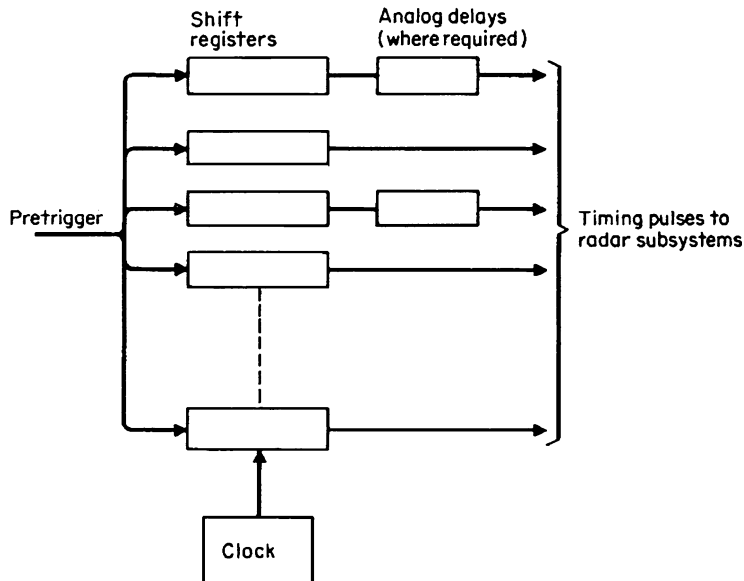

FIGURE 23.2.30 Digital synchronizer.

cycles of a clock, starting with a transmitted pulse and stopping with the received echo. Where high precision is required, the fine range bits are obtained by interpolating between cycles of the clock, using a tapped delay line with coincidence detectors on the taps.

SIGNAL PROCESSING

The term *signal processing* describes those circuits in the signal path between the receiver and the display. The extent to which processing is done in this portion of the signal path depends on the radar application. In search radars, postdetection integration, clutter rejection, and sometimes pulse compression are instrumented in the signal processor. The trend in modern radar has been to use digital techniques to perform these functions, although many analog devices are still in use. The following paragraphs outline the current technology trends in postdetection integration, clutter rejection and digital pulse compression.

Postdetection Integration

Scanning-search radars transmit a number of pulses toward a target as the beam scans past. For best detectability, these returns must be combined before the detection decision is made. In many search radars the returns are displayed on a plan-position indicator (PPI), where the operator, by recognizing target patterns, performs the postdetection integration. When automatic detectors are used, the returns must be combined electrically. Many circuits have been used, but the two most common are the video sweep integrator and binary integrator.

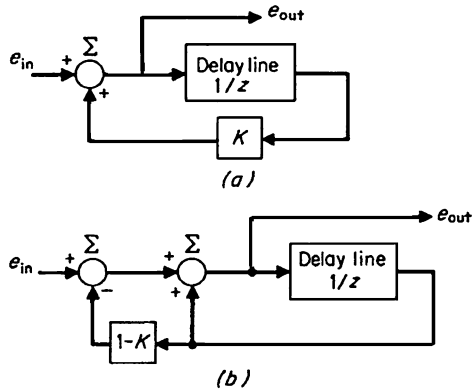

FIGURE 23.2.31 Two forms of sweep integrator.¹⁸

The simplest video integrator uses a single delay line long enough to store all the returns from a single pulse. When the returns from the next pulse are received, they are added to the attenuated delay-line output. Figure 23.2.31 shows two forms of this circuit. The second (Fig. 23.2.31b) is preferred because the gain factor K is less critical to adjust. The circuit weights past returns with an exponentially decreasing amplitude where the time constant is determined by K . For optimum enhancement

$$K = 1 - 1.56/N$$

where N is the number of hits per one-way half-power beamwidth. By limiting the video amplitude into the integrator, the integrator eliminates single-pulse interference. The delay may be analog or digital, but the trend is to digital because the gain of the digital loop does not drift.

The binary integrator or double-threshold detector is another type of integrator used in automatic detectors. With this integrator, the return in each range cell is encoded to 1 bit and the last N samples are stored for each range cell. If M or more of the N stored samples are 1s, a detection is indicated. Figure 23.2.32 shows a functional diagram of a binary integrator. This integrator is also highly immune to single-pulse interference.

Clutter Rejection

The returns from land, sea, and weather are regarded as clutter in an air-search radar. They can be suppressed in the signal processor when the spectrum is narrow compared with the radar's pulse repetition rate (prf). Filters that combine two or more returns from a single-range cell are able to discriminate between the desired targets and clutter. This allows the radar to detect targets with cross section smaller than that of the clutter. It also provides a means of preventing the clutter from causing false alarms. The two classes of clutter filters are moving target indicator (MTI) and pulse doppler.

FIGURE 23.2.32 Binary integrator.³

MTI combines a few pulse returns, usually two or three, in a way that causes the clutter returns to cancel. Figure 23.2.33 shows a functional diagram of a digital vector canceler. The in-phase and quadrature components of the i.f. signal vector are detected and encoded. Stationary returns in each signal component are canceled before the components are rectified and combined. The digital canceler may consist of a shift register memory and a subtractor to take the difference of the succeeding returns. Often only one component of the vector canceler is instrumented, thereby saving about half the hardware, but at the expense of signal detectability in noise.

A pulse doppler processor is another class of clutter filter where the returns in each range resolution cell are gated and put into a bank of doppler filters. The number of filters in the bank approximately equals the number of pulse returns combined. Each filter is tuned to a different frequency, and the passbands contiguously positioned between zero frequency and prf. Figure 23.2.34 shows a functional diagram of a pulse doppler processor. The pulse doppler technique is most often used in either airborne or land-based target-tracking radars, where a high ambiguous prf can be used, thus providing an unambiguous range of doppler frequencies. The filter bank may be instrumented digitally by a special-purpose computer wired according to the fast Fourier transform algorithm.

Digital Pulse Compression

Digital pulse compression performs the same function as the analog pulse compression devices described earlier, except that it is instrumented using digital technology. IF samples of a phase-coded echo are processed to produce samples of a compressed pulse with much shorter duration. Now that the digital technology is comparative in cost with the analog dispersive delay lines, its freedom from temperature variation causes it to be preferred for

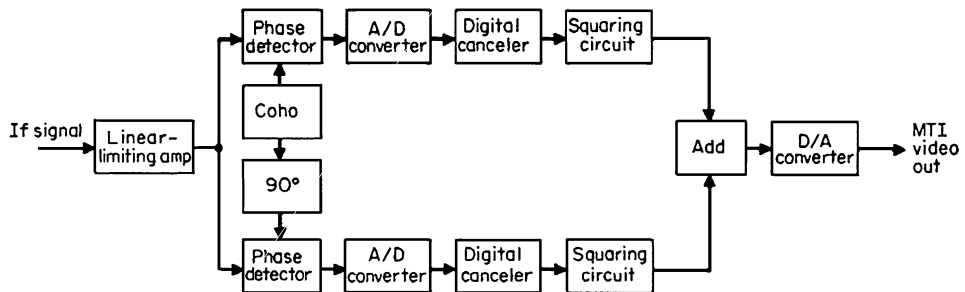

FIGURE 23.2.33 Digital vector canceler.¹⁸

FIGURE 23.2.34 Typical pulse doppler processor.¹⁹

new designs. A typical functional implementation is illustrated in Fig. 23.2.35. Quadrature samples of the IF signal are digitized and stored for an interval at least as long as the transmitted pulse. The stored samples are then correlated with a set of complex weights that represent the time-inverted transmit waveform. The output data stream represents time samples of the compressed IF pulse.

A second important advantage of digital pulse compression is the increased dynamic range compared with analog compression techniques. Since the analog-to-digital converter is usually the limitation on dynamic range, the gain in peak signal provided by pulse compression adds to the dynamic range available to the subsequent digital signal processing.

DISPLAYS

Radar indicators are the coupling link between radar information and a human operator. Radar information is generally a time-dependent function of range or distance. Thus the display format generally uses displacement of signal proportional to time or range. The signal may be displayed as an orthogonal displacement (such as an oscilloscope) or as an intensity modulation of brightening of the display. Most radar signal presentations have the intensity-modulated type of display where additional information such as azimuth, elevation angle, or height can be presented.

A common format is a polar-coordinate, or plan-position, indicator (PPI), which results in a maplike display. Radar azimuth is presented on the PPI as an angle, and range as radial distance. In a cartesian coordinate display, one coordinate may represent range and the other may represent azimuth elevation, or height.

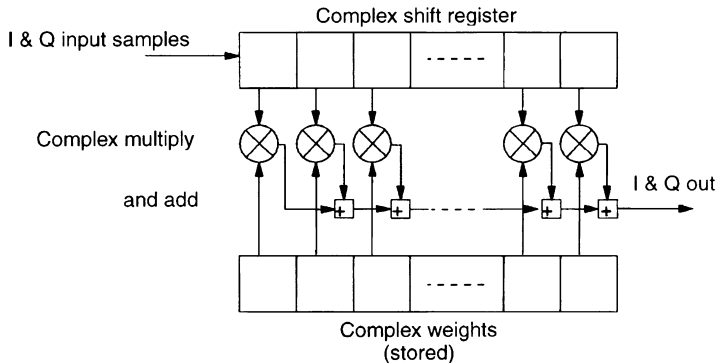

FIGURE 23.2.35 Digital pulse compressor that correlates samples of the receive waveform with a stored replica.

Variations may use one coordinate for azimuth and the other coordinate for elevation and gate a selected time period or range to the display. The increasing use of processed radar data can provide further variations. In each case, the display technique is optimized to improve the information transfer to the operator.

Marker signals may be inserted on the displays as operator aids. These can include fixed and variable range marks, strobes, and cursors as constant-angle or elevation traces. Alphanumeric data, tags, or symbols may be incorporated for operator information or designation of data.

Cathode-Ray Tubes

The cathode-ray tube is the most common display device used for radar indicators. The cathode-ray tube is used most because of its flexibility of performance, resolution, dynamic range, and simplicity of hardware relative to other display techniques. Also, the cathode-ray tube has varied forms, and parameters can be optimized for specific display requirements (see Secs. 5 and 9).

Cathode-ray tubes using charge-storage surfaces are used for specialized displays (see Sec. 5). The direct-view storage tube is a high-brightness display tube. Other charge-storage tubes use electrical write-in and read-out. Such tubes may be used for signal integration, for scan conversion so as to provide simpler multiple displays, for combining multiple sensors on a single display, for increasing viewing brightness on an output display, or for a combination of these functions.

CHAPTER 23.3

ELECTRONIC NAVIGATION SYSTEMS

Walter R. Fried

Some form of electronic navigation system is used in virtually all types of vehicles, including commercial and military aircraft, ships, land vehicles, and space vehicles. In recent years, they have also found application in automobiles and trucks and by individual personnel, both civil and military. Electronic navigation and positioning systems are also used for surveying and for mineral, oil, or other resource applications. Typical parameters measured by electronic navigation systems are the distance and bearing from a vehicle to a known point or the present position of a vehicle in a particular coordinate system. From the knowledge of present position, the course and distance to a destination can then be computed.

Most modern electronic navigation systems are based on the use of electromagnetic (radio) waves. The primary exceptions are systems using gyroscopes and accelerometers; those using optical celestial observations and those using pressure transducers. The use of radio waves has been found attractive because of their nearly constant and known speed of propagation, namely, the speed of light, which is about 3×10^8 m/s. With the knowledge of that velocity of propagation, if the time of travel of the radio signal between two points is accurately measured, the distance (range) between the points can be accurately determined. This is expressed by the equation $d = ct$, where d is the distance between the points, c is the speed of light, and t is the time of travel of the signal between the points. Also, measurement of the phase of the signal can be used for the determination of distance between the points, as well as relative bearing. In addition, the capability of high-frequency electromagnetic systems to generate narrow radiation beams can be useful for the measurement of the relative bearing from a vehicle to another vehicle or from a known point to a vehicle.

TYPES OF SYSTEMS

Electronic navigation systems can be classified in a number of ways, both from an electronics viewpoint and from a navigational viewpoint. From an electronics viewpoint, they can be categorized as *cooperative* or *self-contained*. The cooperative systems, in turn, are divided into *point source* systems and *multiple source* systems. Finally, the multiple source systems can be categorized as hyperbolic systems, pseudorange systems, one-way synchronous (direct) ranging systems, and two-way (round-trip) ranging systems.

From a navigational viewpoint, systems are frequently classified as *positioning* systems and *dead-reckoning* systems. Most positioning systems are cooperative systems, while most dead-reckoning systems are self-contained. In dead-reckoning systems, the initial position of the vehicle must be known, and the system determines the distance and direction traveled from the departure point by continuous mathematical integration of velocity or acceleration. In this handbook, the system technologies are described primarily from the electronics viewpoint. In many modern electronic vehicle navigation systems, the data from cooperative and self-contained sensors are combined, typically using Kalman filters, in order to obtain a more accurate solution for position. Such systems are called *multisensor* or *hybrid* systems.

Cooperative Systems

The two general categories of cooperative electronic navigation systems are *point source* systems and *multiple source* systems. The point source systems typically determine the vehicle's present position by measuring the distance and bearing (azimuth) to a known source. They may determine only distance or only bearing, if these are the only desired parameters. Direction finders are examples of a bearing-only measurement. Multiple source systems determine vehicle position and in some systems also vehicle velocity, either in an absolute or a relative coordinate system. This may be accomplished by multiple ranging (multilateration), differential ranging, multiple angle measurements, multiple pseudorange measurements, or by a combination of these. These methods are also categorized as (1) range and bearing (rho-theta), (2) true ranges (rho-rho or rho-rho-rho), (3) angle-angle (theta-theta), (4) differential ranging, and (5) pseudorange. The first one results in a combination of circular and radial lines of position (LOPs), the second in circular LOPs, the third in radial LOPs, and the fourth in hyperbolic LOPs. The fifth method exhibits spherical LOPs, but they do not cross at the correct position unless the user's time offset is determined. Therefore, its geometric (GDOP) behavior is not exactly equivalent to that of a rho-rho type system discussed later.

Point Source Radio Systems. Perhaps the earliest form of a point source radio system is the *direction finder*. Its principle of operation is based on the use of a single transmitter source whose signal is received at two known points or elements. The direction from the vehicle to the source is determined by the measurement of the differential phase of the signals at the two points or elements. For operational convenience (notably size), it is frequently desirable to have the two receiving points close together and to use common circuitry at both measuring points. A loop antenna fulfills both of these requirements. Typically, a square loop is physically rotated until the currents in the two vertical arms of the loop are equal in amplitude and phase so that the output of the receiver is zero. The transmitter source is then located 90° from the plane of the loop. In simple loops there would be a 180° ambiguity, but this is resolved by temporarily connecting an omnidirectional antenna to the receiver input. Such direction finders are used for backup navigation and emergency homing to a station. Only a single transmitter source (beacon) and a simple rotating antenna and receiver on the vehicle are needed for operation. Lateral navigational error decreases as the transmitter source is approached, which is a property common to all point source angle-measuring systems.

Another class of point source angle-measuring systems are based on the use of scanning antenna beams at the transmitter source and reception of the transmitted signal by the user vehicle receiver. For example, if a ground transmitter generates a rotating cardioid amplitude pattern at a fixed rate plus an omnidirectional reference signal, the user receiver can measure the relative phase difference between these two signals and can thereby determine the bearing to the transmitter source. The operation of the VHF omnidirectional range (VOR), which is used worldwide for short-distance navigation is based on this principle.

The most common type of point-source system for *range* determination is based on the *two-way* (round-trip) ranging principle, which is illustrated in Fig. 23.3.1. The interrogator, which may be located on the navigating vehicle or at a reference site, transmits a signal, typically a pulse (or pair of pulses), at a known time, the transmission time being stored in the equipment. The signal is received at a transponder and, after a fixed known delay, it is retransmitted toward the interrogator, is received by the interrogator's receiver, and input to a ranging circuit. The latter measures the time difference between the original transmission time and the time of reception (less the known fixed delay), which is a direct measure of the two-way distance when multiplied by the speed of light. An important advantage of this technique is that the signal returns to the point of initial generation for the time difference measurement process. Therefore, the interrogator's clock oscillator does not need to be highly stable, since the resulting time error due to any clock instability is only a function of the round-trip time multiplied by the clock drift, the round-trip time being very short, inasmuch as the signal travels at the speed of light. If the transponder in Fig. 23.3.1 is replaced by a passive reflector, for example an aircraft, the principle of operation illustrated is that used in primary surveillance radars, such as those used for air traffic control, as well as military ground-based and airborne radars.

A second fundamental technique of range determination is a *one-way* (versus two-way) signal delay (time of arrival) measurement, between a transmitter source at a known location and a user receiver (Fig. 23.3.2). In this case, an accurate measurement is possible only if the transmitter oscillator (clock) and the user receiver oscillator (clock) are precisely time synchronized. If such time synchronization is not maintained, *true* range cannot be determined, since the exact time of transmission is not known with respect to the user's clock time.

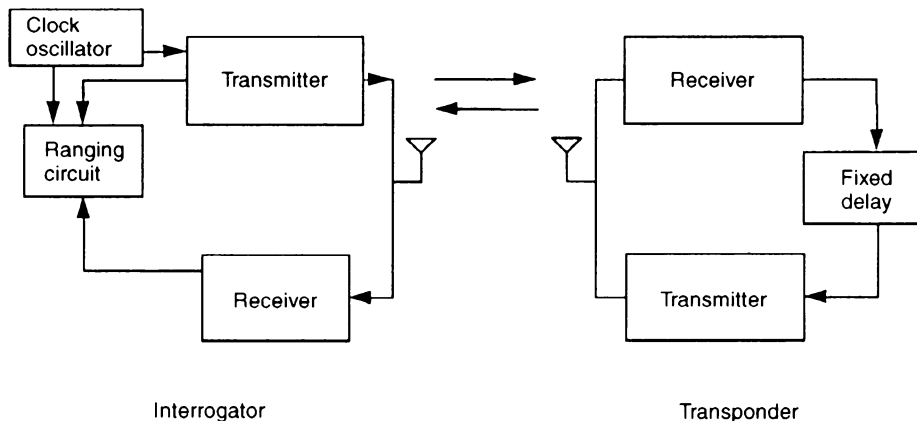

FIGURE 23.3.1 Two-way (round-trip) ranging.

Such precise time synchronization between two individual pieces of equipment is frequently not possible at reasonable equipment cost. Therefore, no practical *point-source* distance measurement system based on this technique has been developed to date; however, several modern multiple source systems (e.g., PLRS, JTIDS-RelNav, and some hyperbolic systems) have modes that use *one-way* synchronous ranging after independent time synchronization has first been accomplished.

Multiple Source Radio Systems. Many systems containing multiple transmitter sources have been developed for the determination of vehicle position. Normally, the user vehicle equipment includes a receiver or a receiver/transmitter. There are five categories of such systems (with some implementations using combinations of these), namely (1) hyperbolic systems, (2) inverse hyperbolic systems, (3) pseudoranging systems, (4) one-way synchronous ranging (direct ranging) systems, and (5) two-way (round trip) ranging systems.

The hyperbolic systems were the first to be developed and are currently in widespread use. The principle of operation is based on the use of three or more transmitter sources, which continuously or periodically transmit time synchronized signals. These may be continuous wave or pulsed signals. The minimum size *chain*, a triad,

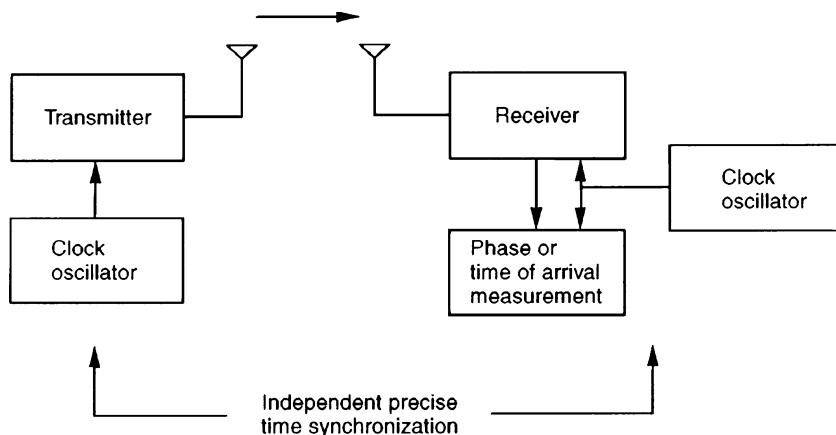

FIGURE 23.3.2 One-way synchronous ranging.

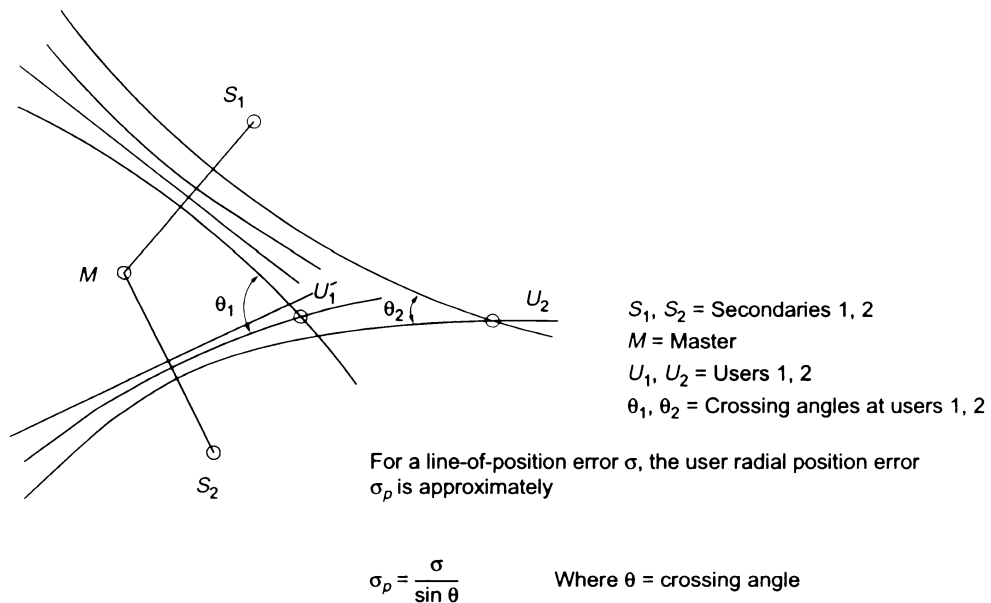

FIGURE 23.3.3 Hyperbolic Navigation System; geometric effects.

usually consists of one Master and two Secondary (slave) stations (Fig. 23.3.3). The user receiver measures the time differences of arrival (TDs or TDOAs) of signals from pairs of stations. Loci of constant time differences of arrival, or (equivalently) constant differences in distance, from two stations form hyperbolic lines of position (LOPs). The point where two lines of position cross is the position of the user vehicle (Fig. 23.3.3). One major advantage of this technique is that the user needs only a receiver and the receiver does not need a high-quality time synchronized clock oscillator, since only *time differences* are used. Theoretically, three pairs of sources are needed for a completely unique horizontal position fix, but in practice two pairs will suffice. The “differences in distance” can be measured either in terms of differences in times of arrival (for example of pulses), differences in electrical carrier phase, or both. As depicted in Fig. 23.3.3, achievable accuracy is very much a function of the relative geometry between the sources and the user, i.e., the crossing angles of the LOPs. The smaller the crossing angle, the larger the position error. This accuracy degradation is called geometric dilution of precision (GDOP). The GDOP is essentially a multiplier on the basic time difference of LOP measurement error.

A related concept, used primarily for external position location, could be called *inverse hyperbolic* system. In this system the vehicle carries a transmitter, which periodically transmits a signal to several receiving stations, whose positions are precisely known. The time differences of arrival (TDOAs) of the signal from the vehicle at pairs of stations is measured and the loci of constant difference in time of arrival form hyperbolic lines of positions. The point where two such lines of positions cross is the position of the vehicle. This technique has been applied to automatic vehicle location (AVL) systems.

The third multiple source radio system concept, which has recently become very important, is called *pseudorangeing*. In this concept, several transmitter sources, whose positions are made known to the user, transmit highly time synchronized signals on established *system time* epochs (Fig. 23.3.4). With these time epochs known to the user, the user measures the time of arrival (TOA) of each signal with respect to its own clock, which normally has some time offset from system time. The resulting range measurement (by multiplying by the speed of light) is called *pseudorange* (PR), since it differs from the *true range*, as a result of the user’s time offset. From several successive or simultaneous such TOA (pseudorange) measurements from four (or more) sources, the user receiver then calculates the three-dimensional position coordinates and its own time offset (from system time). This is accomplished by solving four simultaneous quadratic equations, involving the three known position coordinates of the sources and the four unknowns, namely, the three user position coordinates and the user’s time offset.

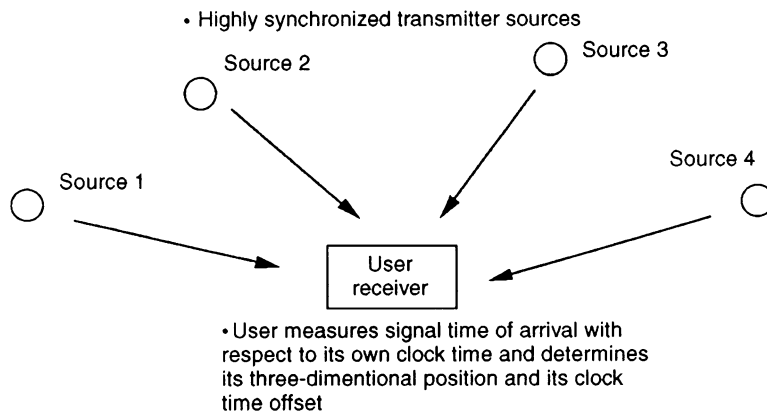

FIGURE 23.3.4 Pseudorange system.

The basic solution equations for the position of a user in a pseudorange multiple source system are given by

$$R_{0i} = c \cdot \text{TOA}_i = [(x_u - x_i)^2 + (y_u - y_i)^2 + (z_u - z_i)^2]^{1/2} - c \cdot \Delta T_u \quad (81)$$

where R_i = pseudorange from the user to source i

c = speed of light

TOA_i = time of arrival of the signal from the i th source

x_u, y_u, z_u = unknown three-dimensional components of the user position

x_i, y_i, z_i = known three-dimensional components of the source i 's position

ΔT_u = user's clock oscillator's time offset

$i = 1, 2, 3, 4$

With x_i, y_i, z_i known and transmitted to the user and four TOAs from four sources measured, the user position coordinates x_u, y_u, z_u and the user's time offset ΔT_u can be determined by solving these four equations with four unknowns. In some implementations, more than four sources are used and the solution is then overdetermined. Thus, this system not only accurately determines the user's three-dimensional position, but also system time, which can be related (in a message from the sources) to standard *universal time coordinated* (UTC). The operation of the satellite-based U.S. Global Positioning System (GPS) and the Russian GLONASS are based on this technique. Also, certain modes of some terrestrial systems, e.g., JTIDS-RelNav use this technique. In addition, by properly combining the known velocity of the sources (from transmitted data) and the measured Doppler shift of the signals received from the sources, the three user velocity coordinates and the user clock frequency offset (drift) can also be determined. Specifically, if the set of Eqs. (81) are differentiated, the basic solution equations for the determination of the user velocity in a pseudorange multisource system can be obtained. In many practical implementations, the delta pseudorange rate or integrated Doppler measurement is used via a Doppler count over a short time interval. Since Eq. (81) is nonlinear, the solution is normally obtained via linearization about an assumed position and time.

In order to provide high-accuracy TOA measurement capability, these pseudorange navigation systems use wide bandwidth, spread spectrum modulation methods, notably *direct sequence spreading*. Propagation delay corrections are made as required.

The fourth multiple source radio system concept is based on one-way synchronous ranging or direct ranging (see Fig. 23.3.2) and the earlier discussion. The concept is used in some military systems (e.g. JTIDS-Relnav and PLRS) and in a second mode of some hyperbolic systems, e.g., Loran-C and Omega. When applied to the latter, the concept is called *direct ranging*. Two implementations are possible, namely, the *rho-rho* method or the *rho-rho-rho* method. The rho-rho method requires only two source transmitters, but it also requires a highly stable user receiver oscillator (clock) and precise knowledge of the time of

transmission from the source station. A *direct range* is then developed to each station. The disadvantage of the rho-rho method is that a very high stability oscillator is required. The rho-rho-rho scheme is an extension of the rho-rho scheme requiring the use of at least three stations. Using three LOPs permits clock oscillator *self-calibration*, somewhat similar to the previously discussed pseudorange concept and therefore leads to a less stringent clock oscillator requirement. The LOPs of both schemes are circles rather than hyperbolas, with the intersection of the circles representing the user position, thereby leading to more favorable geometry conditions.

The fifth multiple source system for position determination is based on multiple two-way (round trip) *true range* measurements. It is therefore a direct extension of the concept depicted in Fig. 23.3.1. To obtain a completely unambiguous horizontal position fix, three two-way ranges are required; however, in most practical cases, two are sufficient. Since the LOPs are circular, the geometric accuracy behavior is generally more favorable than for hyperbolic systems.

Self-Contained Systems

These electronic navigation systems are called self-contained because the navigation equipment required is located totally on the vehicle, i.e., operation of the system is not dependent on any outside sources or stations. These systems can be classified as radiating or nonradiating. The radiating systems described below are (1) the radar altimeter, (2) the airborne mapping radar (3) map matching systems, and (4) Doppler navigation radars. Nonradiating systems offer essentially complete protection against radio interference or jamming. The two systems in this category described below are inertial navigation systems and celestial navigation systems.

Radar Altimeter (Ref. 1, Chapter 10). The device (also known as *radio altimeter*) is a small radar with an antenna on the bottom of an aircraft generating a beam toward the earth's surface. The signal is back-scattered by the surface and received and processed by the radar, which measures the two-way (round-trip) delay experienced by the signal, thereby generating altitude above the surface. The modulation may be frequency-modulated continuous wave (FM-CW) or pulse modulation. For civil aviation use, the systems typically have a range of 0 to 2500 ft (0 to 750 m), are used for landing guidance, and are of the FM-CW type. In FM-CW systems, the carrier is frequency modulated in a triangular pattern, a portion of the transmitted signal is mixed with the received signal and the resulting beat frequency is directly proportional to altitude above terrain. In pulse radar altimeters, primarily used in military aircraft, the carrier is modulated by narrow pulses and the time of reception of the leading edge of the return pulses are measured with respect to their time of transmission. The time difference is a direct measure of the two-way distance to the ground straight below the aircraft. The frequency band of operation in both types of altimeters is 4200 to 4400 MHz. Typical accuracy performance is 2 ft or 2 percent. Military aircraft and helicopters use these altimeters for terrain avoidance.

Mapping Radars (Ref. 1, Chapter 11). These radars scan the ground using specially shaped beams, which effectively map the terrain. They are used by pilots for navigation by recognizing certain terrain features, for example, rivers and bridges, and by manually or semiautomatically position fixing their navigation systems through designation on the known ground mapped objects. Synthetic aperture radars (SARs) provide particularly high resolution of the mapped terrain, making these position update functions very accurate.

Terrain (Map) Matching Systems (Ref. 1 Chapter 2). The output of an airborne mapping radar or a radar altimeter can be used to generate a digital map or terrain profile which is then compared with on-board stored digital maps or terrain profiles, in order to allow a military aircraft or missile to automatically fly a prescribed track.

Doppler Radar Navigation (Ref. 1, Chapter 10). Radio waves that are transmitted from a moving aircraft toward the ground and back-scattered by the ground to the aircraft experience a change of frequency, or Doppler shift, which is directly proportional to the ground speed of the aircraft and the cosine of the angle between the radiated beam center line and the velocity vector. A Doppler navigation radar consists of a transmitter, a receiver, and a frequency tracker which measures and tracks the Doppler shift of the signals in each

of three or four antenna beams directed at steep angles toward the earth's surface. Modern systems operate at the 13.325-GHz frequency. The transmission may be pulse modulated, frequency-modulated continuous-wave (FM-CW), or continuous wave (CW). Because the earlier, pulse modulated systems were less efficient, current systems are either of the FM-CW or CW type. The FM-CW systems transmit sinusoidally modulated signals which are mixed with the back-scattered signal in the receiver. The Doppler shift of one of the (Bessel function) sidebands of the mixed signals is measured and tracked. In the pure CW systems, the beat frequency Doppler between the transmitted and received signals are measured and tracked. Typical transmitted antenna patterns consists of four narrow beams, directed at steep angles toward the ground and are generated by planar array antennas. For the determination of three-dimensional velocity components, a minimum of three such beams are required. However, in modern systems, four beams are used because they are easily generated by planar array antennas and the redundant information can provide higher accuracy and a self-test function. If the antenna is fixed to the airframe the ground velocity components are computed by resolving the beam Doppler shifts through pitch and roll angles obtained from a vertical gyro or inertial navigation system. In order to determine vehicle present position, the velocity components in aircraft coordinates are converted to earth-referenced coordinates by resolving them about true heading obtained from a heading reference, such as a magnetic compass corrected for variation, an attitude-heading reference or an inertial navigation system. The velocity components are then integrated into distance traveled north and east from a previously known position (dead reckoning). The position accuracy of a Doppler navigation system is therefore a function of the accuracy of the heading reference. The basic velocity accuracy of modern lightweight Doppler radars is 0.2 percent or ± 0.2 knot. These systems have been used by military aircraft and transoceanic airliners. Currently, Doppler radar navigation systems are widely used on military helicopters for navigation and hovering. Doppler radars have also been used for achieving lunar and planetary landings. The Doppler velocity measurement concept has been incorporated into modern airborne search and mapping radars (Ref. 1, Chapter 11) and is also used in sonar systems for measuring ship's velocity.

Inertial Navigation Systems (Ref. 1, Chapter 7). Inertial navigation equipment which is based on Newton's second law can determine aircraft acceleration and direction of travel. From Newton's second law, it is known that the force acting on a body is proportional to its mass and acceleration. In one implementation, acceleration may be determined by measuring the deflection of a spring attached to a known mass. If the acceleration is doubly integrated, the distance traveled can be determined. An inertial navigation system (INS), consisting of accelerometers, gyros, and processors, continuously determines position, velocity, acceleration, direction (with respect to north), and attitude (pitch and roll) of a vehicle. Since the position is obtained from doubly integrating acceleration of the vehicle from a known position, an inertial navigation system is inherently a *dead reckoning* system. In a good quality inertial navigation system, the accelerometers must be capable of measuring acceleration with high accuracy; e.g., a 10^{-4} g accelerometer bias error causes a 0.3-nmi-peak position error, where g is the magnitude of the gravitational acceleration (32.2 ft/s^2). Misalignment of an accelerometer with respect to vertical causes it to read a component of the gravity vector g . Therefore, in some systems the three accelerometers (for sensing acceleration in three dimensions) are mounted on a gimballed platform, which is stabilized by gyroscopes in order to keep the accelerometers in a horizontal plane. The drift rate of the gyroscopes must be low, since a 0.017° drift rate gives rise to a 1 nmi/h average position error. In many modern systems, the inertial sensors are strapped to the vehicle, e.g. the aircraft, and data from the gyros are used to correct the data from the accelerometers. These are called *strapdown* systems. The basic inertial navigation system error equations for motion over the earth give rise to a sinusoidal oscillatory behavior at the so-called Schuler frequency. The latter is derived from the square root of the ratio of the magnitude of the gravitational acceleration g and the radius of the earth. Its period is 84.4 min. As a result, the inertial position and velocity errors are oscillatory at that frequency, although increasing linearly with time, with the Schuler oscillations superimposed. Inertial navigation systems must be aligned initially as accurately as possible, and their accuracy degrades with time, even when stationary (due to gyro drift and accelerometer bias). Alignment is degraded at high latitudes (above 75°) and in a moving vehicle. The gyroscopes used in earlier systems were precision mechanical devices. Recently, ring laser gyros (RLGs) have been developed and are used in many modern inertial systems. Their operation is based on the use of an optical laser that generates two counter rotating light beams within a triangular structure. When that structure is physically rotated around the axis normal to the plane of the structure, the beat or difference frequency of the light beams is proportional to the angular rate and is sensed as an output at one corner of the structure (Sagnac effect). This results in the device being a

rate gyro. These gyros are less expensive than mechanical gyros. Another gyro based on a similar optical concept, which has been developed and shows great promise, is the fiberoptic gyro (FOG). Typical modern inertial navigation systems have position accuracies between 0.5 and 1 nmi/h.

Celestial Systems, (Ref. 1, Chapter 12). These systems operate by making optical observations on celestial bodies and solving the astronomical triangle. Accurate knowledge of the position of the vehicle with respect to the local horizontal (pitch and roll) is required to obtain optimum performance with these systems. Fortunately, this information is readily available from inertial instruments or inertial navigation systems. These systems are particularly useful in bounding the long-term errors of inertial navigation systems. Previously they were used extensively on all types of ships and commercial airliners for position fixing. Currently, they are used primarily on military aircraft.

GEOMETRIC DILUTION OF PRECISION

In hyperbolic and pseudorange navigation systems, such as Loran-C and GPS, there is a significant effect on accuracy due to the relative geometric location between the user vehicle and the transmitter sources. This effect is represented by a nondimensional term called *geometric dilution of precision* (GDOP). GDOP is essentially a factor by which the basic range difference or ranging error is multiplied to obtain the resulting position error.

Horizontal Hyperbolic System GDOP

In a two-dimensional hyperbolic navigation system such as Loran-C, using a chain of three stations (triad), the GDOP factor is given by the following equation:

$$\text{GDOP} = \frac{1}{\sin(\phi_1 + \phi_2)} \sqrt{\frac{1}{\sin^2 \phi_1} + \frac{1}{\sin^2 \phi_2} + \frac{2r \cos(\phi_1 + \phi_2)}{\sin \phi_1 \sin \phi_2}} \quad (82)$$

where ϕ_1, ϕ_2 = half-angles subtended by the two station pairs

r = correlation coefficient between two lines of position (LOPs) (typically assumed to be 0.5)

$\phi_1 + \phi_2$ = crossing angle of the LOPs

The radial standard deviation horizontal position error is the product of GDOP and the standard deviation range difference (LOP) measurement error.

Three-Dimensional Pseudorange System GDOP

For pseudorange, satellite-based systems, such as GPS and GLONASS, which provide information on the three-dimensional components of position of the vehicle and time, the GDOP factor is given by the following equation:

$$\text{GDOP} = [\text{Trace}(H^T H)^{-1}]^{1/2} \quad (83)$$

where H is the measurement matrix relating the pseudorange measurements to the three user position components and the user time offset (bias) from system time, i.e.,

$$H X_u = P R$$

H is defined such that the i th row (for satellite i) of $H(h_i)$ is given by $h_i = (1_{xi} \ 1_{yi} \ 1_{zi} \ -1)$ and the elements 1_{xi} , 1_{yi} , 1_{zi} are the unit vectors defining the direction cosines from the user position to the satellite positions; (H has

at least four rows), X_u is the vector of the user xyz position coordinates (m), and the time offset expressed in meters, i.e., $X_u = (x_u, y_u, z_u, c\Delta T_u)^T$, ΔT_u = user time offset (seconds), c = speed of light (3×10^8 m/s). Trace (\bullet) indicates the sum of the diagonal elements of (\bullet). PR = vector of measured pseudoranges to the satellites, including errors. x, y, z can be the orthogonal right-handed cartesian Earth Centered Earth Fixed (ECEF) coordinates, with z from the center of the earth to the North Pole, x through the Greenwich meridian, and y orthogonal to x in the plane of the equator.

The solution for $x_u, y_u, z_u, \Delta T_u$ involves four (or more) pseudoranges and requires linearization about an estimated position. This is typically done using a minimum variance, Kalman filter, or least squares estimator and leads to pseudorange residuals, such that:

$$\delta PR = H(\delta X_u^T c \cdot \delta \Delta T_u) \quad (84)$$

where δ_{PR} = four element pseudorange error vector

δX_u = user position error vector

$\delta \Delta T_u$ = user time offset error

If the four (or more) pseudorange errors are statistically uncorrelated with equal, zero mean one-sigma values of σ_{PR} , the one-sigma position and time error is given by

$$\sigma_{x,t} = \text{GDOP} \cdot \sigma_{PR} = (\sigma_x^2 + \sigma_y^2 + \sigma_z^2 + c^2 \sigma_{\Delta t}^2)^{1/2} \quad (85)$$

The position dilution of precision (PDOP) is computed by deleting the fourth diagonal element in the trace of the GDOP equation. The time dilution of precision (TDOP) is the square root of the fourth element of the GDOP equation. The first two diagonal elements in the trace are used to compute HDOP, and only the third diagonal element is used to compute VDOP. The ECEF coordinate residuals must be transformed to local tangent plane coordinates, in order to compute HDOP and VDOP (Ref. 1, Chapter 5).

INTERNATIONALLY STANDARDIZED SYSTEMS

The systems described next are used by hundreds of thousands of vehicles throughout the world. Standardization is therefore desirable and refers principally to the radiated signal characteristics and the performance of the system. Each manufacturer and country may decide on the equipment design that best satisfies the operational requirements.

Omega (Ref. 1, Chapter 4)

This is a hyperbolic navigation system that provides worldwide service with a high enough data rate to be used by aircraft. It is a hyperbolic phase-comparison system using eight stations located in Norway, Liberia, Hawaii, North Dakota, La Reunion Island, Argentina, Australia, and Japan. The system operates in the 10 to 14-KHz, very low frequency (VLF) band, using a fixed transmission pattern. The overall signal format is shown in Fig. 23.3.5. Each station transmits on four common frequencies and one station-unique frequency. The signal frequencies are time-shared among the stations, so that a given frequency is transmitted by only one station at a given time. Each station transmits on one frequency at a time, for about 1 s, the cycle being repeated every 10 s. At the transmitted VLF frequencies, lane ambiguity occurs approximately every 8 n.mi., i.e., every half-wavelength. However, by using the beats between the basic frequencies, these ambiguities can be extended, e.g., to 24 n.mi for two frequencies and to 72 n.mi for three frequencies. Most modern receivers use at least three frequencies. In addition, continuous lane counting is used from a starting point, in order to avoid any lane ambiguity problems. Omega signal propagation basically takes place in the wave guide formed by the surface of the earth and the ionosphere. Most airborne receivers also use the system in the rho-rho-rho mode, backed up by 10 very low-frequency (VLF) communication transmitter stations in the 16 to 24 kHz band.

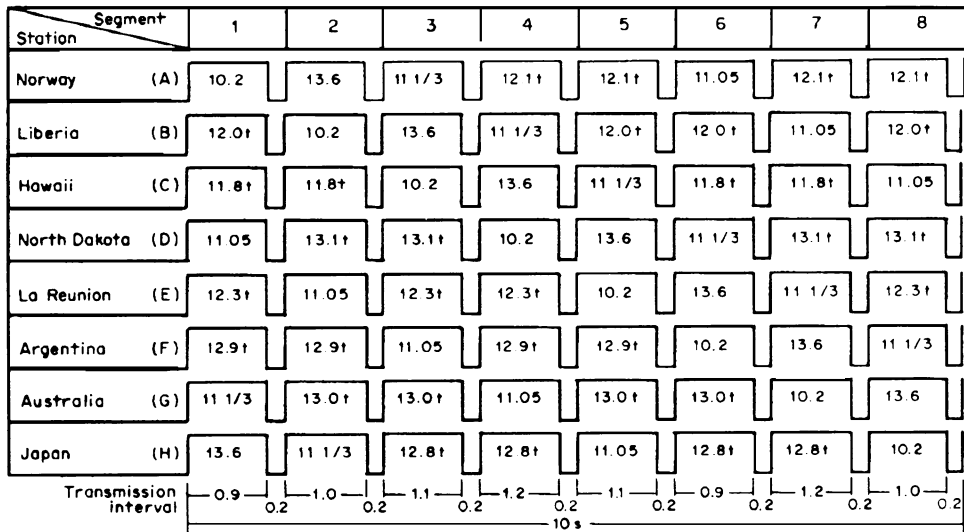

FIGURE 23.2.5 Omega System Signal Transmission Format (frequencies in kilohertz). Frequencies marked † are the unique frequencies for the respective stations.

There is a marked difference in propagation time between day and night (diurnal variation), but this is predictable and amenable to computer storage, and can be applied to the solution in the receiver, as a function of time, data, and approximate user position. Also, an earth's conductivity map can be stored in the computer. The position accuracy of Omega is 2 to 4 n. mi (3.7 to 7.4 km), 2 DRMS.

Loran C (Ref. 1, Chapter 4)

This is a hyperbolic system, with coverage in the United States, the North Atlantic, the Mediterranean, and the North Pacific. The combination of low-frequency transmission and pulses provides long range and eliminates sky waves. The system uses a carrier frequency of 100 kHz and matches the individual rf cycles within each pulse, thereby gaining added resolution and accuracy. Since all stations operate on the same frequency, discrimination between chains is by the pulse-repetition frequency. A typical chain comprises a master and two secondaries about 600 n.mi from the master. At the receiver, the first three rf cycles are used to measure the signal time of arrival. At this point the pulse is about half amplitude. The remainder of the pulse is ignored, since it may be contaminated by skywave interference. To obtain greater average power at the receiver without resorting to higher peak powers, the master transmits groups of nine pulses 1000 μ s apart and the secondaries transmit eight pulses, also 1000 μ s apart. These groups are repeated at rates ranging from 10 to 25/s. Within each pulse, the rf phase can be varied in a code for communication purposes. At the receiver, phase-locked loops track the master and secondary signals and generate their time differences. A digital computer can provide direct readouts in latitude and longitude and steering information. There has been a tremendous growth in the use of Loran by general aviation. Position accuracy is 0.25 n.mi (0.4 km) 2 DRMS.

Decca (Ref. 1, Chapter 4)

Unlike all other systems described herein, Decca is a proprietary system, with most of the stations owned by the Decca company and the receivers leased by it to the users, who are primarily in Europe. It is a continuous-wave hyperbolic system operating in the 70 to 130-kHz band. It uses the same frequency band as Loran-C, but

since it does not use pulses, it is subject to skywave contamination, resulting in reduced range. A typical chain comprises four stations, one master and three secondaries, separated by about 70 n.mi, arranged in a star configuration. Each station is fed with a signal, which is an accurately phase-controlled multiple of a base frequency f in the 14 kHz region, the master at $6f$, the “red” secondary at $8f$, the “green” secondary at $9f$, and the “purple” secondary at $5f$. At the receiver, these four signals are received, multiplied, and phase-compared. There are about 25 Decca chains in Europe and about 20 elsewhere in the world.

Beacons

As sources for shipboard and airborne direction-finders, these are the oldest and most numerous navigation aids in the world. Since the frequency bands of beacons are adjacent to the amplitude-modulation (AM) broadcast band, receivers are easily designed to serve a dual purpose and they are consequently popular with boat operators and with aircraft of all types. Direction-finding accuracy can be as good as $\pm 3^\circ$.

Very High Frequency Omnidirectional Range (VOR) (Ref. 1, Chapter. 4)

This aviation system uses the VHF band and is thus free of atmospheric and skywave contamination. It places the directional burden on the ground, rather than in the aircraft, where more extensive means can be employed to alleviate site errors. Line-of-sight limits its service area to about 200 n.mi for high-flying aircraft, and some stations are intended for only 25 n.mi service to low-flying aircraft. There are more than 1000 stations in the United States and about an equal number in the rest of the world. There are two variations, i.e., conventional VOR and Doppler VOR, with the latter providing increased site error reduction.

Conventional VOR. It operates on 40 channels, 100 kHz apart, between 108 and 112 MHz, interleaved between ILS Localizer channels, and on 120 channels, spaced 50 kHz, between 112 and 118 MHz. The airborne receiver is frequently common with the airborne Localizer receiver and may use the same airborne antenna. Power output from the ground transmitter varies from 25 to 200 W, depending on antenna design and on the desired service area. The ground-antenna pattern forms a cardioid in the horizontal plane which is rotated 30 times per second. The CW transmission is amplitude-modulated by a 9960-Hz tone which is frequency modulated ± 480 Hz at a rate of 30 Hz. This latter, 30-Hz “reference” tone, when extracted in the airborne receiver, is compared with the 30-Hz amplitude modulation provided by the rotating antenna. The phase angle between these two 30-Hz tones is the bearing of the aircraft with respect to north.

VOR is the internationally standardized en route navigation system, widely implemented through-out the world which meets the FAA en route integrity requirements for a warning of within 10 s if there is a failure of ground equipment. The basic VOR instrumental error is $\pm 1.4^\circ$ 2-sigma. Site errors can degrade this error; this lead to the development of the Doppler VOR, described below.

Doppler VOR reduces site error about tenfold by using a large-diameter antenna array at the ground station. This array consists of a 44-ft diameter circle of antennas. Each antenna is sequentially connected to the transmitter in a manner so as to simulate the rotation of a single antenna around the 44-ft diameter circle at 30 rps. The receiver sees an apparent Doppler shift in the received rf of 480 Hz at a 30 rps rate, and at a phase angle proportional to the receiver’s bearing with respect to north. This signal is therefore identical with the conventional VOR reference tone. It remains to transmit a 30-Hz AM tone, separated 9960 Hz as a reference, in order to radiate an identical signal to the conventional one, receivable in an identical receiver but benefiting from a manifold increase in ground-antenna aperture.

Distance-Measuring Equipment (DME) (Ref. 1, Chapter 4)

DME is an interrogator-transponder *two-way* ranging system (Fig. 23.3.1). About 2000 ground stations and 70,000 pieces of airborne equipment are in use worldwide.

The airborne interrogator transmits 1kw pulses of 3.5 μ s duration, 30 times a second, on one of 126 channels 1 MHz apart, in the band 1025 to 1150 MHz. The ground transponder replies with similar pulses on another

channel 63 MHz above or below the interrogating channel. (This allows use of the transmitter frequency as the receiver's local oscillator frequency if the intermediate frequency is 63 MHz). A single antenna is used at both ends of the link. In order to reduce interference from other pulse systems, paired pulses are used in both directions, their spacing being 12, 30, or 36 μs . The fixed delay in the ground transponder is 50 μs .

In the airborne unit, the received signal is compared with the transmitted signal, their time difference derived, and the distance is determined and displayed. Ground transponders are arranged to handle interrogation from up to 100 aircraft simultaneously, each aircraft recognizing the replies to its own interrogation by virtue of the pulse repetition frequency being identical with that of the interrogation. Analog models require about 20 s for identity to be initially established (after which a continuous display is provided); modern digital models perform the search function in less than 1 s.

The DME is nearly always associated with a VOR, the two systems forming the basis for a rho-theta area navigation (RNAV) system. Some use is being made of DME in the rho-rho mode, particularly by airlines. In this mode, the airborne interrogator scans a number of DME channels, automatically selecting two or more having the best signal and thus providing a fix of greater accuracy than would be obtained from VOR/DME. This is known as DME/DME and is thus a way of achieving a two-way ranging *multiple* source navigation system. DME is an international standard which, together with VOR, has been the basis for the most widely used line-of-sight rho-theta aircraft navigation system. Standard airborne DME equipment provides a two-sigma accuracy of ± 0.1 n. mi (± 185 m).

Tacan (Ref. 1, Chapter 4)

This is a military modification of DME, using the same channels, and adding a bearing capability in the same frequency band. This results in a small ground antenna system, a property useful for ships. It is a military system used widely on aircraft carriers. The DME antenna is replaced by a rotating directional antenna generating two superimposed patterns. One of these is a cardioid rotating at 15 rps. The other is a nine-lobe pattern, also rotating at 15 rps. The squitter pulses and replies are amplitude-modulated as the antenna rotates. Reference pulses are transmitted at 15 and 135 Hz. In the aircraft, a coarse phase comparison can then be made at 15 Hz which is supplemented by a fine comparison at 135 Hz. The overall instrumental accuracy of TACAN is 0.2° two-sigma (bearing) and 0.1 n.mi. (185 m) two-sigma (distance).

Vortac (Ref. 1, Chapter 4)

In countries having a common air traffic control system for civil and military users (e.g., the United States and Germany), the civil rho-theta system is implemented by the use of Tacan rather than DME for distance measurement. Tacan transponders are colocated with VOR stations, and civil aircraft get their DME service from the Tacan stations. In the United States, over 700 VORs have colocated Tacan transponders.

Instrument Landing Systems (ILS) (Ref. 1, Chapter 13)

This is the internationally standardized aircraft approach and landing system, which provides a fixed electronic path to almost touchdown at major runways throughout the world. The ground equipment is made up of three separate elements: the *localizer*, giving left-right guidance; the *glide slope*, giving up-down guidance; and the *marker beacons*, which define progress along the approach course. Using VHF, ILS is free of atmospheric and sky-wave effects, but is subject to site effects.

The *localizer* operates on 40 channels spaced 50 KHz apart, in the 108 to 112 MHz band, radiating two antenna patterns which give an equisignal course on the centerline of the runway, the transmitter being located at the far end of the runway. The left-hand pattern is amplitude-modulated by 90 Hz, the right-hand pattern by 150 Hz (Fig. 23.3.6a). The airborne receiver detects these tones, rectifies them, and presents a left-right display in the cockpit. The accuracy is better than $\pm 0.1^\circ$. Minimum performance calls for the airborne meter to remain hard left or hard right to a minimum of $\pm 35^\circ$ from the centerline, i.e., there must be no ambiguous or "false" courses within this region. More sophisticated systems exist in which a usable "back course" (with reverse

FIGURE 23.3.6 Instrument Landing System: (a) minimum ICAO localizer pattern; (b) localizer pattern with back course and clearance; (c) glide slope pattern; (d) marker beacons (From S. H. Dodington, *Electronic Engineers' Handbook*, McGraw Hill, 3d ed.).

sense) is obtained, and a separate transmitter, offset by about 10 kHz, provides “clearance,” so that no ambiguities exist throughout $\pm 180^\circ$ (Fig. 23.3.6b).

The *glide-slope* transmitter, of about 7W power, is located at the approach end of the runway and up to about 500 ft to the side (Fig. 23.3.6c). It operates in the 329 to 335-MHz band, each channel being paired with a localized channel. In the airborne receiver, both channels are selected by the same control. Two antenna patterns are radiated, giving an equisignal course about 3° above the horizontal. The lower pattern is modulated with 150 Hz, and the upper pattern with 90 Hz. The airborne receiver filters these tones, rectifies them, and presents the output on a horizontal zero-centered meter mounted in the same instrument case as the localizer display, the two together being called a *cross-pointer display*. The accuracy is better than $\pm 0.1^\circ$. Required accuracies for ILS and MLS are sometimes specified in distance (meters) at the decision height for the three landing categories described below.⁹ The glide slope suffers from course bends because of the terrain in front of the array, and is generally not depended on below 50 ft of altitude. In this phase of the landing maneuver, either visual observation or a radar altimeter are frequently used.

Marker beacons operate at a fixed frequency of 75 MHz, and radiate about 2 W upward toward the sky with a fan-beam antenna pattern whose major axis is across the direction of flight (Fig. 23.3.6d). There is an “outer” marker about 5 n.mi from touchdown, and a “middle” marker about 3500 ft from touchdown. There can also be an “inner” marker at about 1000 ft from the touchdown threshold. Each type is modulated by audio tones which are easily recognized as the aircraft passes through their antenna pattern. Alternatively, differently colored lamps are set to light in the cockpit as each marker is passed.

Categories of ILS performance have been established for different visibility conditions and the quality of the installation. These place the following minimum limits on how an aircraft may approach the touchdown point:

- Category I: 200-ft ceiling and $\frac{1}{2}$ -mi visibility
- Category II: 100-ft ceiling and $\frac{2}{4}$ -mi visibility
- Category III: zero ceiling and 700-ft visibility

ILS meets the FAA requirements for approach mode integrity; that is, failure of the ground equipment is evident to the pilot within 2 s.

Microwave Landing System (MLS) (Ref. 1, Chapter 13)

While the ILS described above has served well worldwide for over 30 years, it has been thought that requirements for the future will necessitate more channels, more flexible (curved) approach paths, and greater freedom from site effects. These can be obtained at microwave frequencies where greater antenna directivity and a wider frequency spectrum are available. Since a range of only 20 n.mi or so is needed, line-of-sight limitations pose no problem. Angular guidance is obtained from fan-shaped beams that scan the airspace, using 200 radio frequencies between 5.00 and 5.25 GHz. The perceived angle in the aircraft is proportional to the time it takes the beam to pass through the aircraft, first in one direction and then in the other. The scanning rate is 50 μ s/degree. The system is thus known as a time-referenced scanning beam (TRSB) system. Use of the high microwave frequencies and the nature of the ground-based antenna patterns, as well as the possible inclusion of a high-precision version of DME, can provide higher accuracy performance than that of the ILS in some sites and a capability for curved approaches. However, in view of the great potential for using GPS for approach and landing, the U.S. FAA has decided to curtail development efforts of the MLS. In Europe, the civil aviation community, however, has shown continued interest in using MLS, in view of the unique requirements there. Also, the U.S. military services have had continued interest in microwave landing systems. The official, basic specified accuracy performance of MLS is the same as that of ILS.⁹

JTIDS-RelNav (Ref. 1, Chapter 6)

The Joint Tactical Information Distribution System (JTIDS) is a decentralized, military, spread spectrum data communication and navigation system, using wide bandwidth phase coding, frequency hopping and time division multiple access. It operates in the 960 to 1215-MHz band. It includes a *Relative Navigation* (RelNav) function that permits all members of a JTIDS network, such as aircraft and ships, to accurately determine their position in both absolute and relative grid coordinates. Its operation is based on highly precise TOA measurement of signals received by cooperating units. The system includes a means for independent precise time synchronization of each unit with *system time*. The system includes two modes of operation, namely, one-way synchronous ranging and pseudorangeing.

Position Location Reporting System (PLRS) (Ref. 1, Chapter 6)

The Position Location Reporting System (PLRS) is a centralized, military, spread spectrum *position location and navigation system* for military aircraft, land vehicles, and personnel. It uses wide bandwidth phase coding, frequency hopping and time division multiple access and also incorporates data communications capability. It operates in the 420 to 450 MHz frequency band. It provides military commanders with information on the location of all of his elements, as well as own position and relative guidance information to each unit, in the absolute Military Grid Reference System (MGRS). Its operation is based on multilateration using highly precise TOA measurements of signals exchanged between units. Multiple relays are used to combat line-of-sight problems. The system includes two modes of operation, namely, two-way (round-trip) ranging and one-way synchronous ranging.

IFF

To distinguish friend from foe, radars employ an interrogator-transponder system operating at a different set of frequencies from those of the basic radar. The “friend” is assumed to be transponders-equipped and the “foe” is not. The interrogator is pulsed at about the same time as the radar, and the transponder produces coded replies shortly after the direct radar reply from the aircraft skin. In theory, even if the foe used the same transponder equipment, he would not know the code of the day. This “identification of friend or foe” system

became known as *IFF*. Interrogation takes place at 1030 MHz and replies at 1090 MHz. Typical pulse powers are 500 W, with a 1- μ s length for interrogation and 0.5- μ s length for reply.

SSR (Ref. 1, Chapter 14)

Secondary surveillance radar (SSR) is an outgrowth of the military identification of friend or foe (IFF) system, using the same frequencies. It is the principal means by which air traffic controllers identify and track civil and military aircraft worldwide. Secondary surveillance radars are the primary components of the FAA's Air Traffic Control Radar Beacon System (ATCRBS). The *secondary surveillance radar (beacon)* units are frequently co-located with, and mounted on top of, conventional *primary* radars. The beacon ground stations interrogate airborne transponders at 1030 MHz and receive replies at 1090 MHz, in order to measure distance using two-way (round-trip) ranging and bearing to an aircraft using the SSR's narrow antenna beam. Paired pulses are used for interrogation, and a third pulse between the two is radiated omnidirectionally to reduce triggering by side lobes. The airborne transponder replies only when the directional pulses are stronger than the omnidirectional pulse. The reply pulses comprise a train of up to 14 pulses, lasting 21 μ s, which are currently combined into 4094 codes. These can be used to identify the aircraft or to communicate its altitude to the ground controller. The major problem of SSRs is the interference (garbling) which occurs when two or more aircraft are at about the same azimuth and distance from the interrogator. To alleviate this effect, the U.S. FAA has developed a new mode of interrogation coding (Mode S) which will allow each aircraft to be addressed by a discrete code, and thus only "speak when spoken to." This system will be compatible with the present SSRs, to allow an orderly transition. In the current system, the replies are pulse-coded with identity (mode A) and altitude (mode C). Mode S provides higher angular accuracy through monopulse techniques, discrete addressing of each aircraft, more efficient code modulation and a much higher capacity data link capability.

ATCRBS

The ATCRBS is the ICAO standard ground-based civil aircraft surveillance system based on the use of primary radars and secondary radars (SSRs) as sensors, as well as on extensive data processing, display, and communication systems. It is used by the air traffic control authorities to track aircraft.

TCAS

The Traffic Alert and Collision Avoidance System (TCAS) is based on the use of SSR technology. In operation, a TCAS-equipped aircraft interrogates all aircraft in the vicinity; the interrogated aircraft responding by means of the SSR transponder and the response is received by the interrogating aircraft. The latter can thus determine the relative altitudes and positions of the two aircraft. Computation of the relative rate of change (closing velocity) of these aircraft provides an indication of whether the two aircraft are on a collision threat. Thus, unmodified SSR transponders are used at the standard SSR frequencies (1030 and 1090 MHz). Three versions of TCAS have been or are under development, i.e., TCAS I, II, and III. TCAS I is intended for general aviation. It tracks proximate aircraft in range and altitude and displays traffic advisories (TAs) for intruders, thereby aiding the flight crews in visually acquiring threat aircraft. The most widely implemented version is TCAS II, currently used by the commercial airlines. In this version, not only TAs are displayed, but, if a threat is calculated, a resolution advisory (RA) is displayed showing a vertical escape maneuver (e.g., "climb") for avoiding collision. The two TCAS aircraft must exchange escape maneuver intentions in order to assure that they are complementary. The SSR Mode S data link can be used for that purpose. The U.S. Congress has passed a law making TCAS II mandatory on most airline type aircraft. In 1996, improved versions of TCAS were under development, notably those directed at a capability for horizontal-twin escape maneuvers. Also, techniques for the broadcast by each aircraft of on-board derived position via data link is under investigation, called ADS-B and TCAS IV.

Transit (Ref. 6)

This satellite-based system was originally developed for use by the U.S. Navy. However, after its release for civil use, the marine industry and also land mobile users saw its advantage of worldwide service and high accuracy. Each satellite operates in a polar orbit at 600-mi altitude and radiates two CW frequencies near 150 and 400 MHz. As it passes over an observer on the surface of the earth, these frequencies undergo a Doppler shift. The user receiver records the Doppler frequency history of the signal. Since the satellite orbit is accurately known as a function of time, the time of zero Doppler shift and the slope at zero Doppler are sufficient to determine the user's position on the earth. The satellite positions are continually determined by a ground based tracking network and are broadcast by the satellites to the user. The user computes its position from the Doppler history. Six to seven satellites in polar orbit are used to provide global coverage. While a single radiated frequency would lead to a position accuracy of about 500 m 2 DRMS, two frequencies allow errors due to ionospheric propagation effects to be greatly reduced and the resulting accuracy with a two-frequency receiver is 25 m 2DRMS. Most receivers use two transmitted frequencies. The system is not suitable for aircraft because of its low update rate. For six satellites in orbit, the satellites pass a given point, on the average, 90 min apart. The system is in operation in 1996, but the 1992 U.S. Federal Radio Navigation Plan (Ref. 9) lists Transit as a candidate for phase-out in the late 1990s, based on the operational status of GPS.

Global Positioning System (GPS) (Ref. 1, Chapter 5)

This satellite-based radio system was developed by the U.S. Air Force to provide worldwide coverage, high-accuracy three-dimensional position, velocity and time, and permitting completely passive (receive-only) operation by all types of military users. The system has now found wide acceptance by both military and civil users, e.g., military aircraft, ships, land vehicles, and foot soldiers, and a large variety of civil users, such as commercial and general aviation aircraft, commercial ships and pleasure boats, automobiles and trucks, and operators of surveying systems. Two services are available: the precise positioning service (PPS) for authorized (military) users provides horizontal position accuracy of 21 m 2 DRMS, a two-sigma vertical accuracy of 29 m and a one-sigma time accuracy of 100 ns; the standard positioning service (SPS) for all other users provides a two-DRMS, 95 percent probability, horizontal position accuracy of 100 m, a two-sigma vertical accuracy of 140 m, and a one-sigma time accuracy of 170 ns. The orbital configuration of the satellites is designed to provide a GDOP of normally near 2.3, and is intended to always be lower than 6. The GPS consists of 24 satellites, including three operational spares. The satellites are in 12-h orbits with four satellites in six orbit planes inclined at 55°, all at an orbital altitude of 10,900 n.mi. The satellites transmit highly synchronized, pseudonoise coded, wide bandwidth signals, which include data on their ephemerides and clock errors. A ground-based master control station (MCS) and five monitor stations track the satellites and periodically determine satellite ephemerides and clock errors and uplink these to the satellites via three uplink stations. The overall system configuration of GPS is shown in Fig. 23.3.7. The system operates on two frequencies, i.e., 1575.42 MHz (L1) and 1227.5 MHz (L2), to permit compensation for ionospheric propagation delays. The satellites transmit two codes, the 1.023 Mbps C/A code and the 10.23 Mbps P code. The latter code is encrypted into a Y code for military users. Each satellite has a unique code. System data (e.g., satellite ephemeris) is modulo-2 added to both codes at 50 bps.

GPS is a pseudorange system (see Fig. 23.3.3). The user receiver determines at least four *pseudoranges* by TOA measurements with respect to its own clock time, and can also determine four pseudorange rates or *delta pseudoranges* via Doppler measurements with respect to its own clock frequency. From these measurements, the user receiver computes its own three-dimensional position coordinates and its clock time offset, as well as (in some receivers) its three-dimensional velocity coordinates and its clock frequency offset. The basic functional block diagram of a generic GPS receiver is shown in Fig. 23.3.8. GPS receiver processing includes both code and carrier tracking functions, which aid each other in two ways. The carrier (Doppler) tracking function sends Doppler velocity estimates to the code tracking information so that the resulting tracking loop bandwidth can be made very narrow. The code tracking function sends the *prompt* (on-time versus the early or late) estimate of the tracked code to the carrier tracking function, so that the code can be properly removed to allow tracking of the Doppler frequency.

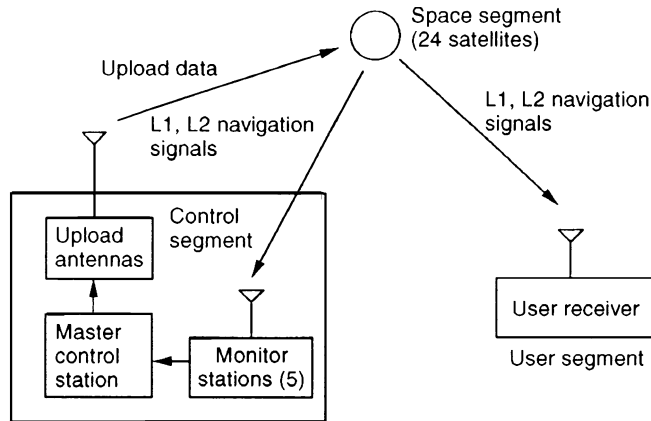

FIGURE 23.3.7 GPS system configuration.

Since the civil aviation community requires a very high integrity, i.e., warning of a failure, a number of system augmentations have been under development for this purpose. One is the receiver autonomous integrity monitoring (RAIM) function within the user receiver, which automatically detects and isolates a satellite failure. The other is the ground integrity broadcast (GIB) which consists of a network of ground-based monitoring stations, which monitor all satellite signals, and transmit certain error data to a central computer which computes integrity data and sends these to a satellite earth station. The latter then transmits appropriate integrity information via geostationary satellites to all GPS user receivers which are equipped to receive these signals. In the United States, this system has been named *Wide Area Augmentation System (WAAS)* and includes additional functions.

Some applications, for example aircraft landing and airport surveillance, require higher accuracies than those available from the basic GPS service. For these, the differential GPS (DGPS) concept has been implemented (Fig. 23.3.9). This concept employs a GPS reference station, whose position is precisely known. The reference station compares the predicted pseudoranges (from its known position) to the actually measured pseudoranges, computes the differences (corrections) for all satellites in its view and broadcasts these over a separate data link to the vehicles in the general vicinity, say at a 100 n.mi (160 km) radius. The user receiver then applies these corrections to its own pseudorange measurements for computation of its position. By means of this process, ionospheric and tropospheric propagation and satellite position errors common to the

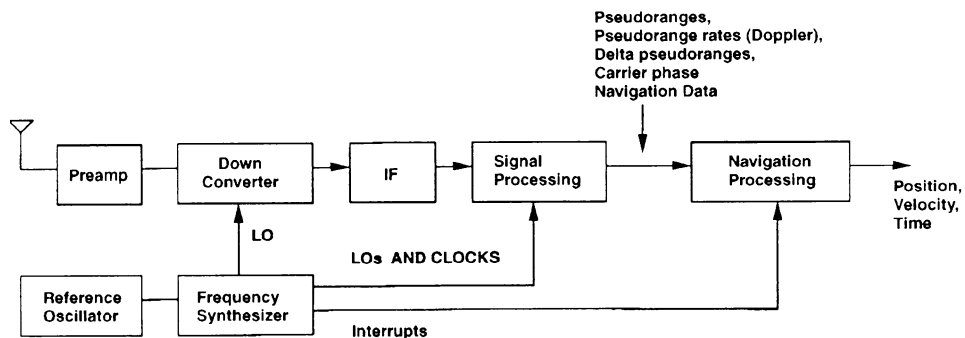

FIGURE 23.3.8 Generic GPS receiver block diagram.

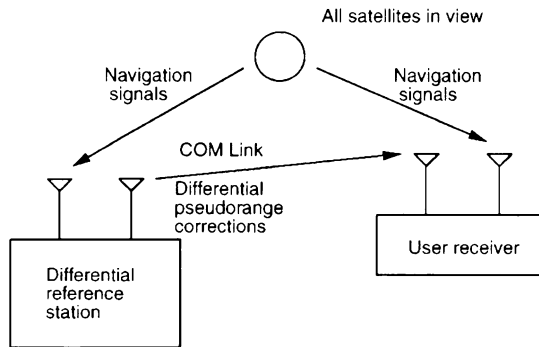

FIGURE 23.3.9 Differential GPS concept.

user and the reference station can be eliminated. With the DGPS technique, user position accuracies of 2 to 5 m can be obtained. A further refinement of this technique is the use of pseudosatellites (*pseudolites*) located on the ground and transmitting GPS-like signals to the user. This technique tends to reduce the GDOP of the system, notably in the vertical dimension. For certain very high accuracy performance applications, such as surveying and category II/III landing, the carrier phase of the GPS signal, rather than only the code phase (pseudorange), is measured to determine user position. In order to do this successfully, the carrier cycle ambiguity (of 19 cm) must be resolved. Using GPS carrier phase measurements on a postprocessing basis, centimeter accuracies have been obtained for surveying applications. In the late 1990s GPS is likely to be in widespread use throughout the world by a very large variety of users. A U.S. Department of Commerce report predicts 1 million commercial users by the year 2000.

Global Navigation Orbiting Satellite System (GLONASS) (Ref. 1, Chapter 5)

The GLONASS is a worldwide satellite radio navigation system being developed by the Russian government, whose concept is very similar to that of the U.S. GPS. It uses 24 satellites in 25,500-km orbits, with eight satellites in three orbital planes, at an inclination of 64.8° and an 8-day ground track repeat. This inclination is somewhat higher than that of GPS, thus providing somewhat better polar coverage. Each GLONASS satellite operates on two codes, one wide band and the other narrow band, and in two frequency bands. Unlike GPS, all satellites use the same two codes, but each satellite operates on slightly different frequencies. The higher frequency band currently goes from 1602 to 1615.5 MHz. The lower frequency band goes from 1246.4 to 1256.5 MHz. The higher GLONASS frequency assignments are likely to be changed in the future, in order to avoid interference with certain communication satellite frequencies. Also, it is currently planned in the future to use the same frequency on satellites in antipodal positions (i.e., halfway around the globe) in order to conserve the frequency spectrum. The two GLONASS code clock frequencies are 0.5 and 5.0 MHz. The accuracy performance of the standard (nonmilitary) GLONASS service is a horizontal position accuracy of 100 m, a vertical accuracy of 150 m, a velocity accuracy of 15 cm/s, and a time accuracy of $1 \mu\text{s}$. Integrated receivers are under development, which can process both GPS and GLONASS signals, thereby providing the use of a total of 48 satellites, increasing system availability.

SUMMARY OF ELECTRONIC NAVIGATION SYSTEM CHARACTERISTICS

Table 23.3.1 presents a summary of the technical and performance characteristics of the major electronic navigation and position location systems currently in operational use worldwide. In the case of the accuracy values,

TABLE 23.3.1 Summary of Electronic Navigation System Characteristics

System	Type ^a	Frequency (MHz)	Accuracy (absolute)	Number of stations
Omega/VLF	H	0.010–0.014	3.7–7.4 km	8

CHAPTER 23.4

UNDERWATER SOUND SYSTEMS

James F. Bartram, Stanley L. Ehrlich, Donald A. Fredenburg,
Jack H. Heimann, Joseph A. Kuzneski, Paul Skitzki,
Joseph E. Blue, A. L. Van Buren, R. Y. Ting

PRINCIPLES, FUNCTIONS, AND APPLICATIONS

Sound energy travels in water as a result of particle motion initiated by the application of physical forces to the particles from a vibrating diaphragm, collapsing air bubbles, or other energy sources with sufficient mechanoacoustical coupling for the transfer of the energy. It can be controlled, directed, and transmitted for many useful purposes.¹⁻³

Water is an excellent medium in which to transmit compressional sound waves. Liquids have higher specific acoustic impedances by several orders of magnitude than gases. The high acoustic impedance of water ($1.5 \text{ MN}\cdot\text{s}/\text{m}^3$ for seawater) makes it possible to design transducers whose internal mechanical impedance approaches the radiation load impedance, with conversion efficiency on the order of 50 percent over a band of an octave or over 80 percent over a narrow band.

The transmission and reception of underwater sound can be controlled and directed to perform the functions of communications, navigation, detection, tracking, classification, and so forth, which in aerospace are accomplished with electromagnetic energy. The wavelengths of underwater sound systems and radar systems are of the same order of magnitude, since the frequencies employed differ by the ratio of the speed of sound to the speed of electromagnetic waves. The term *sonar*, derived from sound navigation and ranging, is used synonymously with *underwater sound* and *underwater acoustics*.

The applications of underwater sound for defense purposes, both pro- and antisubmarine, have advanced with development of the nuclear submarine and other platforms. In military applications, underwater sound is used for depth sounding; navigation; ship and submarine detection, ranging, and tracking (passively and actively); underwater communications; mine detection; and or guidance and control of torpedoes and other weapons. Most systems are monostatic, but bistatic systems are also employed.

Civilian applications of underwater sound are numerous and are containing to increase as attention is focused on the hydrosphere, the ocean bottom, and the subbottom. These applications include depth sounding, bottom topographic mapping, object location, underwater beacons (pingers), wave-height measurement, doppler navigation, fish finding, subbottom profiling, underwater imaging for inspection purposes, buried-pipeline location, underwater telemetry and control, diver communications, ship handling and docking aid, antistranding alert for ships, current flow measurement, and vessel velocity measurement.

PROPAGATION

Propagation of sound in water can be represented by the sound pressure, the sound particle velocity, and/or the sound intensity as a function of position, time, and frequency. Because the sound pressure can usually be measured more nearly directly, it is the preferred parameter for most experimental data.⁴ The

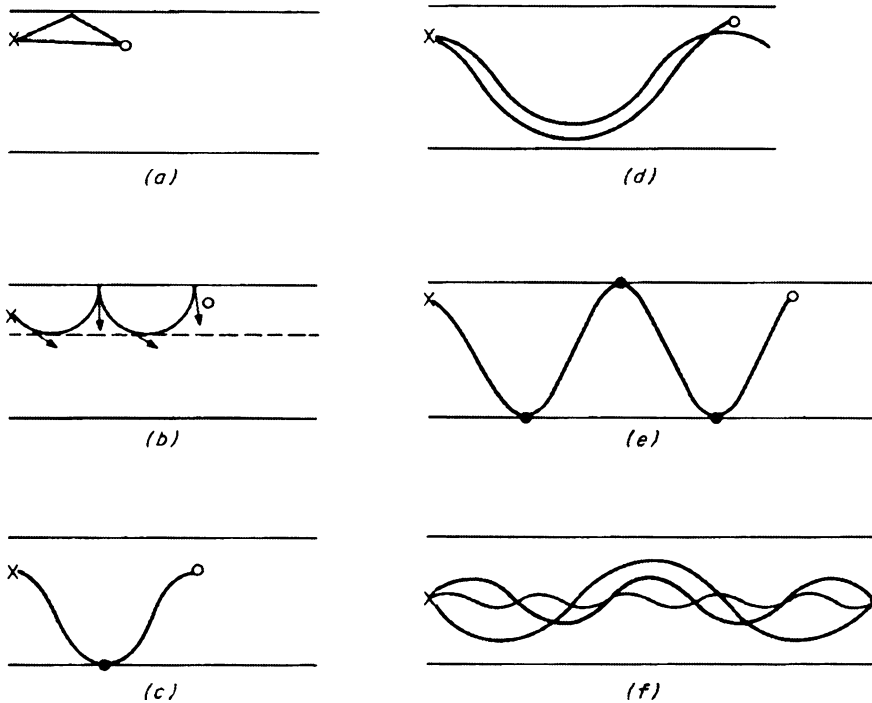

FIGURE 23.4.1 Propagation paths.

sound-pressure amplitude p in water is expressed in pascals.* The logarithmic unit of a sound-pressure level L_p is expressed in decibels with respect to the reference sound pressure amplitude, that is, $1 \mu\text{Pa} = p_o$, where $L_p = 20\log(p/p_o)$. The phase of the sound pressure is expressed in degrees or in radians with respect to a specified reference.

The difference between the sound-pressure level at the reference position and the sound-pressure level at a point in the sound field is called the *propagation loss* N_w for that point. For a small sound source, the reference position may be at a standard distance of 1 m in the direction of the maximum response. For a larger source, far-field data may be extrapolated back to the reference distance r_o .

The propagation loss may be considered^{1,3,5-7} to consist of two basic components, one due to the spreading of sound energy with increasing radial distance r from the sound source N_{spr} and the other to attenuation of sound as it propagates through the medium N_{att}

$$N_w = N_{\text{spr}} + N_{\text{att}}$$

The *spreading loss* is given by $10n \log(r/r_o)$, where n is dependent on the spreading law and is equal to 2 for the theoretical case of *spherical spreading*. The *attenuation loss* is given by $10^{-3} \alpha r$, where α , the *attenuation coefficient*, is as discussed next.

Common propagation paths are illustrated³ in the ray diagrams of Fig. 23.4.1. The paths of the direct ray and a ray with a single surface reflection in water with constant sound speed, are shown in Fig. 23.4.1a. In *b* a surface-layer sound channel confines the ray near the surface, with leakage rays due to diffraction and reflected waves from a rough surface. A ray that experiences a single bottom reflection is shown in *c*, while two bottom reflections with an intermediate surface reflection are shown in *e*. A pair of rays that diverge and return to

*1 pascal = $1 \text{ N/m}^2 = 10 \text{ dyn/cm}^2 = 10 \mu\text{bars}$.

a crossover in the convergence zone is shown in d . The three diverging rays, trapped in a deep sound channel and crossing each other several times before converging at the receiver, are shown in f . The reliable acoustic path, RAP (not shown), exists between a source at moderate depth and a surface receiver.

The theoretical treatment of sound propagation in water depends on assumptions used to simplify the mathematical formulation. Typical assumptions used by various authors include combinations of one or more of the following.^{1,3,8}

- One sound source with constant frequency and spherically isotropic radiation
- Propagation medium with linear transmission characteristics and sound speed dependent only on depth
- An ideal horizontal plane sea surface with zero acoustic impedance
- An ideal horizontal plane sea bottom with infinite acoustic impedance
- A sound receiver with zero rise time, flat frequency response, and spherically isotropic reception

Speed of Sound

Essentially, all seawater can be represented by the following conditions:

$$\begin{aligned} \text{Temperature } T &= -3 \text{ to } +30^\circ\text{C} \\ \text{Depth } d &= 0 \text{ to } 10,000 \text{ m} \\ \text{Salinity } S &= 33 \text{ to } 37 \text{ parts per thousand} \end{aligned}$$

with atmospheric pressure (absolute pressure) 0.1013 MPa at zero depth at sea level. For these conditions, the speed of sound c in seawater is given by an empirical formula due to Wilson,⁹⁻¹¹ here simplified to

$$c = 1449.3 + 4.572T - 0.0445T^2 + 0.0165d + 1.398(S - 35) \text{ m/s}$$

At zero depth the accuracy of c is about 3 m/s, or 0.2 percent; for extreme conditions with comparable accuracy a more complete equation, including higher-order and cross-product terms, becomes necessary. At $T = 0^\circ\text{C}$, $d = 0$ m, and $S = 35$ parts per thousand, $c = 1449.3$ m/s. The nominal value $c = 1500$ m/s, corresponding to about $T = 13^\circ\text{C}$, is convenient for engineering calculations.

Attenuation of Sound

The attenuation of sound in seawater has been studied by many investigators to determine its variation in different frequency bands as well as its dependence on temperature, salinity, and depth. At frequencies greater than 1 MHz, the attenuation mechanism is generally attributed to shear and dilatational viscous losses.¹ In the frequency band between 10 and 40 kHz, the increased attenuation is almost solely because of a relaxation-type mechanism in the MgSO_4 salts dissolved in the seawater.¹² Recent work indicates that between 0.1 and 1.0 kHz another relaxation-type mechanism, not yet identified, dominates the attenuation.¹³ Below 50 Hz other attenuation mechanisms are of greater importance.

An expression for the attenuation coefficient of seawater from 0.1 kHz to 100 MHz includes three components resulting from the three main attenuation mechanisms,^{1,3,13,14} multiplied by a depth-dependent term:¹⁵

$$\alpha = \left[\frac{0.11 f^2}{1 + f^2} + \frac{0.70 f_T f^2 (S/35)}{f_T^2 + f^2} + \frac{0.03 f^2}{f_T} \right] (1 - 65 \times 10^{-6} d) \text{ dB/km}$$

where f = frequency (kHz)

f_T = relaxation frequency¹⁴ (kHz) = $21.9 \times 10^{6-1.520(T+273)}$

T = temperature ($^\circ\text{C}$),

S = salinity (parts per thousand)

d = depth below air-water boundary surface (m)

At $T = 4^\circ\text{C}$ ($f_T \approx 71$ kHz), $d = 0$ m, and $S = 35$ parts per thousand, the equation simplifies to

$$\alpha = \frac{0.11f^2}{1+f^2} + \frac{50f^2}{5000+f^2} + 0.0004f^2 \quad \text{dB/km}$$

Further simplification is possible for the above listed conditions, at frequencies below about 20 kHz, to approximately

$$\alpha = \frac{0.11f^2}{1+f^2} + 0.010f^2 \quad \text{dB/km}$$

and above 200 kHz to approximately

$$\alpha = 50 + 0.004f^2 \quad \text{dB/km}$$

Measured values of attenuation in seawater include absorption losses, scattering losses due to random internal inhomogeneities, and interaction losses with the bottom boundary, the subbottom, and upper surface boundary.

Reflection and Refraction

Reflection and refraction of sound are normally in accordance with Snell's law, which states that $(\cos \theta_i)/c_i$ is a constant, where θ_i is the angle between the direction of propagation and the horizontal plane and c_i is the sound velocity at the point i of the ray. At a boundary where the sound velocity is discontinuous, the angle θ_i is the angle of incidence with respect to the plane tangent to the boundary, which is not necessarily horizontal.

A special case of interest occurs in a region with a constant *sound speed gradient* ∇c . This results in a circular sound ray path with radius equal to $c_i/(\nabla c \cos \theta_i)$. The center of the circle corresponds to a position where c_i becomes zero. In a surface layer, the resultant upward refraction leads to shadow zones which theoretically contain no propagated sound energy.

A second special case occurs at a boundary where the incident sound speed is lower than the refracted sound speed c_r , such as a plane interface between water and air. The well-known phenomenon of total internal reflection results when θ_i is less than a critical angle θ_{crit} , at which $c_i/(\cos \theta_{\text{crit}})$ is equal to c_r .

Another important case occurs when the sound in water is propagated by a direct path and also by a single reflection from a boundary of slower sound speed, such as air. Because of a 180° phase shift in the sound pressure at such a reflecting boundary, the resultant sound pressure exhibits maxima and minima as a function of the position of the receiver. This is called the *Lloyd mirror*, an image interference effect, since the condition can be represented by an additional sound source of equal amplitude and opposite phase as a virtual image that provides the constructive and destructive interference with the real sound source.

Other important cases include a multiple-layered medium where the sound field at each discontinuity must be accounted for; irregular and nonstationary boundaries that tend to randomize the reflection and refraction properties; moving boundaries that tend to modify the frequency of the sound energy because of the doppler effect; and intentional discontinuities introduced in transducer and array designs.

Reverberation

Reverberation of sound in water produces energy usually unwanted at the receiver. It is caused by scattering, i.e., reflection and refraction of sound from discontinuities other than those of primary interest. When the sound source and sound receiver are at the same location, reverberation is produced primarily by backscattering. When the scatterers are boundaries of the medium, the effect is called *surface reverberation*, which may be subdivided into *sea-surface* and *sea-bottom reverberation*. When the scatterers are contained within the medium, the effect is called *volume reverberation*, which may be due to fine particles, fish, or other inhomogeneities, including the structure of the sea.

NOISE

Background Noise

Underwater sound systems operate in a medium that has a very low acoustic-noise level under quiet conditions. Stimulation from natural and human causes, however, can generate and propagate acoustic noise at various levels and frequencies. The acoustic-noise background consists of an *ambient-acoustic-noise level* and a *self-noise level* caused by the sonar-platform presence and its movement.¹⁶ Passive sonar systems detect target-generated noise, while active sonar systems detect target echoes in the presence of the noise background.

Ambient Noise

The main contributions to ambient noise are shown in Fig. 23.4.2. Tides, waves, and seismic disturbances predominate at the very low frequencies, in the region of 1 Hz. At frequencies used for sonar systems, the main sources are sea surface agitation due to meteorological effects, noise from marine life, and human noises from shipping and other activities.³ Of these, surface agitation due to wind and wave actions is most significant. The acoustic spectrum levels for various sea states are shown in Fig. 23.4.3.

At the high frequencies (above 100 kHz), thermal molecular motion of the water is the principal noise contributor but does not limit sonar performance at lower frequencies. It has a spectrum level that rises with frequency at a rate of 6 dB/octave. The mean-square sound pressure in a 1-Hz band is

$$p_T^2 = 4\pi k T \rho c / \lambda^2$$

- where k = Boltzmann's constant
- T = temperature of water (K)
- ρc = specific acoustic impedance
- λ = wavelength

FIGURE 23.4.2 Principal ambient-noise sources.

FIGURE 23.4.3 Average deep water noise.

Acoustic thermal noise is consistent with its more familiar electrical counterpart. It is far below sea state levels at frequencies below 10 kHz. At higher frequencies than 100 kHz, it sets a threshold on the minimum detectable pressure levels in the medium. The ambient-noise level, as a sonar parameter, is the intensity of the noise background as measured with a nondirectional hydrophone, referred to the intensity of a plane wave having an rms pressure of 1 μPa .

Platform Noise

Platform noise is a degrading factor in the performance of underwater sound systems, particularly in the case of mobile platforms such as ships, submarines, aircraft, torpedoes, and other sonar-carrying vehicles. Fixed-position platforms, including sonobuoys, moored structures, bottom-mounted structures, mines, and so forth, are also plagued with platform-noise problems, primarily induced by hydrodynamic flow or motion. Good sonar performance with mobile platforms at any speed above approximately 10 knots is achievable only by most careful attention to platform-noise reduction and by design of the sonar system for minimum susceptibility to local noise.

Platform noise may enter the sonar system via radiation in the medium or by conduction through the platform structure. Generally, conducted noise can be reduced below the level arriving at the array via the medium. The techniques involve sensor design for minimum response to acceleration forces, isolation of the sensor elements from the mounting structure, and isolation and location of the array away from hull-borne and structural vibrations. The noise radiated into the medium may reach the array directly or via reflected paths, as shown in Fig. 23.4.4. The ship's propellers and machinery are the dominant noise sources. Since the noise level is highest on stern bearings, baffles are generally employed behind the sonar array to minimize stern noise, even though this results in loss of sonar performance over a portion of the azimuth.

Radiated Noise

Platform-generated noise, radiated into the medium, produces an acoustic signature that can be detected by passive sonar systems. Machinery noise is defined as noise caused by propulsion and auxiliary machinery on

FIGURE 23.4.4 Paths of self-noise.

the vessel. The noise produced by the various machines, generators, pumps, actuators, and so forth, travels by diverse paths to the hull structure, where it is introduced into the medium. Propeller noise originates outside the hull and is mainly due to cavitation at the propeller blades. Cavitation-produced bubbles generate acoustic noise, the acoustic spectrum of which differs from machinery noise and varies with speed and depth. In addition to the cavitation noise, propellers produce amplitude-modulated noise modulated at a frequency equal to the shaft rotation speed times the number of blades. Such *propeller beats* are most pronounced just beyond the onset of cavitation and are swamped by cavitation noise at higher speeds. Propellers may also produce a “singing” noise due to vibrational resonance of the blades.¹⁶

Hydrodynamic noise results from the flow of fluid past the moving platform. It increases with hydrodynamic structural irregularities of the platform and the fluid flow rate. Breaking bow and stern waves can excite the hull or structural members. Hydrodynamic noise is a minor contributor to the platform-radiated noise, and is usually swamped by machinery and propeller noise. However, it is an important element in consideration of self-noise for underwater sound systems associated with the platform.

Radiated Noise Levels

Radiated noise consists of broadband noise and tonal noise (line components). Measurements of radiated noise are made at some distance, say 200 yd, from the vessel and reduced to source spectrum level values by correction for the test distances and the measurement bandwidths. Tonals are determined by fine-grain spectral analysis. Figure 23.4.5 illustrates broadband and tonal noise from a submarine at two speeds. In *a* the broadband noise from cavitation at the propeller begins to appear, and the tonals from machinery noise are predominant. In Fig. 23.4.5*b* the broadband noise has increased as a result of higher speed, and many tonals are masked by the broadband noise while tonals are changed in amplitude or frequency.³ Figure 23.4.6 shows average radiated-noise spectra for several classes of ships, and Fig. 23.4.7 illustrates noise from running torpedoes.

FIGURE 23.4.6 Average radiated spectrum levels of ships.

TRANSDUCERS AND ARRAYS

Introduction

Transducers for underwater sound applications perform the functions of generating a sound wave in the medium or detecting the existence of a sound wave and its properties (e.g., amplitude and phase) in the medium. In the generating case, the transducer is commonly referred to as a *source*, or *projector*, and in the detecting case, as a *hydrophone*. Often the transducer is required to perform both functions. Single transducers or arrays of transducers may be designed to control the directional properties (i.e., directivity or beam pattern) of the generated acoustic energy, and to discriminate against the noise in the receiving case.

The function of a projecting transducer is to convert the input energy (usually electric) to acoustic energy in a manner that is efficient and compatible with the other components of the transmitting system, e.g., amplifiers. In the hydrophone, linear conversion of the acoustic signal to an electric signal is the basic function, and compatibility must be maintained with the other components of the receiving subsystem.

The conversion of energy is accomplished by any of a variety of physical phenomena, e.g., piezoelectricity and electrostriction, piezomagnetism and magnetostriction, electrodynamics and magnetodynamics, and chemical transformations and hydrodynamics.

The selection of the transduction mechanism and the design of the transducer are based on the following considerations: operating frequency; bandwidth; power (acoustical and electric); directional properties; the characteristics of available energy-converting materials; the characteristics of, and the materials used for, packaging (such factors as stability and static pressure, temperature, and

FIGURE 23.4.7 Noise spectra of torpedoes.

FIGURE 23.4.8 Idealized transmitting current and voltage responses for a piezoelectric transducer: (a) current response; (b) voltage response.

time and resistance to corrosive effects of the medium); cavitation and other nonlinear effects of the medium; and the effect of static pressures encountered at great depths on the overall transducer design and its operating characteristics.

Significant developments have been achieved in the calibration and performance testing of transducers and arrays both in the laboratory and in the ocean environment, and standard techniques have been established.¹⁷

Types of Projectors

There are two main transducer types used as underwater sound sources: those operating with a continuous-wave or modulated (amplitude, frequency) input and those operating as impulse sources. The former are used for most military and many commercial applications;^{18–20} the latter are used mainly for oceanographic and geophysical applications.³

CW and Modulated Sources

Transducers designed for cw or modulated-input underwater applications use piezoelectric, electrostrictive, or magnetostrictive energy-conversion materials. Piezoelectric crystals, e.g., quartz, have a linear relationship between strain and electric field. However, their application is limited by low dielectric constant, low electro-mechanical coupling coefficient (the ratio of the converted energy to the total input energy in a transducer), narrow bandwidth, low power-handling capability, and limited availability of geometrical shapes. They can yield very high conversion efficiencies (quartz transducers having efficiencies in excess of 90 percent have been built).¹⁸

Ferroelectric crystals, in either single-crystal or polycrystalline ceramic form, are often electrostrictive and have higher-order nonlinear properties in their natural state. With the application of a polarizing electric field, the electromechanical processes in these materials can be linearized over a wide range of operating conditions. These materials have the advantage of high dielectric constant (which results in low impedance), high electromechanical coupling coefficients, broad bandwidth, and high power-handling capability when properly used, and are available in a wide variety of shapes (plates, cylinders, rings, spherical zone sections). Efficiencies in excess of 70 percent can be achieved. Operating frequencies from less than 1 Hz to more than 10 MHz can be achieved.

The most widely used materials in the ferroelectric class are modified lead zirconate titanate and modified barium titanate. Idealized transmitting current and voltage responses of a transducer that uses these materials are shown in Fig. 23.4.8a and b, where f_0 is the frequency of mechanical resonance of the transducer. Figure 23.4.9 shows a typical impedance characteristic.

FIGURE 23.4.9 Idealized impedance locus for a piezoelectric transducer.

Magnetostrictive transducers depend on the interchange of energy between magnetic and mechanical forms. In an unpolarized state, such transducers are nonlinear, frequency-doubling devices. However, in a polarized state (achieved by the use of permanent magnets, direct current, or operation at remanence) they are linear (i.e., piezomagnetic). Commonly used materials include various nickel alloys and ferrites.

Properly designed magnetostrictive transducers can achieve radiated acoustic powers up to several kilowatts with efficiencies in excess of 50 percent. Operating frequency is usually limited to frequencies below 100 kHz. Figure 23.4.10 shows a typical idealized transmitting current characteristic.

Electrodynamic sources have been used in underwater acoustics for low-frequency applications. One noteworthy application is the low-frequency *standard projector*.²¹

Impulse Sources

Impulse sound sources produce a short-time duration, high-amplitude transition of more or less regular waveform. For example, explosives (TNT or other high-burning-rate chemical) with provision for hydrostatic, electrical, or fused detonation produce in the ocean medium a pressure wave that is initially steep-fronted, displays approximately exponential decay, and is followed by a sequence of bubble pulses. The shock wave is usually

FIGURE 23.4.10 Idealized transmitting current response for a magnetostrictive transducer.

so intense that the resulting finite-amplitude effects are appreciable. Figure 23.4.11 shows a typical pressure-time characteristic.

FIGURE 23.4.11 Pressure-time characteristic for an explosive source.³

Empirical formulas yield $p_0 = 5.16 \times 10^7 (w^{1/3}/r)^{1.13}$, $t_0 = 92 \times 10^{-6} w^{1/3} (r/w^{1/3})^{0.22}$, and $T = 5.67 w^{1/3} / (3.28d + 33)^{5/6}$, where d is depth (m), r is range (m), and w is equivalent yield of TNT (kg).

Charges ranging in weight from 1 oz to 60 lb are in common use. A 4-lb charge of TNT will produce a peak pressure at 1 km of 26 kPa (that is 208 dB re 1 μ Pa). Other impulse type sources include implosive devices, spark-gap generators, and pneumatic- and mechanical-impact mechanisms.

Hydrophones

The receiver in a sonar system employs a hydrophone or hydrophone array coupled to an amplifier. Hydrophone elements generally use piezoelectric energy-conversion materials, although magnetostrictive and electrodynamic mechanisms are sometimes used. Typical hydrophone sensitivities are on the order of -180 to -200 dB re 1 V/ μ Pa. Proper impedance termination and suitable amplification are necessary to obtain useful electrical levels. Figure 23.4.12 shows a typical idealized open-circuit receiving response for a piezoelectric hydrophone.

PRODUCTION OF SOUND FIELDS

Acoustic Principles

The production of a sound field in the medium involves an electrical input that is converted by the transducing mechanism into the motion of a surface in contact with the medium. The motion initiated by the moving surface of the transducer is communicated to the adjacent water principles, and a sound wave is propagated from its surface.

FIGURE 23.4.12 Idealized open-circuit receiving response for a piezoelectric transducer.

The far-field sound pressure produced by the source can be described in terms of the radiated acoustic power P_a by

$$p^2(r, \phi, \theta) = \rho c P_a D_i R(\phi, \theta) / 4\pi r^2 \tag{86}$$

where $p^2(r, \phi, \theta)$ = mean-square acoustic pressure (Pa): r, ϕ, θ = spherical coordinates, r in meters: ρc = product of density and speed of sound of medium, i.e., specific acoustic impedance of medium ($N \cdot s/m^3$); $R(\phi, \theta)$ = normalized pattern function; and D_i = directivity factor of source.

The directivity factor is defined as

$$\frac{1}{D_i} = \frac{1}{4\pi r_0^2} \iint \frac{p^2(r, \phi, \theta)}{p_0^2} dS \tag{87}$$

where p_0 is the pressure at distance r_0 in direction of maximum response and dS is the element of surface area on sphere having radius r_0 .

An example of a normalized beam pattern is shown in Fig. 23.4.13. This figure shows plot of $10 \log p^2(\theta, \phi)$ versus θ for a particular value of $\phi = \phi_d$. Dividing Eq. (86) by the square of the input current to the transducer I^2 and rearranging gives

$$\frac{p^2(r, \phi, \theta)}{I^2} = \frac{\rho c D_i R(\phi, \theta) R_e P_a}{4\pi r^2 P_e} \tag{88}$$

where P_e is the real part of the electrical input power to transducer (W) and R_e is the electrical input resistance of transducer (Ω).

FIGURE 23.4.13 Typical beam pattern of an underwater sound transducer.

The current transmitting response ($20 \log S_0$) is given by

$$20 \log S_0 = 10 \log R_e + 10 \log D_i + 10 \log \eta_{ea} + 170.8 \text{ dB re } 1 \mu\text{Pa/A at } 1 \text{ m} \quad (89)$$

The term $10 \log D_i$ is referred to as the *directivity index* N_{Di} , or gain, of the transducer, $\eta_{ea} = P_o/P_e$, or electrical efficiency.

The free-field open-circuit receiving response M_0 in volts per micropascal is related to the current transmitting response for a reciprocal transducer by

$$20 \log M_0 = 20 \log S_0 - 20 \log f - 294 \text{ dB re } 1 \text{ V}/\mu\text{Pa} \quad (90)$$

where f is the frequency (Hz) and nominal conditions in the water are assumed.

In determining the reaction of the medium on the moving surface of the transducer, it is assumed that the vibrating surface of the source has a velocity u , and that the surface exerts a force F_r on the water, and the force exerted by the water on the moving surface of the source is $-F_r$. The radiation impedance Z_r is expressed as²²

$$Z_r = -F_r/u = R_r + jX_r \quad (91)$$

where R_r is the radiation resistance and X_r is the radiation reactance.

In a linear system consisting of a continuous source, the value of Z_r is frequency-dependent, but is a constant at constant frequency. If the radiation impedance is known, calculating the acoustic power P_a of the source is greatly simplified, since

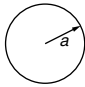

$$P_a = 1/2 u^2_{\text{peak}} R_r = u^2_{\text{rms}} R_r \quad (92)$$

Table 23.4.1 lists the radiation impedances for pistons and spheres, and Fig. 23.4.14 shows plots of radiation impedance for typical surfaces.

Nonlinear Acoustic Principles

The equations governing the propagation of sound in water are in fact nonlinear. The conventional linear relationships are really approximations, strictly valid only in the limit of infinitesimal sound amplitudes. Although the observable effects of this fundamental nonlinearity when relatively intense sound amplitudes are employed have normally been viewed as a source of performance degradation, e.g., distortion and loss, beneficial practical applications have been found.

TABLE 23.4.1 Radiation Impedance for Simple Geometries

Type of radiator		Radiation impedance

Sphere	Pulsating	$Z = \frac{4}{3} \pi a^2 \rho c \frac{(ka)^2 + jka}{1 + (ka)^2}$
	Oscillating	$Z = \frac{4}{3} \pi a^2 \rho c \frac{(ka)^4 + jka(1 + k^2 a^2)}{4 + (ka)^4}$

FIGURE 23.4.14 Radiation resistance and reactance per unit area divided by ρc as a function of a ka (a = radius) for (1) a circular piston in a rigid baffle; (2) a pulsating sphere.

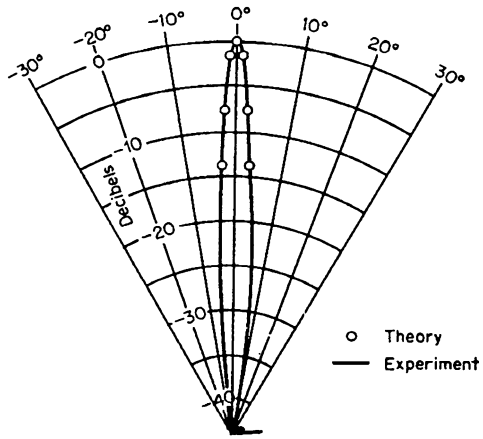

FIGURE 23.4.15 Difference-frequency beam pattern.

In particular, if two relatively intense sound waves of nearly equal frequency are caused to propagate through water in the same direction, the nonlinearity causes them to interact with each other to form waves having the sum and difference frequencies. The original primary waves are eventually absorbed in propagating through the water, and the sum-frequency wave, being at a higher frequency, is absorbed even sooner. The difference-frequency wave, being at a lower frequency, persists and has an independent existence.

The far-field sound pressure (all pressures expressed in pascals) of the difference-frequency wave P_d can be described in terms of the radiated sound pressures, p_1, p_2 of the two collimated primary waves by the following basic equation,²³ which is subject to various refinements discussed below:

$$p_d = \frac{(1 + 1/2 B/A) \omega_d^2 p_1 p_2 S}{8\pi r \rho c^4} \frac{1}{j\alpha + k_d \sin^2(\theta/2)} \tag{92a}$$

- where B/A = parameter of nonlinearity (5.25 in 20°C seawater²⁴)
- ω_d = frequency of difference-frequency wave (rad/s)
- S = cross-sectional area of collimated primary beams (m²)
- r = distance to measuring point (m)
- ρ = density of medium (kg/m³)
- c = speed of sound (m/s)
- α = attenuation coefficient (np/m)
- k_d = wave number of difference-frequency wave (m⁻¹)
- θ = angle to measuring point with respect to axis of beam

Figure 23.4.15 is an example of the difference-frequency wave beam pattern. It will be noticed that this beam has no side lobes and is quite narrow. θ_d , the value of θ for which the intensity is down 3 dB, is that which causes the real and imaginary parts of the denominator of Eq. (92a) to be equal. Because this value of θ is small, it is approximately

$$\theta_d = 2\sqrt{\alpha/k_s} \tag{92b}$$

The beamwidth, which is twice this angle, is narrower than that achievable when a wave of the same (difference) frequency is generated directly using a transducer of the same size. Also, this beamwidth does not vary significantly over a wide frequency range.

Reference 25 provides a nomogram for finding the far-field source level and beamwidth of the difference-frequency wave when the medium is seawater. As an example, assume primary waves with frequencies of 95 and 105 kHz. The mean primary frequency is 100 kHz, and the difference frequency is 10 kHz, resulting in a half beamwidth of 1.1°. A mean primary source level minus directivity index of 170 dB re 1 μPa results in a difference-frequency source level of 143 dB at 1 m re 1 μPa at 1 m.

It will be observed that there is an adverse conversion loss between primary and difference-frequency source levels, particularly if the primary directivity index is taken into account. This is the price paid for the benefits gained in terms of the narrow bandwidth.

Several practical factors serve to modify the above relationships:

1. Equation (29.92a) assumes collimated plane primary waves and essentially zero primary beamwidth. More realistic nonzero primary beamwidths require a modification. Reference 26 provides useful curves for taking the shape and dimensions of the transducer into account.
2. As the intensity of the primary waves increases, a point is reached where a shock wave is formed, at which point a different set of relationships govern the behavior. This phenomenon is still a subject of research; a good current reference is Ref. 27.

In addition to the transmitting-array application described above, it is also possible to create a highly directive receiving array by placing high-frequency high-intensity acoustic source, called a *pump*, at a relatively great distance from the receiver, in line with a relatively low-frequency plane wave arriving from a distant source. Again waves at the sum and difference frequencies are generated by the nonlinear interaction in the medium. One or both of these sidebands are separated from the pump frequency by filtering. This application and the governing relations are presented in Ref. 28.

TRANSDUCER MATERIALS

Piezoelectric Materials

Since 1950, synthetic piezoelectric ceramics as transducing materials have reached maturity by achieving reproducibility for a given composition and by diversification.²⁹

The electromechanical nature of these materials in a polarized state is described by linear equations. With stress and electric field as the independent variables,

$$S = s^E T + dE \quad D = dT + \epsilon^T E \tag{93a}$$

With stress and charge density (electric displacement) as the independent variables,

$$S = s^D T + gD \quad E = -gT + \beta^T D \tag{93b}$$

where S = strain

T = stress

E = electric field

D = electric displacement

s^E = elastic compliance at constant electric field

s^D = elastic compliance at constant electric displacement

ϵ^T = dielectric constant at constant stress

β^T = dielectric impermeability at constant stress

d and g are piezoelectric constants defined as

$$d = (\partial S / \partial E)_T = (\partial D / \partial T)_E \quad g = (-\partial E / \partial T)_D = (\partial S / \partial D)_T \tag{94}$$

The electromechanical coupling coefficient is an important measure of the effectiveness of the energy conversion mechanism and is defined as

$$k = U_m / U_e U_d = d / \epsilon^T s^E \quad (95)$$

where U_m = mutual elastic and dielectric energy density

U_e = elastic self-energy density

U_d = dielectric self-energy density. This is a quasi-static parameter that can be related to the fundamental material constants for one-dimensional transducers. The definition is not necessarily applicable to all geometries.

A more complete treatment of the piezoelectric equations and the measurement of the various constants can be found in Refs. 29–35.

Although piezoelectric ceramics can be operated in various modes, two types are of major importance to underwater sound transducers. In the parallel, or *33-mode* type, the stress, strain, and electric field are in the same direction. In the transverse, or *31-mode* types, the stress and strain are the same direction but orthogonal to the electric field. Each of these mode types is characterized by its associated constants, for example, d_{31} or d_{33} , g_{31} or g_{33} , k_{31} or k_{33} , respectively. The dielectric constant of interest is in the direction of the electric field for both cases and is denoted ϵ_{33} . For the above constants, the direction of the electric vectors are denoted by the three directions, and the direction of the mechanical variable, if different, is the other subscript. An additional electromechanical coupling coefficient k_p is useful for some applications. It is related to k by

$$k_p = \sqrt{2 / (1 - \sigma^E)} k_{31} \quad (96)$$

where σ^E is Poisson's ratio at constant electric field.

The most important piezoelectric ceramic materials for underwater sound transducers are the modified lead zirconate titanate (PZT) compositions and to a lesser extent modified barium titanate and lead titanate compositions. Table 23.4.2 lists some more important properties of these materials. A more comprehensive table of properties is available in Ref. 29, Chapter 3. These materials are characterized as being "very hard" lead zirconate titanate, "hard" lead zirconate titanate, and "soft" lead zirconate titanate. Progress has been made in specifying and classifying the various ceramic compositions.³⁶ The properties of the piezoelectric ceramics vary as functions of time, static stress, stress cycling, and electric field strength.²⁹

When the transducer design calls for operation in a hydrostatic-mode as opposed to the conventional 33- or 31-mode, the commonly known PZT or barium titanate compositions are not useful because of their low hydrostatic piezoelectric coefficients such as g_h , which is $g_h = g_{33} + g_{32} + g_{31}$. Low g_h values are characteristic of bulk ceramics due to the fact that in these materials $g_{32} = g_{31}$, both have an opposite sign to g_{33} and are nearly half the magnitude of g_{33} . In order to improve the hydrostatic piezoelectric properties, multiphase composite materials with different connectivity patterns have been developed.³⁷ The basic concept is to reduce the g_{31} contribution by introducing inert polymeric phases and to maximize the g_{33} effect of the piezoelectric phase. Composite properties are optimized by varying the configurational patterns of the active ceramic component and the inactive polymeric components in the composite. This is achieved by manipulating the connectivity, which describes how one phase connects itself in one or several dimensions. The more popular piezocomposites include the 0-3 and the 1-3 types. The former consists of ceramic particles of lead titanate composition dispersed in a neoprene rubber matrix, whereas the 1-3 piezocomposite is formed by aligning ceramic rods in the poled direction and imbedded them in a polymeric matrix. Because these piezocomposites contain a polymer phase, they are lighter in weight than bulk ceramics, and can be made flexible and/or comfortable to curved surfaces. In general, they can also be processed to form large sheets for large area coverage, as is the case for piezoelectric polyvinylidene fluoride polymers (PVDF). PVDF also exhibits good g_h property, but is more difficult to pole, and its dielectric constant is very low. Mostly formed by using an extrusion process from polymer melts, PVDF also shows higher g_{31} in the extrusion direction than the transverse g_{32} . On the other hand, the inert polymer phase in a piezocomposite can potentially be designed to greatly decouple the g_{31} effect of the ceramic, resulting in a dramatic improvement in the hydrostatic-mode properties. Table 23.4.3 shows the hydrostatic-mode properties of these new piezoelectric materials in comparison with those of well-known ceramic compositions. Hydroacoustic behaviors of these piezocomposites have been investigated.³⁸ Transducers fabricated by using the composite materials showed a constant broadband sensitivity, which in many cases is also independent of temperature and pressure.

TABLE 23.4.2 Characteristics of Commonly Used Piezoelectric Ceramics, Low-Signal Properties at 75°C

Quantity	PZT-4*	PZT-5*	PZT-8*	95% wt BaTiO ₃ , 5% wt CaTiO ₃

[†] N_1 = frequency constant of a thin bar with electric field perpendicular to length, f_l .

[‡] N_3 = frequency constant of a thin plate with electric field parallel to thickness, f_t .

Magnetostrictive Materials

Magnetostrictive materials offer certain advantages for some underwater sound transducer applications. One example is that of a large low-frequency source that is submerged to a great depth and must operate unattended for long periods of time. Two forms of magnetostrictive materials are used, metal alloys and ceramic compositions.

TABLE 23.4.3 Piezoelectric Properties of Composite Materials in Hydrostatic Mode

Composite type	K^* (1 kHz)	d_h (pC/N)	g_h (mV·m/N)

*Dielectric constant (measured at 1 kHz).

The physical quantities regarding the magnetic and mechanical state of a polarized material are the magnetic field strength H , the magnetic flux density B , the mechanical stress T , and the mechanical strain S . For a sinusoidal variation, they are related by

$$S = s^HT + dH \quad B = dT + \mu^TH \quad (97a)$$

or

$$T = c^BS - hB \quad H = -hS + v^sB \quad (97b)$$

where s^H = elastic compliance at constant magnetic field strength

c^B = elastic stiffness at constant magnetic flux density

μ^T = permeability at constant stress

v^s = reluctivity at constant strain

d and h are the piezomagnetic constants, which are defined as

$$d = (\partial S / \partial H)_T = (\partial B / \partial T)_H \quad h = -(\partial T / \partial B)_S = -(\partial H / \partial S)_B \quad (98)$$

More detailed information regarding the magnetostrictive equations and constants can be found in Refs. 29, 39–41.

FIGURE 23.4.16 Eddy-current loss factor, magnitude and phase angle, of magnetic materials; $\theta_h < \mu(0)$.⁴¹

where t is the thickness of sheet of material.

Figure 23.4.16 shows a plot of the magnitude and phase angle of the complex correction factor X versus $mt/2$.

Some important properties of a number of magnetostrictive materials can be found in Ref. 29.

The electromechanical coupling factor k of magnetostrictive materials has the same physical meaning as for piezoelectric materials, with the same limitations.

Eddy currents can play an important role in the efficiency of magnetostrictive materials. For this reason, magnetostrictive assemblies are often constructed from thin laminations cemented together, usually in an annealed state. Eddy current losses can be taken into account by multiplying the permeability by a complex eddy current factor x . This factor depends on the geometry. With a modification of the analysis in Ref. 41, a skin-effect parameter m^2 can be defined as

$$m^2 = j\omega\mu(0)/\rho_e \quad (99)$$

where $\mu(0)$ = permeability with no eddy current effect

ω = angular frequency

ρ_e = resistivity

The apparent permeability is given by

$$\mu = \mu(0) \frac{\tanh(mt/2)}{mt/2} \quad (100)$$

TRANSDUCER ARRAYS

Beam Formation

Transducers and hydrophones can be arranged individually or in arrays to possess omnidirectional or directional characteristics, depending on effective aperture dimensions, geometrical shape, and vibrational modes used. At high frequencies, since the wavelengths are short, highly directional individual units can be designed. At lower frequencies, multiple transducers or hydrophones are used in arrays of planar, cylindrical, spherical, or volumeric configuration.

Directionality is highly desirable in underwater sound detection systems because it makes both directional transmission and the determination of the direction of arrival of a signal possible. As in directional radar or communications antennas, this reduces the noise relative to the signal from other directions. Arrays can be steered mechanically by physical rotation or electrically by phasing or time delay networks. The direction of maximum sensitivity of a plane array of elements can be rotated into a direction lying at angle θ_0 to a reference direction by delaying differentially the output of each element. In this way, an irregular array can be effectively converted into a line array.

In their simplest form, arrays are arranged with elements along a line or distributed along a plane. The acoustic axis of such line or plane arrays, when unsteered, lies at right angles to the line or plane. The beam pattern of a line array may be visualized as a doughnut-shaped figure having supernumerary attached doughnuts formed by the side lobes of the pattern.

Lines of Equally Spaced Elements³

The beam pattern of a line of equally spaced, equally phased (i.e., unsteered) elements is derived as follows. Let a plane sinusoidal sound wave of unit pressure be incident at an angle θ to a line of n such elements, each spaced from the next a distance d . The output of the m th element relative to that of the zeroth element is delayed by the time necessary for sound to travel the distance $l_m = md \sin\theta$. The corresponding phase delay for sound of wavelength λ , at frequency $\omega = 2\pi f$, is $u_m = mu$ where the phase delay between adjacent elements, in radians, is $u = (2\pi d/\lambda) \sin\theta$. The output voltage of the m th element of voltage response R_m is $V_m = R_m \cos(\omega t + mu)$ and the array voltage is the sum of such terms:

$$V = R_0 \cos \omega t + R_1 \cos(\omega t + u) + \dots + R_m \cos(\omega t + mu) + \dots + R_{n-1} \cos[\omega t + (n-1)u]$$

In the complex notation, the array voltage will be

$$V = (R_0 + R_1 e^{iu} + R_2 e^{2iu} + \dots + R_n e^{(n-1)iu}) e^{i\omega t}$$

If the array elements all have unit response ($R = 1$),

$$V = (1 + e^{iu} + e^{2iu} + \dots + e^{(n-1)iu}) e^{i\omega t}$$

Multiplying by e^{iu} and subtracting gives

$$V = [(e^{inu} - 1)/(e^{iu} - 1)] e^{i\omega t}$$

Neglecting the time dependence, this becomes

$$V = [\sin(nu/2)]/[\sin(u/2)]$$

Finally, expressing u in terms of θ , the beam pattern, the square of the function-normalized to unity at $\theta = 0$ is

$$b(\theta) = \left(\frac{V}{n}\right)^2 = \left\{ \frac{\sin(n\pi d \sin\theta/\lambda)}{n \sin(\pi d \sin\theta/\lambda)} \right\}^2 \quad (101)$$

Continuous-Line and Plane Circular Arrays³

When the array elements are so close together that they may be regarded as adjacent, the array becomes a continuous-line transducer and the beam pattern is found by integration rather than by summation. For this case, let the line transducer be of length L and have a response per unit length of R/L . The contribution to the total voltage output produced by a small element of line length dx located at a distance x from the center is (neglecting the time dependence)

$$dv = (R/L) e^{i(2\pi/\lambda)x \sin\theta} dx$$

The beam pattern, the square of V normalized so that $b(\theta) = 1$, is

$$b(\theta) = \left(\frac{V}{R}\right)^2 = \left\{ \frac{\sin[(\pi L/\lambda) \sin\theta]}{(\pi L/\lambda) \sin\theta} \right\}^2 \quad (102)$$

In a similar manner, the beam pattern of a circular-plane array of diameter D of closely spaced elements can be shown to be

$$b(\theta) = \left\{ \frac{2J_1[(\pi D/\lambda) \sin\theta]}{(\pi D/\lambda) \sin\theta} \right\}^2 \quad (103)$$

FIGURE 23.4.17 Beam patterns of a line array of length L , and a circular-plane of diameter D .

where $J_1[\pi D/\lambda] \sin\theta]$ is the first-order Bessel function of argument $(\pi D/\lambda) \sin\theta$.

Generalized beam patterns for continuous-line and circular-plane arrays are drawn in Fig. 23.4.17 in terms of the quantities $(L/\lambda) \sin\theta$ and $(D/\lambda) \sin\theta$.

Figure 23.4.18 is a nomogram for finding the angular width between the axis and the -3 -dB and -10 -dB points of the beam pattern for continuous-line and circular-plane arrays. The dashed lines indicate how the nomogram is to be used. Thus a circular-plane array of 500 mm diameter at a wavelength of 100 mm (corresponding to a frequency of 15 kHz at a sound speed of 1500 m/s) has a beam pattern 6° wide between the axis of the pattern and the -3 -dB points.

PASSIVE SONAR SYSTEMS

Passive sonar systems, also referred to as *listening sonar systems*, are designed to respond to acoustic energy radiated by sources in the band of the sonar receiver. These systems are designed to accentuate the response to wanted signals while suppressing unwanted background noise. Passive systems are designed to maximize the signal-to-noise ratio to the degree that the characteristics of the signal and noise are known or can be predicted.⁴²⁻⁴⁴

Passive Sonar Equations

The fundamental relation of passive sonar can be written in terms of the signal-to-interfering-background ratio. Since in sonar the usual practice is to write equations in the decibel notation, the ratio is defined as the *signal differential* $\Delta L_{S/N}$, in decibels, between the equivalent plane-wave levels of signals and interfering noise at the passive sonar receiving array:

$$\Delta L_{S/N} = (L_{sf} - N_w + N'_{BW}) - [(L_{NF} - N_{DI} + N_{BW}) + N_\delta] \tag{104}$$

where L_{sf} = target-radiated-noise spectrum level versus frequency at 1 m from effective center of radiating source (dB re $1 \mu\text{Pa}/\text{Hz}^{1/2}$), N_w = one-way acoustic propagation loss between radiating source and passive sonar array (dB), $N'_{BW} = 10 \log$ (signal bandwidth) = signal-bandwidth-level correction, L_{NF} = equivalent-plane-wave interfering-noise spectrum level versus frequency at passive sonar array resulting from summation of noise from all sources (dB re $1 \mu\text{Pa}/\text{Hz}^{1/2}$), $N_{DI} = 10 \log D$, where D = effective directivity of the passive sonar array and beam former against isotropic noise (dB) (if the noise background has directional components, the effectiveness of the array in decreased background noise is modified), $N_{BW} = 10 \log$ (noise bandwidth) = (noise-bandwidth-level correction, and N_δ = receiving deviation loss (dB).

The value of the signal difference required at the array output varies with the application, e.g., detection, classification, or localization.

The signal differential can be considered to be the sum of two terms: the detection threshold N_{DT} , defined as that value of the signal differential required to just detect the signal, and the signal excess N_{SE} , which is the amount in decibels by which $\Delta L_{S/N}$ exceeds N_{DT} . A detection threshold N_{DT} adjustment in the system is usually set to a value consistent with a sufficiently low false-alarm rate on the display in use. Substituting this sum into Eq. (92) gives

$$N_{SE} = (L_{sf} - N_w + N'_{BW}) - [(L_{NF} - N_{DI} + N_{BW}) + N_\delta + N_{DT}] \tag{105}$$

Equation (105) is arranged to show that signal excess in decibels is the differential between a set of signal terms and a set of effective-noise terms, i.e.,

$$N_{SE} = L_I - L_{MD} \tag{106}$$

FIGURE 23.4.18 Nomogram for finding width of beam pattern.

where L_I is the incident signal level and L_{MD} is the minimum detectable signal level, given by

$$L_{MD} = L_{Nf} - N_{DI} + N_{BW} + N_{\delta} + N_{DT} \quad (107)$$

Another useful measure is the figure of merit N_{FM} , defined as the maximum allowable one-way propagation loss under the condition of zero signal excess. From Eq. (105),

$$N_{FM} = (L_{Sf} + N'_{BW}) - [(L_{Nf} - N_{DI} + N_{BW}) + N_{\delta} + N_{DT}] \quad (108)$$

and from Eq. (107), the figure of merit can also be written

$$N_{FM} = L_{Sf} + N'_{BW} - L_{MD} \quad (109)$$

Sonar Parameters

The radiated-noise level of a target is usually composed of broadband and narrowband noise from the propeller, machinery, and possibly echo-ranging pings from the target, as well as from other ships.^{3,16} Since this radiation can vary considerably in frequency and transmitted intensity as a function of time, the signal excess, and consequently the maximum detection range, can also vary over a wide range.

Acoustic propagation loss, also called *transmission loss*, varies according to an applicable spreading law modified by absorption, refraction, and reflection. In deep water, spherical spreading applies, and the propagation loss N_w in decibels is given by

$$N_w = 20 \log R + \alpha R + 60 \tag{110}$$

where R = range (km); α = absorption (dB/km), which varies with frequency f , and 60 represents the conversion from meters to kilometers. For shallow sources in deep oceans when a surface layer is present, spherical spreading applies for the first kilometer and cylindrical spreading thereafter, and the propagation loss then becomes

$$N_w = 10 \log R + \alpha R + 60 \tag{111}$$

The interfering background noise places a limit on detectability, but depending on the character of the noise, on the array interelement correlation, and on the signal processing used, the threshold of detection can be lowered considerably below the rms noise band level. Background noise is composed of self-noise, ambient noise, and, when present, reverberation. The noise components in these categories are listed in Table 23.4.4.

Self-noise is generated by all those sources associated with the listening vessel and its interaction with the surrounding water. *Ambient noise* is caused by both natural and man-made sources, while *reverberation* results from reflections of sonar pings by the ocean surface, bottom, volume, and scattering layers.

Self-noise has many directional characteristics (near-field effects); ambient noise generally has an omnidirectional distribution, with exceptions because of man-made and precipitation components; and reverberation is largely directional in nature.

The *effective directivity index* is an indicator of the degree to which the receiving array and beam former discriminates against background noise, assuming that this noise is isotropic in character and that the array geometry results in low correlation from element to element in the operating frequency band.

Examination of Eq. (108) shows that it is possible to distinguish three groups of parameters that determine figure of merit. First, associated with own ship, its sonar, background noise, and the operator are N_{DP} , N_{BW} , N_δ , N_{DT} , and these components of L_N associated with own ship and the surrounding sea. The second group of parameters is associated with the acoustic properties of the sea (or freshwater) medium and its boundaries, and it consists of N_w and the ambient components of L_N , including surface noise and reflections of noise from the sea surface. The third group of parameters, summarized in the terms L_S and N'_{BW} , is concerned with the radiating acoustic source or target, i.e., the description of the characteristics of the target in terms of radiated-noise spectrum level as a function of frequency, including both broadband and narrowband spectra, and the bandwidth of the radiated noise.

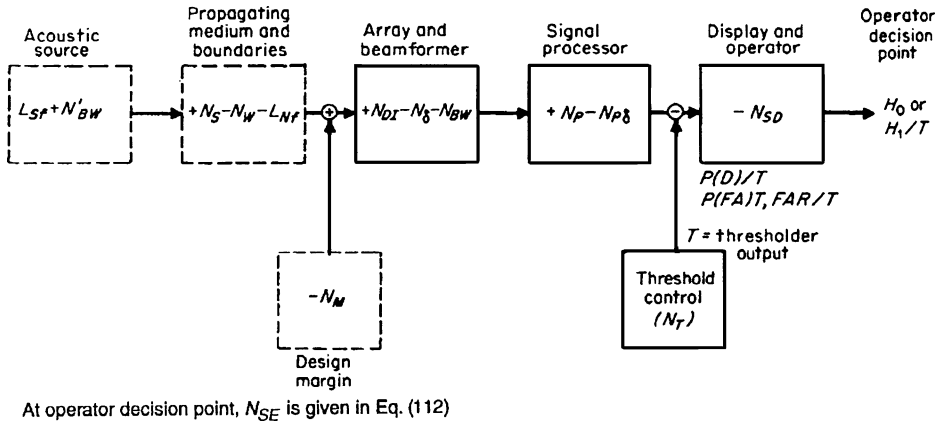

FIGURE 23.4.19 Passive sonar system detection model.

System Configuration and Parameters

A generalized passive sonar detection model, shown in Fig. 23.4.19, depicts all the parameters associated with a passive sonar system and its operator. To account for system hardware and operator gains and losses, terms must be added to Eqs. (104), (105), (107), and (108). While these equations are applicable at the output of the idealized beam former, the modified equations apply at the operator decision point indicated in Fig. 23.4.19. Specifically, at the decision point the signal excess is

$$N'_{SE} = (L_{Sf} + N_S - N_W + N'_{BW} + N_P) - [(L_{Nf} - N_{DI} + N_{BW}) + N_M + N_\delta + N_T + N_{SD}] \tag{112}$$

The added terms are N_S , to account for more than one ray path from the acoustic source to the sonar N_P , for signal processing gain; N_M , for hardware design margin (loss); N_δ , for signal processing loss, as in a clipping processor; N_T for the effect of the threshold level, and N_{SD} , to allow for the signal differential required for signal recognition on the particular display used.

The sonar detection system is placed between the hydrophone array and the decision point. It consists of a receiver, a visual and/or aural display, and an operator. The detection threshold N_{DT} is defined³ as the ratio in decibels of the signal power S in the receiver band to the noise power N_0 in a 1-Hz band, measured at the receiver terminals; i.e.

$$N_{DT} \equiv 10 \log (S/N_0) \tag{113}$$

The signal and signal-plus-noise values are taken in the receiver band, and N_{DT} is computed for use in the sonar equation. Noise backgrounds are expressed as power spectrum levels, i.e., as powers in 1-Hz bands.

Detection decisions are binary in nature; i.e., signal is present or signal is absent. But since a signal can actually be present or actually absent at the receiver input, there are four possible situations, summarized in Table 23.4.5. The correct decisions are shown on the diagonal of the matrix, namely, the detection and null decisions, with probabilities $P(D)$ and $1 - P(FA)$, respectively, where $P(D)$ is the probability of detection and $P(FA)$ is the probability of false alarm. False-alarm and miss decisions can occur with respective probabilities $P(FA)$ and $1 - P(D)$.

To implement the detection threshold criterion, it is necessary to apply a threshold voltage to a comparison circuit, at the receiver output. The threshold voltage is either fixed at a level corresponding to the desired N_{DT} or it can be controlled and calibrated in terms of N_{DT} . Whenever the level of the waveform at the comparison point exceeds the threshold voltage, the decision of signal present is made, unless a rule is adopted or circuit implemented, which, for example, counts the number of times the threshold is exceeded during a fixed time interval and bases the detection decision on this count.

The effects of setting the threshold voltage at various levels are shown in Fig. 23.4.20, at three target signals in a noise background, with two possible threshold voltages. High settings like T_1 allow only strong targets to

TABLE 23.4.5 Binary Decision Matrix

When at the input:	And the decision is	
	Signal present	Signal absent
Signal present	Correct decision: detection with probability $P(D)$	Incorrect decision: miss with probability $1 - P(D)$
Signal absent	Incorrect decision: false alarm with probability $P(FA)$	Correct decision: null with probability $1 - P(FA)$

FIGURE 23.4.20 Signal and noise at two threshold settings.

be detected and extremely few, if any, false alarms; consequently, both $P(D)$ and $P(FA)$ are low. Low settings like T_2 allow many more possible signals to be detected and also many false alarms to occur, consequently both $P(D)$ and $P(FA)$ are high. Both these threshold settings are unsatisfactory. A threshold setting should be found that produces a display with a uniformly distributed (gray) background in the presence of noise only and which prevents the buildup of the number of noise markings as a function of time and the decay rate of the display storage system in use; i.e., the false-alarm rate must be bounded.

Detection decisions depend upon the independent probabilities $P(D)$ and $P(FA)$, and consequently on the distributions of noise and signal-plus-noise at the receiver output. Figure 23.4.21 shows the probability density of noise alone and signal-plus-noise plotted as a function of amplitude³ a . The curves are assumed to have a gaussian distribution with variance σ^2 , the first with the mean noise amplitude $M(N)$ and the second with mean signal-plus-noise amplitude $M(S + N)$. Then the parameter detection index d is defined as

$$d \equiv (M_{S+N} - M_N)^2 / \sigma^2 \tag{114}$$

which is equivalent to the signal-to-noise ratio of the envelope of the receiver output effectively at the terminals where the threshold voltage T is established. The area (integral) under the probability density curve of signal-plus-noise to the right of T in Fig. 23.4.21 is the probability that an amplitude in excess of T is due to signal-plus-noise and is equal to the probability of detection $P(D)$. Similarly, the area under the probability curve of noise alone to the right of T is equal to the probability of false alarm $P(FA)$. Since $P(D)$ and $P(FA)$ vary as the threshold T is changed, their values depend on the parameter d .

The probabilities associated with various threshold voltage levels can be plotted, as shown in Fig. 23.4.22, with the detection index d as a parameter. Thus, for high- T settings, for example, the corresponding low $P(D)$, $P(FA)$ points are plotted in the lower left portion of the figure above the diagonal. These are known as receiver operating characteristic (ROC) curves.

If the curves of Fig. 23.4.21 are imagined to refer to the receiver input, the likelihood ratio for an input sample of amplitude a is

$$L = B/A \tag{115}$$

Thus, the ROC curves are related to the signal-to-noise ratio at the receiver input required for detection.

Following the detector, a postdetection averaging filter is used to smooth out fluctuations due to detector output noise. The optimum integration time T of this filter is the time equal to the signal duration t . In passive sonar systems t can be as long as it is operationally useful to integrate the incoming signal in the noise and/or reverberation background. Here, factors such as stabilization of own ship's receiving beams (for rotating or preformed beams), rotating receiving beam RPM (which determines the time on target during each rotation), receiving beamwidth, possible range of the target, and possible speed of the target must be considered.

FIGURE 23.4.21 Probability density distributions of noise.

ACTIVE SONAR SYSTEMS

Introduction

Active sonar systems, like radar, make use of *reflected energy reception*, referred to as *echo ranging*. Active sonar systems are used primarily to determine target range and bearing. In addition, active systems may be used for determining target depth, aspect angle, course, and speed. Target motion may be computed from successive echo returns or measurement of target-generated doppler on each ping.

FIGURE 23.4.22 Receiver operating characteristic (ROC) curves.

A wide variety of signal waveforms, pulsed or continuous, may be used in echo-ranging operations. Pulsed continuous waves of 1 ms to several seconds duration are commonly used, short pulses providing maximum range resolution and long pulses providing maximum energy return from the target, hence greater detection range. Pulsed FM waves with up or down sweeps and pseudo-random noise waves are used to obtain better target discrimination in a reverberant background. Combinations of the foregoing waveforms may be used to reduce mutual interference.⁴²⁻⁴⁴

Continuous transmission systems (cw or FM) are employed in short-range work, such as navigation sonars. Continuous transmission is not used in long-range detection systems because of the difficulty of acoustic isolation between the receiving and transmitting arrays.

Active Sonar Equation

The active sonar equation, corresponding to the model shown in Fig. 23.4.23, is used for performance prediction. The following equation is commonly used for applications with two-way propagation loss:

$$N_{SE} = L_S - (N_{\delta T} + N_{\delta R}) + N_{TS} - 2N_W - L_B - N_{DT} \tag{116}$$

where N_{SE} = signal excess (dB)

L_S = source level (dB re 1 μ Pa at 1 m) on transmit beam axis

$N_{\delta T}, N_{\delta R}$ = transmit and receive deviation losses due to target ray being off axis of transmit and receive beams, respectively (dB)

N_{TS} = target strength (dB)

N_W = one-way propagation loss (dB)

L_B = noise level in receiver band, including ambient noise, self-noise, and reverberations (dB ar 1 μ Pa)

N_{DT} = detection threshold in receiver band and at receiver input to produce desired display statistic (dB)

Equation (104) also applies to applications with one-way propagation losses, such as communications or telemetry, with only one propagation loss taken into account and background noise corresponding to the receive platform only.

The figure of merit (FOM) is another commonly used criterion for evaluating sonar performance. The FOM is equal to the allowable propagation loss when the signal excess is zero.

Source Level

The radiated acoustic powers of shipboard sonars³ range from a few hundred watts to tens of kilowatts, with transmitting directivity indexes between 10 and 30 dB. The equation for the value of the source level L_S is

$$L_S = 170.8 + 10 \log P_A + N_{DI} - N_D \tag{117}$$

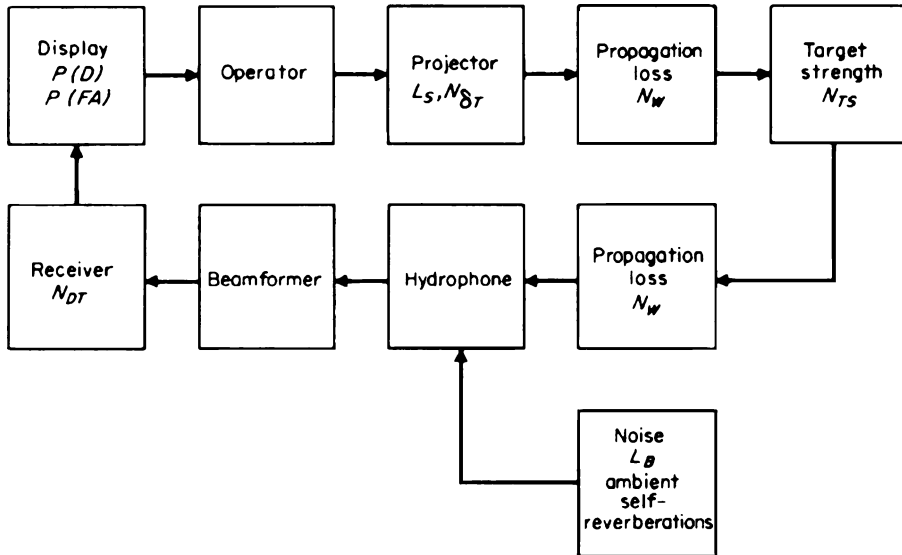

FIGURE 23.4.23 Echo-ranging block diagram.

FIGURE 23.4.24 Plot of Eq. (117)

FIGURE 23.4.25 Cavitation threshold vs. pulse duration.

where P_A = acoustic radiated power (W)
 N_{DI} = directivity index (dB)
 N_D = dome loss (dB) where applicable

A plot of L_S versus P_A is shown in Fig. 23.4.24 with N_{DI} as a parameter. The efficiency of converting electric to acoustic power varies with the transducer design, the match between transmitter source and transducer load impedance, and array-mutual-interaction effects.

There are two major acoustic limitations that limit achievable source level: cavitation and array mutual interaction. Cavitation limits occur³ when power applied to a transducer is such that bubbles begin to form on the face and just in front of transducer. These bubbles are a manifestation of cavitation and are caused by the rupture of water through negative pressure of the generated sound field. Cavitation causes a deterioration of transducer performance and life by erosion of the transducer surface; loss of radiated acoustic power in absorption and scattering by cavitation bubbles; deterioration in beam pattern; and reduction of the acoustic impedance into which the transducer must radiate. Cavitation threshold occurs at the point of departure from linearity of the input-output power curve and is a function of frequency, pulse length, and operating depth.

The effect of increased depth of operation is to increase the cavitation threshold

$$P_C(h) = P_C(0)(1 + 0.1h)^2 \tag{118}$$

where $P_C(h)$ is the cavitation threshold (W/m^2) at operating depth h m. The cavitation threshold increases with decreasing pulse lengths below 5 ms, as shown in Fig. 23.4.25.

Unequal loading effects occur in arrays of transducer elements because of mutual radiation impedances⁴⁵⁻⁴⁷ between independent sound sources. These effects cause hot spots in the array (i.e., one element receives many times the average power per element), so that it may be driven to destruction. Some elements can also absorb the acoustic output of others even when all elements are driven in like manner. Other effects are a gradual deterioration of beam pattern (or directivity index) and reduction of electrical power into the array, with corresponding loss of L_S . Mutual-interaction effects can be controlled by proper spacing between array elements, tuning the transducer element to reduce mutual-radiation impedance, increasing the self-radiation impedance and controlling individual transducer velocity and phase.

Sonar domes may have a significant transmission loss and may distort the beam pattern. Expressions for the transmission loss and specular reflections have been obtained theoretically and verified experimentally. Both increase with frequency and thickness, as well as density of the dome wall.

Target Strength

Target strength relates the echo intensity returning from a target to the incident intensity. The target strength, a concept equally useful for submarine, mine detection, and fish location, is defined as 10 times the logarithm to the base 10 of the ratio of the intensity of the sound returned by the target, at a distance of 1 m from its

acoustic center to the incident intensity from a distant source. The theoretical target strength of a number of geometric shapes and forms is shown in Table 23.4.6. Nominal values of measured target strength for typical underwater targets are tabulated in Table 23.4.7. Target strength is a function of aspect angle, frequency, and pulse length.

Propagation Loss

The *propagation loss* is a highly variable function, and only average values can be predicted. Average propagation-loss data have been published as a function of ocean model, propagation path, wind state, and season.³ In the absence of empirical data, several theoretical models may be used: spherical or cylindrical spreading loss as a function of range, sound absorption loss as a function of range and frequency, and sound wave or ray propagation.

The propagation from the target to the transducer is the same as that from the transducer to the target but may include several propagation paths. Propagation paths of interest for active sonar include in-layer direct path, across-layer direct path, bottom bounce, and convergence zone. Separate elevation angles may be required for the different propagation paths, depending on the ocean model.

Background Noise

Background noise in an active sonar system^{3,16} is the random addition of ambient and self-noise as well as reverberations. Ambient and self-noise are assumed to be stationary during the ping cycle, while reverberations vary with detection range. Ambient and self-noise are usually assumed to be isotropic in azimuth and elevation for performance predictions (i.e., in the active sonar equation), so that the ambient-noise band level L_B at the receiver input is

$$L_B = L_{Nf} + N_{BW} - N_{DI} \quad \text{dB} \quad (119)$$

where L_{Nf} = equivalent isotropic spectrum level of ambient or self-noise (dB re 1 μ Pa) in 1-Hz band
 N_{BW} = receiver input band level (dB re 1 Hz)
 N_{DI} = directivity index (dB)

Neither the ambient nor the self-noise is in fact isotropic, so that performance predictions based on equivalent isotropic noise levels predict average conditions. Ambient noise varies with elevation angle, as shown in Fig. 23.4.26, and varies in azimuth as well as with the maximum noise arriving from the direction of the wave swells. In addition to being anisotropic, ambient noise varies with the ocean configuration, wind, current, diurnal heating and cooling cycles, and widely varying velocity structures.

Self-noise is also highly directional, and, as expected, the highest self-noise on ships and submarines originates at the propeller. Self-noise can be separated into platform and equipment noise. Sonar systems are usually designed so that equipment noise is small compared with ambient or platform noise.

The receiving transducer may be the same as the transmitting transducer or can be completely independent. When the same transducer is used, a transmit/receive switch connects the transducer to either the transmitter or beam former as required. The receiver transducer (or set of transducers) accepts the echo plus noise and furnishes these to a beam former. Beam formers reject noise and have either an adaptive or fixed configuration. Adaptive beam formers are designed to reject variable directional noise sources such as self-noise and reverberations by monitoring the noise field and adjusting internal parameters to minimize the background noise. Fixed beam formers are designed to reject isotropic noise and take advantage of the directional property of the echo.

Reverberation³

Reverberation often limits performance on modern high-power sonars. The boundaries of the ocean at the surface and bottom and inhomogeneities in the ocean, such as schools of fish, layers of air bubbles near the surface, the deep scattering layer, as well as pinnacles and seamounts on the sea bed, all reradiate a portion of

TABLE 23.4.6 Target Strength of Simple Forms

Form	Target strength = $\frac{r}{10 \log t}$	Symbols	Direction of incidence	Conditions
Any convex surface	$\frac{a_1 a_2}{4}$	$a_1, a_2 =$ principal radii of curvature $r =$ range $k = 2\pi/\text{wavelength}$	Normal of surface	$ka_1, ka_2 \gg 1$ $r > a$
Sphere Large	$\frac{a^2}{4}$	$a =$ radius of sphere	Any	$ka \gg 1$ $r > a$
Small	$(61.7) \frac{V^2}{\lambda^4}$	$V =$ volume of sphere $\lambda =$ wavelength	Any	$ka \ll 1$ $kr \gg 1$
Cylinder Infinitely long Thick	$\frac{ar}{2}$	$a =$ radius of cylinder	Normal to axis of cylinder	$ka \gg 1$ $r > a$
Thin	$\frac{9\pi^4 a^4}{\lambda^2} r$	$a =$ radius of cylinder	Normal to axis of cylinder	$ka \ll 1$
Finite	$\frac{aL^2}{2\lambda}$	$L =$ length of cylinder $a =$ radius of cylinder $a =$ radius of cylinder $\beta = kL \sin \theta$	Normal to axis of cylinder Normal to axis of cylinder At angle θ with normal	$ka \gg 1$ $r > L^2/\lambda$
Plate Infinite (plane surface) Finite Any shape	$\frac{r^2}{4}$ $\left(\frac{A}{\lambda}\right)^2$	$A =$ area of plate $L =$ greatest linear dimension of plate $l =$ smallest linear dimension of plate	Normal to plane Normal to plate	$\frac{L^2}{\lambda}$ $r > \frac{L^2}{\lambda}$ $kl \gg 1$
Rectangular	$\left(\frac{ab}{\lambda}\right)^2 \left(\frac{\sin \beta}{\beta}\right)^2 \cos^2 \theta$	$a, b =$ side of rectangle $\beta = ka \sin \theta$	At angle θ to normal in plane containing side a	$\frac{a^2}{\lambda}$ $r > \frac{a^2}{\lambda}$ $kb \gg 1$ $a > b$
Circular	$\left(\frac{\pi a^2}{\lambda}\right)^2 \left(\frac{2J_1(\beta)}{\beta}\right)^2 \cos^2 \theta$	$a =$ radius of plate $\beta = 2ka \sin \theta$	At angle θ to normal	$r > \frac{a^2}{\lambda}$ $ka \gg 1$
Ellipsoid	$\left(\frac{bc}{2a}\right)^2$	$a, b, c =$ semimajor axes of ellipsoid	Parallel to axis of a	$ka, kb, kc \gg 1$ $r \gg a, b, c$

Conical tip	$\left(\frac{\lambda}{8\pi}\right)^2 \tan^4 \psi \left(1 - \frac{\sin^2 \theta}{\cos^2 \psi}\right)^{-3}$	$\psi =$ half angle of cone	At angle θ with axis of cone	$\theta < \psi$
Average overall aspects Circular disk	$\frac{a^2}{8}$	$a =$ radius of disk	Average overall directions	$ka \gg 1$ $r > \frac{(2a)^2}{\lambda}$
Any smooth convex object	$\frac{S}{16\pi}$	$S =$ total surface area of object	Average overall directions	All dimensions and radii of curvature large compared with λ
Triangular corner reflection	$\frac{L^4}{3\lambda^2} (1 - 0.00076\theta^2)$	$L =$ length of edge of reflector	At angle θ to axis of symmetry	Dimensions large compared with λ

acoustic energy incident on them. This reradiation of sound is called *scattering*, and the sum-total acoustic energy at the receiving transducer from all the scatterers is called *reverberation*. There are many different types of reverberation, and it is important to visualize the kinds of reverberation occurring during the ping cycle and what azimuth and elevation angle these will be coming from.

FIGURE 23.4.26 Vertical directivity of ambient sea noise.

Certain characteristics of reverberation can be used to good advantage by the sonar designer. Knowledge of the directions of reverberation may be used to reduce their effect on sonar operations. For instance, with a direct propagation path, a narrow vertical transmit-and-receive beam pattern will first decrease the incident acoustic energy on the bottom, and second, reject reverberation coming from the bottom outside the main lobe of the receive beam pattern.

A knowledge of the reverberation spectrum can also be used to minimize the effect. The sonar system then becomes self-noise or ambient noise limited with a significant drop in the background-noise level and corresponding improvement in system performance. Long cw pulses have reverberation spectrums that are small compared with the receiver input bandwidth and lend themselves readily to this scheme. Own-ship doppler nullification (ODN) circuits compensate for platform velocity-induced shifts in center frequency of the reverberation spectrums. The notch filter needed for rejection of the reverberation has to be wide enough for transmitted pulse spectrum convolved with the scatter motion. Homogeneous scatterer motion causes center-frequency shifts, and random scatterer motion causes frequency spreading. For echo-ranging applications, it is usually possible to reject the reverberations with a notch filter with a bandwidth corresponding to a ± 0.25 m/s random scatterer motion.

The doppler shift of the center frequency of the reverberation from that of the transmitted pulse spectrum can be used to measure ship speed with respect to the immediate surrounding water.

Detection Threshold

The detection threshold N_{DT} is the signal-to-noise ratio S/N required in the receiver input band at the receiver input to produce the desired display statistics.³ The term N_{DT} is usually applied to surveillance displays and refers to the desired single-ping probability of detection and false alarm. For other sonar modes of operation, such as fine-grained measurement of target range, doppler range rate, bearing, and elevation angle, the target has already been detected, and the required S/N at the receiver input is related to the desired standard deviation of the estimator.

The desired display statistics for a surveillance display are usually a 50 percent probability of detection and an acceptably low number of false alarms on the display. A typical surveillance display is a B scan with linear

presentation of range along the vertical axis and linear presentation of bearing along the horizontal axis. The number of independent range cells is usually taken as the echo-ranging time required for the display range gate, in seconds, times the receiver output bandwidth in hertz. The number of independent bearing cells is usually the number of beams required to give continuous bearing coverage for the desired azimuthal sector. The false-alarm probability of any one of the independent range-bearing cells is just the number of allowed false alarms on the display divided by the total number of such range-bearing cells.

Once the desired probability of detection $P(D)$ and probability of false alarm $P(FA)$ have been established, the required S/N at the display input can be derived through the use of receiver operating curve (ROC) as described earlier.

The N_{DT} at the receiver input can be established through the use of S/N transfer functions for a given signal processor.^{3,48-49} It should be noted that the desired $P(FA)$ of independent range-bearing cells is usually also a function of the signal processor because of different receiver output bandwidths for different signal processors.

A sonar receiver for surveillance has to work over a wide range of conditions, which, because of the nature of the targets, are generally unknown. A *robust receiver* (i.e., one that works well over all the expected variations of input parameters) or a combination of several receivers to cover such variations is usually desired. The “ideal” N_{DT} for any particular receiver degrades with target doppler, multipath arrivals, and nonstationary noise background.

The selection of the receiver for a particular application cannot be based on the lowest N_{DT} alone, but has to take many other receiver characteristics into account, such as cost, reliability, maintainability, logistics, power consumption, cooling requirement, operator training, weight, space, plus additional items peculiar to the application.

The optimum receiver for a signal known exactly, with white, stationary, gaussian noise, is a matched filter. The signal processing gain for this type of receiver is 10 times the logarithm to the base 10 of the time-bandwidth product of the signal, and the resulting N_{DT} is the lower limit. Cross-correlators and comb-filter receivers are matched-filter-type receivers.

Incoherent receivers are optimum for unknown signals, with white, stationary, gaussian noise. The signal processing gain for this type of receiver is five times the logarithm to the base 10 of the time-bandwidth product. Energy and envelope detectors, as well as autocorrelators and spatial correlators, are examples of this type of receiver.

Since the echo for an active sonar is neither known exactly nor completely unknown, semicoherent receivers are sometimes used, which have matched-filter features for those echo characteristics which are relatively well known and incoherent receiver characteristics for those echo characteristics which are likely to change significantly. The postdetection pulse-compression receiver is an example of this kind of receiver. The signal processing gain of this type of receiver is between that of the matched-filter type and the incoherent receiver.

Surveillance Receivers

A typical active surveillance display is shown in Fig. 23.4.27. This is a rectangular B-scan format with linear presentation of range along the vertical axis and linear presentation of bearing along the horizontal axis. The center bearing of the B-scan display can usually be selected to be true north or ship's bearing by the operator. It is driven by a thresholded output of a multichannel surveillance receiver. The signal excess over the threshold controls the display intensity in each bearing-range cell. The ability to threshold relies on noise-power normalization, so that changes in background-noise levels caused by variations in ambient noise and/or self-noise, as well as reverberation, do not cause an excessive number of false alarms.

A number of different surveillance receivers are available to drive the display: linear or clipped correlators, autocorrelator, spatial correlator, comb-filter receivers (with or without reverberation suppression), energy or envelope detectors, and pulse compression receivers. Performing prediction for the various types of receivers is covered in the literature on signal processing techniques. It is important to remember that these receivers should be compared on the basis of equal display statistics and nonstationary reverberations, self-noise, and ambient background noise, as well as “ideal” conditions.

Noise-power variations may be reduced by clipping, nonlinear amplification such as logarithmic amplifiers, or variable linear amplification such as time variable gain (TVG), automatic gain control (AGC), or step gain control (SGC) ahead of the receiver. Clipping is inexpensive but has the disadvantage of possible capture of the clipper by strong interfering noises. Logarithmic or other nonlinear amplifications can hold

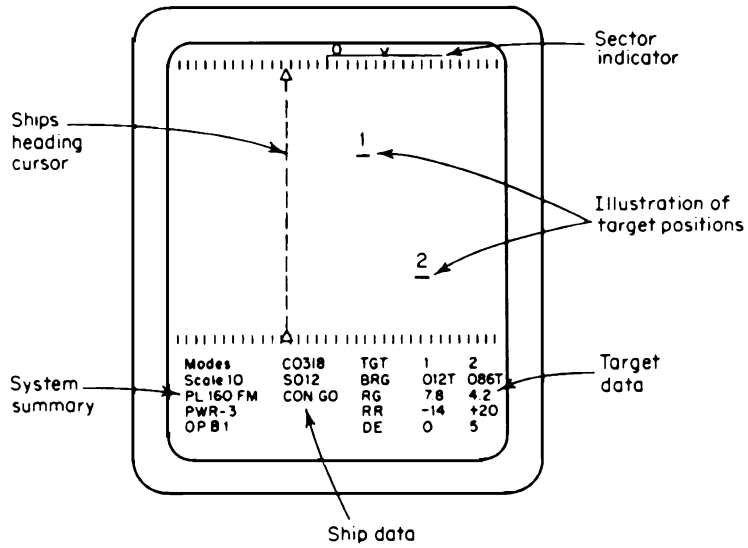

FIGURE 23.4.27 B-scan surveillance display.

FIGURE 23.4.28 Passive sonobuoy system.

the noise power constant but cause frequency distortion and spreading. TVG is generally used clearly in the ping cycle to prevent system saturation right after transmission and then to increase the gain versus time in a predetermined manner as a function of the transmitted source level and pulse length. AGC is closed-loop gain control where the noise power is estimated and the gain inversely controlled to maintain constant noise power. SGC is like AGC except that the gain is controlled in steps, so that inverse proportional gain control is not needed. Both AGC and SGC are sometimes referred to as reverberation gain control (RGC).

Another type of active surveillance display is the plan position indicator (PPI) display. The PPI format has the ship at the display center, with bearing linearly presented as display angle and the ship's heading presented vertically upward. Range is linearly presented as the radius from the display center.

Track and localization displays are usually presented in A-scan format, with a range gate linearly presented along the horizontal axis and either azimuth or elevation angle gate or doppler range rate linearly presented along the vertical axis. Localization and track displays and receivers are generally rated according to the resolution in range, bearing, elevation, and doppler range rate available to the operator as a function of S/N.

Sonobuoy Systems

Sonobuoy systems are miniature passive and/or active sonar systems designed for deployment from aircraft, making use of VHF or UHF radio channels for transmission of information from the buoy to the aircraft. In its simplest configuration, a passive sonobuoy consists of a cable-connected omnidirectional hydrophone, which is released from the buoy after water entry and which sinks to a predetermined operating depth, an amplifier to raise the level of the hydrophone output, a VHF or UHF transmitter, antenna system, and batteries for power. These items are often contained in a canister less than 4 ft long and 5 in. in diameter, fitted with a parachute or other device for control of descent after release from the aircraft. The buoy is designed to float so as to maintain its antenna system above the water surface. On the aircraft the sonobuoy signal is extracted from the radio channel and applied to a processor-recorder and operator's headphones. Multichannel receiving and processing equipment is used to monitor the outputs of several sonobuoys simultaneously (Fig. 23.4.28).

More complex sonobuoy systems result when directional arrays are used in lieu of the simple omnidirectional hydrophone, necessitating the transmission of array orientation and target-bearing information via the radio link. Greater complexity, posing a severe challenge to the sonobuoy designer, results from combination of passive and active systems and control of the sonobuoy functions from the aircraft via a command radio link. Because of the advances made in micro-miniaturization, integrated circuits, multiplexing, miniature acoustic arrays, digital signal processing, and high-density packaging, it is now possible to design sophisticated multifunction sonobuoy systems.

The design of such systems includes heavy emphasis on sonobuoy performance, cost, size, weight, life, and reliability factors—in view of the end use of the buoy as a expendable item. System partitioning, in which the functions to be performed in the buoy and in the aircraft equipment are defined, is an important element of the performance per cost consideration, particularly for the more sophisticated sonobuoy systems. Sonobuoy system design includes the application of passive and active sonar system design techniques described in this section of the handbook, plus aerodynamic and hydrodynamic technologies.

SECTION 24

AUTOMOTIVE ELECTRONICS

The importance of sensors and actuators in automotive electronics cannot be overemphasized. The ability to sense and measure automotive parameters accurately is key to any automotive electronics application, as is the ability to initiate control actions accurately in response to commands. Chapter 24.1 contains a wealth of information on sensors and actuators and their applications in cars.

Major automotive on-board systems are discussed in Chap. 24.2. These systems include engine, transmission, cruise, braking, traction, stability, suspension, and steering control systems. Also presented is information on object detection, collision warning, collision avoidance, and adaptive cruise control. Intelligent transportation systems are discussed in Chap. 24.3.

It should be noted that the information presented in this section is based principally on condensations of chapters in the book, *Automotive Electronics*, 2nd ed., Ronald K. Jurgen (ed.), McGraw-Hill, 1999. Credit to individuals who provided the original material for that book is given where appropriate in the following three chapters. R.J.

CHAPTER 24.1

AUTOMOTIVE SENSORS AND ACTUATORS

Ronald K. Jurgen

INTRODUCTION

Automotive sensors and actuators are key to all automotive electronic control systems. Sensors, which send electric signals proportional to the parameters they measure to a car's control systems, are grouped herein by the parameters they sense (pressure, force, position, flow, and the like). Actuators, which take action upon receiving signals from the car's control systems, are classified as either electromechanical or electrical.

PRESSURE SENSORS*

Various pressure measurements are required to optimize performance, determine safe operation, assure conformance to government regulations, and to advise the driver. Those measurements can also be used to provide data log information for diagnostic purposes.

Different units for indicating pressure are used, depending on the particular application, e.g., tire pressure in psi and manifold pressure in kPa. Table 24.1.1 lists the various pressure units together with their conversion constants. The type of pressure measurement that is made can be divided into five basic areas: gage, absolute, differential, liquid level, and pressure switch.

Figure 24.1.1 illustrates the basic differences in gage pressure, absolute pressure, and differential pressure measurements. For gage pressure measurements, the pressure is applied to the top of a silicon diaphragm creating a positive output. The back side of the diaphragm is exposed to atmospheric pressure. Absolute pressure measurement is made with respect to a fixed (usually a vacuum) reference sealed within the sensor. Differential or Delta-P measurements are made with the higher pressure applied to the top of the diaphragm and the lower pressure (possibly a reference) to the opposite side.

Technologies for Sensing Pressure

Among the technologies used for on-vehicle measurements of static and dynamic pressure are diaphragm-potentiometer, linear variable differential transformer (LVDT), aneroid, silicon or ceramic capacitive,

*Frank, R., Chapter 2, "Pressure Sensors," in *Automotive Electronics Handbook*, 2nd ed., Ronald K. Jurgen (ed.), McGraw-Hill, 1999, pp. 2.3–2.25.

piezoresistive strain gage, piezoelectric ceramic or film, and optical phase shift (combustion pressure). Common mechanical devices include the Bourdon tube, bellows, diaphragms, deadweight gage, and manometer.

Diaphragm-Potentiometer Pressure Sensors. These sensors are based on the principle that the distance that a rubber diaphragm travels when pressure is applied is a mechanical indication of pressure. The movement of the diaphragm also moves the sliding element or wiper of a potentiometer to provide an electric signal that can be applied to a remote gage such as an oil pressure gage.

Linear Variable Differential Transformer. In an LVDT pressure sensor, Fig. 24.1.2, the moving core is attached to a force collector that provides differential coupling from the primary to the secondaries resulting in a position output that is proportional to pressure. A pressure applied to a Bourdon tube or diaphragm causes the core to be displaced from its null position and the coupling between the primary and each of the

FIGURE 24.1.1 Types of pressure measurements: (a) gage, (b) absolute, and (c) differential.

FIGURE 24.1.2 LVDT pressure sensor.

secondaries is no longer equal. The resulting output varies linearly within the design range of the transducer and has a phase change of 180° from one side of the null position to the other.

Dual-sealed aneroid diaphragms are bonded and sealed with a vacuum inside each unit to a metallized conductive ring on opposite sides of a ceramic substrate. The substrate serves as the fixed plates of two separate capacitors. Manifold vacuum is applied to one chamber and the second chamber serves as a reference for compensating and signal conditioning that minimizes common mode errors due to vibration and shock.

Capacitive Pressure Sensors. These sensors have one plate connected to a force collector (usually a diaphragm) and the distance between the two plates of the capacitor varies as a result of the applied pressure. A silicon capacitive absolute pressure (SCAP) sensing element is shown in Fig. 24.1.3. The value of the capacitor changes linearly from approximately 32 to 39 pF with applied pressure from 17 to 105 kPa. The output of the sensor is typically signal-conditioned to provide a frequency variation with applied pressure for easy interface to microcontrollers.

Strain Gage Pressure Sensors. These sensors convert the change in resistance in four (sometimes in two) arms of a Wheatstone bridge. The change in the resistance of a material when it is mechanically stressed is called piezoresistivity. Different approaches to piezoresistive strain gages range from traditional bonded and unbonded to integrated silicon pressure sensors. A bonded sensor consists of a filament-wire or foil, metallic or semiconductor, and bulk material or deposited film bonded to the surface of a diaphragm. Pressure applied to the diaphragm produces a change in the dimension of the diaphragm and, consequently, in the length of the gage, and therefore a change in its resistance. When a pressure sensor is used for measuring an applied force it is called a local cell.

With integrated silicon pressure sensors, the sensor signal can be provided from a single piezoresistive element located at a 45° angle in the center of the edge of a square diaphragm that provides an extremely linear measurement. In addition to the basic sensing element, an interactively laser-trimmed four-stage network has also been integrated into a single monolithic structure (Fig. 24.1.4). A polysilicon thin-film sensor that consists of a thin film of silicon that is doped with boron and vapor-deposited over a stainless steel diaphragm is shown in Fig. 24.1.5.

Piezoelectric Pressure Sensors. Piezoelectric pressure sensors produce a change in electric charge when a force is applied across the face of a crystal or piezoelectric film. Transducers are constructed with rigid multiple plates

FIGURE 24.1.3 Silicon capacitive absolute pressure (SCAP) sensor.

and a cultured-quartz-sensing element that contains an integral accelerometer to minimize vibration sensitivity and suppress resonances. A typical unit also contains a built-in microelectronic amplifier to transform the high-impedance electrostatic charge output from the crystals into a low-impedance voltage signal (Fig. 24.1.6). Surface micromachining techniques have been combined with piezoelectric thin-film materials, such as zinc oxide, to produce a semiconductor piezoelectric pressure sensor.

Fiber Optic Combustion Pressure Sensor. For extremely high pressure (0 to 1000 psi normal, 3000 psi over-range) or pressure measurements at high temperatures (up to 550°C), a fiber optic combustion pressure sensor (Fig. 24.1.7) can be used. The amount of light that is returned to the sensor fiber after it is reflected from the diaphragm depends on the gap D between the fiber and the diaphragm. The diaphragm can be sized to allow the sensor to be integrated into a spark plug for easy access to the combustion pressure of each cylinder.

FIGURE 24.1.4 Cross section of piezoresistive silicon pressure sensor for measuring absolute pressure.

FIGURE 24.1.5 Polysilicon pressure sensor on stainless steel diaphragm.

Pressure Switch. In a pressure switch, sufficient motion of the force-collecting diaphragm allows a spring to be compressed and a set of contacts to be closed in a traditional mechanical switch.

Automotive Applications for Pressure Sensors

Table 24.1.2 lists a number of potential pressure measurements versus vehicle systems and provides an indication of the pressure range and type of measurement.

FIGURE 24.1.6 Piezoelectric pressure sensor.

TABLE 24.1.2 Pressure Sensing Requirements for Various Vehicle Systems

System	Parameter	Pressure range	Type
Engine control	Manifold absolute pressure	100 kPa	Absolute
	Turbo boost pressure	200 kPa	Absolute
	Barometric pressure (altitude)	100 kPa	Absolute
	EGR pressure	7.5 psi	Gage
	Fuel pressure	15 psi—450 kPa (13.5 MPa peak)	Gage
	Fuel vapor pressure	15 in H ₂ O	Gage
	Mass air flow	—	Differential
	Combustion pressure	100 Bar (16.7 MPa peak)	Differential
	Exhaust gas pressure	100 kPa	Gage
	Secondary air pressure	100 kPa	Gage
Elect transmission (continuously variable transmission)	Transmission oil pressure	80 psi	Gage
	Vacuum modulation	100 kPa	Absolute
Idle speed control	AC clutch sensor/switch	300–500 psi	Absolute*
	Power steering pressure	500 psi	Absolute*
Elect power steering (also elect assisted)	Hydraulic pressure	500 psi	Absolute*
Antiskid brakes/ traction control	Brake pressure	500 psi	Absolute*
	Fluid level	12 in H ₂ O	Gage
Air bags	Bag pressure	7.5 psi	Gage
Suspension	Pneumatic spring pressure	1 MPa	Absolute*
Security/keyless entry	Passenger compartment pressure	100 kPa	Absolute
HVAC (climate control)	Air flow (PC) Compressor pressure	300–500 psi	Absolute*
Driver information	Oil pressure	80 psi	Gage
	Fuel level	15 in H ₂ O	Gage
	Oil level	15 in H ₂ O	Gage
	Coolant pressure	200 kPa	Gage
	Coolant level	24 in H ₂ O	Gage
	Windshield washer level	12 in H ₂ O	Gage
	Transmission oil level	12 in H ₂ O	Gage
	Tire pressure	50 psi	Gage/absolute
	Battery fluid level	1-2 in below	Optical
	Memory seat	Lumbar pressure	7.5 psi
Multiplex/diagnostics	Multiple usage of sensors	—

TABLE 24.1.3 Potentiometer Specifications

Parameter	Minimum	Maximum
Electrical travel	90°, 10 mm	360°, 3000 mm
Nominal resistance	500 Ω	20 k Ω
Resistance tolerance	10%	20%
Resistance temperature coefficient (TC)		500 ppm/°C
TC of V_{out} in voltage divider mode		5 ppm/°C
Linearity error	0.01%	1%

LINEAR AND ANGLE POSITION SENSORS*

Position sensors are electromechanical devices that translate position information into electric signals and can be grouped into two basic categories: incremental and absolute. Incremental sensors measure position as the distance from an arbitrary index or zero and must rely on some method of pulse counting. One pulse in the sequence is designed to be wider or of opposite polarity than the others so that it may be used as a nominal zero. Absolute position sensors produce an unambiguous output at power-up. Each position or angle has a unique value. The output may be a voltage or frequency or other analog of the input position.

Position sensors may be directly coupled by some shaft or linkage or by some noncontact or proximity means. The most common forms of proximity sensors are based on various methods of magnetic field detection.

Position Sensor Technologies

Microswitches. The simplest form of contact sensor is a switch and may be as simple as a microswitch that operates anything from brake lights to courtesy lights in an automobile. Many applications of microswitches in position sensing are as limit switches, usually wired to limit or warn of the extent of travel of a mechanical component by disconnecting power to an electric motor or by operating an indicator lamp.

Optical Angle Encoders. These encoders for incremental shaft angular position measurement are constructed of a disk with a series of transparent- and opaque-spaced sectors. The disk is illuminated on one side and light sensors on the other side detect the passage of light and dark sectors as the disk is rotated. Linear incremental optical encoders allow direct measurement of linear motion.

Potentiometers. Potentiometers are widely used as position sensors in automotive applications such as throttle and accelerator pedal position measurement. Potentiometers have been developed that are capable of operational life far in excess of the life of the average car and in some cases capable of continuous rotational speeds of above 1000 rpm for more than 1000 h.

All potentiometers are ratiometric sensors. That is, the wiper voltage at a given position is some fraction of the reference voltage applied across the resistive track. If the reference voltage is varied, the potentiometer output remains in the same ratio to the reference voltage. Typical potentiometer specifications are shown in Table 24.1.3.

Magnetic. The largest category of position sensors relies on electromagnetic induction principles. Variable reluctance devices operate by sensing changes in the reluctance within a magnetic circuit and are used to detect the position and speed of rotating toothed or slotted wheels in crank-, cam-, and wheel-monitoring applications.

*Nickson, P., Chapter 3, "Linear and Angle Position Sensors," in *Automotive Electronics Handbook*, 2nd ed., Ronald K. Jurgen (ed.), McGraw-Hill, 1999, pp. 3.1–3.21.

FIGURE 24.1.8 Hall-effect device.

Hall-effect devices rely on a galvanomagnetic effect in which a transverse direct voltage is developed across a current-carrying conductor inserted in a magnetic field so that its direction is perpendicular to the direction of current flow in the conductor. Devices can be constructed using semiconductor materials that can use the Hall effect to detect the strength of magnetic fields. Figure 24.1.8 illustrates the construction and operation of a silicon Hall-effect device. Hall-effect-integrated circuits are best categorized in terms of their output characteristics. Digital devices are commonly used for speed or incremental position sensing. Analog output devices produce a voltage proportional to magnetic field and can be used as components in sensor assemblies that are designed to replace contacting potentiometric sensors. A Hall probe gear position sensor is shown in Fig. 24.1.9. A Hall probe rotary position sensor is shown in Fig. 24.1.10.

FIGURE 24.1.9 Hall probe gear position sensor.

Synchro resolvers, or simply resolvers, are absolute angle transducers. Resolvers are basically rotating transformers. The construction of a typical device is shown in Fig. 24.1.11.

Shading ring or short-circuit ring sensors (Fig. 24.1.12) are absolute displacement sensors consisting of an E-shaped core with a winding on the central leg of the E. The winding is excited with high-frequency alternating current. An electrically conducting ring of Al or Cu is allowed to

slide, maintaining an air gap along the central leg. The ring is attached to the mechanical component, whose position is to be measured.

Another form of absolute linear displacement sensor is the LVDT. LVDTs are used, for example, mounted inside hydraulic cylinders in suspension control systems.

FIGURE 24.1.10 Rotary position sensor.

FIGURE 24.1.11 Resolver construction.

FIGURE 24.1.12 SCR sensor construction.

Magnetostrictive sensors use the property of some FeNi alloys such that their resistivity is strongly affected by the presence of a magnetic field. Despite the nonlinearity of the phenomenon, accurate linear sensors can be constructed by using the sensor in a bridge arrangement together with flux nulling means, such as a servo-driven coil surrounding the sensor to effectively operate the sensor at constant resistance.

Magnetostrictive linear displacement sensors take advantage of the phenomenon that the magnetostriction is a property of materials that respond to a change of magnetic flux by developing an elastic deformation of their crystal structure.

FLOW SENSORS*

Measurement of flow rate is important to optimize the performance of several key engine control subsystems. Mass air flow sensors are replacing the indirect calculation of intake mass air flow for improved performance driveability, and economy. New requirements for on-board diagnostics are opening new applications for flow sensing in the automobile.

If the parameter to be measured is a gaseous mass flow as opposed to a volume flow, this further focuses the sensing technology selection since only a few technologies inherently measure mass flow. For liquid flow, either a mass flow or volumetric flow approach may be used since the density of a liquid changes only a small amount with atmospheric pressure and temperature.

Flowing fluid possesses both potential and kinetic energy. One approach to flow measurement extracts energy from the flow. Alternatively, energy may be added to the flow and its effect observed.

Flow Measurement Technologies

Gaseous Flow. A vane or paddle located in the flow duct is restrained by a spring so that it blocks the duct with no flow. The deflection of the vane is thus proportional to flow. This deflection is read out by a potentiometer. A preferred approach is a thermal one. A variety of designs exist, from the straightforward hot-wire air flow sensor to more complex schemes. The basic idea is to heat a fine wire, and then as the gas flows past the wire, convection removes heat. The amount of heat removed can be measured with an electronic circuit and is proportional to mass air flow rate. A hot-wire air flow sensor and its control circuit is shown in Fig. 24.1.13. Control circuits typically either supply constant power to the heated element or operate it at a constant temperature delta above the ambient temperature. Micromachined air flow sensors are beginning to be used in automotive applications. Table 24.1.4 compares the main types of thermal mass air flow sensors.

A simple way to measure volumetric flow is to place an obstruction in a flow channel and measure the differential pressure drop across it. The flow is proportional to the square root of the differential pressure. This only works well for narrow flow ranges because to operate over a given flow range, the pressure sensor must operate over the square of that range. The differential pressure approach could be suitable for some low accuracy or low dynamic range applications such as exhaust gas recirculation (EGR) valve flow. Venturis, flow restrictions, and pitot tubes all operate on the same principle.

Liquid Flow. The previous discussion on differential pressure sensing applies equally to liquid flows. A turbine blade placed in a flow channel can offer low restriction to flow, and by counting the speed of rotation, it can also measure flow. Oscillations may be induced in a fluid by placing an obstruction in the flow stream. The oscillations may be measured thermally, by pressure changes or using ultrasonics. This approach doesn't work well at low flow rates because of instability in the vortex shedding mechanism.

*Bicking, R. E., "Flow Sensors," in *Automotive Electronics Handbook*, 2nd ed., Ronald K. Jurgen (ed.), McGraw-Hill, 1999, pp. 4.1–4.9.

FIGURE 24.1.13 Hot-wire air flow sensor.

Automotive Applications of Flow Sensors

Intake Air Mass Flow. To do electronic fuel injection, the mass flow rate of air going into the engine must be determined. The speed density approach calculates the mass flow rate by measuring engine speed, intake air temperature, and intake manifold pressure.

Fuel Flow for Gas Mileage Measurement. Fuel flow is calculated from air flow and these data are already in the engine control computer. By simply summing the injector “on” time over a revolution or multiple revolutions, the fuel flow is known. Another approach is to measure the difference between the fuel coming into the fuel rail and that being returned.

Exhaust Gas Recirculation Flow. Exhaust gas recirculation is performed to reduce the emission of nitrous oxides by cooling the combustion process. Measurement of the flow is one way to diagnose a faulty EGR valve.

Secondary Air Pump Flow. The secondary air pump is used to reduce the emissions of carbon monoxide and hydrocarbons. Measurement of its flow rate is an approach to verify that it is operating properly and is doing its part to reduce emissions.

Fuel Flow for Fuel-Air Ratio Feedback Control. By measuring the fuel flow, the accuracy of fuel injection could be improved. Table 24.1.4 summarizes the performance requirements by application.

TABLE 24.1.4 Performance Requirements for Fuel-Air Ratio Feedback Control

Application	Measurement type	Range, kg/h	Accuracy, %
Intake air	Mass	10–1000	±4
Fuel flow	Mass/vol.	1–66	±10
EGR flow	Mass	30–100	±10
Air pump flow	Vol.	50	±20
Fuel flow	Mass/vol.	1–66	±4

TABLE 24.1.5 Heat Sources in Vehicles

General category	Example	Max. temperature °C
Engine	Combustion/ignition process	>1000
Catalytic converter	Chemical reaction	>1000
Road/tire friction	Tires	<100
Brakes	Disk/drum	250
Mechanical motion (gears, bearings)	Transmission/rear axle/air pump/ power steering pump	200
Heat exchangers	Radiator (coolant, transmission), heater, heatsink	>175
Electric heaters	Windshield, backlight, seats, mirrors	Ta + 25
Electric windings	Motors, alternator, solenoids	<180 (Class H)
Resistors	Ballast resistor	150
Lamps	Headlamps, tail lamps, dash lamps	125
Power transistors	Ignition driver, voltage regulator	Up to 200
Electric vehicle battery	Sodium sulfur	300

TEMPERATURE, HEAT, AND HUMIDITY SENSORS*

Temperature sensing and taking into account the effect of temperature on the performance and reliability of automotive components, and therefore the systems that contain these components, is one of the more important aspects of vehicle design. The heat sources that are present on modern automobiles are given in Table 24.1.5. Temperatures at various vehicle locations are given in Table 24.1.6.

Humidity affects the comfort of the drivers and the passengers as well as the performance of the engine and impacts the reliability of vehicle components. High humidity and low dew point can lead to increased moisture content that can affect the operation of vehicle fluids such as fuel and brake fluid and impact solid surfaces such as the windshield or brake linings.

TABLE 24.1.6 Temperatures at Various Vehicle Locations

Location	Temperature, °C		Slew rate	Humidity		
	Low	High		High	Low	Frost
<i>Underhood—Engine</i>						
Exhaust manifold	-40	+649	-7°C/min	95% at 38°C	0	Yes
Intake manifold	-40	+121	-7°C/min	95% at 38°C	0	Yes
<i>Underhood—Dash Panel</i>						
Normal	-40	+121	Open	95% at 38°C		
Extreme	-40	+141	Open	80% at 66°C		
<i>Chassis</i>						
Isolated	-40	+85	NA	98% at 38°C	0	Yes
Near heat source	-40	+121	NA	80% at 66°C	0	Yes
At drivetrain temperature	-40	+177	NA	80% at 66°C	0	Yes

Automotive Temperature and Humidity Measurements

A list of the potential temperature and humidity measurements that can be made and may be incorporated in future systems is shown in Table 24.1.7. The choice in technology for production sensors depends on performance, reliability, and cost.

Measuring Liquid Temperature. Mounting location, fluid contacting the sensor, and packaging are critical concerns for liquid temperature sensors. Upper temperature limits are typically around 150 to 200°C and operation down to -40°C is usually required. Battery temperature measurements in vehicle development use glass thermometers or glass-shielded thermocouple probes to protect the sensor from the corrosive electrolyte.

The charging voltage of a lead-acid battery must be modified for temperature. Compensation circuitry in the voltage regulator in the charging system is designed to provide a voltage that is within an acceptable range over the entire vehicle-operating temperature range. Semiconductor sensing techniques are used in this approach.

Air Temperature Measurements. Air is measured for ambient temperature, passenger compartment temperature, and inlet air on production vehicles. Upper temperature ranges are lower than liquid measurements, with 85 or 125°C being common upper limits.

Catalyst Temperature. Measuring catalyst temperature during vehicle development has been performed since the earliest implementation of these devices. The converter must be at a minimum temperature, usually above 350°C, to be effective. A linear temperature sensor has been developed to measure the temperature across the catalyst.

Tire Temperature Sensing. Sensing the temperature within a tire is part of the pressure measurement and fault detection provided by tire pressure measuring and automatic adjustment systems. In a system such as the one developed by Michelin (Fig. 24.1.14), both a pressure and a temperature sensor are located on each wheel. A circular antenna and a transceiver allow these signals to be sent to an electronic processing module. An air compressor attempts to maintain desired tire pressure under normal conditions.

Humidity Sensing. Correlation of a number of vehicle tests requires that humidity be monitored. Variations in humidity can explain variations that occur in test results. Significant, repeatable, and controllable results

FIGURE 24.1.14 Temperature sensing in tire pressure control.

TABLE 24.1.8 Temperature Sensing Techniques versus Operating Range

Sensing technique	Temperature range, °C	Usage: production (P)
		development (D) future (F)
Thermistor	0 to 500	P
Thermocouple	-200 to +3000	D
Bimetallic switch	-50 to +400 (650)	P
Potentiometer temperature sensor	-40 to +125	P
Platinum wire resistor (RTD)	-200 to +850 (-40 to + 200)	P
Semiconductor (junction)	-40 to +200	P
Thermostat (pressure spring)	-50 to +500	P
Fiber optic temperature sensor	+1800	D/F
Temperature indicator	+40 to +1350	D
Infrared	>Ta	D
Liquid thermometer	-200 to +1000	D

may lead to humidity sensing being part of future engine control systems and passenger compartment comfort control systems.

Temperature Sensors

Several different sensing techniques are used in production vehicles and during vehicle development to provide the needed temperature measurements. Table 24.1.8 shows a list of these techniques and the temperature range that is typical for each approach. Table 24.1.9 shows common types of thermocouples and their operating characteristics.

Humidity Sensors

Techniques to measure humidity are listed in Table 24.1.10. Most of these are actually laboratory instruments. Three sensing techniques that have potential for future vehicle use are capacitive, resistive, and oxidized porous silicon.

TABLE 24.1.9 Common Thermocouples and Application Factors

ISA code	Conductor		Temperature range, °C	Standard error limit, °C	Seebeck coefficient, $\mu V/^{\circ}C$
	Positive	Negative			
E*	Chromel	Constantan	0 to +316	± 2	62
J*	Iron	Constantan	0 to +277	± 2	51
T*	Copper	Constantan	-59 to +93	± 1	40
K*	Chromel	Alumel	0 to +277	± 2	40
N*	Nicrosil	Nisil	0 to +277	± 2	38

Gold/aluminum oxide	Production sensor
Oxidized porous silicon (OPS)	Experimental sensor

EXHAUST GAS SENSORS*

From the model year 1994 onward, on-board devices capable of monitoring the operation of all emission-relevant vehicle components have been required in the United States. Pollutant emission sensors to measure levels of CO, NO_x, and HC emissions downstream from the catalytic converter represent an ideal means of monitoring the performance of both converter and oxygen sensor. There also exist concepts that employ a second oxygen sensor behind the catalytic converter to detect aging in the converter and/or the lambda sensor. This concept is currently used in almost all On-Board Diagnosis II applications worldwide.

Lambda Sensors

Lambda = 1 Sensor: Nernst Type (ZrO₂). The lambda sensor operates as a solid-electrolyte galvanic oxygen-concentration cell (Fig. 24.1.15). A ceramic element consisting of zirconium oxide and yttrium oxide is employed as a gas-impermeable solid electrolyte designed to separate the exhaust gas from the reference atmosphere.

Lambda = 1 Sensor: Semiconductor Type. Oxidic semiconductors such as TiO₂ and SrTiO₃ rapidly achieve equilibrium with the oxygen partial pressure in the surrounding gas phase at relatively low temperatures. Changes in the partial pressure of the adjacent oxygen produce variations in the oxygen vacancy concentration of the material, thereby modifying its volume conductivity.

Lean A/F Sensor: Nernst Type. It is always possible to employ a potentiometric lambda = 1 sensor as a lean A/F sensor by using the flat part of the Nerst voltage curve to derive the values at lambda > 1.

Lean A/F Sensor: Limiting Current Type. An external electrical voltage is applied to two electrodes on a heated ZrO₂ electrolyte to pump O₂ ions from the cathode to the anode. When a diffusion barrier impedes the flow of O₂ molecules from the exhaust gas to the cathode, the result is current saturation beyond a certain

*Weidenmann, H. M., Hotzel, G., Neumann, H., Riegel, J., Stanglmeier, F., and Weyl, H., "Exhaust Gas Sensors," in *Automotive Electronics Handbook*, 2nd ed., Ronald K. Jurgen (ed.), McGraw-Hill, 1999, pp. 6.1–6.25.

FIGURE 24.1.15 Diagram illustrating design and operation of a lambda = 1 sensor.

pumping voltage threshold. The resulting limiting current is roughly proportional to the exhaust gas's oxygen concentration.

Wide-Range A/F Sensor: Single-Cell. When the anode of a limiting current sensor is exposed to reference air instead of to the exhaust gas, the total voltage at the probe will be the sum of the effective pumping voltage and a superimposed Nernst voltage. In operation, holding the total voltage to, as an example, 500 mV will produce a positive pumping voltage in lean exhaust gases. The diffusion limits the rate at which O₂ is pumped from the cathode to the anode. At lambda = 1, the pumping voltage and, with it, the pumping current drop toward zero.

Wide-Range A/F Sensor: Dual-Cell. Skillful combination of a limiting-current sensor with a Nernst concentration cell on a single substrate will produce a dual-cell, wide-range A/F sensor. An electronic circuit regulates the current applied to the pumping cell to maintain a constant gas composition in the measurement gap. If the exhaust gas is lean, the pumping cell drives the oxygen outward from the measurement gap. If the exhaust gas is rich, the flow direction is reversed and oxygen from the surrounding exhaust gas is pumped into the measurement gap.

Other Exhaust Gas Components

Sensors capable of monitoring the levels of the regulated toxic exhaust substances—CO, NO_x, and HC—would be desirable as elements of the On-Board Diagnosis Systems specified by the California Air Resources Board and EURO III/IV, especially for Gasoline Direct Injection systems. For the more stringent emissions standards, the need for selective exhaust gas sensors have to be developed.

Mixed-Potential Sensors. If reduced catalytic activity prevents gas equilibrium from being achieved at the electrode of a galvanic ZrO₂ cell, competing reactions can occur. These, in turn, prevent a state of reduction/oxidation equilibrium in the oxygen, and lead to the formation of a mixed potential. Mixed-potential exhaust gas sensors are available for NO_x, HC, CO, and NH₃ to study new diagnostic concepts.

Dual Pumping Cell Gas Sensors. These sensors are based on a zirconia planar type similar to the wide-range A/F sensor and contain two different chambers with gas-selective electrodes. The exhaust gas penetrates into the first chamber through the first diffusion barrier. By a selective O_2 electrode, oxygen is removed from the exhaust gas. In the second chamber, NO_x is decomposed into N_2 and O_2 and the O_2 is pumped out of the chamber. The associated pumping current is a measure of the NO_x concentration in the exhaust gas.

Semiconductor Gas Sensors. On the surface of nonstoichiometric metal oxides such as SnO_2 , TiO_2 , InO_3 , and Fe_2O_3 , oxygen is absorbed and dissociated in air at high temperatures and is bonded to the crystal lattice. This leads to the formation of a thin depletion layer at the crystallite surface with a resultant arch in the potential curve. This phenomenon produces reductions in surface conductivity and higher intercrystalline resistance at the boundaries between the two crystallites; this is the major factor determining the total resistance of the polycrystalline metal oxide. Oxidation gases such as CO, H_2 , and C_xH_y , which react with surface oxygen, increase the density of charge carriers in the boundary layer and reduce the potential barrier. Reduction gases such as NO_x and SO_x raise the potential barrier and, with it, the surface/intercrystalline resistance.

Catalytic Gas Sensors. The catalytic gas sensor is essentially a temperature sensor featuring a catalytically active surface. An exothermic reaction at the catalytically active surface causes the temperature of the sensor to rise. The increase in temperature is proportional to the concentration of an oxidation gas in an excess-oxygen atmosphere.

SPEED AND ACCELERATION SENSORS*

Speed sensing can be divided into rotational and linear applications. Rotation speed sensing has two major application areas: engine speed monitoring to enhance engine control and performance and antilock braking and traction control systems for improved road handling and safety. Linear sensing can be used for ground-speed monitoring for vehicle control, obstacle detection, and crash avoidance. Acceleration sensors are used in air bag deployment, ride control, antilock brake, traction, and inertial navigation systems.

Speed-Sensing Devices

Variable Reluctance Devices. These devices are essentially small ac generators with an output voltage proportional to speed, but they are limited in applications where zero speed sensing is required. These devices have a linear output voltage with frequency and need an A/D converter to generate a digital signal for compatibility with the master control unit.

Hall-Effect Devices. A Hall-effect device can be used for zero speed sensing (it can give an output when there is no rotation). Hall devices give a frequency output that is proportional to speed, making them compatible with microcontrollers.

Magnetoresistive Devices. The magnetoresistive effect is the property of a current-carrying ferromagnetic material to change its resistivity in the presence of an external magnetic field. The resistivity value rises to a maximum when the direction of current and magnetic field are coincident, and is a minimum when the fields are perpendicular to each other. These devices give an output frequency that is proportional to speed, making for ease of interfacing with an MCU.

Ultrasonic Devices. Ultrasonic devices can be used to measure distance and ground speed. They can also be used as proximity detectors. To give direction and beam shape, the signals are transmitted and received via specially

*Dunn, W. C., "Speed and Acceleration Sensors," in *Automotive Electronics Handbook*, 2nd ed., Ronald K. Jurgen (ed.), McGraw-Hill, 1999, pp. 7.1-7.29.

configured horns and orifices. To measure speed, the distance variation with time can be measured and the velocity calculated. A more common method is to use the Doppler effect, which is a change in the transmitted frequency as detected by the receiver due to motion of the target (or, in this case, the motion of the transmitter and receiver).

Optical and Radio Frequency Devices. Optical devices are still being used for rotational speed sensing. They normally consist of light-emitting diodes (LEDs) with optical sensors. An optical sensor detects light from an LED through a series of slits cut into the rotating disc, so that the output from the sensor is a pulse train whose frequency is equal to the rpm of the disc multiplied by the number of slits. Radio frequency devices use gallium arsenide on Gunn devices to obtain the power and high frequency (about 100 GHz) required in the transmitter.

Automotive Applications for Speed Sensing

There are several applications for speed sensing. First it is necessary to monitor engine speed. This information is used for transmission control, engine control, cruise control, and possibly for a tachometer. Wheel speed sensing is required for use in transmissions, cruise control, speedometers, antilock brake systems, traction control, variable ratio power steering assist, four-wheel steering, and possibly in inertial navigation and air bag deployment applications. Linear speed sensing is used to measure the ground speed and could also be used in antilock brake systems, traction control, and inertial navigation.

Acceleration Sensing Devices

Acceleration sensors vary widely in their construction and operation. In applications such as crash sensors for air bag deployment, mechanical devices (simple mechanical switches) have been developed and are in use. Solid-state analog accelerometers have also been designed for air bag applications.

Mechanical Sensing Devices. Mechanical switches are simple make-break devices. Figure 24.1.16 shows the cross section of a Breed-type of switch or sensor.

Piezoelectric Sensing Devices. Piezoelectric devices (Fig. 24.1.17) consist of a layer of piezoelectric material (such as quartz) sandwiched between a mounting plate and a seismic mass. Electric connections are made to both sides of the piezoelectric material.

Piezoresistive Sensing Devices. The property of some materials to change their resistivity when exposed to stress is called the piezoresistive effect. Piezoresistive sensing can be used with bulk micromachined accelerometers (Fig. 24.1.18).

FIGURE 24.1.16 Cross section of a mechanical sensor.

FIGURE 24.1.17 Cross section of a piezoelectric accelerometer.

Capacitive Sensing Devices. Differential capacitive sensing has a number of attractive features when compared to other methods of sensing: easily implement self-test, temperature insensitivity, and smaller size. Capacitive sensing has the advantages of dc and low-frequency operation and well-controlled damping.

Open-loop signal-conditioning circuits amplify and convert the capacitance changes into a voltage. Such a CMOS circuit using switched capacitor techniques is shown in Fig. 24.1.19. A closed-loop system (Fig. 24.1.20) can be configured to give an analog or digital output.

Automotive Applications for Accelerometers

Accelerometers have a wide variety of uses in the automobile. The initial application is as a crash sensor for air bag deployment. An extension of this application is the use of accelerometers for the detection of side

FIGURE 24.1.18 Bulk micromachined accelerometer.

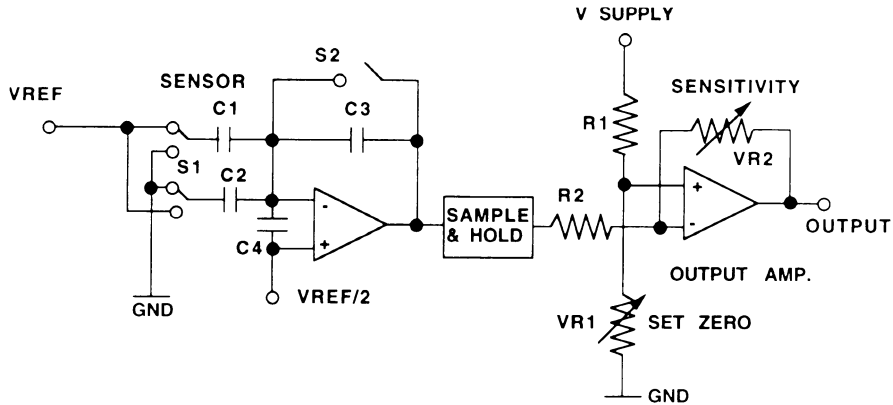

FIGURE 24.1.19 Capacitive sensing integrator circuit.

impact or rollover. Low *g* sensors are being developed for ride control, antilock braking, traction, and inertial navigation requirements.

New Sensing Devices

New cost-effective sensors are continually being developed. For rotational speed sensing, a number of new devices are being investigated to detect magnetic fields: flux gate, Weigand effect, magnetic transistor, and magnetic diode. For linear speed-sensing, ultrasonics, infrared, laser, and microwaves (radar) can be used in the detection of objects behind vehicles and in the blind areas. Recent developments in solid-state technology

have made possible very small cost-effective devices to sense angular rotation. The implementation of one such gyroscopic device is shown in Fig. 24.1.21.

ENGINE KNOCK SENSORS*

Knock is a phenomenon characterized by undesirable structural vibration and noise generation and is peculiar to spark-ignited engines. The terms *ping* (light, barely observable knock) and *predetonation* (knock caused by ignition of the charge slightly before the full ignition of the flame front by the spark plug) are also commonly used in the industry.

An attempt to measure the cause of the phenomenon leads one to the difficult problem of observing pressure waves in the cylinder. In fact, over the years these difficulties led the industry to devise an experimental comparison technique that measured the octane rating of the fuel, not of the engine.

Technologies for Sensing Knock

A number of different technologies have been selected for measuring knock in real time on board, and sensors have been developed for this purpose. These sensors measure the magnitude of a consequential parameter

*Wolber, W. G., "Engine Knock Sensors," in *Automotive Electronics Handbook*, 2nd ed., Ronald K. Jurgen (ed.), McGraw-Hill, 1999, pp. 8.1-8.10.

FIGURE 24.1.22 An exploded view of a jerk sensor.

driven by the knock, rather than the knock phenomenon itself. The overall effectiveness of the control is determined not only by the intrinsic performance and stability of the sensor and control, but also by how robust the chain of causality is between the knock phenomenon and the parameter measured. Knock can be controlled either by retarding spark timing or by opening a manifold boost wastegate valve.

Jerk Sensor. The first turbocharged engine knock control used a jerk sensor, a productionized version of the kind of sensor used in the laboratory (Fig. 24.1.22). When the sensor is fully assembled, the spider spring is preloaded, and all parts of the sensor except the coil cover are in compression. The vibrations picked up and transmitted from the engine block through the mounting study appear in the nickel alloy rods. The waves present in the rods linearly modulate the magnetic reluctance of the magnetic circuit. The many-turn coil wound around the magnetostrictive rods generates a voltage proportional to the rate of change of the magnetic reluctance of the rods. Since the vibrations picked up are already due to accelerations from the knock reverberations transmitted through the engine block, the voltage from the coil represents the third-time derivative of displacement, or jerk.

Accelerometer Sensors. The jerk sensor has too many parts to be a low-cost solution to measuring knock on board. A more economical approach is to use the second-time derivative of displacement—acceleration. Piezoelectric, piezoceramic, and silicon accelerometers can be used.

Other Sensors. An instantaneous cylinder pressure sensor permits the extraction of the pressure reverberation signal, which is the direct cause of knock, but it has not been implemented in on-board knock control systems for several reasons:

- Either the same cylinder must always be the one to experience knock first and most severely or one must have a sensor on every cylinder.
- The cylinder pressure wave is complex, and knock is only one of many signature elements present. Deriving a unique knock signal requires considerable signal processing in real time.
- While cylinder pressure sensors exist, which are suitable for test purposes, a durable, low-cost, mass-producible on-board pressure sensor is not yet available.

Piezoceramic Accelerometers. These accelerometers (Fig. 24.1.23) lend themselves to low-cost mass production. As a result they have become pretty much the knock sensor of choice for the automobile industry.

FIGURE 24.1.23 A piezoceramic accelerometer knock sensor.

ENGINE TORQUE SENSORS*

Torque can be defined as the moment produced by the engine crankshaft tending to cause the output driveline to turn and thereby deliver power to the load.

Direct Torque Sensors

Magnetic Vector Sensors. A strain-gaged torsional Hooke's law sensor has been used in off-board torque measurements. A more practical approach to an on-board torque sensor is a noncontacting design called a magnetic vector sensor. It operates on the principle that the magnetic domains in a ferromagnetic shaft delivering torque are randomly distributed when no torque is being delivered, but that each domain, on average, is slightly rotated in the tangential direction when torque is delivered by the shaft and twists it. If an ac-driven coil is placed near the shaft and surrounded by four sensing coils arranged mechanically and electrically as a bridge, the amplitude of the bridge offset is proportional to the magnetic vector tangential component, and therefore to twist and torque.

Optical Twist Measurement. Research has been reported on a sensor that changes the duty factor of light pulses sensed after passing through sets of slits at both ends of a shaft. The principle of its operation is shown in Fig. 24.1.24.

*Wolber, W. G., "Engine Torque Sensors," in *Automotive Electronic Handbook*, 2nd ed., Ronald K. Jurgen (ed.), McGraw-Hill, 1999, pp. 9.1–9.14.

FIGURE 24.1.24 Optical torque meter. (Courtesy of The Bendix Corp.)

Capacitive Twist Sensor. An electrode pattern can be made using interdigitated electrodes spaced one or two degrees apart on two facing discs. One of the discs is stationary; the other rotates with the crankshaft. Two such pairs of electrodes can be operated with phase detection measurement to provide a virtually instantaneous signal proportional to the twist of the shaft. The rotating halves of the electrode pairs are attached to the ends of the Hooke's law torsional spring.

Inferred Torque Measurement

Instantaneous Cylinder Pressure Sensors. Much work continues on development of a mass-producible on-board cylinder pressure sensor. The signals from cylinder pressure sensors need considerable real-time data processing to produce inferred "torque" signals.

Digital Period Analysis (DPA). When an engine is run at low speed and heavy load, the instantaneous angular velocity of its output shaft on the engine side of the flywheel varies at the fundamental frequency of the cylinders, since the compression stroke of each cylinder abstracts torque and the power stroke adds a larger amount. The signal-to-noise ratio of the measurement of instantaneous angular velocity (or rather of its reciprocal, instantaneous period) degrades with increasing engine speed and lighter load, but is a useful way to infer torque-like measures of engine performance.

ACTUATORS*

Actuators in automobiles respond to position commands from the electronic control unit to regulate energy, mass, and volume flows. Basic actuator elements are shown in Fig. 24.1.25. Either the control unit or the actuator itself will feature an integral electronic output amplifier.

FIGURE 24.1.25 Basic actuator elements.

*Müller, K., "Actuators," in *Automotive Electronics Handbook*, 2nd ed., Ronald K. Jurgen (ed.), McGraw-Hill, 1999, pp. 10.1–10.35.

FIGURE 24.1.26 Flat-armature solenoid featuring field excitation (a) via coil, (b) via permanent magnet.

Types of Electromechanical Actuators

Magnetic Actuators. In order to operate, these actuators depend on the forces found at the interfaces in a coil-generated magnetic field when current passes through it. With a flat armature solenoid (Fig. 24.1.26), a particular solenoid force is specified for each technical application. The pole face area, the magnetic circuit, and the coil are then determined for this force.

Torque Motors. The torque motor consists of a stator and an armature—both made of soft magnetic material—and a permanent magnet. The pivoting armature can be equipped with either one or two coils.

Electrostatic Step Motors. Electrostatic step motors are drive elements in which a special design operates in conjunction with pulse-shaped control signals to carry out rotary or linear-stepped movements. The step motor is capable of transforming digital control signals directly into discontinuous rotary motion. In principle, the step motor is essentially a combination of dc solenoids. Depending on the configuration of the magnetic circuit, a distinction is made between three types of step motors: the variable-reluctance step motor (neutral magnetic circuit), heteropolar units (polarized magnetic circuit), and hybrid devices.

Moving Coils. The moving coil is an electrodynamic device (force is applied to a current-saturated conductor in a magnetic field). A spring-mounted coil is located in the ring gap of a magnetic circuit featuring a permanent magnet. When current flows through the coil, a force is exerted against it. The direction of this force is determined by the flow direction of the current itself.

Electrical Actuators

Piezoelectric Actuators. When mechanical compression and tension are brought to bear on a piezoelectric body, they produce an asymmetrical displacement in the crystal structure and in the charge centers of the affected crystal ions. The result is charge separation. An electric voltage proportional to the mechanical pressure can be measured at the metallic electrodes. If electric voltage is applied to the electrodes on this same body, it will respond with a change in shape; the volume remains constant. This piezoelectric effect can be exploited to produce actuators.

Electrostatic Actuators. Microactuator technology makes it possible to apply small electrical field forces in mechanical drive devices. They combine high switching speeds with much smaller energy loss than that found in electromagnetic actuators. The disadvantages are the force-travel limitations and the high operating voltages.

Electrorheological Fluids. The electrorheological effect is based on polarization processes in minute particles suspended in a fluid medium. These particles modify the fluid's viscosity according to the orientation in the electrical field. This effect is exploited in controlled transfer and damping elements.

Thermal Actuators

Temperature-Sensitive Bimetallic Elements. The temperature-sensitive bimetallic element is composed of at least two bonded components of varying thermal-expansion coefficients. When heat is applied, the components expand at different rates, causing the bimetallic element to bend. When electrically generated heat is applied, these devices become actuators.

Memory Alloys. Memory alloys are metallic materials that exhibit a substantial degree of "shape memory." If the element is heated to beyond the transformation temperature (from martensitic to austenitic), it returns to its former shape. If the component is then reshaped after cooling, the entire process can be repeated.

Automotive Actuators

Actuators for Braking Intervention. Braking pressure is regulated normally via 2/2 solenoid valves, that is, valves with two ports and two switch positions. When no current is applied, the inlet valve remains open and the outlet valve is closed, allowing unrestricted wheel braking.

Electronic Throttle Control (ETC) with Throttle-Aperture Adjustment. Either of two standard methods can be employed for throttle regulation. ETC systems feature an actuator (servo motor) mounted directly at the throttle valve. On systems incorporating a traction-control actuator, the servo motor is installed in the throttle cable. Another approach to engine intervention is embodied in a design in which the linkage spring is integrated within the throttle body.

Fuel Injection for Spark-Ignition Engines. Electronically controlled fuel injection systems meter fuel with the assistance of electromagnetic injectors. The injector's opening time determines the discharge of the correct amount of fuel.

Fuel Injection for Diesel Engines. Distributor-type fuel injection pumps contain rotary solenoid actuators for injection quantity, and two position valves for engine operation and shutoff.

Passenger-Safety Actuators. Pyrotechnical actuators are used for passenger-restraint systems such as the air bag and the automatic seat belt tensioner. When an accident occurs, the actuators inflate the air bag (or tension the seat belt) at precisely the right instant.

Electronic Transmission Control. Continuous operation actuators are used to modulate pressure, while switching actuators function as supply and discharge valves for shift-point control. Types of actuators used included on/off solenoid valves, variable-pressure switches, and pulse-width-modulated solenoid valves.

Headlight Vertical Aim Control. Headlight-adjustment actuators are dc or step motors producing a rotary motion that gear-drive units then convert to linear movement.

Future Actuators

The motivation to develop new actuators is created by the potential advantages of new manufacturing and driving techniques in combination with new materials. Representative new fields of innovation include micro-mechanical valves and positive-engagement friction drive (ultrasonic motor).

CHAPTER 24.2

AUTOMOTIVE ON-BOARD SYSTEMS

Ronald K. Jurgen

INTRODUCTION

In the previous chapter in this section, the significance of sensors at the input of electronic automotive systems and actuators at the output of such systems was stressed. Equally important, of course, are the automotive microcontrollers that accept the sensor signals, process them, and then send command signals to the actuators. The combination of sensors, microcontrollers, and actuators is what makes possible the myriad of automotive control systems now in use in production cars.

This chapter begins with a brief discussion of microcontrollers and then proceeds with descriptions of most major automotive control systems.

MICROCONTROLLERS*

A microcontroller can be found at the heart of almost any automotive electronic control module or electronic control unit (ECU) in production today. Automotive systems such as antilock braking control (ABS), engine control, navigation, and vehicle dynamics all incorporate at least one microcontroller within their ECU to perform necessary control functions.

A microcontroller can essentially be thought of as a single-chip computer system and is often referred to as a single-chip microcomputer. It detects and processes input signals, and responds by asserting output signals to the rest of the ECU. Fabricated on a highly integrated, single piece of silicon are all of the features necessary to perform embedded control functions. Microcontrollers are fabricated by many manufacturers and are offered in just about any imaginable mix of memory, input/output (I/O), and peripheral sets. The user customizes the operation of the microcontroller by programming it with his or her own unique program. The program configures the microcontroller to detect external events, manipulate the collected data, and respond with appropriate output. The user's program is commonly referred to as code and typically resides on-chip in either read-only memory (ROM) or erasable programmable read-only memory (EPROM). In some cases where an excessive amount of code space is required, memory may exist off-chip on a separate piece of silicon. After power-up, a microcontroller executes the user's code and performs the desired embedded control function.

*Boehmer, D. S., "Automotive Microcontrollers," in *Automotive Electronics Handbook*, 2nd ed., Ronald K. Jurgen (ed.), McGraw-Hill, 1999, pp. 11.3–11.55.

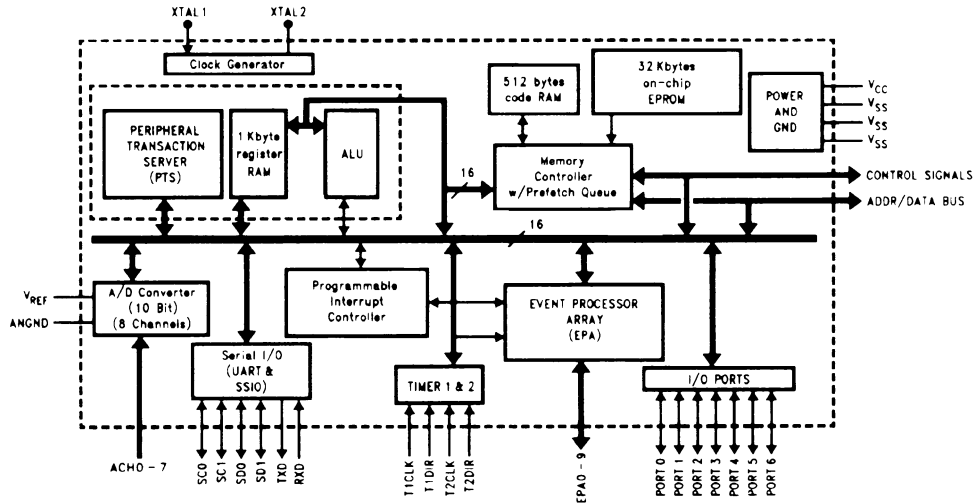

FIGURE 24.2.1 Microcontroller block diagram.

Microcontrollers differ from microprocessors in several ways. A microcontroller can be thought of as a complete microcomputer on a chip that integrates a central processing unit (CPU) with memory and various peripherals such as analog-to-digital (A/D) converters, serial communication units, high-speed input and output units, timer/counter units, and standard low-speed I/O ports. Microcontrollers are designed to be embedded within event-driven control applications and generally have all necessary peripherals integrated onto the same piece of silicon.

Microprocessors, on the other hand, typically require external peripheral devices to perform their intended function and are not suited to be used in single-chip designs. Microprocessors basically consist of a CPU with register arrays and interrupt handlers. Peripherals such as A/D are rarely integrated onto microprocessor silicon. Microprocessors are designed to process large quantities of data and have the capability to handle large amounts of external memory.

Choosing a microcontroller for an application is a process that takes careful investigation and thought. Items such as memory size, frequency, bus size, I/O requirements, and temperature range are all basic requirements that must be considered when choosing a microcontroller. The microcontroller family must possess the performance capability necessary to successfully accomplish the intended task. The family should also provide a memory, I/O, and frequency growth path that allows easy upgradability to meet market demands. Additionally, the microcontroller must meet the application's thermal requirements in order to guarantee functionality over the intended operating temperature range. Items such as these must all be considered when choosing a microcontroller for an automotive application.

A typical block diagram of a microcontroller is shown in Fig. 24.2.1.

ENGINE CONTROL*

An electronic engine control system consists of sensing devices that continuously measure the operating conditions of the engine, an ECU that evaluates the sensor inputs using data tables and calculations and determines

*Hirschlieb, G. C., Schiller, G., and Stotler, S., "Engine Control," in *Automotive Electronics Handbook*, 2nd ed., McGraw-Hill, 1999, pp. 12.1-12.36.

the output to the actuating devices, and actuating devices that are commanded by the ECU to perform an action in response to the sensor inputs.

The motive for using an electronic engine control system is to provide the needed accuracy and adaptability in order to minimize exhaust emissions and fuel consumption, provide optimum driveability for all operating conditions, minimize evaporative emissions, and provide system diagnosis when malfunctions occur.

In order for the control system to meet these objectives, considerable development time is required for each engine and vehicle application. A substantial amount of development must occur with an engine installed on an engine dynamometer under controlled conditions. Information gathered is used to develop the ECU data tables. A considerable amount of development effort is also required with the engine installed in the vehicle. Final determination of the data tables occurs during vehicle testing.

Spark Ignition (SI) Engines

Fuel Delivery Systems. Fuel management in the spark ignition system consists of metering the fuel, formation of the air/fuel mixture, transportation of the air/fuel mixture, and distribution of the air/fuel mixture. The driver operates the throttle valve, which determines the quantity of air inducted by the engine. The fuel delivery system must provide the proper quantity of fuel to create a combustible mixture in the engine cylinder. In general, two fuel delivery system configurations exist: single-point and multi-point (Fig. 24.2.2).

For single-point systems such as carburetors or single-point fuel injection (Fig. 24.2.3), the fuel is metered in the vicinity of the throttle valve. Mixture formation occurs in the intake manifold. Some of the fuel droplets evaporate to form fuel vapor (desirable) while others condense to form a film on the intake manifold walls (undesirable). Mixture transport and distribution is a function of intake manifold design. Uniform distribution under all operating conditions is difficult to achieve in a single-point system.

For multipoint systems, the fuel is injected near the intake valve. Mixture formation is supplemented by the evaporation of the fuel on the back of the hot intake valve. Mixture transport and distribution occurs only in

FIGURE 24.2.2 Air-fuel mixture preparation: right, single-point fuel injection; left, multipoint fuel injection with fuel (1), air (2), throttle valve (3), intake manifold (4), injector(s) (5), and engine (6).

FIGURE 24.2.3 Single-point injection unit: pressure regulator (1), injector (2), fuel return (3), stepper motor for idle speed control (4), to intake manifold (5), throttle valve (6), and fuel inlet (7).

the vicinity of the intake valve. The influence of the intake manifold design on uniform mixture distribution is minimized. Since mixture transport and distribution is not an issue, the intake manifold design can be optimized for air flow.

Ignition Systems. The general configuration of an ignition system consists of the following components: energy storage device, ignition timing mechanism, ignition triggering mechanism, spark distribution system, and spark plugs and high-tension wires. Table 24.2.1 summarizes the various ignition systems used on SI engines.

Compression Ignition Engines

Electronic engine controls are now being used on compression ignition (diesel) engines. These controls offer greater precision and control of fuel injection quantity and timing, engine speed, exhaust gas recirculation (EGR), turbocharger boost pressure, and auxiliary starting devices. The following inputs are used to provide the ECU with information on current engine operating conditions: engine speed; accelerator position; engine coolant, fuel, and inlet air temperatures; turbocharger boost pressure; vehicle speed; control rack or control collar position

TABLE 24.2.1 Overview of Various Ignition Systems

Ignition function	Ignition designation				
	Coil system	Transistorized coil system	Capacitor discharge system	Electronic system with distributor	Electronic distributorless system

(for control of fuel quantity; and atmospheric pressure). Figure 24.2.4 is a schematic of an electronic engine control system on an in-line diesel fuel injection pump application.

Engine Control Modes

Engine Crank and Start. During engine cranking, the goal is to get the engine started with the minimal amount of delay. To accomplish this, fuel must be delivered that meets the requirements for starting for any combination of engine coolant and ambient temperatures. For a cold engine, an increase in the commanded air-fuel ratio is required due to poor fuel vaporization and “wall wetting,” which decreases the amount of usable fuel. Wall wetting is the condensation of some of the vaporized fuel on the cold metal surfaces in the intake port and combustion chamber. It is critical that the fuel does not wet the spark plugs, which reduces the effectiveness of the spark plug and prevent the plug from firing. Should plug wetting occur, it may be impossible to start the engine.

Engine Warm-Up. During the warm-up phase, there are three conflicting objectives: keep the engine operating smoothly (i.e., no stalls or driveability problems), increase exhaust temperature to quickly achieve operational temperature for the catalyst and lambda sensor so that closed-loop fuel control can begin operating, and keep exhaust emissions and fuel consumption to a minimum. The best method for achieving these objectives is very dependent on the specific engine application.

Transient Compensation. During transitions such as acceleration or deceleration, the objective of the engine control system is to provide a smooth transition from one engine operating condition to another

(i.e., no hesitations, stalls, bumps, or other objectionable driveability concerns), and keep exhaust emissions and fuel consumption to a minimum.

Full Load. Under steady-state full-load conditions, such as for climbing a grade, it is desirable to control the air/fuel mixture and ignition timing to obtain maximum power and to also limit engine and exhaust temperatures.

Idle Speed Control. The objectives of the engine control system during idle are to provide a balance between the engine torque produced and the changing engine loads, thus achieving a constant idle speed even with various load changes due to accessories (i.e., air conditioning, power steering, and electrical loads) being turned on and off and during engagement of the automatic transmission. In addition the idle speed control must be able to compensate for long-term changes in engine load, such as the reduction in engine friction that occurs with engine break-in. The idle speed control must also provide the lowest idle speed that allows smooth running to achieve the lowest exhaust emissions and fuel consumption (up to 30 percent of a vehicle's fuel consumption in city driving occurs during idling).

To control the idle speed, the ECU uses inputs from the throttle position sensor, air conditioning, automatic transmission, power steering, charging system, engine RPM, and vehicle speed.

TRANSMISSION CONTROL*

Since the introduction of electronic transmission control units in the early 1980s, the acceptance of the automatic transmission (AT) rose sharply. The market for ATs is divided into stepped and continuously variable transmissions (CVTs). For both types the driver gets many advantages. In stepped transmissions, the smooth shifts can be optimized by the reduction of engine torque during gear shift, combined with the correctly matched oil pressure for the friction elements (clutches, brake bands). The reduction of shift shocks to a very low or even to an unnoticeable level has allowed the design of five-speed ATs where a slightly higher number of gear shifts occur.

With the CVT, one of the biggest obstacles to the potential reduction in fuel consumption by operating the engine at its optimal point is the power loss from the transmission's oil pump. Only with electronic control is it possible to achieve the required yield by matching the oil mass-stream and oil pressure for the pulleys to the actual working conditions.

To guarantee the overall economic solution for an electronically controlled transmission, either stepped or CVT, the availability of precision electrohydraulic actuators is imperative.

System Components

Transmission. The greatest share of electronically controlled transmissions currently on the market consists of four- or five-speed units with a torque converter lockup clutch, commanded by the control unit. In a conventional pure hydraulic AT, the gear shifts are carried out by mechanical and hydraulic components. These are controlled by a centrifugal governor that detects the vehicle speed and a wire cable connected to the throttle plate lever. With an electronic shift point control, on the other hand, an electronic control unit detects and controls the relevant components.

Present electronically controlled ATs usually have an electronically commanded torque converter clutch, which can lock up the torque converter between the engine output and the transmission input. The torque converter clutch is activated under certain driving conditions by a solenoid controlled by the electronic TCU. Locking up the torque converter eliminates the slip of the converter, and the efficiency of the transmission system is increased. This results in an even lower fuel consumption for cars equipped with ATs.

*Neuffer, K., and Engelsdorf, K., "Transmission Control," in *Automotive Electronics Handbook*, 2nd ed., Ronald K. Jurgen (Ed.), McGraw-Hill, 1999, pp. 13.1–13.23.

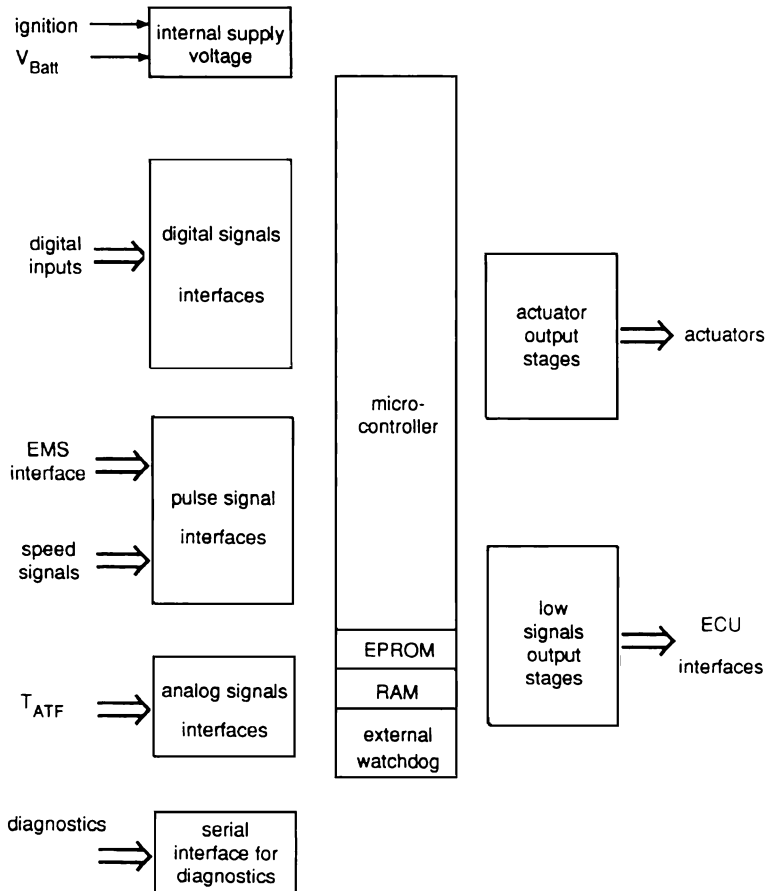

FIGURE 24.2.5 Overview of hardware parts.

Electronic Control Unit. Another important component in electronic transmission control is the ECU, which is designed according to the requirements of the transmission and the car environments. The ECU can be divided into two main parts: the hardware and the corresponding software.

The hardware consists of the housing, the plug, the carrier for the electronic devices, and the devices themselves. The housing, according to the requirements, is available as an unsealed design for applications inside the passenger compartment or within the luggage compartment. It is also possible to have sealed variants for mounting conditions inside the engine compartment or at the bulkhead. An overview of hardware parts is shown in Fig. 24.2.5.

The software within the electronic transmission control system is gaining increasing importance because of the increasing number of functions, which, in turn, requires increasing software volume. The software for the control unit can be divided into two parts: the program and the data. The program structure is defined by the functions. The data are specific for the relevant program parts and have to be fixed during the calibration stage. The most difficult software requirements result from the real-time conditions coming from the transmission design. This is also the main criterion for the selection of the microcontroller (Fig. 24.2.6).

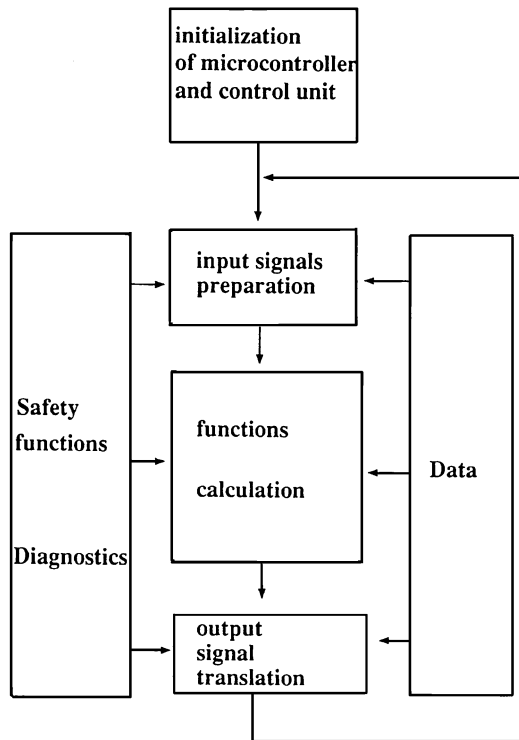

FIGURE 24.2.6 Software structure overview.

Actuators. Electrohydraulic actuators are important components of the electronic transmission control systems. Continuously operating actuators are used to modulate pressure, while switching actuators functions as supply and discharge valves for shift-point control.

System Functions

Functions can be designated as system functions if the individual components of the total electronic transmission control system cooperate efficiently to provide a desired behavior of the transmission and the vehicle.

Basic Functions. The basic functions of the transmission control are the shift point control, the lockup control, engine torque control during shifting, related safety functions, and diagnostic functions for vehicle service. The pressure control in transmission systems with electrical operating possibilities for the pressure during and outside shifting can also be considered as a basic function. Figure 24.2.7 shows the necessary inputs and outputs as well as the block diagram of an electronic TCU suitable for the basic functions.

Shift Point Control. The basic shift point control uses shift maps that are defined in data in the unit memory. These shift maps are selectable over a wide range. The shift point limitations are made, on the one hand, by the highest admissible engine speed for each application and, on the other hand, by the lowest engine speed that is practical for driving comfort and noise emission. The inputs of the shift point determination

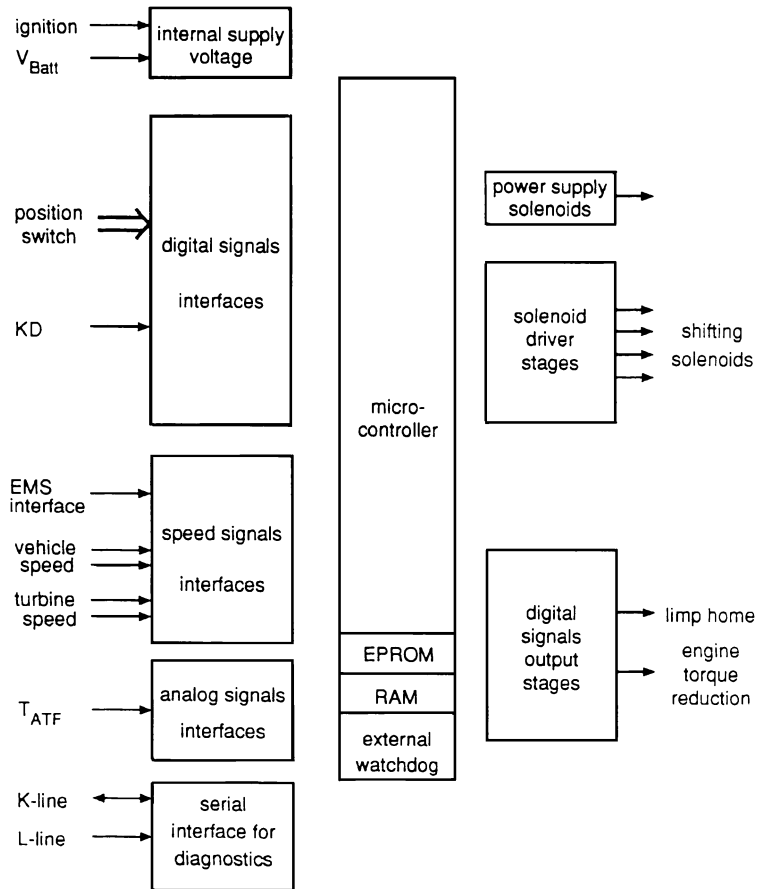

FIGURE 24.2.7 Structure of a basic transmission electronic control unit.

are the throttle position, the accelerator pedal position, and the vehicle speed (determined by the transmission output speed).

Lockup Control/Torque Converter Clutch. The torque converter clutch connects both functional components of the hydraulic converter, the pump and the turbine. The lockup of the clutch reduces the power losses coming from the torque converter slip. To increase the efficiency of the lockup, it is necessary to close the clutch as often as possible but the activation of the lockup is a compromise between low fuel consumption and high driving comfort.

Engine Torque Control During Shifting. The engine torque control requires an interface to an electronic engine management system. The target of the engine torque control, torque reduction during shifting, is to support the synchronization of the transmission and to prevent shift shocks.

Pressure Control. The timing and absolute values of the pressure, which is responsible for the torque translation of the friction elements is aside from the engine torque reduction, the most important influence to shift

comfort. The electronic TCU offers additional possibilities for better function than a conventional hydraulic system. The pressure values during and outside shifting can be calculated by different algorithms or can be determined by characteristic maps. The inputs for a pressure calculation are engine torque, transmission input speed, turbine torque, throttle position, and so on.

Safety and Diagnostic Functions. The functions, which are usually known as diagnostic functions of the electronic TCU, can be divided into real safety functions to prevent critical driving conditions and diagnostic functions that affect an increasing availability of the car and a better failure detection for servicing.

Improvement of Shift Control

Shift Point Control. This basic function can be improved significantly by adding a software function, the so-called adaptive shift point control. This function requires only signals that are available in an electronic TCU with basic functions. The adaptive shift point control is able to prevent an often-criticized attribute, the tendency for shift hunting especially when hill climbing and under heavy load conditions.

Lockup Control. There are some additional functions that can improve considerably the shift comfort of the lockup. In a first step, it is possible to replace the on/off control of the lockup actuator by a pulse control during opening and closing. This can be achieved using conventional hardware only by a software modification. In a further step, the on/off solenoid is replaced by a pressure regulator or a PWM solenoid.

By coordinating intelligent control strategies and corresponding output stages within the electronic TCU, a considerable improvement of the shift behavior of the lockup results.

Engine Torque Reduction During Gear Shifting. By an improved interface design to the engine management system, it is possible to extend the engine torque reduction function. It is necessary to use a PWM signal with related fixed values or a bus interface. The engine torque reduction is controlled directly by the TCU.

Pressure Control. The pressure control can be improved in a similar way as the shift point control with an adaptive software strategy. The required inputs for the adaptive pressure control are calculated from available signals in the transmission control. The main reasons for the implementation of the adaptive pressure control are the variations of the attributes of the transmission components such as clutch surfaces and oil quality as well as the changing engine output torque over the lifetime of the car.

Adaptation to Driver's Behavior and Traffic Situations

In certain driving conditions, some disadvantages of the conventional AT can be prevented by using self-learning strategies. The intention of the self-learning functions is to provide the appropriate shift characteristic suitable to the driver under all driving conditions. Additionally, the behavior of the car under special conditions can be improved by suitable functions. The core of the adaptive strategies is the driver's style detection, which can be detected by monitoring the accelerator pedal movements.

Future Developments

Independent of the type of automatic transmission, the shift or ratio control of the future will be part of a coordinated powertrain management, which, in turn, will be included in an overall control architecture encompassing all electronic systems of a vehicle. In the next years, development work on transmission control will concentrate on improving production costs, reliability, and size and weight, which are relevant to the product success in the market. A fundamental step toward these targets is higher integration of the components of the control system (i.e., combining mechanical, hydraulic, and electronic elements in mechatronic modules).

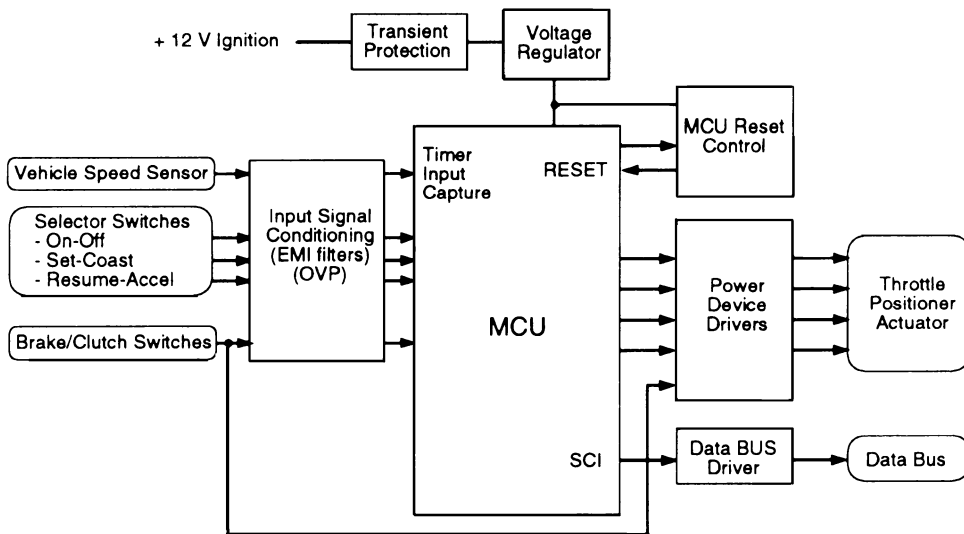

FIGURE 24.2.8 Cruise control system.

CRUISE CONTROL*

A vehicle speed control system can range from a simple throttle-latching device to a sophisticated digital controller that constantly maintains a set speed under varying driving conditions. The next generation of electronic speed control systems will probably still use a separate module (black box), the same as present-day systems, but will share data from the engine, ABS, and transmission control systems. Futuristic cruise control systems that include radar sensors to measure the rate of closure to other vehicles and adjust the speed to maintain a constant distance are possible but need significant cost reductions for widespread private vehicle use.

The objective of an automatic vehicle cruise control is to sustain a steady speed under varying road conditions, thus allowing the vehicle operator to relax from constant foot throttle manipulation. In some cases, the cruise control system may actually improve the vehicle's fuel efficiency value by limiting throttle excursions to small steps. By using the power and speed of a microcontroller device and fuzzy logic software design, an excellent cruise control system can be designed.

The cruise control system is a close-loop speed control as shown in Fig. 24.2.8. The key input signals are the driver's speed setpoint and the vehicle's actual speed. Other important inputs are the faster-accel/slower-coast driver adjustments, resume, on/off, brake switch, and engine control messages. The key output signals are the throttle control servo actuator values. Additional output signals include cruise ON and service indicators, plus messages to the engine and/or transmission control system and possibly data for diagnostics.

The ideal cruise system features would include the following specifications:

- Speed performance: ± 0.5 percent m/h control at less than 5 percent grade, and ± 1 m/h control or vehicle limit over 5 percent grade.
- Reliability: Circuit designed to withstand overvoltage transients, reverse voltages, and power dissipation of components kept to minimum.
- Application options: By changing EEPROM via a simple serial data interface or over the multiplexing network, the cruise software can be upgraded and optimized for specific vehicle types. These provisions allow for various sensors, servos, and speed ranges.

*Valentine, R., "Cruise Control," in *Automotive Electronics Handbook*, 2nd ed., Ronald K. Jurgen (ed.), McGraw-Hill, 1999, pp. 14.1–14.10.

- Driver adaptability: The response time of the cruise control can be adjusted to match the driver's preferences within the constraints of the vehicle's performance.
- Favorable price-to-performance ratio: The use of integrated actuator drivers and a high-functionality MCU reduce component counts, increase reliability, and decrease the cruise control module's footprint.

The MCU for cruise control applications requires high functionality. The MCU would include the following: a precise internal timebase for the speed measurement calculations, A/D inputs, PWM outputs, timer input capture, timer output compares, serial data port (MUX), internal watchdog, EEPROM, and low-power CMOS technology.

Insofar as cruise control software is concerned, the cruise error calculation algorithm can be designed around traditional math models such as PI or fuzzy logic. Fuzzy logic allows somewhat easier implementation of the speed error calculation because its design syntax uses simple linguistics. For example, *if* speed difference is negative and small, *then* increase throttle slightly. The output is then adjusted to slightly increase the throttle. The throttle position update rate is determined by another fuzzy program that looks for the driver's cruise performance request (slow, medium, or fast reaction), the application type (small, medium, or large engine size), and other cruise system factor preset parameters.

ADAPTIVE CRUISE CONTROL*

Adaptive cruise control (ACC) introduces a function to automobiles, which relieves the driver of a significant amount of the task of driving, in a comfortable manner. ACC differs from other vehicle control functions, especially in that the function is performed by several ECUs. While conventional control systems consist of a sensor and actuator environment around a central ECU, ACC adds functions to existing systems. A truly new component is the sensor for measuring the distance, relative speed, and lateral position of potential target vehicles, using laser optics or millimeter waves. This component often contains the logic for controlling vehicle movement. The latter is effected by commands to ECUs for engine and brake control electronics. Existing components are also used or adapted for operator use and display. The example in Fig 24.2.9 shows all basic components of an ACC system as a broad overview.

FIGURE 24.2.9 Basic components for typical adaptive cruise control.

*Winner, H., "Adaptive Cruise Control," in *Automotive Electronics Handbook*, Ronald K. Jurgen, (ed.), McGraw-Hill, 1999, pp. 30.1–30.30.

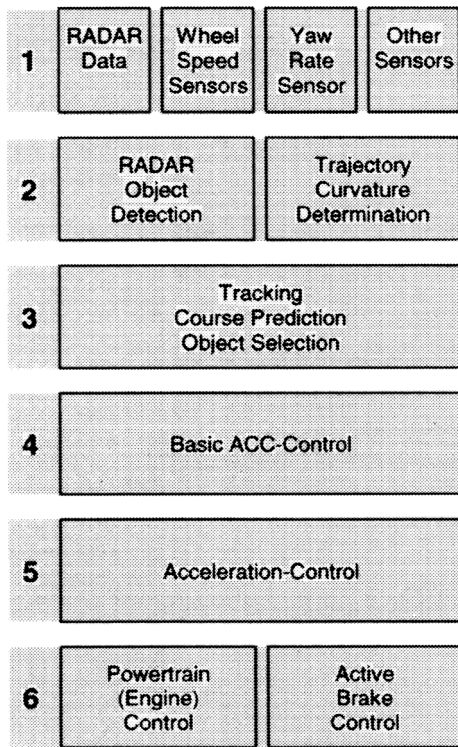

FIGURE 24.2.10 Levels of ACC signal processing and control.

The significant new function of ACC, compared to cruise control, consists of following a preceding vehicle that is being driven slower than the desired speed set by the driver of the ACC vehicle. If the preceding vehicle is being driven at a constant speed, the ACC vehicle follows at the same speed at an approximately constant distance. In general, this distance depends on the speed.

If the sensor's field of view in sharp curves is not sufficient to maintain detection with the target vehicle while following it at an adequate distance, then resumption of set-speed control can be delayed. An additional reason for reducing the acceleration and possibly even the current speed can be to achieve a comfortable reduction in the lateral acceleration while in the curve.

The ACC system, with its ACC sensor for monitoring the environment, and its access to vehicle dynamics variables and driver information systems, provides a good basis for simple collision warning functions.

Currently known ACC designs target use on freeways and other high-speed roads. Extension to urban traffic and to automatic traffic congestion following is desirable, but has not yet been satisfactorily achieved with the technology currently available.

An especially severe limitation of the ACC function is the discrimination of stationary targets. The result of this is that ACC only considers objects for which a minimum speed has been measured (typical values are 20 km/h or 20 percent of the speed of the ACC vehicle). This limitation is necessary not only because of the sensor's limited capabilities, but also because of the control definition.

Signal Processing and Control

Even though it can be assumed that there are as many controller variations as there are ACC development teams, it is still possible to define a common level structure (Fig. 24.2.10) that is valid for most variations.

ACC Sensor

The most elementary task of the ACC sensor is to measure the distance to preceding vehicles in a range that extends from about 2 to 150 m. A maximum allowable error of about 1 m or 5 percent is generally adequate.

The relative speed toward the target vehicle is of special importance for the ACC control cycle, since this variable is much more strongly weighted in the controller. It should be possible to detect all relevant speeds of possible target objects.

Since several targets can be present in the sensor range, multiple target capability is very important. This means especially the capability of distinguishing between relevant objects in the ACC vehicle's lane and irrelevant objects (e.g., in the next lane). This can be achieved by a high capability of distinction of at least one measurement variable (distance, relative speed, or lateral position).

Especially in Japan, infrared laser light sources with wavelengths around $\lambda = 800$ nm are used as ACC sensors. They are often called Lidar (light detection and ranging) or sometimes laser-radar. Their basic element (Fig. 24.2.11) is a laser diode, which is stimulated by a pulse controller to emit short light pulses. Another type of ACC sensor is a millimeter-wave radar sensor operating in the frequency band from 76 to 77 GHz. The use of the Doppler shift for direct determination of the relative speed is a prominent feature of millimeter-wave

FIGURE 24.2.11 Lidar block diagram.

technology. It allows a high separation capability of objects with this variable and delivers the primary control variable for ACC at high quality.

ACC Controller

The basic structure of an ACC controller is shown in Fig. 24.2.12. The first step is to select the relevant preceding vehicle, which is done by comparing the object data with the geometry of the predicted course. Once the target vehicle is selected (several vehicles may be in the range of the predicted course), the required acceleration is calculated based on the distance and the relative speed.

BRAKING CONTROL *

The braking force generated at each wheel of a vehicle during a braking maneuver is a function of the normal force on the wheel and the coefficient of friction between the tire and the road, which is not a constant. It is a function of factors, most prominent being type of road surface and the relative longitudinal slip between the tire

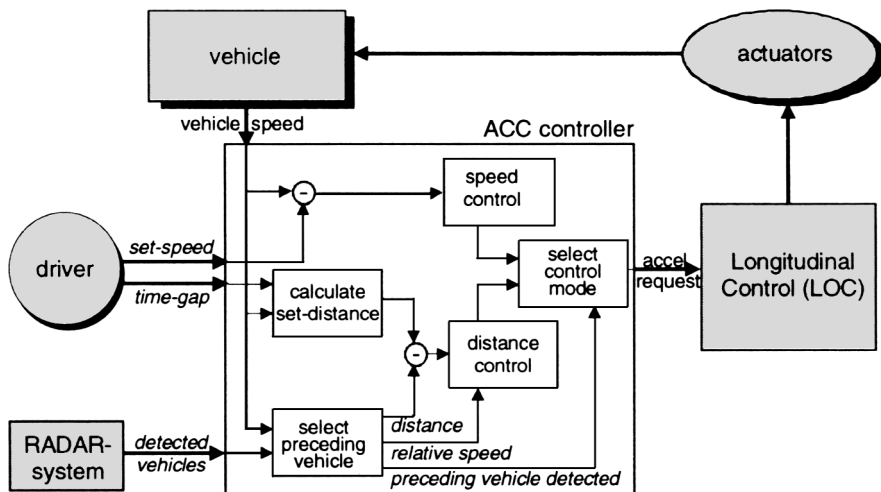

FIGURE 24.2.12 Basic structure of the ACC controller.

*Cage, J. L., "Braking Control," in *Automotive Electronics Handbook*, 2nd ed., Ronald K. Jurgen, (ed.), McGraw-Hill, 1999, pp. 15.1–15.17.

FIGURE 24.2.13 Disk brake schematic.

FIGURE 24.2.14 Drum brake schematic.

and the road. Another characteristic of automotive tires important in braking is lateral force versus slip. Lateral force is the force keeping a tire from sliding in a direction normal to the direction of the vehicle. The lateral coefficient of friction drops off quickly once a wheel begins to slip longitudinally, as can happen during braking. Excessive wheel slip at the rear wheels of a vehicle and the resulting loss of lateral frictional force will contribute to instability as the rear of the vehicle tends to slide sideways with relatively small lateral forces on the vehicle. Excessive wheel slip and the resulting loss of lateral friction force on the front wheels of a vehicle will contribute to loss of steerability.

Brake System Components

Figure 24.2.13 shows a schematic of a disc brake. In this type of brake, force is applied equally to both sides of a rotor and braking action is achieved through the frictional action of inboard and outboard brake pads against the rotor. Figure 24.2.14 depicts a schematic diagram of a drum brake. In drum brakes, force is applied to a pair of brake shoes in a variety of configurations.

In addition to the brakes, other brake system components include a booster and master cylinder, and a proportioning valve.

Antilock Systems

Although antilock concepts have been known for decades, widespread use of antilock (also called antiskid and ABS) began in the 1980s with systems developed with digital microprocessors/microcontrollers replacing the earlier analog units. A conventional antilock system consists of a hydraulic modulator and hydraulic power source that may or may not be integrated with the system master cylinder and booster, wheel speed sensors, and an ECU. The fundamental function of an antilock system is to prohibit wheel lock by sensing impending wheel lock and taking action through the hydraulic modulator to reduce the brake pressure in the wheel sufficiently to bring the wheel speed back to the slip level range necessary for near-optimum braking performance.

Antilock components include wheel speed sensors, hydraulic modulators, electric motor/pump, and an ECU (Fig. 24.2.15).

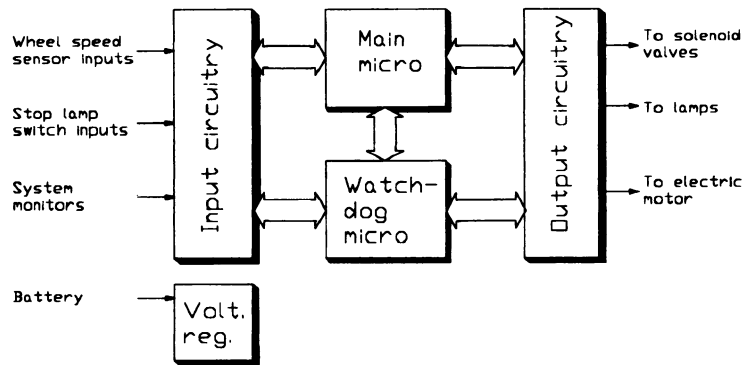

FIGURE 24.2.15 Electronic control unit block diagram.

Future Vehicle Braking Systems

A number of trends are developing relative to future vehicle braking systems. Some of the prominent ones are as follows:

- The expanding use of multiplexing
- Vehicle dynamics control during nonbraking as well as braking maneuvers
- Collision-avoidance systems
- Regenerative braking in electric vehicles
- Brake-assist systems
- Electrohydraulic brake by wire
- Electric actuators

TRACTION CONTROL*

Traction control systems or ASRs designed to prevent the drive wheels from spinning in response to application of excess throttle have been on the market since 1987. Vehicles with powerful engines are particularly susceptible to drive-wheel slip under acceleration from standstill and/or on low-traction road surfaces. The results include attenuated steering response on front-wheel-drive (FWD) vehicles, diminished vehicle stability on rear-wheel-drive (RWD) cars, and both on four-wheel-drive (4WD) cars—depending on their concept.

One technique for optimizing traction is to apply braking force to the spinning wheel. A second option is the application of fixed, variable, or controlled differential-slip limitation mechanisms. These provide fixed coupling to ensure equal slippage rates at the drive wheels, thereby allowing them to develop maximum accelerative force.

System Arrangements

The demand on the reaction time from the intervention up to the effect at the driven wheels depends on the drive concept. Different philosophies of the optimization of driving stability, traction, and comfort (and also the costs of the setting element) bring about the existence of different ASR system arrangements. Table 24.2.2 shows different types of engine interventions and their setting elements. Figure 24.2.16 shows an ASR system overview.

*Sauter, T., "Traction Control," in *Automotive Electronics Handbook*, 2nd ed., Ronald K. Jurgen (ed.), McGraw-Hill, 1999, pp. 16.1–16.19.

TABLE 24.2.2 Different Types of Engine Intervention

Type of intervention	Setting element
Airflow control	Electronic throttle control (ETC)
Fuel-injection suppression	Ignition and fuel-injection unit (MOTRONIC)
Spark retard	Ignition and fuel-injection unit (MOTRONIC)

Control Algorithm

The wheel velocities are determined by the speed sensors in the ABS/ASR control unit. If the drive wheels spin as a result of too high engine torque, the ASR determines a transferable moment, which corresponds to the friction coefficient and which is transferred by a data bus to the engine control unit. Meanwhile the spinning wheels are decelerated by the ASR hydraulic unit. By the reduction of engine torque, which can either be effected by closing the throttle valve or by injection suppression and spark retard, wheel slip is limited to such a degree that the lateral forces can be transferred again and the vehicle gets stabilized.

By the influence of the transmission control with vehicles with automatic transmissions, additional safety can be obtained, for example, by early shifting into a higher gear or by preventing downshifting when cornering. Figure 24.2.17 demonstrates the interaction of different ECUs and setting elements of a traction control system.

STABILITY CONTROL*

Driving a car at the physical limit of adhesion between the tires and the road is an extremely difficult task. Most drivers with average skills cannot handle those situations and will lose control of the vehicle. Several solutions for the control of vehicle maneuverability in physical-limit situations have been published.

**FIGURE 24.2.16** ASR system overview.

*Van Zanten, A., Erhardt, R. Landesfeind, K., and Pfaff, G., "Stability Control," in *Automotive Electronics Handbook*, 2nd ed., Ronald K. Jurgen (ed.), McGraw-Hill, 1999, pp. 17.1–17.33.

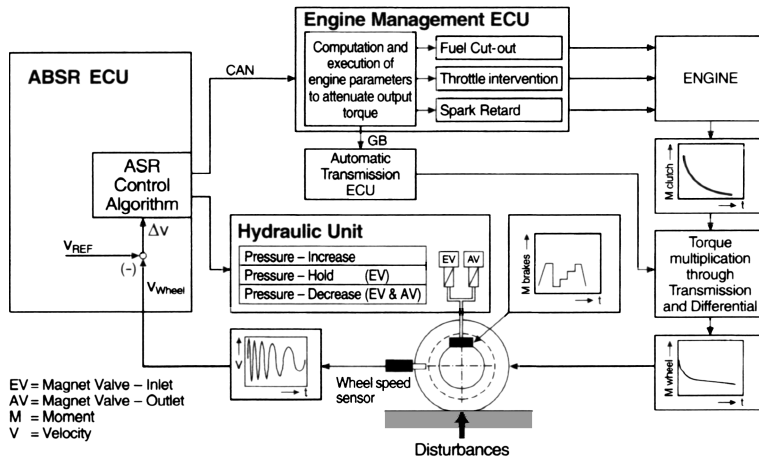

FIGURE 24.2.17 ASR control loop.

Physical Concept

Since the nominal trajectory desired by the driver is unknown, the driver’s inputs are taken to obtain nominal state variables that describe the desired vehicle motion instead. These inputs are the steering wheel angle, the engine drive torque as derived from the accelerator pedal position, and the brake pressure. To determine which state variables describe the desired motion best, a special situation is taken (Fig. 24.2.18). In this illustration a vehicle is shown negotiating a turn after a step input in the steering angle. The lower curve shows the path the vehicle will follow if its lateral acceleration is smaller than the coefficient of friction of the road for the given tires. In this case the vehicle follows the nominal motion. If the road is slippery, with a coefficient of friction smaller than the nominal lateral acceleration, the vehicle will not follow the nominal value and the radius of the turn will become larger than that of the nominal motion.

FIGURE 24.2.18 VDC versus yaw rate control.

angle of the vehicle increases rapidly as is shown by the upper curve in Fig. 24.2.18. Therefore both the yaw rate and the slip angle of the vehicle must be limited to values that correspond to the coefficient of friction of the road. For this reason in the Bosch vehicle dynamics control (VDC) system, both the yaw rate and the vehicle slip angle are taken as the nominal state variables and thus as the controlled variables. The result is shown by the curve in the middle of Fig. 24.2.18. It requires the installation of a yaw rate sensor and a lateral acceleration sensor.

One of the basic state variables that describe the lateral motion of the vehicle is its yaw rate. It therefore seems reasonable to design a control system that makes the yaw rate of the vehicle equal to the yaw rate of the nominal motion (yaw rate control). If this control is used on the slippery road, the lateral acceleration and the yaw rate will not correspond to each other as they do during the nominal motion. The slip

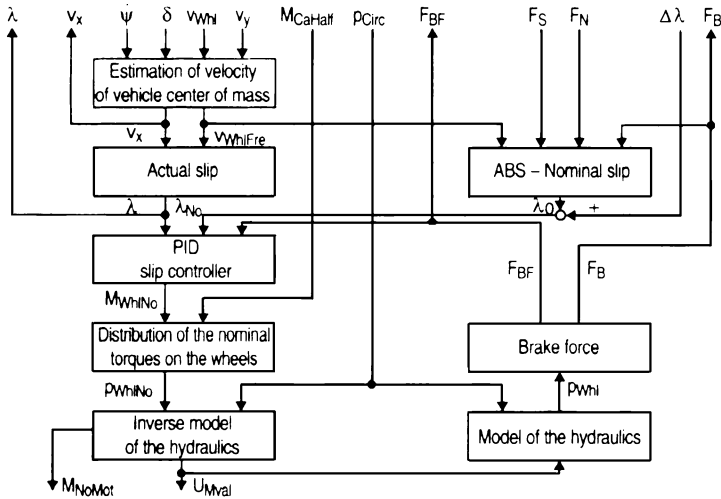

FIGURE 24.2.19 Brake slip controller.

Control Concept

From the driver’s inputs, measured by a steering wheel angle sensor, a throttle position sensor, and a brake pressure sensor, the nominal behavior as described by the nominal values of the controlled variables must be determined. From the signal values of the wheel speed sensors, the yaw rate sensor, and the lateral acceleration sensor, the actual behavior of the vehicle as described by the actual values of its controlled variables is determined. The difference between the nominal and the actual behavior is then used as the set of actuating signals of the VDC.

The Slip Controller. The slip controller consists of two parts—the brake slip controller (Fig. 24.2.19) and the drive slip controller (Fig. 24.2.20). Depending on which slip controller is used, different nominal variables are passed by the VDC to the slip controller. The drive slip controller is used only for the slip control of the driven wheels during driving. Otherwise the brake slip controller is used.

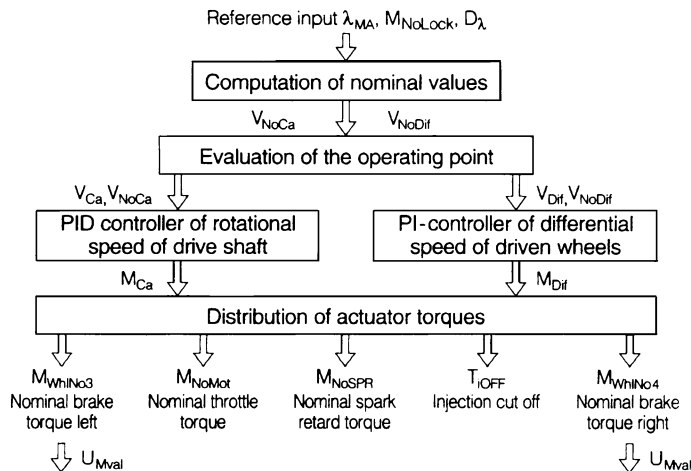

FIGURE 24.2.20 Drive slip controller.

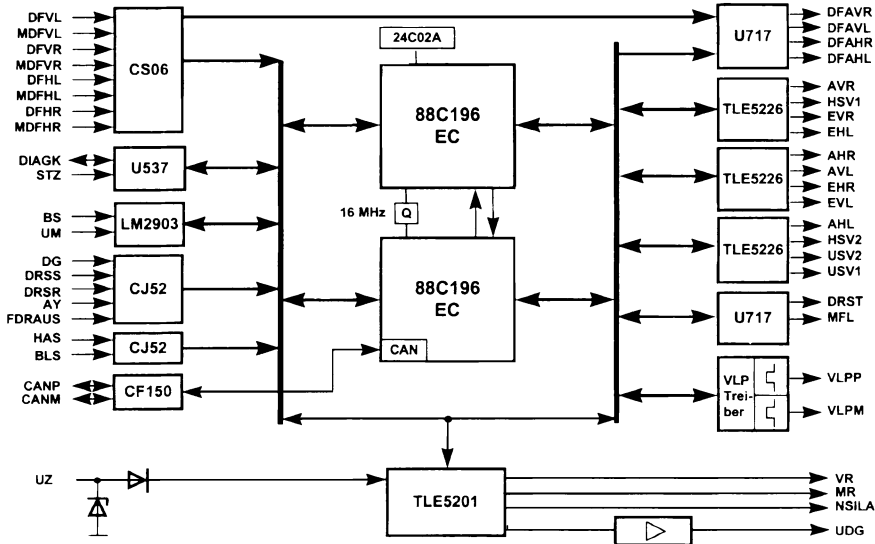

FIGURE 24.2.21 Block diagram of a typical ECU for VDC.

Electronic Control Units

There are two different types of ECUs. One is attached to the hydraulic unit and the other is separated from it. Figure 24.2.21 shows a typical separated ECU.

SUSPENSION CONTROL*

The function of a suspension system in an automobile is to improve ride comfort and stability. An important consideration in suspension design is how to obtain both improved ride comfort and stability, since they are normally in conflict. Advances in electronic control technology, applied to the automobile, can resolve this conflict.

Shock Absorber Control System

There are three main parts of a damping control system: a damping control device (actuator), sensors, and software (control strategy). Optimum damping forces should be set for various running conditions in order to improve ride comfort and handling stability. One damping control system configuration is shown in Fig. 24.2.22. It uses five sensors to detect running conditions: vehicle speed sensor, steering angle sensor, acceleration and deceleration sensor, a brake sensor, and a supersonic sensor to detect road conditions. Control signals are sent to adjust the damping force of the variable shock absorbers to optimum values.

Hydropneumatic Suspension Control System

A hermetically sealed quantity of gas is used in the hydropneumatic suspension control system. The gas and hydraulic oil are separated by a rubber diaphragm (Fig. 24.2.23). The mechanical springs are replaced by gas. The shock absorber damping mechanism is achieved by the orifice fitted with valves.

*Yohsuke, A., "Suspension Control," in *Automotive Electronics Handbook*, 2nd ed., Ronald K. Jurgen (ed.), McGraw-Hill, 1999, pp. 18.1–18.19.

FIGURE 24.2.22 Principal components of a damping control system.

Electronic Leveling Control System

An electronic leveling control system (Fig. 24.2.24) permits a low spring rate to achieve good ride comfort independent of load conditions, an increase in vehicle body height on rough road surfaces, and a changing spring rate and damping force in accordance with driving conditions and road surfaces.

Active Suspension

An active suspension (Fig. 24.2.25) is one where energy is supplied constantly to the suspension and the force generated by that energy is continuously controlled. The suspension incorporates various types of sensors and a unit for processing their signals that generate forces that are a function of the signal outputs.

FIGURE 24.2.23 (a) Hydropneumatic suspension system; (b) Controllable hydropneumatic suspension system.

STEERING CONTROL*

Electronically Controlled Power Steering

Electronically controlled power steering improves steering feel and power-saving effectiveness and increases steering performance. It does so with control mechanisms that reduce the steering effort. An electronic control system, for example, may be added to the hydraulic booster or the whole system may be composed of electronic and electric components.

The intent of electronic controls, initially, was to reduce the steering effort when driving at low speeds and to supply feedback for the appropriate steering reaction force when driving at high speeds. In order to achieve these goals, devices such as vehicle speed sensors were used to detect vehicle speed in order to make smooth and continuous changes in the steering assist rate under conditions ranging from steering maneuvers at zero speed to those at high speeds. However, as vehicles became equipped with electrohydraulic systems and fully electronic and electric systems, the emphasis for these systems started to include reduction in power requirements and higher performance.

The main functions required for electronically controlled power steering are listed in Table 24.2.3 and the various types of electronically controlled power systems are given in Table 24.2.4.

Electric power steering is a fully electric system, which reduces the amount of steering effort by directly applying the output from an electric motor to the steering system. This system consists of vehicle speed sensors, a steering sensor (torque, angular velocity), an ECU, a drive unit, and a motor (Fig. 24.2.26).

Hybrid systems use a flow control method in which the hydraulic power steering pump is driven by an electric motor. The steering effort is controlled by controlling the rotating speed of the pump (discharge flow).

Four-Wheel Steering Systems (4WS)

For vehicles with extremely long wheel bases and vehicles that need to be operated in narrow places, the concept of a four-wheel steering system is attractive. In such systems, the rear wheels are turned in the opposite direction to the steering direction of the front wheels in order to make the turning radius as small as possible and to improve the handling ability. Four-wheel steering systems that are currently being implemented in vehicles are classified according to their functions and mechanisms. The aims and characteristics of each system are briefly explained in Tables 24.2.5 and 24.2.6.

OBJECT DETECTION, COLLISION WARNING, COLLISION AVOIDANCE*

Although object detection and collision-avoidance systems may still be regarded as being in their infancy, their perceived value in enhancing safety and reducing accidents is high. Two categories of systems are currently available or under development: passive collision-warning systems and active collision-avoidance systems. A passive system will detect a hazard and alert the driver to risks, whereas an active system will detect the hazard and then take preventive action to avoid a collision. Both types require object detection. The only difference between them is in how a collision-diverting event is actuated following object detection—by the driver or automatically.

Development engineers are proceeding cautiously with active-collision work. Any systems that take control of the brakes (and, in the future, steering) from the driver are potential sources of litigation, particularly in North America. Standards and federal regulations will emerge during the next few years that will cover such systems.

Active and Passive Systems

A passive collision-warning system (Fig. 24.2.27) includes a visual and/or audible warning signaled to the driver, but there is no intervention to avoid a collision. An active collision-warning system (Fig. 24.2.28) interacts with the powertrain, braking, and even the steering systems with the objective of sensing objects that present a collision risk with the host vehicle, then taking preventative measures to avoid an accident.

The most essential element in both passive and active systems is the object detection system. A key difference between the object detection systems used in active and passive systems is that the active system will require more accurate object recognition, so as to prevent collision-avoidance maneuvers against objects such as road signs.

Vehicular Systems

There are three types of warning systems: front, rear, and side. Frontal systems, both active and passive, operate on the same principles of object detection. There are different techniques used for obstacle detection.

TABLE 24.2.6 Four-Wheel Steering Systems: Mechanisms and Features

Classification by mechanism	Feature
Full mechanical system	Simple mechanism
Electronic-hydraulic system	High degree for control freedom (compact actuator)
Electronic-mechanical-hydraulic system	High degree of freedom (mechanism is not simple)
Full electric system (electronic-electric system)	High degree of control freedom simple mechanism

*Bannatyne, R., "Object Detection, Collision Warning, Collision Avoidance," in *Automotive Electronics Handbook*, 2nd ed., Ronald K. Jurgen (ed.), McGraw-Hill, 1999, pp. 29.3–29.22.

FIGURE 24.2.27 Passive collision-warning system.

FIGURE 24.2.28 Active collision-warning system.

The main approaches are a scanning laser radar sensor, a frequency modulated constant wavelength (FMCW), or a video camera used in conjunction with an algorithm that will detect hazardous objects. This detection system is usually mounted at the front of the host vehicle to detect objects in the vehicle's forward path. Other techniques may involve a combination of different sensors, including backup sensors.

To be a hazardous obstacle, the target must lie in the corridor or the intended path for the host vehicle (Fig. 24.2.29).

Rear warning systems can use shorter-range, often nonscanning sensors to provide close-range sensing for parking assist capability, or scanning radar for more advanced sensing capability. Some systems use a combination of both types of sensors.

Side-warning systems use radar sensors to detect objects in the traditional blind spots that are often responsible for causing accidents. The sensors are mounted in the rear quarter area of the vehicle and detect objects in adjacent lanes.

An active collision-avoidance system interacts with other vehicle systems, as well as providing a warning (usually via the audio system and perhaps a head-up display). The most critical system with which it interacts is the braking system. A simplified algorithm that senses hazards and adjusts brake pressure accordingly is shown in Fig. 24.2.30.

Future Systems

A fully equipped, high-end system, such as that shown in Fig. 24.2.31, would support an advanced system such as the automated highway. The collision-avoidance electronic control unit is at the center of the diagram. The frontal vehicular detection system features two sensors: a 77-GHz FMCW and a camera system. Data from both of these sources are fused to map out a reliable picture of the potential hazards.

FIGURE 24.2.29 Trajectory corridor.

FIGURE 24.2.30 Object detection system with braking system interaction.

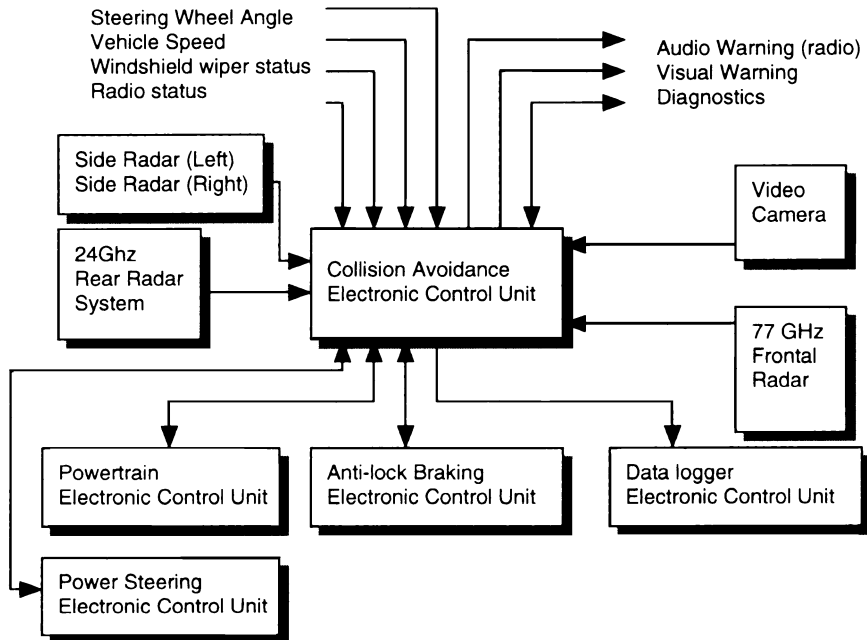

FIGURE 24.2.31 Complete "high-end" collision-avoidance system.

NAVIGATION AIDS AND DRIVER INFORMATION SYSTEMS*

Navigation aids and driver information systems provide various combinations of communicated, stored, and derived information to aid drivers in effectively planning and executing trips. Navigation aids and driver information systems are a major subset of advanced traveler information systems, which, in turn, are a subset of intelligent transportation systems (ITS) as discussed in Chap. 25.3.

Automobile Navigation Technologies

Positioning technologies are fundamental requirements of both vehicle navigation systems and vehicle tracking systems. Almost all current vehicular navigation systems include a global positioning system (GPS) receiver, and most also include dead reckoning with map matching.

Map matching as well as route guidance must be supported by digital road maps. Another important supporting technology is mobile data communications for traffic and other traveler information.

Radiopositioning. Radiopositioning is based on processing special signals from one or more radio transmitters at known locations to determine the position of the receiving equipment. Although a number of radiopositioning technologies are potentially applicable, satellite-based GPS is by far the most popular. GPS, which is operated by the U.S. Department of Defense, includes 24 satellites spaced in orbits such that a receiver can determine its position by simultaneously analyzing the travel time of signals from at least four satellites.

Proximity beacons provide another form of radiopositioning, which is used in some vehicle navigation systems, particularly those that also use proximity beacons for communications purposes. Proximity beacons are installed at key intersections and other strategic roadside locations that communicate their location and/or other information to receivers in passing vehicles via very short-range radio, microwave, or infrared signals. The reception of a proximity beacon signal means that the receiving vehicle is within 50 m or so of the beacon, and provides an occasional basis for confirming vehicle position.

Dead Reckoning. Dead reckoning, the process of calculating location by integrating measured increments of distance and direction of travel relative to a known location, is used in virtually all vehicle navigation systems. Dead reckoning gives a vehicle's coordinates relative to earlier coordinates. Distance measurements are usually made with an electronic version of the odometer. Electronic odometers provide discrete signals from a rotating shaft or wheel, and a conversion factor is applied to obtain the incremental distance associated with each signal. Vehicle heading may be measured directly with a magnetic compass, or indirectly by keeping track of heading relative to an initial heading by accumulating incremental changes in heading.

Digital Road Maps. The two basic approaches to digitizing maps are matrix encoding and vector encoding. A matrix-encoded map is essentially a digitized image in which each image element or pixel, as determined by an X - Y grid with arbitrary spacing, is defined by digital data-giving characteristics such as shade or color. The vector-encoding approach applies mathematical modeling concepts to represent geometrical features such as roadways and boundaries in abstract form with a minimum of data. By considering each road or street as a series of straight lines and each intersection as a node, a map may be viewed as a set of interrelated nodes, lines, and enclosed areas.

Map Matching. Map matching is a type of artificial intelligence process used in virtually all vehicle navigation and route guidance systems that recognize a vehicle's location by matching the pattern of its apparent

*French, R. L., and Krakivsky, E. J., "Navigation Aids and Driver Information Systems," in *Automotive Electronics Handbook*, Ronald K. Jurgen (ed.), McGraw-Hill, 1999, pp. 31.1–31.15.

FIGURE 24.2.32 Typical components and subsystems of vehicle navigation system.

path (as approximated by dead reckoning and/or radiopositioning) with the road patterns of digital maps stored in computer memory. Most map-matching software may be classified as either semideterministic or probabilistic.

Navigation Systems

Figure 24.2.32 is a block diagram showing the major elements of a typical automobile navigation system. Distance and heading (or heading change) sensors are almost invariably included for dead-reckoning calculations, which, in combination with map matching, form the basic platform for keeping track of vehicle location. However, dead reckoning with map matching has the drawback of occasionally failing due to dead-reckoning anomalies, extensive travel off mapped roads, ferry crossings, and so forth.

The “location sensor” indicated by dashed lines in Fig. 24.2.32 is an optional means of providing absolute location to avoid occasional manual reinitialization when dead reckoning with map matching fails. Although proximity beacons serve to update vehicle location in a few systems, almost all state-of-the-art systems used GPS receivers instead.

CHAPTER 24.3

INTELLIGENT TRANSPORTATION SYSTEMS*

Ronald K. Jurgen

INTRODUCTION

Intelligent transportation systems (ITS) is an umbrella term that covers the application of a wide variety of communication, positioning, sensing, control, and other information-related technologies to improve the efficiency, safety, and environmental aspects of surface transportation. Major categories of ITS include advanced traffic management systems, advanced public transportation systems, advanced traveler information systems, advanced vehicle safety systems, and commercial vehicle operations.

The U.S. National ITS Architecture was developed under a three-year program funded by the U.S. Department of Transportation (DOT) that included a parallel consensus-building effort with industry and local governments. The architecture provides a consistent basis for establishing standards and assuring ITS interoperability throughout the country. To this end, ITS installations by state and local governments using federal funding are required by legislation to be consistent with the National Architecture.

Table 24.3.1 gives a comprehensive list of ITS user services that are candidates for an emerging ISO standard based in part on program information from many countries around the world. Although the level of emphasis for individual user services may vary greatly from country to country, generally similar ITS user services are defined in the United States, Europe, and Asia.

Table 24.3.2 gives a brief statement of the function of each of the 29 user services originally defined by the National ITS Program Plan developed jointly by DOT and ITS America.

SYSTEM ARCHITECTURE

The system architecture identifies necessary subsystems, defines the functions to be performed by each subsystem, and identifies the data that must flow among them, thus providing a consistent basis for system design. In particular, it defines the input, output, and functional requirements of several hundred individual processes required for implementing ITS. More important, the architecture defines the intricate interconnections required among the myriad subsystems in order to synergistically integrate ITS services ranging from advanced traffic management, which has already been implanted extensively, to future automated highway systems. It is important to understand,

however, that the architecture is neither a design nor a set of physical specifications. Instead the architecture provides a basis for developing standards and protocols required for exchanging data among subsystems.

Logical Architecture

The logical architecture presents a functional interpretation of the ITS user services, which is divorced from likely implementations and physical interface requirements. In particular, it defines all functions (called process specifications) necessary to perform the user services and indicates the data flows required among these functions.

Physical Architecture

The physical architecture identifies the physical subsystems and the architecture flows between subsystems that implement the processes and support the data flows of the logical architecture. It assigns processes from the logical architecture to each of the subsystems and defines the data flows between the subsystems based on the data exchange implied by the process specifications. The physical architecture consists of the four top-level categories of subsystems shown in Fig. 24.3.1.

TABLE 24.3.2 Functions of ITS User Services

User service	Function
En route driver information	Provides driver advisories and in-vehicle signing for convenience and safety
Route guidance	Provides travelers with simple instructions on how to best reach their destinations
Traveler information services	Provides a business directory of “yellow pages” containing service information
Traffic control	Manages the movement of traffic on streets and highways
Incident management	Helps public and private organizations identify incidents quickly and implement a response to minimize their effects on traffic
Emissions testing and mitigation	Provides information for monitoring air quality and developing air quality improvement strategies
Demand management and operations	Supports policies and regulations designed to mitigate the environmental and social impacts of traffic congestion
Pretrip travel information	Provides information for selecting the best transportation mode, departure time, and route
Ride matching and reservation	Makes ride sharing easier and more convenient
Public transportation	Automates operations, planning, and management functions of public transit systems
En route transit information	Provides information to travelers using public transportation after they begin their trips
Personalized public transit	Provides flexibility-routed transit vehicles to offer more convenient customer service
Public travel security	Creates a secure environment for public transportation patrons and operators
Electronic payment services	Allows travelers to pay for transportation services electronically
Commercial vehicle electronic clearance	Facilitates domestic and international border clearance, minimizing stops
Automated roadside safety inspections	Facilitates roadside inspections
Onboard safety monitoring	Senses the safety status of a commercial vehicle, cargo, and driver
Commercial vehicle administration	Provides electronic purchasing of credentials and automated mileage and fuel reporting and auditing
Hazardous material incident response	Provides immediate description of hazardous materials to emergency responders
Freight mobility	Provides communication between drivers, dispatchers, and intermodal transportation providers
Emergency notification	Provides immediate notification of an incident and an immediate request for assistance
Emergency vehicle management	Reduces the time needed for emergency vehicles to respond to an incident
Longitudinal collision avoidance	Helps prevent head-on, rear-end, or backing collisions between vehicles, or between vehicles and objects or pedestrians
Lateral collision avoidance	Helps prevent collisions when vehicles leave their lane of travel
Intersection collision avoidance	Helps prevent collisions at intersections
Vision enhancement for crash avoidance	Improves the driver’s ability to see the roadway and objects that are on or along the roadway
Safety readiness	Provides warnings about the conditions of the driver, the vehicle, and the roadway
Preocrash restraint deployment	Anticipates an imminent collision and activates passenger safety systems before the collision occurs, or much earlier in the crash event than would otherwise be feasible
Automated highway systems	Provide a fully automated, hands-off operating environment

FUTURE DIRECTIONS

A new DOT initiative in 1998 is the Intelligent Vehicle Initiative (IVI). The objective of the IVI is to improve significantly the safety and efficiency of motor vehicle operations by reducing the probability of crashes. To accomplish this, the IVI will accelerate the development, availability, and use of driving-assistance and control-intervention systems to reduce deaths, injuries, property damage, and the societal loss that results from motor vehicle crashes. These systems include provisions for warning drivers, recommending control

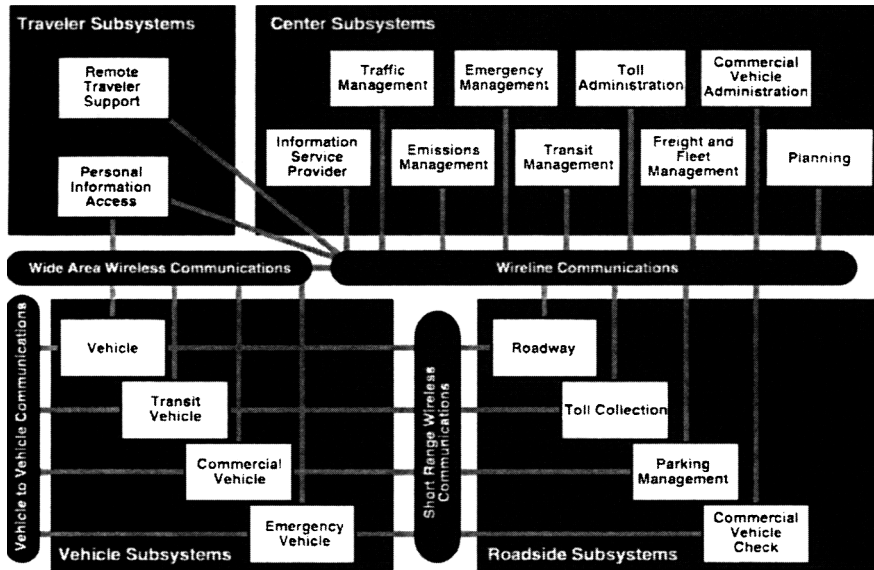

FIGURE 24.3.1 National ITS architecture for the United States.

actions, intervening with driver control, and introducing temporary or partial automated control of the vehicle in hazardous situations.

The improve safety category includes nine candidate IVI services: rear-end collision avoidance, road departure collision avoidance, lane-change and merge collision avoidance, intersection collision avoidance, railroad crossing collision avoidance, vision enhancement, location-specific alert and warning, automatic collision notification, and smart restraints and occupant protection systems.

The safety impacting category includes four services: navigation/routing, real-time traffic and traveler information, driver comfort and convenience, and vehicle stability warning and assistance.

SECTION 25

INSTRUMENTATION AND TEST SYSTEMS

The increasing importance of instrumentation in all phases of design, development, manufacture, deployment, and maintenance of electronic systems has prompted us to add this entirely new section to this edition of the handbook. It complements Sec. 15, Measurement Circuits, but deals with the instruments themselves and how they are used.

The first two chapters are devoted to instruments for measuring basic parameters: current, voltage, frequency, and time. Chapter 25.3 covers signal sources, and Chap. 25.4 logic analyzers.

Arguably the most powerful instrument, the oscilloscope, is treated in some detail in Chap. 25.5. During its 60-year history, it has been constantly improved in performance and sophistication.

Chapter 25.6 deals with reconfigurable instruments. One example would be configuring a portable ground support test system for military avionics from VXI modules configured in a dual-rack structure. Finally, the embedment of sensor- and computer-based instrumentation into complex systems can enable the implementation of self-repair concepts.

The editors wish to thank Stephen E. Grossman, a consultant to Agilent Technologies, for his invaluable assistance in organizing this section. C.A.

CHAPTER 25.1

INSTRUMENTS FOR MEASURING FREQUENCY AND TIME*

Rex Chappell

INTRODUCTION

For measurements of frequency, time interval, phase, event counting, and many other related signal parameters, the ideal instrument to use is an electronic counter or its cousin, the frequency and time-interval analyzer. These instruments offer high precision and analysis for research and development applications, high throughput for manufacturing applications, and low cost and portability for service applications.

Electronic counters come in a variety of forms (Fig. 25.1.1).

FREQUENCY COUNTERS

The earliest *electronic counters* were used to count such things as atomic events. Before counters were invented, frequency measurement was accomplished with a frequency meter, a tuned device with low accuracy. *Frequency counters* were among the first instruments to digitally measure a signal parameter, yielding a more precise measurement. Today, they are still among the most precise instruments. Characterizing transmitters and receivers is the most common application for a frequency counter. The transmitter's frequency must be verified and calibrated to comply with government regulations. The frequency counter can measure the output frequency as well as key internal points, such as the local oscillator, to be sure that the radio meets specifications.

Other applications for the frequency counter can be found in the computer world where high-performance clocks are used in data communications, microprocessors, and displays. Lower-performance applications include measuring electromechanical events and switching power-supply frequencies.

UNIVERSAL COUNTERS

Electronic counters can offer more than just a frequency measurement. When it offers a few simple additional functions, such as period (the reciprocal of frequency), the instrument is sometimes known as a *multifunction*

*Adapted from Chapter 19, "Electronic Instrument Handbook," 3rd ed., Clyde Coombs Jr. (ed.), McGraw-Hill, 1999.

25.4 INSTRUMENTATION AND TEST SYSTEMS

FIGURE 25.1.1 Frequency counters have become the most commonly employed instrument for measuring frequencies. The counter shown here is the Agilent Technologies 53131A with 10-digit resolution, 20-mV sensitivity, and frequency coverage up to 225 MHz.

counter. When two-channel functions, such as time interval, are provided, the instrument is usually called a *universal counter*. This name reflects this instrument's wide variety of applications. Several measurement functions provided by universal counters are shown in Fig. 25.1.2.

Time interval measures the elapsed time between a start signal and a stop signal. The start signal is usually fed into one channel (A), while the stop signal is fed into a second channel (B). The function is often called time interval A to B. The resolution of the measurement is usually 100 ns or better, depending on the *time interpolators* employed. Applications range from the measurement of propagation delays in logic circuits to the measurement of the speed of golf balls.

Variations of time interval that are particularly useful for digital circuit measurements are pulse width, rise time, and fall time. And, if the trigger points are known for rise and fall time, a calculation of the slew rate (volts-per-second) can be displayed. In all of these measurements the trigger levels are set automatically by the counter.

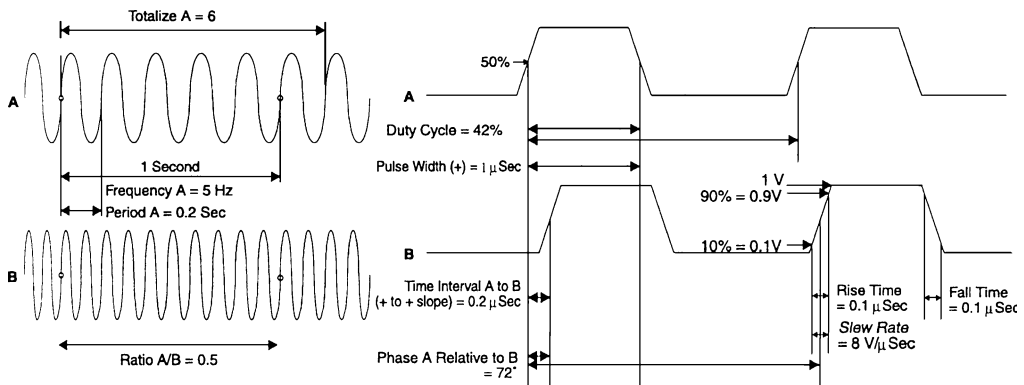

FIGURE 25.1.2 Several measurements that a universal counter can make. The A and B refer to the channels of the arriving signals. Frequency counters often have just one input channel, but universal counters need two for performing timing and signal comparison measurements.

Time interval average is a function that yields more resolution and can be used to filter out jitter in signals. *Totalize* is the simple counting of events. It is useful for counting electronic or physical events, or where a digitized answer is needed for an automated test application. The counter accumulates and displays event counts while the gate is open. In some instruments, this function is called *count*.

Frequency ratio A/B compares the ratio between two frequencies. It can be used to test the performance of a frequency doubler or a prescaler (frequency divider).

Phase A relative to B compares the phase delay between two signals with similar frequencies. The answer is usually displayed in degrees. Some instruments display only positive phase, but it is more convenient to allow a display range of $\pm 180^\circ$, or 0° to 360° .

CW MICROWAVE COUNTERS

Continuous wave (CW) microwave counters are employed for frequency measurements in the microwave bands. Applications include calibrating the local oscillator and the transmitting frequencies in a microwave communication link. These counters can measure 20 GHz and higher. They offer relatively good resolution, down to 1 Hz, in a short measurement time. This makes them popular for manufacturing test applications. Their low cost and high accuracy, relative to a spectrum analyzer, make them popular for service applications. Some microwave counters also include the ability to measure power. This is a typical measurement parameter in service applications.

FREQUENCY AND TIME-INTERVAL ANALYZERS

Modern applications, particularly those driven by digital architectures, often have more complex measurement requirements than those satisfied by a counter. These measurements are often of the same basic parameters of frequency, time, and phase—but with the added element of being variable over time. For example, digital radios often modulate either frequency or phase. In *frequency shift keying* (FSK), one frequency represents a logic “0” and another frequency represents a “1.” It is sometimes necessary to view frequency shifts in a frequency-versus-time graph. A class of instruments called *frequency and time-interval analyzers* (FTIA) can be used for this measurement. An FTIA provides a display that is similar to the output of a frequency discriminator displayed on an oscilloscope, but with much greater precision and accuracy (Fig. 25.1.3). This type of instrument is also referred to as a *modulation domain analyzer*. Other applications to which an FTIA can be applied include voltage-controlled oscillator (VCO) analysis, phase lock loop (PLL) analysis, and the tracking of frequency agile or hopping systems.

A variation of the frequency and time-interval analyzer simply measures time. These are called *time-interval analyzers* (TIA), and they tend to be focused on data and clock jitter applications. These are generally a subset of an FTIA, although some may offer special arming and analysis features tuned to particular applications, such as testing the read/write channel timing in hard-disk drives.

SPECIFICATIONS AND SIGNIFICANCE

Product data sheets and manuals often provide fairly detailed specifications. This section covers how to interpret some of the more important specifications.

Universal Counter Specifications

Many of the specifications found in a universal counter data sheet will also be found in other types of counters and analyzers.

FIGURE 25.13 The display of a frequency-shift-keyed digital radio signal on a frequency and time-interval analyzer. Although it resembles an oscilloscope display, it is actually showing frequency vs. time, not voltage vs. time. The two frequencies, representing 0 and 1, are about 33 kHz apart. Each bit is about 15 μ s long.

Sensitivity and Bandwidth. *Sensitivity* refers to how small a signal the instrument can measure. It is usually given in mV rms and peak-to-peak (p-p) values. In RF and microwave counters, it is given in dBm. Because of the element of noise and the broadband nature of a counter's front end, the sensitivity is rarely better than 10 mV rms or 30 mV p-p.

For frequency measurements, the sensitivity can be important if measuring a signal off the air with an antenna. Under most situations, however, there is sufficient signal strength to measure, and sensitivity is not an issue.

The counter's front-end *bandwidth* is not always the same as the counter's ability to measure frequency. If the bandwidth is lower than the top frequency range, the sensitivity at the higher frequencies will be reduced. This is not necessarily a problem if there is enough signal strength at the frequencies being measured. For timing measurements, however, bandwidth can affect accuracy. An input channel with a low front-end bandwidth can restrict the minimum pulse width of the signal it can measure, and, for very precise measurements, it can distort the signal. So, if precise timing measurements are being made, it is best to get a counter with as high a bandwidth as possible.

Resolution. Counters are commonly used because they can provide reasonably good resolution in a quick, affordable way. This makes resolution an important specification to understand. As will be seen, frequency measurement resolution is one of the specifications most dependent on the instrument's architecture.

The older *basic counter* architecture is still used in very low-cost counters and in some DVMs, oscilloscopes, and spectrum analyzers that include a frequency or time function. This architecture has the advantages of a simple low-cost design and rapid measurement, but has lower resolution and reduced measurement flexibility. For example, frequency resolution is limited, particularly for low frequencies, where resolution greater than 1 Hz is desired (assuming measurement times greater than 1 s are impractical).

The basic counter was invented well before digital logic was able to economically perform an arithmetic division. Division is needed because a general way of calculating frequency is to divide the number of periods (called *events*) counted by the time it took to count them ($events/time = frequency$). The basic counter accomplishes the division by restricting the denominator (time) to decade values. After it became practical to perform a full division, the instrument no longer had to be restricted to decade gate times. More importantly, the time base could be synchronized to the input signal and not the other way around. This means that the resolution of the measurement

can be tied to the time base (usually time-interpolated) and not to the input frequency. This particularly improves the measurement of low frequencies (see Fig. 25.1.4). This class of instrument is called a *reciprocal counter*.

Microwave Counter Specifications

A few specifications are unique to microwave counters, and some of the most common are covered here.

FIGURE 25.1.4 Frequency resolution of a reciprocal counter with 1-ns interpolators vs. a basic counter, given a 1-s gate time. The reciprocal counter has the advantage of a constant number of digits of display, no matter what the input frequency.

down-converter-type counter is realized, but this may not be a problem if advanced interpolators are used. Prescaling to 12.4 GHz is available in some counters today.

Power. Some microwave counters have the ability to measure the signal's power. This is useful for checking to see if a transmitter is within specifications or for finding faults in the cabling or connectors. Two main methods are used—true rms and detectors. The former produces much better accuracy, down to 0.1 dB, and the latter is less expensive, but has an accuracy of around 1.5 dB.

Frequency and Time Interval Analyzer Specifications

Although many specifications are similar to those found in a counter, two are unique and need some explanation.

Sample Rate. Also called *measurement rate*, this is how rapidly the instrument can make measurements. The speed needed depends on the phenomenon being measured. For example, to measure the 5-MHz jitter bandwidth of a clock circuit, the instrument must sample at 10 MHz (or faster). Sample rates in the 1-MHz range are good for moderate data-rate communications, VCO testing, and electromechanical measurements. Sample rates of 10 MHz (and higher) are better for high data-rate communications, data storage, and radar applications.

Memory Depth. Memory depth for storing the digitized data is the other important instrument parameter. Some applications only need a short amount of memory to take a look at transient signals, such as the step response of a VCO. Other applications need a very deep memory, where probably the most extreme is the surveillance of unknown signals.

Acquisition Time. Because of the way that most microwave counters operate, using a harmonic sampler technique or a YIG preselector, a time lapse is required to determine where in the spectrum the signal is. This is called *acquisition time*. This is usually in the 50 to 250 ms range. YIG-based counters generally exhibit longer acquisition times. If there is a general idea of where the signal already is, some counters work in a manual acquisition mode. The counter then skips the acquisition phase of the measurement and makes the measurement after properly positioning the LO to the manually specified area, taking less time (< 20 ms).

FM Tolerance. This is largely determined by the IF bandwidth of the counter or the bandwidth of the preselector. If the input signal's FM *deviation* is such that the signal occasionally falls outside of these bandwidths, the measurement will be in error. Also, because the IF or preselector is seldom exactly centered on the signal, a margin is accounted for that narrows the FM tolerance of the instrument.

Counters that use prescaler technology do not have a problem with FM tolerance—or with acquisition time—for that matter. The trade-off is that some loss of resolution compared with a

CHAPTER 25.2

INSTRUMENTS FOR MEASURING CURRENT, VOLTAGE, AND RESISTANCE

Scott Stever

INTRODUCTION

Voltage, and current, both ac and dc, and resistance are quantities commonly measured by electronic instruments. In the simplest case, each measurement type is performed by an individual instrument—a voltmeter measures voltage, an ammeter measures current, and an ohmmeter measures resistance. These instruments have many elements in common. The more classical, *electromechanical meters* are the easiest-to-use instrument for performing these measurements. A *multimeter* combines these instruments, and sometimes others, together into a single, general-purpose multifunction instrument.

Categories of Meters

There are two primary types of meters—*general purpose* and *specialty*. General-purpose meters measure several types of electrical parameters such as voltage, resistance, and current. A *digital multimeter* (DMM) is an example of a general-purpose meter (Fig. 25.2.1). Specialty meters are generally optimized to measure a single parameter very well, emphasizing either measurement accuracy, bandwidth, or sensitivity. Listed in Table 25.2.1 are various types of meters and their measuring capabilities.

The general-purpose multimeter is a flexible cost-effective solution. It is most suitable for most common measurements. Although DMMs can achieve performance rivaling the range and sensitivity of specialty meters while delivering superior flexibility and value, the presence of many display digits on a digital meter does not automatically mean that the meter has high accuracy. Meters often display significantly more digits of resolution than their accuracy specifications support. This can be very misleading to the uninformed user.

General Instrument Block Diagram

The function of a meter is to convert an analog signal into a human- or machine-readable equivalent. Analog signals may be quantities such as a voltage or current, ac or dc, or a resistance. Shown in Fig. 25.2.2 is a block diagram of a typical signal-conditioning process used with meters.

FIGURE 25.2.1 Multimeters are obtainable with varying degrees of resolutions and accuracies. Shown here are the Agilent Technologies 34401A, 34420A, and 3458A Digital Multimeters. They provide resolutions of $6\frac{1}{2}$, $7\frac{1}{2}$, and $8\frac{1}{2}$ digits, respectively, along with corresponding increases in accuracy on both their voltage and resistance measurement ranges.

Signal Conditioning, Ranging, and Amplification

The input signal must first pass through some type of signal conditioner that typically comprises switching, ranging, and amplification circuits, as shown in Fig. 25.2.2. If the input signal to be measured is a dc voltage, the signal conditioner may be composed of an attenuator for the higher voltage ranges and a dc amplifier for the lower ranges, whereas if the signal is an ac voltage, a converter is employed to change the ac signal to its equivalent dc value. Resistance measurements are performed by supplying a known dc current to an unknown resistance, thereby converting the unknown resistance value to an easily measurable dc voltage. In nearly all cases, the input signal switching and ranging circuits, along with the amplifier circuits, convert the unknown quantity to a dc voltage that falls within the measuring range of the analog-to-digital converter (ADC).

TABLE 25.2.1 Meters—Types and Features

Type of meter	Multi-function	Measuring range	Frequency range	Speed, max readings/second	Best accuracy	Digits
<i>General Purpose</i>						
Handheld DMM	Y	10 μ V–1000 V; 1 nA–10 A; 10 m Ω –50 M Ω	20 Hz–20 kHz	2	0.1%	$3\frac{1}{2}$ – $4\frac{1}{2}$
Bench DMM	Y	10 μ V–1000 V; 1 nA–10 A; 10 m Ω –50 M Ω	20 Hz–100 kHz	10	0.01%	$3\frac{1}{2}$ – $4\frac{1}{2}$
System DMM	Y	10 nV–1000 V; 1 pA–1 A; 10 μ Ω –1 G Ω	1 Hz–10 MHz	50–100,000	0.0001%	$4\frac{1}{2}$ – $8\frac{1}{2}$
<i>Specialty</i>						
ac Voltmeter	N	100 μ V–300 V	20 Hz–20 MHz	1–10	0.1%	$3\frac{1}{2}$ – $4\frac{1}{2}$
Nanovoltmeter	N	1 nV–100 V		1–100	0.005%	$3\frac{1}{2}$ – $7\frac{1}{2}$
Picoammeter	N	10 fA–10 mA		1–100	0.05%	$3\frac{1}{2}$ – $5\frac{1}{2}$
Electrometer	pA, high Ω	1 Ω –100 M Ω				
Microohmmeter	N			1–100	0.05%	$3\frac{1}{2}$ – $4\frac{1}{2}$
High resistance	N	>10 T Ω		1–10	0.05%	$3\frac{1}{2}$ – $4\frac{1}{2}$

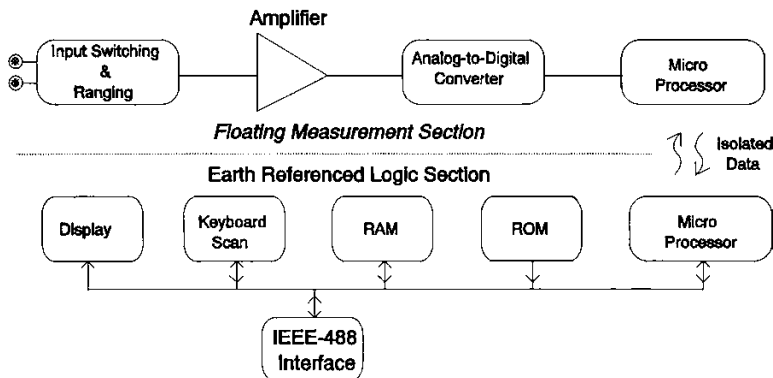

FIGURE 25.2.2 Generalized block diagram of most modern meters.

Analog-to-Digital Conversion

The role of the ADC is to transform a prescaled dc voltage into digits. For example, the ADC for a $6\frac{1}{2}$ digit resolution (21-bit) instrument is capable of producing over 2.4-million unique reading values. You can think of this as a bar chart with 2.4 million vertical bars with each bar increasing in size from the previous bar by an identical amount. Converting the essentially infinite resolution of the analog input signal to a single bar in our chart is the sole function of the ADC. However, the continuum of analog input values is partitioned—quantized—into 2.4-million discrete values in our example.

The ADC used in a meter governs some of its most basic characteristics. These include its measurement resolution, its speed, and in some cases, its ability to reject spurious noise. The various methods used for analog-to-digital conversion can be divided into two groups—*integrating* and *nonintegrating*. Integrating techniques measure the average input value over a relatively long interval, while nonintegrating techniques sample the instantaneous value of the input—plus noise—during a very short interval.

ADCs are designed strictly for dc voltage inputs. They are single-range devices with some exhibiting a 3-V full-scale input, while others have a 12-V full-scale input. For this reason, the input switching and ranging circuits must attenuate higher voltages and amplify lower voltages to enable the meter to provide a selection of ranges.

Managing the Flow of Information

The first three blocks in Fig. 25.2.2 combine to produce a meter's overall analog performance characteristics—measuring functions, ranges, sensitivity, reading resolution, and reading speed. The two microprocessor blocks manage the flow of information within the instrument, ensuring that the various subsystems are properly configured and that internal computations are performed in a systematic and repeatable manner. Convenience features such as automatic range selection are managed by these microprocessors. Electrical isolation is provided between the earth-referenced outside world and sensitive measuring circuits. The earth-referenced microprocessor also acts as a communications interpreter, receiving keyboard and programming instructions and managing the outward flow of data to the display, or the IEEE-488 computer interface.

DC Voltage Measurement Techniques

Signal conditioning and analog-to-digital conversion circuits have the greatest influence on the characteristics of a dc meter. The ADC measures over only a single range of dc voltage and it usually exhibits a relatively low input resistance. To configure a useful dc meter, a *front end* is required to condition the input before

the analog-to-digital conversion. Signal conditioning increases the input resistance, amplifies small signals, and attenuates large signals to produce a selection of measuring ranges.

Signal Conditioning for DC Measurements

Input signal conditioning for dc voltage measurements includes both amplification and attenuation. Shown in Fig. 25.2.3 is a typical configuration for a dc input switching and ranging section of a meter. The input signal is applied directly to the amplifier input through switches K_1 and S_1 for lower voltage inputs—generally those less than 12 V dc. For higher voltages, the input signal is connected through relay K_2 to a precision 100:1 divider network formed by resistors R_4 and R_5 . The low voltage output of the divider is switched to the amplifier input through switch S_2 .

The gain of amplifier A_1 is set to scale the input voltage to the full-scale range of the ADC, generally 0 ± 12 V dc. If the nominal full-scale input to the ADC is 10 V dc, the dc input attenuator and amplifier would be configured to amplify the 100-mV range by 100 times and to amplify the 1-V range by 10 times. The input amplifier would be configured for unity gain, $X1$, for the 10-V measuring range. For the upper ranges, the input voltage is first divided by 100, and then gain is applied to scale the input back to 10 V for the ADC—inside the meter, for instance, 100 V dc is reduced to 1 V dc for the amplifier, whereas 1000 V dc is divided down to become 10 V dc.

For the lower voltage measuring ranges, the meter's input resistance is essentially that of amplifier A_1 . The input amplifier usually employs a low bias current—typically less than 50 pA. It is often an FET input stage providing an input resistance greater than 10 G Ω . The meter's input resistance is determined by the total resistance of the 100:1 divider for the upper voltage ranges. Most meters provide a 10-M Ω input resistance for these ranges.

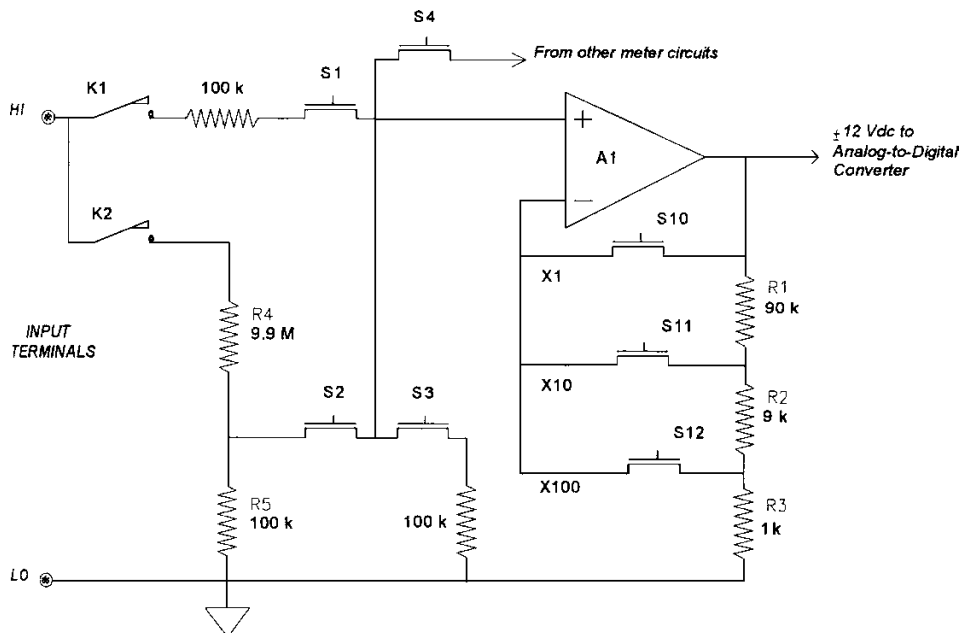

FIGURE 25.2.3 Simplified schematic of the input switching, measuring range selection, and amplifier for a dc voltage meter.

Amplifier Offset Elimination (Autozero)

The main performance limitation of the dc signal-conditioning section is usually its offset voltage. This affects the meter's ability to read zero volts with a short applied. Most meters employ some method for automatically zeroing out amplifier offsets. Switch S_3 in Fig. 25.2.3 is used to periodically *short* the amplifier input to ground to measure the amplifier offset voltage. The measured offset is stored and then subtracted from the input signal measurement to remove amplifier offset errors. Switches S_1 and S_2 are opened simultaneously during the offset measurement to avoid shorting the meter's input terminals together.

In a multifunction instrument, all measurements are eventually converted into a dc voltage, which is measured by an ADC. Other dc signals are often routed to the ADC through a dc voltage measuring front end. Switch S_4 in Fig. 25.2.3 could be used to measure the dc output of an ac voltage function or a dc current measuring section.

AC VOLTAGE MEASUREMENT TECHNIQUES

The main purpose of an ac front end is to change an incoming ac voltage into a dc voltage that can be measured by the meter's ADC. The type of ac voltage to dc voltage converter employed in a meter is quite critical. There are vast differences in behavior between rms, average-responding, and peak-responding converters.

Signal Conditioning for AC Measurements

The input signal conditioning for ac voltage measurements includes both attenuation and amplification, similar to the dc voltage front end already discussed. Shown in Fig. 25.2.4 are typical input switching and ranging circuits for an ac-voltage instrument. Input-coupling-capacitor C_1 blocks the dc portion of the input signal so

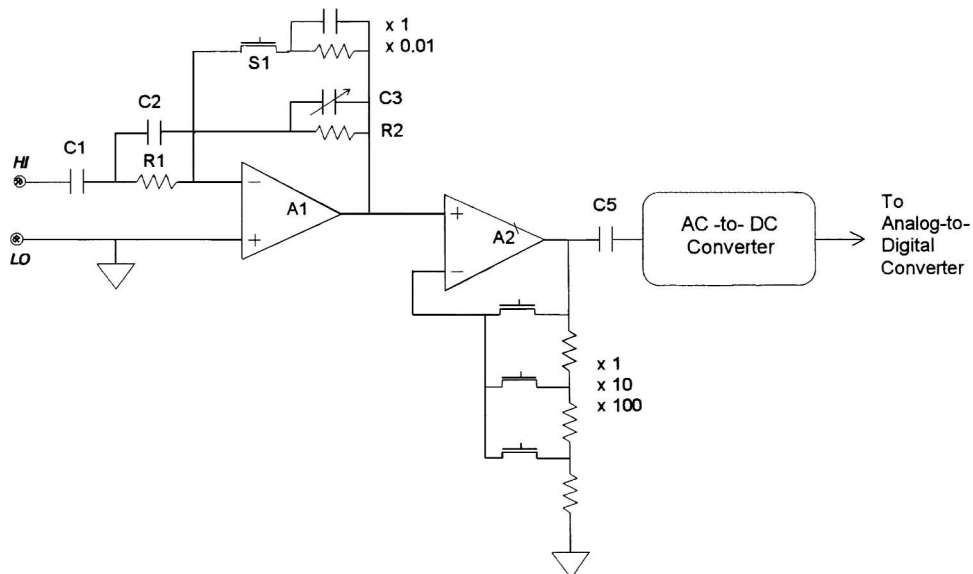

FIGURE 25.2.4 The input switching and ranging sections of a typical ac voltage measurement section—simplified schematic.

that only the ac component is measured by the meter. Ranging is accomplished by combining signal attenuation from first-stage amplifier A_1 and gain from second-stage amplifier A_2 .

The first stage implements a high input impedance—typically 1-M Ω switchable compensated attenuator. The value of capacitor C_3 is adjusted so that the R_2C_3 time constant precisely matches the R_1C_2 time constant, yielding a compensated attenuator in which the division ratio does not vary with frequency. Switch S_1 is used to select greater attenuation for the higher input voltage ranges. The second stage provides variable-gain, wide-bandwidth signal amplification to scale the input to the ac converter to the full-scale level. The output of the second stage is connected to the ac converter circuit. Residual dc offset from the attenuator and amplifier stages is blocked by capacitor C_5 .

An ac-voltage front end, similar to the one discussed above, is also used in ac-current-measuring instruments. Shunt resistors are used to convert the ac current into a measurable ac voltage. Current shunts are switched to provide selectable ac current ranges.

Amplifier bandwidth and ac converter limitations are the main differences between various ac front ends. As mentioned earlier, the type of ac-to-dc converter circuit has a profound effect on overall measurement accuracy and repeatability. True rms converters are superior to both *average responding* and *peak-responding* ac converters in almost every application.

CURRENT MEASUREMENT TECHNIQUES

An ammeter measures the current flowing through it, while approximating a short circuit between its terminals. A conventional ammeter is connected in series with the circuit or device being measured so that current flows through both the meter and the test circuit. There are two basic techniques for making current measurements: *in-circuit methods* and *magnetic field sensing methods*.

In-Circuit Methods

In-circuit current sensing meters employ either a *current shunt* or *virtual ground amplifier* technique, similar to those shown in Fig. 25.2.5a and b. Shunt-type meters are very simple. A resistor R_S , shown in Fig. 25.2.5a, is connected across the input terminals so that a voltage drop proportional to the input current is developed. The value of R_S is kept as low as possible to minimize the instrument's *burden voltage*, or *IR* drop. This voltage drop is sensed by an internal voltmeter and scaled to the proper current value.

Virtual-ground-type meters are generally better suited for measuring smaller current values—usually 100 mA to below 1 pA. These meters rely on low-noise, low-bias-current operational amplifiers to convert the input current to a measurable voltage, as illustrated in Fig. 25.2.5b. Negligible input current flows into the negative input terminal of the amplifier. Therefore the input current is forced to flow through the amplifier's feedback resistor R_f , causing the amplifier output voltage to vary by IR_f . The meter burden voltage, which is the voltage drop from input to LO, is maintained near 0 V by the high-gain amplifier forming a *virtual ground*. Since the amplifier must source or sink the input current, the virtual ground technique is generally limited to low current measurements.

Magnetic Field Sensing Methods

Current measurements employing magnetic field sensing techniques are extremely convenient. The reason is that measurements can be performed without interrupting the circuit or producing significant loading errors. Since there is no direct contact with the circuit being measured, complete dc isolation is also ensured. These meters use a transducer—usually a *current transformer* or *solid-state Hall-effect sensor*—to convert the magnetic field surrounding a current-carrying conductor into an ac or dc value that is proportional. Sensitivity can be very good, since simply placing several loops of the current-carrying conductor through the probe aperture will increase the measured signal level by the same factor as the number of turns.

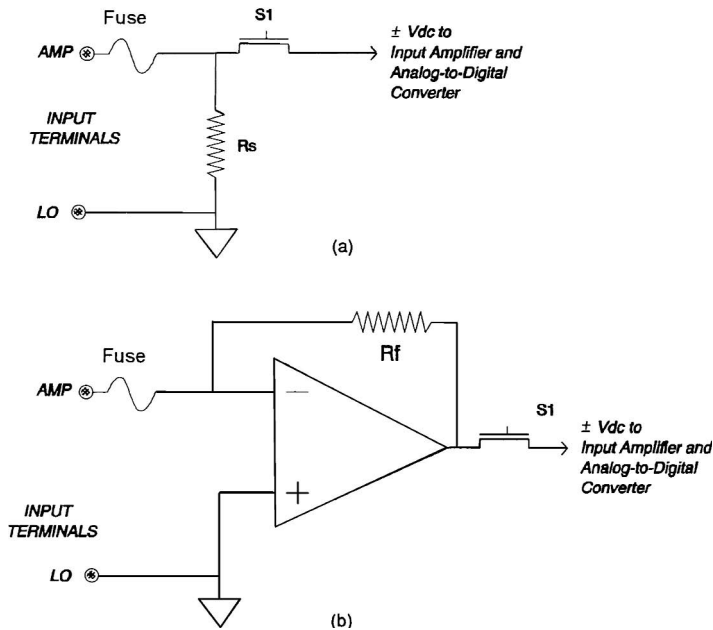

FIGURE 25.2.5 Two common methods for in-circuit current measurements. (a) Shunt resistor R_s is connected across the input terminals, developing a voltage proportional to the input current. (b) The input current is forced to flow through R_f , while the meter burden voltage is limited to the drop across the fuse and the amplifier offset voltage.

Alternating Current

Alternating current measurements are very similar to dc measurements. However, ac measurements employ *shunt-type current-to-voltage converters* almost exclusively. The output of the current-to-voltage sensor is measured by an ac voltmeter. Signal and ac converter issues discussed in “AC Voltage Measurement Techniques” are relevant to ac measurements as well. The input terminals of in-circuit ac meters are always direct coupled—ac + dc coupled—to the shunt so that the meter maintains dc continuity in the test circuit. The meter’s internal ac voltmeter section can be either ac coupled or ac + dc coupled to the current-to-voltage converter.

RESISTANCE MEASUREMENT TECHNIQUES

An ohmmeter measures the dc resistance of a device or circuit connected to its input. Resistance measurements are performed by supplying a known dc to an unknown resistance, thereby converting the resistance value to an easily measured dc voltage. Most meters use an *ohms converter* technique similar to the current source or voltage ratio types shown in Fig. 25.2.6.

Signal Conditioning for Resistance Measurements

The current-source method shown in Fig. 25.2.6a employs a known current source value I that flows through the unknown resistor when it is connected to the meter’s input. This produces a dc voltage proportional to the unknown resistor value: by Ohm’s law, $E = IR$. Thus dc voltmeter input-ranging and signal-conditioning circuits

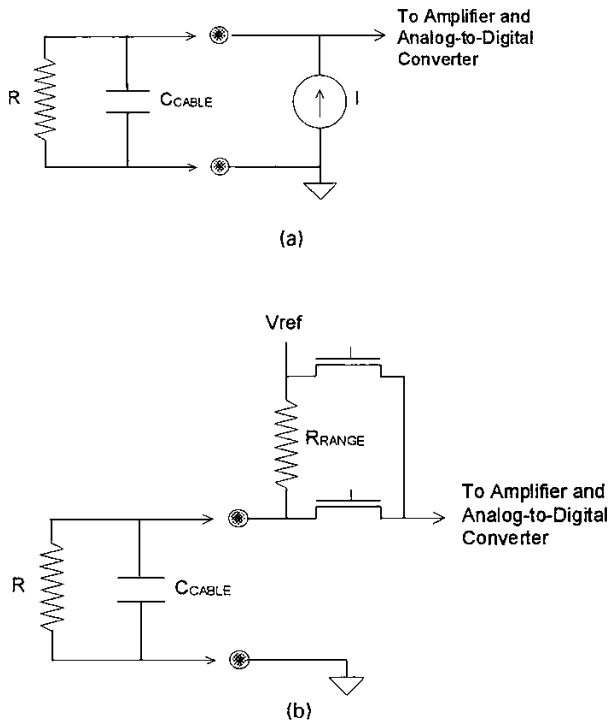

FIGURE 25.2.6 Ohms converter circuits used in meters. (a) The current-source ohms converter employs a constant current source, forcing current I through unknown resistance R , developing a voltage to be measured by a dc voltage front end. (b) The voltage-ratio type ohms converter calculates the unknown resistor value R from dc voltage measurements in a voltage divider circuit.

are used to measure the voltage developed across the resistor. The result is scaled to read directly in ohms. Shown in Fig. 25.2.6b is the *voltage-ratio-type* ohms converter technique.

This method uses a known voltage source V_{ref} and a known *range* resistor R_{range} to compute the unknown resistor value. The range resistor and the unknown resistor form a simple voltage divider circuit. The meter measures the dc voltage developed across the unknown resistor. This voltage, along with the values of the internal voltage source and range resistor, is used to calculate the unknown resistor value. In practice, meters have a variety of resistance-measuring ranges. To achieve this, the ohms test current—or range resistor—is varied to scale the resulting dc voltage to a convenient internal level, usually between 0.1 and 10 V dc. This measurement is relatively insensitive to lead resistances R_l in the high-impedance input of the dc voltmeter. Voltage drops in the current source leads do not affect the voltmeter measurement. However, they can affect the accuracy of the current source itself.

Two-Wire Sensing

The ohms converters discussed above use *two-wire sensing*. When the same meter terminals are used to measure the voltage dropped across the unknown resistor as are used to supply the test current, a meter is said to use a two-wire ohms technique. With two-wire sensing, the lead resistances R_l shown in Fig. 25.2.7a, are indistinguishable from the unknown resistor value, causing potentially large measurement errors for lower-value resistance measurements.

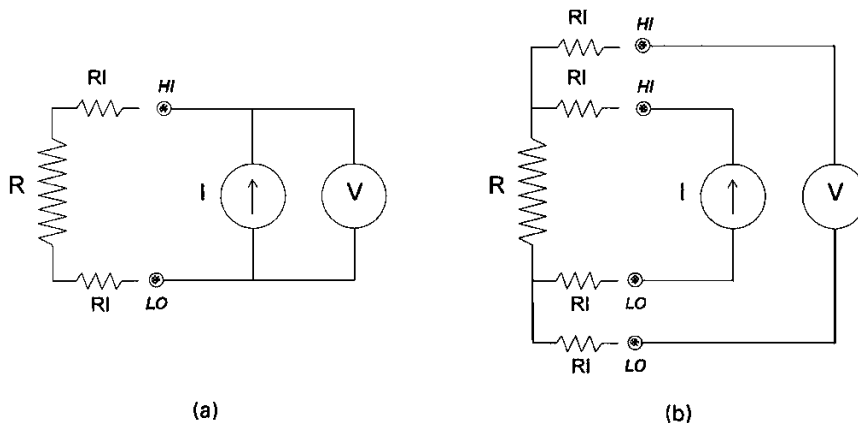

FIGURE 25.2.7 (a) Simplified schematic for two-wire sensing. Lead resistances R_l are inseparable from the unknown resistance measurement. (b) Simplified schematic for four-wire sensing.

The two-wire technique is widely used by all types of ohmmeters because of its simplicity. Often, meters provide a *relative* or *null* math function to allow lead resistances to be measured and subtracted from voltage, current, and resistance-measuring instruments' subsequent resistance measurements. This works well unless the lead resistances vary due to temperature or connection integrity. The *four-wire sensing* technique, or *Kelvin sensing*, is designed to eliminate lead resistance errors.

Four-Wire Sensing

The four-wire sensed-resistance technique is the most accurate way to measure small resistances. Lead resistances and contact resistances are virtually eliminated using this technique. A four-wire converter senses the voltage drop across only the unknown resistor. The voltage drops across the lead resistances are excluded from measurement, as shown in Fig. 25.2.7b.

The four-wire converter employs two separate pairs of connections to the unknown resistor. One connection pair, often referred to as the *source leads*, supplies the test current that flows through the unknown resistor, similar to the two-wire measurement case. Voltage drops are still developed across the source lead resistances.

A second connection pair, referred to as the *sense leads*, connects directly across the unknown resistor. These leads connect to the input of a dc voltmeter. The dc voltmeter section is designed to exhibit an extremely large input resistance so that virtually no current flows in the sense input leads. This enables the meter to measure only the voltage drop across the unknown resistor. This scheme thereby removes from the measured voltage, the drops in both the source leads and the sense leads.

Generally, lead resistances are limited by the meter manufacturer. There are two main reasons for this. First, the total voltage drop in the source leads will be limited by the design of the meter and is usually limited to a fraction of the meter measuring range being used. Second, the sense lead resistances will introduce additional measurement noise if they are allowed to become too large. Sense leads less than 1 k Ω usually will contribute negligible additional error.

The four-wire technique is widely used in situations where lead resistances can become quite large and variable. It is used almost exclusively for measuring lower resistor values in any application, especially for measuring values of 10 Ω or less. It is also used in automated test applications where cable lengths can be quite long and numerous connections or switches may exist between the meter and the device under test. In a multichannel system, the four-wire method has the obvious disadvantage of requiring twice as many switches and twice as many wires as the two-wire technique.

CHAPTER 25.3

SIGNAL SOURCES

Tomas Fetter

INTRODUCTION

The simplest useful definition for a *signal* is an electrical voltage (or current) that varies with time. To characterize a signal, an intuitive yet accurate concept is to define the signal's waveform. A waveform is easy to visualize by imagining the picture a pen, moving up and down in proportion to the signal voltage, would draw on a strip of paper being steadily pulled at right angles to the pen's movement. Shown in Fig. 25.3.1 is a typical periodic waveform and its dimensions. A *signal source*, or *signal generator*, is an electronic instrument that generates a signal according to the user's commands with regard to its waveform (Fig. 25.3.2). Signal sources serve the frequent need in engineering and scientific work for energizing a circuit or system with a signal whose characteristics are known.

KINDS OF SIGNAL WAVEFORMS

Most signals fall into one of two broad categories—*periodic* and *nonperiodic*. Signal source instruments generate one or the other, and sometimes both. A periodic signal has a waveshape, which is repetitive: the pen, after drawing one period of the signal waveform, is in the same vertical position where it began, and then it repeats exactly the same drawing. A sine wave is the best-known periodic signal. By contrast, a nonperiodic signal has a nonrepetitive waveform. The best-known nonperiodic signal is random noise.

The familiar sinusoid, illustrated in Fig. 25.3.3, is the workhorse signal of electricity. The simple mathematical representation of a sine wave can be examined to determine the properties that characterize it:

$$s(t) = A \sin(2\pi ft)$$

where s = represents the signal, a function of time

t = time, s

A = peak amplitude of the signal, V or A

f = signal frequency, cycles/second (Hz)

HOW PERIODIC SIGNALS ARE GENERATED

Introduction

Periodic signals are generated by *oscillators*. Some signal generators use the waveform produced directly by an oscillator. However, many signal generators combine a number of different techniques to increase the

FIGURE 25.3.1 Waveform of an active typical period signal.

generator's performance and capabilities. Key performance attributes include frequency range, frequency accuracy, amplitude accuracy, frequency switching speed, types of waveforms produced, and various modes of signal modulation.

Oscillators

Electronic oscillators are the basic building blocks of signal generators. Any oscillator circuit fits into one of these broad categories:

- AC amplifier with filtered feedback
- Threshold decision circuit

FIGURE 25.3.2 Today's signal generators must meet demanding specifications, including accuracy, spectral purity, and low phase noise. This Agilent Technologies 4422B Signal Generator covers 225 kHz to 4 GHz and can be tailored to meet changing requirements as technologies evolve.

FIGURE 25.3.3 A typical sine wave.

Feedback Oscillators

The feedback technique is historically the original, and still the most common form of oscillator circuit. Shown in Fig. 25.3.4 are the bare essentials needed for the feedback oscillator. The output from the amplifier is applied to a frequency-sensitive filter network. The output of the network is then connected to the input of the amplifier. Under certain conditions, the amplifier output signal, passing through the filter network, emerges as a signal, which, if supplied to the amplifier input produces the output signal. Because of the feedback connection, the circuit is capable of sustaining a particular output signal indefinitely. This is, in fact, an oscillator. The circuit combination of the amplifier and the filter is called a feedback loop. To understand how the combination can oscillate, mentally break open the loop at the input to the amplifier; this is called the open-loop condition. The open loop begins at the amplifier input and ends at the filter output. Here are the particular criteria that the open loop must satisfy in order that the closed loop will generate a sustained signal at some frequency f_0 :

1. The power gain through the open loop (amplifier power gain times filter power loss) must be unity at f_0 .
2. The total open-loop phase shift at f_0 must be 0° (or 360° , 720° , ...).

FIGURE 25.3.4 Oscillator, using an amplifier and a filter to form a feedback loop.

Both criteria are formal statements of what was said previously: the loop must produce just the signal at the input of the amplifier to maintain the amplifier output. Criterion 1 specifies the amplitude and criterion 2 the phase of the requisite signal at the input.

When the above criteria are met, the poles of the oscillator are on the $j\omega$, or imaginary, axis when plotted on the complex s -plane, which corresponded to a stable amplitude oscillation. The loop gain actually must be greater than unity for the oscillation to start and build to the final stable amplitude, which corresponds to poles being in the right half plane. Once the final amplitude is reached, something must reduce the loop gain to exactly 1. In a gain controlled oscillator, some form of level detection and a variable gain element are used as a part of the oscillator circuit feedback loop to precisely sustain the conditions of oscillation, keeping the poles on the imaginary axis. Self-limiting oscillators, such as the single transistor Colpitts

oscillator, rely on the nonlinear large signal gain characteristics of the transistor to produce a stable amplitude oscillation. As the signal amplitude increases to the point the transistor goes into saturation or cutoff, the large signal gain decreases automatically to the level necessary to ensure a loop gain of 1.

Threshold Decision Oscillators

Threshold decision oscillators generally consist of an integrator or capacitor, which is driven from a current source switched by level detectors. The integrator signal ramps up to a preset high level. The current source is then reversed, and the integrator integrates down to a preset low level, where the process is started over. The result is a triangle wave. The triangle wave can be filtered or shaped to form a sine wave, or run through a high gain-limiting amplifier to produce a square wave. Threshold decision oscillators are generally used at frequencies below RF.

The Colpitts oscillator

The Colpitts oscillator (Fig. 25.3.5) and circuits derived from it that operate on the same basic principle are the most commonly used configurations in transistor oscillator design. The inductor L and the capacitors C , C_1 , and C_2 form a parallel resonant circuit. The output voltage is fed back to the input in the proper phase to sustain oscillation via the voltage divider formed by C_1 and C_2 , parts of which may be internal to the transistor itself. Typically bipolar *silicon* (Si) transistors are used up to 10 or 12 GHz and *gallium arsenide* (GaAs) FETs are usually selected for coverage above this range, though bipolar Si devices have been used successfully to 20 GHz. Bipolar Si devices generally have been favored for lower phase noise, but advances in GaAs FET design have narrowed the gap, and their superior frequency coverage has made them the primary choice for many designs.

Electrically Tuned Oscillators

The use of an electrically tuned capacitor, such as C_R in Fig. 25.3.6, enables the frequency of oscillation to be varied and to be phase-locked to a stable reference. A common technique for obtaining a voltage-variable capacitor is to employ a *variable-capacitance diode*, or *varactor*. This device consists of a reverse-biased junction diode with a structure optimized to provide a large range of depletion-layer thickness variation with voltage as well as low losses (resistance) to ensure high Q . Major advantages of varactor oscillators are the potential for obtaining high tuning speed and the fact that a reverse-biased varactor diode does not dissipate dc power, as does a magnetically biased oscillator. Typical tuning rates in the microsecond range are realized without great difficulty.

FIGURE 25.3.5 Colpitts oscillator circuit.

FIGURE 25.3.6 Negative-resistance oscillator. C_R , L_R , and R_R represent a resonator. The inductance L is required to achieve a negative resistance in Z_{in} .

YIG-Tuned Oscillators

High Q resonant circuits suitable for tuning oscillators over very broad frequency ranges can be realized with polished, single-crystal spheres of *yttrium-iron-garnet* (YIG). When placed in a dc magnetic field, ferromagnetic resonance is attained at a frequency that is a linear function of the field. The microwave signal is usually coupled into the sphere (typically about 0.5 mm in diameter) via a loop, as shown in Fig. 25.3.7. The equivalent circuit presented to the transistor is a shunt-resonant tank that can be tuned linearly over several octaves in the microwave range. Various rare earth *dopings* of the YIG material have been added to extend performance to lower frequency ranges in terms of spurious resonances (other modes) and nonlinearities at high power, but most ultra-wideband oscillators have been built above 2 GHz. Frequencies as high as 40 GHz have been achieved using pure YIG, and other materials, such as hexagonal ferrites, have been used to extend frequencies well into the millimeter range.

Frequency Multiplication

Another approach to signal generation involves the use of frequency multiplication to extend lower-frequency sources up into the microwave range. By driving a nonlinear device at sufficient power levels, harmonics of

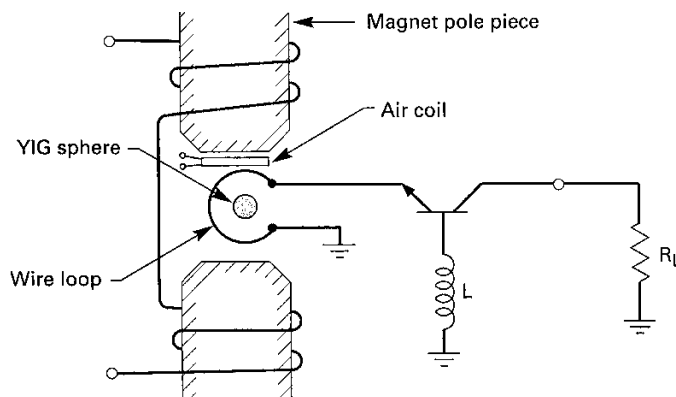

FIGURE 25.3.7 YIG-tuned oscillator.

the fundamental are generated that can be selectively filtered to provide a lower-cost, less complex alternative to a microwave oscillator. The nonlinear device can be a diode driven through its nonlinear i versus v characteristic, or it can be a varactor diode with a nonlinear capacitance versus voltage. Another type of device consists of a *pin* structure (p -type and n -type semiconductor materials separated by an intrinsic layer) in which charge is stored during forward conduction as minority carriers. On application of the drive signal in the reverse direction, conductivity remains high until all the charge is suddenly depleted, at which point the current drops to zero in a very short interval. When this current is made to flow through a small drive inductance, a voltage impulse is generated once each drive cycle which is very rich in harmonics. Such *step-recovery diodes* are efficient as higher-order multipliers.

Crystal Oscillator

A crystal oscillator can be made by using a quartz crystal resonator as the frequency selective element in a transistor amplifier-based oscillator. The equivalent circuit of a crystal is a series resonant LC circuit, so the oscillator must be designed around a series resonator. A quartz crystal is a very high Q resonator that delivers two major benefits. First, the accuracy and stability of the frequency of the resonance of the crystal makes the crystal oscillator a very good frequency reference for a signal generator. Second, the very high Q , or narrow bandwidth, of the resonator allows very little of the broadband noise of the transistor, and other components, to modulate the oscillator signal. Noise that is present on an oscillator and affects the phase stability is called phase noise. Low phase noise is important if a signal is to be modulated onto a carrier signal because the phase noise will limit the dynamic range of the modulated signal.

Frequency Synthesis

The methods by which frequencies can be generated using addition, subtraction, multiplication, and division of frequencies derived from a single reference standard are called *frequency synthesis techniques*. The accuracy of each of the frequencies generated becomes equal to the accuracy of the reference. Normally, an oscillator that covers a wide range of frequencies cannot, by itself, be tuned to an absolute frequency accurately. And an oscillator that is very accurate in absolute frequency, such as a crystal oscillator, cannot be tuned over a wide range of frequencies, due to its high Q . Even if it could be tuned, the crystal oscillator would then lose its absolute frequency accuracy because some element in addition to the crystal would be determining the frequency of oscillation. However, if that wide ranging oscillator is *locked* to the accurate fixed frequency reference oscillator through synthesis techniques, then the absolute frequency accuracy of the reference oscillator can be extended to the full frequency range of the wide tuning oscillator. Three classifications are commonly referred to: *indirect synthesis*, *direct synthesis*, and *direct digital synthesis* (DDS).

Direct Synthesis

By assembling a circuit assortment of frequency dividers and multipliers, mixers and bandpass filters, an output m/n times the reference can be generated. There are many possible ways to do this, and the configuration actually used is chosen primarily to avoid strong spurious signals, which are low-level, nonharmonically related sinusoids. The principal advantage of the direct synthesis technique is the speed with which the output frequency may be changed. Shown in Fig. 25.3.8 is one way to produce a 13-MHz output from a 10-MHz reference. The inputs to the mixer are 10 and 3 MHz, the mixer produces sum and difference frequency outputs, and the bandpass filter on the output selects the 13-MHz sum. Notice that another bandpass filter could have been used to select the 7-MHz difference, if that were wanted.

A key advantage of direct synthesis is frequency switching speed. Because no control loops are directly involved in the signal generation that have relatively slow time constants, switching speeds in the microsecond range are easily achievable.

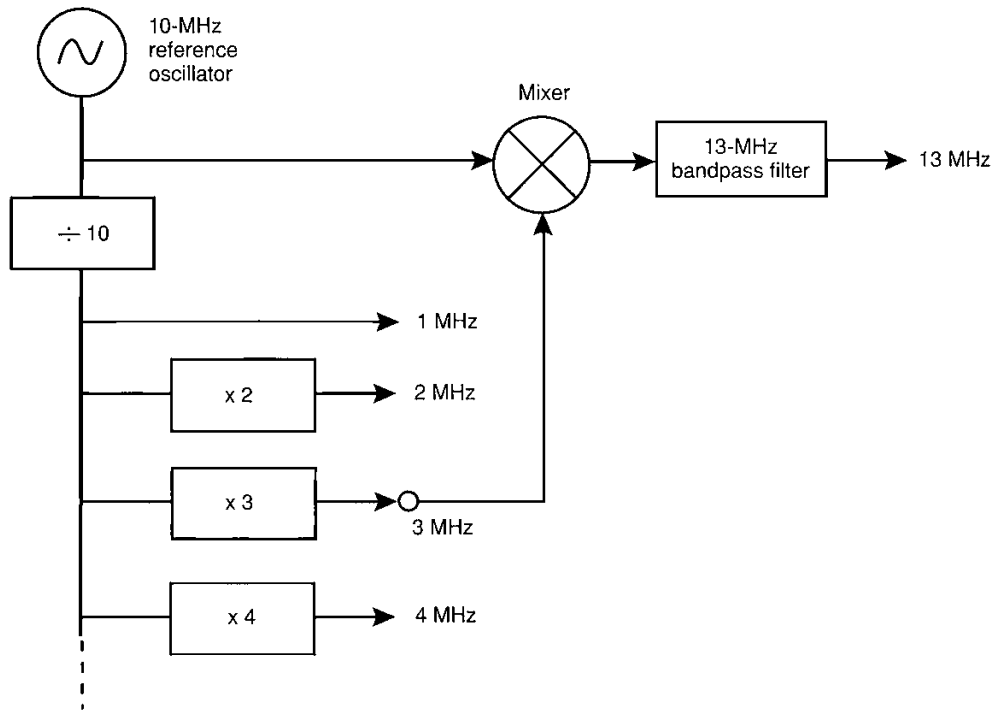

FIGURE 25.3.8 Direct frequency synthesis.

Indirect Synthesis

This name derives from the use of an oscillator other than the reference to generate the output. This technique involves placing the oscillator in a *phase-locked loop* (PLL). The phase-locked loop starts with a tunable oscillator, or voltage-controlled oscillator (VCO). The output of the oscillator is then divided down in frequency by a frequency divider with a divide number m . The divided down signal is compared to a reference oscillator signal in a device called a phase detector. A phase detector produces a voltage output that is proportional to the difference in phase between the two input signals. The output voltage of the phase detector, or error signal, is then fed into an integrator/loop filter, which produces the voltage that is necessary to tune the tunable oscillator to minimize the error voltage, or phase difference between the reference oscillator and divided down tunable oscillator. If the phase difference between the two signals is minimized, then the two signals must also be at the same frequency. But the tunable oscillator is actually running at m times the reference oscillator due to the divider. When this occurs, the two oscillators are said to be *phase-locked* together. If the loop filter is a true integrator, then the steady-state frequency error must be zero.

The finest frequency resolution of a phase-locked loop is called the step size of the synthesizer. For a simple phase-locked loop with a single divider in the feedback path between the tunable oscillator and the phase detector, output frequency is m times the frequency at the phase detector, and the step size is the frequency of the reference signal. For higher frequency resolution, or smaller step size, more sophisticated phase-locked loop topologies are required. Shown in Fig. 25.3.9 is a slightly more complicated phase-locked loop synthesizer in which the reference oscillator is also divided down by a divide number n . The tunable oscillator is then locked to m/n times the reference frequency. If the dividers are programmable, then a wide range of

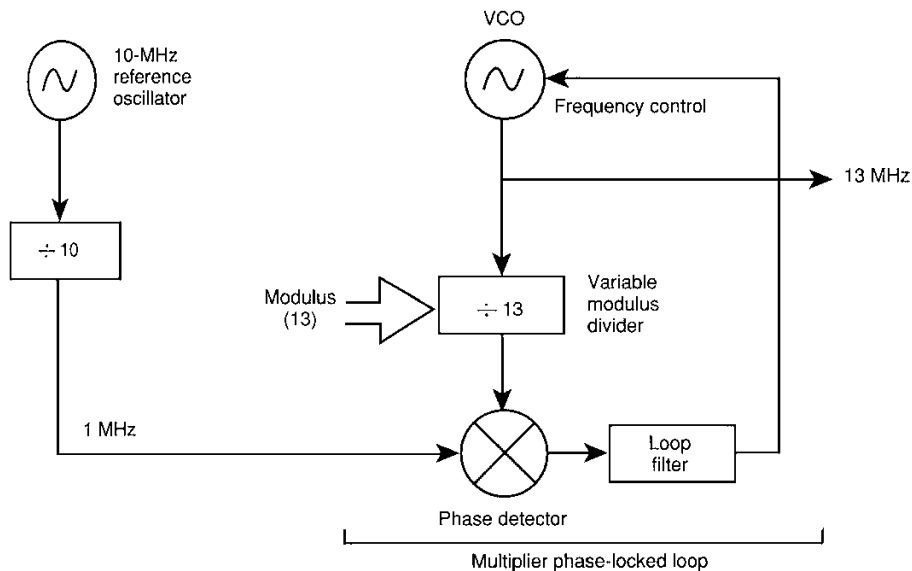

FIGURE 25.3.9 Indirect frequency synthesis.

output frequencies that are m/n times the reference can be generated by this technique. As the divide number n is increased, the resolution of the phase-locked loop increases because the step size becomes smaller. As n is increased to reduce the step size of the loop, m must be increased to maintain the same range of output frequencies.

A practical limitation to resolution is reached due to the noise performance of the phase-locked loop. Any additive noise generated in the phase detector sees a gain of m to the output of the tunable oscillator within the bandwidth of the phase-locked loop. So effectively, as the resolution of the loop increases, so does the phase noise. This limitation is overcome either by summing multiple synthesis loops together in a way to reduce the maximum divide number and thus the noise gain of each while preserving the resolution and frequency range, or by using sophisticated frequency interpolation techniques known as fractional frequency dividers, or *fractional- n* . When the tunable oscillator is divided by a divider that has both an integer and fractional part, the resolution can be extended without increasing the noise gain simply by increasing the number of digits of fractional resolution. Fractional- n dividers work by switching between two adjacent whole divide numbers at a rate that time averages to the correct fraction between those two numbers. The output frequency averages to exactly the correct frequency, but it also has a large frequency modulation due to the divider changing back and forth between two divide numbers. Several techniques can be used to remove the FM component and leave a spectrally pure output signal. A key advantage of indirect synthesis is the simplicity of the design required to produce a wide range of output frequencies that are locked to a fixed reference frequency by simply changing the divider numbers.

Arbitrary Waveform Synthesizers

In this technique, the complete period of some desired waveshape is defined as a sequence of numbers representing sample values of the waveform, uniformly spaced in time. These numbers are stored in digital memory and then, paced by the reference, repetitively read out in order. The sequence of numbers is then converted into a sequence of voltage levels using a *digital-to-analog converter* (DAC). The output

of the DAC is then filtered to produce an accurate replica of the numerically defined signal. Any *arbitrary* waveform can be produced with this technique with frequency components from DC up to half the sample frequency.

TYPES OF SIGNAL GENERATORS

Introduction

The various types of signal generators are categorized by frequency range and functional capability. Many of the historical boundaries between generator types have changed over the years as the technology for generating electrical signals has changed. For example, the digitally based arbitrary waveform generator has mostly replaced the traditional function generator for producing complex, sinusoidal, and nonsinusoidal baseband waveforms.

In addition to generating a signal at a specific frequency, a signal generator accurately controls the amplitude of the signal, sometimes over a wide range of amplitudes through use of precision level control circuitry and precision step attenuators. Absolute amplitudes accurate to within several dB over the full frequency range of a frequency generator are possible.

Audio Oscillators

At audio frequencies (~ 1 Hz to 100 KHz), there is more emphasis on purity of waveform than at RF, so it is natural to use an oscillator circuit that generates a sine wave as its characteristic waveform. This is, in effect, an amplifier with filtered feedback. For audio frequencies, however, the elements of an LC resonant circuit for the filter become expensive and large, with iron or ferrite core construction necessary to realize the large values of inductance required. Another handicap is that ferroc core inductors exhibit some nonlinear characteristics which increase harmonic output when they are used in a resonant filter circuit. Using resistors and capacitors, it is possible to establish a voltage transfer function that resembles that of a resonant circuit in both its phase and amplitude response. The four-element RC network in the dashed portion of Fig. 25.3.10 is

FIGURE 25.3.10 Wien bridge oscillator.

characterized by an input-output voltage ratio V_1/V_0 (called a transfer function) that varies with frequency. This transfer function has an amplitude peak of $(1/3)V_0$ at the *resonant frequency* $(1/2)\pi RC$ and a phase shift passing through zero at this frequency. Very low distortion audio oscillators use some form of level detection and variable gain as a part of the oscillator circuit feedback loop to precisely sustain the conditions of oscillation, keeping the poles on the imaginary axis, without adding distortion. Self-limiting oscillators, such as the single transistor Colpitts, rely on the nonlinear large signal gain characteristics of the transistor to produce a stable amplitude oscillation at the expense of harmonic distortion performance. Because the gain of the active device in a self-limiting oscillator changes throughout the cycle of the sinusoidal oscillation to sustain an average loop gain of 1, the waveform is distorted, and harmonics of the frequency of oscillation are created. The effects of the distortion can be minimized by taking advantage of the filtering action of the resonator, but a highly linear gain-controlled oscillator can have much lower distortion.

Function Generators

The term *function generator* describes a class of oscillator-based signal sources in which the emphasis is on versatility. Primarily, this means providing a choice of output waveforms. It also connotes continuous tuning over wide bands with max-min frequency ratios, sub-Hz to MHz frequencies, flat output amplitude, and sometimes modulation capabilities—*frequency sweeping*, *frequency modulation* (FM), and *amplitude modulation* (AM). With regard to their frequency accuracy and stability, function generators are inferior to sine-wave oscillators, but their performance is quite adequate for many applications. Some frequency synthesizers are also called *precision function generators* by their manufacturers. What this means is that circuitry has been added to the synthesizer to produce other waveforms in addition to sine waves.

Early function generators were based on integrators driven from current sources switched by level detectors to form triangle wave generators, which is a form of threshold decision circuit. The triangle waves were then either put through high gain-limiting circuits to produce square waves, or shaped with diode-shaping circuits to produce sine waves. Because the signal was based on the RC time constant of an integrating amplifier, traditional function generators are not synthesized. Modern function generators are based on digital arbitrary waveform generators and are capable of generating an infinite variety of waveforms. And because arbitrary waveform generators are based on a single clock frequency, they are technically synthesizers. Function generators, and now mostly arbitrary waveform generators, are often included in RF and microwave signal generators that offer signal modulation capabilities. Because these function generators create the baseband signal that contains the information that is then modulated onto the RF or microwave carrier signal, these function generators are often called *baseband generators*.

Pulse Generators

A *pulse generator* is an instrument that can provide a voltage or current output whose waveform may be described as a continuous pulse stream. A *pulse stream* is a signal that departs from an initial level to some other single level for a finite duration, then returns to the original level for a finite duration. This type of waveform is sometimes referred to as a *rectangular pulse*.

Pulse Nomenclature. The common terms that describe an ideal pulse stream are identified in Fig. 25.3.11. However, in order to describe real pulses, some additional terms are needed. These terms are explained in Fig. 25.3.12. If a pulse generator provides more than just a single channel output, the multiple outputs do not necessarily have to be time synchronous. The majority of these instruments have the capability of delaying the channels with respect to each other. This delay may be entered as an absolute value (e.g., 1 ns) or as a phase shift (e.g., $90^\circ = 25$ percent of the period). Sometimes, especially in single-channel instruments, these values are referenced to the trigger output. The maximum delay or phase range is limited and in most cases dependent on the actual pulse period.

All pulse generators offer variable levels (HIL, LOL, AMP, OFS), variable pulse period (PER, FREQ), and variable pulse width (PWID, NWID, DCYC). Some instruments also offer variable transition times

FIGURE 25.3.11 Ideal pulse nomenclature. HIL = high level (voltage or current); LOL = low level (voltage or current); AMP = HIL - LOL = amplitude (voltage or current); OFS = (HIL + LOL)/2 = offset (voltage or current); $A1 = LOL + X \cdot AMP$, $A2 = HIL - X \cdot AMP$, where X is defined as 0.1 (normally) or as 0.2 (for ECL devices). PER = $t7 - t2$ = pulse period; FEWQ = $1/PER$ = pulse frequency; PWID = $t5 - t2$ = positive pulse width; NWID = $t7 - t5$ = negative pulse width; DCYC = PWID/PER = duty cycle; TRISE = $t3 - t1$ = rise time; TFALL = $t6 - t4$ = fall time; $t1, t7$ rising edge crosses A1; $t2$ = rising edge crosses A1; $t4$ = rising edge crosses OFS; $t3$ = rising edge crosses A2; $t2$ = falling edge crosses A2; $t5$ = falling edge crosses OFS; $t6$ = falling edge crosses A1. Remarks: ECL stands for emitter-coupled logic. Rise and fall times are sometimes also referred to as transition times or edge rates.

(TRISE, TFALL). The minimum and maximum values and the resolution with which these parameters can be varied are described in pulse-generator data sheets.

Special Pulse Generators

This section describes pulse generators with special capabilities and distinguishes them from instruments called data generators.

Programmable Data. Some pulse generators can generate not only repetitive pulse but also serial data streams. These instruments have a memory with a certain depth and an address counter in the signal path of

FIGURE 25.3.12 Real pulse generator nomenclature. NP = negative prehoot; PO = positive overshoot; PR = positive ringing; PP = positive prehoot; NO = negative overshoot; NR = negative ringing. Remark: Preshoot, overshoot, and ringing are sometimes also referred to as pulse distortions.

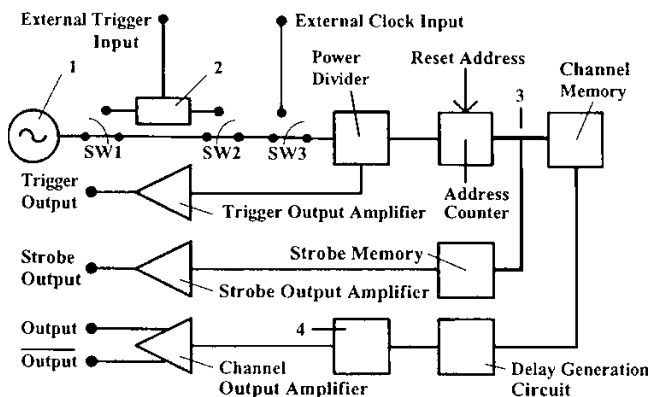

FIGURE 25.3.13 Block diagram of a single-channel pulse generator with data capabilities. 1: Internal clock generation circuit; 2: start/stop generation circuit; 3: memory address bus (n lines); 4: width generation circuit (NRZ, RZ with variable duty cycle). Data stream length (selected by the user): m bit ($m < 2^n$); memory depth: 2^n ; reset address: 2^{n-m} . Remark: When the address counter value reaches 2^{n-1} , the counter resets itself to the reset address (calculated and programmed by the microprocessor).

each channel, as shown in Fig. 25.3.13. Thus, single-shot or repetitive data streams of a programmable length can be generated. The maximum length of such a data stream is limited by the memory depth. The strobe output provided by these instruments can be used to generate a trigger signal that is synchronous to one specific bit of this data stream, which is useful when this bit—or the corresponding reaction of the Device Under Test (DUT)—has to be observed with an oscilloscope.

There are several different *data formats*, as shown in Fig. 25.3.14. The most popular one is Non-Return-to-Zero modulation (NRZ), because the bandwidth of a data stream with that format and a data rate of, for instance, 100 Mbit/s is only 50 MHz (100 MHz if the format is RZ, R1, or RC). RC is used if the average duty

FIGURE 25.3.14 Different data formats. NRZ: nonreturn to zero (zero = logic “0” = –LOL); RZ: return to zero; R1: return to “1” (Logic “1” = HIL); RC: return to complement (“0” “1”; “1” “0”).

cycle (see Fig. 25.3.11) of the data stream has to be 50 percent, no matter what the data that are being transmitted look like.

For instance, if the data link that has to be tested cannot transmit a dc signal, an offset (or threshold) of 0 V (or 0 A, respectively) and the data format RC has to be chosen. Sometimes, when selecting RZ, users can even select the duty cycle of the signal. If they choose 25 percent, for instance, a logic “1” will return to “0” after 25 percent of the pulse period. In Fig. 25.3.14, a duty cycle of 50 percent was chosen.

Random Data. Some pulse generators with data capabilities can generate random data streams, which are also referred to as *pseudorandom binary sequences* or *pseudorandom bit sequences* (PRBS). These sequences are often generated according to an international standard.

Difference between Data/Word Generators and Pulse Generators. In contrast to pulse generators, most *data generators* are modular systems that can provide up to 50 channels, or more. Data generators usually exhibit a much higher memory depth and more functionality in terms of sequencing—*looping* or *branching*. Some data generators even can provide asynchronous data streams (generated with several independent clock sources). This means that a pulse generator with data capabilities cannot replace a data generator, especially if more than one or two channels are needed. However, having some data capabilities in a pulse generator can be very beneficial.

Frequency Synthesizers

Starting in the early 1960s, frequency synthesis techniques have grown steadily in instrument applications and have become the dominant technology in signal sources. Now, almost all signal generators, whether baseband, RF, or microwave, are based on synthesis technology and offer very good frequency resolution, stability, and absolute frequency accuracy. Many also offer the option of locking to an external reference frequency, often 10 MHz. If all the instruments in a system are locked to the same external reference, then there will be no relative frequency error among the instruments. If the external reference has very good absolute frequency stability and absolute accuracy such as a rubidium or cesium atomic clock frequency standard, then the entire system will have the same stability and absolute frequency accuracy.

Radio-Frequency (RF) Signal Generators

Frequencies from 100 kHz to 1 GHz. This important class of instrument was developed in the late 1920s when the need was recognized for producing radio receiver test signals with accurate frequencies (1 percent) and amplitudes (1 or 2 dB) over wide ranges. The basic block diagram of these instruments remained nearly unchanged until about 1970, when frequency synthesizer circuits began to usurp *free-running oscillators* in the waveform generator section of the instruments. Shown in Fig. 25.3.15 is a simplified form of a typical RF sine-wave oscillator used in a signal generator. An amplifier producing an output current proportional to its input voltage (a transconductance amplifier) drives a tunable filter circuit consisting of a parallel LC resonant circuit with a magnetically coupled output tap. The tap is connected to the amplifier input with the proper polarity to provide positive feedback at the resonant frequency of the filter. To assure oscillation, it is necessary to design the circuit so that the gain around the loop—the amplifier gain times the filter transfer function—remains greater than unity over the desired frequency tuning range. But since the output signal amplitude remains constant only when the loop gain is exactly unity, the design must also include level-sensitive control of the loop gain.

Microwave Signal Generators

Frequencies from 1 to 30 GHz are usually designated as being in the microwave range. The lower boundary corresponds approximately to the frequency above which lumped-element modeling is no longer adequate for

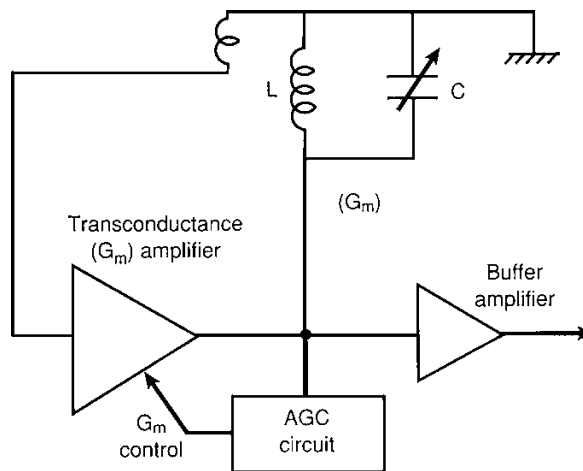

FIGURE 25.3.15 Radio-frequency sine-wave oscillator.

most designs. The range above is commonly referred to as the *millimeter range* because wavelengths are less than 1 cm. It extends up to frequencies where the small wavelengths compared with practically achievable physical dimensions require quasi-optical techniques to be used for transmission and for component design.

Previous generations of microwave sources were designed around vacuum tubes such as the klystron and the backward-wave oscillator. These designs were bulky, often requiring very high voltages and currents, and were subject to drift with environmental variations. More recently, compact solid-state oscillators employing field-effect transistors (FET) or bipolar transistors and tuned by electrically or magnetically variable resonators have been employed with additional benefits in ruggedness, reliability, and stability. Frequency synthesis techniques are now used to provide accurate, programmable sources with excellent frequency stability, and low phase noise. Several varieties of microwave signal generators, each optimized for certain ranges of applications, are described in this section.

CW Signal Generators

For certain applications, a *continuous-wave* (CW) signal generator without modulation capability may be all that is required, providing a cost savings over more sophisticated models. Output power is of importance in typical applications such as where the signal generator serves as a local oscillator (LO) driving a mixer in an up- or down-converter. The signal level needs to be high enough to saturate the mixer to assure good amplitude stability and low noise. If the phase noise of the converted signal is not to be degraded, the phase noise of the signal generator must be sufficiently low.

Other applications for CW sources include exciters, in transmitter testing, sources driving amplifiers, and modulators. High-level accuracy, low spurious and harmonic signal levels, and good frequency resolution may all be important specifications in these and other applications.

Swept Signal Generators

Frequency swept signal generators are used for the test and characterization of components and subsystems and for general-purpose applications. They can be used with scalar and vector network analyzers or with power meters or detectors. Sweep can be continuous across a span, or in precise discrete steps. Techniques exist for phase locking throughout a continuous sweep, allowing for high accuracy in frequency. Step sweep techniques,

in which the source is phase-locked at each discrete frequency throughout the sweep, are more compatible with some measurement systems.

Signal Generators with Modulation

Microwave signal generators designed to test increasingly sophisticated receivers are being called upon to provide a growing variety of modulations at accurately calibrated signal levels over a wide dynamic range, without generating undesired spurious signals and harmonics. Application-oriented signal generators are available, which provide combinations of modulation formats. These range from simple amplitude and frequency modulation to those that employ a wide variety of digital modulation formats in which discrete symbols are transmitted as combinations of phase and amplitude of the carrier.

For applications where simulations of complex scenarios involving multiple targets or emitters need to be carried to test radar or Electronic Warfare (EW) receivers, or to perform certain tests on satellite and communications receivers, higher-performance signal generators featuring very fast frequency switching and/or sophisticated modulation capabilities are employed. These sources may also feature a variety of software interfaces that can provide suitable *personalities* for various receiver test applications, allowing entry of parameters in familiar form and enabling the creation of complex scenarios involving lengthy sequences of a number of signals.

Types of Modulation

Some of the more commonly required modulation formats found in signal generators are described below, along with some common applications.

Pulse Modulation. Pulse modulation is used to simulate target returns to a radar receiver, to simulate active radar transmitters for testing EW surveillance or threat warning receivers, or to simulate pulse code modulation for certain types of communications or telemetry receivers. Microwave signal generators can have inputs for externally applied pulses from a system under test or from a pulse generator.

Some microwave signal generators have built-in pulse sources, which may be free-running at selectable rates or can be triggered externally with selectable pulse widths and delays—the latter being used to simulate a variety of distances to a radar target.

Amplitude Modulation (AM). In addition to the simulation of microwave signals having AM and for AM to PM (amplitude to phase modulation) conversion measurements, amplitude modulation of a microwave signal generator may be needed for simulation of signals received from remote transmitters in the presence of fading phenomena in the propagation path, or from rotating radar antennas. AM should be externally applicable or internally available over a broad range of modulation frequencies without accompanying undesired (incidental) variations in phase.

Frequency Modulation (FM). For applications where signals with FM need to be provided, signal generators with an external input and/or an internal source are available. The *modulation index* β is defined as

$$\beta = \Delta f / f_m$$

where Δf is the peak frequency deviation and f_m is the modulation frequency.

I/Q (Vector) Modulation. Digital modulation techniques have essentially supplanted analog modulation methods for communications and broadcasting applications. Modulation is said to be digital if the signal is allowed to assume only one of a set of discrete states (or symbols) during a particular interval when it is to be read. Data are transmitted sequentially at a rate of n bits per symbol, requiring 2^n discrete states per symbol. By representing the unmodulated microwave carrier as a vector with unity amplitude and zero phase, as shown in Fig. 25.3.16, we can display various modulation formats on a set of orthogonal axes commonly labeled I (*in-phase*) and Q (*quadrature phase*).

FIGURE 25.3.16 (a) Unmodulated carrier displayed as a vector with zero phase. (b) Some examples of digital modulation formats. In biphase modulation, there are two states characterized by a carrier at 0° or 18° of relative phase. QPSK (quadrature phase shift keying) has the four states shown and 8-psk (eight-phase shift keying) has the eight states of equal amplitude. The last example illustrates 16QAM (quadrature amplitude modulated) where there are three different amplitudes.

CHAPTER 25.4

LOGIC AND PROTOCOL ANALYZERS

Steven B. Warntjes, Steve Witt

LOGIC ANALYZERS

Steven B. Warntjes

Introduction

The advent of digital circuits dramatically changed the concerns of engineers and technicians working with electronic circuits. Ignoring for a moment digital signal quality or signal integrity, the issues switched from the world of bias points and frequency response to the world of logic ones, zeros, and logic states (see Fig. 25.4.1). This world has been called the *data domain*. Using off-the-shelf components virtually guarantees correct values of voltage and current if clocks are kept to moderate speeds—less than 50 MHz—and fan-in/fan-out rules are observed. The objective for circuit verification and testing focuses on questions of proper function and timing. Although parametric considerations are simplified, the functional complexity and sheer number of circuit nodes are increased tremendously. Measurements to address these questions and to manage the increased complexity are the forte of the *logic analyzer* (Fig. 25.4.2). Logic analyzers collect and display information in the format and language of digital circuits. Microprocessors and microcontrollers are the most common logic-state machines. Software written in either high-level languages, such as C, or in the unique form of a processor's instruction set—*assembly language*—provide the direction for these state machines that populate every level of electronic products.

Most logic analyzers can be configured to format their output as a sequence of assembly processor instructions or as high-level language source code. This makes them very useful for debugging software. For real-time or time-critical embedded controllers, a logic analyzer is a superb tool to trace program flow and to measure event timing. Because logic analyzers do not affect the behavior of processors, they are excellent tools for system performance analysis and verification of real-time interactions.

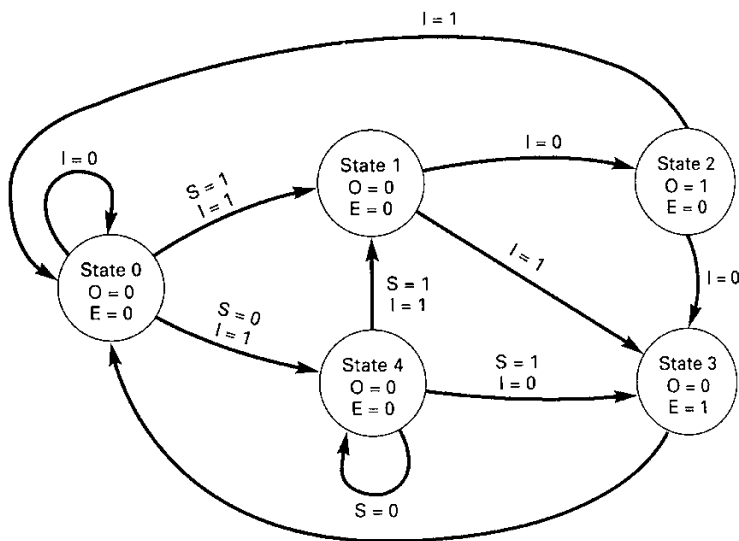

Data-stream analysis is also an excellent application for logic analyzers. A stream of data from a digital signal processor or digital communications channel can be easily captured, analyzed, or uploaded to a computer.

Basic Operation

The basic operation of logic analysis consists of acquiring data in two modes of operation: *asynchronous timing mode* and *synchronous state mode*. Logic analysis also consists of emulation solutions used to control the processor in the embedded system under development and the ability to time correlate high-level language source with the captured logic analyzer information.

(a)

(b)

FIGURE 25.4.1 (a) Logic timing diagram. Logic values versus time is shown for four signals. (b) Logic state diagram. Inputs *I* and *S* control transitions from state to state. *O* and *E* are outputs set to new values on entry to each state.

Asynchronous Mode. On screen, the asynchronous mode looks very much like an oscilloscope display. Waveforms are shown, but in contrast to an oscilloscope’s two or four channels, there are a large number of channels—eight to several hundred. The signals being probed are recorded either as a 1 or a 0. Voltage variation—other than being above or below the specified logic threshold—is ignored, just as the physical logic elements would do. In Fig. 25.4.3, an analog waveform is compared with its digital equivalent. A logical view of signal timing is captured. As with an oscilloscope, the logic analyzer in the timing mode provides the time base that determines when data values are clocked into instrument storage. This time base is referred to as the

FIGURE 25.4.2 Logic analyzers are supplied as PC-hosted or benchtop versions. Shown here at right is the Agilent Technologies 1680 Benchtop Protocol Analyzer. Note the pods that connect to the device under test in the foreground.

internal clock. A sample logic analyzer display, showing waveforms captured in timing mode, appears in Fig. 25.4.4.

Synchronous Mode. The synchronous state mode samples the signal values into memory on a clock edge supplied by the system under test. This signal is referred to as the *external clock*. Just as a flip-flop takes on data values only when clocked, the logic analyzer samples new data values or states only when directed by the clock signal. Groupings of these signals can represent state variables. The logic analyzer displays the

FIGURE 25.4.3 Analog versus digital representations of a signal.

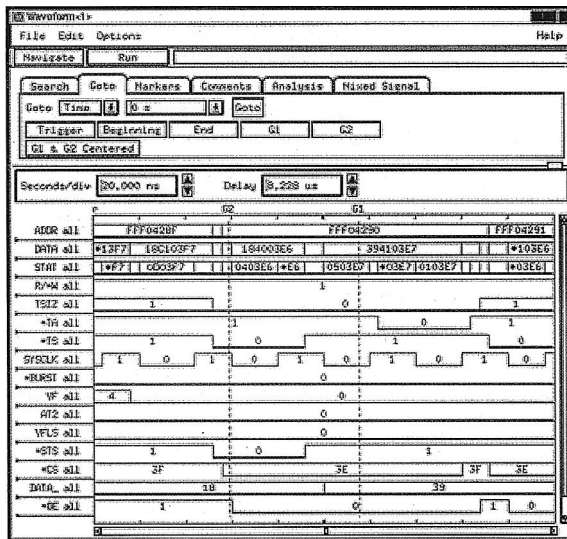

FIGURE 25.4.4 Timing mode display. Display and acquisition controls are at the top. Waveforms are displayed on the bottom two-thirds of the display. Note the multibit values shown for “A8-15.”

progression of states represented by these variables. A sample logic analyzer display showing a trace listing of a microprocessor’s bus cycles, in *state mode*, is shown in Fig. 25.4.5.

Block Diagram

An understanding of how logic analyzers work can be gleaned from the block diagram in Fig. 25.4.6. Logic analyzers have six key functions: the probes, the high-speed memory, the trigger block, the clock generator, the storage qualifier, and the user interface.

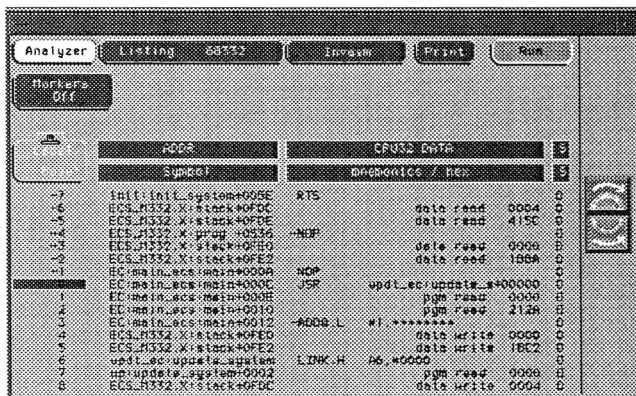

FIGURE 25.4.5 State mode display. Listing shows inverse assembly of microprocessor bus cycles.

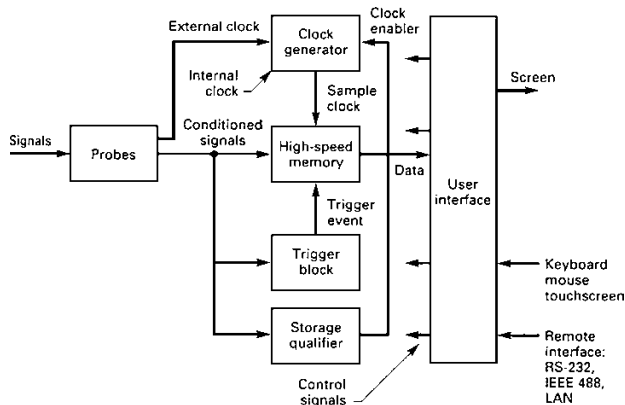

FIGURE 25.4.6 Logic analyzer block diagram.

Probes. The first function block is the probes. The function of the probes is to establish physical connections with the target circuit under test. To maintain proper operation of the target circuit, it is vital that the probes do not unduly load down the logic signal of interest or disturb its timing. It is common for these probes to operate as voltage dividers. By dividing down the input signal, voltage comparators in the probe function are presented with the lowest possible voltage slew rate. Higher-speed signals can be captured with this approach. The voltage comparators transform the input signals into logic values. Different logic families, such as TTL, ECL, and CMOS, have different voltage thresholds, so the comparators must have adjustable thresholds.

High-Speed Memory. The second function is high-speed memory, which stores the sampled logic values. The memory address for a given sample is supplied internally. The typical memory depth is hundreds of thousands of samples. Some analyzers can store several megasamples. Usually the analyzer user is interested in observing the logic signals around some event. This event is called the *measurement trigger*. It is described in the next functional block. Samples have a timing or sequence relationship with the trigger event, but are arbitrarily placed in the sample memory, depending on the instantaneous value of the internally supplied address. The memory appears to the user as a continuously looping storage system.

Trigger Block. The third functional block is the trigger block. Trigger events are a user-specified pattern of logical ones and zeros on selected input signals. Shown in Fig. 25.4.7 is how a sample trigger pattern corresponds with timing and state data streams. Some form of logic comparator is used to recognize the pattern of interest. Once the trigger event occurs, the storage memory continues to store a selected number of post-trigger samples. Once the post-trigger store is complete, the measurement is stopped. Because the storage memory operates as a loop, samples before the trigger event are captured, representing time before the event. Sometimes this pre-trigger capture is referred to as *negative time capture*. When searching for the causes of a malfunctioning logic circuit, the ability to view events leading up to the problem—the *trigger event*—makes the logic analyzer extremely useful.

Clock Generator. The fourth block is the clock generator. Depending on which of the two operating modes is selected, state or timing, sample clocks are either user supplied or instrument supplied. In the state mode, the analyzer clocks in a sample based on a rising or falling pulse edge of an input signal. The clock generator function increases the usability of the instrument by forming a clock from several input signals. It forms the clocking signal by *ORing* or *ANDing* input signals together. The user could create a composite clock using

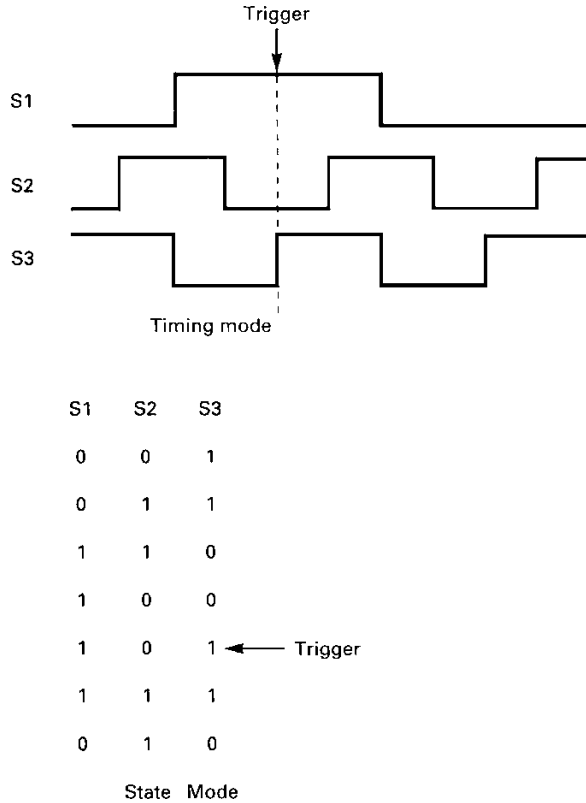

FIGURE 25.4.7 Example of trigger pattern showing match found with timing mode data and then state mode data. Trigger pattern is “1 0 1” for input signals S_1 , S_2 , and S_3 .

logic elements in the circuit under test, but it is usually more convenient to let the analyzer’s clock generator function do it. In timing mode, two different approaches are used to generate the sample clock. Some instruments offer both approaches, so understanding the two methods will help obtain more from the instrument. The first approach, or *continuous storage mode*, simply generates a sample clock at the selected rate. Regardless of the activity occurring on the input signals, the logic values at the time of the internal clock are entered in memory (see Fig. 25.4.8).

The second approach is called *transitional timing mode*. The input signals are again sampled at a selected rate. The clock-generator-function clocks the input signal values into memory only if one or more signals change their value. Measurements use memory more efficiently because storage locations are used only if the inputs change. For each sample, a time stamp is recorded. Additional memory is required to store the time stamp. The advantage of this approach over continuous storage is that long-time records of infrequent activity or bursts of finely timed events can be recorded, as shown in Fig. 25.4.9.

Storage Qualifier. The fifth function is the storage qualifier. It also has a role in determining which data samples are clocked into memory. As samples are clocked, either externally or internally, the storage qualifier function looks at the sampled data and tests them against a criterion. Like the trigger event, the qualifying

FIGURE 25.4.8 Continuous storage mode. A sample value is captured at each sample clock and stored in memory.

criterion is usually a one-zero pattern of the incoming signal. If the criterion is met, then the clocked sample is stored in memory. If the circuit under test is a microprocessor bus, this function can be used to separate bus cycles, steering them to a specific input/output (I/O) port—distinct from instruction cycles or cycles steered to other ports.

User Interface. The sixth function, the user interface, allows the user to set up and observe the outcome of measurements. Benchtop analyzers typically use a dedicated keyboard and either a *cathode-ray tube* (CRT) or a *liquid crystal display* (LCD). Many products use *graphic user interfaces* similar to those available on personal computers. *Pull-down menus*, *dialog boxes*, *touch screens*, and *mouse pointing devices* are available.

Since logic analyzers are used sporadically in the debug process, careful attention to a user interface that is easy to learn and use is advised when purchasing. Not all users operate the instrument from the built-in keyboard and screen. Some operate from a personal computer or workstation. In this case, the *user interface* is the remote interface: IEEE-488 or local area network (LAN). Likewise, the remote interface could be the user's Web browser of choice, if the logic analyzer is Web enabled.

FIGURE 25.4.9 Transitional storage mode. The input signal is captured at each sample clock, but is stored into memory only when the data changes. A time value is stored at each change so that the waveform can be reconstructed properly.

FIGURE 25.4.10 Example of an emulation solution with a PC connected to a customer target to control the processor under development.

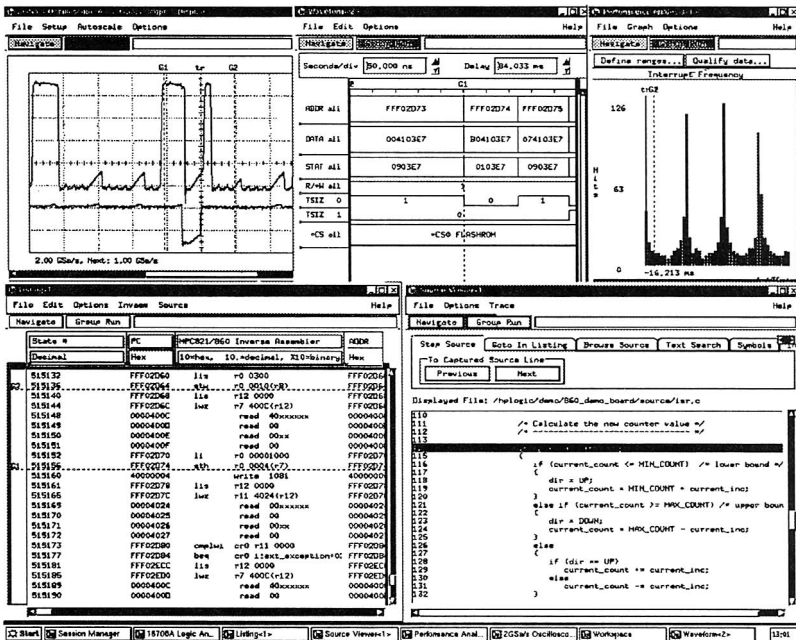

FIGURE 25.4.11 Correlated high-level language display. Lower right is the high-level source code; lower left, the assembly code listing. Upper left is a time-correlated oscilloscope display; upper middle, a timing waveform display; upper right, a performance analysis snapshot.

Emulation Solutions

An emulation solution is a connection to the processor in the embedded system used to control the program execution. The connection is usually on the order of five to 10 processor signals. These signals control the program execution, including the state of the processor, such as *running*, *reset*, or *single stepping*, and also the ability to quickly download the processor's executable code and examine/modify processor memory and registers. This processor control is usually accomplished through dedicated, on-processor debug resources. An emulation solution enable the user to perform software and hardware debugging as well as time correlate software and hardware activity (see Fig. 25.4.10).

High-Level Language Source Correlation

High-level language source correlation provides a real-time trace or acquisition of processor address, data, and status information linked to a software high-level source language view. This information is then *time correlated* to activity captured by the rest of the logic analyzer's acquisition modules, such as oscilloscope channels. Symbols from the user's software program can also be used to specify trigger conditions and are listed in the analyzer display (Fig. 25.4.11). This feature uses the information provided in the object file from the customer's compiler to build a database of source files, line numbers, and symbolic information. The HLL source correlation is a nonintrusive tool that typically does not require any major changes in the software compilation process.

PROTOCOL ANALYZERS

Steve Witt

Introduction

Computer communication networks are made up of many different computer systems, applications, and network topologies. The capital investment in cabling and transmission infrastructure is massive. The number of users demanding access to computer networks is ever increasing and these users are demanding more bandwidth, increased performance, and new applications. There is a constant stream of new equipment and services being introduced in the marketplace. In this complex environment, computer networking is made possible only by equipment and services vendors adhering to standards covering protocols, physical connectors, electrical interfaces, topologies, and data formats. Protocol analysis is used to ensure that the products implemented according to these standards behave as per specifications.

The term protocol analyzer describes a class of instruments that are dedicated to performing protocol analysis. The instruments are special-purpose computer systems that act as a node on the network, but, unlike a typical node on the network, monitor and capture all of the network traffic for analysis and testing.

Protocol Definition. Generally speaking, a protocol is a code or a set of rules specifying the correct procedure for a diplomatic exchange. In terms of computer networks, a protocol is a specific set of rules, procedures, and conventions defining the format and timing of data transmission between devices connected to a computer network. Protocols are defined so that devices communicating on a computer network can exchange information in a useful and efficient manner. Protocols handle synchronization, addressing, error correction, header and control information, data transfer, routing, fragmentation and reassembly, encapsulation, and flow control. Protocols provide a means for exchanging information so that computer systems can provide services and applications to end users. The wide range of protocols in use is a result of the wide range of transmission medium in use, the wide range of applications and services available to end users, and the numerous independent organizations and vendors creating protocol standards.

Communication via a computer network is possible only when there is an agreed-upon format for the exchange of information and when there is a common understanding of the content of the information being

exchanged. Therefore, protocols must be defined by both semantic and syntactic rules. Semantics refers to the meaning of the information in the frame of data including control information for coordination and error handling. An example of the semantic information in a frame is a request to establish a connection, initiated by one computer and sent to another computer. Syntax refers to the structure, arrangement, and order of the protocol including data format and signal levels. An example of the syntax of a protocol is the relative position of a protocol field in the frame, such as the network address. Protocol analysis is concerned with both the syntax and the semantics of the protocols.

Protocol Standards. Communication between devices connected to computer networks is controlled by transmission and protocol standards and recommendations. These standards are necessary for different vendors to offer equipment and services that interoperate with one another. While standards can be defined and implemented in the private sector by computer and network component vendors such as Cisco Systems, Hewlett-Packard, and IBM, most standards and recommendations are created by organizations including but not limited to ANSI (American National Standards Institute), CCITT (Consultative Committee on International Telegraphy and Telephony), ETSI (European Telecommunications Standards Institute), IEEE (Institute of Electrical and Electronic Engineers), ISO (International Standards Organization), and the ITU (International Telecommunications Union). The ATM Forum and the IETF (Internet Engineering Task Force) are technical working bodies that develop standards for networking products.

The OSI Reference Model. The ISO, located in Geneva, Switzerland, is responsible for many of the international standards in computer networking. The ISO defined a model for computer communications networking called the Open Systems Interconnection Reference Model. This model, commonly called the OSI model, defines an open framework for two computer systems to communicate with one another via a communications network. The OSI model (see Fig. 25.4.12) defines a structured, hierarchical network architecture. The OSI model consists of the communications subnet, protocol layers 1 to 3, and the services that interface to the applications executing in the host computer systems (protocol layers 4 to 7). The combined set of protocol layers 1 to 7 is often referred to as a protocol stack. Layer 7, the applications layer, is the interface to the user application executing in the host computer system. Each layer in the protocol stack has a software interface to the application below it and above it. The protocol stack executes in a host computer system. The only actual physical connection between devices on the network is at the physical layer where the interface hardware connects to the physical media. However, there is a logical connection between the two corresponding layers in communicating protocol stacks. For example, the two network layers (layer 3 in the OSI reference model) in two protocol stacks operate as if they were communicating directly with one another, when in actuality they are communicating by exchanging information through their respective data link layers (layer 2 in the OSI reference model) and physical layers (layer 1 in the OSI reference model).

Current network architectures are hierarchical, structured, and based in some manner on the OSI reference model. The functionality described in the OSI reference model is embodied in current network architectures, albeit at different layers or combined into multiple layers.

Network Troubleshooting Tools. There are two broad categories of products used to implement and manage computer networks—those that test the transmission network and those that test the protocol information transferred over the transmission network. Testing the protocols is commonly referred to as protocol analysis and it can be accomplished with several different types of products including:

Network Management Systems—comprehensive, integrated networkwide systems for managing and administrating systems and networks. Protocol analysis is one of many applications performed by network management systems. Network troubleshooting is performed by acquiring network data from devices on the network and from instrument probes distributed through the network.

Distributed Monitoring Systems—performance monitoring and troubleshooting applications that are implemented with instrument probes or protocol analyzers that are distributed throughout the network. The probes and analyzers are controlled with a management application running on a workstation or PC.

THE OSI REFERENCE MODEL

The OSI Reference Model defines an internationally accepted standard for computer network communications. Host system applications exchange information in a hierarchical and structured manner.

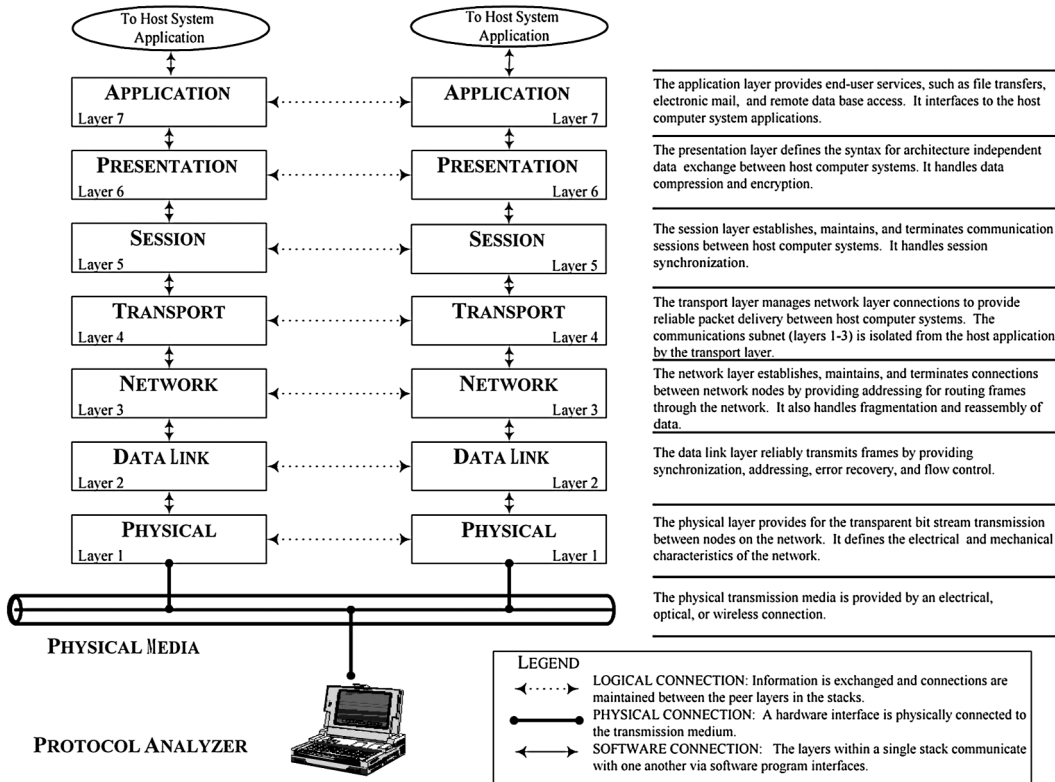

FIGURE 25.4.12 OSI model.

Protocol Analyzers—specialized instrumentation dedicated to protocol analysis. Protocol analyzers are used to troubleshoot network problems and to monitor the performance of networks.

Handheld Test Tools—special purpose tools that are very small, lightweight, and usually battery operated. They perform a variety of measurements such as continuity tests, transmission tests, and simple protocol analysis measurements such as simple statistics and connectivity tests.

The Need for Protocol Analysis. In order for two applications running on two different computer systems to communicate with one another (e.g., a database application executing on a server and a client application performing database queries), meaningful information must be continually, efficiently, and correctly exchanged. This requires a physical connection to exist, either twisted pair copper wire, coaxial cable, optical fiber, or wireless (e.g., radio transmission). The physical characteristics and specifications of the transmission media must be standardized so that different computer systems can be electrically connected to one another. The bit streams exchanged over the physical media must be encoded such that the analog stream of information can be converted to digital signals. In order for two people to effectively communicate they must speak the same language. Similarly, for two computer systems to communicate

they must speak the same “language.” Therefore, the bit stream must conform to a standard that defines the encoding scheme, the bit order (least significant bit first or most significant bit first), and the bit sense (a high value defined either as a 1 or a 0). Any errors in the transmission must be detected and recovered and, if necessary, the data must be retransmitted. A protocol analyzer is used to examine the bit stream and ensure that it conforms to the protocol standards that define the encoding schemes, bit sequences, and error conditions.

Once a bit stream can be transmitted and received, the physical communication is established and the exchange of information can be accomplished. Information is exchanged in logical units of information. A protocol frame, packet, message, or cell (in this chapter, the term frame will be used to mean any or all of these) is the logical unit of information transmitted on the physical infrastructure of a computer network. Depending on the type of network and protocols, these frames of data are either fixed in size, such as the 53 byte cells used by ATM networks, or they can be variable in size, such as the 64 to 1518 byte frames used by Ethernet networks. The most fundamental aspect of protocol analysis is the collection and analysis of these frames.

Networks usually have more than one path connecting different devices. Therefore, the frames in which the data are contained must be addressed properly so that they can traverse single or multiple routes through the network. Fragmentation and reassembly issues must be properly handled—frames are often disassembled and reassembled so that they can be of a proper size and can be encapsulated with the proper header information to ensure that the intermediate and end devices in the network can properly manipulate them. The network must also handle error conditions such as nodes that stop responding on the network, nodes that transmit error frames or signals, and nodes that use excessive bandwidth. A protocol analyzer is used to examine the addresses of the frames, check fragmentation and reassembly, and investigate errors.

Connections are established so that communication is efficient. This prevents the communication channel from being redundantly set up each time a frame is transmitted. This is similar to keeping a voice line open for an entire telephone conversation between two people, rather than making a phone call for each sentence that is exchanged. To ensure this efficiency, connections or conversations are established by devices on the network so that the formal handshaking doesn't have to be repeated for each information exchange. Protocol analysis includes scrutinizing protocol conversations for efficiency and errors.

The data that are transferred to the host system application in the frames must conform to an agreed-upon format, and if necessary it must be converted to an architecture-independent format so that both computer systems can read the information. Each time a user enters a command, downloads a file, starts an application, or queries a database, the preceding sequence of processes is repeated. A computer network is continuously performing these operations in order to execute an end user's application. Protocol analysis involves critically examining the formatted data that are exchanged between host system applications.

Protocol Analyzers

A protocol analyzer is a dedicated, special purpose computer system that acts as a node on the network but, unlike a typical node on the network, it monitors and captures *all* of the network traffic for analysis and testing (Fig. 25.4.13). Protocol analyzers provide a “window into the network” to allow users to see the type of traffic on the network. Many problems can be solved quickly by determining what type of traffic is or is not present on the network and if protocol errors are occurring. Without a “window into the network” network managers must rely on indirect measures to determine the network behavior, such as observing the nodes attached to the network and the problems the users are experiencing.

Protocol analyzers provide capabilities to compare data frames with the protocol standards (protocol decodes), load and stress networks with traffic generation, and monitor network performance with statistical analysis. The measurement capabilities have expanded to focus on a broad set of applications such as network troubleshooting, network performance monitoring, network planning, network security, protocol conformance testing, and network equipment development. These new applications go far beyond simply examining network traffic with protocol decodes.

The term protocol analyzer most commonly refers to the portable instruments that are dispatched to trouble sites on the network, i.e., the critical links or segments that are experiencing problems. The emphasis in these products is

FIGURE 25.4.13 Protocol analyzers come in a number of physical configurations. Shown here are 3 Agilent Technologies E2920 PCI/PCI-X Exerciser and Analyzer cards plugged into a server undergoing production testing.

portability—products that are light-weight, rugged, and include the maximum amount of functionality. Network troubleshooters require a product that connects to any point in an internetwork, regardless of the physical implementation of the network. Therefore, most protocol analyzers are able to accommodate multiple network interface modules. To avoid multiple trips back to the office to get additional equipment, network troubleshooters require a “one handle solution,” a product that integrates as much test capability as possible into one portable product.

Portable protocol analyzers are most commonly used for network troubleshooting in installation and maintenance applications. Such products focus on installing networks and troubleshooting network problems. Installing networks requires the network engineer to stress the network or network devices using scripts that emulate setting up logical connections, placing calls, and creating high traffic scenarios. Troubleshooting network problems requires that the network engineer have extensive protocol decodes available to examine what-ever frames are present on the network. Protocol statistics and expert analysis are used to identify network errors.

Protocol Analysis

A network fault is any degradation in the expected service of the network. Examples of service degradation include an excessively high level of bit errors on the transmission medium, a single user monopolizing the network bandwidth, a misconfigured device, or a software defect in a device on the network. Regardless of the cause, the network manager’s fundamental responsibility is to ensure that such problems are fixed and that the expected level of service is restored. To accomplish this, the network manager must troubleshoot the network and isolate faults when the inevitable problems occur. Many of the difficult to detect, intermittent problems can only be recreated if the network is stressed by sending frames. Many of the network problems are caused by the constantly changing configurations of the devices attached to the network, so the network manager must manage the configuration of the network devices. In order to ensure

the bandwidth and performance that users demand, the network manager must monitor the performance of the network and plan accordingly for future growth. Network managers are also concerned with the security of their networks and use protocol analysis tools to monitor for illegal or unauthorized frames on network segments.

Protocol Analysis Applications

Fault isolation and troubleshooting. Most network problems (e.g., network down time) are solved by following a rigorous troubleshooting methodology. This methodology, not unique to network troubleshooting, consists of observing that a problem has occurred, gathering data about the problem, formulating a hypothesis, and then proving or disproving the hypothesis. This process is repeated until the problems are resolved. Protocol analysis is used in the network troubleshooting process for first observing that a problem has occurred, and next gathering data (using protocol analysis measurements such as protocol decodes and protocol statistics, as described in the section entitled “Protocol Analysis Measurements”). The user then formulates a hypothesis and uses the protocol analysis measurements to confirm cause of the problem, ultimately leading to a solution. The protocol analyzers can then be used to confirm that the problem has indeed been repaired.

Performance monitoring. Determining the current utilization of the network, the protocols in use, the errors occurring, the applications executing, and the users on the network is critical to understanding if the network is functioning properly or if problems such as insufficient capacity exist. Monitoring performance can be used over short time periods to troubleshoot problems or it can be used over long time periods to determine traffic profiles and optimize the configuration and topology of the network.

Network baselining. Every network is unique—different applications, distinct traffic profiles, products from numerous vendors, and varying topologies. Therefore, network managers must determine what is normal operation for their particular network. A network baseline is performed to determine the profile of a particular network over time. A profile is made up of statistical data including a network map, the number of users, protocols in use, error information, and traffic levels. This information is recorded on a regular basis (typically daily or weekly) and compared to previously recorded results. The baselining information is used to generate reports describing the network topology, performance, and operation. It is used to evaluate network operation, isolate traffic-related problems, assess the impact of hardware and software changes, and plan for future growth.

Security. Networks are interconnected on a global scale; therefore, it is possible for networks to be illegally accessed. Illegal access can be knowingly performed by someone with criminal intent or it can be the result of an error configuration of a device on the network. Protocol analysis tools, with their powerful filtering, triggering, and decoding capabilities can detect security violations.

Stress testing. Many errors on networks are intermittent and can only be recreated by generating traffic to stress network traffic levels, error levels, or by creating specific frame sequences and capturing all of the data. By stress testing a network and observing the results with protocol statistics and decodes many difficult problems can be detected.

Network mapping. Networks continually grow and change, so one of the big challenges facing network engineers and managers is determining the current topology and configuration of the network. Protocol analysis tools are used to provide automatic node lists of all users connected to the network as well as graphical maps of the nodes and the internetworks. This information is used to facilitate the troubleshooting process by quickly being able to locate users. It is also used as a reference to know the number and location of network users to plan for network growth.

Connectivity testing. Many network problems are the result of not being able to establish a connection between two devices on the network. A protocol analyzer can become a node on the network and send frames, such as a PING, to a device on the network and determine if a response was sent and the response time. A more sophisticated test can determine, in the case of multiple paths through the network, which paths were taken. In many WANs connectivity can be verified by executing a call placement sequence that establishes a call connection to enable a data transfer.

Conformance testing. Conformance testing is used to test data communications devices for conformance to specific standards. These conformance tests consist of a set of test suites (or scenarios) that exercise data

communications equipment fully and identify procedural violations that will cause problems. These conformance tests are used by developers of data communications equipment and by carriers to prevent procedural errors before connection to the network is allowed. Conformance tests are based on the applicable protocol standard.

Protocol Analysis Measurements. Protocol analyzer functionality varies depending on the network technology (e.g., LAN vs. WAN), the targeted user (e.g., R&D vs. installation), and the specific application (e.g., fault isolation vs. performance monitoring). Protocol analysis includes the entire set of measurements that allow a user to analyze the information on a computer communications network. These measurements include:

- Protocol decodes
- Protocol statistics
- Expert analysis
- Traffic generation
- Bit error rate tests
- Stimulus/response testing
- Simulation

Because protocol analysis requires associating the results of different measurements, the above measurements are typically made in combination. Thus, protocol analyzers include different sets or combination of these measurements. A good user interface combines pertinent information for the user and integrates the results of the different measurements.

Protocol decodes. Protocol decodes, also referred to as packet traces, interpret the bit streams being transmitted on the physical media. A protocol decode actually *decodes* the transmitted bit stream. The bit stream is identified and broken into fields of information. The decoded fields are compared to the expected values in the protocol standards, and information is displayed as values, symbols, and text. If unexpected values are encountered, then an error is flagged on the decode display. Protocol decodes follow the individual conversations and point out the significance of the frames on the network by matching replies with requests, monitoring packet sequencing activity, and flagging errors. Protocol decodes let the user analyze data frames in detail by presenting the frames in a variety of formats.

Figure 25.4.14a shows a summary of protocol packets that have been captured on the network. Figure 25.4.14b shows a detailed view of one particular packet, in this case, the packet with reference number 4264. It displays all of the detailed fields of an http packet.

Protocol statistics. An average high-speed computer network such as a 10 Mbit/s Ethernet handles thousands of frames per second. Protocol statistics reduce the volumes of data captured into meaningful statistical information providing valuable insight for determining the performance of a network, pinpointing bottlenecks, isolating nodes or stations with errors, and identifying stations on the network. Protocol analyzers keep track of hundreds of different statistics. The statistical information is typically displayed as histograms, tables, line graphs, and matrices.

Expert analysis. Troubleshooting computer networks is made complicated by the wide range of network architectures, protocols, and applications that are simultaneously in use on a typical network. Expert analysis reduces thousands of frames to a handful of significant events by examining the individual frames and the protocol conversations for indications of network problems. It watches continuously for router and bridge misconfigurations, slow file transfers, inefficient window sizes, connection resets, and many other problems. Thus, data are transformed into meaningful diagnostic information.

Traffic generation. Many network problems are very difficult to diagnose because they occur intermittently, often showing up only under peak load. Traffic generators provide the capability to simulate network problems by creating a network load that stresses the network or a particular device sending frame sequences on to the network.

FIGURE 25.4.14 (a) Summary view of protocol packets as captured on a network. (b) Detailed view of a particular packet, with reference number 4264.

Bit error rate tests. Bit error rate (BER) tests are transmission tests used to determine the error rate of the transmission media or the end-to-end network. While advanced BER measurements reside in the domain of sophisticated transmission test sets, protocol analysis, particularly in a WAN or ATM environment, often requires a verification of the media. BER tests are performed by transmitting a known bit pattern onto the network, looping it back at a point on the network, and receiving the sequence. The bit error rate is calculated as a percentage of the bits in error compared to the total number of bits received.

Stimulus/response testing. While many networking problems can be quickly solved with decodes and statistics, many of the more difficult problems cannot be solved in a nonintrusive manner. In this case, it is necessary to actively communicate with the devices on the network in order to recreate the problem or obtain necessary pieces of information to further isolate a problem. So, the user can actively query or stress the network and observe the results with decodes and statistics.

Simulation. In the context of protocol analysis, simulation can take two forms: protocol simulation and protocol emulation. Protocol simulation allows the user to send strings of data containing selected protocol headers along with the encapsulated data. In this way, the operation of a network device can be simulated for the purpose of testing a suspected problem or for establishing a link to confirm operation. Protocol emulators are software that controls the operation of the protocol analyzer automatically.

Protocol Analysis Measurement Functions. Protocol analysis consists of using measurements such as those described in the previous section to isolate network problems or monitor network performance. The protocol analysis measurement options described in this section are a set of orthogonal capabilities to the measurements described in the previous section. For example, a protocol analyzer can gather statistics on the network traffic, but a more effective troubleshooting approach is to set a capture filter and run the statistics so only the data between a file server and a router is analyzed.

Data capture. The most fundamental attribute of protocol analysis is the ability to capture the traffic from a live network and to store these data into a capture buffer. The captured data can then be analyzed and reanalyzed at the user's discretion. Once data are captured in the capture buffer they can be repeatedly examined for problems or events of significance. Search criteria, such as filter criteria, are based on address, error, protocol, and bit patterns.

Data logging. Many network troubleshooting sessions can be spread over hours and days. The capture buffer on a typical protocol analyzer is filled in seconds on a high-speed network. Therefore, data logging capabilities are crucial for setting up long troubleshooting sessions. The user can specify a file name and a time interval for recording critical information. This information is then regularly stored to hard disk and can be examined by the user at a later time. Information that is typically stored to disk includes frames matching a user specified filter, statistics results, or the results of a programmed test.

Filtering. The key to successfully troubleshooting network problems is based on eliminating the unnecessary information and focusing on the critical information that is essential to solving the problem. Computer networks process thousands of frames per second. A protocol analyzer can quickly fill a capture buffer with frames, and a user can sift through protocol decodes searching for the errors. But this is a time-consuming and tedious task. The most powerful function of protocol analysis is the ability to filter the data on the network in order to isolate problems. The function of a filter is very similar to that of a trigger (sometimes called a trap). Specific filter patterns are set by the user of a protocol analyzer, and these filters are then compared with the data from the network. Filters range from simple bit pattern matching to sophisticated combinations of address and protocol characteristics. Fundamentally, there are two types of filters—capture filters and display filters.

Capture filters are used to either include or exclude data from being stored in a protocol analyzer's capture buffer. Capture filters make it possible to only collect the frames of interest by eliminating extraneous frames. This effectively increases the usage of the capture buffer. Rather than a capture buffer that only contains six error frames out of 40,000 captured frames in the buffer, the data are filtered so that only error frames are in the buffer. More frames of interest can be captured, and they can be located more quickly. A disadvantage of capture filters is that it is necessary for the user to know what to filter, i.e., to have some idea of what problem to investigate. A second disadvantage is that the frames that were filtered out may contain the sequence of events leading up to the error frame.

In many situations the source of a network problem is not known; therefore it is necessary to capture all of the frames on the network and use display filters to repeatedly filter the frames. Because all of the frames are

stored in the capture buffer, the frames can be played back through the display filters. Display filters act on the frames once they have been captured. Frames can be selected for display by measurements such as protocol decodes.

Filter conditions can be combined to form more powerful filter criteria. Typically, as the troubleshooting process progresses, the user discovers more and more information about the network problem. As each new fact is discovered, it can be added to the filter criteria until finally the problem is identified. For example, to isolate a faulty Ethernet network interface card it is necessary to filter on the MAC address of the suspicious node and bad frame check sequence (FCS) simultaneously.

Triggers and actions. In order to troubleshoot network problems, it is often necessary to identify specific frames or fields in frames. Triggers are used to detect events of significance to the user and then initiate some action. Triggers and filters operate the same way in terms of recognizing conditions on the network. The parameters for setting trigger criteria are the same as the “filter types.” The trigger is a key capability of protocol analyzers, since it allows the automatic search of a data stream for an event of significance, resulting in some action to be taken. Possible trigger actions include:

- Visual alarm on the screen
- Audible alarm
- Start capturing data in the capture buffer continuously
- Start capturing data, fill the capture buffer and stop
- Position the trigger in the capture buffer and stop capturing data
- End the data capture
- Increment a counter
- Start a timer
- Stop a timer
- Make an entry in the event log
- Start a specific measurement
- Send an SNMP trap
- Log data to disk

Protocol Analyzer Block Diagram

There are three main components to any protocol analyzer:

- Computing platform
- Analysis and acquisition system
- Line interface

The functions of a protocol analyzer are described in Fig. 25.4.15.

Computing Platform. The computing platform is a general-purpose processing system—typically a PC or a UNIX workstation. The computing platform executes the user interface for the product and controls the measurements that are executed in the analysis and acquisition systems. It is very common for other applications to be run in conjunction with a protocol analyzer. These include spreadsheet applications for analyzing data and measurement results, network management software, and terminal emulation applications that log into computer systems on the network. Therefore, computing platforms are usually based on an industry standard system that allows a user to openly interact with the application environment.

Analysis and Acquisition System. Fundamentally a protocol analyzer *acquires* data from the network and then *analyzes* the data. Thus, the analysis and acquisition system is the core of a protocol analyzer. This system

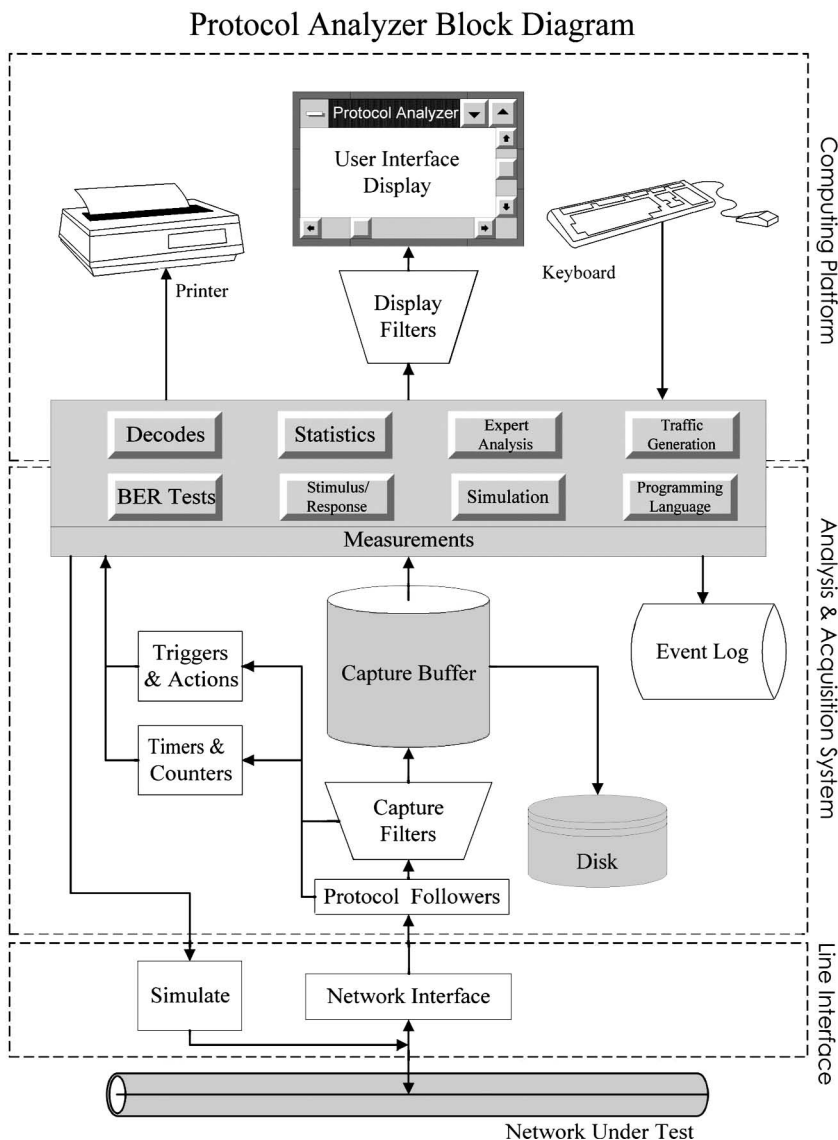

FIGURE 25.4.15 A protocol analyzer block diagram.

is essentially responsible for transferring data from the line interface to the capture buffer, ensuring that all of the error conditions, the protocol state information, and the protocol data are correctly stored and time stamped. During real-time and in postprocess mode the triggers and actions, the timers and counters, and the protocol followers are executed in the analysis and acquisition system. Additionally the measurements are typically executed in a distributed fashion between the computing platform and the analysis and acquisition system. In low-cost software-based analyzers the analysis and acquisition system functions are performed by the

25.52 INSTRUMENTATION AND TEST SYSTEMS

computing platform. In high-performance protocol analyzers a dedicated processor and special-purpose hardware are used to implement the processing required by the analysis and acquisition functions.

Line Interface. The physical hardware and firmware necessary to actually attach to the network under test are implemented in the line interface. Additionally the line interface includes the necessary transmit circuitry to implement simulation functions for intrusive testing. The function of the line interface is to implement the physical layer of the OSI reference model and provide framed data to the analysis and acquisition system.

CHAPTER 25.5

OSCILLOSCOPES

Jay A. Alexander

INTRODUCTION

The word *oscilloscope* has evolved to describe any of a variety of electronic instruments used to observe, measure, and record transient physical phenomena and present the results in graphic form (Fig. 25.5.1). Perhaps the popularity and usefulness of the oscilloscope spring from its exploitation of the relationship between vision and understanding. In any event, several generations of technical workers have found it to be an important tool in a wide variety of settings.

Basic Functions

The prototypical oscilloscope produces a two-dimensional graph with the voltage applied at the input plotted on the *vertical axis* and time plotted on the *horizontal axis* (Fig. 25.5.2). Usually the image appears as an illuminated trace on the screen of a cathode-ray tube (CRT) or liquid-crystal display (LCD) and is used to construct a model or representation of how the instantaneous magnitude of some quantity varies during a particular time interval. The quantity measured is often a changing voltage in an electronic circuit. However, it could be something else, such as electric current, acceleration, or light intensity, which has been changed into a voltage by a suitable transducer. The time interval over which the phenomenon is viewed may vary over many orders of magnitude, allowing measurements of events that proceed too quickly to be observed directly with the human senses. Instruments currently available measure events occurring over intervals as short as picoseconds (10^{-12} s) and up to tens of seconds.

The measured quantities can be uniformly repeating or essentially nonrecurring. The most useful oscilloscopes have multiple input channels so that simultaneous observation of multiple phenomena is possible, enabling the measurement of the time relationships among events.

GENERAL OSCILLOSCOPE CONCEPTS

General-purpose oscilloscopes are classified as *analog oscilloscopes* or *digital oscilloscopes*. Newly produced models are almost exclusively of the digital variety, although many lower-bandwidth (< 100 MHz) analog units are still being used in various industrial and educational settings. Digital oscilloscopes are often called *digital storage oscilloscopes* (DSOs), for reasons that will become apparent below.

Analog and Digital Oscilloscope Basics

The classic oscilloscope is the analog form, characterized by the use of a CRT as a direct display device. A beam of electrons, *cathode rays*, is formed, accelerated, and focused in an electron gun and strikes a phosphor

FIGURE 25.5.1 Epitomizing recent developments in oscilloscopes is the mixed analog and digital signal oscilloscope, recently introduced by several manufacturers. The version shown here is the Agilent Technologies 54642D. Mixed signal oscilloscopes are discussed later.

screen, causing visible light to be emitted from the point of impact (Fig. 25.5.3). The voltage signals to be displayed are amplified and applied directly to vertical deflection plates inside the CRT, resulting in an angular deflection of the electron beam in the vertical direction. This amplifier system is referred to as the *vertical amplifier*. The linear vertical deflection of the point at which the electron beam strikes the screen is thus proportional to the instantaneous amplitude of the input voltage signal. Another voltage signal, generated inside the oscilloscope and increasing at a uniform rate, is applied directly to the horizontal deflection plates of the CRT, resulting in a simultaneous, uniform, left-to-right horizontal motion of the point at which the electron beam strikes the phosphor screen. The operator of the oscilloscope may specify the rate of this signal using the *time-per-division* or horizontal scale control. For example, with the control set to $100\ \mu\text{s}/\text{div}$ on a typical oscilloscope with 10 horizontal divisions, the entire horizontal extent of the display will represent a time span of 1 ms.

FIGURE 25.5.2 Voltage is plotted on the vertical axis and time horizontally on the classic oscilloscope display.

FIGURE 25.5.3 Analog oscilloscope cathode-ray tube.

The electronic module that generates the signals that sweep the beam horizontally and controls the rate and synchronization of those signals is called the *time base*. The point on the phosphor screen illuminated by the electron beam thus moves in response to the vertical and horizontal voltages, and the glowing phosphor traces out the desired graph of voltage versus time.

The digital oscilloscope has been made practical and useful by advances in the state of the art of digitizing devices called *analog-to-digital converters* (ADCs). For the purposes of this discussion, an ADC is a device, which at suitable regular intervals measures or *samples* the instantaneous value of the voltage at the oscilloscope input and converts it into a digital value (a number), representing that instantaneous value (Fig. 25.5.4). The oscilloscope function of recording a voltage signal is achieved by storing in a digital memory a series of samples taken by the ADC. At a later time, the series of numbers can be retrieved from memory and the desired graph of volts versus time can be constructed. The graphing or display process, since it is distinct from the recording process, can be performed in several different ways. The display device can be a CRT employing direct beam deflection methods. More commonly, a *raster-scan display*, similar to that used in a conventional television receiver or a computer monitor, can be used. The samples may also be plotted on paper using a printer with graphics capability.

The digital oscilloscope is usually configured to resemble the traditional analog instrument in the arrangement and labeling of its controls, the features included in the vertical amplifier, and the labeling and presentation of the display. In addition, the circuits that control the sample rate and timing of the data-acquisition cycle are configured to emulate the functions of the time base in the analog instrument. This has allowed users who

FIGURE 25.5.4 Sampling in a digital oscilloscope.

and one or more *attenuators*, usually implemented with switches or relays, are available for reducing the amplitude of large signals. Together, the preamp and attenuator settings typically manifest as a vertical sensitivity or *scale* control on the oscilloscope's control panel. The scale control is specified in terms of *volts per division* (volts/div), where a division corresponds to a fixed fraction (typically 1/8th) of the vertical extent of the display. Thus when the scale control is set to 100 mV/div, for example, a signal with a peak-to-peak amplitude of 800 mV will occupy the full vertical extent of the display. A provision for injecting dc-shift or *offset* is also provided; this aids in measuring signals that are not symmetric about zero volts. Circuits and controls for changing the input *coupling* and *impedance* are often included as well. Coupling options usually consist of ac and dc, and sometimes GROUND, which is useful for quickly viewing a 0 V reference trace on the display. Impedance selections are generally 50 Ω and 1 M Ω . The 50 Ω selection is useful for making measurements where input sources having 50 Ω output impedance are connected to the oscilloscope with 50 Ω cables. In this situation the oscilloscope preserves the impedance of the entire system and does not introduce undesirable effects such as signal reflections. The 50- Ω selection is also used for many active probes, whose output amplifiers are commonly designed to drive a 50- Ω load. The 1-M Ω selection is appropriate for most other measurements, including those employing passive probes.

Trigger

In Fig. 25.5.6, the signals occurring at the indicated nodes in Fig. 25.5.5 are shown for a single acquisition cycle of a signal connected to the channel 1 input. The trigger source is set to the *internal, channel 1* position, and a positive slope-edge trigger is selected, so a trigger pulse is generated as the input signal crosses the indicated trigger level. In response to the trigger pulse, the ramp signal initiates the motion of the spot position on the display from left to right, and the unblanking gate signal reduces the CRT grid-to-cathode negative bias, causing the spot to become visible on the display screen. The ramp increases at a precisely controlled rate,

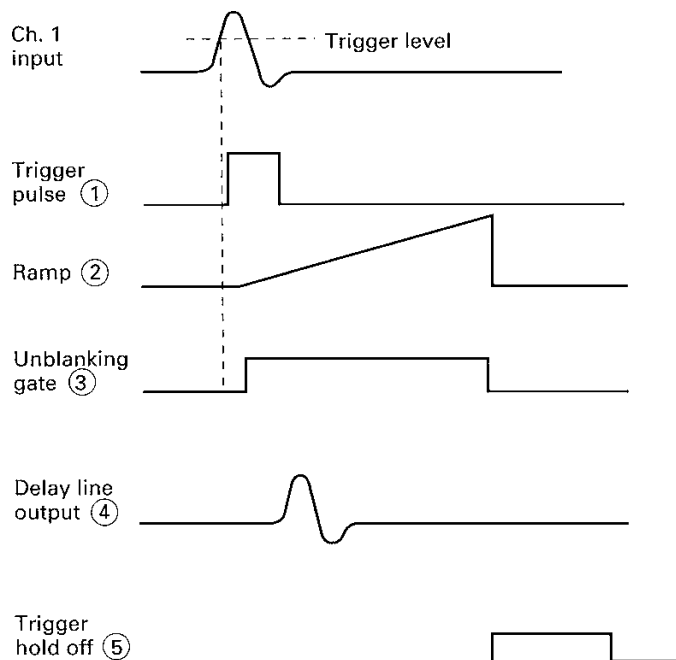

FIGURE 25.5.6 Waveforms from a single acquisition cycle.

causing the spot to progress across the display screen at the horizontal rate determined by the current time-per-division setting. When the spot has moved across the horizontal extent of the display, the unblanking gate switches negative, the trigger holdoff period begins, and the ramp retraces the spot to the starting point. At the end of trigger holdoff, the system is ready to recognize the next trigger and begin the next signal acquisition.

Delay Line

Some time is necessary after initiation of the trigger pulse for the sweep to attain a linear rate and for the display spot to reach full brightness. Since it is desirable to be able to view the voltage transient that has caused the trigger, a means of storing the input signal during the startup delay is needed. This is accomplished by placing a delay line in the vertical path. The triggering signal at the output of the delay line is visible on the display screen while the unblanking gate signal is at its most positive level (Fig. 25.5.6). A total delay time of between 25 and 200 ns is required depending on the oscilloscope model, with higher bandwidth units requiring shorter delays.

Dual-Trace Operation

Oscilloscopes are equipped with two or more channels because the most important measurements compare time and amplitude relationships on multiple signals within the same circuit. However, a conventional analog oscilloscope CRT has only one write beam and thus is inherently capable of displaying only one signal. Thus the channel switch (see Fig. 25.5.5) is used to timeshare, or *multiplex*, the single display channel among the multiple inputs. The electronically controlled channel switch can be set manually first to channel 1 and then later switched by the user to channel 2. However, a better emulation of simultaneous display is attained by configuring the oscilloscope to automatically and rapidly switch between the channels. Two different switching modes are implemented, called *alternate* and *chop*. In *alternate mode*, the channel switch changes position at the end of each sweep during retrace while the write beam is blanked. This method works best at relatively fast sweep speeds and signal repetition rates. At slow sweep speeds the alternating action becomes apparent, and the illusion of simultaneity is lost. In *chop mode*, the channel switch is switched rapidly between positions at a rate that is not synchronized with the input signals or the sweep. This method is effective at slower sweep speeds but requires a relatively higher bandwidth output amplifier to accurately process the combined chopped signal. Many analog oscilloscopes provide a control for the user to select between alternate and chop modes as appropriate to their measurement situation.

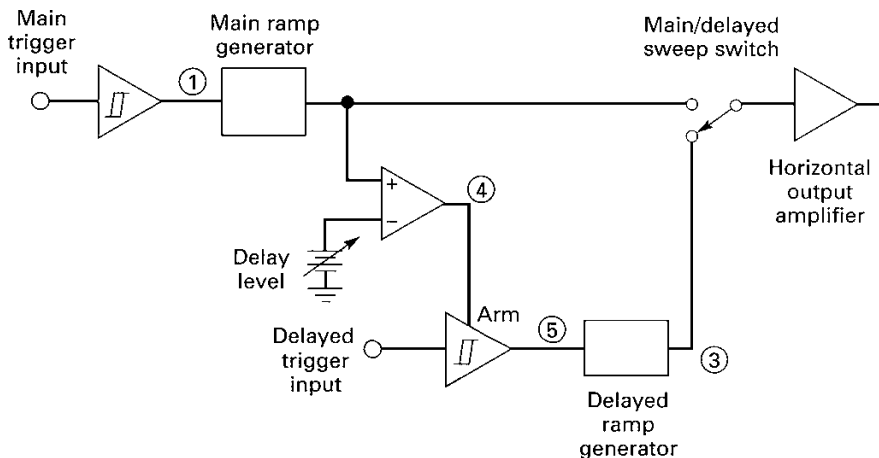

FIGURE 25.5.7 Main and delayed sweep generator block diagram.

FIGURE 25.5.8 Delayed sweep starting when the main sweep ramp exceeds the delay level.

Delayed Sweep

Some analog oscilloscope models include a second ramp generator, called a *delayed sweep*, and a second trigger generator, called a *delayed trigger* (Fig. 25.5.7), providing an additional method for controlling the placement of the *window* in time relative to the main trigger event.

The horizontal amplifier can still be connected to the output of the main ramp generator, in which case the operation is identical to that of the standard oscilloscope configuration described earlier. A comparator circuit is added whose output (4) switches when the main ramp signal exceeds a voltage called the *delay level* (Fig. 25.5.8). This dc voltage can be adjusted by the oscilloscope operator using a calibrated front panel control. The main ramp is initiated by the main trigger pulse and increases at a precisely controlled rate (volts per second) determined by the sweep-speed setting. Therefore, the time elapsed between the trigger pulse and comparator output state change is the reading on the delay control (in divisions) multiplied by the sweep-speed setting (in seconds per division). The delayed sweep ramp is initiated after the delay period in one of two ways: The *normal* method immediately starts the delayed sweep when the delay comparator switches (see Fig. 25.5.8). The *delayed trigger* mode uses the delay comparator output to arm the delayed trigger circuit. Then when the delayed trigger condition is met, the delayed sweep starts (Fig. 25.5.9). The delayed sweep rate always has a shorter time-per-division setting than the main sweep.

THE DIGITAL OSCILLOSCOPE

A block diagram of a two-channel digital oscilloscope is shown in Fig. 25.5.10. Signal acquisition is by means of an ADC. The ADC samples the input signal at regular time intervals and stores the resulting digital values in memory. Once the specified trigger condition is satisfied, the sampling process is interrupted, the stored samples are read from the acquisition memory, and the volts-versus-time waveform is constructed and graphed on the display screen. In some advanced models, the storage and readout of the samples is managed using two or more memory blocks, so that the oscilloscope can continue to acquire new data associated with the next trigger event while the display operation is proceeding. This keeps the display update rate high and helps to reduce the *dead time* during which the oscilloscope is unable to acquire data. The time interval between samples is called the *sample time* and is the reciprocal of the *sample rate*. The signal that regulates the sampling process in the ADCs is called the *sample clock*, and it is generated and controlled by the time base circuit. A crystal

FIGURE 25.5.9 The delayed trigger starts the delayed sweep.

oscillator is used as a reference for the time base to ensure the accuracy of the sample interval and ultimately of the time measurements made using the digital oscilloscope.

Sampling Methods

The exact process by which the digital oscilloscope samples the input signal in order to present a displayed waveform is called the *sampling method*. Three primary methods are employed. In *real-time* or “single-shot” sampling, a complete memory record of the input signal is captured on every trigger event. This is the most

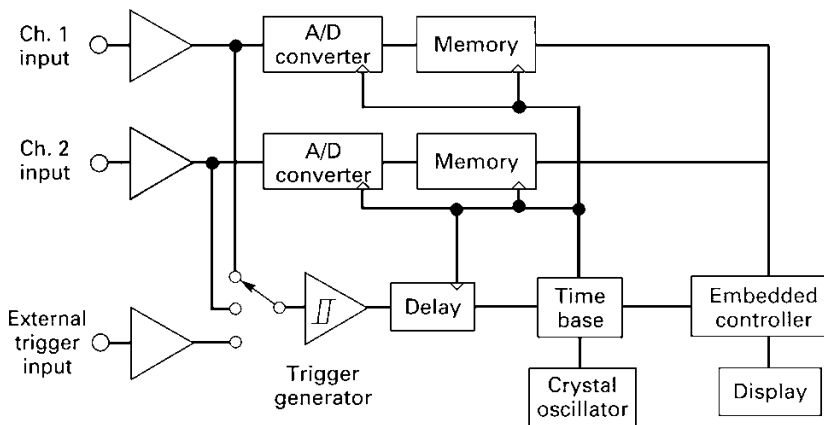

FIGURE 25.5.10 Digital oscilloscope block diagram.

FIGURE 25.5.11 Random repetitive sampling builds up the waveform from multiple data acquisitions. Dots from the same acquisition bear the same number.

conceptually straightforward type of sampling and its main advantage is that it can capture truly transient or nonrecurring events, provided the sample rate is sufficiently fast. Another advantage is the ability to capture “negative time,” or time before the trigger event. This is especially valuable in fault analysis, where the oscilloscope is used to trigger on the fault and the operator may look “backward in time” to ascertain the cause. The main disadvantage of real-time sampling is that the effective bandwidth of the oscilloscope can be no higher than 50 percent of the maximum sample rate of the ADC. When higher bandwidths are desired, *random repetitive sampling* may be used. This method is also called *equivalent-time sampling*. In this method, a complete waveform for display is built up from multiple trigger events. The ADC samples at a slower rate, and the samples are taken with a random time offset from the trigger event in order to ensure adequate coverage of all time regions of the input signal. This process is illustrated in Fig. 25.5.11. The major disadvantage of random repetitive sampling is that a repetitive input signal and stable trigger event are required. Many digital oscilloscopes are capable of sampling in either real-time or repetitive mode, with the selection performed either by the operator or automatically by the oscilloscope based on the sweep speed.

The final type of sampling is referred to as *sequential sampling*. In this method, only one point is acquired per trigger event, and successive samplings take place farther away from the trigger point. This is illustrated in Fig. 25.5.12. Sequential sampling is used to achieve even higher bandwidths (20 GHz and above) than are possible with random repetitive sampling due to the nature of the ADCs required. Oscilloscopes that use sequential sampling are not capable of capturing negative time and typically contain very limited trigger functionality.

FIGURE 25.5.12 Sequential sampling captures one sample per trigger and increases the delay t_{ds} after each trigger.

Quantization

Converting a continuous waveform into a series of discrete values is called *quantization* and several practical limitations apply to this process, as it is used in the digital oscilloscope. The signal is resolved into discrete levels only if it is within a specific range of voltages (Fig. 25.5.13). If the input signal is outside this range when a sample is taken, either the maximum code or the minimum code will be the output from the ADC. The limited *window* in voltage is similar to that encountered in the analog oscilloscope CRT. A sufficiently large signal amplitude causes the trace to disappear off the edge of the display screen. As in the analog instrument, the vertical scale and offset controls are used to adjust the input waveform so that the desired range of voltages on the waveform will fall within the digitizer voltage window.

Resolution

Voltage resolution is determined by the total number of individual codes that can be produced. A larger number permits a smoother and more accurate reproduction of the input waveform, but increases both the cost of the oscilloscope and the difficulty in achieving a high sample rate. ADCs are usually designed to produce a total code count that is an integer power of 2, and a unit capable of 2^n levels of resolution is called an *n-bit digitizer*. Digital oscilloscopes are available in resolutions from 6 to 12 bits, with the resolution varying generally in an inverse relationship to the maximum sample rate. Eight bits is the most frequently used resolution. The best possible intrinsic voltage resolution, expressed as a fraction of the full-scale range, is 2^{-n} , e.g., 0.4 percent for an 8-bit ADC. Many digital oscilloscopes provide averaging and other types of filtering modes that can be used to increase the effective resolution of the data.

Acquisition Memory

Each sample code produced must be stored immediately in the acquisition memory and so that memory must be capable of accepting data from the digitizer continuously at the oscilloscope's sample rate. For example, the memory in each channel of an 8-bit, 2 GSa/s oscilloscope must store data at the rate of 2×10^9 bytes/s. The memory is arranged in a serially addressed, conceptually circular array (Fig. 25.5.14). Each storage location is written to in order, progressing around the array until every cell has been filled. Then each subsequent sample overwrites what has just become the oldest sample contained anywhere in the memory, the progression continues, and a memory with n_m storage locations thereafter always contains the most recent n_m samples. The n_m samples captured in memory represent a total time of waveform capture of n times the sample time interval. For example, an oscilloscope operating at 2 GSa/s with a 32,000-sample acquisition memory captures a 16- μ s segment of the input signal.

If sampling and writing to acquisition memory stop immediately when the trigger pulse occurs (delay = 0 in Fig. 25.5.15), then the captured signal entirely precedes the trigger point (Fig. 25.5.15a). Setting delay greater than zero enables sampling to continue for a predetermined number of samples after the trigger point. Thus a signal acquisition could capture part of the record before and part after the trigger (Fig. 25.5.15b), or capture information after the trigger (Fig. 25.5.15c).

FIGURE 25.5.13 An ADC quantizes a continuous signal into discrete values having a specific range and spacing.

FIGURE 25.5.14 Acquisition memory is arranged in a circular array so that the next sample always overwrites the oldest sample in memory.

In recent years, deep memory (>1 M sample) digital oscilloscopes have become more prevalent. Deep memory is valuable because it allows the oscilloscope to capture longer periods of time while maintaining a high sample rate. To see why this is so, consider an oscilloscope with a maximum sample rate of 5 GSa/s and 10k acquisition memory. If the operator sets the horizontal scale control to 100 us/div, the oscilloscope must capture 1 ms of time in order to present a full screen of information. To do this, it must reduce the sample rate to 10 MSa/s (10k samples/1 ms) or lower. The oscilloscope will exhaust its memory if it samples faster than 10 MSa/s. An oscilloscope with a maximum sample rate of 2 GSa/s but 8M of memory, on the other hand,

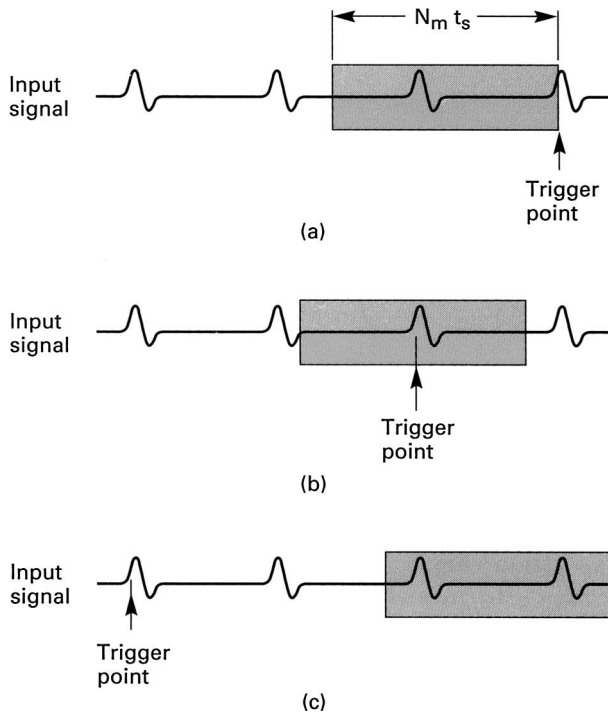

FIGURE 25.5.15 Trigger point can be placed anywhere within or preceding the captured record. (a) Delay = 0; (b) delay = $n_m/2$; (c) delay = n_m .

FIGURE 25.5.16 The relationship between memory depth and sample rate.

is able to maintain its maximum sample rate even at the 100 $\mu\text{s}/\text{div}$ setting. Maintaining sample rate in a digital oscilloscope is important because it reduces the likelihood of *aliasing* (undersampling) the high-frequency components of the input signal, and ensures that all the signal details will be captured, even at slower sweep speeds. Figure 25.5.16 shows the relationship between sweep speed and actual sample rate for the two oscilloscopes discussed in this section. Deep memory both delays the onset of the sample rate reduction as the oscilloscope is slowed down and reduces the extent of the reduction once it does occur.

Advanced Digital Oscilloscope Features

Modern digital oscilloscopes typically contain many features that never appeared in their analog counterparts. These include automatic signal scaling, automatic measurements, extensive waveform math functions, signal mask testing, saving and recalling of setup information, waveform data, and display images to internal or external storage media, and integrated calibration and self-test capabilities. Many of these features are made possible by the fact that these instruments are controlled by increasingly powerful microprocessors. Indeed, most digital oscilloscopes now contain more than one microprocessor, with each one focused on a different aspect of the overall product operation. In recent products, one of the processors is often a complete personal computer (PC) that is an integrated part of the oscilloscope. This has led to still more features in the areas of communications and connectivity. For example, PC-based oscilloscopes are currently available with capabilities such as networking, voice control, and web control. Advances in integrated circuit (IC) capabilities have also led to new features such as units with more than two channels; units with advanced trigger modes like pattern, state, sequence, risetime, and pulse width; and units with segmented memory, for storing separate acquisitions from different trigger events for later recall and analysis.

Mixed Analog and Digital Signal Oscilloscopes

In response to the growing digital signal content in electronic circuits, several manufacturers have developed *mixed analog and digital signal oscilloscopes* (abbreviated as MSO) that contain 16 digital inputs in addition

to the two or four standard oscilloscope channels. These digital inputs pass through comparators (1-bit ADCs) and function similar to the inputs on a logic timing analyzer. They are displayed along with the standard channels, and may also be used for triggering and automatic measurements. Measuring up to 20 channels with these oscilloscopes provides the user with more information at one time about his or her circuit. An example of a display from an MSO is shown in Fig. 25.5.1.

THE FUTURE OF OSCILLOSCOPES

Oscilloscopes have existed in various forms for over 60 years. They are at once basic general-purpose tools and advanced powerful measurement systems. As with other technology-based products, they will continue to evolve, in response to both emerging user needs and the availability of new technologies. Bandwidths, sample rates, and memory depths will continue to increase, and the trend toward more postacquisition analysis will continue. An area of increased attention is customization and application-specific measurement sets. Another is the combination of classic oscilloscope capabilities with those of other test and measurement products such as logic analyzers and signal generators. Mixed signal oscilloscopes are an example of such a combination. While the primary value of the oscilloscope, showing the user a picture of his or her signals versus time, will remain unchanged, many other attributes will indeed change, likely in as big a way as the digital oscilloscope has changed from its analog predecessor.

CHAPTER 25.6

STANDARDS-BASED MODULAR INSTRUMENTS

William M. Hayes

INTRODUCTION

Modular instruments employ a frame (Fig. 25.6.1) that serves as a host. These frames allow multiple switch, measurement, and source cards to share a common backplane. This makes it possible to configure instruments that can accommodate a range of input/output (I/O) channels. It also makes possible tailoring measurement capabilities to the specific applications being addressed.

Modular Standards

The modular standards described below are industry standards:

- VME standard
- VXI standard
- Personal computer (PC) plug-ins
- CompactPCI standard.

PC plug-ins are not part of a formal instrument standard. However, the ubiquity of the personal computer has made the PC motherboard I/O bus a de facto standard for instruments. Although all these standards are used for instrument systems, only VXI and a derivative of CompactPCI, called PXI, were developed expressly for instrumentation. For general-purpose instrumentation, VXI has the most products. PXI is emerging in the market, and generally offers the same features as VXI.

Open standards-based modular instruments are compatible with and can therefore accept products from many different vendors, as well as user-defined and constructed modules. Modular instruments generally employ a computer user interface instead of displays and controls embedded in the instrument's frame or package. By sharing a computer display, modular instruments save the expense of multiple front-panel interfaces. Without the traditional front panel, the most common approach to using modular instruments involves writing a test program that configures the instruments, conducts the measurements, and reports results. For this reason, modular instruments typically are supplied with programmatic software interfaces, called *drivers*, to ease the task of communicating with an instrument module from a programming language.

FIGURE 25.6.1 A typical modular instrument: VXI modules have been configured in this dual-rack structure, set on castors, to serve as a portable ground support test system for military avionics. (Photo courtesy of Agilent Technologies)

Advantages of Modular Instruments

Modular instruments are an excellent choice for high-channel-count measurements, automated test systems, applications where space is at a premium, and complex measurements where several instruments need to be coordinated.

ELEMENTS OF MODULAR INSTRUMENTS

Figure 25.6.2 shows the key elements of modular, standard-based instruments including a frame that contains a backplane with measurement and switching modules—all working with the *device under test* (DUT). Control is by system software, running on the computer, including the programming language and drivers that make up the test program.

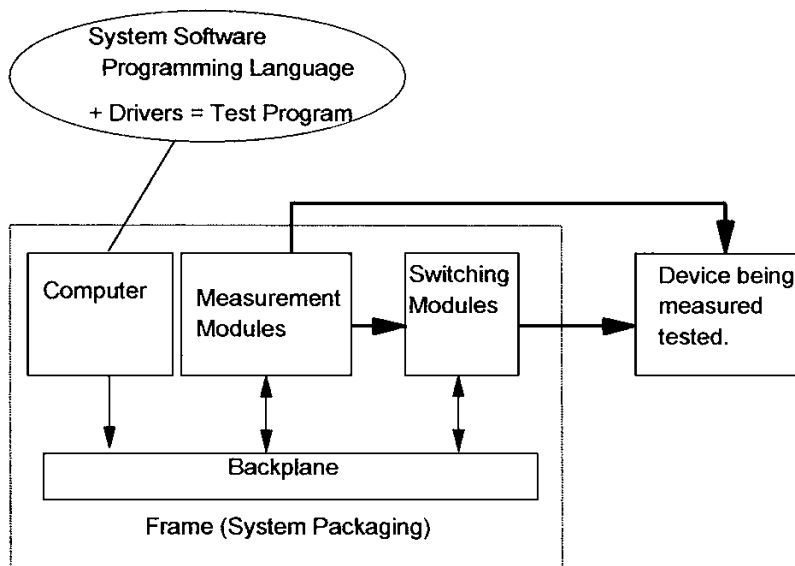

FIGURE 25.6.2 Key elements of modular standards-based instruments.

THE SYSTEM BACKPLANE

At the heart of a modular instrument is the system backplane, or set of buses connecting system modules together. These buses are high-speed parallel buses. All of the modular standards have a data-transfer bus, a master/slave arbitration bus—except ISA PC plug-ins—an interrupt bus and a bus for special functions. The VME (32-bit) backplane is one example.

FORM FACTORS

One place to begin understanding the similarities and differences between standards is board size.

Board Size

To ensure interchangeability among vendors, standardization of the instrument module's board size and spacing is important. With the exception of the PC plug-ins, all the other modular forms use Eurocard board sizes (see Table 25.6.1). These board sizes were standardized as IEEE 1101.1, ANSI 310-C, and IEC 297.

VME and VXI Standards

The VME standard uses the first two sizes, referring to them as single-height and double-height boards. The VXI standard uses all four sizes and refers to them as sizes A, B, C, and D, respectively. Most VXI manufacturers have adopted the B and C sizes. Compact PCI uses sizes 1 and 2, referring to the Eurocard 3U and 6U sizes.

TABLE 25.6.1 Eurocard Sizes

Eurocard Size	VME name	VXI name	CompactPCI name
10 × 16 cm	Single height	A	3U
23 × 16 cm	Double height	B	6U
23 × 34 cm	—	C	—
36 × 34 cm	—	D	—

PC Plug-in Modules

PC plug-in modules use the full- and half-card sizes adopted in the original IBM PC. The board size is approximately 12.2 cm × 33.5 cm for the full-size card and 12.2 cm × 18.3 cm for the half-size card.

VMEBUS (VME STANDS FOR VERSAMODULE EUROCARD)

The VMEbus specification was developed for microcomputer systems using single or multiple microprocessors. The specification was not originally intended for instrumentation, but the concept of computer functions integrated with measurement and control functions on a single backplane was a factor in its creation. The VMEbus International Trade Association (VITA) released the specification in August 1982. It was approved as IEEE 1014-87 in March 1987. In 1994, the VMEbus specification was amended to include 64-bit buses and became known as *VME64*. Additional backplane connectors are involved with VME64, so care in choosing system components is required. VMEbus products are used in a wide variety of applications including industrial controls and telecommunications.

VME System Hardware Components

A VME system comprises one or more frames, an embedded controller module, optionally various computer storage and I/O modules (e.g., LAN), and various measurement and switch modules. There is not a common programming model or instrument driver standard. As with other devices on a computer bus, programs must read/write device registers. In some cases, vendors supply software functions or subroutines to help with the programming.

VME Frames. *Frames* refer to the backplane, power supply as well as the packaging that encloses a system (Fig. 25.6.3). System builders can choose a solution at many different levels from the component level (i.e., a backplane) to complete powered desktop enclosures. Backplanes, subracks, and enclosures are available from many manufacturers, in single-, double-, and mixed-height sizes. Typically a 19-inch rack will accommodate 21 cards. Power supplies are available from 150 to 1500 W.

VME-Embedded Computers. VME is well suited for building single- and multiple-processor computer systems. A large number of embedded processors are available.

VME Switching. Many measurement systems require switching between measurement channel and signal paths from the device being tested. Typically these switches are multiplexers or matrix switches. There are several simple relay cards available in VME, but few multiplexers or matrix switches.

VME Software. Many VME systems are developed with real-time operating systems. Software is available for VxWorks, pSOS+, OS-9, and various other computer operating systems. Source code for the C programming language is the most common. There is no standardized driver software.

FIGURE 25.6.3 VME Backplanes and subracks are available in many different configurations.

VXI (VMEBUS EXTENSIONS FOR INSTRUMENTATION)

The VXI standard is a derivative of the VME standard. It was driven by a U.S. Air Force program in the 1980s to design a single *Instrument-on-A-Card* (IAC) standard with the objective to substantially reduce the size of electronic test and operational systems. In April 1987, a number of companies started discussions on creating an IAC standard that would benefit both the commercial and military test communities. The VXIbus consortium was formed and the VXIbus system specification was released in July of 1987. The IEEE adopted it as IEEE 1155 in 1992. After the basic VXIbus specification was adopted, it was recognized that the software aspect of test system development should be addressed. In 1993, the VXIplug&play Systems Alliance was formed. Several system *frameworks* were defined, based on established industry-standard operating systems. The Alliance released Revision 1.0 of the VXIplug&play specification in 1994; the latest revision, Revision 2, was released in 1998.

Common VXI Functions and Applications. VXI is used for most instrument and switching applications, including:

- *Automated test systems.* With its aerospace/defense roots, some of the specific applications have been for weapons and command/control systems, and as the foundation for operational systems, such as an artillery firing control system.
- *Manufacturing test systems.* Examples include cellular phone testing and testers for automotive engine-control modules.
- *Data acquisition.* In particular, DAC applications include physical measurements such as temperature and strain. Examples include complex and sophisticated measurements, such as satellite thermal vacuum testing or aircraft stress analysis.

VXII Standard

The VXI standard including VXIplug&play is a comprehensive system-level specification. It defines backplane functionality, electrical specifications, mechanical specifications, power management, electromagnetic

compatibility (EMC), system cooling, and programming model. The backplane functionality has features intended specifically for instrumentation.

VXI System Hardware Components

VXI systems can be configured with either an external computer connected to a VXI mainframe, or with an embedded computer. External computers are the more common configuration because the cost is low and they allow the user to choose the latest and fastest PC available. A VXI system configured with an embedded computer is formed with an VXI computer module, a mainframe, various measurement and switching modules, and the supporting software including VXI Plug-and-Play drivers.

VXI Mainframes. VXI system builders have a choice of backplanes or complete mainframes. Mainframes are the most common choice (Fig. 25.6.4). They include backplane, power supply, and enclosure. B-size mainframes are typically available with 9 or 20 slots and supply up to 300 W. Mainframes for C-size modules are available with 4, 5, 6, or 13 slots. D-size mainframes are available with 5 or 13 slots. Power capabilities range from 550 to 1500 W. Backplanes are available with basically the same slot choices as mainframes.

VXI External Connection to Computers. A VXI module is required to connect and communicate with an external computer. Two choices are available: *Slot 0 controllers* and *bus extenders*. The most common bus extender is called MXIbus. Slot 0 controllers and bus extenders must be placed in a unique slot of the mainframe. They receive commands from the external computer, interpret them and then direct them to the various measurement and switch modules. Both provide special VXI functions that include the *Resource Manager*. Bus extenders translate a personal computer's I/O bus to the VXI backplane using a unique high-speed parallel bus. Transactions over a bus extender have a register-to-register bit level flavor. The advantage of bus extenders is high speed. Cable lengths must be relatively short.

FIGURE 25.6.4 A 13-slot C-size VXI mainframe. Notice the system monitoring displays, which are unique, relative to other modular instrument types. (Photo courtesy of Agilent Technologies)

Slot 0 controllers support these register level transactions but also support message-based transactions. These transactions are ASCII commands following the standard commands for programmable instrumentation (*SCPI*) standard, accepted by the instrument industry in 1990. SCPI commands are very readable, although slower to interpret. The advantages of message-based transactions is easy and fast program development. The introduction of VXI plug-&-play drivers has superseded SCPI for easier, quicker programming.

Slot 0 controllers require a relatively high-speed communication interface to communicate with an external computer. *GP-IB*, known as *IEEE-488*, and *Firewire*, known as *IEEE-1394*, are the standard interfaces for Slot 0 controllers. The external computer must have a matching communication interface to the Slot 0 controller.

Firewire interfaces are a computer-industry standard and are often built into PCs as standard equipment. Basic Firewire software-driver support was included in Windows 98 from Microsoft. GP-IB has been an instrument communication standard since 1975. Because it is not a computer standard, a plug-in interface board

FIGURE 25.6.5 VXI switch module and termination blocks for wiring, C-size. (Photo courtesy of Agilent Technologies)

must be added to the external PC for connection to the Slot 0 controller. GP-IB interfaces are about five times slower than Firewire.

VXI Embedded Computers. Embedded controllers are available for C-size main-frames. Products with Intel-architecture processors running Windows 3.11/ 95/98/NT are available from several vendors.

VXI Measurement Modules. VXI offers the broadest and most complete line of instrumentation modules (see Fig. 25.6.5 for an example of a VXI measurement module). Like the other modular standards, VXI offers a full line of digital I/O modules and modules containing ADCs and DACs. These functions are commonly used for data-acquisition and industrial-control applications.

Switching Modules. VXI also has the broadest line of switching modules among the modular instrument standards (see Fig. 25.6.5 for an example of a switching module). Switching can be used in many different ways and include simple relays, multiplexers and matrices, RF/microwave switches, and analog/FET switches.

VXI Software

The VXI standard has emphasized system software as an important element to improve the interoperability of modules from multiple vendors and to provide system developers a head start in developing their software. The VXIplug&play Systems Alliance developed a series of system frameworks encompassing both hardware and software. Six frameworks have been defined:

- Windows 3.1
- Windows 95
- Windows NT
- HP-UX
- Sun
- GWIN

In common with all of the frameworks is a specification for basic instrument communication called *virtual instrument software architecture* (VISA). It is a common communications interface regardless of whether the physical interconnect is GP-IB, Ethernet, or Firewire. Also in common among the frameworks is a specification for instrument drivers. *Instrument drivers* are functions, which are called from programming languages to control instruments. VXIplug&play drivers must include four features:

- C function library files
- Interactive soft front panel
- Knowledge base file
- Help file

The C function library files must include a dynamic link library (.DLL or .SL), ANSI C source code, and a function panel file (.FP). The function must use the VISA I/O library for all I/O functions. The interactive soft-front panel is a graphical user interface for directly interacting with a VXI instrument module. Some front panels closely resemble the front panel of a traditional box instrument. The *knowledge base file* is an ASCII description of all the instrument module's specifications. The *help file* provides information on the C function library, on the soft front panel, and on the instrument itself.

VXI Standard Specifications

Because the intent of the VXI standard was to create a standard specifically for instruments, several extensions were made to the VME specification. These extensions include additions to the backplane bus, and power, cooling, and RFI specifications.

Unique VXI Signals

The A-board size has only one connector (P1) and has no backplane extensions over VME. The B-, C-, and D-size boards have at least a second connector (P2). On P2 are the following additions:

- Additional supply voltages to support analog circuits: -5.2 V, -2 V, $+24$ V, and -24 V.
- Additional pins were also added for an increase in the maximum current capacity of the $+5$ V supply.
- 10-MHz differential ECL clock for synchronizing several modules.
- Two parallel ECL trigger lines.
- Eight parallel TTL trigger lines.
- A module identification signal.
- A 12-line local bus that connects adjacent modules. The manufacturer of the module defines the functionality of these lines.
- An analog summing bus terminated in 50Ω .

Trigger Lines

The TTL and ECL trigger lines are open collector lines used between modules for *trigger*, *handshake*, *clock*, and *logic state* communications. Several standard protocols have been defined for these lines, including *synchronous* (SYNC), *asynchronous* (ASYNC), and *start/stop* (STST).

Module Power

The VXIbus specification has set standards for mainframe and module power, mainframe cooling, and electromagnetic compatibility between modules. This ensures that products from multiple vendors will operate together.

Cooling Specification

The mainframe and module-cooling specification focuses on the test method for determining whether proper cooling will be available in a system.

PERSONAL COMPUTER PLUG-INS (PCPIS)

Since the IBM PC was introduced in the mid-1970s, a number of companies have designed products to plug into the open slots of the PC motherboard. Three standards have defined those open slots. They are the ISA (Industry Standard Architecture), EISA (Extended Industry Standard Architecture), and PCI (Peripheral Component Interconnect) standards. EISA is an extension of ISA. All three were defined by the computer industry and none have support for instrumentation. In 1994, a group of industrial computer vendors formed a consortium to develop specifications for systems and boards used in industrial computing applications. They called themselves PICMG (PCI Industrial Computer Manufacturers Group). Today, it includes more than 350 vendors. The group's first specification defined passive backplane computers. PICMG 1.0 *PCI-ISA Passive Backplane* was adopted in October 1994. A second specification, PICMG 1.1 *PCI-PCI Bridge Board*, was adopted in May 1995.

PCPI Common Functions AND Applications

The most common applications are data-acquisition, industrial-control, and custom electronic-control systems.

FIGURE 25.6.6 PC plug-in: Multifunction data acquisition module, 16 analog inputs, 2 analog outputs, 24 digital I/O. (Photo courtesy of ComputerBoards, Inc)

PCPI System Components

Two different configurations are common with PC plug-in measurement systems. The first configuration consists simply of a personal computer and a few measurement modules. The second configuration comprises a passive backplane, a single-board computer, and several measurement modules. This latter approach can also be referred to as an *industrialized PC*. In both cases, the measurement modules are the same (Fig. 25.6.6).

PCPI Frames. In the simplest and most common configuration, the personal computer comprises the backplane, power supply, and packaging for the measurement system. System builders can choose a variety of PC form factors—from desktops to server towers. PC backplanes usually provide seven or eight slots. After the installation of standard PC peripherals, only a couple of slots are free for instrumentation. Extender frames are available, but not common. This type of PC plug-in system tends to be small, where only a few instrument functions are needed.

PCPI Measurement Modules. PC plug-in instrument functions are primarily digital I/O modules and modules containing ADCs and DACs. In addition, there is a small number of basic instruments including oscilloscopes, digital multimeters, and pulse/function generators.

COMPACTPCI

CompactPCI is a derivative of the Peripheral Component Interconnect (PCI) specification from the personal-computer industry. CompactPCI was developed for industrial and embedded applications, including real-time data acquisition and instrumentation. The specification is driven and controlled by PICMG, the same group covered in PC plug-ins. The CompactPCI specification was released in November 1995. To support the needs of general-purpose instrumentation, a PICMG subgroup developed a CompactPCI instrumentation specification, called PXI (PCI *eXtended for Instrumentation*). The first public revision of PXI was released in August 1997. The PXI specification continues to be developed and maintained by the PXI Systems Alliance (PXISA), a separate industry group.

CompactPCI Specification

Similar to VME, the CompactPCI specification defines backplane functionality, electrical specifications, and mechanical specifications. The functionality is the same as the PCI bus, as defined by the PCI local bus specification, but with some additions. These additions provide pushbutton reset, power-supply status, system-slot identification, and legacy IDE interrupt features. A unique feature of CompactPCI is *Hot Swap*, the ability to insert or remove modules while power is applied. This is an extension to the core specification.

CompactPCI System Components

A CompactPCI measurement system usually consists of one or more frames, an embedded computer module, and various measurement modules.

Frames. Frames refer to the backplane, power supply, and packaging that encloses a system. System builders can choose a solution at many different levels from the component level (i.e, a backplane to complete powered desktop enclosures). CompactPCI backplanes are available with two, four, six, or eight slots. It is possible to go beyond eight slots using a bridge chip on the frame or a bridge card.

Embedded Computers. The PCI bus is commonly used in many computers, from personal computers to high-end workstations. For that reason, a large number of CompactPCI embedded processors are available.

Measurement Modules. Instrument functions in CompactPCI are primarily digital I/O modules and modules containing ADCs and DACs. In addition, there is a small but growing number of traditional instruments, including oscilloscopes, digital multimeters, and serial data analyzers.

Switching Modules CompactPCI, specifically PXI, includes a wide range of switching products, including simple relays, multiplexers and matrices, RF switches, and FET switches.

Compact PCI Software. PXI adopted as part of its specification many of the features of VXI plug&play software. It adopted software frameworks for Windows 95 and Windows NT. These frameworks are required to support the VISA I/O standard.

CHAPTER 25.7

EMBEDDED COMPUTERS IN ELECTRONIC INSTRUMENTS

Tim Mikkelsen

INTRODUCTION

All but the simplest electronic instruments have some form of embedded computer system. More and more computing is being embedded in the instrument because of reductions of computing cost and size. This is increasing computing power as well as increasing the number of roles for computing in the instrument domain. Consequently, systems that were previously a computer or PC and an instrument are now just an instrument.

This transition is happening because of the demand for functionality, performance, and flexibility in instruments and also because of the low cost of microprocessors. Embedded computers are almost always built from microprocessors or microcontrollers. In fact, the cost of microprocessors is sufficiently low and their value sufficiently high, hence most instruments have more than one embedded computer.

Embedded Computer Model

The instrument and its embedded computer normally interact with four areas of the world: the measurement, the user, peripherals, and external computers. The instrument needs to receive measurement input and/or send out source output. A *source* is defined as an instrument that generates or synthesizes signal output. An *analyzer* is an instrument that analyzes or measures input signals. These signals can consist of analog and/or digital signals. The *front end* of the instrument is the portion of the instrument that conditions, shapes, and modifies the signal to make it suitable for acquisition by the analog-to-digital converter.

The instrument normally interacts with the user of the measurement. The instrument also generally interacts with an external computer that is usually connected for control or data-connectivity purposes. Finally, the instrument is often connected to local peripherals, primarily for printing and storage. Figure 25.7.1 is an example of an embedded computer. A generalized block diagram for the embedded computers in an instrumentation environment appears in Fig. 25.7.2.

The embedded computer is typically involved in the control and transfer of data via external interfaces. This enables the connection of the instrument to external PCs, networks, and peripherals. Examples include local area networks (LAN), *IEEE 488* (also known as *GPIB* or *HP-IB*), *RS-232* (serial), *Centronics* (parallel), *Universal Serial Bus* (USB), and *IEEE 1394* (Firewire).

The embedded computer is also typically involved in the display to and input from the user. Examples include *keyboards*, *switches*, *rotary pulse generators* (RPGs, i.e. knobs), *LEDs* (single or alpha-numeric displays), *LCDs*, *CRTs*, and *touch screens*.

Agilent E1498A

FIGURE 25.7.1 Typical of the embedded computers on the marketplace is the Agilent Technologies E1498A Embedded Controller. This single-slot, C-sized message-based computer was developed specifically for VXI.

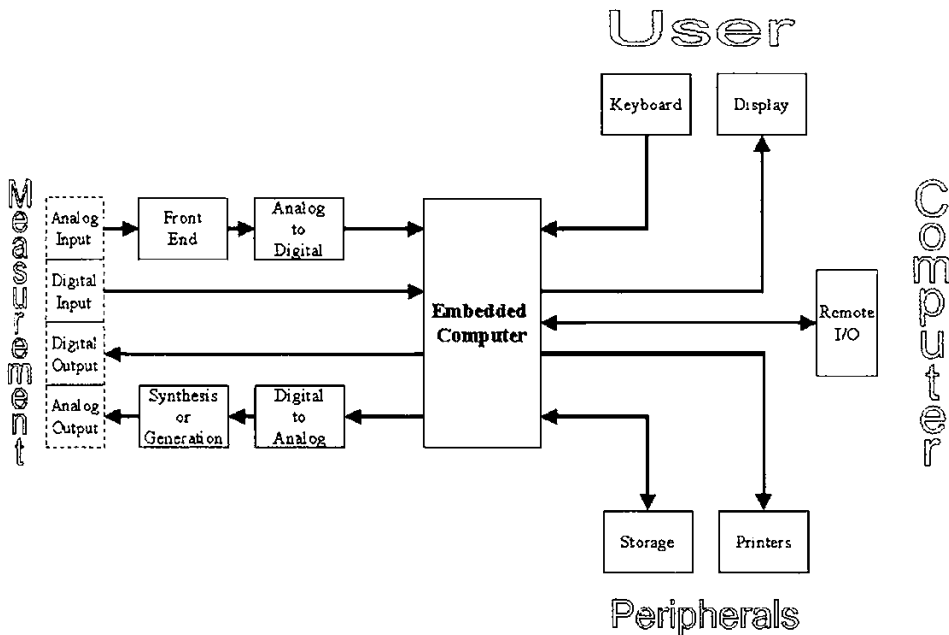

FIGURE 25.7.2 An embedded computer generalized block diagram.

Many instruments often have a large amount of configuration information because of their advanced capabilities. The embedded computer enables saving and recalling of the instrument state. Also, the embedded computer is used sometimes for user customization of the instrument. This can range from simple configuration modifications to complete instrument programmability.

With very powerful embedded computers available in instruments, it is often unnecessary to connect the instrument to an external computer for more-advanced tasks. Examples include *go/no-go*, also known as *pass/fail* testing and data logging.

The embedded computer almost always performs calculations, ranging from very simple to very complex, which convert the raw measurement data to the target instrument information for measurement or vice versa for source instruments. The embedded computer generally controls the actual measurement process. This can include control of a range of functions such as analog-to-digital conversion, switching, filtering, detection, and shaping. The embedded computer is almost always used to perform at least a small amount of self-testing. Most instruments use embedded computers for more extensive calibration tests.

BENEFITS OF EMBEDDED COMPUTERS IN INSTRUMENTS

In addition to the direct uses of embedded computers, it is instructive to think about the value of an embedded computer inside an instrument. The benefits occur throughout the full life cycle of an instrument, from development through maintenance.

One of the biggest advantages of embedding computers within an instrument is that they allow several aspects of the hardware design to be simplified. In many instruments, the embedded computer participates in acquisition of the measurement data by servicing the measurement hardware. Embedded computers also simplify the digital design by providing mathematical and logical manipulations, which would otherwise be done in hardware. They also provide calibration both through numerical manipulation of data and by controlling calibration hardware. This is the classic transition of function from hardware to software.

The embedded computer allows for lower manufacturing costs through effective automated testing of the instrument. They are also a benefit because they allow for easier and lower-cost defect fixes and upgrades (with a ROM or program change).

When used as a stand-alone instrument, embedded computers can make the setup much easier by providing online help or setup menus. This also includes automatic or user-assisted calibration. Although many are stand-alone instruments, a large number are part of a larger system. The embedded computers often make it easier to connect an instrument to a computer system by providing multiple interfaces and simplified or automatic setup of interface characteristics.

Support Circuitry

Although requirements vary, most microprocessors require a certain amount of support circuitry. This includes the generation of a system clock, initialization hardware, and bus management. In a conventional design, this often requires two or three external integrated circuits (ICs) and five to ten discrete components. The detail of the design at this level depends heavily on the microprocessor used. In complex or high-volume designs, an *application-specific integrated circuit* (ASIC) can be used to provide much of this circuitry.

Memory

The microprocessor requires memory both for program and data store. Embedded computer systems usually employ both ROM and RAM.

Read-only memory (ROM) retain their contents if power is removed.

Random access memory (RAM) is a historical but inadequate term that really refers to read/write memory—memory whose contents can be changed. RAM memory is volatile; it will lose its contents when power is no longer applied. RAM is normally implemented as either static or dynamic devices.

Static memory is a type of electrical circuit that will retain its data, with or without access, as long as power is supplied. It is normally built with latches or flip-flops.

Dynamic memory is built out of a special type of circuit that requires periodic memory access (every few milliseconds) to refresh and maintain the memory state. It uses a switched capacitor for the storage element. This is handled by memory controllers and requires no special attention by the developer.

The advantage of the dynamic memory RAM is that it consumes much less power and space. ROM is used for program storage because the program does not usually change after power is supplied to the instrument. A variety of technologies are used for ROM in embedded applications.

Nonvolatile memory. Some instruments are designed with special nonvolatile RAM that retains its contents after power has been removed. This is necessary for storing such information as calibration and configuration data. This can be implemented with regular RAM memory that has a battery backup. It can also be provided by special nonvolatile memory components, most commonly, flash memory devices.

Flash memory is a special type of EEPROM that uses block transfers—instead of individual bytes—and has a fairly slow, in computer terms, write time. So, it is not useful as a general read/write memory device, but is perfect for nonvolatile memory purposes. Also, a limited number of writes are allowed (on the order of 10,000). All embedded systems have either a ROM/RAM or a flash/RAM memory set so that the system will be able to operate the next time the power is turned on.

INSTRUMENT HARDWARE

Given that the role of these microprocessors is instrumentation (measurement, analysis, synthesis, switches, and the like), the microprocessor needs to have access to the actual hardware of the instrument. This instrument hardware is normally accessed by the microprocessor like other peripheral components such as registers or memory locations. Microprocessors frequently interface with the instruments' analog circuits using *analog-to-digital converters* (ADCs) and *digital-to-analog converters* (DACs).

In an analog instrument, the ADC bridges the gap between the analog domain and the digital domain. In many cases, substantial processing is performed after the input has been digitized. Increases in the capabilities of ADCs enable the analog input to be digitized closer to the front end of the instrument, allowing a greater portion of the measurement functions to occur in the embedded computer system. This has the advantages of providing greater flexibility and eliminating errors introduced by analog components.

Just as ADCs are crucial to analog measuring instruments, DACs play an important role in the design of source instruments such as signal generators. They are also very powerful when used together. For example, instruments can have automatic calibration procedures where the embedded computer adjusts an analog circuit with a DAC and measures the analog response with an ADC.

PHYSICAL FORM OF THE EMBEDDED COMPUTER

Embedded computers in instruments take one of three different forms: a separate circuit board, a portion of a circuit board, or a single chip. In the case of a separate circuit board, the embedded computer is a board-level computer that is a circuit board separate from the rest of the measurement function. An embedded computer that is a portion of a circuit board contains a microprocessor, its associated support circuitry and some portion of the measurement functions on the same circuit board. A single-chip embedded computer can be a microcontroller, digital signal processor, or microprocessor core with almost all of the support circuitry built into the chip.

Digital Signal Processor (DSP)

A DSP is a special type of microcontroller that includes special instructions for digital signal processing, allowing it to perform certain types of mathematical operations very efficiently. These math operations are primarily *multiply and accumulate* (MAC) functions, which are used in filter algorithms.

Microprocessor Cores

These are custom microprocessor, IC segments, or elements that are used within custom-designed ICs. Assume an instrument designer has a portion of an ASIC that is the CPU core. The designer can then integrate much of the rest of the system, including some analog electronics, on the ASIC, creating a custom microcontroller. This approach minimizes size and power. In very high volumes, the cost can be very low. However, these chips are intended for very specific applications and are generally difficult to develop.

Architecture of the Embedded Computer Instrument

Just as an embedded computer can take a variety of physical forms, there are a number of ways to configure an embedded computer instrument. The architecture of the embedded computer has significant impact on many aspects of the instrument including cost, performance, ease of development, and expandability. The range of choices include:

- Peripheral-style instruments (externally attached to a PC)
- PC plug-in instruments (circuit boards inside a PC)
- Single-processor instruments
- Multiple-processor instruments
- Embedded PC-based instruments (where the embedded computer is a PC)
- Embedded workstation-based instruments.

EMBEDDED COMPUTER SYSTEM SOFTWARE

As stated earlier, the embedded computer in an instrument requires both hardware and software components. Embedded computer system software includes:

- *Operating system*—the software environment that the instrument applications run within
- *Instrument application*—the software program that performs the instrument functions on the hardware
- *Support and utility software*—additional software the user of the instrument requires to configure, operate, or maintain the instrument such as reloading or updating system software, saving and restoring configurations.

USER INTERFACES

Originally, instruments used only panel-mounted, *direct controls* that were connected directly to the analog and digital circuits. As embedded computers became common, instruments began employing *menu* or *keypad-driven* systems, in which the user input was read by the computer, which then modified the circuit operation. Today, designs have progressed to the use of *graphical user interfaces* (GUIs). Although some instruments are intended for automated use or are *faceless* (have no user interface), most need some way for the user to interact with the measurement or instrument. All of these user interface devices can be mixed with direct control devices such as meters, switches, and potentiometers/knobs. There are a variety of design challenges in developing effective user interfaces in instruments.

EXTERNAL INTERFACES

Most instruments include external interfaces to a *peripheral*, another instrument device, or to an external computer. An interface to a peripheral allows the instrument to use the external peripheral, normally printing or plotting the measurement data. An interface to another device allows the instrument to communicate with or

control another measurement device. The computer interface provides a communication channel between the embedded computer and the external computer. This allows the user to:

- Log (capture and store) measurement results
- Create complex automatic tests
- Combine instruments into systems
- Coordinate stimulus and response between instruments

The external computer accomplishes these tasks by transferring data, control, setup, and/or timing information to the embedded computer. At the core of each of these interfaces is a mechanism to send and receive a stream of data bytes.

Hardware Interface Characteristics. Each interface that has been used and developed has a variety of interesting characteristics, quirks, and trade-offs. However, external interfaces have some common characteristics to understand and consider:

- *Parallel or serial*—How is information sent (a bit at a time or a byte at a time)?
- *Point to point or bus/network*—How many devices are connected via the external interface?
- *Synchronous or asynchronous*—How are the data clocked between the devices?
- *Speed*—What is the data rate?

Probably the most fundamental characteristic of hardware interfaces is whether they send the data stream one bit at a time, *serial*, or all together, *parallel*. Most interfaces are serial. The advantage of serial is that it limits the number of wires down to a minimum of two lines (data and ground). However, even with a serial interface, additional lines are often used (transmitted data, received data, ground, power, request to send, clear to send, and so forth). Parallel interfaces are normally 8 bit or 16 bit. Some older instruments had custom *binary-coded decimal* (BCD) interfaces, which usually had six sets of 4-bit BCD data lines. Parallel interfaces use additional lines for handshaking-explicit indications of *data ready* from the sender and *ready for data* from the receiver.

TABLE 25.7.1 Common Instrument Software Protocols

Software protocol	Description
The IEEE 488.2	The <i>IEEE 488.2, Codes, Formats, Protocols and Common Commands for Use with IEEE 488.1</i> is a specification that defines: 39 common commands and queries for instruments, the syntax for new commands and queries, and a set of protocols for how a computer and the instrument interact in various situations. Although this is a companion to the IEEE 488.1 interface, it is independent of the actual interface, but it does depend on certain interface characteristics.
SCPI	The <i>Standard Commands for Programmable Instruments</i> (SCPI) is a specification of common syntax and commands so that similar instruments from different vendors can be sent the same commands for common operations. It also specifies how to add new commands that are not currently covered in the standard.
TCP/IP	The <i>Transmission Control Protocol/Internet Protocol</i> (TCP/IP) specification is the underlying protocol used to connect devices over network hardware interfaces. The network hardware interface can be a LAN or a WAN.
FTP	The <i>File Transfer Protocol</i> (FTP) specification is a protocol used to request and transfer files between devices over network hardware interfaces.
HTTP	The <i>HyperText Transfer Protocol</i> (HTTP) specification is a protocol used to request and transfer Web (HyperText Markup Language, HTML) pages over network hardware interfaces.
VXI-11	The <i>VXI-11 plug-and-play specification</i> is a protocol for communicating with instruments that use the VXI-bus (an instrument adaptation of the VME bus), GPIB/HP-IB, or a network hardware interface.

SOFTWARE PROTOCOL STANDARDS

The software protocol standards listed in Table 25.7.1 provide the hardware interface between devices and computers. The *physical layer* is necessary, but not sufficient. To actually exchange information, the devices (and/or computers) require defined ways to communicate, called *protocols*. If a designer is defining and building two or more devices that communicate, it is possible to define special protocols (simple or complex). However, most devices need to communicate with standard peripherals and computers that have predefined protocols that need to be supported. The protocols can be very complex and layered (one protocol built on top of another). This is especially true of networked or bus devices.

USING EMBEDDED COMPUTERS

Instruments normally operate in an analog world. It has characteristics, such as noise and nonlinearity of components, that introduce inaccuracies in the instrument. Instruments generally deal with these incorrect values and try to correct them by using software in the embedded computer to provide calibration (adjusting for errors inside the instrument) and correction (adjusting for errors outside of the instrument).

Using Instruments That Contain Embedded Computers

In the process of selecting or using an instrument with an embedded computer, a variety of common characteristics and challenges arise. This section covers some of the common aspects to consider:

- *Instrument customization*—What level of instrument modification or customization is needed?
- *User access to the embedded computer*—How much user access to the embedded computer as a general-purpose computer is needed?
- *Environmental considerations*—What is the instrument's physical environment?
- *Longevity of instruments*—How long will the instrument be in service?

User Access to an Embedded Computer

As described earlier, many instruments now use an embedded PC or workstation as an integral part of an instrumentation system. However, the question arises: "Is the PC or workstation visible to the user?" This is also related to the ability to customize or extend the system. Manufacturers realize benefits from an embedded PC because there is less software to write and it is easy to extend the system (both hardware and software). Manufacturers realize these benefits—even if the PC is not visible to the end user. If the PC is visible, users often prefer an embedded PC because it is easy to extend the system, the extensions (hardware and software) are less expensive, and they don't require a separate PC. However, there are problems in having a visible embedded PC. For the manufacturer, making it visible exposes the internal architecture. This can be a problem because competitors can more easily examine their technologies. Also users can modify and customize the system. This can translate into the user overwriting all or part of the system and application software. This is a serious problem for the user, but is also a support problem for the manufacturer. Many instrument manufacturers who have faced this choice have chosen to keep the system closed, and not visible to the user, because of the severity of the support implications.

The user or purchaser of an instrument has a choice between an instrument that contains a visible embedded PC and an instrument that is just an instrument, independent of whether it contains an embedded PC.

It is worth considering how desirable access to the embedded PC is to the actual user of the instrument. The specific tasks that the user needs to perform using the embedded PC should be considered carefully. Generally, the instrument with a visible embedded PC is somewhat more expensive.
