SECTION 1

INFORMATION, COMMUNICATION, NOISE, AND INTERFERENCE

The telephone profoundly changed our methods of communication, thanks to Alexander Graham Bell and other pioneers (Bell, incidentally, declined to have a telephone in his home!). Communication has been at the heart of the information age. Electronic communication deals with transmitters and receivers of electromagnetic waves. Even digital communications systems rely on this phenomenon. This section of the handbook covers information sources, codes and coding, communication channels, error correction, continuous and band-limited channels, digital data transmission and pulse modulation, and noise and interference. C.A.

CHAPTER 1.1

COMMUNICATION SYSTEMS

Geoffrey C. Orsak, H. Vincent Poor, John B. Thomas

CONCEPTS

The principal problem in most communication systems is the transmission of information in the form of messages or data from an originating *information source* S to a *destination* or *receiver* D . The method of transmission is frequently by means of electric signals under the control of the sender. These signals are transmitted via a channel C , as shown in Fig. 1.1.1. The set of messages sent by the source will be denoted by $\{U\}$. If the channel were such that each member of U were received exactly, there would be no communication problem. However, because of channel limitations and noise, a corrupted version $\{U^*\}$ of $\{U\}$ is received at the information destination. It is generally desired that the distorting effects of channel imperfections and noise be minimized and that the number of messages sent over the channel in a given time be maximized.

These two requirements are interacting, since, in general, increasing the rate of message transmission increases the distortion or error. However, some forms of message are better suited for transmission over a given channel than others, in that they can be transmitted faster or with less error. Thus it may be desirable to modify the message set $\{U\}$ by a suitable *encoder* E to produce a new message set $\{A\}$ more suitable for a given channel. Then a decoder E^{-1} will be required at the destination to recover $\{U^*\}$ from the distorted set $\{A^*\}$. A typical block diagram of the resulting system is shown in Fig. 1.1.2.

SELF-INFORMATION AND ENTROPY

Information theory is concerned with the quantification of the communications process. It is based on probabilistic modeling of the objects involved. In the model communication system given in Fig. 1.1.1, we assume that each member of the message set $\{U\}$ is expressible by means of some combination of a finite set of symbols called an *alphabet*. Let this source alphabet be denoted by the set $\{X\}$ with elements x_1, x_2, \dots, x_M , where M is the size of the alphabet. The notation $p(x_i)$, $i = 1, 2, \dots, M$, will be used for the probability of occurrence of the i th symbol x_i . In general the set of numbers $\{p(x_i)\}$ can be assigned arbitrarily provided that

$$p(x_i) \geq 0 \quad i = 1, 2, \dots, M \quad (1)$$

and

$$\sum_{i=1}^M p(x_i) = 1 \quad (2)$$

FIGURE 1.1.1 Basic communication system.

A measure of the amount of information contained in the i th symbol x_i can be defined based solely on the probability $p(x_i)$. In particular, the *self-information* $I(x_i)$ of the i th symbol x_i is defined as

$$I(x_i) = \log 1/p(x_i) = -\log p(x_i) \tag{3}$$

This quantity is a decreasing function of $p(x_i)$ with the endpoint values of infinity for the impossible event and zero for the certain event.

It follows directly from Eq. (3) that $I(x_i)$ is a discrete random variable, i.e., a real-valued function defined on the elements x_i of a probability space. Of the various statistical properties of this random variable $I(x_i)$, the most important is the expected value, or mean, given by

$$E[I(x_i)] = H(X) = \sum_{i=1}^M p(x_i)I(x_i) = -\sum_{i=1}^M p(x_i)\log p(x_i) \tag{4}$$

This quantity $H(X)$ is called the *entropy* of the distribution $p(x_i)$. If $p(x_i)$ is interpreted as the probability of the i th state of a system in phase space, then this expression is identical to the entropy of statistical mechanics and thermodynamics. Furthermore, the relationship is more than a mathematical similarity. In statistical mechanics, entropy is a measure of the disorder of a system; in information theory, it is a measure of the uncertainty associated with a message source.

In the definitions of self-information and entropy, the choice of the base for the logarithm is arbitrary, but of course each choice results in a different system of units for the information measures. The most common bases used are base 2, base e (the natural logarithm), and base 10. When base 2 is used, the unit of $I(\cdot)$ is called the *binary digit* or *bit*, which is a very familiar unit of information content. When base e is used, the unit is the *nat*; this base is often used because of its convenient analytical properties in integration, differentiation, and the like. The base 10 is encountered only rarely; the unit is the *Hartley*.

ENTROPY OF DISCRETE RANDOM VARIABLES

The more elementary properties of the entropy of a discrete random variable can be illustrated with a simple example. Consider the binary case, where $M = 2$, so that the alphabet consists of the symbols 0 and 1 with probabilities p and $1 - p$, respectively. It follows from Eq. (4) that

$$H_1(X) = -[p \log_2 p + (1 - p) \log_2 (1 - p)] \text{ (bits)} \tag{5}$$

FIGURE 1.1.2 Communication system with encoding and decoding.

FIGURE 1.1.3 Entropy in the binary case.

Equation (5) can be plotted as a function of p , as shown in Fig. 1.1.3, and has the following interesting properties:

1. $H_1(X) \geq 0$.
2. $H_1(X)$ is zero only for $p = 0$ and $p = 1$.
3. $H_1(X)$ is a maximum at $p = 1 - p = 1/2$.

More generally, it can be shown that the entropy $H(X)$ has the following properties for the general case of an alphabet of size M :

1. $H(X) \geq 0$. (6)
2. $H(X) = 0$ if and only if all of the probabilities are zero except for one, which must be unity. (7)
3. $H(X) \leq \log_b M$. (8)
4. $H(X) = \log_b M$ if and only if all the probabilities are equal so that $p(x_i) = 1/M$ for all i . (9)

MUTUAL INFORMATION AND JOINT ENTROPY

The usual communication problem concerns the transfer of information from a source S through a channel C to a destination D , as shown in Fig. 1.1.1. The source has available for forming messages an alphabet X of size M . A particular symbol x_1 is selected from the M possible symbols and is sent over the channel C . It is the limitations of the channel that produce the need for a study of information theory.

The information destination has available an alphabet Y of size N . For each symbol x_i sent from the source, a symbol y_j is selected at the destination. Two probabilities serve to describe the “state of knowledge” at the destination. Prior to the reception of a communication, the state of knowledge of the destination about the symbol x_i is the a priori probability $p(x_i)$ that x_i would be selected for transmission. After reception and selection of the symbol y_j , the state of knowledge concerning x_i is the conditional probability $p(x_i|y_j)$, which will be called the a posteriori probability of x_i . It is the probability that x_i was sent given that y_j was received. Ideally this a posteriori probability for each given y_j should be unity for one x_i and zero for all other x_i . In this case an observer at the destination is able to determine exactly which symbol x_i has been sent after the reception of each symbol y_j . Thus the uncertainty that existed previously and which was expressed by the a priori probability distribution of x_i has been removed completely by reception. In the general case it is not possible to remove all the uncertainty, and the best that can be hoped for is that it has been decreased. Thus the a posteriori probability $p(x_i|y_j)$ is distributed over a number of x_i but should be different from $p(x_i)$. If the two probabilities are the same, then no uncertainty has been removed by transmission or no information has been transferred.

Based on this discussion and on other considerations that will become clearer later, the quantity $I(x_i; y_j)$ is defined as the information gained about x_i by the reception of y_j , where

$$I(x_i; y_j) = \log_b [p(x_i|y_j)/p(x_i)] \tag{10}$$

This measure has a number of reasonable and desirable properties.

Property 1. The information measure $I(x_i; y_j)$ is symmetric in x_i and y_j ; that is,

$$I(x_i; y_j) = I(y_j; x_i) \tag{11}$$

Property 2. The mutual information $I(x_i; y_j)$ is a maximum when $p(x_i|y_j) = 1$, that is, when the reception of y_j completely removes the uncertainty concerning x_i :

$$I(x_i; y_j) \leq -\log p(x_i) = (x_i) \tag{12}$$

1.10 INFORMATION, COMMUNICATION, NOISE, AND INTERFERENCE

Property 3. If two communications y_j and z_k concerning the same message x_i are received successively, and if the observer at the destination takes the a posteriori probability of the first as the a priori probability of the second, then the total information gained about x_i is the sum of the gains from both communications:

$$I(x_i; y_j, z_k) = I(x_i; y_j) + I(x_i; z_k | y_j) \quad (13)$$

Property 4. If two communications y_j and y_k concerning two *independent* messages x_i and x_m are received, the total information gain is the sum of the two information gains considered separately:

$$I(x_i, x_m; y_j, y_k) = I(x_i; y_j) + I(x_m; y_k) \quad (14)$$

These four properties of mutual information are intuitively satisfying and desirable. Moreover, if one begins by requiring these properties, it is easily shown that the logarithmic definition of Eq. (10) is the simplest form that can be obtained.

The definition of mutual information given by Eq. (10) suffers from one major disadvantage. When errors are present, an observer will not be able to calculate the information gain even after the reception of all the symbols relating to a given source symbol, since the same series of received symbols may represent several different source symbols. Thus, the observer is unable to say which source symbol has been sent and at best can only compute the information gain with respect to each possible source symbol. In many cases it would be more desirable to have a quantity that is independent of the particular symbols. A number of quantities of this nature will be obtained in the remainder of this section.

The mutual information $I(x_i; y_j)$ is a random variable just as was the self-information $I(x_i)$; however, two probability spaces X and Y are involved now, and several ensemble averages are possible. The *average mutual information* $I(X; Y)$ is defined as a statistical average of $I(x_i; y_j)$ with respect to the joint probability $p(x_i; y_j)$; that is,

$$I(X; Y) = E_{XY}\{I(x_i; y_j)\} = \sum_i \sum_j p(x_i, y_j) \log[p(x_i|y_j)/p(x_i)] \quad (15)$$

This new function $I(X; Y)$ is the first information measure defined that does not depend on the individual symbols x_i or y_j . Thus, it is a property of the whole communication system and will turn out to be only the first in a series of similar quantities used as a basis for the characterization of communication systems. This quantity $I(X; Y)$ has a number of useful properties. It is nonnegative; it is zero if and only if the ensembles X and Y are *statistically independent*; and it is symmetric in X and Y so that $I(X; Y) = I(Y; X)$.

A source entropy $H(X)$ was given by Eq. (4). It is obvious that a similar quantity, the destination entropy $H(Y)$, can be defined analogously by

$$H(Y) = - \sum_{j=1}^N p(y_j) \log p(y_j) \quad (16)$$

This quantity will, of course, have all the properties developed for $H(X)$. In the same way the *joint or system entropy* $H(X, Y)$ can be defined by

$$H(X, Y) = - \sum_{i=1}^M \sum_{j=1}^N p(x_i, y_j) \log p(x_i, y_j) \quad (17)$$

If X and Y are *statistically independent* so that $p(x_i, y_j) = p(x_i)p(y_j)$ for all i and j , then Eq. (17) can be written as

$$H(X, Y) = H(X) + H(Y) \quad (18)$$

On the other hand, if X and Y are not independent, Eq. (17) becomes

$$H(X, Y) = H(X) + H(Y|X) = H(Y) + H(X|Y) \quad (19)$$

where $H(Y|X)$ and $H(X|Y)$ are *conditional entropies* given by

$$H(Y|X) = -\sum_{i=1}^M \sum_{j=1}^N p(x_i, y_j) \log p(y_j|x_i) \quad (20)$$

and by

$$H(X|Y) = -\sum_{i=1}^M \sum_{j=1}^N p(x_i, y_j) \log p(x_i|y_j) \quad (21)$$

These conditional entropies each satisfies an important inequality

$$0 \leq H(Y|H) \leq H(Y) \quad (22)$$

and

$$0 \leq H(X|Y) \leq H(X) \quad (23)$$

It follows from these last two expressions that Eq. (15) can be expanded to yield

$$I(X; Y) = -H(X, Y) + H(X) + H(Y) \geq 0 \quad (24)$$

This equation can be rewritten in the two equivalent forms

$$I(X; Y) = H(Y) - H(Y|X) \geq 0 \quad (25)$$

or

$$I(X|Y) = H(X) - H(X|Y) \geq 0 \quad (26)$$

It is also clear, say from Eq. (24), that $H(X, Y)$ satisfies the inequality

$$H(X, Y) \leq H(X) + H(Y) \quad (27)$$

Thus, the joint entropy of two ensembles X and Y is a maximum when the ensembles are independent.

At this point it may be appropriate to comment on the meaning of the two conditional entropies $H(Y|X)$ and $H(X|Y)$. Let us refer first to Eq. (26). This equation expresses the fact that the average information gained about a message, when a communication is completed, is equal to the average source information less the average uncertainty that still remains about the message. From another point of view, the quantity $H(X|Y)$ is the average additional information needed at the destination after reception to completely specify the message sent. Thus, $H(X|Y)$ represents the information lost in the channel. It is frequently called the *equivocation*. Let us now consider Eq. (25). This equation indicates that the information transmitted consists of the difference between the destination entropy and that part of the destination entropy that is not information about the source; thus the term $H(Y|X)$ can be considered a *noise entropy* added in the channel.

CHAPTER 1.2

INFORMATION SOURCES, CODES, AND CHANNELS

Geoffrey C. Orsak, H. Vincent Poor, John B. Thomas

MESSAGE SOURCES

As shown in Fig. 1.1.1, an information source can be considered as emitting a given message u_i from the set $\{U\}$ of possible messages. In general, each message u_i will be represented by a sequence of symbols x_j from the source alphabet $\{X\}$, since the number of possible messages will usually exceed the size M of the source alphabet. Thus sequences of symbols replace the original messages u_i , which need not be considered further. When the source alphabet $\{X\}$ is of finite size M , the source will be called a *finite discrete source*. The problems of concern now are the interrelationships existing between symbols in the generated sequences and the classification of sources according to these interrelationships.

A random or stochastic process $x_t, t \in T$, can be defined as an indexed set of random variables where T is the *parameter set* of the process. If the set T is a sequence, then x_t is a stochastic process with discrete parameter (also called a *random sequence* or *series*). One way to look at the output of a finite discrete source is that it is a discrete-parameter stochastic process with each possible given sequence one of the ensemble members or realizations of the process. Thus the study of information sources can be reduced to a study of random processes.

The simplest case to consider is the *memoryless source*, where the successive symbols obey the same fixed probability law so that the one distribution $p(x_i)$ determines the appearance of each indexed symbol. Such a source is called *stationary*. Let us consider sequences of length n , each member of the sequence being a realization of the random variable x_i with fixed probability distribution $p(x_i)$. Since there are M possible realizations of the random variable and n terms in the sequence, there must be M^n distinct sequences possible of length n . Let the random variable X_i in the j th position be denoted by X_{ij} , so that the sequence set (the message set) can be represented by

$$\{U\} = X^n = \{X_{i1}, X_{i2}, \dots, X_{in}\} \quad i = 1, 2, \dots, M \quad (1)$$

The symbol X^n is sometimes used to represent this sequence set and is called the *n th extension of the memoryless source X* . The probability of occurrence of a given message u_i is just the product of the probabilities of occurrence of the individual terms in the sequence so that

$$p\{u_i\} = p(x_{i1})p(x_{i2}) \cdots p\{x_{in}\} \quad (2)$$

Now the entropy for the extended source X^n is

$$H(X^n) = -\sum_{x^n} p\{u_i\} \log p\{u_i\} = nH(X) \quad (3)$$

as expected. Note that, if base 2 logarithms are used, then $H(X)$ has units of bits per symbol, n is symbols per sequence, and $H(X^n)$ is in units of bits per sequence. For a memoryless source, all sequence averages of information measures are obtained by multiplying the corresponding symbol by the number of symbols in the sequence.

MARKOV INFORMATION SOURCE

The memoryless source is not a general enough model in most cases. A constructive way to generalize this model is to assume that the occurrences of a given symbol depends on some number m of immediately preceding symbols. Thus the information source can be considered to produce an m th-order Markov chain and is called an m th-order Markov source.

For an m th-order Markov source, the m symbols preceding a given symbol position are called the *state* s_j of the source at that symbol position. If there are M possible symbols x_k , then the m th-order Markov source will have $M^m = q$ possible states s_j making up the *state set*

$$S = \{s_1, s_2, \dots, s_q\} \quad q = M^m \quad (4)$$

At a given time corresponding to one symbol position the source will be in a given state s_j . There will exist a probability $p(s_k | s_j) = p_{jk}$ that the source will move into another state s_k with the emission of the next symbol. The set of all such conditional probabilities is expressed by the *transition matrix* T , where

$$T = [p_{jk}] = \begin{bmatrix} p_{11} & p_{12} & \cdots & p_{1q} \\ p_{21} & p_{22} & \cdots & p_{2q} \\ \cdots & \cdots & \cdots & \cdots \\ p_{q1} & p_{q2} & \cdots & p_{qq} \end{bmatrix} \quad (5)$$

A *Markov matrix* or *stochastic matrix* is any square matrix with nonnegative elements such that the row sums are unity. It is clear that T is such a matrix since

$$\sum_{j=1}^q p_{ij} = \sum_{j=1}^q p(s_j | s_i) = 1 \quad i = 1, 2, \dots, q \quad (6)$$

Conversely, any stochastic matrix is a possible transition matrix for a Markov source of order m , where $q = M^m$ is equal to the number of rows or columns of the matrix.

A Markov chain is completely specified by its transition matrix T and by an *initial distribution vector* π giving the probability distribution for the first state occurring. For the memoryless source, the transition matrix reduces to a stochastic matrix where all the rows are identical and are each equal to the initial distribution vector π , which is in turn equal to the vector giving the source alphabet a priori probabilities. Thus, in this case, we have

$$p_{jk} = p(s_k | s_j) = p(s_k) = p(x_k) \quad k = 1, 2, \dots, M \quad (7)$$

For each state s_i of the source an entropy $H(s_i)$ can be defined by

$$H(s_i) = - \sum_{j=1}^q p(s_j | s_i) \log p(s_j | s_i) = - \sum_{k=1}^M p(x_k | s_i) \log p(x_k | s_i) \quad (8)$$

The source entropy $H(S)$ in information units per symbol is the expected value of $H(s_i)$; that is,

$$H(S) = - \sum_{i=1}^q \sum_{j=1}^q p(s_i) p(s_j | s_i) \log p(s_j | s_i) = - \sum_{i=1}^q \sum_{k=1}^M p(s_i) p(x_k | s_i) \log p(x_k | s_i) \quad (9)$$

1.14 INFORMATION, COMMUNICATION, NOISE, AND INTERFERENCE

where $p(s_i) = p_i$ is the *stationary state probability* and is the i th element of the vector \mathbf{P} defined by

$$\mathbf{P} = [p_1 p_2 \cdots p_q] \tag{10}$$

It is easy to show, as in Eq. (8), that the source entropy cannot exceed $\log M$, where M is the size of the source alphabet $\{X\}$. For a given source, the ratio of the actual entropy $H(S)$ to the maximum value it can have with the same alphabet is called the *relative entropy* of the source. The *redundancy* η of the source is defined as the positive difference between unity and this relative entropy:

$$\eta = 1 - \frac{H(S)}{\log M} \tag{11}$$

The quantity $\log M$ is sometimes called the *capacity* of the alphabet.

NOISELESS CODING

The preceding discussion has emphasized the information source and its properties. We now begin to consider the properties of the communication channel of Fig. 1.1.1. In general, an arbitrary channel will not accept and transmit the sequence of x_i 's emitted from an arbitrary source. Instead the channel will accept a sequence of some other elements a_i chosen from a *code alphabet* A of size D , where

$$A = \{a_1, a_2, \dots, a_D\} \tag{12}$$

with D generally smaller than M . The elements a_i of the code alphabet are frequently called *code elements* or *code characters*, while a given sequence of a_i 's may be called a *code word*.

The situation is now describable in terms of Fig. 1.1.2, where an encoder E has been added between the source and channel. The process of *coding*, or *encoding*, the source consists of associating with each source symbol x_i a given code word, which is just a given sequence of a_i 's. Thus the source emits a sequence of a_i 's chosen from the source alphabet A , and the encoder emits a sequence of a_i 's chosen from the code alphabet A . It will be assumed in all subsequent discussions that the code words are distinct, i.e., that each code word corresponds to only one source symbol.

Even though each code word is required to be distinct, sequences of code words may not have this property. An example is code A of Table 1.2.1, where a source of size 4 has been encoded in binary code with characters 0 and 1. In code A the code words are distinct, but sequences of code words are not. It is clear that such a code is not *uniquely* decipherable. On the other hand, a given sequence of code words taken from code B will correspond to a distinct sequence of source symbols. An examination of code B shows that in no case is a code word formed by adding characters to another word. In other words, no code word is a *prefix* of another. It is clear that this is a *sufficient* (but not necessary) condition for a code to be uniquely decipherable. That it is not necessary can be seen from an examination of codes C and D of Table 1.2.1. These codes are uniquely decipherable even though many of the code words are prefixes of other words. In these cases any sequence of code words can be decoded by subdividing the sequence of 0s and 1s to the left of every 0 for code C and to the right of every 0 for code D. The character 0 is the first (or last) character of every code word and acts as a comma; therefore this type of code is called a *comma code*.

TABLE 1.2.1 Four Binary Coding Schemes

Source symbol	Code A	Code B	Code C	Code D
x_1	0	0	0	0
x_2	1	10	01	10
x_3	00	110	011	110
x_4	11	111	0111	1110

Note: Code A is not uniquely decipherable; codes B, C, and D are uniquely decipherable; codes B and D are instantaneous codes; and codes C and D are comma codes.

In general the channel will require a finite amount of time to transmit each code character. The code words should be as short as possible in order to maximize information transfer per unit time. The average length L of a code is given by

$$L = \sum_{i=1}^M n_i p(x_i) \tag{13}$$

where n_i is the length (number of code characters) of the code word for the source symbol x_i and $p(x_i)$ is the probability of occurrence of x_i . Although the average code length cannot be computed unless the set $\{p(x_i)\}$ is given, it is obvious that codes C and D of Table 1.2.1 will have a greater average length than code B unless $p(x_4) = 0$. Comma codes are not optimal with respect to minimum average length.

Let us encode the sequence $x_3x_1x_3x_2$ into codes B, C, and D of Table 1.2.1 as shown below:

Code B:	110011010
Code C:	011001101
Code D:	110011010

Codes B and D are fundamentally different from code C in that codes B and D can be decoded word by word *without examining subsequent code characters* while code C cannot be so treated. Codes B and D are called *instantaneous codes* while code C is noninstantaneous. The instantaneous codes have the property (previously maintained) that no code word is a prefix of another code word.

The aim of noiseless coding is to produce codes with the two properties of (1) *unique decipherability* and (2) *minimum average length L* for a given source S with alphabet X and probability set $\{p(x_i)\}$. Codes which have both these properties will be called *optimal*. It can be shown that if, for a given source S , a code is optimal among instantaneous codes, then it is optimal among all uniquely decipherable codes. Thus it is sufficient to consider instantaneous codes. A *necessary* property of optimal codes is that source symbols with higher probabilities have shorter code words; i.e.,

$$p(x_i) > p(x_j) \Rightarrow n_i \leq n_j \tag{14}$$

The encoding procedure consists of the assignment of a code word to each of the M source symbols. The code word for the source symbol x_i will be of length n_i ; that is, it will consist of n_i code elements chosen from the code alphabet of size D . It can be shown that a necessary and sufficient condition for the construction of a uniquely decipherable code is the *Kraft inequality*

$$\sum_{i=1}^M D^{-n_i} \leq 1 \tag{15}$$

NOISELESS-CODING THEOREM

It follows from Eq. (15) that the average code length L , given by Eq. (13), satisfies the inequality

$$L \geq H(X)/\log D \tag{16}$$

Equality (and minimum code length) occurs if and only if the source-symbol probabilities obey

$$p(x_i) = D^{-n_i} \quad i = 1, 2, \dots, M \tag{17}$$

A code where this equality applies is called *absolutely optimal*. Since an integer number of code elements must be used for each code word, the equality in Eq. (16) does not usually hold; however, by using one more code element, the average code length L can be bounded from above to give

$$H(X)/\log D \leq L \leq H(X)/\log D + 1 \tag{18}$$

This last relationship is frequently called the *noiseless-coding theorem*.

CONSTRUCTION OF NOISELESS CODES

The easiest case to consider occurs when an absolutely optimal code exists; i.e., when the source-symbol probabilities satisfy Eq. (17). Note that code B of Table 1.2.1 is absolutely optimal if $p(x_1) = 1/2$, $p(x_2) = 1/4$, and $p(x_3) = p(x_4) = 1/8$. In such cases, a procedure for realizing the code for arbitrary code-alphabet size ($D \geq 2$) is easily constructed as follows:

1. Arrange the M source symbols in order of decreasing probability.
2. Arrange the D code elements in an arbitrary but fixed order, i.e., a_1, a_2, \dots, a_D .
3. Divide the set of symbols x_i into D groups with equal probabilities of $1/D$ each. This division is always possible if Eq. (17) is satisfied.
4. Assign the element a_1 as the first digit for symbols in the first group, a_2 for the second, and a_i for the i th group.
5. After the first division each of the resulting groups contains a number of symbols equal to D raised to some integral power if Eq. (17) is satisfied.

Thus, a typical group, say group i , contains D^{k_i} symbols, where k_i is an integer (which may be zero). This group of symbols can be further subdivided k_i times into D parts of equal probabilities. Each division decides one additional code digit in the sequence. A typical symbol x_i is isolated after q divisions. If it belongs to the i_1 group after the first division, the i_2 group after the second division, and so forth, then the code word for x_i will be $a_{i_1} a_{i_2} \dots a_{i_q}$.

An illustration of the construction of an absolutely optimal code for the case where $D = 3$ is given in Table 1.2.2. This procedure ensures that source symbols with high probabilities will have short code words and vice versa, since a symbol with probability D^{-n_i} will be isolated after n_i divisions and thus will have n_i elements in its code word, as required by Eq. (17).

TABLE 1.2.2 Construction of an Optimal Code; $D = 3$

Source symbols x_i	A priori probabilities $p(x_i)$	Step			Final code		
		1	2	3			
x_1	$1/3$	1			1		
x_2	$1/9$	0	1		0	1	
x_3	$1/9$	0	0		0	0	
x_4	$1/9$	0	-1		0	-1	
x_5	$1/27$	-1	1	1	-1	1	1
x_6	$1/27$	-1	1	0	-1	1	0
x_7	$1/27$	-1	1	-1	-1	1	-1
x_8	$1/27$	-1	0	1	-1	0	1
x_9	$1/27$	-1	0	0	-1	0	0
x_{10}	$1/27$	-1	0	-1	-1	0	-1
x_{11}	$1/27$	-1	-1	1	-1	-1	1
x_{12}	$1/27$	-1	-1	0	-1	-1	0
x_{13}	$1/27$	-1	-1	-1	-1	-1	-1

Note: Average code length $L = 2$ code elements per symbol; source entropy $H(X) = 2 \log_2 3$ bits per symbol.

$$L = \frac{H(X)}{\log_2 3}$$

TABLE 1.2.3 Construction of Huffman Code; $D = 2$

Source symbols x_i	A priori probabilities $p(x_i)$	Final code	Reduction 1	Reduction 2	Reduction 3	Reduction 4	Reduction 5
			Step 5	Step 4	Step 3	Step 2	Step 1
x_1	0.40	0	0.40	0	0.40	0	0
x_2	0.20	111	0.20	111	0.24	10	0.40
x_3	0.12	101	0.12	101	0.20	111	0.24
x_4	0.08	1101	0.12	100	0.16	110	0.16
x_5	0.08	1100	0.08	1101	0.12	100	0.12
x_6	0.08	1001	0.08	1100			
x_7	0.04	1000	0.08				

Average code length $L = 1(0.40) + 3(0.20) + 3(0.12) + 4(0.08) + 4(0.08) + 4(0.08) + 4(0.04)$
 $= 2.48$ code elements/symbol

The code resulting from the process just discussed is sometimes called the *Shannon-Fano* code. It is apparent that the same encoding procedure can be followed whether or not the source probabilities satisfy Eq. (17). The set of symbols x_i is simply divided into D groups with probabilities as nearly equal as possible. The procedure is sometimes ambiguous, however, and more than one Shannon-Fano code may be possible. The ambiguity arises, of course, in the choice of approximately equiprobable subgroups.

For the general case where Eq. (17) is not satisfied, a procedure owing to Huffman guarantees an optimal code, i.e., one with minimum average length. This procedure for code alphabet of arbitrary size D is as follows:

1. As before, arrange the M source symbols in order of decreasing probability.
2. As before, arrange the code elements in an arbitrary but fixed order, that is, a_1, a_2, \dots, a_D .
3. Combine (sum) the probabilities of the D least likely symbols and reorder the resulting $M - (D - 1)$ probabilities; this step will be called *reduction 1*. Repeat as often as necessary until there are D ordered probabilities remaining. *Note:* For the binary case ($D = 2$), it will always be possible to accomplish this reduction in $M - 2$ steps. When the size of the code alphabet is arbitrary, the last reduction will result in exactly D ordered probabilities if and only if

$$M = D + n(D - 1)$$

where n is an integer. If this relationship is not satisfied, *dummy* source symbols with zero probability should be added. The entire encoding procedure is followed as before, and at the end the dummy symbols are thrown away.

4. Start the encoding with the last reduction which consists of exactly D ordered probabilities; assign the element a_1 as the first digit in the code words for all the source symbols associated with the first probability; assign a_2 to the second probability; and a_i to the i th probability.
5. Proceed to the next to the last reduction; this reduction consists of $D + (D - 1)$ ordered probabilities for a net gain of $D - 1$ probabilities. For the D new probabilities, the first code digit has already been assigned and is the same for all of these D probabilities; assign a_1 as the second digit for all source symbols associated with the first of these D new probabilities; assign a_2 as the second digit for the second of these D new probabilities, etc.
6. The encoding procedure terminates after $1 + n(D - 1)$ steps, which is one more than the number of reductions.

As an illustration of the Huffman coding procedure, a binary code is constructed in Table 1.2.3.

CHANNEL CAPACITY

The average mutual information $I(X; Y)$ between an information source and a destination was given by Eqs. (25) and (26) as

$$I(X; Y) = H(Y) - H(Y|X) = H(X) - H(X|Y) \geq 0 \tag{19}$$

1.18 INFORMATION, COMMUNICATION, NOISE, AND INTERFERENCE

The average mutual information depends not only on the statistical characteristics of the channel but also on the distribution $p(x_i)$ of the input alphabet X . If the input distribution is varied until Eq. (19) is a maximum for a given channel, the resulting value of $I(X; Y)$ is called the *channel capacity* C of that channel; i.e.,

$$C = \max_{p(x)} I(X; Y) \quad (20)$$

In general, $H(X)$, $H(Y)$, $H(X|Y)$, and $H(Y|X)$ all depend on the input distribution $p(x_i)$. Hence, *in the general case*, it is not a simple matter to maximize Eq. (19) with respect to $p(x_i)$.

All the measures of information that have been considered in this treatment have involved only probability distributions on X and Y . Thus, for the model of Fig. 1.1.1, the joint distribution $p(x_i, y_j)$ is sufficient. Suppose the source [and hence the input distribution $p(x_i)$] is known; then it follows from the usual conditional-probability relationship

$$p(x_i, y_j) = p(x_i)p(y_j|x_i) \quad (21)$$

that only the distribution $p(y_j|x_i)$ is needed for $p(x_i|y_j)$ to be determined. This conditional probability $p(y_j|x_i)$ can then be taken as a description of the information channel connecting the source X and the destination Y . Thus, a *discrete memoryless channel* can be defined as the probability distribution

$$p(y_j|x_i) \quad x_i \in X \text{ and } y_j \in Y \quad (22)$$

or, equivalently, by the *channel matrix* D , where

$$D = [p(y_j|x_i)] = \begin{bmatrix} p(y_1|x_1) & p(y_2|x_1) & \dots & p(y_N|x_1) \\ p(y_1|x_2) & p(y_2|x_2) & \dots & p(y_N|x_2) \\ \dots & \dots & \dots & \dots \\ p(y_1|x_M) & \dots & \dots & p(y_N|x_M) \end{bmatrix} \quad (23)$$

A number of special types of channels are readily distinguished. Some of the simplest and/or most interesting are listed as follows:

(a) *Lossless Channel*. Here $H(X|Y) = 0$ for all input distribution $p(x_i)$, and Eq. (20) becomes

$$C = \max_{p(x)} H(X) = \log M \quad (24)$$

This maximum is obtained when the x_i are equally likely, so that $p(x_i) = 1/M$ for all i . The channel capacity is equal to the source entropy, and no source information is lost in transmission.

(b) *Deterministic Channel*. Here $H(Y|X) = 0$ for all input distributions $p(x_i)$, and Eq. (20) becomes

$$C = \max_{p(x)} H(Y) = \log N \quad (25)$$

This maximum is obtained when the y_j are equally likely, so that $p(y_j) = 1/N$ for all j . Each member of the X set is uniquely associated with one, and only one, member of the destination alphabet Y .

(c) *Symmetric Channel*. Here the rows of the channel matrix D are identical except for permutations, and the columns are identical except for permutations. If D is square, rows and columns are identical except for permutations. In the symmetric channel, the conditional entropy $H(Y|X)$ is independent of the input distribution $p(x_i)$ and depends only on the channel matrix D . As a consequence, the determination of channel capacity is greatly simplified and can be written

$$C = \log N + \sum_{j=1}^N p(y_j|x_i) \log p(y_j|x_i) \quad (26)$$

This capacity is obtained when the y_i are equally likely, so that $p(y_j) = 1/N$ for all j .

(d) *Binary Symmetric Channel (BSC)*. This is the special case of a symmetric channel where $M = N = 2$. Here the channel matrix can be written

FIGURE 1.2.1 Capacity of the binary symmetric channel.

$$D = \begin{bmatrix} p & 1-p \\ 1-p & p \end{bmatrix} \quad (27)$$

and the channel capacity is

$$C = \log 2 - G(p) \quad (28)$$

where the function $G(p)$ is defined as

$$G(p) = -[p \log p + (1-p) \log (1-p)] \quad (29)$$

This expression is mathematically identical to the entropy of a binary source as given in Eq. (5) and is plotted in Fig. 1.1.3 using base 2 logarithms. For the same base, Eq. (28) is shown as a function of p in Fig. 1.2.1.

As expected, the channel capacity is large if p , the probability of correct transmission, is either close to unity or to zero. If $p = 1/2$, there is no statistical evidence which symbol was sent and the channel capacity is zero.

DECISION SCHEMES

A decision scheme or decoding scheme B is a partitioning of the Y set into M disjoint and exhaustive sets B_1, B_2, \dots, B_M such that when a destination symbol y_k falls into set B_i , it is decided that symbol x_i was sent. Implicit in this definition is a *decision rule* $d(y_j)$, which is a function specifying uniquely a source symbol for each destination symbol. Let $p(e | y_j)$ be the probability of error when it is decided that y_j has been received. Then the *total error probability* $p(e)$ is

$$p(e) = \sum_{j=1}^N p(y_j) p(e | y_j) \quad (30)$$

For a given decision scheme β , the conditional error probability $p(e | y_j)$ can be written

$$p(e | y_j) = 1 - p[d(y_j) | y_j] \quad (31)$$

where $p[d(y_j) | y_j]$ is the conditional probability $p(x_i | y_j)$ with x_i assigned by the decision rule; i.e., for a given decision scheme $d(y_j) = x_i$. The probability $p(y_j)$ is determined only by the source a priori probability $p(x_i)$ and by the channel matrix $= D [p(y_j | x_i)]$. Hence, only the term $p(e | y_j)$ in Eq. (30) is a function of the decision scheme. Since Eq. (30) is a sum of nonnegative terms, the error probability is a minimum when each summand is a minimum. Thus, the term $p(e | y_j)$ should be a minimum for each y_j . It follows from Eq. (31) that the minimum-error scheme is that scheme which assigns a decision rule

$$d(y_j) = x^* \quad j = 1, 2, \dots, N \quad (32)$$

where x^* is defined by

$$p(x^* | y_j) \geq p(x_i | y_j) \quad i = 1, 2, \dots, M \quad (33)$$

In other words, each y_j is decoded as the *a posteriori most likely* x_i . This scheme, which minimizes the probability of error $p(e)$, is usually called the *ideal observer*.

1.20 INFORMATION, COMMUNICATION, NOISE, AND INTERFERENCE

The ideal observer is not always a completely satisfactory decision scheme. It suffers from two major disadvantages: (1) For a given channel D , the scheme is defined only for a given input distribution $p(x_i)$. It might be preferable to have a scheme that was insensitive to input distributions. (2) The scheme minimizes average error but does not bound certain errors. For example, some symbols may always be received incorrectly. Despite these disadvantages, the ideal observer is a straightforward scheme which does minimize average error. It is also widely used as a standard with which other decision schemes may be compared.

Consider the special case where the input distribution is $p(x_i) = 1/M$ for all i , so that all x_i are equally likely. Now the conditional likelihood $p(x_i | y_j)$ is

$$p(x_i | y_j) = \frac{p(x_i)p(y_j | x_i)}{p(y_j)} = \frac{p(y_j | x_i)}{Mp(y_j)} \quad (34)$$

For a given y_j , that input x_i is chosen which makes $p(y_j | x_i)$ a maximum, and the decision rule is

$$d(y_j) = x^\dagger \quad j = 1, 2, \dots, N \quad (35)$$

where x^\dagger is defined by

$$p(y_j | x^\dagger) \geq p(y_j | x_i) \quad i = 1, 2, \dots, M \quad (36)$$

The probability of error becomes

$$p(e) = \sum_{j=1}^N p(y_j) \left[1 - \frac{p(y_j | x^\dagger)}{Mp(y_j)} \right] \quad (37)$$

This decoder is sometimes called the *maximum-likelihood* decoder or decision scheme.

It would appear that a relationship should exist between the error probability $p(e)$ and the channel capacity C . One such relationship is the *Fano bound*, given by

$$H(X | Y) \leq G[p(e)] + p(e) \log(M - 1) \quad (38)$$

and relating error probability to channel capacity through Eq. (20). Here $G(\cdot)$ is the function already defined by Eq. (29). The three terms in Eq. (38) can be interpreted as follows:

$H(X | Y)$ is the equivocation. It is the average additional information needed at the destination after reception to completely determine the symbol that was sent.

$G[p(e)]$ is the entropy of the binary system with probabilities $p(e)$ and $1 - p(e)$. In other words, it is the average amount of information needed to determine whether the decision rule resulted in an error.

$\log(M - 1)$ is the maximum amount of information needed to determine which among the remaining $M - 1$ symbols was sent if the decision rule was incorrect; this information is needed with probability $p(e)$.

THE NOISY-CODING THEOREM

The concept of channel capacity was discussed earlier. Capacity is a fundamental property of an information channel in the sense that it is possible to transmit information through the channel at any rate less than the channel capacity with arbitrarily small probability of error. This result is called the *noisy-coding theorem* or *Shannon's fundamental theorem for a noisy channel*.

The noisy-coding theorem can be stated more precisely as follows: Consider a discrete memoryless channel with nonzero capacity C ; fix two numbers H and ϵ such that

$$0 < H < C \quad (39)$$

and

$$\epsilon > 0 \quad (40)$$

Let us transmit m messages u_1, u_2, \dots, u_m by code words each of length n binary digits. The positive integer n can be chosen so that

$$m \geq 2^{nH} \quad (41)$$

In addition, at the destination the m sent messages can be associated with a set $V = \{v_1, v_2, \dots, v_m\}$ of received messages and with a decision rule $d(v_j) = u_j$ such that

$$p[d(v_j) | v_j] \geq 1 - \epsilon \quad (42)$$

i.e., decoding can be accomplished with a probability of error that does not exceed ϵ . There is a converse to the noisy-coding theorem which states that it is not possible to produce an encoding procedure which allows transmission at a rate greater than channel capacity with arbitrarily small error.

ERROR-CORRECTING CODES

The codes considered earlier were designed for minimum length in the noiseless-transmission case. For noisy channels, the noisy-coding theorem guarantees the existence of a code which will allow transmission at any rate less than channel capacity and with arbitrarily small probability of error; however, the theorem does not provide a constructive procedure to devise such codes. Indeed, it implies that very long sequences of source symbols may have to be considered if reliable transmission at rates near channel capacity are to be obtained. In this section, we consider some of the elementary properties of simple *error-correcting codes*; i.e., codes which can be used to increase reliability in the transmission of information through noisy channels by correcting at least some of the errors that occur so that overall probability of error is reduced.

The discussion will be restricted to the BSC, and the noisy-coding theorem notation will be used. Thus, a source alphabet $X = \{x_1, x_2, \dots, x_m\}$ of M symbols will be used to form a message set U of m messages u_k , where $U = \{u_1, u_2, \dots, u_m\}$. Each u_k will consist of a sequence of the x_i 's. Each message u_k will be encoded into a sequence of n binary digits for transmission over the BSC. At the destination, there exists a set $V = \{v_1, v_2, \dots, v_{2^n}\}$ of all possible binary sequences of length n . The inequality $m \leq 2^n$ must hold. The problem is to associate with each sent message u_k a received message v_j so that $p(e)$, the overall probability of error, is reduced.

In the discussion of the noisy-coding theorem, a decoding scheme was used that examined the received message v_j and identified it with the sent message u_k which differed from it in the least number of binary digits. In all the discussions here it will be assumed that this decoder is used. Let us define the *Hamming distance* $d(v_j, v_k)$ between two binary sequences v_j and v_k of length n as the number of digits in which v_j and v_k disagree. Thus, if the distance between two sequences is zero, the two sequences are identical. It is easily seen that this distance measure has the following four elementary properties:

$$d(v_j, v_k) \geq 0 \text{ with equality if and only if } v_j = v_k \quad (43)$$

$$d(v_j, v_k) = d(v_k, v_j) \quad (44)$$

$$d(v_j, v_l) \leq d(v_j, v_k) + d(v_k, v_l) \quad (45)$$

$$d(v_j, v_k) \leq n \quad (46)$$

The decoder we use is a *minimum-distance* decoder. As mentioned earlier, the ideal-observer decoding scheme is a minimum-distance scheme for the BSC.

1.22 INFORMATION, COMMUNICATION, NOISE, AND INTERFERENCE

It is intuitively apparent that the sent messages should be represented by code words that all have the greatest possible distances between them. Let us investigate this matter in more detail by considering all binary sequences of length $n = 3$; there are $2^n = 2^3 = 8$ such sequences, viz.,

000	001	011	111
	010	110	
	100	101	

It is convenient to represent these as the eight corners of a unit cube, as shown in Fig. 1.2.2a, where the x axis corresponds to the first digit, the y axis to the second, and the z axis to the third. Although direct pictorial representation is not possible, it is clear that binary sequences of length n greater than 3 can be considered as the corners of the corresponding n -cube.

Suppose that all eight binary sequences are used as code words to encode a source. If any binary digit is changed in transmission, an error will result at the destination since the sent message will be interpreted incorrectly as one of the three possible messages that differ in one code digit from the sent message. This situation is illustrated in Fig. 1.2.2 for the code words 000 and 111. A change of one digit in each of these code words produces one of three possible other code words.

Figure 1.2.2 suggests that only two code words, say 000 and 111, should be used. The distance between these two words, or any other two words on opposite corners of the cube, is 3. If only one digit is changed in the transmission of each of these two code words, they can be correctly distinguished at the destination by a minimum-distance decoder. If two digits are changed in each word in transmission, it will not be possible to make this distinction.

This reasoning can be extended to sequences containing more than three binary digits. For any $n \geq 3$, single errors in each code word can be corrected. If double errors are to be corrected without fail, there must be at least two code words with a minimum distance between them of 5; thus, for this case, binary code words of length 5 or greater must be used.

Note that the error-correcting properties of a code depend on the distance $d(v_j, v_k)$ between the code words. Specifically, single errors can be corrected if all code words employed are at least a distance of 3 apart, double errors if the words are at a distance of 5 or more from each other, and, in general, q -fold errors can be corrected if

$$d(v_j, v_k) \geq 2q + 1 \quad j \neq k \quad (47)$$

Errors involving less than q digits per code word can also be corrected if Eq. (63) is satisfied. If the distance between two code words is $2q$, there will always be a group of binary sequences which are in the middle, i.e., a distance q from *each* of the two words. Thus, by the proper choice of code words, q -fold errors can be *detected* but not corrected if

$$d(v_j, v_k) = 2q \quad j \neq k \quad (48)$$

FIGURE 1.2.2 Representation of binary sequences as the corners of an n -cube, $n = 3$; (a) the eight binary sequences of length 3; (b) shift in sequences 000 and 111 from a single error.

TABLE 1.2.4 Parity-Check Code for Single-Error Detection

Message digits	Check digit	Word	Message digit	Check digit	Word
000	0	0000	110	0	1100
100	1	1001	101	0	1010
010	1	0101	011	0	0110
001	1	0011	111	1	1111

Now consider the maximum number of code words r that can be selected from the set of 2^n possible binary sequences of length n to form a code that will correct all single, double, . . . , q -fold errors. In the example of Fig. 1.2.2, the number of code words selected was 2. In fact, it can be shown that there is no single-error-correcting code for $n = 3, 4$ containing more than two words. Suppose we consider a given code consisting of the words . . . , u_k, u_j, \dots . All binary sequences of distance q or less from u_k must “belong” to u_k , and to u_k only, if q -fold errors are to be corrected. Thus, associated with u_k are all binary sequences of distance 0, 1, 2, . . . , q from u_k . The number of such sequences is given by

$$\binom{n}{0} + \binom{n}{1} + \binom{n}{2} + \dots + \binom{n}{q} = \sum_{i=0}^q \binom{n}{i} \tag{49}$$

Since there are r of the code words, the total number of sequences associated with all the code words is

$$r \sum_{i=0}^q \binom{n}{i}$$

This number can be no larger than 2^n , the total number of distinct binary sequences of length n . Therefore the following inequality must hold:

$$r \sum_{i=0}^q \binom{n}{i} \leq 2^n \quad \text{or} \quad r \leq \frac{2^n}{\sum_{i=0}^q \binom{n}{i}} \tag{50}$$

This is a *necessary* upper bound on the number of code words that can be used to correct all errors up to and including q -fold errors. It can be shown that it is not *sufficient*.

Consider the eight possible distinct binary sequences of length 3. Suppose we add one binary digit to each sequence in such a way that the total number of 1s in the sequence is *even* (or *odd*, if you wish). The result is shown in Table 1.2.4. Note that all the word sequences of length 4 differ from each other by a distance of at least 2. In accordance with Eq. (48), it should be possible now to *detect single errors* in all eight sequences. The detection method is straightforward. At the receiver, count the number of 1s in the sequence; if the number is odd, a single error (or, more precisely, an odd number of errors) has occurred; if the number is even, no error (or an even number of errors) has occurred. This particular scheme is a good one if only single errors are likely to occur and if detection only (rather than correction) is desired. Such is often the case, for example, in closed digital systems such as computers. The added digit is called a *parity-check digit*, and the scheme is a very simple example of a *parity-check code*.

PARITY-CHECK CODES

More generally, in parity-check codes, the encoded sequence consists of n binary digits of which only $k < n$ are *information digits* while the remaining $l = n - k$ digits are used for error detection and correction and are called *check digits* or *parity checks*. The example of Table 1.2.4 is a single-error-detecting code, but, in general, q -fold

1.24 INFORMATION, COMMUNICATION, NOISE, AND INTERFERENCE

errors can be detected and/or corrected. As the number of errors to be detected and/or corrected increases, the number l of check digits must increase. Thus, for fixed word length n , the number of information digits $k = n - l$ will decrease as more and more errors are to be detected and/or corrected. Also the total number of words in the code cannot exceed the right side of Eq. (50) or the number 2^k .

Parity-check codes are relatively easy to implement. The simple example given of a single-error-detecting code requires only that the number of 1s in each code word be counted. In this light, it is of considerable importance to note that these codes satisfy the noisy-coding theorem. In other words, it is possible to encode a source by parity-check coding for transmission over a BSC at a rate approaching channel capacity and with arbitrarily small probability of error. Then, from Eq. (41), we have

$$2^{nH} = 2^k \quad (51)$$

or H , the rate of transmission, is given by

$$H = k/n \quad (52)$$

As $n \rightarrow \infty$, the probability of error $p(e)$ approaches zero. Thus, in a certain sense, it is sufficient to limit a study of error-correcting codes to the parity-check codes.

As an example of a parity-check code, consider the simplest nondegenerate case where l , the number of check digits, is 2 and k , the number of information digits, is 1. This system is capable of single-error detection and correction, as we have already decided from geometric considerations. Since $l + k = 3$, each encoded word will be three digits long. Let us denote this word by $a_1 a_2 a_3$, where each a_i is either 0 or 1. Let a_1 represent the information digit and a_2 and a_3 represent the check digits.

Checking for errors is done by forming two independent equations from the three a_i , each equation being of the form of a modulo-2 sum, i.e., of the form

$$a_i \oplus a_j = \begin{cases} 0 & a_i = a_j \\ 1 & a_i \neq a_j \end{cases}$$

Take the two independent equations to be

$$a_2 \oplus a_3 = 0 \quad \text{and} \quad a_1 \oplus a_3 = 0$$

for an *even-parity* check. For an *odd-parity* check, let the right sides of both of these equations be unity. If these two equations are to be satisfied, the only possible code words that can be sent are 000 and 111. The other six words of length 3 violate one or both of the equations.

Now suppose that 000 is sent and 100 is received. A solution of the two independent equations gives, for the received word,

$$\begin{aligned} a_2 \oplus a_3 &= 0 \oplus 0 = 0 \\ a_1 \oplus a_3 &= 1 \oplus 0 = 1 \end{aligned}$$

The check yields the binary check number 1, indicating that the error is in the first digit a_1 , as indeed it is. If 111 is sent and 101 received, then

$$\begin{aligned} a_2 \oplus a_3 &= 0 \oplus 1 = 1 \\ a_1 \oplus a_3 &= 1 \oplus 1 = 0 \end{aligned}$$

and the binary check number is 10, or 2, indicating that the error is in a_2 .

In the general case, a set of l independent linear equations is set up in order to derive a binary checking number whose value indicates the position of the error in the binary word. If more than one error is to be detected and corrected, the number l of check digits must increase, as discussed previously.

In the example just treated, the l check digits were used only to check the k information digits immediately preceding them. Such a code is called a *block code*, since all the information digits and all the check digits are contained in the block (code word) of length $n = k + l$. In some encoding procedures, the l check digits may also be used to check information digits appearing in preceding words. Such codes are called *convolutional* or

recurrent codes. A parity-check code (either block or convolutional) where the word length is n and the number of information digits is k is usually called an (n, k) code.

OTHER ERROR-DETECTING AND ERROR-CORRECTING CODES

Unfortunately, a general treatment of error-detecting and error-correcting codes requires that the code structure be cast in a relatively sophisticated mathematical form. The commonest procedure is to identify the code letters with the elements of a finite (algebraic) field. The code words are then taken to form a vector subspace of n -tuples over the field. Such codes are called *linear codes* or, sometimes, *group codes*. Both the block codes and the convolutional codes mentioned in the previous paragraph fall in this category.

An additional constraint often imposed on linear codes is that they be *cyclic*. Let a code word a be represented by

$$a = (a_0, a_1, a_2, \dots, a_{n-1})$$

Then the i th *cyclic permutation* a^{-i} is given by $a^i = (a_i, a_{i+1}, \dots, a_{n-1}, a_0, a_1, \dots, a_{i-1})$. A linear code is cyclic if, and only if, for every word a in the code, there is also a word a^i in the code. The permutations need not be distinct and, in fact, generally will not be. The eight code words

0000 0110 1001 1010
0011 1100 0101 1111

constitute a cyclic set. Included in the cyclic codes are some of those most commonly encountered such as the Bose and Ray-Chaudhuri (BCH) codes and shortened Reed-Muller codes.

CONTINUOUS-AMPLITUDE CHANNELS

The preceding discussion has concerned discrete message distributions and channels. Further, it has been assumed, either implicitly or explicitly, that the time parameter is discrete, i.e., that a certain number of messages, symbols, code digits, and so forth, are transmitted per unit time. Thus, we have been concerned with *discrete-amplitude, discrete-time* channels and with messages which can be modeled as *discrete random processes* with *discrete parameter*. There are three other possibilities, depending on whether the process amplitude and the time parameter have discrete or continuous distributions.

We now consider the *continuous-amplitude, discrete-time* channel, where the input messages can be modeled as *continuous random processes* with *discrete parameter*. It will be shown later that continuous-time cases of engineering interest can be treated by techniques which amount to the replacement of the continuous parameter by a discrete parameter. The most straightforward method involves the application of the sampling theorem to band-limited processes. In this case the process is sampled at equispaced intervals of length $1/2W$, where W is the highest frequency of the process. Thus the continuous parameter t is replaced by the discrete parameter $t_k = k/2W, k = \dots, -1, 0, 1, \dots$

Let us restrict our attention for the moment to continuous-amplitude, discrete-time situations. The discrete density $p(x_i), i = 1, 2, \dots, M$, of the source-message set is replaced by the continuous density $f_x(x)$, where, in general, $-\infty < x < \infty$, although the range of x may be restricted in particular cases. In the same way, other discrete densities are replaced by continuous densities. For example, the destination distribution $p(y_j), j = 1, 2, \dots, N$, becomes $f_y(y)$, and the joint distribution $p(x_i, y_j)$ will be called $f_2(x, y)$.

In analogy with the discrete-amplitude case [Eq. (4)], the entropy of a continuous distribution $f_x(x)$ can be defined as

$$H(X) = - \int_{-\infty}^{\infty} f_x(x) \log f_x(x) dx \tag{53}$$

1.26 INFORMATION, COMMUNICATION, NOISE, AND INTERFERENCE

This definition is not completely satisfactory because of some of the properties of this new $H(X)$. For example, it can be negative and it can depend on the coordinate system used to represent the message.

Joint and conditional entropies can also be defined in exact analogy to the discrete case discussed in Chap. 1.1. If the joint density $f_2(x, y)$ exists, then the joint entropy $H(X, Y)$ is given by

$$H(X, Y) = - \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f_2(x, y) \log f_2(x, y) dx dy \quad (54)$$

and the conditional entropies $H(X|Y)$ and $H(Y|X)$ are

$$H(X|Y) = - \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f_2(x, y) \log \frac{f_2(x, y)}{f_y(y)} dx dy \quad (55)$$

and

$$H(Y|X) = - \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f_2(x, y) \log \frac{f_2(x, y)}{f_x(x)} dx dy \quad (56)$$

where

$$f_x(x) = \int_{-\infty}^{\infty} f_2(x, y) dy \quad \text{and} \quad f_y(y) = \int_{-\infty}^{\infty} f_2(x, y) dx$$

The average mutual information follows from Eq. (15) and is

$$I(X; Y) = - \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f_2(x, y) \log \frac{f_x(x)f_y(y)}{f_2(x, y)} dx dy \quad (57)$$

Although the entropy of a continuous distribution can be negative, positive, or zero, the average mutual information $I(X; Y) \geq 0$ with equality when x and y are statistically independent, i.e., when $f_2(x, y) = f_x(x)f_y(y)$.

MAXIMIZATION OF ENTROPY OF CONTINUOUS DISTRIBUTIONS

The entropy of a discrete distribution is a maximum when the distribution is uniform, i.e., when all outcomes are equally likely. In the continuous case, the entropy depends on the coordinate system, and it is possible to maximize this entropy subject to various constraints on the associated density function.

The Maximization of $H(X)$ for a Fixed Variance of x . Maximizing $H(X)$ subject to the constraint that

$$\int_{-\infty}^{\infty} x^2 f_x(x) dx = \sigma^2 \quad (58)$$

yields the gaussian density

$$f_x(x) = (1 / \sqrt{2\pi\sigma}) e^{-x^2/2\sigma^2} \quad -\infty < x < \infty \quad (59)$$

Thus, for fixed variance, the normal distribution has the largest entropy. The entropy in this case is

$$H(X) = 1/2 \ln 2\pi\sigma^2 + 1/2 \ln e = 1/2 \ln 2\pi e\sigma^2 \quad (60)$$

This last result will be of considerable use later. For convenience, the natural logarithm has been used, and the units of H are nats.

The Maximization of $H(X)$ for a Limited Peak Value of x . In this case, the single constraint is

$$\int_{-M}^M f_x(x) dx = 1 \quad (61)$$

One obtains the uniform distribution

$$f_x(x) = \begin{cases} 1/2M & |x| \leq M \\ 0 & |x| > M \end{cases}$$

and, the associated entropy is

$$H(X) = -\int_{-M}^M \frac{1}{2M} \log \frac{1}{2M} dx = \log 2M \quad (62)$$

The Maximization of $H(X)$ for x Limited to Nonnegative Values and a Given Average Value. The constraints

$$\int_0^{\infty} f_x(x) dx = 1$$

and

$$\int_0^{\infty} x f_x(x) dx = \mu \quad (63)$$

lead to the *exponential distribution*

$$f_x(x) = \begin{cases} 0 & x < 0 \\ (1/\mu)e^{-(x/\mu)} & x \geq 0 \end{cases}$$

The entropy associated with this distribution is

$$H(X) = \ln \mu + 1 = \ln \mu e \quad (64)$$

GAUSSIAN SIGNALS AND CHANNELS

Let us assume that the source symbol x and the destination symbol y are jointly gaussian, i.e., that the joint density $f_2(x, y)$ is

$$f_2(x, y) = \frac{1}{2\pi\sigma_x\sigma_y\sqrt{1-\rho^2}} \exp \left\{ -\frac{1}{2(1-\rho^2)} \left[\left(\frac{x}{\sigma_x} \right)^2 - 2\rho \frac{xy}{\sigma_x\sigma_y} + \left(\frac{y}{\sigma_y} \right)^2 \right] \right\} \quad (65)$$

where σ_x^2 and σ_y^2 are the variances of x and y , respectively, and ρ is the correlation coefficient given by

$$\rho = \frac{E\{xy\}}{\sigma_x\sigma_y} \quad (66)$$

1.28 INFORMATION, COMMUNICATION, NOISE, AND INTERFERENCE

The univariate densities of x and y are given, of course, by

$$f_x(x) = \frac{1}{\sqrt{2\pi}\sigma_x} \exp\left[-\frac{1}{2}\left(\frac{x}{\sigma_x}\right)^2\right] \quad -\infty < x < \infty \quad (67)$$

and

$$f_y(y) = \frac{1}{\sqrt{2\pi}\sigma_y} \exp\left[-\frac{1}{2}\left(\frac{y}{\sigma_y}\right)^2\right] \quad -\infty < y < \infty \quad (68)$$

In this case we have

$$I(X; Y) = -\frac{1}{2} \ln(1 - \rho^2) \quad (69)$$

Thus the average mutual information in two jointly gaussian random variables is a function only of the correlation coefficient ρ and varies from zero to infinity since $-1 \leq \rho \leq 1$.

The noise entropy $H(Y|X)$ can be written

$$H(Y|X) = H(Y) - I(X; Y) = \frac{1}{2} \ln 2\pi e \sigma_y^2 (1 - \rho^2) \quad (70)$$

Suppose that x and y are jointly gaussian as a result of independent zero-mean gaussian noise n being added in the channel to the gaussian input x , so that

$$y = x + n \quad (71)$$

In this case the correlation coefficient ρ becomes

$$\rho = \frac{E\{x^2 + nx\}}{\sigma_x \sigma_y} = \frac{\sigma_x^2}{\sigma_x \sigma_y} = \frac{\sigma_x}{\sigma_y} \quad (72)$$

and the noise entropy is

$$H(Y|X) = \frac{1}{2} \ln 2\pi e \sigma_n^2 \quad (73)$$

where σ_n^2 is the noise variance given by

$$\sigma_n^2 = E\{n^2\} = \sigma_y^2 - \sigma_x^2 \quad (74)$$

In this situation, Eq. (69) can be rewritten as

$$I(X; Y) = \frac{1}{2} \ln(1 + \sigma_x^2 / \sigma_n^2) \quad (75)$$

It is conventional to define the signal power as $S_p = \sigma_x^2$ and the noise power as $N_p = \sigma_n^2$ and to rewrite this last expression as

$$I(X; Y) = \frac{1}{2} \ln(1 + S_p / N_p) \quad (76)$$

where S_p/N_p is the signal-to-noise power ratio.

Channel capacity C for the continuous-amplitude, discrete-time channel is

$$C = \max_{f_X(x)} I(X; Y) = \max_{f_X(x)} [H(Y) - H(Y|X)] \quad (77)$$

Suppose the channel consists of an additive noise that is a sequence of independent gaussian random variables n each with zero mean and variance σ_n^2 . In this case the conditional probability $f(y/x)$ at each time instant is normal with variance σ_n^2 and mean equal to the particular realization of X . The noise entropy $H(Y|X)$ is given by Eq. (73), and Eq. (77) becomes

$$C = \max_{f_X(x)} [H(Y)] - 1/2 \ln 2\pi e \sigma_n^2 \quad (78)$$

If the input power is fixed at σ_x^2 then the output power is fixed at $\sigma_y^2 = \sigma_x^2 + \sigma_n^2$ and $H(Y)$ is a maximum if $Y = X + N$ is a sequence of independent gaussian random variables. The value of $H(Y)$ is

$$H(Y) = 1/2 \ln 2\pi e (\sigma_x^2 + \sigma_n^2)$$

and the channel capacity becomes

$$C = 1/2 \ln (1 + \sigma_x^2 / \sigma_n^2) = 1/2 \ln (1 + S_p / N_p) \quad (79)$$

where S_p/N_p is the signal-to-noise power ratio. Note that the input X is a sequence of independent gaussian random variables and this last equation is identical to Eq. (76). Thus, for additive independent gaussian noise and an input power limitation, the discrete-time continuous-amplitude channel has a capacity given by Eq. (79). This capacity is realized when the input is an independent sequence of independent, identically distributed gaussian random variables.

BAND-LIMITED TRANSMISSION AND THE SAMPLING THEOREM

In this section, messages will be considered which can be modeled as continuous random processes $x(t)$ with continuous parameter t . The channels which transmit these messages will be called *amplitude-continuous, time-continuous* channels. Specifically attention will be restricted to signals (random processes) $x(t)$, which are *strictly band-limited*.

Suppose a given arbitrary (deterministic) signal $f(t)$ is available for all time. Is it necessary to know the amplitude of the signal for every value of time in order to characterize it uniquely? In other words, can $f(t)$ be represented (and reconstructed) from some set of *sample values* or *samples* . . . , $f(t), f(t_0), f(t_1), \dots$? Surprisingly enough, it turns out that, under certain fairly reasonable conditions, a signal can be represented exactly by samples spaced relatively far apart. The reasonable conditions are that the signal be *strictly band-limited*.

A (real) signal $f(t)$ will be called *strictly band-limited* ($-2\pi W, 2\pi W$) if its Fourier transform $F(\omega)$ has the property

$$F(\omega) = 0 \quad |\omega| > 2\pi W \quad (80)$$

Such a signal can be represented in terms of its sample taken at the *Nyquist sampling times*, $t_k = \frac{k}{2W}$ $k = 0, \pm 1, \dots$ via the *sampling representation*

$$f(t) = \sum_{k=-\infty}^{\infty} f\left(\frac{k}{2W}\right) \frac{\sin(2\pi Wt - k\pi)}{2\pi Wt - k\pi} \quad (81)$$

1.30 INFORMATION, COMMUNICATION, NOISE, AND INTERFERENCE

This expression is sometimes called the *Cardinal series* or *Shannon's sampling theorem*. It relates the discrete time domain $\{k/2W\}$ with sample values $f(k/2W)$ to the continuous time domain $\{t\}$ of the function $f(t)$.

The interpolation function

$$k(t) = (\sin 2\pi Wt) / 2\pi Wt \quad (82)$$

has a Fourier transform $K(\omega)$ given by

$$K(\omega) = \begin{cases} 1/4\pi W & |\omega| < 2\pi W \\ 0 & |\omega| > 2\pi W \end{cases} \quad (83)$$

Also the shifted functions $k(t - k/2W)$ has the Fourier transform

$$\mathfrak{F}\{k(t - k/2W)\} = K(\omega)e^{j\omega k/2W} \quad (84)$$

Therefore, each term on the right side of Eq. (81) is a time function which is strictly band-limited $(-2\pi W, 2\pi W)$. Note also that

$$k\left(t - \frac{k}{2W}\right) = \frac{\sin(2Wt - k\pi)}{2\pi Wt - k\pi} = \begin{cases} 1 & t = t_k = k\pi/2W \\ 0 & t = t_n, \quad n \neq k \end{cases} \quad (85)$$

Thus, this sampling function $k(t - k/2W)$ is zero at all Nyquist instants except t_k , where it equals unity.

Suppose that a function $h(t)$ is not strictly band-limited to at least $(-2\pi W, 2\pi W)$ rad/s and an attempt is made to reconstruct the function using Eq. (81) with sample values spaced $1/2W \cdot s$ apart. It is apparent that the reconstructed signal [which is strictly band-limited $(-2\pi W, 2\pi W)$, as already mentioned] will differ from the original. Moreover, a given set of sample values $\{f(k/2W)\}$ could have been obtained from a whole class of different signals. Thus, it should be emphasized that the reconstruction of Eq. (81) is unambiguous only for signals strictly band-limited to at least $(-2\pi W, 2\pi W)$ rad/s. The set of different possible signals with the same set of sample values $\{f(k/2W)\}$ is called the *aliases* of the band-limited signal $f(t)$.

Let us now consider a signal (random process) $X(t)$ with *autocorrelation function* given by

$$R_x(\tau) = E\{X(t)X(t + \tau)\} \quad (86)$$

and *power spectral density*

$$\varphi_x(\omega) = \int_{-\infty}^{\infty} R_x(r)e^{-j\omega r} dr \quad (87)$$

which is just the Fourier transform of $R_x(\tau)$. The process will be assumed to have zero mean and to be strictly *band-limited* $(-2\pi W, 2\pi W)$ in the sense that the power special density $\varphi_x(\omega)$ vanishes outside this interval; i.e.,

$$\varphi_x(\omega) = 0 \quad |\omega| > 2\pi W \quad (88)$$

It has been noted that a deterministic signal $f(t)$ band-limited $(-2\pi W, 2\pi W)$ admits the *sampling representation* of Eq. (81). It can also be shown that the random process $X(t)$ admits the same expansions; i.e.,

$$X(t) = \sum_{k=-\infty}^{\infty} X\left(\frac{k}{2W}\right) \frac{\sin(2\pi Wt - k\pi)}{2\pi Wt - k\pi} \quad (89)$$

The right side of this expression is a random variable for each value of t . The infinite sum means that

$$\lim_{N \rightarrow \infty} E\{|X(t) - X_N(t)|^2\} = 0$$

where

$$X_N(t) = \sum_{k=-N}^N X\left(\frac{k}{2W}\right) \frac{\sin(2\pi Wt - k\pi)}{2\pi Wt - k\pi}$$

Thus, the process $X(t)$ with continuous time parameter t can be represented by the process $X(k/2W)$, $k = \dots, -2, -1, 0, 1, 2, \dots$, with discrete time parameter $t_k = k/2W$. For band-limited signals or channels it is sufficient, therefore, to consider the discrete-time case and to relate the results to continuous time through Eq. (89).

Suppose the continuous-time process $X(t)$ has a spectrum $\varphi_x(\omega)$ which is *flat and band-limited* so that

$$\varphi_x(\omega) = \begin{cases} N_0 & |\omega| \leq 2\pi W \\ 0 & |\omega| > 2\pi W \end{cases} \quad (90)$$

Then the autocorrelation function passes through zero at intervals of $1/2W$ so that

$$R_x(k/2W) = 0 \quad k = \dots, -2, -1, 1, 2, \dots \quad (91)$$

Thus, samples spaced $k/2W$ apart are *uncorrelated if the power spectral density is flat and band-limited* ($-2\pi W, 2\pi W$). *If the process is gaussian, the samples are independent.* This implies that continuous-time band-limited ($-2\pi W, 2\pi W$) gaussian channels, where the noise has a flat spectrum, have a capacity C given by Eq. (79) as

$$C = 1/2 \ln(1 + S_p/N_p) \quad (\text{nats/sample}) \quad (92)$$

Here N_p is the variance of the additive, flat, band-limited gaussian noise and S_p is $R_x(0)$, the fixed variance of the input signal. The units of Eq. (92) are on a per sample basis. Since there are $2W$ samples per unit time, the capacity C' per unit time can be written as

$$C' = W \ln(1 + S_p/N_p) \quad (\text{nats/s}) \quad (93)$$

The ideas developed thus far in this section have been somewhat abstract notions involving information sources and channels, channel capacity, and the various coding theorems. We now look more closely at conventional channels. Many aspects of these topics fall into the area often called *modulation theory*.

CHAPTER 1.3

MODULATION

Geoffrey C. Orsak, H. Vincent Poor, John B. Thomas

MODULATION THEORY

As discussed in Chap. 1.1 and shown in Fig. 1.1.1, the central problem in most communication systems is the transfer of information originating in some source to a destination by means of a channel. It will be convenient in this section to call the sent message or intelligence $a(t)$ and to denote the received message by $a^*(t)$, a distorted or corrupted version of $a(t)$.

The message signals used in communication and control systems are usually limited in frequency range to some maximum frequency $f_m = \omega_m/2\pi$ Hz. This frequency is typically in the range of a few hertz for control systems and moves upward to a few megahertz for television video signals. In addition the bandwidth of the signal is often of the order of this maximum frequency so that the signal spectrum is approximately low-pass in character. Such signals are often called *video signals* or *baseband signals*. It frequently happens that the transmission of such a spectrum through a given communication channel is inefficient or impossible. In this light, the problem may be looked upon as the one shown in Fig. 1.1.2, where an encoder E has been added between the source and the channel; however, in this case, the encoder acts to *modulate* the signal $a(t)$, producing at its output the *modulated wave* or signal $m(t)$.

Modulation can be defined as the modification of one signal, called the *carrier*, by another, called the *modulating signal*. The result of the modulation process is a modulated wave or signal. In most cases a frequency shift is one of the results. There are a number of reasons for producing modulated waves. The following list gives some of the major ones.

- (a) *Frequency Translation for Efficient Antenna Design.* It may be necessary to transmit the modulating signal through space as electromagnetic radiation. If the antenna used is to radiate an appreciable amount of power, it must be large compared with the signal wavelength. Thus translation to higher frequencies (and hence to smaller wavelengths) will permit antenna structures of reasonable size and cost at both transmitter and receiver.
- (b) *Frequency Translation for Ease of Signal Processing.* It may be easier to amplify and/or shape a signal in one frequency range than in another. For example, a dc signal may be converted to ac, amplified, and converted back again.
- (c) *Frequency Translation to Assigned Location.* A signal may be translated to an assigned frequency band for transmission or radiation, e.g., in commercial radio broadcasting.
- (d) *Changing Bandwidth.* The bandwidth of the original message signal may be increased or decreased by the modulation process. In general, decreased bandwidth will result in channel economies at the cost of fidelity. On the other hand, increased bandwidth will be accompanied by increased immunity to channel disturbances, as in wide-band frequency modulation or in spread-spectrum systems, for examples.
- (e) *Multiplexing.* It may be necessary or desirable to transmit several signals occupying the same frequency range or the same time range over a single channel. Various modulation techniques allow the signals to share the same channel and yet be recovered separately. Such techniques are given the generic name of

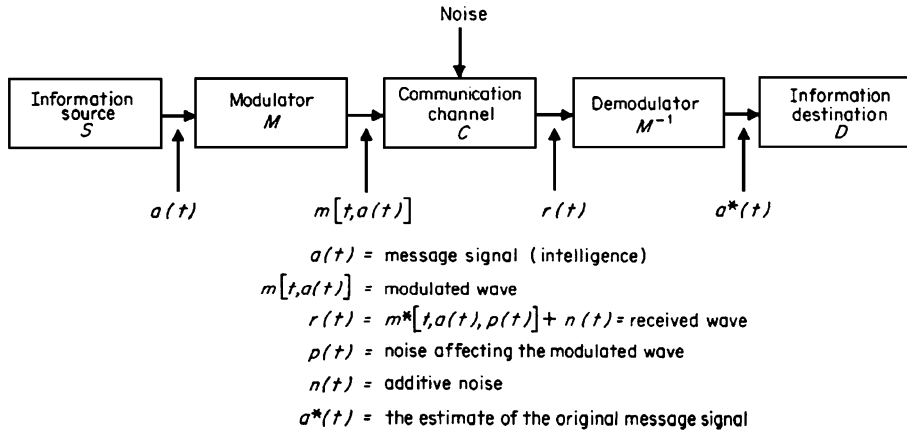

FIGURE 1.3.1 Communication system involving modulation and demodulation.

multiplexing. As will be discussed later, multiplexing is possible in either the frequency domain (frequency-domain multiplexing FDM) or in the time domain (time-domain multiplexing, TDM). As a simple example, the signals may be translated in frequency so that they occupy separate and distinct frequency ranges as mentioned in item (b).

Thus, the process of modulation can be considered as a form of encoding used to match the message signal arising from the information source to the communication channel. At the same time it is generally true that the channel itself has certain undesirable characteristics resulting in distortion of the signal during transmission. A part of such distortion can frequently be accounted for by postulating noise disturbances in the channel. These noises may be additive and may also affect the modulated wave in a more complicated fashion, although it is usually sufficient (and much simpler) to assume additive noise only. Also, the received signal must be decoded (demodulated) to recover the original signal.

In view of this discussion, it is convenient to change the block diagram of Fig. 1.1.2 to that shown in Fig. 1.3.1. The waveform received at the demodulator (receiver) will be denoted by $r(t)$, where

$$r(t) = m^*[t, a(t), p(t)] + n(t) \tag{1}$$

where $a(t)$ is the original message signal, $m[t, a(t)]$ is the modulated wave, $m^*[t, a(t), p(t)]$ is a corrupted version of $m[t, a(t)]$, and $p(t)$ and $n(t)$ are noises whose characteristics depend on the channel. Unless it is absolutely necessary for an accurate characterization of the channel, we will assume that $p(t) \equiv 0$ to avoid the otherwise complicated analysis that results.

The aim is to find modulators M and demodulators M^{-1} that make $a^*(t)$ a “good” estimate of the message signal $a(t)$. It should be emphasized that M^{-1} is not uniquely specified by M ; for example, it is not intended to imply that $MM^{-1} = 1$. The form of the demodulator, for a given modulator, will depend on the characteristics of the message $a(t)$ and the channel as well as on the criterion of “goodness of estimation” used.

We now take up a study of the various forms of modulation and demodulation, their principal characteristics, their behavior in conjunction with noisy channels, and their advantages and disadvantages. We begin with some preliminary material on signals and their properties.

ELEMENTS OF SIGNAL THEORY

A real time function $f(t)$ and its Fourier transform form a Fourier transform pair given by

$$F(\omega) = \int_{-\infty}^{\infty} f(t)e^{-j\omega t} dt \tag{2}$$

FIGURE 1.3.2 Duration and delay: (a) typical pulse; (b) integral of pulse.

and

$$f(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\omega) e^{j\omega t} d\omega \tag{3}$$

It follows directly from Eq. (2) that the transform $F(\omega)$ of a real-time function has an even-symmetric real part and an odd-symmetric imaginary part.

Consider the function $f(t)$ shown in Fig. 1.3.2a. This might be a pulsed signal or the impulse response of a linear system, for example. The time ΔT over which $f(t)$ is appreciably different from zero is called the *duration* of $f(t)$, and some measure, such as τ_d , of the center of the pulse is called the *delay* of $f(t)$. In system terms, the quantity ΔT is the system *response time* or *rise time*, and τ_d is the system delay. The integral of $f(t)$, shown in Fig. 1.3.2b, corresponds to the step-function response of a system with impulse response $f(t)$.

If the function $f(t)$ of Fig. 1.3.2 is nonnegative, the new function

$$\frac{f(t)}{\int_{-\infty}^{\infty} f(t) dt}$$

is nonnegative with unit area. We now seek measures of duration and delay that are both meaningful in terms of communication problems and mathematically tractable. It will be clear that some of the results we obtain will not be universally applicable and, in particular, must be used with care when the function $f(t)$ can be negative for some values of t ; however, the results will be useful for wide classes of problems.

Consider now a frequency function $F(\omega)$, which will be assumed to be real. If $F(\omega)$ is not real, either $|F(\omega)|^2 = F(\omega)F(-\omega)$ or $|F(\omega)|$ can be used. Such a function might be similar to that shown in Fig. 1.3.3a. The radian frequency range $\Delta\Omega$ (or the frequency range ΔF) over which $F(\omega)$ is appreciably different from zero is called the *bandwidth* of the function. Of course, if the function is a *bandpass* function, such as that shown in Fig. 1.3.3b, the bandwidth will usually be taken to be some measure of the width of the positive-frequency

FIGURE 1.3.3 Illustrations of bandwidth: (a) typical low-pass frequency function; (b) typical bandpass frequency function.

(or negative-frequency) part of the function only. As in the case of the time function previously discussed, we may normalize to unit area and consider

$$\frac{F(\omega)}{\int_{-\infty}^{\infty} F(\omega) d\omega}$$

Again this new function is nonnegative with unit area.

Consider now the Fourier pair $f(t)$ and $F(\omega)$ and let us change the time scale by the factor a , replacing $f(t)$ by $af(at)$ so that both the old and the new signal have the same area, i.e.,

$$\int_{-\infty}^{\infty} f(t) dt = \int_{-\infty}^{\infty} af(at) dt \tag{4}$$

For $a < 1$, the new signal $af(at)$ is stretched in time and reduced in height; its “duration” has been increased. For $a > 1$, $af(at)$ has been compressed in time and increased in height; its “duration” has been decreased. The transform of this new function is

$$\int_{-\infty}^{\infty} af(at)e^{-j\omega t} dt = \int_{-\infty}^{\infty} f(x)e^{-j(\omega/a)x} dt = F\left(\frac{\omega}{a}\right) \tag{5}$$

The effect on the bandwidth of $F(\omega)$ has been the opposite of the effect on the duration of $f(t)$. When the signal duration is increased (decreased), the bandwidth is decreased (increased) in the same proportion. From the discussion, we might suspect that more fundamental relationships hold between properly defined durations and bandwidths of signals.

DURATION AND BANDWIDTH-UNCERTAINTY RELATIONSHIPS

It is apparent from the discussion above that treatments of duration and bandwidth are mathematically similar although one is defined in the time domain and the other in the frequency domain. Several specific measures of these two quantities will now be found, and it will be shown that they are intimately related to each other through various *uncertainty relationships*. The term “uncertainty” arises from the *Heisenberg uncertainty principle* of quantum mechanics, which states that it is not possible to determine simultaneously and exactly the position and momentum coordinates of a particle. More specifically, if Δx and Δp are the uncertainties in position and momentum, then

$$\Delta x \Delta p \geq h \tag{6}$$

where h is a constant. A number of inequalities of the form of Eq. (6) can be developed relating the duration ΔT of a signal to its (radian) bandwidth $\Delta\Omega$. The value of the constant h will depend on the definitions of duration and bandwidth.

Equivalent Rectangular Bandwidth DW1 and Duration DT1. The equivalent rectangular bandwidth DW1 of a frequency function $F(\omega)$ is defined as

$$\Delta\Omega_1 = \frac{\int_{-\infty}^{\infty} F(\omega) d\omega}{F(\omega_0)} \tag{7}$$

where ω_0 is some characteristic center frequency of the function $F(\omega)$. It is clear from this definition that the original function $F(\omega)$ has been replaced by a rectangular function of equal area, width $\Delta\Omega_1$, and height $F(\omega_0)$. For the low-pass case ($\omega_0 \equiv 0$), it follows from Eqs. (2) and (3) that Eq. (7) can be rewritten

$$\Delta\Omega_1 = \frac{2\pi f(0)}{\int_{-\infty}^{\infty} f(t) dt} \tag{8}$$

where $f(t)$ is the time function which is the inverse Fourier transform of $F(\omega)$.

The same procedure can be followed in the time domain, and the *equivalent rectangular duration* ΔT_1 of the signal $f(t)$ can be defined by

$$\Delta T_1 = \frac{\int_{-\infty}^{\infty} f(t) dt}{f(t_0)} \tag{9}$$

where t_0 is some characteristic time denoting the center of the pulse. For the case where $t_0 \equiv 0$, it is clear, then, from Eqs. (8) and (9) that equivalent rectangular duration and bandwidth are connected by the uncertainty relationship

$$\Delta T_1 \Delta\Omega_1 = 2\pi \tag{10}$$

Second-Moment Bandwidth DW2 and Duration DT2. An alternative uncertainty relationship is based on the second-moment properties of the Fourier pair $F(\omega)$ and $f(t)$.

A *second-moment bandwidth* $\Delta\Omega_2$ can be defined by

$$(\Delta\Omega_2)^2 = \frac{1}{2\pi} \int_{-\infty}^{\infty} (\omega - \bar{\omega})^2 |F(\omega)|^2 d\omega / \epsilon \tag{11}$$

and a *second-moment duration* ΔT_2 by

$$(\Delta T_2)^2 = \int_{-\infty}^{\infty} (t - \bar{t})^2 |f(t)|^2 dt / \epsilon \tag{12}$$

where the total energy ϵ is given by

$$\epsilon = \frac{1}{2\pi} \int_{-\infty}^{\infty} |F(\omega)|^2 d\omega = \int_{-\infty}^{\infty} |f(t)|^2 dt = 1$$

These quantities are related by the inequality

$$\Delta\Omega_2 \Delta T_2 \geq 1/2 \tag{13}$$

This expression is a second uncertainty relationship connecting the bandwidth and duration of a signal. Many other such inequalities can be obtained.

CONTINUOUS MODULATION

Modulation can be defined as the modification of one signal, called the *carrier*, by another, called the *modulation*, *modulating signal*, or *message signal*. In this section we will be concerned with situations where the carrier and the modulation are both continuous functions of time. Later we will treat the cases where the carrier and/or the modulation have the form of pulse trains.

For our analysis, Fig. 1.3.1 can be modified to the system shown in Fig. 1.3.4 in which the message is sent through a modulator (or transmitter) to produce the modulated continuous signal $m[t, a(t)]$. This waveform is corrupted by additive noise $n(t)$ in transmission so that the received (continuous) waveform $r(t)$ can be written

$$r(t) = m[t, a(t)] + n(t) \tag{14}$$

The purpose of the demodulator (or receiver) is to produce some best estimate $a^*(t)$ of the original message signal $a(t)$. As pointed out earlier a more general model of the transmission medium would allow corruption of the modulated waveform itself so that the received signal was of the form of Eq. (1). For example, in wireless systems, multiplicative disturbances can result because of multipath transmission or fading so that the received signal is of the form

$$r_1(t) = p(t)m[t, a(t)] + n(t) \tag{15}$$

- $a(t)$ = message signal (intelligence)
- $m[t, a(t)]$ = modulated signal
- $r(t) = m[t, a(t)] + n(t)$ = received signal
- $n(t)$ = additive noise
- $a^*(t)$ = the estimate of the original message signal

FIGURE 1.3.4 Communication-system model for continuous modulation and demodulation.

where both $p(t)$ and $n(t)$ are noises. However, we shall not treat such systems, confining ourselves to the simpler additive-noise model of Fig. 1.3.4.

LINEAR, OR AMPLITUDE, MODULATION

In a general way, *linear (or amplitude) modulation* (AM) can be defined as a system where a *carrier wave* $c(t)$ has its amplitude varied linearly by some *message signal* $a(t)$. More precisely, a waveform is linearly modulated (or amplitude-modulated) by a given message $a(t)$ if the partial derivative of that waveform with respect to $a(t)$ is independent of $a(t)$. In other words, the modulated $m[t, a(t)]$ can be written in the form

$$m[t, a(t)] = a(t)c(t) + d(t) \quad (16)$$

where $c(t)$ and $d(t)$ are independent of $a(t)$. Now we have

$$\frac{\partial m[t, a(t)]}{\partial a(t)} = c(t) \quad (17)$$

and $c(t)$ will be called the *carrier*. In most of the cases we will treat, the waveform $d(t)$ will either be zero or will be linearly related to $c(t)$. It will be more convenient, therefore, to write Eq. (16) as

$$m[t, a(t)] = b(t)c(t) \quad (18)$$

where $b(t)$ will be either

$$b_1(t) \equiv 1 + a(t) \quad (19)$$

or

$$b_2(t) \equiv a(t) \quad (20)$$

Also, at present it will be sufficient to allow the carrier $c(t)$ to be of the form

$$c(t) = C \cos (\omega_0 t + \theta) \quad (21)$$

where C and ω_0 are constants and θ is either a constant or a random variable uniformly distributed on $(0, 2\pi)$.

Whenever Eq. (19) applies, it will be convenient to assume that $b_1(t)$ is nearly always nonnegative. This implies that if $a(t)$ is a deterministic signal, then

$$a(t) \geq -1 \quad (22)$$

It also implies that if $a(t)$ is a random process, the probability that $a(t)$ is less than -1 in any finite interval $(-T, T)$ is arbitrarily small; i.e.,

$$p[a(t) < -1] \leq \epsilon \ll 1 \quad -T \leq t \leq T \quad (23)$$

The purpose of these restrictions on $b_1(t)$ is to ensure that the carrier is not overmodulated and that the message signal $a(t)$ is easily recovered by simple receivers.

We can take the Fourier transform of both sides of Eq. (18) to obtain an expression for the frequency spectrum $M(\omega)$ of the general form of the linear-modulated waveform $m[t, a(t)]$:

$$M(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} B(\omega - \nu)C(\nu) d\nu \quad (24)$$

where $B(\omega)$ and $C(\omega)$ are Fourier transforms of $b(t)$ and $c(t)$, respectively. If the carrier $c(t)$ is the sinusoid of Eq. (21), then

$$C(\omega) = \pi C e^{j\theta} \delta(\omega - \omega_0) + \pi C e^{-j\theta} \delta(\omega + \omega_0) \quad (25)$$

and Eq. (24) becomes

$$M(\omega) = (C/2)e^{j\theta}B(\omega - \omega_0) + (C/2)e^{-j\theta}B(\omega + \omega_0) \quad (26)$$

Thus, for a sinusoidal carrier, linear modulation is essentially a symmetrical frequency translation of the message signal through an amount ω_0 rad/s, and no new signal components are generated. On the other hand, if $c(t)$ is not a sinusoid, so that the spectrum $C(\omega)$ has nonzero width, then $M(\omega)$ will represent a spreading and shaping as well as a translation of $B(\omega)$.

Suppose that the message signal $a(t)$ [and hence $b(t)$] is low-pass and strictly band-limited $(0, \omega_s)$ rad/s where $\omega_s < \omega_0$. Then the frequency spectrum of $b(t)$ obeys $B(\omega) = 0, |\omega| > \omega_s$, and $B(\omega - \omega_0)$ and $B(\omega + \omega_0)$ do not overlap. The spectrum $B(\omega + \omega_0)$ occupies only a range of positive frequencies while $B(\omega - \omega_0)$ occupies only negative frequencies.

The *envelope* of the modulated waveform $m[t, a(t)]$ is the magnitude $|b(t)|$. If, as mentioned earlier, the function $b(t)$ is restricted to be nonnegative almost always, then this envelope becomes just $b(t)$. In such cases, an *envelope detector* will uniquely recover $b(t)$ and hence $a(t)$. We now consider the common forms of simple amplitude, or linear, modulation.

DOUBLE-SIDEBAND AMPLITUDE MODULATION (DSBAM)

In this case the function $b(t)$ is given by Eq. (13) so that

$$m[t, a(t)] = C[1 + a(t)] \cos(\omega_0 t + \theta) \quad (27)$$

The transform of $b_1(t)$ is just

$$B_1(\omega) = \mathfrak{F}[1 + a(t)] = 2\pi\delta(\omega) + A(\omega) \quad (28)$$

where $A(\omega)$ is the Fourier transform of $a(t)$ and $\delta(\omega)$ is the Dirac delta function. It follows, therefore, from Eq. (26) that the frequency spectrum of $m[t, a(t)]$ is given by

$$M(\omega) = \frac{C}{2}e^{j\theta}[2\pi\delta(\omega - \omega_0) + A(\omega - \omega_0)] + \frac{C}{2}e^{-j\theta}[2\pi\delta(\omega + \omega_0) + A(\omega + \omega_0)] \quad (29)$$

Depending on the form of $a(t)$ a number of special cases can be distinguished, but in any case the spectrum is given by Eq. (26).

The simplest case is where $a(t)$ is the *periodic function* given by

$$a(t) = \eta \cos \omega_s t \quad \omega_s < \omega_0 \text{ and } 0 \leq \eta \leq 1 \quad (30)$$

Then the frequency spectrum $A(\omega)$ is

$$A(\omega) = \pi\eta\delta(\omega - \omega_s) + \pi\eta\delta(\omega + \omega_s) \quad (31)$$

For convenience, let us take the phase angle θ to be zero so that

$$M(\omega) = \pi C \left[\delta(\omega - \omega_0) + \delta(\omega + \omega_0) + \frac{\eta}{2}\delta(\omega - \omega_0 - \omega_s) + \frac{\eta}{2}\delta(\omega - \omega_0 + \omega_s) + \frac{\eta}{2}\delta(\omega + \omega_0 - \omega_s) + \frac{\eta}{2}\delta(\omega + \omega_0 + \omega_s) \right] \quad (32)$$

FIGURE 1.3.5 (a) Double-sideband AM signal and (b) frequency spectrum.

This spectrum is illustrated in Fig. 1.3.5 together with the corresponding modulated waveform

$$m[t, a(t)] = C(1 + \eta \cos \omega_s t) \cos \omega_0 t \tag{33}$$

Note that this last equation can also be written as

$$m[t, a(t)] = \underbrace{C \cos \omega_0 t}_{\text{carrier}} + \underbrace{(C/2)\eta \cos (\omega_0 - \omega_s)t}_{\text{lower sideband}} + \underbrace{(C/2)\eta \cos (\omega_0 + \omega_s)t}_{\text{upper sideband}} \tag{34}$$

In this form it is easy to distinguish the *carrier*, the *lower sideband*, and the *upper sideband*.

Suppose that $a(t)$ is not a single sinusoid but is periodic with period P . Then it may be expanded in a Fourier series and each term of the series treated as in Eq. (32).

DOUBLE-SIDEBAND AMPLITUDE MODULATION, SUPPRESSED CARRIER

If $b(t)$ is given by Eq. (20) so that

$$m[t, a(t)] = Ca(t) \cos (\omega_0 t + \theta) \tag{35}$$

then the carrier is suppressed and Eq. (29) reduces to

$$M(\omega) = (C/2)e^{j\theta} A(\omega - \omega_0) + (C/2)e^{-j\theta} A(\omega + \omega_0) \tag{36}$$

The principal advantage of this technique (DSBAM-SC) over DSBAM is that the carrier is not transmitted in the former case, with a consequent saving in transmittal power. The principal disadvantages relate to problems in generating and demodulating the suppressed-carrier waveform.

VESTIGIAL-SIDEBAND AMPLITUDE MODULATION (VSBAM)

It is apparent from Eq. (29) that the total information regarding the message signal $a(t)$ is contained in either the upper or lower sideband in conventional DSBAM. In principle the other sideband could be eliminated, say by filtering, with a consequent reduction in bandwidth and transmitted power. Such a procedure is actually followed in single-sideband amplitude modulation (SSBAM), discussed next. However, completely filtering out one sideband requires an ideal bandpass filter with infinitely sharp cutoff or an equivalent technique. A technique intermediate between the production of DSBAM and SSBAM is vestigial sideband amplitude modulation (VSBAM), where one sideband is attenuated much more than the other with some saving in bandwidth and transmitted power. The carrier may be present or suppressed.

The principal use of VSBAM has been in commercial television. The video (picture) signal is transmitted by VSBAM with a consequent reduction in the total transmitted signal bandwidth and in the frequency difference that must be allowed between adjacent channels.

SINGLE-SIDEBAND AMPLITUDE MODULATION (SSBAM)

This important type of AM can be considered as a limiting form of VSBAM when the filter for the modulated waveform is an ideal filter with infinitely sharp cutoff so that one sideband, e.g., the lower, is completely eliminated.

BANDWIDTH AND POWER RELATIONSHIPS FOR AM

It is clear that the bandwidth of a given AM signal is related in a simple fashion to the bandwidth of the modulating signal since AM is essentially a frequency translation. If the modulating signal $a(t)$ is assumed to be low-pass and to have a bandwidth of W Hz, then the bandwidth ΔF of the modulated signal $m[t, a(t)]$ must satisfy

$$W \leq \Delta F \leq 2W \quad (37)$$

The upper limit of $2W$ Hz holds for double-sideband modulation and the lower limit of W Hz for single-sideband. For the concept of bandwidth to be meaningful for a single-frequency sinusoidal modulating signal, it is assumed, of course, that a low-frequency sinusoid of frequency W Hz has a bandwidth W . Actually, what is really being assumed is that this sinusoid is the highest-frequency component in the low-pass modulating signal.

The only case where intermediate values of the inequality of Eq. (37) are encountered is in VSBAM. In principle any bandwidth between W and $2W$ Hz is possible. In this respect SSBAM can be considered as a limiting case of VSBAM. From a practical point of view, however, it is difficult (or expensive) to design a filter whose gain magnitude drops off too rapidly.

Power relationships are also simple and straightforward for AM signals. Consider Eq. (27) which is a general expression for the modulated AM waveform $m(t)$. Let the average power in this signal be denoted by P_{av} . The phase angle θ will be fixed if $a(t)$ is deterministic and will be taken to be a random variable uniformly distributed on $(0, 2\pi)$ if $a(t)$ is a random process. Also, it will be assumed that $a(t)_{av}$ is zero. It is clear that P_{av} is given by

$$P_{av} = (C^2/2)[1 + a^2(t)_{av}] \quad (38)$$

where $a^2(t)_{av}$ is the average power in $a(t)$. The first term, $C^2/2$, is the carrier power, and the second term, $C^2/2 a^2(t)_{av}$, is the signal power in the upper and lower sidebands. If $|a(t)| \leq 1$ to prevent overmodulation, then at least half the transmitted power is carrier power and the remainder is divided equally between the upper and lower sideband.

In double-sideband, suppressed-carrier operation, the carrier power is zero, and half the total power exists in each sideband. The fraction of information-bearing power is $1/2$. For single-sideband, suppressed-carrier systems,

all the transmitted power is information-bearing, and, in this sense, SSB-SC has maximum transmission efficiency.

The disadvantages of both suppressed-carrier and single-sideband operation lie in the difficulties of generating the signals for transmission and in the more complicated receivers required. Demodulation of suppressed-carrier AM signals involve the reinsertion of the carrier or an equivalent operation. The local generation of sinusoid at the exact frequency and phase of the missing carrier is either difficult or impossible unless a pilot tone of reduced magnitude is transmitted with the modulated signal for synchronization purposes or unless some nonlinear operation is performed on the suppressed-carrier signal to regenerate the carrier term at the receiver. In SSBAM, not only is the receiver more complicated, but transmission is considerably more difficult. It is usually necessary to generate the SSB signal at a low power level and then to amplify with a linear power amplifier to the proper level for transmission. On the other hand, DSB signals are easily generated at high power levels so that inefficient linear power amplifiers need not be used.

ANGLE (FREQUENCY AND PHASE) MODULATION

In angle modulation, the carrier $c(t)$ has either its phase angle or its frequency varied in accordance with the intelligence $a(t)$.

The result is not a simple frequency translation, as with AM, but involves both translation and the production of entirely new frequency components. In general, the new spectrum is much wider than that of the intelligence $a(t)$. The greater bandwidth may be used to improve the signal-to-noise performance of the receiver. This ability to *exchange* bandwidth for signal-to-noise enhancement is one of the outstanding characteristics and advantages of angle modulation.

In the form of angle modulation, which will be called *phase modulation* (PM), the phase of the carrier is varied linearly with the intelligence $a(t)$. Thus, the modulated signal is given by

$$m(t) = C \cos [\omega_0 t + \theta + k_p a(t)] \quad (39)$$

where k_p is a constant and the *modulation index* \varnothing_m is defined by

$$\varnothing_m = \max |k_p a(t)| \quad (\text{rad}) \quad (40)$$

In *frequency modulation*, the instantaneous frequency is made proportional to the intelligence $a(t)$. The modulated signal is given by

$$m(t) = C \cos \left[\omega_0 t + k_f \int_{-\infty}^t a(\tau) d\tau \right] \quad (41)$$

where k_f is a constant. The *maximum deviation* $\Delta\omega$ is given by

$$\Delta\omega = \max |k_f a(t)| \quad (\text{rad/s}) \quad (42)$$

and, as before, a *modulation index* \varnothing_m by

$$\varnothing_m = \max \left| k_f \int_{-\infty}^t a(\tau) d\tau \right| \quad (43)$$

In general, the analysis of angle-modulated signals is difficult even for simple modulating intelligence. We will consider only the case where the modulating intelligence $a(t)$ is a sinusoid. Let $a(t)$ be given by

$$a(t) = \eta \cos \omega_s t \quad \omega_s < \omega_0 \quad (44)$$

Then the corresponding PM signal is

$$m(t) = C \cos(\omega_0 t + k_p \eta \cos \omega_s t) \quad (45)$$

where the phase angle θ has been set equal to zero. In the same way, the FM signal is

$$m(t) = C \cos[\omega_0 t + (k_f \eta / \omega_s) \sin \omega_s t] \quad (46)$$

Let us now consider the FM signal of this last equation. Essentially the same results will be obtained for PM. The equation can be expanded to yield

$$m(t) = C \cos(\varnothing_m \sin \omega_s t) \cos \omega_0 t - C \sin(\varnothing_m \sin \omega_s t) \sin \omega_0 t \quad (47)$$

where the modulation index \varnothing_m is given by $\varnothing_m = k_f \eta / \omega_s$. Sinusoids with sinusoidal arguments give rise to Bessel functions, and Eq. (47) can be expanded and rearranged to obtain

$$\begin{aligned} m(t) = & \underbrace{C J_0(\varnothing_m) \cos \omega_0 t}_{\text{carrier}} + C \sum_{n=1}^{\infty} J_{2n}(\varnothing_m) \underbrace{[\cos(\omega_0 + 2n\omega_s)t]}_{\text{USB}} + \underbrace{\cos(\omega_0 - 2n\omega_s)t}_{\text{LSB}} \\ & + C \sum_{n=1}^{\infty} J_{2n-1}(\varnothing_m) \underbrace{\{\cos[\omega_0 + (2n-1)\omega_s]t\}}_{\text{USB}} - \underbrace{\cos[\omega_0 - (2n-1)\omega_s]t}_{\text{LSB}} \end{aligned} \quad (48)$$

where $J_m(x)$ is the Bessel function of the first kind and order m . This expression for $m(t)$ is relatively complicated even though the modulating intelligence is a simple sinusoid. In addition to the carrier, there is an infinite number of upper and lower sidebands separated from the carrier (and from each other) by integral multiples of the modulating frequency ω_s . Each sideband, and the carrier, has an amplitude determined by the appropriate Bessel function. When there is more than one modulating sinusoid, the complexity increases rapidly.

In the general case, an infinite number of sidebands exist dispersed throughout the whole frequency domain. In this sense, the bandwidth of an FM (or PM) signal is infinite. However, outside of some interval centered on ω_0 , the magnitude of the sidebands will be negligible; this interval may be taken as a practical measure of the bandwidth. An approximation can be obtained by noting that $J_n(\varnothing_m)$, considered as a function of n , decreases rapidly when $n < \varnothing_m$. Therefore only the first \varnothing_m sidebands are significant. If the highest-frequency sideband of significance is $\varnothing_m \omega_s$, then the bandwidth is given approximately by

$$BW \approx 2\omega_s \varnothing_m \quad (\text{rad/s}) \quad (49)$$

A more accurate rule of thumb is the slightly revised expression

$$BW \approx 2\omega_s(\varnothing_m + 1) \quad (\text{rad/s}) \quad (50)$$

which may be considered a good approximation when $\varnothing_m \geq 5$.

CHAPTER 1.5

NOISE AND INTERFERENCE

Geoffrey C. Orsak, H. Vincent Poor, John B. Thomas

GENERAL

In a general sense, *noise* and *interference* are used to describe any unwanted or undesirable signals in communication channels and systems. Since in many cases these signals are random or unpredictable, some study of random processes is a useful prelude to any consideration of noise and interference.

RANDOM PROCESSES

A random process $X(t)$ is often defined as an indexed family of random variables where the *index* or *parameter* t belongs to some set T ; that is, $t \in T$.

The set T is called the *parameter set* or *index set* of the process. It may be finite or infinite, denumerable or nondenumerable; it may be an interval or set of intervals on the real line, or it may be the whole real line $-\infty < t < \infty$. In most applied problems, the index t will represent time, and the underlying intuitive notion will be a random variable developing in time. However, other parameters such as position and temperature may also enter in a natural manner.

There are at least two ways to view an arbitrary random process: (1) as a set of random variables: this viewpoint follows from the definition. For each value of t , the random process reduces to a random variable; and (2) as a set of functions of time. From this viewpoint, there is an underlying random variable each realization of which is a time function with domain T . Each such time function is called a *sample function* or *realization* of the process.

From a physical point of view, it is the sample function that is important, since this is the quantity that will almost always be observed in dealing experimentally with the random process. One of the important practical aspects of the study of random processes is the determination of properties of the random variable $X(t)$ for fixed t on the basis of measurements performed on a single sample function $x(t)$ of the process $X(t)$.

A random process is said to be *stationary* if its statistical properties are invariant to time translation. This invariance implies that the underlying physical mechanism producing the process is not changing with time. Stationary processes are of great importance for two reasons: (1) they are common in practice or approximated to a high degrees of accuracy (actually, from the practical point of view, it is not necessary that a process be stationary for all time but only for some observation interval that is long enough to be suitable for a given problem); (2) many of the important properties of common stationary processes are described by first and second moments. Consequently, it is relatively easy to develop a simple but useful theory (*spectral theory*) to describe these processes. Processes that are not stationary are called *nonstationary*, although they are also sometimes referred to as *evolutionary* processes.

The mean $m(t)$ of a random process $X(t)$ is defined by

$$m(t) = E\{X(t)\} \quad (1)$$

where $E\{\cdot\}$ is the mathematical expectation operator defined in Chap. 1.1. In many practical problems, this mean is independent of time. In any case, if it is known, it can be subtracted from $X(t)$ to form a new “centered” process $Y(t) = X(t) - m(t)$ with zero mean.

The autocorrelation function $R_x(t_1, t_2)$ of a random process $X(t)$ is defined by

$$R_x(t_1, t_2) = E\{X(t_1)X(t_2)\} \quad (2)$$

In many cases, this function depends only on the time difference $t_2 - t_1$ and not on the absolute times t_1 and t_2 . In such cases, the process $X(t)$ is said to be *at least wide-sense stationary*, and by a linear change in variable Eq. (2) can be written

$$R_x(\tau) = E\{X(t)X(t + \tau)\} \quad (3)$$

If $R_x(\tau)$ possesses a Fourier transform $\varphi_x(\omega)$, this transform is called the *power spectral density* of the process and $R_x(\tau)$ and $\varphi_x(\omega)$ form the Fourier-transform pair

$$\varphi_x(\omega) = \int_{-\infty}^{\infty} R_x(\tau) e^{-j\omega\tau} d\tau \quad (4)$$

and

$$R_x(\tau) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \varphi_x(\omega) e^{j\omega\tau} d\omega \quad (5)$$

For processes that are at least wide-sense stationary, these last two equations afford a direct approach to the analysis of random signals and noises on a power ratio or mean-squared-error basis. When $\tau = 0$, Eq. (5) becomes

$$R_x(0) = E\{X^2(t)\} = \frac{1}{2\pi} \int_{-\infty}^{\infty} \varphi_x(\omega) d\omega \quad (6)$$

an expression for the normalized power in the process $X(t)$.

As previously mentioned, in practical problems involving random process, what will generally be available to the observer is not the random process but one of its sample functions or realizations. In such cases, the quantities that are easily measured are various time averages, and an important question to answer is: Under what circumstances can these time averages be related to the statistical properties of the process?

We define the *time average* of a sample function $x(t)$ of the random process $X(t)$ by

$$A\{x(t)\} = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T x(t) dt \quad (7)$$

The *time autocorrelation function* $\mathfrak{R}_x(t)$ is defined by

$$\mathfrak{R}_x(\tau) = A\{x(t)x(t + \tau)\} = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T x(t)x(t + \tau) dt \quad (8)$$

It is intuitively reasonable to suppose that, for stationary processes, time averages should be equal to expectations; e.g.,

$$E\{X(t)X(t + \tau)\} = A\{x(t)x(t + \tau)\} \quad (9)$$

for every sample function $x(t)$. A heuristic argument to support this claim would go as follows. Divide the parameter t of the random process $V(t)$ into long intervals of T length. If these intervals are long enough (compared with the time scale of the underlying physical mechanism), the statistical properties of the process in one interval T should be very similar to those in any other interval. Furthermore, a new random process $X(t)$ could be formed in the interval $(0, T)$ by using as sample functions the segments of length T from a single sample function of the original process. This new process should be statistically indistinguishable from the original process, and its ensemble averages would correspond to time averages of the sample function from the original process.

The foregoing is intended as a very crude justification of the condition of *ergodicity*. A random process is said to be *ergodic* if time averages of sample functions of the process can be used as approximations to the corresponding ensemble averages or expectations. A further discussion of ergodicity is beyond the scope of this treatment, but this condition can often be assumed to exist for stationary processes. In this case, time averages and expectations can be interchanged at will, and, in particular,

$$E\{X(t)\} = A\{x(t)\} = u = \text{a constant} \quad (10)$$

and

$$R_x(\tau) = \mathfrak{R}_x(\tau) \quad (11)$$

CLASSIFICATION OF RANDOM PROCESSES

A central problem in the study of random processes is their classification. From a mathematical point of view, a random process $X(t)$ is defined when all n -dimensional distribution functions of the random variables $X(t_1), X(t_2), \dots, X(t_n)$ are defined for arbitrary n and arbitrary times t_1, t_2, \dots, t_n . Thus classes of random processes can be defined by imposing suitable restrictions on their n -dimensional distribution functions. In this way, we can define the following (and many others):

- (a) *Stationary processes*, whose joint distribution functions are invariant to time translation.
- (b) *Gaussian (or normal) processes*, whose joint distribution functions are multivariate normal.
- (c) *Markov processes*, where given the value of $X(t_1)$, the value of $X(t_2)$, $t_2 > t_1$, does not depend on the value of $X(t_0)$, $t_0 < t_1$; in other words, the future behavior of the process, given its present state, is not changed by additional knowledge about its past.
- (d) *White noise*, where the power spectral density given by Eq. (4) is assumed to be a constant N_0 . Such a process is not realizable since its mean-squared value (normalized power) is not finite; i.e.,

$$R_x(0) = E\{X^2(t)\} = \frac{N_0}{2\pi} \int_{-\infty}^{\infty} d\omega = \infty \quad (12)$$

On the other hand, this concept is of considerable usefulness in many types of analysis and can often be postulated where the actual process has an approximately constant power spectral density over a frequency range much greater than the system bandwidth.

Another way to classify random processes is on the basis of a model of the particular process. This method has the advantage of providing insights into the physical mechanisms producing the process. The principal disadvantage is the complexity that frequently results. On this basis, we may identify the following (natural) random processes.

- (a) *Thermal noise* is caused by the random motion of the electrons within a conductor of nonzero resistance. The mean-squared value of the thermal-noise voltage across a resistor of resistance $R \Omega$ is given by

$$\bar{v}^2 = 4kTR\Delta f \quad (\text{volts}^2) \quad (13)$$

where k is Boltzmann's constant, T is the absolute temperature in kelvins, and Δf is the bandwidth of the measuring equipment.

- (b) *Shot noise* is present in any electronic device (e.g., a transistor) where electrons move across a potential barrier in a random way. Shot noise is usually modeled as

$$X(t) = \sum_{i=-\infty}^{\infty} f(t-t_i) \quad (14)$$

where the t_i are random emission times and $f(t)$ is a basic pulse shape determined by the device geometry and potential distribution.

- (c) *Defect noise* is a term used to describe a wide variety of related phenomena that manifest themselves as noise voltages across the terminals of various devices when dc currents are passed through them. Such noise is also called current noise, excess noise, flicker noise, contact noise, or $1/f$ noise. The power spectral density of this noise is given by

$$\phi_x(\omega) = kI^\alpha/\omega^\beta \quad (15)$$

where I is the direct current through the device, ω is radian frequency, and k , α , and β are constants. The constant α is usually close to 2, and β is usually close to 1. At a low enough frequency this noise may predominate because of the $1/\omega$ dependence.

ARTIFICIAL NOISE

The noises just discussed are more or less fundamental and are caused basically by the noncontinuous nature of the electronic charge. In contradistinction to these are a large class of noises and interferences that are more or less artificial in the sense of being generated by electrical or electronic equipment and hence, in principle, are under our control. The number and kinds here are too many to list and the physical mechanisms usually too complicated to describe; however, to some degree, they can be organized into three main classes.

1. *Interchannel Interference*. This includes the interference of one radio or television channel with another, which may be the result of inferior antenna or receiver design, variation in carrier frequency at the transmitter, or unexpectedly long-distance transmission via scatter or ionospheric reflection. It also includes crosstalk between channels in communication links and interference caused by multipath propagation or reflection. These types of noises can be removed, at least in principle, by better equipment design, e.g., by using a receiving antenna with a sufficiently narrow radiation pattern to eliminate reception from more than one transmitter.

2. *Co-channel Interference*. In wireless systems, this refers to interference from other communication systems operating in the same frequency band. It arises, for example, in cellular telephony systems, owing to interference from adjacent cells. It also arises in many types of consumer systems, such as wireless local area networks, that operate in lightly regulated bands.

3. *Multiple-access Interference*. This refers to intranetwork interference that results from the use of nonorthogonal modulation schemes in networks of multiple communicating pairs. Many cellular telephony systems, such as those using code-division multiple-access (CDMA) protocols, involve this kind of interference.

4. *Hum*. This is a periodic and undesirable signal arising from the power lines. Usually it is predictable and can be eliminated by proper filtering and shielding.

5. *Impulse Noise*. Like defect noise, this term describes a wide variety of phenomena. Not all of them are artificial, but the majority probably are. This noise can often be modeled as a low-density shot process or, equivalently, as the superposition of a small number of large impulses. These impulses may occur more or less periodically, as in ignition noise from automobiles or corona noise from high-voltage transmission lines. On the other hand, they may occur randomly, as in switching noise in telephone systems or the atmospheric noise

1.56 INFORMATION, COMMUNICATION, NOISE, AND INTERFERENCE

from thunderstorms. The latter type of noise is not necessarily artificial, of course. This impulse noise tends to have an amplitude distribution that is decidedly non-gaussian, and it is frequently highly nonstationary. It is difficult to deal with in a systematic way because it is ill-defined. Signal processors that must handle this type of noise are often preceded by limiters of various kinds or by noise blankers which give zero transmission if a certain amplitude level is surpassed. The design philosophy behind the use of limiters and blankers is fairly clear. If the noise consists of large impulses of relatively low density, the best system performance is obtained if the system is limited or blanked during the noisy periods and behaves normally when the (impulse) noise is not present.

SECTION 2

SYSTEMS ENGINEERING AND SYSTEMS MANAGEMENT

The origins of systems engineering concepts are indeterminate, although the complexity of weapons systems and other military systems during World War II helped formalize the practice. It would be impossible to approach anything near optimization of today's complex systems without the use of systems engineering. It should be no surprise that an important element of systems engineering is the partitioning of a system into smaller components that are more readily managed. But this leads to the necessity for careful, considered communication between and among engineers working on distinctive subsystems, attention to interdisciplinary issues, and an overall management philosophy (and practice) that fosters good communication and good systems engineering at all phases of a system's life cycle.

The two chapters in this section are designed to define the various facets of systems engineering and systems management and to identify some of the techniques and procedures employed in its practice. D.C.

CHAPTER 2.1

INTRODUCTION TO SYSTEMS ENGINEERING

Andrew P. Sage, William B. Rouse

FACETS AND DEFINITIONS

In this chapter, we summarize relevant facets of systems engineering support for management that we believe are essential to the definition, development, and deployment of innovative technologies that feature electronics engineering contributions.

Systems engineering generally involves breaking down a large problem into smaller component problems that are more easily resolved, determining the solution to this collection of subproblems, and then aggregating the solutions such that, hopefully, resolution to the initial larger problem or issue results.

A simple functional definition of systems engineering is that systems engineering is the art and science of producing a product or a service, or a process—based on phased efforts that involve *definition* or the desired end result of the effort followed by *development* of the product or service or process, and culminating with *deployment* of this in an operational setting—that satisfies user needs. The system is functional, reliable, of high quality, and trustworthy, and has been developed within cost and time constraints through use of an appropriate set of methods and tools.

PURPOSES AND APPLICATIONS

The purposes of systems engineering can be defined as follows: *Systems engineering is management technology to assist and support policymaking, planning, decision-making, and associated resource allocation or action deployment.* Systems engineers accomplish this by quantitative and qualitative *formulation, analysis, and interpretation* of the impacts of action alternatives on the needs perspectives, the institutional perspectives, and the value perspectives of their clients or customers. Each of these three steps is generally needed in solving systems engineering problems. Issue formulation is an effort to identify the needs to be fulfilled and the requirements associated with these in terms of objectives to be satisfied, constraints and alterables that affect issue resolution, and generation of potential alternate courses of action. Issue analysis enables us to determine the impacts of the identified alternative courses of action, including possible refinement of these alternatives. Issue interpretation helps to rank order the alternatives in terms of need satisfaction and to select one for implementation or additional study.

This particular listing of three systems engineering steps and their descriptions is rather formal. Issues are often resolved this way, especially when there is initially only limited experiential familiarity with the issue under consideration. The steps of formulation, analysis, and interpretation may also be accomplished

2.4 SYSTEMS ENGINEERING AND SYSTEMS MANAGEMENT

on an “as-if” basis by application of a variety of often-useful heuristic approaches. These may well be quite appropriate in situations where the problem solver is experientially familiar with the task at hand and the environment into which the task is embedded, so as to enable development of an appropriate context for issue resolution. This requires information. It also requires knowledge, as information embedded into experience-based context and environment, and this may lead to very useful heuristic approaches to use of this knowledge.

The systems approach gains ready acceptance if one or more of these characteristics apply:

1. Complexity cannot be otherwise addressed, and a completely intuitive and unorchestrated approach simply will not work.
2. We are dealing with high-risk situations, and the consequences of errors are too large to be acceptable.
3. There are major investments involved and the potential loss of financial resources because use of inefficient processes to engineer the system is unacceptable.

HUMAN AND SOCIETAL FACTORS

One of the most essential notions is that systems engineering does not deal exclusively with physical products. While the ultimate aim of systems engineering efforts may well be to produce a physical product or service, there are humans and organizations involved, as well as technologies.

Systems engineering and systems management concern more than the specific technical efforts that occur inside a factory. One of the major needs is for a multiple perspective viewpoint across the various issues affecting the engineering of systems. Fundamentally, systems engineers act as brokers and communicators of knowledge across the various stakeholders having interest in a given issue concerned with product or service deployment. These certainly include the enterprise organization for which a system is being engineered. It also includes the technology implementation organization(s) that will be responsible for the detailed internal design efforts needed to bring about a system. This is represented in Fig. 2.1.1. The issues being considered may also

		Information interrogatives				Knowledge interrogatives

include impacted publics and public sector policy-making bodies, especially when the system being engineered has public sector impacts and implications.

A reduced perspective version of this figure is shown in Fig. 2.1.2. The three rows here correspond to the enterprise perspective, which represents that of the group which desires the system, the systems engineering and management perspective, and the perspective of the group or organization that physically implements the system. The columns contain a total of six interrogatives. The first four of these (what, where, who, and when) generally correspond to structural elements or interrogatives needed to represent the structural issues associated with the phase (definition, development, and deployment) of the system being engineered. The “how” element or interrogative generally corresponds to a functional and activity-based representation of the phase of the system being engineered, and the “why” element generally corresponds to purposeful interrogatives associated with the phase of the system being engineered. It is generally felt that we may define subject matter from a structural, functional, or purposeful perspective. Thus, the representations shown in Figs. 2.1.1 and 2.1.2 are very useful and generally comprehensive ones.

The need for this multiple perspective viewpoint is a major one for successful systems engineering practice. It is a major need in developing an appropriate framework for a system to be engineered, as represented in Fig. 2.1.1.

Systems engineering, applied in its best sense, approaches the problem at three levels: symptoms, institutions and infrastructures, and values. Too often, problems are approached only at the level of symptoms: bad housing, inadequate healthcare delivery to the poor, pollution, hunger, and so forth. “Technological” fixes are developed, and the resulting hardware creates the illusion that solution of real-world problems requires merely the outpouring of huge quantities of funds. Attacking problems at the level of institutions and infrastructures, such as to better enable humans and organizations to function, would allow the adaptation of existing organizations, as well as the design of new organizations and institutions, to make full and effective use of new technologies and technological innovations and to be fully responsive to potentially reengineered objectives and values. Thus, human and organizational issues are all important in seeking technological solutions. Approaching issues in a satisfactory manner at all three levels will guarantee not only that we resolve issues correctly, but will also guarantee that we resolve the correct issues.

BARRIERS TO ADOPTION

There are significant barriers to adoption of the full armament of systems engineering and management. However, a few central elements of this body of concepts, principles, processes, and methods and tools can be adopted and exploited quite easily. Perhaps most central is the basic question: What’s the system? At the very least, the overall enterprise, rather than a particular product, is usually the system that provides the context for formulation, analysis, and interpretation. In many cases, it is important and useful to define the system as the enterprise, competitors, markets, and economy. This broader view enables clearer understanding of the full range of stakeholders and interests.

With the scope of the system defined, the choice among elements of the systems approach depends on the purpose of the effort at hand. It is useful to think of the purposes of the systems engineering and management approach to include understanding, prediction, control, adaptation and emergence, and design. Understanding why the system behaves as it does is a starting point. Predicting what it will do in the future is the next step. Affecting what it will do next, that is to say controlling it or planning for emergence and adaptation, is next. Finally, designing the system to achieve desired objectives involves the full scope of systems engineering and management. Adoption of the systems engineering and management approach involves deciding how to implement the associated activities so as to achieve organizational objectives.

Regarding barriers to adoption and use, it is quite possible to view these as elements of the overall system. This requires adding stakeholders and issues related to power, culture, and so forth. The tasks of formulation, analysis, and interpretation across each of the phases of a systems engineering effort are correspondingly more complicated, but there is, we hope, a greater opportunity for issue resolution by implementing them in a thoughtful manner.

There are many complex situations where the systems approach is warranted, but, being perceived as discretionary, does not gain wide acceptance. These are discussed on the accompanying CD-ROM under “Discretionary Uses of Systems Engineering” (Sage and Rouse).

THE SYSTEMS VIEWPOINT

The systems viewpoint stresses that there usually is not a single correct answer or solution to a large-scale issue. Instead, there are many different alternatives that can be developed and implemented depending on the objectives the system is to serve and the values and perspectives of the people and organizations with a stake in the solution such that they are rightfully called stakeholders. A system may be defined simply as a group of components that work together in order to achieve a specified purpose. Purposeful action is a basic characteristic of a system. A number of functions must be implemented in order to achieve these purposes. This means that systems have functions. They are designed to do specific tasks. Systems are often classified by their ultimate purpose: service-oriented, product-oriented, or process-oriented systems. We note here that the systems considered by systems engineers may be service systems, product systems, process systems, or management systems. The systems may be systems designed for use by an individual or by groups. These systems may be private sector systems, or they may be government or public sector systems.

SYSTEMS THINKING

“Systems thinking” may be defined in part by the following elements (Senge, 1990):

1. Contemporary and future problems often come about because of what were presumed to be past solutions.
2. For every action, there is a reaction.
3. Short-term improvements often lead to long-term difficulties.
4. The easy solution may be no solution at all.
5. The solution may be worse than the problem.
6. Quick solutions, especially at the level of symptoms, often lead to more problems than existed initially. Thus, quick solutions may be counterproductive solutions.
7. Cause and effect are not necessarily related closely, either in time or in space. Sometimes actions implemented here and now will have impacts at a distance and much later time.
8. The actions that will produce the most effective results are not necessarily obvious at first glance.
9. Low cost and high effectiveness do not necessarily have to be subject to compensatory tradeoffs over all time.
10. The entirety of an issue is often more than the simple aggregation of the components of the issue.
11. The entire system, comprising the organization and its environment, must be considered together.

Systems thinking alone is insufficient for success of an organization. Other necessary disciplines include personal mastery through proficiency and lifelong learning; shared mental models of the organization's markets and competition; shared vision for the future of the organization; and team learning (Argyris and Schon, 1978).

Minimizing Ambiguity

Information and Knowledge. One of the major tasks of management planning and control is that of minimizing the ambiguity of the information that results from the organization's interaction with its external environment (Weick, 1979).

This task is primarily that of systems management or management control. It is done subject to the constraints imposed by the strategic plan of the organization. In this way, the information presented to those responsible for task control is unequivocal. This suggests that there are appropriate planning and control activities at each of the functional levels in an organization. The nature of these planning and control activities is different across these levels, however, as is the information that flows into them.

Various systems-based approaches to management experience periodic naissance and revival. Characteristically, these revivals are associated with the rediscovery that dynamic phenomena and feedback loops abound in the worlds of organizations. Another common motivation is rediscovery of the importance of getting "out of the box" of looking at microlevel details and looking at the "whole system" from both "inside the box" (system) and "outside the box" from the perspective of all the stakeholders who are impacted by the system.

KNOWLEDGE MANAGEMENT

Efficient Knowledge Conversion

Knowledge management in systems engineering, as in a more general sense, is a very broad concept, and involves many complex interactions between people, process, and technology. Depending on the objectives at hand, knowledge management activities may focus on the explicit or tacit knowledge, or may focus on an integrated approach that considers both explicit and tacit knowledge (Nonaka and Takeuchi, 1995). The Nonaka and Takeuchi theory of knowledge creation comprise four knowledge conversion stages as suggested in Fig. 2.1.3: socialization, externalization, combination, and internalization. The conversion takes place in five

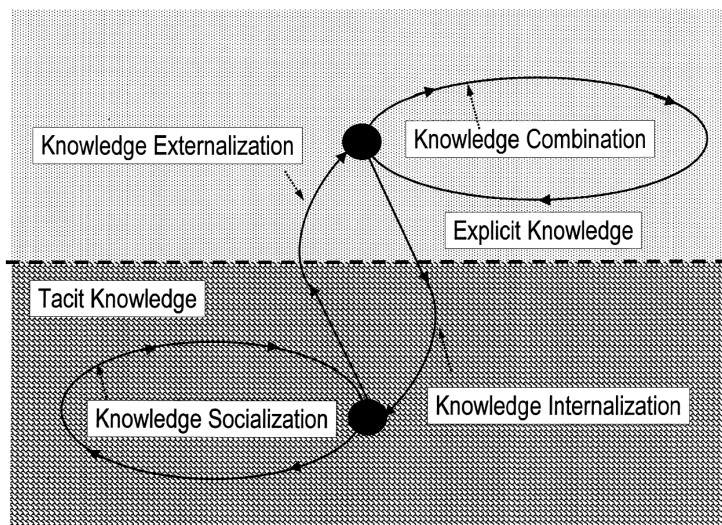

FIGURE 2.1.3 Representation of the four modes of knowledge conversion.

phases: sharing of tacit knowledge, creating concepts, justifying concepts, building an archetype, and cross-level knowledge. Critical to this theory is the concept of levels of knowledge: individual, group, organizational, and interorganization. Sharing primarily occurs during the socialization, externalization, and combination stages. During the socialization stage, sharing occurs primarily at the individual and group levels. In the externalization stage, knowledge is codified and shared at group and organizational levels. In the cross-leveling of knowledge phase, an enterprise shares knowledge both intra- and interorganizationally. This may result in different knowledge content being associated with some emerging issue and thereby enable knowledge creation.

The distinctions between data, information, and knowledge are important. Data represent points in space and time that relate to particular temporal or spatial points. Information is data that are potentially relevant to decision-making. Thus, information relates to description, definition, or outlook. Generally, information is responsive to questions that relate to structural issues of *what*, *when*, *where*, or *who*. Knowledge is information embedded in context and may comprise approach, method, practice, or strategy. Generally, knowledge is responsive to questions that relate to functional issues associated with a *how* interrogative. It is sometimes desirable to distinguish wisdom as a higher-level construct that represents insights, prototypes or models, or principles and which would be responsive to questions concerning purpose or *why*. If the distinction is not made, knowledge is needed to respond to the *how* and *why* questions that are generally associated with function and purpose. These six important questions or concerns might be collectively called “contextual awareness interrogatives.”

Each of these six interrogatives is important and is needed to be responsive to broad scope inquire regarding modern transdisciplinary endeavors. Systems engineering is one such area.

Knowledge management involves levels of understanding that may differ for various actors in a systems project. For a more detailed discussion of this topic, see “Levels of Understanding, Knowledge Management, and Systems Engineering” (Sage and Rouse, 1999) on the accompanying CD-ROM.

Organizations are beginning to realize that knowledge is the most valuable asset of employees and the organization. This recognition must be converted into pragmatic action guidelines, plans, and specific approaches. Effective management of knowledge, which is assumed to be equivalent to effective management of the environmental factors that lead to enhanced learning and transfer of information into knowledge, also requires organizational investments in terms of financial capital for technology and human labor to ensure appropriate knowledge work processes. It also requires knowledge managers to facilitate identification, distribution, storage, use, and sharing of knowledge. Other issues include incentive systems and appropriate rewards for active knowledge creators, as well as the legalities and ethics of knowledge management. In each of these efforts, it is critical to regard technology as a potential enabler of human effort, not as a substitute for it.

CHAPTER 2.2

ELEMENTS AND TECHNIQUES OF SYSTEMS ENGINEERING AND MANAGEMENT

Andrew P. Sage, William B. Rouse

SYSTEMS ENGINEERING AS A MANAGEMENT TECHNOLOGY

Systems engineering is a management technology. Technology is organization, application, and delivery of scientific and other forms of knowledge for the betterment of a client group. This is a functional definition of technology as a fundamentally human activity. A technology inherently involves a purposeful human extension of one or more natural processes. For example, the stored program digital computer is a technology in that it enhances the ability of a human to perform computations and, in more advanced forms, to process information.

Management involves the interaction of the organization with the environment. A purpose of management is to enable organizations to better cope with their environments so as to achieve purposeful goals and objectives. Consequently, a management technology involves the interaction of *technology*, *organizations* that are collections of *humans* concerned with both the evolution and use of technologies, and the *environment*. Figure 2.2.1 illustrates these conceptual interactions. Information and associated knowledge represents the “glue” that enables the interactions shown in this figure. Information and knowledge are very important quantities that are assumed to be present in the management technology that is systems engineering. This strongly couples notions of systems engineering with those of technical direction or systems management of technological development, rather than exclusively with one or more of the methods of systems engineering, important as they may be for the ultimate success of a systems engineering effort.

Figure 2.2.2 illustrates the view that systems engineering knowledge comprises:

1. *Knowledge principles*—which generally represent formal problem solving approaches to knowledge, generally employed in new situations and/or unstructured environments.
2. *Knowledge practices*—which represent the accumulated wisdom and experiences that have led to the development of standard operating policies for well-structured problems.
3. *Knowledge perspectives*—which represent the view that is held relative to future directions and realities in the knowledge areas under consideration.

Clearly, one form of knowledge leads to another. Knowledge perspectives may create the incentive for research that leads to the discovery of new knowledge principles. As knowledge principles emerge and are

FIGURE 2.2.1 Systems engineering as a management technology.

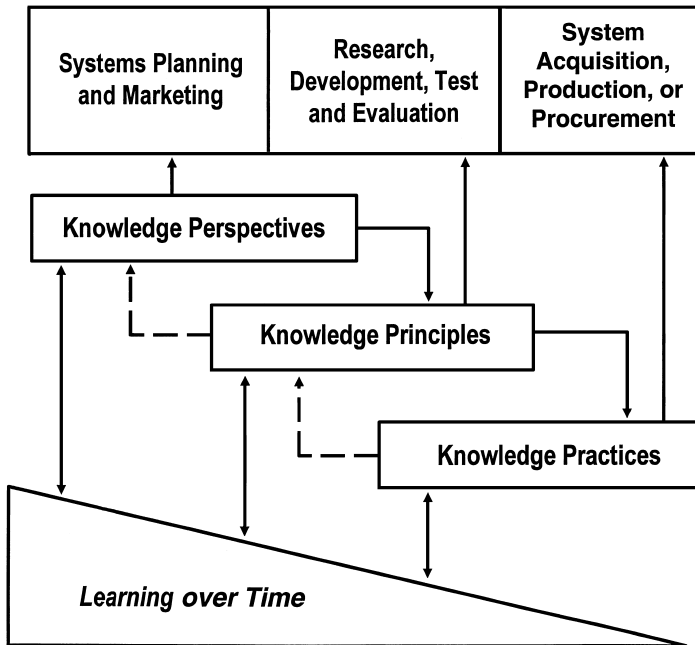

FIGURE 2.2.2 Knowledge types and support for systems engineering efforts.

2.12 SYSTEMS ENGINEERING AND SYSTEMS MANAGEMENT

refined, they generally become embedded in the form of knowledge practices. Knowledge practices are generally the major influences of the systems that can be acquired or fielded. These knowledge types interact as suggested in Fig. 2.2.2, which illustrates how these three types of knowledge support one another. In a nonexclusive way, they each support one of the principal life cycles associated with systems engineering. Figure 2.2.2 also illustrates a number of feedback loops that are associated with learning to enable continual improvement in performance over time. This supports the view that it is a mistake to consider these life cycles in isolation from one another.

It is on the basis of the appropriate use of the three knowledge types—principles, practices, and perspectives—depicted in Fig. 2.2.2, that we are able to accomplish the technological system planning and development and the management system planning and development that lead to new and innovative products, technologies, and services. All three types of knowledge are needed. The environment associated with this knowledge needs to be managed, and this is generally what is intended by use of the term *knowledge management*. Also, the learning that results from these efforts is very much needed, both on an individual and an organizational basis.

LIFE CYCLES

Three Essential Life Cycles. There are three major and quite purposefully different life cycles for technology evolution through systems engineering: system planning and marketing; research, development, test and evaluation (RDT&E); and system acquisition, production, or procurement. These are needed for evolution of trustworthy products and services, and each involves use of one of the three types of knowledge: knowledge perspectives, knowledge principles, and knowledge practices.

Systems engineers are concerned with the appropriate definition, development, and deployment of systems. These comprise a set of phases for a systems engineering life cycle. There are many ways to describe the life-cycle phases of systems engineering life-cycle processes. Each of these basic life-cycle models, and those that are outgrowths of them, comprise these three phases of definition, development, and deployment. For pragmatic reasons, a typical life cycle will almost always contain more than three phases. Generally, they take on a “waterfall” like pattern, although there are a number of modifications of the basic waterfall, or “grand design” life cycle, to allow for incremental and evolutionary development of systems. Figure 2.2.3 represents such a life cycle. It shows the three basic phases of efforts associated with a systems engineering life cycle. It also shows an embedding of the notions of three basic steps within these phases.

Figure 2.2.4 suggests the essential three systems-engineering life cycles. Each is responsive to a particular question:

- Planning and Marketing: What is in demand?
- RDT&E: What is possible?
- Acquisition: What can be developed?

It is only in the response space that is common to all three questions, as suggested in Fig. 2.2.5, that it will truly be feasible to build a trustworthy productive product or system. The life-cycle processes shown in Figs. 2.2.3 and 2.2.4 will often need to be repeated in an evolutionary manner to accommodate successive builds of a technology product.

DEVELOPING TRUSTWORTHY SYSTEMS

Management of systems engineering processes, which we call systems management (Sage, 1995), is necessary for success. Systems engineering may fail at the level of systems management. Often, the purpose, function, and structure of a new system are not identified sufficiently before the system is defined, developed, and

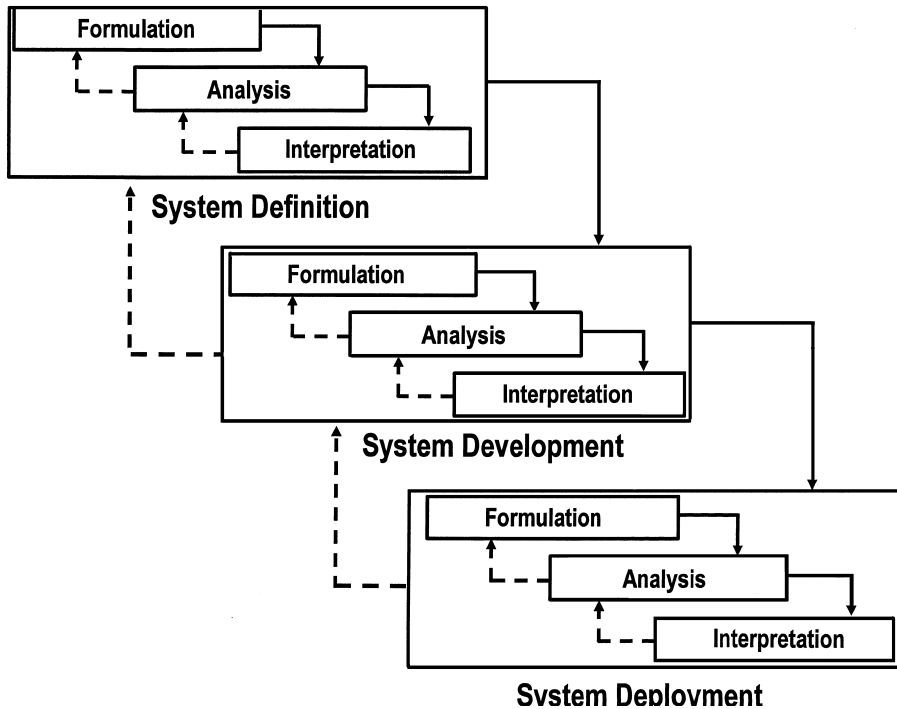

FIGURE 2.2.3 A systems engineering life cycle comprising of three phases and three steps per phase.

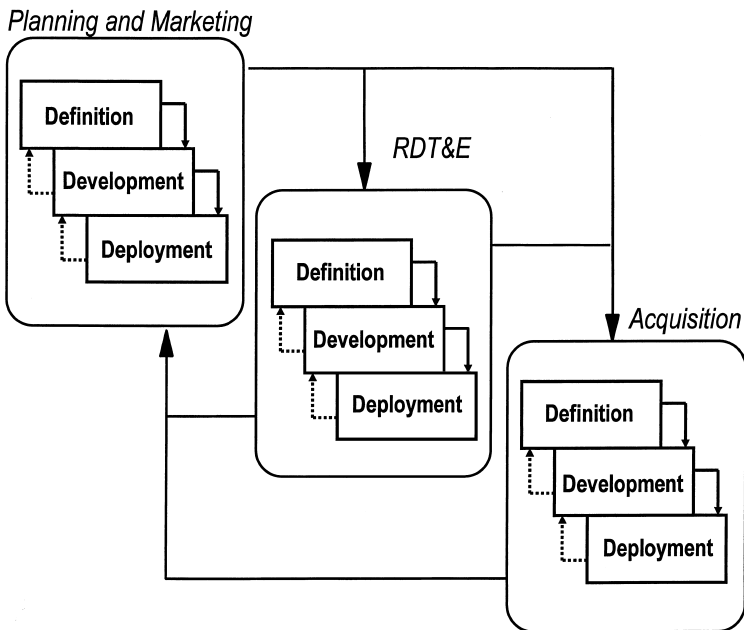

FIGURE 2.2.4 Major systems engineering life cycles and three phases within each.

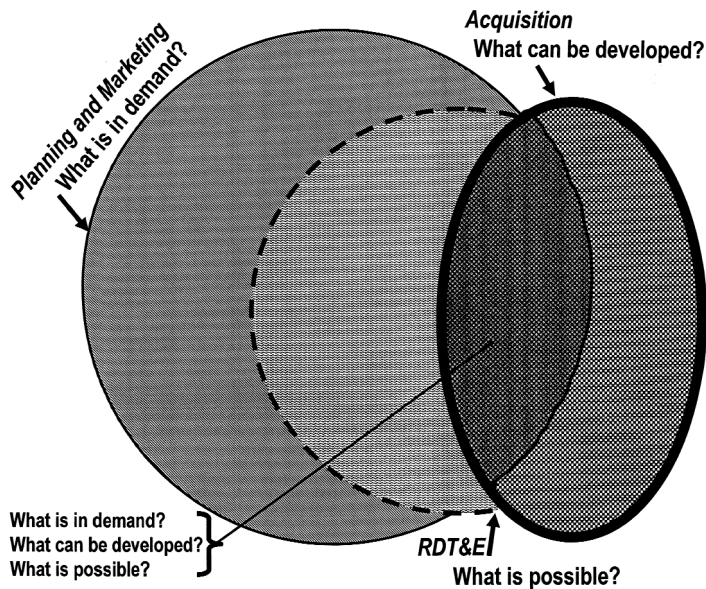

FIGURE 2.2.5 Illustration of the need for coordination and integration across life cycles.

deployed. These failures, generally, are the result of costly mistakes that could have been avoided by more diligent use of systems engineering and systems management.

System management and integration issues are of major importance in determining the effectiveness, efficiency, and overall functionality of system designs. To achieve a high measure of functionality, it must be possible for a system to be efficiently and effectively produced, used, maintained, retrofitted, and modified throughout all phases of a life cycle. This life cycle begins with need conceptualization and identification, through specification of system requirements and architectures, to ultimate system installation, operational implementation or deployment, evaluation, and maintenance throughout a productive lifetime.

There are many difficulties associated with the production of functional, reliable, and trustworthy systems of large scale and scope. Among them are:

1. Inconsistent, incomplete, and otherwise imperfect system requirements and specifications
2. System requirements that do not provide for change as user needs evolve over time
3. Lack of proper concern for satisfying the functional needs of the customer and inappropriate attention to assurance that the overall life cycle of product development and use is conservative of natural resource use
4. Poorly defined management structures for product, or service, development, and deployment

These lead to delivered products and services that are difficult to use, that do not solve the intended problems, that operate in an unreliable fashion, that are not maintainable, that are overly consumptive of natural resources and damaging to the environment, and that, as a result, may become quickly obsolete. Sometimes these failures are so great that products and services are never even fully developed, much less operationally deployed, before they are abruptly canceled.

The major problems associated with the production of trustworthy systems often have more to do with the organization and management of complexity than with direct technological concerns that affect individual subsystems and specific physical science areas. Often more attention should be paid to the definition, development, and use of an appropriate process for production of a product than to the actual product itself. Direct attention to the product or service without appropriate attention to the process leads to the fielding of a low quality and expensive product or service that is unsustainable.

Management and Metrics. Systems engineering efforts are very concerned with technical direction and management of the process of systems definition, development, and deployment, or systems management. Through adopting and applying the management technology of systems engineering, we attempt to be sure that correct systems are designed, and not just that system products are correct according to some potentially ill-conceived notions of what the system should do. Appropriate metrics to enable efficient and effective error prevention and detection at the level of systems management, and at the process and product level will enhance the production of systems engineering products that are “correct” in the broadest possible meaning of this term. To assure that correct systems are produced requires that considerable emphasis be placed on the front-end of each of the systems engineering life cycles.

ACCURATE DEFINITION OF A SYSTEM

There must be considerable emphasis on the accurate definition of a system, what it should do, and how people should interact with it before one is produced and implemented. In turn, this requires emphasis on conformance to system requirements and specifications, and the development of standards to ensure compatibility, integrability, and sustainability of system products and services. Such areas as documentation and communication are important. Thus, we see the need for the technical direction and management technology efforts that comprise systems engineering, and the strong role for process and systems management related concerns.

Ingredients associated with the development of trustworthy systems include the following:

- Systems engineering processes, including process development life cycles and process configuration management
- Process risk management, operational level quality assurance and evaluation, and product and process development standards and associated maturity models
- Metrics for quality assurance, to ensure standardization, and for process and product evaluation
- Metrics for cost estimation, and product cost and operational effectiveness evaluation
- Strategic quality assurance and management, or total quality management
- Organizational cultures, leadership, and process maturity
- Reengineering at the levels of systems management, organizational processes and product lines, and products

These ingredients and issues often strongly interact. One of the first efforts in systems management is to identify an appropriate process life cycle that is sustainable and that will lead to production of a trustworthy and sustainable system. This life cycle for the engineering of a system involves a sequence of phases. These phases include identification of client requirements, translation of these requirements into hardware and software requirements specifications, development of system architectures and conceptual designs of the system, detailed design and production of the system, operational implementation and evaluation, and maintenance of the delivered system over time. The precise life cycle that is followed will depend on the client needs. It will also depend on such overall environmental factors as the presence of existing system components, or subsystems, into which a new system must be integrated, natural resource considerations, and the presence of existing software modules that may be retrofitted and reused as part of the new system. These needs generally result in continued evolution and emergence of solutions that are adaptive to organizational needs that are similarly evolving and emergent.

SYSTEM REQUIREMENTS

A necessary first step in the engineering of any system is to determine just what the user wants, the purpose that is to be fulfilled by the resulting system in fulfilling these needs, and the necessary accompanying non-functional requirements, such as reliability and quality of the system. The resulting *definition* of user functional

2.16 SYSTEMS ENGINEERING AND SYSTEMS MANAGEMENT

needs and associated nonfunctional requirements represent the first and most important phase in the effort to engineer a system. These requirements must be clear, concise, consistent, unambiguous, and represent user goals and purposes for the system to be engineered. A process to identify user needs and requirements must include:

1. Identification of purposes for the system, and associated constraints, functions, and operational environment; and translation of these into a set of functional requirements.
2. Assessment of the allowable risks and the desired quality of the system, and translation of these into a set of nonfunctional requirements
3. Transformation of these functional and nonfunctional requirements into the concise and formal language of a technical specification.

Successful systems engineering is very dependent on the ability to identify user needs in the form of (functional and nonfunctional) requirements and to reflect them in specifications for the delivered system. User needs and requirements that are complete, correct, consistent, and error free, play a major role in ensuring that the delivered system meets the intended purpose.

While there is widespread and general acceptance of the necessity to provide adequate requirements definition, there is often controversy as to the ultimate need, purpose, and cost of performing the requirements and system definition associated activities that are necessary to assure that the engineered system meets user needs. The controversy arises both because detailed system developers often do not visualize that the benefits that may accrue to the final product through implementation of what may be viewed as an expensive total requirements process is comparable to the time and effort involved. System users generally do not understand the complexity associated with transforming their needs to requirements and specifications documents that detailed system developers can use.

Production of well-understood and well-developed requirements information, and the identification and management of risk in the requirements engineering, is a major concern to assure production of systems that meet user needs by engineering a system that is delivered on time and within budget. Many studies suggest that between 50 and 80 percent of the errors found in deployed systems can be traced to errors in identification and interpretation of requirements.

Difficulties related to requirements definition generally revolve around the necessity to elicit or develop requirements information from a variety of sources, including users and/or existing systems. There is usually a lack of definitive information from the user and a lack of agreement on mechanisms to transform these concepts to technical specification documents for use by the detail system developer. These difficulties lie at the interface between the humans involved in the systems engineering process, especially system users and detailed system developers. Once user requirements have been established, these must be transformed to the exact language of technical system specifications; another source of potential problems. There are also potential technical difficulties that relate to hardware, performance, capacity, interfaces, and other issues.

Most often, user originated system level requirements are stated in natural language, and this brings about a high possibility of incorporation of ambiguities, conflicts, inconsistencies, and lack of completeness in the resulting requirements. These problems must be addressed prior to transformation from the informal language of system users' requirements to the formal or semiformal languages of detailed system design. Otherwise, these deficiencies may be incorporated in the final engineered product rather than being resolved at the time of requirements development. If this occurs, these requirements deficiencies must be corrected during later phases of systems development, or following system deployment provided the system is considered to be acceptable at all by the user such as to merit initial deployment.

Strategies for Determining Information Requirements

Davis (1982) has identified four strategies for determining information requirements. Taken together, these yield approaches that may be designed to ameliorate the effect of three human limitations: limited information processing ability, bias in the selection and use of information, and limited knowledge of what is actually needed.

1. The first strategy is to simply ask people for their requirements. The usefulness of this approach will depend on the extent to which the interviewers can define and structure issues and compensate for biases in issue formulation. There are a variety of methods that can be used to assist in this.
2. The second strategy is to elicit information requirements from existing systems that are similar in nature and purpose to the one in question. Examination of existing plans and reports represent one approach of identifying information requirements from an existing, or conceptualized, system.
3. The third strategy consists of synthesizing information requirements from characteristics of the utilizing system. This permits one to obtain a model or structure for the problem to be defined, from which information requirements can be determined. This strategy would be appropriate when the system in question is in a state of change and thus cannot be compared to an existing system.
4. The fourth strategy consists of discovering needed information requirements by experimentation, generally through constructing a prototype. Additional information can be requested as the system is employed in an operational, or simulated setting, and problem areas are encountered. The initial set of requirements for the system provides a base point for the experimentation. This represents an expensive approach, but is often the only alternative when there does not exist the experience base to use one of the other approaches. This approach is therefore equivalent to use of a prototype, either an evolutionary prototype or throwaway prototype.

Each of these four strategies has advantages and disadvantages, and it is desirable to be able to select the best mix of strategies. One's choice will depend on the amount of risk or uncertainty in information requirements that results from each strategy. Here, uncertainty is used in a very general sense to indicate information imperfection.

Information Uncertainties

Five steps are useful in identifying information uncertainties and then selecting appropriate strategies.

1. Identify characteristics of the utilizing system, technology system, users, and system development personnel as they affect information uncertainty.
2. Evaluate the effect of these characteristics on three types of information requirements determination uncertainties:
 - a. Availability of a set of requirements
 - b. Ability of users to specify requirements
 - c. Ability of systems engineers to elicit and specify requirements
3. Evaluate the combined effect of the requirements determination process uncertainties on overall requirements volatility.
4. Select a primary requirements determination strategy.
5. Select a set of specific steps and methods to implement the primary requirements determination strategy.

These steps may be used to identify an appropriate mix of requirements identification strategies. The uncertainty associated with requirements determination, that is to say the amount of information imperfection that exists in the environment for the particular task, influences the selection from among the four basic strategies as indicated in Fig. 2.2.6. This illustrates the effects of experiential familiarity on the part of the system users that are used by a generally experienced requirements engineering team to identify requirements. The factors that influence this information imperfection include:

1. Stability of the environment
2. Stability of organizational management and system users
3. Previous experience of system users with efforts associated with systems engineering and management
4. The extent to which there exists a present system that is appropriate
5. The extent to which a change in requirements will change the usage of present system resources and thereby degrade the functionality of legacy systems and result in this needing to be considered as part of the overall effort

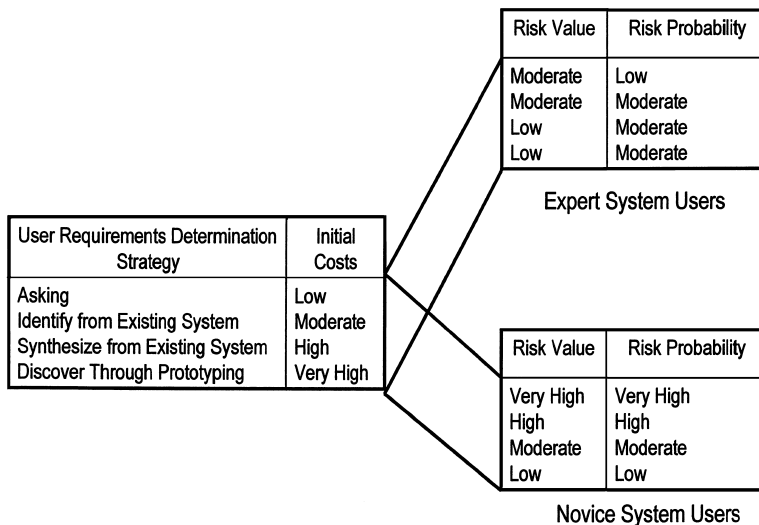

FIGURE 2.2.6 Effects of user familiarity on selecting requirements-determination strategy.

Used appropriately, this effort should enable selection of an appropriate requirements determination approach that can cope with the three essential contingency dependent variables owing to risk elements in requirements determination. To fully enable this it is desirable to also consider the effects of experiential familiarity of the requirements engineering team with both requirements determination in general and for the specific task at hand.

Requirements determination must lead to technological specifications for detailed design and fielding of the system. A purpose of the system definition phase of the life cycle is to determine possibilities of insufficient and/or inappropriate information; that is, information that is sufficiently imperfect such as to make the risk of an unacceptable design too high to be tolerated. The requirements elicitation team should be able to determine the nature of the missing or otherwise imperfect information, and suggest steps to remedy this deficiency. These are truly major efforts in systems and software engineering efforts today and are the subject of many contemporary writings on requirements (Andriole, 1996; Robertson and Robertson, 1999; Sommerville and Sawyer, 1997; Thayer and Dorfman, 1997; Young, 2001).

SYSTEMS ARCHITECTING, DESIGN, AND INTEGRATION

Stakeholder Viewpoints

From a customer point of view, a system is everything that is required to meet the need of the customer to achieve some particular purpose. A system designer may view the system as the product or service described by the design specifications. A logistician may view a system as the system maintenance and logistics efforts. A systems architect may view the system as the structures and interfaces needed to represent the system in a conceptual fashion. Systems engineering is concerned with the total view of the system and encompasses each of these perspectives, and others. Systems engineering must necessarily relate to the enterprise or organization for which the system is being built. It is necessarily concerned with the process for building the system. It is concerned with the systems management and technical direction relative to the implementation agents that construct the system. It is concerned with the technologies and metrics associated with constructing the systems as

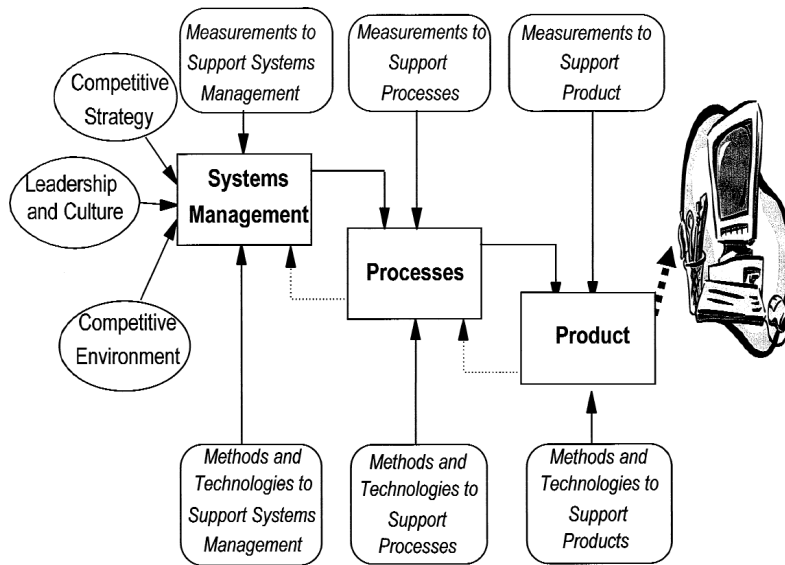

FIGURE 2.2.7 A model for engineering of a system.

well as those associated with the technical direction of this effort. It is concerned with the environment surrounding all of these. Thus, systems engineering is concerned with:

- People
- Processes
- Technologies, in the form of methods and tools
- Metrics
- Systems management
- Environments

All of these considerations are needed in order to engineer a system in the form of a product, service, or process that supports customer needs in an effective manner. Figure 2.2.7 (Sage, 1995) presents a model of system engineering that incorporates these elements. Thus, we see that a multiple perspective view of systems engineering and management is needed. Also needed is a multiple perspective view of systems architecting, design, and integration as an essential ingredient in systems engineering and management.

Integration Issues

Integration is defined in conventional dictionaries as the making of a whole entity by bringing all of the components of that entity together. In other words, integration involves blending, coordinating, or incorporating components into a functioning whole. This definition, while appropriate for systems integration, needs greater specificity in order to illustrate the many facets of integration. We may immediately think of product system integration. This refers to integration of the product or service, which is delivered to the customer. This is the most often used context for the term systems integration. To accomplish external systems integration effectively requires that new system elements be appropriately interfaced with existing, or legacy, systems components. Sometimes these legacy systems are sufficiently “stovepipe” in nature such that the integration with a new system is not possible without reengineering the legacy system. It also requires that it is possible to accomplish integration with later arriving, and potentially unplanned for initially, additional systems elements.

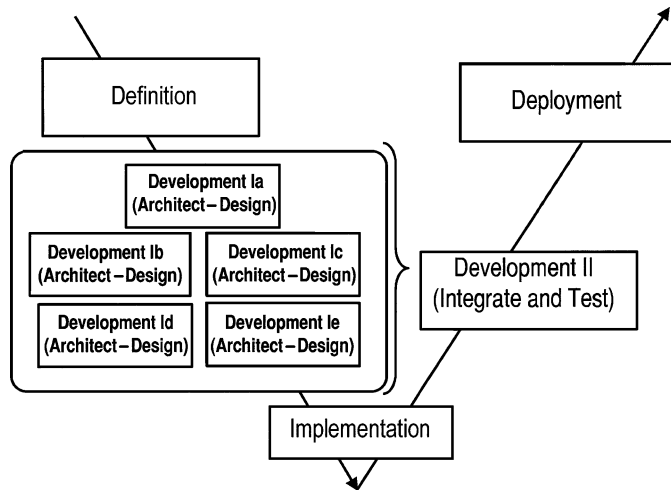

FIGURE 2.2.8 Concurrent engineering “V” model illustrating the need for integration following architecting and design.

This requires much attention to systems level architecting, and design and integration architectures (Sage and Lynch, 1998; Maier and Rehtin, 2001).

This need for system integration brings about a host of systems management and, in many cases, legal and regulatory issues that are much larger in scale and scope than those associated with product development only. In a similar manner, the development of appropriate system level architectures is very important in that efficiency and effectiveness in systems architecting is very influential of the ease with which systems can be integrated and maintained and, therefore, of the extent to which an operational system is viewed as trustworthy in satisfying user functional needs and nonfunctional needs related to quality and sustainability.

Functional, Physical, and Operational Architectures

As we have noted, the life cycle of a system comprises a number of phases that, when completed results in the satisfactory definition, development, and deployment of a system. Three phases are usually not sufficient (without each of them becoming vastly complicated) to represent the plethora of activities needed to properly engineer a system. There are such efforts as the engineering of the functional architecture, followed by the physical architecture, and following this the development of an implementation or operational architecture. This requires detailed design and associated production or manufacturing, operations and support, and other systems deployment efforts that may include disposal or reengineering. These need to be included as phased efforts in any realistic life cycle. Figure 2.2.8 recasts the basic three phase model for engineering a system into a “V” model that more explicitly shows the role of architecting, design and integration in the systems engineering life cycle. Sometimes, the initial efforts in the systems engineering life cycles of Fig. 2.2.8 are called “down-stroke” efforts and those in the latter part of the life cycle are called “up-stroke” efforts.

Not explicitly shown in Fig. 2.2.8 are the drivers for the engineering of a system and how these influence the need for systems integration. It is a rare situation that a new stand-alone system is called for and where this system does not have to be compatible with or interfaced to an existing, or legacy, system. There also exists such drivers for change as:

- A changing technology base because of the emergence of new and innovative technologies and improvements in existing technologies
- Changing organizational needs because of newly emerged competitors, the desire to acquire additional critical core capabilities
- Changing human needs because of the need for better knowledge management and enhanced organizational learning

Thus, we see that systems integration needs and considerations find importance in the:

- Planning effort that results in the very high level definition of a “new” system,
- Classical systems engineering and technical direction efforts that result in management controls for development, and
- Actual implementation engineering efforts that lead to realization of the new system.

It is also very important to determine whether some process or organizational restructuring, or reengineering, is needed to accommodate a new system, or whether a new system should be planned such as to accommodate existing organizational structure and functions. The effort associated with building a system must, if it is to be efficient and effective, consider not only the needs of the system using organization for the new system, but also the capabilities of the teams and organizations that, collectively, are responsible for engineering of the system. In effect, all of these ingredients should be integrated. These create the requirements for systems engineering and management efforts that are enterprise and knowledge management focused. These are major issues in systems and implementation of a system. Each of these views or perspectives needs to be accommodated when determining the architecture of a system to be engineered if the resulting system is to be trustworthy and, ultimately, used to fulfill its intended purpose.

SYSTEMS CONFIGURATION

Following the identification of an appropriate systems engineering process life cycle to use in engineering the system, configuration management plans are identified. This involves defining a specific development process for the set of life-cycle tasks at hand. Metrics of cost analysis or cost estimation are needed to enable this to be done effectively. Today, virtually every new system is software and information technology intensive. Thus, there are major roles for cost and economic estimation for software and information technology based systems. They also include effectiveness analysis or estimation of software productivity indices using various metrics. This couples the notion of development of an information technology or software (or other) product into notions concerning the process needs associated with developing this product. These metrics and indices form a part of a systems management approach for process, and ultimately, product improvement.

Critical aspects of a problem are often a function of how the components interact. Simple aggregation of individual aspects of a problem is intuitively appealing but often wrong. The whole is often not simply the sum of its parts. This does not suggest at all that scientific analysis, in which an issue is disaggregated into a number of component issues and understanding sought of the individual issues, is in any way improper. The formal approach involves three basic efforts:

1. Disaggregation or decomposition of a large issue into smaller, more easily understandable parts
2. Analysis of the resulting large number of individual issues
3. Aggregation of the results to attempt to find a solution to the major issue

APPROACH TO SYSTEMS MATURITY

Problems and issues arise in the course of systems engineering a product or service. Three organizational approaches may be useful in addressing them:

Reactive. Examines a potential issue only after it has developed into a real problem.

Interactive. Examines issues while they are evolving, diagnoses and corrects problems upon detection.

Proactive. Predicts the potential for debilitating issues/problems. Synthesizes a life-cycle process to minimize their likelihood.

While proactive and interactive efforts are associated with greater capability and process maturity, reactive efforts are still generally needed. Of course, another option is the “inactive” approach, favored by an organization that worries little about issues that may well become serious problems if not promptly dealt with.

COMMUNICATIONS AND COMPUTING

The role of communications and computing is ubiquitous in systems engineering and management. Major growth in power of computing and communicating and associated networking is quite fundamental and has changed relationships among people, organizations, and technology. These capabilities allow us to study much more complex issues than was formerly possible. They provide a foundation for dramatic increases in learning and associated increases in both individual and organizational effectiveness. In large part, this is because of the networking capability that enables enhanced coordination and communications among humans in organizations. It is also because of the vastly increased potential availability of knowledge to support individuals and organizations in their efforts.

The need for integration of information technology issues with organizational issues has led to the creation of a field of study, the objectives of which generally include:

- Capturing human information and knowledge needs in the form of system requirements and specifications
- Developing and deploying systems that satisfy these requirements
- Supporting the role of cross-functional teams in work
- Overcoming behavioral and social impediments to the introduction of information technology systems in organizations
- Enhancing human communication and coordination for effective and efficient workflow through knowledge management
- Encouraging human and organizational evolution and adaptation in coping with these challenges.

SPECIFIC APPLICATIONS

There are many specific applications as well as specific issues where systems engineering and management is germane. For example, when a system is to be developed and deployed using concurrent engineering techniques, as opposed to strictly sequential techniques, systems engineering and management is particularly important. Indeed, it may reveal that concurrent engineering is inappropriate to a particular project. Conversely, it may enable successful concurrent engineering of a system that might otherwise fail to meet its expected performance and deadline requirements. See Sage and Rouse (1999). Andrews and Leventhal (1993), Kronlof (1993), and Fiksel (1993).

Another issue on which systems engineering and management has a strong influence is that of physically partitioning a system. The factors bearing on this problem can perhaps best be expressed by these questions:

1. Where ought it to be partitioned from a design standpoint?
2. Where ought it to be partitioned from a development and prototyping standpoint?
3. Where ought it to be partitioned from a fabrication standpoint?
4. Where ought it to be partitioned from a deployment and maintainability standpoint?

The final decision will be a compromise, in which one or more of the factors may have a prevailing influence.

For elaborations and in-depth treatment of topics covered in this chapter, the reader is referred to the "Handbook of Systems Engineering and Management" (Sage and Rouse, 1999).

SECTION 3

RELIABILITY

Reliability of a component or a system can be considered a design parameter, but, in fact, the intrinsic design reliability may not be realized because of manufacturing defects or misapplication. Thus, the definition of reliability is the probability that a device or system will perform a specified function for a specified period of time under a specific set of conditions. The conditions may also include required maintenance procedures. The first chapter in this section expands on the definitional issues of reliability, including parts and systems modeling, reliability theory and practice, and failure analysis and prediction techniques. Chapter 3.2 discusses very high reliability techniques developed for military and aerospace applications. The special issues involved in semiconductor component reliability are covered in Chap. 3.3.

In a completely new chapter (3.4) the exceptional considerations needed in predicting reliability when using electromechanical and microelectromechanical devices are treated. Although many of the stress-strength relationships applicable to conventional electromechanical components apply to microelectromechanical devices, too, differences in the reliability of microelectromechanical systems (MEMS) that may be related to materials, geometries, and failure mechanisms are still under study. Thus far there is a limited amount of parts failure data available; it will be augmented as MEMS technologies mature and as the application of MEMS broadens. Additional material related to this chapter is included on the accompanying CD-ROM.

The design and modeling of electronic systems is covered in greater detail in Chap. 3.5. Finally, in another completely new chapter (3.6), the special concerns of designing software and assuring its reliability are treated. Because military specifications and standards underlie the reliable design and operation of many electronic systems, a summary description of important military reliability documents is included on the CD-ROM. On the CD-ROM:

- *Reliability Standards and Handbooks.* A brief description of 8 MIL handbooks and 12 standards that cover sampling procedures, reliability growth, reliability prediction, reliability/design thermal applications, electrostatic discharge, stress screening, definition of terms, reliability modeling, design qualification, test methods, reliability of space and missile systems, FMECA techniques, failure reporting, analysis, and corrective action.
- *Commonly Used Formulas.* Formulas and equations useful in electromechanical reliability analysis.
- Concepts and Principles useful in probabilistic stress and strength analysis of electromechanical components.

CHAPTER 3.1

RELIABILITY DESIGN AND ENGINEERING

Ronald T. Anderson, Richard L. Doyle, Stanislaw Kus,
Henry C. Rickers, James W. Wilbur

RELIABILITY CONCEPTS AND DEFINITIONS

Intrinsic Reliability

The intrinsic reliability of a system, electronic or otherwise, is based on its fundamental design, but its reliability is often less than its intrinsic level owing to poor or faulty procedures at three subsequent stages: manufacture, operation, or maintenance.

Definitions

The definition of reliability involves four elements: *performance requirements*, *mission time*, *use conditions*, and *probability*. Although reliability has been variously described as “quality in the time dimension” and “system performance in the time dimension,” a more specific definition is *the probability that an item will perform satisfactorily for a specified period of time under a stated set of use conditions*.

Failure rate, the measure of the number of malfunctions per unit of time, generally varies as a function of time. It is usually high but decreasing during its *early life*, or *infant-mortality* phase. It is relatively constant during its second phase, the *useful-life period*. In the third, *wear-out* or *end-of-life*, period the failure rate begins to climb because of the deterioration that results from physical or chemical reactions: oxidation, corrosion, wear, fatigue, shrinkage, metallic-ion migration, insulation breakdown, or, in the case of batteries, an inherent chemical reaction that goes to completion.

The failure rate of most interest is that which relates to the useful life period. During this time, reliability is described by the single-parameter exponential distribution

$$R(t) = e^{-\lambda t} \quad (1)$$

where $R(t)$ = probability that item will operate without failure for time t (usually expressed in hours) under stated operating conditions

e = base of natural logarithms = 2.7182

λ = item failure rate (usually expressed in failures per hour) = constant for any given set of stress, temperature, and quality level conditions

It is determined for parts and components from large-scale data-collection and/or test programs. When values of λ and t are inserted in Eq. (1), the *probability of success*, i.e., reliability, is obtained for that period of time.

3.4 RELIABILITY

The reciprocal of the failure rate $1/\lambda$ is defined as the *mean time between failures* (MTBF). The MTBF is a figure of merit by which one hardware item can be compared with another. It is a measure of the failure rate λ during the useful life period.

Reliability Degradation

Manufacturing Effects. To access the magnitude of the reliability degradation because of manufacturing, the impact of manufacturing processes (process-induced defects, efficiency of conventional manufacturing and quality-control inspection, and effectiveness of reliability screening techniques) must be evaluated. In addition to the latent defects attributable to purchased parts and materials, assembly errors can account for substantial degradation. Assembly errors can be caused by operator learning, motivational, or fatigue factors.

Manufacturing and quality-control inspections and tests are provided to minimize degradation from these sources and to eliminate obvious defects. A certain number of defective items escaping detection will be accepted and placed in field operation. More importantly, the identified defects may be over-shadowed by an unknown number of *latent defects*, which can result in failure under conditions of stress, usually during field operation. Factory screening tests are designed to apply a stress of given magnitude over a specified time to identify these kinds of defects, but screening tests are not 100 percent effective.

Operational Effects. Degradation in reliability also occurs as a result of system operation. Wear-out, with *aging* as the dominant failure mechanism, can shorten the useful life. Situations also occur in which a system may be called upon to operate beyond its design capabilities because of an unusual mission requirement or to meet a temporary but unforeseen requirement. These situations could have ill-effects on its constituent parts.

Operational abuses, e.g., rough handling, over stressing, extended duty cycles, or neglected maintenance, can contribute materially to reliability degradation, which eventually results in failure. The degradation can be a result of the interaction of personnel, machines, and environment. The translation of the factors which influence operational reliability degradation into corrective procedures requires a complete analysis of functions performed by personnel and machines plus fatigue and/or stress conditions which degrade operator performance.

Maintenance Effects. Degradation in inherent reliability can also occur as a result of maintenance activities. Excessive handling from frequent preventive maintenance or poorly executed corrective maintenance, e.g., installation errors, degrades system reliability. Several trends in system design have reduced the need to perform adjustments or make continual measurements to verify peak performance. Extensive replacement of analog by digital circuits, inclusion of more built-in test equipment, and use of fault-tolerant circuitry are representative of these trends.

These factors, along with greater awareness of the cost of maintenance, have improved ease of maintenance, bringing also increased system reliability. In spite of these trends, the maintenance technician remains a primary cause of reliability degradation. Reliability is affected by poorly trained, poorly supported, or poorly motivated maintenance technicians where maintenance tasks require careful assessment and quantification.

Reliability Growth

Reliability growth represents the action taken to move a hardware item toward its reliability potential, during development or subsequent manufacturing or operation. During early development, the achieved reliability of a newly fabricated item or an off-the-board prototype is much lower than its predicted reliability because of initial design and engineering deficiencies as well as manufacturing flaws. The reliability growth process, when formalized and applied as an engineering discipline, allows management to exercise control of, allocate resources to, and maintain visibility of, activities designed to achieve a mature system before full production or field use.

Reliability growth is an iterative test-fail-correct process with three essential elements: detection and analysis of hardware failures, feedback and redesign of problem areas, and implementation of corrective action and retest.

Glossary

Availability. The availability of an item, under the combined aspects of its reliability and maintenance, to perform its required function at a stated instant in time.

Burn-in. The operation of items before their ultimate application to stabilize their characteristics and identify early failures.

Defect. A characteristic that does not conform to applicable specification requirements and that adversely affects (or potentially could affect) the quality of a device.

Degradation. A gradual deterioration in performance as a function of time.

Derating. The intentional reduction of stress-strength ratio in the application of an item, usually for the purpose of reducing the occurrence of stress-related failures.

Downtime. The period of time during which an item is not in a condition to perform its intended function.

Effectiveness. The ability of the system or device to perform its function.

Engineering reliability. The science that takes into account those factors in the basic design that will assure a required level of reliability.

Failure. The inability (more precisely termination of the ability) of an item to perform its required function.

Failure analysis. The logical, systematic examination of an item or its diagram(s) to identify and analyze the probability, causes, and consequences of potential and real failures.

Failure, catastrophic. A failure that is both sudden and complete.

Failure mechanism. The physical, chemical, or other process resulting in a failure.

Failure mode. The effect by which a failure is observed, e.g., an open or short circuit.

Failure, random. A failure whose cause and/or mechanism makes its time of occurrence unpredictable but that is predictable in a probabilistic or statistical sense.

Failure rate. The number of failures of an item per unit measure of life (cycles, time, etc.); during the useful life period, the failure rate λ is considered constant.

Failure rate change ($\dot{\lambda}$). The change in failure rate of an item at a given point in its life; $\dot{\lambda}$ is zero for an exponential distribution (constant failure rate), but represents the slope of the failure rate curve for more complex reliability distributions.

Failure, wear-out. A failure that occurs as a result of deterioration processes or mechanical wear and whose probability of occurrence increases with time.

Hazard rate $Z(t)$. At a given time, the rate of change of the number of items that have failed divided by the number of items surviving.

Maintainability. A characteristic of design and installation that is expressed as the probability that an item will be retained in, or restored to, a specified condition within a given time when the maintenance is performed in accordance with prescribed procedures and resources.

Mean maintenance time. The total preventive and corrective maintenance time divided by the number of preventive and corrective maintenance actions accomplished during the maintenance time.

Mean time between failures (MTBF). For a given interval, the total functioning life of a population of an item divided by the total number of failures in the population during the interval.

Mean time between maintenance (MTBM). The mean of the distribution of the time intervals between maintenance actions (preventive, corrective, or both).

Mean time to repair (MTTR). The total corrective-maintenance time divided by the total number of corrective-maintenance actions accomplished during the maintenance time.

Redundancy. In an item, the existence of more than one means of performing its function.

Redundancy, active. Redundancy in which all redundant items are operating simultaneously rather than being switched on when needed.

3.6 RELIABILITY

Redundancy, standby. Redundancy in which alternative means of performing the function are inoperative until needed and are switched on upon failure of the primary means of performing the function.

Reliability. The characteristic of an item expressed by the probability that it will perform a required function under stated conditions for a stated period of time.

Reliability, inherent. The potential reliability of an item present in its design.

Reliability, intrinsic. The probability that a device will perform its specified function, determined on the basis of a statistical analysis of the failure rates and other characteristics of the parts and components that constitute the device.

Screening. The process of performing 100 percent inspection on product lots and removing the defective units from the lots.

Screening test. A test or combination of tests intended to remove unsatisfactory items or those likely to exhibit early failures.

Step stress test. A test consisting of several stress levels applied sequentially for periods of equal duration to a sample. During each period, a stated stress level is applied, and the stress level is increased from one step the next.

Stress, component. The stresses on component parts during testing or use that affect the failure rate and hence the reliability of the parts. Voltage, power, temperature, and thermal environmental stress are included.

Test-to-failure. The practice of inducing increased electrical and mechanical stresses in order to determine the maximum capability. A device in conservative use will increase its life through the derating based on these tests.

Time, down (downtime). See downtime.

Time, mission. The part of uptime during which the item is performing its designated mission.

Time, up (uptime). The element of active time during which an item is alert, reacting, or performing a mission.

Uptime ratio. The quotient determined by dividing uptime by uptime plus downtime.

Wear-out. The process of attrition which results in an increased failure rate with increasing age (cycles, time, miles, events, and so forth, as applicable for the item).

RELIABILITY THEORY AND PRACTICE

Exponential Failure Model

The life-characteristic curve (Fig. 3.1.1) can be defined by three failure components that predominate during the three periods of an item's life. The shape of this curve suggests the usual term *bathtub curve*. The components are illustrated in terms of an *equipment failure rate*. The failure components include:

1. *Early failures* because of design and quality-related manufacturing, which have a decreasing failure rate.
2. *Stress-related failures* because of application stresses, which have a constant failure rate.
3. *Wear-out failures* because of aging and/or deterioration, which have an increasing failure rate.

From Fig. 3.1.1 three conclusions can be drawn: (1) that the *infant-mortality* period is characterized by a high but rapidly decreasing failure rate that comprises a high quality-failure component, a constant-stress-related failure component, and a low wear-out-failure component. (2) The *useful-life* period is characterized by a constant failure rate comprising a low (and decreasing) quality-failure component, a constant stress-related-failure component, and a low (but increasing) wear-out-failure component. The combination of these three components results in a nearly constant failure rate because the decreasing quality failures and increasing wear-out failures tend to offset each other and because the stress-related failures exhibit a relatively larger amplitude. (3) The *wear-out period* is characterized by an increasing failure rate comprising a negligible quality-failure component, a constant stress-related-failure component, and an initially low but rapidly increasing wear-out-failure component.

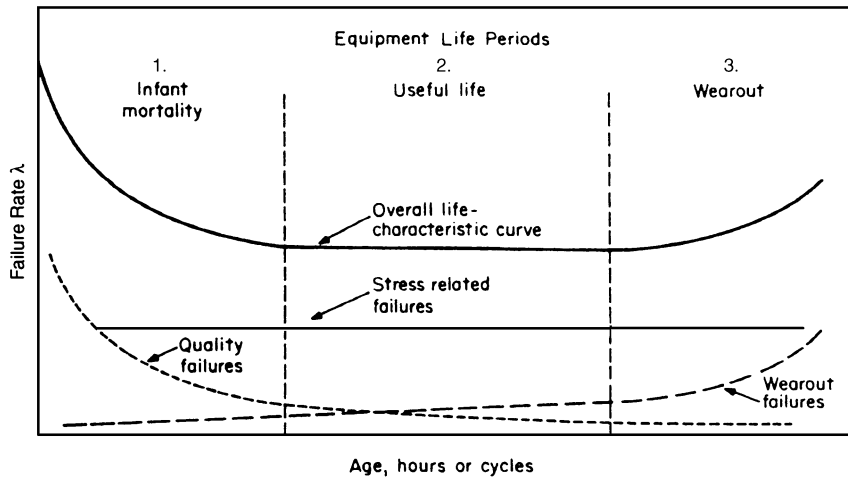

FIGURE 3.1.1 Life-characteristic curve, showing the three components of failure (when superimposed, the three failures provide the top curve).

The general approach to reliability for electronic systems is to minimize early failures by emphasizing factory test and inspection and to prevent wear-out failures by replacing short-lived parts before they fail. Consequently, the useful life period characterized by stress-related failures is the most important period and the one to which design attention is primarily addressed.

Figure 3.1.1 illustrates that during the useful life period the failure rate is constant. A constant failure rate is described by the exponential-failure distribution. Thus, the exponential-failure model reflects the fact that the item must represent a mature design whose failure rate, in general, is primarily because of stress-related failures. The magnitude of this failure rate is directly related to the stress-strength ratio of the item.

The validity of the exponential reliability function, Eq. (1), relates to the fact that the failure rate (or the conditional probability of failure in an interval given at the beginning of the interval) is independent of the accumulated life.

The use of this type of “failure law” for complex systems is judged appropriate because of the many forces that can act on the item and produce failure. The stress-strength relationship and varying environmental conditions result in effectively random failures. However, this “failure law” is not appropriate if parts are used in their wear-out phase (Phase 3 of Fig. 3.1.1).

The approach to randomness is aided by the mixture of part ages that results when failed elements in the system are replaced or repaired. Over time the system failure rate oscillates, but this cyclic movement diminishes in time and approaches a stable state with a constant failure rate.

Another argument for assuming the exponential distribution is that if the failure rate is essentially constant, the exponential represents a good approximation of the true distribution over a particular interval of time. However, if parts are used in their wear-out phase, then a more sophisticated failure distribution must be considered.

System Modeling

To evaluate the reliability of systems and equipment, a method is needed to reflect the *reliability connectivity* of the many part types having different stress-determined failure rates that would normally make up a complex equipment. This is accomplished by establishing a relationship between equipment reliability and individual part or item failure rates.

Before discussing these relationships, it is useful to discuss system reliability objectives. For many systems, reliability must be evaluated from the following three separate but related standpoints: reliability as it

FIGURE 3.1.2 Serial connectivity.

affects personnel safety, reliability as it affects mission success, and reliability as it affects unscheduled maintenance or logistic factors. In all these aspects of the subject, the rules for reliability connectivity are applicable. These rules imply that failures are stress-related and that the exponential failure distribution is applicable.

Serial Connectivity. The serial equipment configuration can be represented by the block diagram, shown in Fig. 3.1.2. The reliability of the *series configuration* is the product of the reliabilities of the individual blocks

$$R_s(t) = R_1(t)R_2(t) \cdots R_i(t) \cdots R_n(t) \quad (2)$$

where $R_s(t)$ is the series reliability and $R_i(t)$ is the reliability of i th block for time t .

The concept of constant failure rate allows the computation of system reliability as a function of the reliability of parts and components:

$$R(t) = \prod_{i=1}^n e^{-\lambda_i t} = e^{-\lambda_1 t} e^{-\lambda_2 t} \cdots e^{-\lambda_n t} \quad (3)$$

This can be simplified to

$$R(t) = e^{-(\lambda_1 t + \lambda_2 t + \cdots + \lambda_n t)} = e^{-(\lambda_1 + \lambda_2 + \cdots + \lambda_n)t} \quad (4)$$

The general form of this expression can be written

$$R(t) = \exp \left[-t \sum_{i=1}^n \lambda_i \right] \quad (5)$$

Another important relationship is obtained by considering the j th subsystem failure rate λ_j to be equal to the sum of the individual failure rates of the n independent elements of the subsystems such that

$$\lambda_j = \sum_{i=1}^n \lambda_i \quad (6)$$

Revising the MTBF formulas to refer to the system rather than an individual element gives the *mean time between failures* of the system as

$$\text{MTBF} = \frac{1}{\lambda_j} = \frac{1}{\sum_{i=1}^n \lambda_i} \quad (7)$$

Successive estimates of the j th subsystem failure rate can be made by combining lower-level failure rates using

$$\lambda_j = \sum_{i=1}^n \lambda_{i,j} \quad j = 1, \dots, m \quad (8)$$

where $\lambda_{i,j}$ is the failure rate of the i th component in the j th-level subsystem and λ_j is the failure rate of the j th-level subsystem.

Parallel Connectivity. The more complex configuration consists of equipment items or parts operating both in series and parallel combinations, together with the various permutations. A parallel configuration accounts for the fact that alternate part or item configurations can be designed to ensure equipment success by redundancy.

FIGURE 3.1.3 Parallel connectivity.

A two-element parallel reliability configuration is represented by the block diagram in Fig. 3.1.3. To evaluate the reliability of parallel configurations, consider, for the moment, that a reliability value (for any configuration) is synonymous with probability, i.e., probability of successful operation, and can take on values ranging between 0 and 1. If we represent the reliability by the symbol R and its complement $1 - R$, that is, unreliability, by the symbol Q , then from the fundamental notion of probability,

$$R + Q = 1 \quad \text{and} \quad R = 1 - Q \quad (9)$$

From Eq. (9) it can be seen that a probability can be associated with successful operation (reliability) as well as with failure (unreliability). For a single block (on the block diagram) the above relationship is valid. However, in the two-element parallel reliability configuration shown in Fig. 3.1.3, two paths for successful operation exist, and the above relationship becomes

$$(R_1 + Q_1)(R_2 + Q_2) = 1 \quad (10)$$

Assuming that $R_1 = R_2$ and $Q_1 = Q_2$, that is, the blocks are identical, this can be rewritten as

$$(R + Q)^2 = 1 \quad (11)$$

Upon expansion, this becomes

$$R^2 + 2RQ + Q^2 = 1 \quad (12)$$

We recall that reliability represents the probability of successful operation. This condition is represented by the first two terms of Eq. (12). Thus, the *reliability of the parallel configuration* can be represented by

$$R_p = R^2 + 2RQ \quad (13)$$

Note that either both branches are operating successfully (the R^2 term) or one has failed while the other operates successfully (the $2RQ$ term).

Substituting the value of $R = 1 - Q$ into the above expression, we obtain

$$R_p = (1 - Q)^2 + 2(1 - Q)Q = 1 - 2Q + Q^2 + 2Q - 2Q^2 = 1 - Q^2 \quad (14)$$

To obtain an expression in terms of reliability only, the substitution $Q = 1 - R$ can be made, which yields

$$R_p = 1 - (1 - R)(1 - R) \quad (15)$$

The more general case where $R_1 \neq R_2$ can be expressed

$$R_p = 1 - (1 - R_1)(1 - R_2) \quad (16)$$

By similar reasoning it can be shown that for n blocks connected in a parallel reliability configuration, the reliability of the configuration can be expressed by

$$R_p(t) = 1 - (1 - R_1)(1 - R_2) \cdots (1 - R_n) \quad (17)$$

The series and parallel reliability configurations (and combinations of them), as described above in Eqs. (5) and (17), are basic models involved in estimating the reliability of complex equipment.

Redundancy. The serial and parallel reliability models presented in the preceding paragraphs establish the mathematical framework for the reliability connectivity of various elements. Their application can be illustrated to show both the benefits and penalties of redundancy when considering safety, mission, and unscheduled maintenance reliability. Simplified equipment composed of three functional elements (Fig. 3.1.4) can be used to illustrate the technique.

3.10 RELIABILITY

FIGURE 3.1.4 Serial and parallel connectivity.

Elements 1 and 2 are identical and represent one form of functional redundancy operating in series with element 3.

Reliability block diagrams can be defined corresponding to *nonredundant serial*, *safety*, *mission*, and *unscheduled maintenance* reliability. The block diagrams show only those functional elements that must operate properly to meet that particular reliability requirement. Figure 3.1.5 depicts the various block diagrams, reliability formulas, and typical values

corresponding to these requirements. It indicates that the use of redundancy provides a significant increase in safety and mission reliability above that of a serial or nonredundant configuration; however, it imposes a penalty by adding an additional serial element in the scheduled maintenance chain.

Part-Failure Modeling

The basic concept that underlies reliability prediction and the calculation of reliability numerics is that system failure is a reflection of *part failure*. Therefore, a method for estimating part failure is needed. The most direct approach to estimating part-failure rates involves the use of large-scale data-collection efforts to obtain the relationships, i.e., models, between engineering and reliability variables. The approach uses controlled test

Reliability requirement	Reliability block diagram	Calculated values
1. Serial (nonredundant) reliability		$R = R_1 R_3 = 0.842$ MTBF = 575 hr
2. Safety (or mission) reliability		$R = [2R_1 - R_1^2] R_3$ = 0.97
3. Unscheduled maintenance reliability		$R = R_1 R_2 R_3 = 0.715$ MTBF = 298 hr

$$R_{\text{Serial}} = R_1 \cdot R_2 \cdot \dots \cdot R_n$$

where

$$R_n = e^{-\lambda_n t} \qquad R_1 = 0.85$$

$$\text{MTBF} = \frac{1}{\lambda_n} \qquad R_2 = 0.85$$

$$R_{\text{Parallel}} = 1 - (1 - R)(1 - R) \qquad R_3 = 0.99$$

$$= 2R - R^2 \qquad t = 100 \text{ h}$$

FIGURE 3.1.5 Calculations for system reliability.

FIGURE 3.1.6 Conceptual part-failure model.

data to derive relationships between design and generic reliability factors and to develop factors for adjusting the reliability to estimate field reliability when considering application conditions.

These data have been reduced through *physics-of-failure techniques and empirical data* and are included in several different failure rate databases. Some of the more common failure rate databases are: MIL-HDBK-217, Telcordia/Bellcore SR-332, CNET's RDF 2000, British Telecom's database, Reliability Analysis Center's PRISM, and IEEE STD 493. All are suitable for estimating stress-related failure rates. Some even include thermal cycling, on/off switching, and dormant (shelf time) effects. This section will use MIL-HDBK-217 as an example, but all databases provide excellent guidance during design and allow individual part failure rates to be combined within a suitable system reliability model to arrive at an estimate of system reliability.

Although part-failure models (Fig. 3.1.6) vary with different part types, their general form is

$$\lambda_{part} = \lambda_b \pi_E \pi_A \pi_Q \dots \pi_n \tag{18}$$

where λ_{part} = total part-failure rate
 λ_b = base or generic failure rate
 π 's = adjustment factors

The value of λ_b is obtained from reduced part-test data for each generic part category, where the data are generally presented in the form of failure rate versus normalized stress and temperature factors. The part's primary-load stress factor and its factor of safety are reflected in this basic failure-rate value. As shown in Fig. 3.1.6, the value of λ_b is generally determined by the anticipated stress level, e.g., power and voltage, at the expected operating temperature. These values of applied stress (relative to the part's rated stress) represent the variables over which design control can be exercised and which influence the item's ultimate reliability.

π_E is the environmental adjustment factor which accounts for the influences of environments other than temperature; it is related to the operating conditions (vibration, humidity, and so forth) under which the item must perform. These environmental classes have been defined in MIL-HDBK-217. Table 3.1.1 defines each class in terms of its nominal environmental conditions. Depending on the specific part type and style, the value of π_E may vary from 0.2 to 120. The missile-launch environment is usually the most severe and generally dictates the highest value of π_E . Values of π_E for monolithic microelectronic devices have been added to Table 3.1.1 to characterize this range for a particular part type.

π_A is the application adjustment factor. It depends on the application of the part and takes into account secondary stress and application factors considered to be reliability-significant.

π_Q is the quality adjustment factor, used to account for the degree of manufacturing control with which the part was fabricated and tested before being shipped in the user. Many parts are covered by specifications that

TABLE 3.1.1 Environmental Symbols and Adjustment Factors

Environment	π_E symbol	Nominal environmental conditions	π_E value*
Ground, benign	G_B	Nearly zero environmental stress with optimum engineering operation and maintenance	0.5
Fixed	G_F	Conditions less than ideal to include installation in adequate racks with adequate cooling air, maintenance by military personnel and possible installation in unheated buildings	2.0
Mobile	G_M	Conditions more severe than those for G_I mostly for vibration and shock; cooling-air supply may also be more limited and maintenance less uniform	4.0
Naval, sheltered	N_S	Surface ship conditions similar to G_F but subject to occasional high shock and vibration	4.0
Unsheltered	N_U	Nominal surface shipborne conditions but with repetitive high levels of shock and vibration	6.0
Airborne, inhabited, cargo	A_{IC}	Typical conditions in cargo compartments and can be occupied by aircrew without environmental extremes of pressure, temperature, shock, and vibration and installed on long-mission aircraft such as transports and bombers	4.0
Fighter	A_{IF}	Same as A_{IC} but installed on high-performance aircraft such as fighters and interceptors	5.0
Uninhabited, cargo	A_{UC}	Bomb bay, equipment bay, tail, or wing installations where extreme pressure, vibration, and temperature cycling may be aggravated by contamination from oil, hydraulic fluid, and engine exhaust; installed on long-mission aircraft such as transports and bombers	5.0
Fighter	A_{UF}	Same as A_{UC} but installed on high-performance aircraft such as fighters and interceptors	8.0
Space, flight	S_F	Earth orbital; approaches G_B conditions without access for maintenance; vehicle neither under powered flight nor in atmospheric reentry	0.5
Airborne, rotary winged	A_{RW}	Equipment installed on helicopters	8.0
Missile, flight	M_F	Conditions related to powered flight of air-breathing missiles, cruise missiles, and missiles in unpowered free flight	5.0
Cannon, launch	C_L	Extremely severe conditions related to cannon launching of 155 mm and 5 in guided projectiles; conditions also apply to projectile from launch to target impact	220.0
Missile, launch	M_L	Severe conditions of noise, vibration, and other environments related to missile launch and space-vehicle boost into orbit, vehicle reentry, and landing by parachute; conditions may also apply to installation near main rocket engines during launch operations	12.0

*Values for monolithic microelectronic devices.

have several quality levels. Several parts have multilevel quality specifications. Values of π_Q relate to both the generic part and its quality level.

π_N is the symbol for a number of additional adjustment factors that account for cyclic effects, construction class, and other influences on failure rate.

The data used as the basis of MIL-HDBK-217 consisted of both controlled test data and field data. The controlled test data directly related stress-strength variables on a wide variety of parts and were suitable for establishing the base failure rates λ_b .

TABLE 3.1.2 Representative Part-Failure-Rate Calculations

Value	Model		
	Microcircuits, Gate/Logic Arrays and Microprocessors $\lambda_p = \pi_1 \pi_Q (C_1 \pi_T + C_2 \pi_E)$	Fixed resistor $\lambda_p = \lambda_b \pi_T \pi_p \pi_s \pi_Q \pi_E$	Fixed capacitor $\lambda_p = \lambda_b \pi_T \pi_c \pi_v \pi_{SR} \pi_Q \pi_E$
λ_b	...	0.0017	0.00099
π_E	6.0	4.0	20.0
π_Q	2.0	3.0	1.0
π_L	1.0		
π_T	1.9	1.1	1.9
C_1	0.005		
C_2	0.002		
π_C	0.81
π_V	1.6
π_{SR}	1.0
π_S	...	1.5	
π_p	...	0.44	
$\lambda_p \times 10^{-6}$	0.043	0.015	0.049

MIL-HDBK-217 completely describes failure-rate models, failure-rate data, and adjustment factors to be used in estimating the failure rate for the individual generic part types. Table 3.1.2 presents a tabulation of several models, their base failure rates λ_b , associated π factors, and failure-rate values for several representative part types. The specific procedures for deriving the failure rates differ according to part class and type.

RELIABILITY EVALUATION

Summary

Reliability prediction, failure mode and effects analysis (FMEA), and reliability growth techniques represent prediction and design evaluation methods that provide a quantitative measure of how reliably a design will perform. These techniques help determine where the design can be improved. Since specified reliability goals are often contractual requirements that must be met along with functional performance requirements, these quantitative evaluations must be applied during the design stage to guarantee that the equipment will function as specified for a given duration under the operational and environmental conditions of intended use.

Prediction Techniques

Reliability prediction is the process of quantitatively assessing the reliability of a system or equipment during its development, before large-scale fabrication and field operations. During design and development, predictions serve as quantitative guides by which design alternatives can be judged for reliability. Reliability predictions also provide criteria for reliability growth and demonstration testing, logistics cost studies, and various other development efforts.

Thus, reliability prediction is a key to system development and allows reliability to become an integral part of the design process. To be effective, the prediction technique must relate engineering variables (the language of the designer) to reliability variables (the language of the reliability engineer).

A prediction of reliability is obtained by determining the reliability of the item at the lowest system level and proceeding through intermediate levels until an estimate of system reliability is obtained. The prediction

3.14 RELIABILITY

method depends on the availability of accurate *evaluation models* that reflect the reliability connectivity of lower-level items and substantial *failure data* that have been analyzed and reduced to a form suitable for application to low-level items.

Various formal prediction procedures are based on theoretical and statistical concepts that differ in the level data on which the prediction is based. The specific steps for implementing these procedures are described in detail in reliability handbooks. Among the procedures available are parts-count methods and stress-analysis techniques. Failure data for both models are available in most reliability data bases like MIL-HDBK-217.

Parts-Count Method. The parts-count method provides an estimate of reliability based on a count by part type (resistor, capacitor, integrated circuit, transistor, as so forth). This method is applicable during proposal and early design studies where the degree of design detail is limited. It involves counting the number of parts of each type, multiplying this number by a generic failure rate for each part type, and summing up the products to obtain the failure rate of each functional circuit, subassembly, assembly, and/or block depicted in the system block diagram.

The advantage of this method is that it allows rapid estimates of reliability to determine quickly the feasibility (from the reliability standpoint) of a given design approach. The technique uses information derived from available engineering information and does not require detailed part-by-part stress and design data.

Stress-Analysis Method. The stress-analysis technique involves the same basic steps as the parts-count technique but requires detailed part models plus calculation of circuit stress values for each part before determining its failure rate. Each part is evaluated in its electric-circuit and mechanical-assembly application based on an electrical and thermal stress analysis. Once part-failure rates have been established, a combined failure rate for each functional block in the reliability diagram can be determined.

To facilitate calculation of part-failure rates, worksheets based on part-failure-rate models are normally prepared to help in the evaluation. These worksheets are prepared for each functional circuit in the system. When completed, these sheets provide a tabulation of circuit part data, including part description, electrical stress factors, thermal stress factors, basic failure rates, the various multiplying or additive environmental and quality adjustment factors, and the final combined part-failure rates. The variation in part stress factors (both electrical and environmental) resulting from changes in circuits and packaging is the means by which reliability is controlled during design. Considerations for, and effects of, reduced stress levels (derating) that result in lower failure rates are treated in the chapter "Derating Factors and Application Guidelines."

Failure Analysis

Failure mode and effects analysis is an iterative documented process performed to identify basic faults at the part level and determine their effects at higher levels of assembly. The analysis can be performed with actual failure modes from field data or hypothesized failure modes derived from design analyses, reliability-prediction activities, and experience of how parts fail. In their most complete form, failure modes are identified at the part level, which is usually the lowest level of direct concern to the equipment designer. In addition to providing insight into failure cause-and-effect relationships, the FMEA provides the discipline method for proceeding part by part through the system to assess failure consequences.

Failure modes are analytically induced into each component, and failure effects are evaluated and noted, including severity and frequency (or probability) of occurrence. As the first mode is listed, the corresponding effect on performance at the next higher level of assembly is determined. The resulting failure effect becomes, in essence, the failure mode that affects the next higher level.

Iteration of this process results in establishing the ultimate effect at the system level. Once the analysis has been performed for all failure modes, each effect or symptom at the system level usually may be caused by several different failure modes at the lowest level. This relationship to the end effect provides the basis for grouping the lower-level failure modes.

Using this approach, probabilities of the occurrence of the system effect can be calculated, based on the probability of occurrence of the lower-level failure modes, i.e., modal failure rate times time. Based on these probabilities and a severity factor assigned to the various system effects, a *criticality number* can be calculated. Criticality numerics provide a method of ranking the system-level effects derived previously and the basis for corrective-action priorities, engineering-change proposals, or field retrofit actions.

Fault-Tree Analysis. Fault-tree analysis (FTA) is a tool that lends itself well to analyzing failure modes found during design, factory test, or field data returns. The fault-tree-analysis procedure can be characterized as an iterative documented process of a systematic nature performed to identify basic faults, determine their causes and effects, and establish their probabilities of occurrence.

The approach involves several steps, among which is the structuring of a highly detailed logic diagram that depicts basic faults and events that can lead to system failure and/or safety hazards. Then follows the collection of basic fault data and failure probabilities for use in computation. The next step is the use of computational techniques to analyze the basic faults, determine failure-mode probabilities, and establish criticalities. The final step involves formulating corrective suggestions that, when implemented, will eliminate or minimize faults considered critical. The steps involved, the diagrammatic elements and symbols, and methods of calculation are shown in Fig. 3.1.7.

This procedure can be applied at any time during a system's life cycle, but it is considered most effective when applied (1) during preliminary design, on the basis of design information and a laboratory or engineering test model, and (2) after final design, before full-scale production, on the basis of manufacturing drawings and an initial production model.

The first of these (in preliminary design) is performed to identify failure modes and formulate general corrective suggestions (primarily in the design area). The second is performed to show that the system, as manufactured, is acceptable with respect to reliability and safety. Corrective actions or measures, if any, resulting from the second analysis would emphasize controls and procedural actions that can be implemented with respect to the "as manufactured" design configuration.

The outputs of the analysis include:

1. A detailed logic diagram depicting all basic faults and conditions that must occur to result in the hazardous condition(s) under study.
2. A probability-of-occurrence numeric value for each hazardous condition under study.
3. A detailed fault matrix that provides a tabulation of all basic faults, their occurrence probabilities and criticalities, and the suggested change or corrective measures involving circuit design, component-part selection, inspection, quality control, and so forth, which, if implemented, would eliminate or minimize the hazardous effect of each basic fault.

Reliability Testing

Reliability Growth. Reliability growth is generally defined as the improvement process during which hardware reliability increases to an acceptable level. The measured reliability of newly fabricated hardware is much less than the potential reliability estimated during design, using standard handbook techniques. This definition encompasses not only the technique used to graph increases in reliability, i.e., "growth plots," but also the management-resource-allocation process that causes hardware reliability to increase.

The purpose of a growth process, especially a reliability-growth test, is to achieve acceptable reliability in field use. Achievement of acceptable reliability depends on the extent to which testing and other improvement techniques have been used during development to "force out" design and fabrication flaws and on the rigor with which these flaws have been analyzed and corrected.

A primary objective of growth testing is to provide methods by which hardware reliability development can be dimensioned, disciplined, and managed as an integral part of overall development. Reliability-growth testing also provides a technique for extrapolating the current reliability status (at any point during the test) to some future result. In addition, it provides methods for assessing the magnitude of the test-fix-retest effort before the start of development, thus making trade-off decisions possible. Many of the models for reliability growth represent the reliability of the system as it progresses during the overall development program. Also, it is commonly assumed that these curves are nondecreasing; i.e., once the system's reliability has reached a certain level, it will not drop below that level during the remainder of the development program. This assumes that any design or engineering changes made during the development program do not decrease the system's reliability.

For complex electronic and electromechanical avionic systems, a model traditionally used for reliability-growth processes, and in particular reliability-growth testing, is one originally published by Duane (1964). It

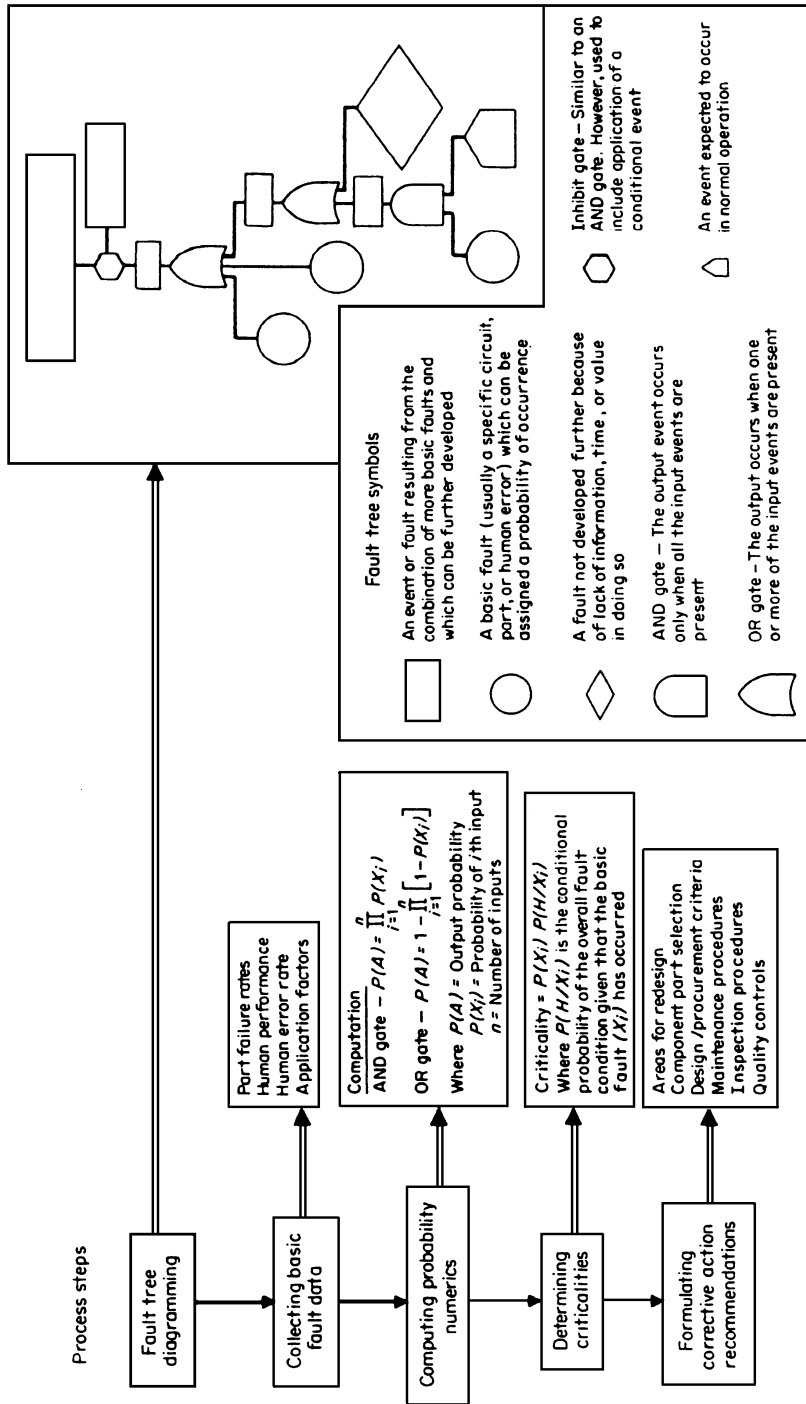

FIGURE 3.17 Fault-tree analysis.

provides a deterministic approach to reliability growth such that the system MTBF versus operating hours falls along a straight line when plotted on log-log paper. That is, the change in MTBF during development is proportional to T^d , where T is the cumulative operating time and d is the rate of growth corresponding to the rapidity with which faults are found and changes made to permanently eliminate the basic faults observed.

To structure a growth test program (based on the Duane model) for a newly designed system, a detailed test plan is necessary. This plan must describe the test-fix-retest concept and show how it will be applied to the system hardware under development. The plan requires the following:

1. Values for specified and predicted (inherent) reliabilities. Methods for predicting reliability (model, database, and so forth) must also be described.
2. Criteria for reliability starting points, i.e., criteria for estimating the reliability of initially fabricated hardware. For avionics systems, the initial reliability for newly fabricated systems has been found to vary between 10 and 30 percent of their predicted (inherent) values.
3. Reliability-growth rate (or rates). To support the selected growth rate, the rigor with which the test-fix-retest conditions are structured must be completely defined.
4. Calendar-time efficiency factors, which define the relationship of test time, corrective-action time, and repair time to calendar time.

Each of the factors listed above affects the total time (or resources) that must be scheduled to grow reliability to the specified value. Figure 3.1.8 illustrates these concepts and the four elements needed to structure and plan a growth test program.

1. *Inherent reliability* represents the value of design reliability estimated during prediction studies; it may be greater than that specified in procurement documents. Ordinarily, the contract specifies a value of reliability that is somewhat less than the inherent value. The relationship of the inherent (or specified) reliability to the starting point greatly influences the total test time.
2. *Starting point* represents an initial value of reliability for the newly manufactured hardware, usually falling within the range of 10 to 30 percent of the inherent or predicted reliability. Estimates of the starting point can be derived from previous experience or based on percentages of the estimated inherent reliability. Starting points must take into account the amount of reliability control exercised during the design program and the relationship of the system under development to the state of the art. Higher starting points minimize test time.

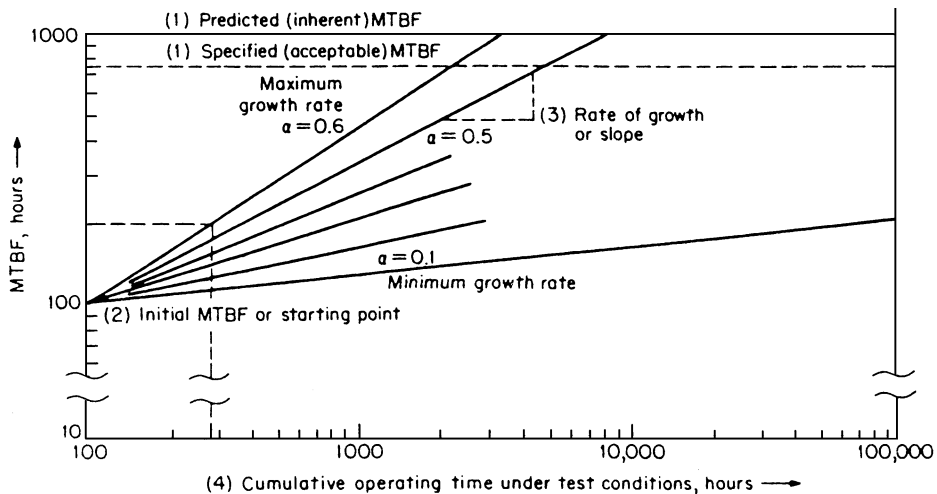

FIGURE 3.1.8 Reliability-growth plot.

3.18 RELIABILITY

3. *Rate of growth* is depicted by the slope of the growth curve, which is, in turn, governed by the amount of control, rigor, and efficiency by which failures are discovered, analyzed, and corrected through design and quality action. Rigorous test programs that foster the discovery of failures, coupled with management-supported analysis and timely corrective action, will result in a faster growth rate and consequently less total test time.
4. The ratio of *calendar time to test time* represents the efficiency factors associated with the growth test program. Efficiency factors include repair time and the ratio of operating and nonoperating time as they relate to calendar time. Lengthy delays for failure analysis, subsequent design changes, implementation of corrective action, or short operating periods will extend the growth test period.

Figure 3.1.8 shows that the value of the growth-rate parameter can vary between 0.1 and 0.6. A growth rate of 0.1 can be expected in programs where no specific consideration is given to reliability. In those cases, growth is largely because of solution of problems affecting production and corrective action taken as a result of user experience. A growth rate of 0.6 can be realized from an aggressive reliability program with strong management support. Such a program must include a formal stress-oriented test program designed to aggravate and force defects and vigorous corrective action.

Figure 3.1.8 also shows the requisite hours of operating and/or test time and continuous effort required for reliability growth. It shows the dramatic effect that the rate of growth α has on the cumulative operating time required to achieve a predetermined reliability level. For example, for a product whose MTBF potential is 1000 h it shows that 100,000 h of cumulative operating time is required to achieve an MTBF of 200 h when the growth rate is $\alpha = 0.1$. A rate of 0.1 is expected when no specific attention is paid to reliability growth. However, if the growth rate can be accelerated to 0.6, only 300 h of cumulative operating time is required to achieve an MTBF of 200 h.

Reliability Demonstration. Reliability-demonstration tests are designed to prove a specific reliability requirement with a stated statistical confidence, not specifically to detect problems or for reliability growth. The test takes place after the design is frozen and its configuration is not permitted to change. However, in practice, some reliability growth may occur because of the subsequent correction of failures observed during the test.

Reliability demonstration is specified in most military-system procurement contracts and often involves formal testing conducted per MIL-STD-781. This standard defines test plans, environmental exposure levels, cycle times, and documentation required to demonstrate formally that the specified MTBF requirements of the equipment have been achieved. Demonstration tests are normally conducted after growth tests in the development cycles using initial production hardware.

Reliability-demonstration testing carries with it a certain statistical confidence level; the more demonstration testing, the greater the confidence. The more reliability-growth testing performed, the higher the actual reliability. Depending on the program funding and other constraints, system testing may follow one of two options. The first option maximizes growth testing and minimizes demonstration testing, resulting in a high MTBF at a low confidence. The second option minimizes reliability growth testing with a resultant lower MTBF at higher confidence.

RELIABILITY DESIGN DATA

Data Sources

Reliability design data are available from a number of sources. Both the parts-count and stress-analysis methods of predicting reliability rely on part-failure-rate data. One source of such data is MIL-HDBK-217. Other sources may be sought, or estimating techniques using comparative evaluations may be used. Provided similarity exists, comparative evaluations involve the extrapolation of failure data from well-documented parts to those having little or no failure data.

Publications containing up-to-date experience data for a variety of parts, including digital and linear integrated circuits, hybrid circuits, and discrete semiconductor devices, are available through the Reliability Analysis Center, P.O. Box 4700, Rome, NY 13442-4700. The publications include malfunction through distributions, screening fallout, and experienced failure rates. They also publish the PRISM reliability design database.

Physics of Failure

The physical or chemical phenomena leading to the deterioration or failure of electron devices or components in storage under operating conditions is termed *physics of failure* or *reliability physics*. A major source of information on reliability-physics phenomena of electron devices is the *Annual Proceedings of the International Reliability Physics Symposium* (IRPS). This symposium is jointly sponsored by IEEE's Electron Devices Society and IEEE's Reliability Society and continues yearly.

Failure Modes. A knowledge of the physics of device failure is helpful in predicting and avoiding device failure. Prevalent failure modes are identified in a number of publications, besides the *IRPS Proceedings*. Other sources include MIL-HDBK-217F, and MIL-STD-1547(USAF).

Suspect Devices. In selecting parts for a particular application and in designing screens to identify potential early-life failures, it is helpful to be aware of failure-aspect device designs. A standard intended for the procurement of "space quality" piece parts for space missions, MIL-STD-1547(USAF), includes an identification of reliability-suspect items. Clearly the identification of such parts *does not suggest their inapplicability for all types of electronic systems*.

CHAPTER 3.2

DERATING FACTORS AND APPLICATION GUIDELINES

**W. R. Lehmann, Kurt E. Gonzenbach, Neil V. Owen,
Edwin W. Kimball**

INTRODUCTION

The following derating guidelines were developed and adopted for use in designing equipment manufactured by Martin Marietta Orlando Aerospace, and it must be recognized that they may be too strict for use by designers of equipment for other markets, such as non-space or nonmilitary applications. It is also recognized that to achieve higher projected reliability, customers for certain specialized equipment may impose derating factors even more severe than those given here. Nevertheless, the principles underlying the idea of derating are useful in all applications.

Derating is the reduction of electrical, thermal, mechanical, and other environmental stresses on a part to decrease the degradation rate and prolong its expected life. Through derating, the margin of safety between the operating stress level and the permissible stress level for the part is increased, providing added protection from system overstresses unforeseen during design.

The criteria listed in this section indicate maximum application stress values for design. Since safety margins of a given part at failure threshold and under time-dependent stresses are based on statistical probabilities, parts should be derated to the maximum extent possible consistent with good design practice.

When derating, the part environmental capabilities defined by specification should be weighed against the actual environmental and operating conditions of the application. Derating factors should be applied so as not to exceed the maximum recommended stresses.

For derating purposes the *allowable application stress* is defined as the *maximum allowable percentage of the specified part rating at the application environmental and operating condition*. Note that ambient conditions specified by the customer usually do not include temperature rise within a system that results from power dissipation. Thus, a thermal analysis must be performed early in the development phase to be used in the derating process.

Experience has shown that electronic part derating is the single most significant contributor to high reliability. Going from no derating to 50 percent derating can conservatively raise circuit mean time between failure by a factor of two to five times. In addition, important cost benefits can be achieved by optimized electronic part derating. Powerful analytical methodology is presently available for performing trade-off studies aimed at determining the amount of derating most desirable for various product lines.

RESISTOR DERATING AND APPLICATION GUIDELINES

Resistor Types

Variable and fixed resistors are of three types: composition, film, or wire-wound (see Sec. 5). The composition type is made of a mixture of resistive materials and a binder molded to lead wires. The film type is composed of

a resistive film deposited on, or inside, an insulating cylinder or filament. The wire-wound type consists of a resistance wire wound on an appropriate structural form.

General Applications. For ordinary military uses *established-reliability* (ER) part types are contractually required as preferred parts.

1. MIL-R-39005, RBR (fixed, wire-wound, accurate). Higher stability than any composition or film resistors, where high-frequency performance is not critical. Extremely close tolerances of ± 1 to ± 0.01 percent, with end-of-life tolerance shifts of ± 0.02 percent. Operation is satisfactory from dc to 50 kHz. Relatively high cost and large size.

2. MIL-R-39007, RWR (fixed, wire-wound power type). Select for large power dissipation and where high-frequency performance is relatively unimportant. Generally satisfactory for use at frequencies up to 20 kHz, but the reactive characteristics are uncontrolled except for available "noninductive"-type windings at reduced resistance ranges. Wattage and working voltage must not be exceeded. Power derating begins at 25°C ambient. Bodies get very hot at rated power and may affect adjacent components or materials. Also the silicon coating used on some of the RWR resistors can be dissolved by some cleaning solvents. Regardless of purchase tolerance, the design will meet an end-of-life tolerance of ± 1 percent.

3. MIL-R-39008, RCR (fixed, composition-insulated). Select for general-purpose resistor applications where initial tolerance need be no closer than ± 8 percent and long-term stability no better than ± 20 percent at room temperature under fully rated operating conditions. RF characteristics in resistance values higher than about 500 Ω are unpredictable. These resistors generate thermal "noise" that would be objectionable in low-level circuits. They are generally capacitive, are very reliable in catastrophic failure modes, and are also very inexpensive.

4. MIL-R-39009, RER (fixed, wire-wound power type, chassis mounted). Relatively large power dissipation in a given unit size. RF performance is limited. Minimum chassis area for heat dissipation is stated in the specifications and is essential to reach rated wattage. Not as good as RWRs in low-duty-cycle pulsed operation where peaks exceed steady-state rating. End-of-life tolerance of ± 1.5 percent.

5. MIL-R-39015, RTR (variable, wire-wound, lead-screw-actuated trimmer). Use for adjusting circuit variables. Requires special consideration in severe environments. These resistors are not hermetically sealed and are susceptible to degraded performance because of ingestion of soldering flux, cleaning solvents, and conformal coating during manufacturing. Should be used with fixed resistors, if possible, in a circuit designed to reduce sensitivity to movable contact shift. Use larger sizes if possible.

6. MIL-R-39017, RLR (fixed, metal film). These resistors (mostly thick film) have semiprecision characteristics and small size. These size and wattage ratings are comparable to those of MIL-R-39008, and stability is between that of MIL-R-39008 and MIL-R-55182. Design-parameter tolerances are looser than those of MIL-R-55182, but good stability makes them desirable in most electronic circuits. RF characteristics in values above 500 Ω are much superior to composition types. Initial tolerances are ± 2 percent and ± 1 percent, with an end-of-life tolerance of ± 5 percent.

7. MIL-R-39035, RJR (variable, non-wire-wound, lead-screw-actuated trimmer). Use for adjusting circuit variables. Use of potentiometers in severe environments requires special consideration. These resistors are not hermetically sealed and are susceptible to degraded performance because of ingestion of soldering flux, cleaning solvents, and conformal coating during equipment manufacturing. Should be used with fixed resistors, if possible, in a circuit designed to reduce sensitivity to movable contact shift.

8. MIL-R-55182, RNR/RNC (fixed, film, high stability). RNR/RNC resistors are available in hermetic and nonhermetic cases. For most applications, where a moderate degree of protection from the environments is provided, the nonhermetic parts have been proven reliable. Use in circuits requiring higher stability than provided by composition resistors or thick-film, insulated resistors and where high-frequency requirements are significant. These thin-film resistors provide the best high-frequency characteristics available unless special shapes are used. Metal films are characterized by low temperature coefficient and are usable for ambient temperatures of 125°C or higher with small degradation. End-of-life tolerance is ± 2 percent.

9. MIL-R-55342, RM (fixed, film, chip). Primarily intended for incorporation into hybrid microelectronic circuits. These resistors are uncased, leadless chip devices and have a high degree of stability with respect to time, under severe environmental conditions.

3.22 RELIABILITY

10. MIL-R-83401, RZ (networks, fixed, film). Resistor networks come in dual-in-line, single-in-line, or flat pack configuration. Use in critical circuitry where stability, long life, reliability, and accuracy are of prime importance. They are particularly desirable where miniaturization and ease of assembly are important.

Mounting Guide

Since improper heat dissipation is the predominant contributing cause of wear-out failure for any resistor type, the lowest possible resistor surface temperature should be maintained. The intensity of radiated heat varies inversely with the square of the distance from the resistor. Maintaining maximum distance between heat-generating components serves to reduce cross-radiation heating effects, and promotes better convection by increasing airflow. For optimum cooling without a heat sink, small, power resistors should have large leads of minimum length terminating in tie points of sufficient mass to act as heat sinks. All resistors have a maximum surface temperature that must not be exceeded. Resistors should be mounted so that there are no abnormal hot spots on the resistor surface. Most solid surfaces, including insulators, are better heat conductors than air.

Rating Factors

The permissible power rating of a resistor is another factor that is initially set by the use to which the circuit is put, but it is markedly affected by the other conditions of use. It is based on the hot-spot temperature the resistor will withstand while still meeting other requirements of resistance variation, accuracy, and life.

Self-generated heat in a resistor is equal to I^2R . It is a usual practice to calculate this value and to use the next larger power rating available in conjunction with the derating guides.

Ambient Conditions versus Rating. The power rating of a resistor is based on a certain temperature rise from a specified ambient temperature. If the ambient temperature is greater than this value, the amount of heat the resistor can dissipate is even less and must be recalculated.

Accuracy versus Rating. Because all resistors have a temperature coefficient of resistance, a resistor expected to remain near its measured value under conditions of operation must remain relatively cool. For this reason, all resistors designated as “accurate” are very much larger, physically, for a certain power rating than ordinary “nonaccurate” resistors. In general, any resistor, accurate or not, must be derated if it is to remain very near its original measured value when it is being operated.

Life versus Rating. If especially long life is required of a resistor, particularly when “life” means remaining within a certain limit of resistance drift, it is usually necessary to derate the resistor, even if ambient conditions are moderate and if accuracy by itself is not important. A good rule to follow when choosing a resistor size for equipment that must operate for many thousands of hours is to derate it to one-half of its nominal power rating. Thus, if the self-generated heat in the resistor is $1/10$ W, do not use a $1/8$ W resistor but a $1/4$ W size. This will automatically keep the resistor cooler, will reduce the long-term drift, and will reduce the effect of the temperature coefficient.

In equipment that need not live so long and must be small, this rule may be impractical, and the engineer should adjust his dependence on rules to the circumstances at hand. A “cool” resistor will generally last longer than a “hot” one and can absorb transient overloads that might permanently damage a “hot” resistor.

Pulsed Conditions and Intermittent Loads. RWR and RER wire-wound resistors can reliably withstand pulse voltages of much greater amplitude than permitted for steady-state operation. When a resistor is used in circuits where power is drawn intermittently or in pulses, the actual power dissipated with safety during the pulses can sometimes be much more than the maximum rating of the resistor. For short pulses the actual heating is determined by the duty factor and the peak power dissipated. Before approving such a resistor application, however, the design engineer should be sure of the following:

1. The maximum voltage applied to the resistor during the pulses is never greater than its permissible maximum voltage.
2. The circuit cannot fail in such a way that continuous excessive power can be drawn through the resistor.

3. The average power being dissipated is well within the rating of the resistor.
4. Continuous steep wavefronts applied to the resistor do not cause malfunctions because of electromechanical effects of high voltage gradients.

Encapsulants. Resistors embedded in encapsulants require special considerations. Generally, below 1 W all encapsulants raise local temperatures by 20 to 50 percent. Foams increase temperatures in all cases with the effect more pronounced as free air hot-spot temperatures become greater than 100°C. All are highly dependent on the installation's thermal configuration.

Resistor Derating

Resistors that have smaller temperature excursions have a narrower range of resistance shifts because of temperature effects and have slower aging shift rates. In addition, conditions for material and construction failure that may have escaped product testing proceed at a slower rate with lower temperatures and smaller temperature excursions. Derating, therefore, improves stability as well as reliability. For very low power stress, a possible exception is that of carbon composition resistors where a major cause of resistance shift is absorption of atmospheric moisture that can be baked out by moderate self-heating in service.

The resistor derating factors shown in Table 3.2.1 require the application of the principles illustrated in the preceding and following paragraphs. The percentages or ratios are applied to the characteristic or rating that is established, taking into consideration the temperature and duty cycle of actual operation.

Power Derating. The objective of power derating is to establish the worst-case hot-spot temperature for the resistor. The power dissipated by a resistor causes the temperature to rise above ambient by an amount directly proportional to the amount of power dissipated. The maximum allowable power can vary because of applied voltage and temperature.

Computations of derated power apply to the maximum power permissible under conditions of voltage and ambient temperature. The derating percentage is applied after the permissible power is determined from the specification rating when all conditions and recommendations are observed. For instance, chassis-mounted resistors are designed to conduct most of the heat through the chassis. Thus, power ratings require knowing the thermal resistivity of the mounting surface and its temperature. MIL-STD-1995 defines chassis areas upon which power ratings are based.

TABLE 3.2.1 Resistor Derating Factors

Resistor type	Military specifications (MIL-R-)	Style	Maximum permissible percentage of military specification stress rating		
			Rated power	Voltage*	Current
Wire-wound, accurate, fixed 1.0 percent	39005	RBR	50	80	
Wire-wound, accurate, fixed 0.1 percent			25	80	
Wire-wound, power, fixed	39007	RWR	50	80	
Composition, insulated, fixed	39008	RCR	50	80	
Wire-wound, power, chassis-mounted, fixed	39009	RER	50	80	
Wire-wound, lead-screw-actuated	39015	RTR	50	80	70
Film, metal, fixed	39017	RLR	50	80	
Non-wire-wound, lead-screw-actuated	39035	RJR	50	80	70
Film, fixed, high stability	55182	RNR/RNC	50	80	
Chip, film, fixed	55342	RM	50	80	
Networks, film, fixed	83401	RZ	50	80	

*Voltage applied should be no more than the smaller of V_{d1} or V_{d2} .

3.24 RELIABILITY

Voltage Derating. The voltage should be derated to a percentage of the maximum allowable voltage as determined for the specification rating. This voltage may be limited by derated power as well as by the maximum voltage of the resistor. The derated voltage should be the smaller of

$$V_{d1} = C_u V_r \quad \text{and} \quad V_{d2} = \sqrt{P_d R} \quad (1)$$

where V_d = derated voltage

P_d = derated power

C_u = derating constant = (percent derating)/100

V_r = rated voltage

R = resistance value

For ohmic values above the critical value (which depends on the power rating of the device). RCR, RNR/RNC, RLR, and RBR resistors are voltage-limited rather than power-limited. The voltage limitation is related to dielectric breakdown rather than to heat dissipation.

Ratings, Military versus Commercial. The military ratings of resistors are realistic for long-life performance; commercial resistors with equivalent size, material, and leads which advertise superior ratings should have those ratings subjected to careful scrutiny. Of particular importance is the size (diameter) of the resistance wire used in wire-wound resistors (RWR and RER). The use of smaller wire, of course, allows for higher resistance values in a given size, but the smaller wire is very susceptible to failure. For resistors on cores (both wire-wound and film), the thermal conductivity of the core contributes to both total heat removal and uniformity of the temperature rise along the resistance element. Generally, a size comparison of the commercial resistor with the specified dimensions of a military part with equivalent ratings will indicate whether or not the commercial rating could be acceptable in a military application.

CAPACITOR DERATING FACTORS AND APPLICATION GUIDELINES

Capacitor Types

Electrostatic capacitors, widely used in electronic equipment, include mica, glass, plastic film, paper-plastic, ceramic, air, and vacuum. Electrolytic types are aluminum and tantalum foil and wet or dry tantalum slug. All are affected by three primary stresses: voltage, temperature, and frequency.

Environmental Factors

The characteristic behavior and service life of all capacitors are highly dependent on the environments to which they are exposed. A capacitor may fail when subjected to environmental or operational conditions for which the capacitor was not designed or manufactured. Many perfectly good capacitors are misapplied and will fail when they are used in equipment that subsequently must see environmental conditions that exceed, or were not considered in, the design capabilities of the capacitor. Designers must understand the safety factors built into a given capacitor, the safety factors they add of their own accord, and the numerous effects of circuit and environmental conditions on the parameters. It is not enough to know only the capacitance and the voltage ratings. It is important to know to what extent the characteristics change with age and environment.

Temperature Variations. Temperature variations have an effect on the capacitance of all types of capacitors. Capacitance change with temperature is directly traceable to the fact that the dielectric constant of the materials changes with temperature.

In general, the lower-dielectric-constant materials tend to change less with temperature.

Capacitance will vary up or down with temperature depending on the dielectric and construction. The temperature can cause two distinct actions to take place that will affect capacitance. Both the dielectric constant

of the material and the spacing between the electrodes can be altered. Again, depending on the materials, these two actions tend to either reinforce or offset each other.

The capacitance of polarized dielectrics is a complex function of temperature, voltage, and frequency; non-polarized dielectrics exhibit less change than polarized materials. Many dielectrics exhibit a very large decrease in capacitance with a relatively small decrease in temperature. The increased power factor at this temperature may raise the dielectric temperature sufficiently to recover lost capacitance. When a capacitor is initially energized at low temperatures, the capacitance will be a small percentage of the nominal value, and if the internal heating is effective, the thermal time constant of the capacitor must be considered.

The *operating temperature* and changes in temperature also affect the mechanical structure in which the dielectric is housed. The terminal seals, using elastomeric materials or gaskets, may leak because of internal pressure buildup. Expansion and contraction of materials with different thermal-expansion coefficients may also cause seal leaks and cracks in internal joints. Electrolysis effects in glass-sealed terminals increase as the temperature increases.

If the capacitor is operated in the vicinity of another component operating at high temperature, the flash-point of the impregnant should be considered.

Voltage Rating. Voltage ratings of nonelectrolytic capacitors are uniformly based on some life expectancy before catastrophic failure at some temperature and some voltage stress, since catastrophic failures of capacitors are usually caused by dielectric failure. Dielectric failure is typically a chemical effect and, for hermetically sealed parts where atmospheric contamination of the dielectric does not contribute, is a function of time, temperature, and voltage. The time-temperature relationship is well expressed by assuming that the chemical activity, and therefore degradation, proceeds at a doubled rate for each 10°C rise in temperature; e.g., a capacitor operating at 100°C will have half the life of a similar one operating at 90°C.

Frequency. This is a capacitor stress most often overlooked by the circuit designer. There are both inductance and capacitance in each capacitor, and obviously, there is a resonant frequency. Depending upon the capacitor type, this resonant frequency may or may not fall in a range troublesome to the designer. In high-frequency applications, NPO ceramic, extended foil-film, mica, and glass capacitors are usually used.

Insulation Resistance. Increasing temperature usually reduces insulation resistance, increases leakage current and power factor/dissipation factor, and reduces the voltage rating of the part. Conversely, reducing temperature normally improves most characteristics; however, at cold temperature extremes some impregnants and electrolytes may lose their effectiveness. The time of electrification is most critical in the determination of insulation resistance. The effect of the insulation resistance value is also quite critical in many circuit designs and can cause malfunctions if its magnitude and variation with temperature are not considered. The dielectric strength decreases as the temperature increases.

Moisture. Moisture in the dielectric decreases the dielectric strength, life, and insulation resistance and increases the power factor of the capacitor. Capacitors operated in high humidities should be hermetically sealed.

Aging. The extent and speed of aging of a capacitor depend on the dielectric materials used in its construction. Aging does not affect glass, mica, or stable ceramic capacitors. The most common capacitors with significant aging factors are the medium-K and hi-K ceramic type (CKR series) and aluminum electrolytic types. Detailed aging and storage-life data are given in MIL-STD-198.

External Pressure. The altitude at which hermetically sealed capacitors are to be operated will control the voltage rating of the capacitor terminals. As barometric pressure decreases, the ability of the terminals to withstand voltage arcing also decreases. External pressure is not usually a factor to be considered unless it is sufficient to change the physical characteristics of the container housing, the capacitor plates, and the dielectric. Heat transfer by convection is decreased as the altitude is increased. Certain high-density CKR-type capacitors demonstrate piezoelectric effects.

Shock, Vibration, and Acceleration. A capacitor can be mechanically destroyed or damaged if it is not designed or manufactured to withstand whatever mechanical stresses are present in the application. Movement

3.26 RELIABILITY

of the internal assembly inside the container can cause capacitance changes and dielectric or insulation failures because of the physical movement of the electrode and fatigue failures of the terminal connections. The capacitors and mounting brackets, when applicable, must be designed to withstand the shock and vibration requirements of the particular application. Internal capacitor construction must be considered when selecting a capacitor for a highly dynamic environment.

Series Impedance. For solid tantalum electrolytic capacitors, the traditional criterion for their application was to ensure that the circuit provided for a minimum of 3 Ω of impedance for each volt of potential (3 Ω /V) applied to the capacitor. However, advances in the state of the art in recent years (in the control of the purity of tantalum powder and in manufacturing technology) make it possible to use these capacitors in circuits with series impedance as low as 0.1 Ω /V, without a significant impact on equipment reliability. For reliable operation follow these ground rules:

1. Never select the highest voltage rating and capacitance value in a given case size. These parts represent the ultimate in manufacturing capability, are costly, and are a reliability risk.
2. Never select a voltage rating greater than that needed to satisfy the voltage derating criteria herein. The higher voltage ratings require thicker dielectrics, increasing the probability of the inclusion of impurities. Also, the

^aManufacturer's derating factors must be applied before applying these factors.

^bVoltage equals instantaneous total of dc, ac, surge, and transient voltage.

^cRated current is defined as $I_R = \sqrt{P_{\max} / R_{\max}}$ and by limiting the current to 0.70 times rated current, power is limited to 0.50 maximum.

^dLimited to 85°C ambient temperature.

^ePackage for maximum thermal dissipation.

^fNot hermetically sealed.

lower-voltage-rated parts will typically have smaller slug sizes, which results in a greater internal equivalent series resistance (ESR), which tends to compensate for the reduction of the external series resistance.

3. Always specify the lowest established reliability failure rate available from two or more suppliers. S-level parts are typically manufactured under more rigorous process controls than higher-failure-rate-level parts.

Commercial versus Military-Type Capacitors. Valid conclusions can be reached concerning life and reliability to be expected from commercial capacitors by comparing their values with those of similar military capacitors of the same dielectric and capacitance. If the commercial capacitor is appreciably smaller than the corresponding military device, it can be safely assumed that the commercial unit has a shorter life and is less reliable.

Capacitor Derating

The capacitor derating factors (Table 3.2.2) should be applied after all derating (stated or implied by the MIL-SPEC or manufacturer) has been applied in the circuit design. The table shows the maximum allowable percentage of voltage and current.

Precautions. The following checklist will help achieve high reliability:

- Do not exceed the current rating on any capacitor, taking into account the duty cycle. Provide series resistance or other means in charge-discharge circuits to control surge currents.
- Include dc, superimposed peak ac, peak pulse, and peak transients when calculating the voltage impressed on capacitors.
- The MIL-SPEC or manufacturer's recommendations for frequency, ripple voltage, temperature, and so forth, should also be followed for further derating.

SEMICONDUCTOR DERATING FACTORS AND APPLICATION GUIDELINES

General Considerations

Semiconductor device derating should be applied after all deratings stated or implied by the part MIL-SPEC have been used in the circuit design.

For designs using silicon active components, transistors, and diodes, the maximum junction temperature must not exceed 110°C for ground and airborne applications. If the maximum rated junction temperature of the device is ≤150°C, the maximum junction temperature for missile-flight applications must not exceed 110°C. If the maximum rated junction temperature of the device is ≥175°C, the maximum junction temperature for missile-flight applications must not exceed 140°C. (See Table 3.2.3.)

A maximum power rating on any semiconductor device is by itself a meaningless parameter. The parameters of value are maximum operating junction temperature, thermal resistance, and/or thermal derating (reciprocal of thermal resistance). For all semiconductor devices, the mechanism for removal of heat from a junction is usually that of conduction through the leads, not convection. For all silicon transistors and diodes, the maximum operating junction temperature should be 110 or 140°C, respectively.

The method for calculating device junction temperature is

$$T_J = T_A + \theta_{J-A} P_D \quad (2)$$

where T_J = junction temperature

T_A = maximum ambient temperature at component

θ_{J-A} = thermal resistance from junction to air

P_D = power dissipated in device

TABLE 3.2.3 Transistor Derating Factors

Parameter	Derating factor*
Voltage (V_{CEO} , V_{CBO} , V_{EBO})	0.75
Current	0.75
Junction temperature:	
Ground and airborne use	110°C
Missile-flight use ($T_1 \leq 150^\circ\text{C}$)	110°C
Missile-flight use ($T_1 \geq 175^\circ\text{C}$)	140°C
Allowing for:	
Increase in leakage (I_{CBO} or I_{CEO})	+100 percent
Increase in h_{FE}	+50 percent
Decrease in h_{FE}	-50 percent
Increase in $V_{CE(SAT)}$	+10 percent

*Derating factor (applicable to all transistor types) = Maximum allowable stress/Rated stress

where heat sinks are used, the expression is expanded to

$$T_J = T_A + (\theta_{J-C} + \theta_{C-S} + \theta_{S-A})P_D \quad (3)$$

where

$$\theta_{J-C} + \theta_{C-S} + \theta_{S-A} = \theta_{J-A}$$

where θ_{C-S} = thermal resistance between case to heat sink (usually includes mica washer and heat-sink compound)

θ_{S-A} = thermal resistance of heat sink

θ_{J-C} = thermal resistance from junction to case

Examples for calculation of junction temperature for various conditions follow.

Thermal Resistance and Power Calculations

Using the types of inputs described above, the following examples demonstrate the ease with which thermal calculations can be performed.

Example 1. Given: 1N753 reference diode; find: θ_{J-A} . Specifications: $P_D = 400$ mW (max power), $T_J = 175^\circ\text{C}$ (max junction), $T_A = 25^\circ\text{C}$ (max ambient).

The manufacturer does not give θ_{J-A} , but it can be calculated using the above data. The maximum power dissipation is calculated from specified maximums at room temperature:

$$\begin{aligned} T_J &= T_A + \theta_{J-A}P_D \\ 175^\circ\text{C} &= 25^\circ\text{C} + (\theta_{J-A})(0.4) \\ \theta_{J-A} &= 375^\circ\text{C/W} \end{aligned}$$

Example 2. Determine the thermal resistance of a heat sink required for a 2N3716 power transistor that is to dissipate 14 W at an ambient temperature of 70°C .

$$\begin{aligned} \theta_{J-C} &= 1.17^\circ\text{C/W} && \text{from 2N3716 specifications} \\ \theta_{C-S} &= 0.5^\circ\text{C/W} \end{aligned}$$

TABLE 3.2.4 Contact Thermal Resistance of Insulators

Insulator	Thickness, in	θ_{C-S} , °C/W
No insulation	0.4
Anodized aluminum	0.016	0.4
	0.125	0.5
Mica	0.002	0.5
	0.004	0.65
Mylar	0.003	1.0
Glass cloth (Teflon-coated)	0.003	1.25

($\theta_{C-S} = 0.5^\circ\text{C/W}$ for mica washer; Table 3.2.4)

$$110^\circ\text{C} = 70^\circ\text{C} + \theta_{J-A} P_D$$

$$\theta_{J-A} = (110 - 70) \frac{1}{P_D} = \frac{40}{14} \approx 2.9^\circ\text{C/W}$$

$$\theta_{J-A} = \theta_{J-C} + \theta_{C-S} + \theta_{S-A}$$

$$2.9 = 1.17 + 0.5 + \theta_{S-A}$$

$$\theta_{S-A} \leq 1.23^\circ\text{C/W}$$

(Heat-sink thermal resistance required; note Table 3.2.5 for thermal resistance of some common commercially available heat sinks. The lowest value of thermal resistance results in the lowest junction temperature of the part.)

Example 3. Determine the maximum power that the 2N3716 can dissipate without a heat sink in an ambient of 70°C ;

$$\theta_{J-A} = 35^\circ\text{C/W}$$

(Not given on Motorola data sheets, but for almost all TO-3 devices $\theta_{J-A} = 35^\circ\text{C/W}$; see Table 3.2.6.)

$$T_J = T_A + \theta_{J-A} P_D$$

$$P_D = \frac{T_J - T_A}{\theta_{J-A}} = \frac{110 - 70}{35} = 1.14 \text{ W}$$

Example 4. Determine the maximum power that can be dissipated by a 2N2222 transistor (missile-flight use) with an ambient temperature of 70°C . Derating given: $3.33 \text{ mW}/^\circ\text{C}$ for 2N2222, TO-18. Therefore

$$\theta_{J-A} = \frac{1^\circ\text{C}}{3.33 \text{ mW}} = 300^\circ\text{C/W}$$

and

$$P_D = \frac{T_J - T_A}{\theta_{J-A}} = \frac{140 - 70}{300} = 233 \text{ mW}$$

Semiconductor Derating

Power Derating. The objective of power derating is to hold the worst-case junction temperature to a value below the normal permissible rating. The typical diode specification for thermal derating expresses the change in junction temperature with power for the worst case. The actual temperature rise per unit of power will be considerably less, but this is not a value that can readily be determined for each unit.

Junction-Temperature Derating. Junction-temperature derating requires the determination of ambient temperature or case temperature. The worst-case ambient temperature or case temperature for the part is established for the area and for the environmental conditions that will be encountered in service. The ambient temperature for a

device that does not include some means for thermal connection to a mounting surface should include the temperature rise because of the device, adjacent devices, and any heating effect that can be encountered in service.

Voltage Derating. The voltage rating of a semiconductor device can vary with temperature, frequency, or bias condition. The rated voltage implied by the tabulated rating is the voltage compensated for all factors determined from the manufacturer's data sheet. Derating consists of the application of a percentage figure to the voltage determined from all factors of the rating. Three distinct deratings cover the conditions that can be experienced in any design situation.

1. *Instantaneous peak-voltage derating* is the most important and least understood derating. It is required to protect against the high-voltage transient spike that can occur on power lines as a result of magnetic energy stored in inductors, transformers, or relay coils. Transient spikes also can result from momentary unstable conditions that cause high amplitude during switching turnon or turnoff.

Transient spike or oscillating conditions in test sets or life-test racks or resulting from the discharge of static electricity will cause minute breakdown of surface or the bulk silicon material.

Lightning transients, which enter a circuit along power lines or couple from conducting structural members, are a frequent cause of failure or of damage that increases the probability of failure during service.

2. The *continuous peak voltage* is the voltage at the peak of any signal or continuous condition that is a normal part of the design conditions.
3. The *design maximum voltage* is the highest average voltage. This is essentially the dc voltage as read by a dc meter. The ac signals can be superimposed on the dc voltage to produce a higher peak voltage, providing the continuous peak voltage is not exceeded.

3.32 RELIABILITY

Transistor Guidelines

The major failure modes are the degradation of h_{FE} and increased leakage with prolonged use at elevated temperatures. Depending on the application, this parameter degradation can result in a catastrophic failure or decrease in system performance outside the bound of the worst-case design. It is necessary to maintain the junction operating temperature below 110°C for ground and airborne use (140°C for missile-flight use if device rated $T_j \geq 175^\circ\text{C}$). The principle design criteria for silicon transistors are shown in Table 3.2.3. This derating is applicable to all transistor types.

Transistor Application Information. These general guidelines apply:

- h_{FE} has a positive temperature coefficient. This criterion may not be valid for some power transistors operating at high current levels where h_{FE} decreases with temperature.
- If a maximum leakage is specified at 110°C for ground and airborne use (140°C for missile use if device rated $T_j \geq 175^\circ\text{C}$), double the leakage value for end of life condition.
- The ratings of Table 3.2.3 apply for operating junction temperature, not just ambient temperature.
- Typical thermal resistances for common case sizes are described in Table 3.2.6.

Thermal Resistance and Heat Sinks. Table 3.2.4 lists contact thermal resistance for various insulators, and Table 3.2.5 gives the thermal resistance for various heat sinks. Figure 3.2.1 is used to calculate θ_{s-A} for solid copper or aluminum plates. This is helpful in determining the thermal capabilities of metal chassis. Note that a vertically mounted plate has better thermal properties than a horizontally mounted plate. A list of approximate thermal resistances for various package sizes is given in Table 3.2.6.

Diode Guidelines

The junction-temperature limits specified for semiconductors apply to all diodes. For non-heat-sinked components, a quick calculation can be made to determine the power a given device may dissipate. The calculation described in “Thermal Resistance and Power Calculations,” p. 3.28, can be used to determine this parameter. The derating for silicon diodes is given in Table 3.2.7.

For zener diodes, the best worst-case end-of-life tolerance that can be guaranteed is ± 1 percent. This places a limitation on the final accuracy of any analog system end of life at some value greater than 1 percent.

Zener-Diode Voltage-Variation Calculation. The change in zener voltage over a specified operating range is primarily a function of the zener temperature coefficient (TC) and dynamic resistance. The temperature to be used for the TC is the junction temperature of the device in question.

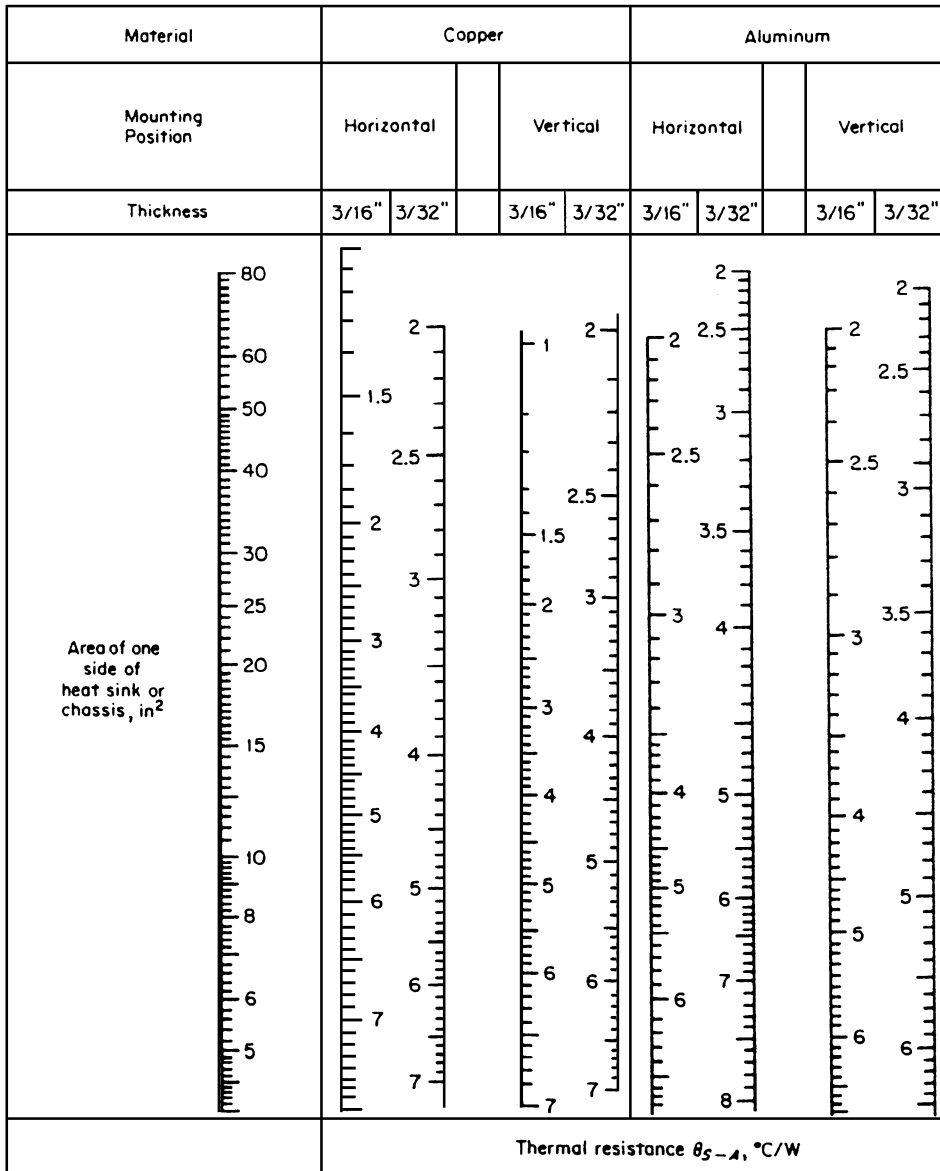

Given: 1N3020B; 10-V zener ± 5 percent (add 1 percent end of life)

$$\begin{aligned} P &= 1 \text{ W} && \text{derate } 6.67 \text{ mW}/^\circ\text{C} \\ Z_z &= 7 \ \Omega && \text{at } 25 \text{ mA} = I_{zT} \\ \text{TC} &= 0.055 \text{ percent}/^\circ\text{C} && V_{CC} = 30 \text{ V } \pm 5 \text{ percent (See Fig. 3.2.2.)} \end{aligned}$$

The ambient range is -25 to 70°C , V_{CC} (applied through a resistor R) = $30 \text{ V } \pm 5$ percent, and $R = 800 \pm 20$ percent.

(a) Calculation for the worst-case maximum power of zener and θ_{J-A}

$$\begin{aligned} P &= V_z I_z && \text{neglect TC initially} \\ &= (10.6 \text{ V}) \frac{31.5 - 10.6}{640} \end{aligned}$$

Instructions for use: Select the heat sink area at left and draw a horizontal line across the chart from this value. Read the values of θ_{S-A} depending on the thickness of the material, type of material, and mounting position.

FIGURE 3.2.1 Thermal resistance as a function of heat-sink dimensions.

TABLE 3.2.7 Silicon Diode Derating Factors

Parameter	Factor*
Voltage	0.75
Current	0.75
Junction temperature, ground and airborne use	110°C
Missile-flight use ($T_1 \leq 150^\circ\text{C}$)	110°C
Missile-flight use ($T_1 \geq 175^\circ\text{C}$)	140°C
Allowing for:	
Increase in leakage I_R	+100 percent
Increase in V_F	+10 percent

$$^*\text{Derating factor} = \frac{\text{maximum allowable stress}}{\text{rated stress}}$$

$$= (10.6)(32.7 \text{ mA}) = 0.347 \text{ W}$$

$$\theta_{J-A} = \frac{1^\circ\text{C}}{6.67 \text{ mW}} = 149^\circ\text{C/W}$$

(b) Calculation for maximum junction temperature

$$T_J = T_A + P_D \theta_{J-A} = 70^\circ\text{C} + (0.347)(149^\circ\text{C/W}) = 121.7^\circ\text{C}$$

(c) Calculation for minimum power in zener

$$P = V_z I_z = (9.4) \frac{28.5 - 9.4}{960} = 0.180 \text{ W}$$

(d) Calculation for minimum junction temperature

$$\begin{aligned} T_J &= T_A + P_D \theta_{J-A} \\ &= -25^\circ\text{C} + (0.180)(149^\circ\text{C/W}) = 1.8^\circ\text{C} \end{aligned}$$

(e) Calculation for overall maximum V_z

$$\begin{aligned} V_z &= V_{z,\text{MAX}} + I_z Z_z + (T_J - T_{\text{amb}})(\text{TC})(V_z) \\ &= 10.6 \text{ V} + (32.7 \text{ mA})(7) + (121.7 - 25)(0.00055)(10) \\ &= 11.36 \text{ V} \end{aligned}$$

(f) Calculation for overall minimum V_z

$$\begin{aligned} V_z &= V_{z,\text{MIN}} - I_z Z_z - (T_{\text{amb}} - T_J)(\text{TC})(V_z) \\ &= 9.4 - (19.1)(7) - (25 - 1.8)(0.00055)(10) = 9.138 \text{ V} \end{aligned}$$

**FIGURE 3.2.2** Zener diode V_{CC}

Several iterations may be necessary to determine maximum and minimum zener voltages, because steps (a) and (c) used 10.6 and 9.4 V, respectively, for computing maximum and minimum V_z , while we calculate 11.36 and 9.138. This affects P , which in turn affects the TC term of V_z and maximum and minimum zener currents.

TABLE 3.2.8 Microcircuit Derating Factors*

$$^* \text{Derating factor} = \frac{\text{maximum allowable stress}}{\text{rated stress}}$$

[†]For devices with dynamic supply voltage ranges only; all others will use manufacturers' recommended supply voltage. Derating below 75 percent of the supply voltage may cause the device to operate below recommended operating voltages.

Integrated-Circuit Guidelines

Derating is a process that improves in-use reliability of a component by reducing the life stress on the component or making numerical allowances for minor degradation in the performance of the component. This technique is applied to integrated circuits in two separate and distinct ways.

The first is to specify a derating factor in the application of the component. Derating factors (Table 3.2.8) are applied to the voltage, current, and power stresses to which the integrated circuit is subjected during operation. Derating factors must be applied knowledgeably and singly; i.e., they must be applied only to a degree that improves reliability, and they must be applied only once throughout the entire cycle that stretches from the design of the integrated circuit to its application in a system.

From the outset, integrated circuits are designed to a set of conservative design-rating criteria. The currents that flow through the conductors and through the wire bonds on a chip, the voltages applied to the semiconductor junctions, and the overall power stress on the entire chip are conservatively defined during the design of an integrated circuit. Therefore it may not be appropriate to derate the integrated circuit further in its application. Derating power consumption of a digital integrated circuit may not be possible, since the circuit must operate at a specified level of power-supply voltage for maximum performance. However, some linear circuits designed to operate over an extended range of power-supply voltages and power dissipations may accept some degree of derating when it is appropriately applied.

Thus, the main area of derating in integrated circuits is not in derating the *stresses* applied to the circuit but in derating the expected and required *performance*. The designer must fully recognize potential performance degradation of integrated circuits over their life. This parametric degradation can require using a digital circuit at less than its full fanout. It can mean designing for an extra noise margin, sacrificing some of it to the degradation of the integrated circuit. It can also mean applying the integrated circuit at performance levels below those guaranteed by the circuit's characterization-specification sheet.

Establishment of derating factors for integrated-circuit parameters must be made after careful analysis of each particular parameter in the circuit. Parameters depending directly on transistor beta, resistor value, or junction leakage are most prone to shift during life. Parameters depending directly on the saturation voltages of junctions and on the ratios of resistors are most likely to remain stable. For digital microcircuits, device fanout should be derated by a factor of 20 percent, logic noise-margin levels should be derated by a factor of 10 percent, and the maximum operating frequency should be derated by a factor of 25 percent. For linear microcircuits, the input offset and input signal voltages should be derated by a factor of 20 percent. The output current and maximum operating frequency should be derated by a factor of 25 percent.

3.36 RELIABILITY

The severity of the application further establishes the degree of proper derating. It is not customary to derate ac parameters, such as delay times or rates, as these parameters do not vary greatly over the life of an integrated circuit. Allowances should be made, however, for unit-to-unit variation within a given integrated-circuit chip. The delay times of separate gates within one integrated-circuit package can vary greatly. These parameters are usually not measured on 100 percent of the units.

Although one may be able to derate an integrated circuit for reliability in specified special cases, one cannot take advantage of the derating designed into the integrated circuit and use it beyond its rating or specified capability.

TRANSFORMER, COIL, AND CHOKE DERATING

General Considerations

The ratings and deratings of transformers, chokes, and coils are covered in the following paragraphs. Transformers are frequently designed for a particular application and can become a major source of heat. Two major considerations result: derating of transformers must include consideration of their heating effects on other parts; and transformer derating requires control of ambient plus winding-temperature rises.

Voltage Derating

Winding voltages are fixed voltages and cannot be derated to any significant degree as a means of improving reliability. The voltages present between any winding and case or between any winding and shield, as specified, should be derated in accordance with the voltage derating factors of Table 3.2.9.

Power Derating

The power dissipated in a transformer should be derated to control the winding temperature to the maximum derated temperature under full load conditions that are normal to the worst-case service conditions.

Temperature rise is determined for service conditions by measurement of winding resistance using the procedure of MIL-T-27B.

The insulation grade of a transformer is rated for a maximum operating temperature. Deratings shown in Table 3.2.9 are allowances of temperature to be subtracted from the rated temperature to determine derated temperature. All considerations of frequency, hot-spot temperature, and other factors included in the manufacturer's data must be allowed for before applying this reliability derating temperature.

TABLE 3.2.9 Coil, Transformer, and Choke Derating Factors

Type	Maximum permissible percent of manufacturer's stress rating			Allowable winding temp rise, °C
	Insulation breakdown voltage		Operating current, A	
	Maximum	Transient		
Coil				
Inductor, saturable reactor	60	90	80	30
General	60	90	80	30
RF, fixed	60	90	80	35
Transformer				
Audio	50	90	80	35
Pulse, low-power	60	90	80	30
RF	60	90	80	30
Saturable-core	60	90	80	30

Current Derating

The maximum current in each winding should be derated in accordance with the percentage deratings shown in Table 3.2.9. The derated current should be considered as the largest current that can flow in the winding under any combination of operating conditions.

In-rush transient currents should be limited to the maximum allowable in-rush or surge rating of the transformer, as shown in Table 3.2.9. The current in all windings should not cause a power dissipation or temperature in excess of the derated temperature requirements.

SWITCHES AND RELAYS

Switch Considerations

Switches are to be applied in circuits with operating current loads and applied voltages well within the specified limits of the type designated. A major problem is contamination, which includes particles and contaminant films on contacts. The storage life on switches may exceed 10 years if they are hermetically sealed. The cycle life for switches can be in excess of 100,000 cycles.

Switch Derating

The contact power (volt-amperes) for general-purpose switches (1 to 15 A) should be derated as shown in Table 3.2.10 from the maximum rated contact power within the maximum current and voltage ratings.

Temperature. Switches should not be operated above rated temperature. Heat degrades insulation, weakens bonds, increases rate of corrosion and chemical action, and accelerates fatigue and creep in detent springs and moving parts. The derating factor in Table 3.2.10 is defined as the maximum allowable stress divided by the rated stress.

For capacitor loads, capacitive peak in-rush current should not exceed the derated limit. If the relay-switch specification defines inductive, motor, filament (lamp), or capacitive load ratings, they should be derated 75 percent instead of the derating specified in Table 3.2.10.

Relay Considerations

Relays are to be used in circuits with operating current load and applied coil and contact voltage well within specified ratings. The application for each device should be reviewed independently.

Relay cycle life varies from 50,000 to more than 1 million cycles depending on the relay type, electrical loads of the contacts, duty cycle, application, and the extent to which the relay is derated. The storage life of hermetically sealed relays, with proper materials and processes employed to eliminate internal outgassing, is over 10 years.

TABLE 3.2.10 Relay and Switch Derating Factors

Type of load	Percent of rated value
Resistive	75
Inductive	40
Motor	20
Filament	10
Capacitive	75
Contact power*	50

*Applicable to reed, mercury-wetted, or other loads rated in watt or volt-amperes.

The chief problem in electromechanical relays is contamination. Even if cleaning processes eliminate all particulates, the problem of internal generation of particles, owing wear, is still present.

Relay Derating

The contact power (volt-amperes) should be derated as shown in Table 3.2.10 from the maximum rated stress level for loads of 1 to 15 A.

Film formation on relay contacts, as discussed in Chap. 5.4 can cause excessive resistance. This can be a serious reliability problem with contacts that switch very low voltage or when relays are subjected to long periods of dormancy. Hermetically sealed relays are recommended for military applications, and vendors should be consulted to determine if a particular device is rated for “dry contact” service.

Resistive Loads. The resistive load is basically what is used to rate relays and what most designers use when calculating the size of the relay needed for a particular circuit. In a resistive load the current flow is practically constant, with the exception of some minor arcing on make or break. As long as the limits of the contacts are not exceeded, the relay should operate reliably throughout its rated life. Unfortunately, this ideal standard is sometimes the most difficult to find in “real world” engineering. When applying derating to a purely resistive load, accepted industry practice would suggest going to 75 percent of the rated value for the device in question.

Capacitive Loads. The in-rush current in a capacitive load can be very high. This is due to the fact that a capacitor, when charging, acts as a short circuit limited only by whatever resistance may be in the circuit. Therefore, the best way to control this initial surge, and thereby protect the relay contacts, is to add a series limiting resistance. Without the series limiting resistance, contact welding or contact deterioration will shorten the life of the relay. Accepted industry practice would suggest that a derating of 75 percent of the resistive load rating should be applied. Should the relay in question already have a capacitive rating, the same 75 percent of this rating would apply.

Inductive Loads. Inductors, transformers, coils, chokes, and solenoids are all high inductive loads. In-rush currents may or may not be a problem with such loads, particularly with transformers and solenoids. However, when the circuit is broken, the stored energy in the collapsing magnetic field is dissipated across the opening contacts. The resultant arcing will cause excessive contact deterioration. This situation will be further aggravated when the load circuit has a long time constant. When size and weight preclude the use of a relay with sufficient capacity to handle the transient conditions, arc-suppression circuits should be added. These can be as simple as a diode to a diode-RC network. An added benefit to such circuits will be increased contact life. Accepted industry practice would be to derate the contacts to 40 percent of their resistive load rating. If the relay in question has an inductive load rating, then the derating should be 75 percent of this specified value.

Motor Loads. A motor, in the nonrunning condition, has a very low input impedance and consequently a large in-rush current. As the current starts to flow through the windings, a torque is developed because of the interaction of the magnetic field in the motor and the current in the winding. As the armature of the motor begins to turn, it generates a back emf in the opposite direction of the original applied voltage thus reducing the current flow. However, the greater the load on the motor, the longer the starting time and thus the longer the high starting current will persist in the circuit. Conversely, when the applied voltage is removed, a high inductive spike is produced. Therefore, on turn-on the controlling relay contacts will see very high in-rush currents, for a varying period of time, depending on the motor load: conversely on turnoff, an arc will be produced across the opening contacts. Accepted industry practice for motor loads would suggest a derating to 20 percent of the resistive load rating of the relay. If, however, the relay in question has a motor load rating then the derating should be 75 percent of this specified value.

Incandescent Lamp Loads. An incandescent lamp filament is considered to be a resistive load. When cold, the resistance of the filament is very low. When power is applied, an in-rush current results that can be as much as 15 times greater than the final steady-state value. The magnitude of these in-rush currents can cause the contacts to either weld shut or degrade to the point where they can no longer be used. Accepted industry practice

would be to derate the contacts to 10 percent of their resistive load ratings. If, however, the specific relay in question already has a lamp load rating, then the derating should be 75 percent of this specified value. Good design practice would also dictate that, wherever possible, a series current limiting resistor be used to control these in-rush currents.

Relay Coils. Coils should not be derated. Any change from nominal voltage, other than ± 5 percent tolerance, can have a serious effect on the operation of a relay.

Temperature. Relays should not be operated above rated temperature because of resulting increased degradation and fatigue. The best practice is to derate 20°C from the maximum rated temperature limit.

CIRCUIT BREAKERS, FUSES, AND LAMPS

Circuit Breakers

Circuit breakers should be sized for each application to protect the circuit adequately from overvoltage or overcurrent. For optimum reliability *thermal circuit breakers* should not be subjected to operation in environments where temperatures vary from specified rating(s) because the current-carrying capability of the sensing element is sensitive to temperature variations. For optimum reliability *magnetic circuit breakers* should not be subjected to dynamic environments exceeding the device limitations.

Derating should depend on the type of circuit breaker or circuit being protected. Normally, circuit breakers of the magnetic type, which are relatively insensitive to temperature, should not be derated except for the interrupting capacity, which should be derated up to 75 percent of maximum rated interrupting capacity. Derating of standard circuit breakers used in high-reactance-type circuits may be required to avoid undesired tripping from high in-rush current.

Thermal-sensitive circuit breakers used outside of specified ratings should be derated to compensate for effects of operating ambient temperatures.

Fuses

Fuses should have ratings that correspond to those of the parts and circuits they protect. These fuse ratings should be compatible with starting and operating currents as well as ambient temperatures. Current-carrying capacity may vary with temperature. An example is given in MIL-F-23419/9.

Fusing should be arranged so that fuses in branch circuits will open before fuses in the main circuit.

Indicator Lamps

Incandescent and gaseous indicator lamps should be protected from voltage or current surges above ratings.

Derating. Operating incandescent lamps at 94 percent of rated voltage will double the life of the lamp, with only a 16 percent drop in light output. Current is the principal stress parameter for gaseous lamps. Derating current to 94 percent of the lamp's rating will double the life expectancy.

Leds

Temperature and current are the primary stress parameters for light-emitting diodes. The designer should keep maximum junction temperature below 105°C and should maintain average forward current at a level no greater than 65 percent of the rated value.

CHAPTER 3.3

SEMICONDUCTOR RELIABILITY

Clarence M. Bailey, Jr., Richard L. Doyle

INTRODUCTION

Electronic systems are designed to operate for a specified period, which is determined by customer requirements, as well as by cost and performance. Since electronic systems consist largely of electronic devices, the system reliability is mostly dependent on the reliability of the individual devices in the system application environment. Semiconductor devices, particularly integrated circuits, considering their fundamental and complex functions, are at the heart of most modern electronic systems.

It is not possible to predict the lifetime or degradation rate (reliability) of any *individual* semiconductor device. However, it is possible to treat populations of such devices probabilistically, and thereby predict average lifetimes. This probabilistic approach is discussed here in terms of different failure rate models, which can be used to describe and predict reliability (on the average) for semiconductor devices. Failure rate λ for all electronic components including semiconductors is considered constant when used in the various reliability databases described in "Part-Failure Modeling," p. 3.10, since these databases use the exponential reliability distribution. However, these databases do not account for failure rate change ($\dot{\lambda}$). $\dot{\lambda}$ is a first-order derivative of failure rate and exhibits a sloped straight line on a linear failure rate chart. When this slope is positive, failure rate is increasing (wear-out); when this slope is negative, failure rate is decreasing (infant mortality). The slope is zero when the failure rate is constant, which is generally considered the useful life of the part. However, all three regions are becoming more important as the result of more complex ICs, less than 100 micron trace widths, and lower operating and gate voltages.

This section accounts for all three regions of the failure rate curve by using a more complex reliability distribution such as the Weibull distribution. For the more complex distributions, the hazard rate $\lambda(t)$ is used to represent the instantaneous rate of failure for units of a population that have survived to time t . Electronic device reliability is usually described in terms of a particular hazard rate model, and particular parameter values, given that model. It is noted that the model also applies to electronic passive devices as well; and, in the final analysis, to electronic systems composed of such semiconductor and passive devices. The discussion here is confined, however, to semiconductors, and the model is referred to as the device hazard rate model.

DEVICE HAZARD RATE MODEL

General

Historically, hazard rates have been modeled in terms of the traditional bathtub curve. Such a curve has three regions that are associated with infant mortality, steady-state operation, and wearout. Infant mortality is characterized by an initially high, but rapidly decreasing hazard rate. These early failures come from a small fraction of the population that can be considered weak. The defects in these weak units are usually not immediately fatal

FIGURE 3.3.1 Conceptual reliability model.

but cause failure within a short period of time. After the majority of the weak units fail, operation moves into the steady-state region, in which failures occur at a much slower rate. The steady-state region is therefore characterized by a constant or slowly changing hazard rate. Wearout occurs when the hazard rate rises and the remaining units fail. For most semiconductor devices in normal environments the wearout period is far enough away to have little or no impact on the reliability of the device through normal equipment service life. However, as ICs continue to develop in complexity and physical parameters become smaller, the wearout region is starting to infringe on the useful life of the part. This may have to be addressed in the near future, but at the present time we are only concerned with the infant mortality and steady-state regions of the curve. The wearout region will have to be fit with a separate distribution in the future.

Figure 3.3.1 shows a conceptual reliability model for devices. The failures that occur very early in life are called dead-on-arrivals (DOAs), which are a part of infant mortality and are represented by the vertical box shown in Fig. 3.3.1. Most frequently they occur at first circuit board test. They may have been good when shipped but were found to have failed at various levels of equipment assembly and test. They are sometimes found at first equipment turn-on after shipment to the field. DOAs cannot be related to operating time. A device can test as satisfactory, be assembled into equipment, and then fail to work before the equipment has been in operation. The rate of such failures may in some cases be time-dependent, resulting from the same failure mechanisms as found later in infant mortality. On the other hand, others seem to be event-dependent, owing to handling during equipment manufacture and test. Although their existence is recognized, an accurate quantitative estimate of failure owing to DOAs is not possible; and we do not attempt to include them in our reliability model. Fortunately, most DOAs are found during the equipment manufacturing process. The failures that occur during operation are called “device operating failures” (DOFs). DOFs, with the exception of DOAs, encompass the infant mortality as well as the steady-state failures. Wearout is not included in this conceptual model because, as stated previously, it is not expected to occur during service life.

Failure Time Distributions

The model uses two statistical distributions that are useful in modeling device failures. The *exponential distribution* is characterized by a constant failure rate and is used to describe the steady-state hazard rate beyond the infant mortality region of device life. Pertinent functions for the exponential distribution are listed as follows and are illustrated in Fig. 3.3.2.

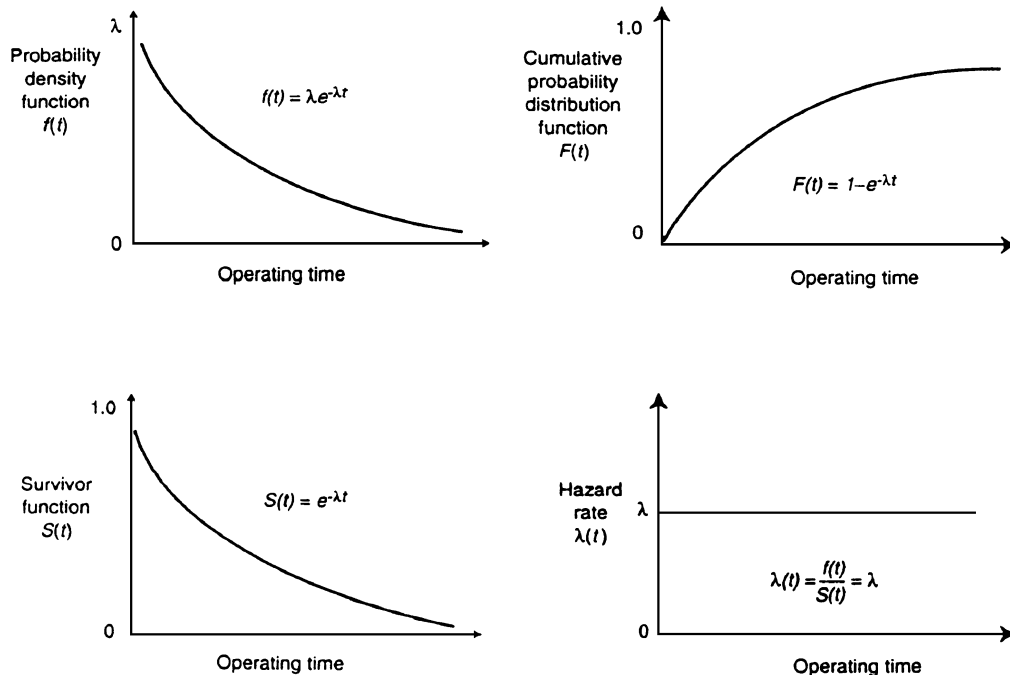

FIGURE 3.3.2 Exponential distribution.

- The probability of failure within some time interval $0, t_0, t$ the probability density function, is

$$f(t) = \lambda e^{-\lambda t} \quad (t \geq 0, \lambda > 0)$$

- The probability that a device fails at or before a time t , the cumulative distribution function, is

$$F(t) = 1 - e^{-\lambda t}$$

- The probability of surviving to time t , the survivor function, is

$$S(t) = e^{-\lambda t}$$

- The hazard rate is constant:

$$\lambda(t) = \frac{f(t)}{S(t)} = \lambda$$

The Weibull distribution is especially used for modeling infant mortality failures. For the Weibull distribution, the hazard rate varies as a power of device age. The pertinent functions of the Weibull distribution are listed as follows and are illustrated in Fig. 3.3.3.

- The probability density function is

$$f(t) = \lambda_1 t^{-\alpha} e^{-\lambda_1 t^{1-\alpha}} \quad (t \geq 0, \lambda_1 > 0, \alpha < 1)$$

where $\lambda_1 > 0$ is the scale parameter of the distribution hazard rate, and α is the shape parameter of the distribution.

3.44 RELIABILITY

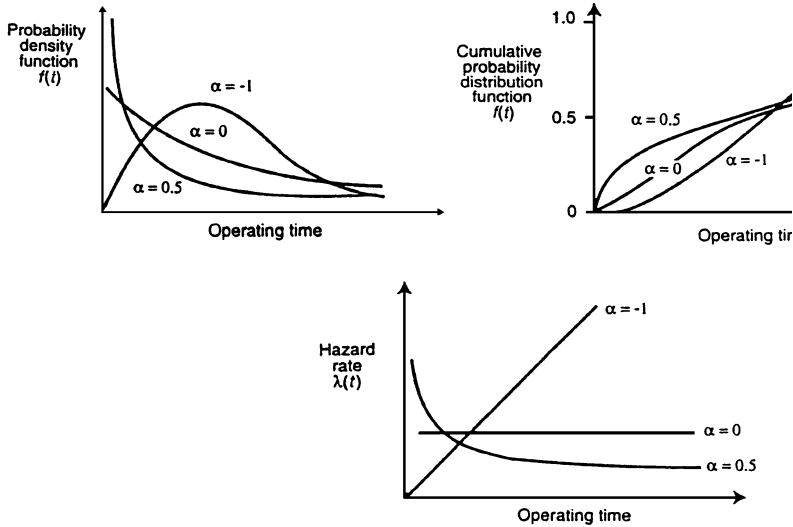

FIGURE 3.3.3 Weibull distribution.

- The cumulative distribution is

$$F(t) = 1 - e^{-\frac{\lambda_1 t^{1-\alpha}}{1-\alpha}}$$

- The hazard rate is

$$\lambda(t) = \lambda_1 t^{-\alpha}, \alpha < 1, t > 0$$

- The failure rate change ($\dot{\lambda}$) is

$$\dot{\lambda}(t) = -\alpha \lambda, t^{-(\alpha+1)}, \alpha < 1, t > 0$$

- The survivor function is

$$S(t) = e^{-\frac{\lambda_1 t^{1-\alpha}}{1-\alpha}}$$

When $0 < \alpha < 1$, the hazard test rate decreases with time ($\dot{\lambda}$ is negative). Therefore a positive α is used to model infant mortality. If $\alpha < 0$ the Weibull increases with device age ($\dot{\lambda}$ is positive) and device wearout may be modeled for this range of the shape parameter. If $\alpha = 0$, the hazard rate is constant ($\dot{\lambda}$ is zero) showing that the exponential distribution is a special case of the Weibull distribution. Since the shape of the Weibull distribution changes with α , it is called the shape parameter.

Specific Hazard Rate Model

Figure 3.3.4 shows the specific hazard rate model used to characterize semiconductor device reliability as well as other electronic devices and systems. The hazard rate in the infant mortality region is modeled by a Weibull hazard rate that decreases with time. In the steady-state region, the reliability is characterized by the exponential distribution where the failure rate is constant. A feature of the Weibull is that the hazard rate is a straight

FIGURE 3.3.4 A hazard rate model for electronic components is the basis for the electronic equipment and systems model.

line when plotted on log-log scales as in Fig. 3.3.4. In such a plot, the slope is $-\alpha$, with $0 \leq \alpha < 1$, and the intercept at $t = 1$ h is λ_1 , and hazard rate in infant mortality is described by

$$\lambda(t) = \lambda_1 t^{-\alpha}, \quad 0 \leq \alpha < 1, \quad 0 < t < t_c \quad (1)$$

Beyond some time t_c , assumed to be 10^4 h (slightly over the approximately one year of infant mortality), the hazard rate is assumed to remain constant; that is

$$\lambda(t) = \lambda_L, \quad \text{for } t \geq t_c = 10^4 \text{ h}$$

The hazard rate unit is the FIT (or one failure in 10^9 device hours). The hazard rate shown in Fig. 3.3.4 is typical but does not necessarily correspond to any particular device. As background for this model we note that there are two distinct, but different sources for information on semiconductor device reliability: accelerated life tests, and factory- and field-monitored performance. The former provide information about reliability in the very long term, the latter primarily gives information in the short term. Accelerated test conditions are required to determine the main lifetime distribution of the main population of the devices. For semiconductor devices this is usually well described by the lognormal distribution, and, based on such accelerated tests, we can relate the distribution to normal use conditions. Specifically, the maximum hazard rate, at use conditions, can be determined from accelerated life test data. Figure 3.3.5 shows a possible relationship between accelerated stress test results and the hazard rate model. In contrast, short-term hazard rates can be directly measured from field studies of no more than 2 to 3 years' duration. In those studies, a plot of the logarithm of the observed hazard rate versus the logarithm of time is usually found to fit a straight line and can be modeled by the Weibull distribution. Beyond the infant mortality period, such field studies

FIGURE 3.3.5 This device failure-rate model is a combination of a Weibull and an exponential distribution. Possible relationships between accelerated-stress results and the model are shown by the two-dashed lognormal curves.

have not contributed much significant information about the hazard rate, except that it is believed that the hazard rate continues to fall or levels off. Hence, we adopt the exponential distribution, with its constant failure rate, beyond 10,000 h—a conservative approach. The 10,000 h crossover point is arbitrary but reasonable. Beyond that point, the hazard rate is changing very little, and the constant failure rate model should be adequate.

Accelerated Life Model

Most modern semiconductor devices are so reliable that at normal use conditions only a very few failures are encountered. Many months of operation of large populations of devices might be needed to acquire statistically significant information on the hazard rate of those devices—at, in many cases, large costs. Another method, requiring less time, quantities of devices, and costs is accelerated testing. In an accelerated life test, a number of devices are subjected to failure-causing stresses that are at levels above what those devices would experience in use conditions. This type of accelerated aging test allows a distribution of failure times to be obtained, albeit at more stressful conditions than use conditions. In order to use this method, we must have a relationship between the distributions of the failure times at accelerated aging conditions to the distribution of failure times at use conditions, called an “accelerated life model.” Not only does this accelerated life model allow us to “qualify” or prove-in devices, but it also allows us to develop accelerated stress tests for screening out some infant mortality failures; and, more importantly, relate hazard rate data acquired at one use condition to another different, use condition. Concerning the latter, it is noted that Table 3.3.3 provides possible hazard rate estimates at a reference temperature of 40°C.

We usually characterize an accelerated life model by a linear relationship between failure times at different conditions. If we designate t_1 as the failure time of a device at use conditions, t_2 as the failure time of the device

at accelerated (more stressful) conditions, A as an accelerated factor, and $\lambda_1(t)$ and $\lambda_2(t)$ are the hazard rates at use and more stressful conditions, respectively, then

$$\lambda_1(t) = \frac{1}{A} \lambda_2(t/A) \quad (2)$$

The acceleration factor in the preceding equation may be a result of several stress variables. The stress variable of most importance and significance for semiconductor and other electronic devices as well as electronic systems is temperature. For this we use the well-known Arrhenius relationship. Arrhenius fits the temperature dependence of a rate constant k , independent of time, to the general form:

$$k = k_0 e^{-E_a/k_B T} \quad (3)$$

where T = absolute temperature (degree, Kelvin)

E_a = activation energy

k_B = Boltzmann constant

k_0 = constant

We can derive from this general form, for two different temperatures T_1 and T_2 , an acceleration factor owing temperature:

$$A_T = e^{(E_a/k_B)((1/T_1)-(1/T_2))} \quad (4)$$

If the activation energy for the process leading to device failure is known, then the acceleration factor for comparing reliability at two different temperatures can be calculated from the preceding equation. The Boltzmann constant is 8.6×10^{-5} eV/K. ($^{\circ}\text{Kelvin}$ is $^{\circ}\text{Celsius} + 273$.) The activation energy eV is in electron volts.

INFANT MORTALITY CONSIDERATIONS

Infant Mortality Device Defects

These stem from a variety of device design, manufacturing, handling, and application related defects. Even though the failure mechanisms may vary from product to product and lot to lot, infant mortality can still be modeled adequately. Infant mortality failures are generally caused by manufacturing defects—including such defects as oxide pinholes, photoresist or etching defects, conductive debris on the chip, contaminants, scratches, weak bonds, and partially cracked chips and ceramics. Some infant mortality defects result from surface inversion problems, likely because of gross contamination or gross passivation defects. Many defects result from packaging problems. Some can be attributed to workmanship and manufacturing variations. Such variations can be reduced by changes in design or fabrication techniques, or in handling of the devices during manufacture. One important factor is a result of voltage spikes from *electrostatic discharge* (ESD), particularly at the circuit board manufacturing level. Some devices such as CMOS are more susceptible to this mechanism. Other infant mortality defects are inherent in design rules and constraints, or in the practical limitations of the manufacturing process and material control.

Effect of Temperature on Infant Mortality Hazard Rates

Studies of the infant mortality period show a low activation energy for the failure mechanisms contributing to semiconductor (and other electronic device) failures during infant mortality. These studies indicate an effective activation energy may be in the range of 0.37 to 0.42 eV, indicating that a single energy activation of 0.4 eV is a reasonable estimate for establishing time-temperature tradeoffs in infant mortality. Based on this value of 0.4 eV

3.48 RELIABILITY

activation energy, the temperature acceleration factor, A_T , can easily be calculated from Eq. (4). It cannot, however, be used directly as a multiplier for the hazard rate at the desired operating temperature. (That procedure is only correct when the hazard rate is constant as in the exponential distribution.) Instead, it can be shown that when the distribution is Weibull, as in the infant mortality period, the multiplier for the hazard rate is $(A_{IM})^{1-\alpha}$. The hazard rate is then given by

$$\lambda(t) = (A_{IM})^{1-\alpha} \lambda_1 t^{1-\alpha} \quad (5)$$

Effect of Operating Voltage on Infant Mortality Hazard Rates

The dielectric breakdown of an oxide field, in say metal oxide semiconductor (MOS) devices, has been shown to be accelerated by an electric field. Failure analysis of such devices shows that about 30 percent of infant mortality failures are because of oxide-related failures, which are a function of applied voltage and of oxide thickness. Further investigations have established a voltage-dependent acceleration factor, which can be applied to device burn-in, where a voltage stress in excess of operating voltage is applied. Namely, the acceleration factor owing voltage stress is

$$A_V = e^{C/t_{ox}(V_1-V_2)} \quad (6)$$

where C is the voltage acceleration factor in angstroms per volt, t_{ox} is the oxide thickness in angstroms, V_1 is the stress voltage in volts, and V_2 is the operating voltage in volts. A conservative estimate of C is 290 \AA/V .

Effect of Temperature Cycling on Infant Mortality Hazard Rates

Mechanical defects such as weak wire bonds, poor pad adhesion, and partially cracked chips on ceramics constitute a significant portion of infant mortality failures. These failure mechanisms involve either plastic deformation or crack propagation, which can be caused by repeated stress in alternate directions resulting in fatigue failure. Fatigue failure can be increased indirectly by increasing the range of ΔT . There is much evidence that temperature cycling of devices results in decreasing hazard rates, and the decrease is a function of the number of cycles. However, there appears to be no general form for an acceleration factor. More than likely, the acceleration factor is a primary function of the materials and geometries of the specific device construction, and would have to be determined by experimentation. Temperature cycling is the major methodology for a technique known as *environmental stress screening* (ESS) or *sampling testing* (EST). The commonly used technique of step-stress testing is the most effective means for determining what kinds and levels of temperature cycling would be most effective for ESS or EST of the particular semiconductor device design type.

Infant Mortality Screening

The term *screening* here refers to the use of some environmental stress as a screen for reducing infant mortality defects. Involved are such accelerated stresses as temperature, temperature cycling, combined temperature and bias, and voltage (as discussed previously for CMOS devices). The selection of the proper stress depends largely on the semiconductor design and the nature and degree of the failure mechanisms contributing to the majority of the infant mortality defects.

Temperature cycling, discussed previously, followed by gross functional and continuity testing is very effective in screening out many mechanical defects. In addition to the defects mentioned before, it will accelerate failures caused by intermetallics in gold-aluminum wirebond systems, if temperature cycling follows a high temperature bake. Temperature cycling is an effective screen for poor seals of hermetic devices; and, in plastic encapsulated devices, temperature cycling accelerates defects caused by fatigue stressing of wire bonds because of plastic material surrounding the lead and bond area.

Screening with temperature alone—called “stabilization bake” or “temperature storage”—is an effective technique for certain failure mechanisms. It involves storing devices at an elevated temperature for a specific

period of time. It is used to find diffusion and chemical effects, as well as material deterioration. It accelerates failures caused by oxide and gross contamination defects. It will accelerate the formation of intermetallics in a gold-aluminum wirebond system; if followed by temperature cycling, bond failures are likely to occur sooner. One effective method, referred to commonly as *burn-in*, is discussed in the following section.

Burn-in

Burn-in is an effective means for screening out defects contributing to infant mortality. Burn-in combines electrical stresses with temperature and time, and can be characterized as either static or dynamic. In static burn-in, a dc bias is applied to the device at an elevated temperature. The bias is applied in such a way as to reverse bias as many of the device junctions as possible. In dynamic burn-in the devices are operated so as to exercise the device circuit by simulating actual system operation. Static burn-in is only performed at the device level. Dynamic burn-in offers the option of use at both the device and the system level. When performed at the device level, dynamic system operation is simulated at a high temperature within the capabilities of the device. When performed at the system level, the system is operated at an elevated temperature. Since parts of the system are relatively limited in terms of temperature capability, the system burn-in is generally limited to lower temperatures than device burn-in. Static burn-in appears to be more effective for defects resulting from corrosion and contamination. Dynamic burn-in does not appear to be as effective for these problems. On the other hand, dynamic burn-in provides more access and complete exercise of internal device elements. It appears to be a much more effective screen for more complex, higher scale of integration devices. The choices of the type of burn-in (static or dynamic) and the specific stress conditions therefore depend on the device technologies, complexities, and predominant failure mechanisms, as well as the reliability requirements.

We concentrate here on a dynamic device burn-in based on the assumption of the Weibull distribution for infant mortality. This model assumes that the hazard rates of semiconductor devices are monotonically decreasing. Operation during device or system burn-in produces a certain amount of aging, and will result in a reduced hazard rate during subsequent aging. Subsequent operation begins at the reduced hazard rate and continues to decrease with additional operating time. The effect of burn-in is a function of the burn-in temperature and the subsequent operating temperature. The effective operating time is

$$t_{\text{eff}} = A_T A_V t_{bi}$$

when t_{bi} is the burn-in time at T_{bi} , the ambient burn-in temperature. (A_V is the voltage acceleration factor if performed as a part of the burn-in.) The Arrhenius equation is used to find the acceleration factor, A_{bi} , for burn-in compared to normal operation at the device hazard rate reference temperature. The hazard rate at the reference ambient temperature is

$$\lambda(t) = \lambda_1 (t_{\text{eff}} + t)^{-\alpha}$$

where $t = 0$ corresponds to the start of the device age after the burn-in. Figure 3.3.6 shows that the effect of burn-in is a decrease in the early life hazard rate. It is noted that the modeled burn-in assumes that all infant mortality defects would appear in the equivalent time of burn-in. This is a simplified effect. The stress is typically temperature, but temperature alone may not necessarily eliminate failures that might result from other stresses such as temperature cycling. Experience may well show a higher hazard rate after burn-in than predicted, followed by a more rapid decrease in hazard rate. If the temperature of subsequent operation is not at the device hazard rate reference temperature, then calculation of the hazard rate after burn-in is only slightly more complicated. The hazard rate after burn-in is then

$$\lambda_a(t) = (A_{op})^{1-\alpha} \lambda_1 [t + t_{bi} (A_{bi}/A_{op})]^{-\alpha} \quad (7)$$

where A_{op} is the acceleration factor for the operating temperature relative to the reference temperature, and

$$A_{bi} = A_T A_V$$

3.50 RELIABILITY

FIGURE 3.3.6 Effect of burn-in.

Infant Mortality Example

Question 1. If a device has an infant mortality hazard rate, at a reference and use temperature of 40°C, characterized by $\lambda_1 = 15775$ FITs, and $\alpha = 0.7$, and if no burn-in is performed, what percentage of the devices will fail in a year (8760 h)?

Solution. The expected percent of failures, with no replacement, is given by

$$\frac{\bar{N}}{n} = F(t) = 1 - e^{-(\lambda_1 / 1 - \alpha)t^{1-\alpha}} \tag{8}$$

where \bar{N} = expected number of failures
 n = number of devices
 $F(t)$ = Weibull cumulative distribution function

Then

$$F(t) = 1 - e^{-[10^{-9}(15775)/(1-0.7)](8760)^{1-0.7}} = 0.0008 = 0.08 \text{ percent}$$

Question 2. What percentage of such devices will fail in a year if they have been burned in for 10 h at 125°C?

Solution. The hazard rate after burn-in is

$$\lambda(t) = \lambda_1(t_{\text{eff}} + t)^{-\alpha} \quad (9)$$

If $\int_0^t \lambda(t') dt' \ll 1$, then we may use an approximate equation for dropout:

$$\text{percent failing} = 10^{-7} \int_0^{8760} \lambda_1(t_{\text{eff}} + t')^{-\alpha} dt' = 10^{-7} \lambda_1 \int_{t_{\text{eff}}}^{t_{\text{eff}} + 8760} t^{-\alpha} dt$$

$$\text{percent failing} = 10^{-7} \frac{15775}{1-0.7} \left[(t_{\text{eff}} + 8760)^{1-0.7} - (t_{\text{eff}})^{1-0.7} \right]$$

$$\text{percent failing} = 0.00525 \left[(t_{\text{eff}} + 8760)^{0.3} - (t_{\text{eff}})^{0.3} \right]$$

Using $E_a = 0.4$ eV, the acceleration factor, A_T , owing to temperature calculates to be approximately = 24. If, in addition, the device is an MOS device with gate oxide thickness of 250 Å, nominally operated at 5.5 V but is burned in at 7.5 V, the equation for voltage acceleration gives a voltage acceleration factor, A_V , approximately = 10. So the total burn-in acceleration factor = (24)(10) = 240, and the $t_{\text{eff}} = 2400$ h. The percentage failing then in 1 year after burn-in is

$$\text{percent failing} = 0.00525[(2400 + 8760)^{0.3} - (2400)^{0.3}] = 0.03 \text{ percent}$$

STEADY-STATE (LONG-TERM) CONSIDERATIONS

Long-term device reliability is defined as the reliability in the postinfant mortality period of device life, also referred to as the steady-state period of life. The hazard rate during this period is modeled as an exponential, constant failure rate. Since experience and theory indicate that, during the steady-state period, the hazard rate is near-constant and slowly changing, the assumption of the constant failure rate is felt to be a reasonable approximation. A knowledge of the contributing failure modes and mechanisms, and how to control them, is necessary to interpret and estimate long-term hazard rates. The discussion of the long-term reliability of semiconductor devices then includes a discussion of the steady-state failure mechanisms and the accelerating stresses.

Steady-State (Long-Term) Failure Mechanisms

Table 3.3.1 is a summary of many of the failure mechanisms in silicon devices. This table lists the processes leading to failure, appropriate accelerating stresses, and the ranges of activation energies. It is important to understand the accelerating stresses, as related to the specific failure mechanism, if one is to use accelerated test data to control and predict long-term hazard rates. Based on the known activation energies for the device failure mechanisms in steady-state, high temperature and other accelerated stress tests can be conducted to determine the effects of the accelerated stress tests on the device failure distribution and lifetime. Hazard rates at lower (use) stress can be extrapolated from the stress test data based on the assumed activation energy. In this activity, the lognormal distribution is found to be extremely valuable. There is much available information on the use of the lognormal distribution in analyzing accelerated testing data. The interested reader is urged to investigate the literature as needed.

Although it is difficult to list all failure mechanisms, it is possible to group some mechanisms together according to the accelerated stresses which affect them:

- (a) Chemical reaction in contact areas, where contact metals react with the semiconductor material, and growth of intermetallic materials at the bonds of dissimilar metals such as gold and aluminum—elevated temperature, no electrical bias.

TABLE 3.3.1 Time-Dependent Failure Mechanisms in Silicon Devices

Device association	Failure mechanism	Relevant factors	Accelerating factors	Acceleration (apparent E_a)
Silicon-oxide and silicon-oxide interface	Surface charge accumulation	Mobile ions V, T	T	$eV = 1.0 - 1.05$
	Dielectric breakdown	E, T	E	
	Charge injection	E, T, Q_{ss}	E, T	$eV = 1.3$ (slow trapping)
Metallization	Electromigration	T, j, A , gradients of T and j , grain size	T, j	$eV = 0.5 - 1.2$ j to j^4 dependence
	Corrosion (chemical, galvanic, electrolytic)	contamination H, V, T	H, V, T	Strong H effect $eV = 0.3 - 0.6$ (for electrolysis); V may have thresholds
	Contact degradation	T , metals, impurities	Varied	
Bonds and other mechanical interfaces	Intermetallic growth	T , impurities, bond strength	T	Al-Au $eV = 1.0 - 1.05$
	Fatigue	Bond strength temperature cycling	T extremes in cycling	
Metal penetration	Aluminum penetration into silicon	T, j, A	T, j	$eV = 1.4 - 1.6$
Hermeticity	Seal leaks	Pressure, differential atmosphere	Pressure	

V = voltage, T = temperature, E = electric field, j = current density, A = area, H = humidity, Q_{ss} = interfacial fixed charge.

- (b) Surface inversion, surface charge movement, and dielectric breakdown—elevated temperature and voltage.
- (c) Weak wire bonds, mismatches of seal materials in hermetic packages, and mismatches of thermal expansion of the chip and its package—temperature cycling.
- (d) Corrosion of materials, such as electrolytic corrosion of aluminum or gold producing opens (aluminum) or dendritic growth causing shorts (gold)—temperature, humidity, and voltage aided by some contamination.
- (e) Electromigration of metallization stripes resulting in opens at one end of the stripe—elevated temperature and high current density.
- (f) Soft errors in MOS DRAM devices, caused by α -particles—the errors are temporary depending largely on the memory cell size or the charge being stored, and the incidence of random α -particles. Accelerated test by a particle source.

Determining Semiconductor Failure Rate

The following is the standard method of determining semiconductor failure rate based on stress testing samples of the integrated circuit of interest.

Example. Determine the constant failure rate in FITs (failures per billion hours) at 90 percent confidence at a junction temperature of 75°C. Use the following test results: Use an activation energy of 1.0 eV. One lot of 40 pieces tested at 150°C for 1500 with no failures. The other lot of 44 pieces tested at 150°C for

2500 h with no failures. Assume that the 150°C was junction temperature and not a die temperature or environmental chamber temperature.

This section explains how to calculate the failure rate using the summary test data. The failure rate resulting from these data is an average, or estimate, of the typical expected failure rate for this type of product and process technology. This calculation is made for the upper 90 percent confidence limit for the failure rate estimate using Chi-square statistics. The following formula predicts the maximum failure rate or worst-case condition:

$$\lambda(\text{max}) = \frac{\chi^2(1-a)}{2t} \quad (10)$$

with dof = 2($r + 1$)

where χ^2 = Chi-square distribution value

r = number of failures

dof = degrees of freedom

t = device hours

a = statistical error expected in estimate.

For 90 percent confidence, $a = 0.1$ or $1 - a = 0.9$, ($1 - a$) can be interpreted to mean that we can state with statistical confidence of $1 - a$: (i.e., 90 percent) that the actual failure rate is equal to or less than the calculated maximum $\lambda(\text{max})$ failure rate.

To get the total number of device-hours, multiply the total samples tested (survivors) times the total hours of test.

The test results represent different operating and test conditions, therefore, temperature corrections are required for the data. These data require a correction using the Arrhenius equation for an activation energy of 1.0 eV. The acceleration factor is 369.6 for converting test data from 150 to 75°C.

To find the maximum failure rate at normal operating temperature (30°C) and junction temperature (75°C) with 90 percent confidence, using Eq. (10) we have

$$\chi^2 = 4.61^*$$

$$r = 0$$

$$\text{dof} = 2$$

$$t = (40 \times 1500 + 44 \times 2500 \text{ h}) \text{ unit hours} = 3,240,026 \text{ h}$$

$$a = 0.1$$

For 90 percent confidence, $a = 0.1$ for Q failures, since $1 - a = 0.9$ equals 90 percent for P success.

Steady-State (Long-Term) Example

Question. If a VLSI semiconductor device has a long-term hazard rate, λ_L , of 40 FITs at 40°C, what percent of such devices will fail per year, after infant mortality, when operated at a temperature of 50°C? The activation energy is 0.4 eV.

Solution. The acceleration factor for operation at 50°C from a reference temperature of 40°C is

$$A_r = e^{(E_a/k_B)(1/T_1) - (1/T_2)} = e^{(0.4/8.6 \times 10^{-5})(1/273+40) - (1/273+50)} = 1.58 \quad (11)$$

*For a total of 0 failures, $\chi^2 = 4.61$ with 90 percent confidence. Values of χ^2 can be found in a number of statistical tables or using Excel.

$$\lambda(\text{max}) = 4.61/[2 \times (40 \times 1500 + 44 \times 2500 \text{ h})]$$

$$\lambda(\text{max}) = 13.559 \times 10^{-6} \text{ failures per hour} \quad \text{or}$$

$$\lambda_{\text{max}}(150^\circ\text{C}) = 13.559 \text{ failures per million hours} = 13,559 \text{ FITs}$$

$$\lambda_{\text{max}}(75^\circ\text{C}) = 13,559 \text{ FITs}/369.6 = 36.7 \text{ FITs}$$

3.54 RELIABILITY

Since, in the steady-state, constant failure rate period, the acceleration factor is A_T times the hazard rate at the reference temperature, the hazard rate at the operating temperature is approximately = 63 FITs. The percent failure per year is

$$\begin{aligned}\frac{\bar{N}}{n} &= 1 - F(t) = 1 - e^{-(63 \times 10^{-9})8760} \\ &= 0.00055 \\ &= 0.055 \text{ percent}\end{aligned}$$

Crossover Time from Infant Mortality to Steady State

Under the reference operating conditions, the crossover time is that time when infant mortality ends and the long term starts, and they have the same value of hazard rate at 10,000 h. However, for increased temperature, the constant hazard rate of the model increases more than the infant mortality hazard rate, leading to an apparent discontinuity in the model at 10,000 h. But the infant mortality region of the model is only intended to model failures that occur at a rate greater than the long-term rate. Therefore the transition time may be taken to be that time when the infant mortality hazard rate becomes equal to the steady-state hazard rate. Then for operation at accelerated conditions, the transition should occur before 10,000 h.

SEMICONDUCTOR DEVICE HAZARD RATE DATA

General

Semiconductor device hazard rate estimates are presented in this section. These estimates are based on experience, from various sources, with the various devices in communications systems in the field and in factory testing, as well as in accelerated testing. The hazard rates presented are believed to be typical of product from device suppliers who incorporate good quality and reliability programs as a part of their normal manufacturing procedures. The estimates are believed to be well within the current state of the art, and good suppliers should have little or no difficulty in producing devices that meet or exceed these hazard rate estimates.

Reference Operating Temperature

Reference conditions, for the reference operating temperature (case temperature) of 40°C, are similar to those for central office type telephone equipment; that is, the environment is air conditioned, humidity is not a significant factor, and the room ambient temperature is about 25°C. Implicit in this is the assumption that operation of the device in equipment causes its internal ambient to rise 15°C above a 25°C room ambient. If the internal ambient temperature is above 40°C, the hazard rates will be higher than the tabulated numbers.

Hazard Rate Multipliers

The hazard rates of semiconductor devices are affected by the environmental application of the devices, as well as temperature. Table 3.3.2 gives an example of the environmental application factors developed to relate the hazard rates to the environment in which the device is being used. Typically a reliability analysis will be performed using a standard failure rate database. Then one should use the failure rate multipliers specified by the database. These reliability databases are described on p. 3.10, "Part-Failure Modeling," and include: MIL-HDBK-217, Telcordia/Bellcore SR-332, CNET's RDF 2000, British Telecom's database, Reliability Analysis Center's PRISM, and IEEE STD 493.

Activation Energies

As stated previously an activation energy of 0.4 eV is used for all devices in the infant-mortality period. The acceleration factor, A_{IM} , thus calculated is applied to the hazard rate by the factor, $(A_{IM})^{1-\lambda}$. An activation energy of 0.4 eV may also be used for devices in the steady-state region. This is an “effective activation energy” based on the variety of different failure mechanisms. In the steady state case, the acceleration factor, A_T , thus calculated, is applied directly to the long-term hazard rate.

Hazard Rate Table

If you are using a standard failure rate database, you should use the failure rates of the parts as specified by the database. These reliability databases are described in “Part-Failure Modeling,” p. 3.10. You may want to apply the following techniques to the infant mortality portion of the system. Table 3.3.3 presents the hazard rate estimates by device type, and generally by scale of integration, at the reference operating temperature of 40°C. The long-term hazard rate is presented in terms of the parameter λ_L in FITs. The Weibull slope during infant mortality is listed in terms of the parameter α . The infant mortality hazard rate λ_1 is not listed but may be calculated from the relationship

$$\lambda_1 = \lambda_L (10,000)^\alpha$$

As stated before, the activation energy which applies during infant mortality and possibly during steady state is 0.4 eV.

CHAPTER 3.4

ELECTROMECHANICAL AND MICROELECTROMECHANICAL SYSTEMS (MEMS) RELIABILITY

Richard L. Doyle

INTRODUCTION

Reliability of electromechanical and microelectromechanical systems (MEMS), like other important design parameters, is established by the design and manufacturing process. Actual reliability (time-to-failure) rarely exceeds desired reliability primarily because of wearout of these systems. The reliability design and analyses techniques discussed in this chapter will aid the designer in using reliability tools to provide a more reliable electromechanical component or system. One must focus attention on design weaknesses so that they may be corrected, protected against, or accepted after consideration. These techniques also provide a means of ensuring that a design will meet specified time-to-failure (reliability to life) requirements.

It is generally true that one can demonstrate electromechanical reliability by test with a sufficient degree of statistical confidence prior to and during production. This is because of the short life that these electromechanical systems have. Their wearout time or cycles is relatively short and the mean-time-between-failures (MTBFs) is measured in hours rather than hundreds of years as is the case with electronic parts. These actual MTBFs can be demonstrated during accelerated life testing.

There are two fundamental types of failures. One results from higher stresses than the part can withstand. The second is caused by the part literally wearing out. Both types of failures are covered in this chapter. However, the second is the most intriguing since wearout comes in many different forms. Wearout can be a result of fatigue, like a spring failing after being subjected to the same load for many years. It can be the result of abrasion, like tire wear on a car. Wear and wearout also are caused by friction, thermal cycling, and so forth. Generally all mechanical parts have a finite life. It can be very long like the pyramids of Egypt or very short like some MEMS motors. We will attempt to quantify the wearout time for all mechanical parts based on stresses and wear in this chapter. In this way, one can predict the MTBF and determine when to perform maintenance.

The classic bathtub curve shown in Chap. 3.1 also applies to mechanical failures. Stage 1 (infant mortality) is very short. It is therefore not necessary to test mechanical components for extended lengths of time to screen out infant mortality failures. The majority of a mechanical component's life is spent in Stages 2 and 3, which show a gradual increase in failure rate during Stage 2 and an accelerated failure rate during Stage 3. This is because mechanical components have continuous wear and fatigue throughout their operating life. An excellent method of selecting an appropriate service time is to determine when (number of operating hours) the failure rate curve begins to accelerate the sharpest, sometimes called the knee of the hazard rate curve. As illustrated in Fig. 3.4.1, higher operating stresses result in shorter life of the part.

Examples of electromechanical devices include motors, sensors, switches, connectors, and so forth. Samples of the MEMS devices and additional applications are presented in Chap. 8.5, "Microsensors and

FIGURE 3.4.1 Effect of stress levels on mechanical failure rates.

Actuators.” In the design of these systems, and operational requirements must be translated into design requirements, which are then verified by analysis (to provide an assessment of the design) and possibly by testing. The results can be compared with the operational requirements.

MECHANICAL STRESS ANALYSIS

Mechanical stress analysis is an important design procedure by which the maximum actual stresses induced on a material in its application are identified, so that adequate safety margins can be designed in.

Life-cycle phase. Stress analysis is normally conducted during full-scale development as the detailed design definition progresses.

Purpose. Stress analysis provides identification of the stresses, and confirmation of compliance with safety margins.

Objectives. The primary objective of stress analysis conducted on electromechanical systems/equipment is to identify any life-limiting stresses. This is performed by comparing stress-strength characteristics of parts and materials with internal and/or external loadings so that when the design is exposed to stress levels experienced in service, its life meets the requirements for that equipment. Stress analysis requirements should be invoked as a design technique to reveal system/equipment design deficiencies.

Material Stress-Strength Comparison

A material’s strength or capability of handling a given stress varies from lot to lot and manufacturer to manufacturer. This variation for all materials of the same type can be represented by a statistical distribution of material strength. Similarly, the stress applied to a material changes from one point in time to another, with instantaneous changes occurring in temperature, mechanical stresses, transients, vibration, shock, and other deleterious environments.

At a random point in time the environmental effects can combine, reaching stress levels beyond the material’s strength, resulting in failure of the material.

This strength-stress relationship can be described graphically by two overlapping statistical probability density distributions as shown in Fig. 3.4.2. For materials rated at the mean distribution used in an environment with an average stress equal to the mean of the stress distribution, the probability of failure is equal to the product of the areas of the two distributions where overlap occurs (i.e., the probability of the stress being greater than the minimum strength times the probability of the strength being lower than the maximum stress). This probability of failure is represented by the solid dark area of Fig. 3.4.2.

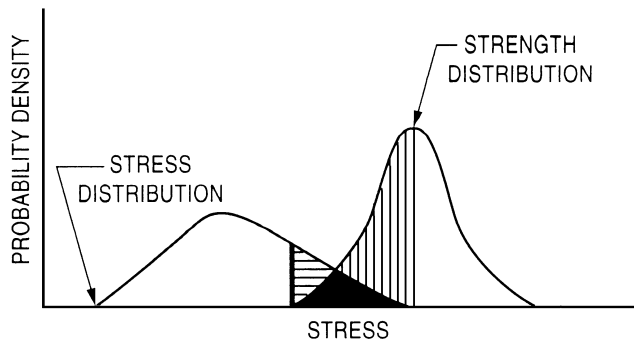

FIGURE 3.4.2 Two overlapping statistical probability-density distributions.

To reduce the probability of failure the potential stress levels can be reduced to a point where there is a very small probability of the stress exceeding the material's strength (stress distribution is shifted to the left), or the material's strength can be increased so that the probability of the combined stresses reaching or exceeding this strength is very small (strength distribution is shifted to the right). In most cases, the strength of the material cannot be increased and the only approach is to decrease the stress on the part. Alternatively, sometimes a different or stronger material can be used that can withstand the higher stresses. Either technique reduces material internal temperatures, decreasing the rate of chemical time-temperature reaction.

Procedure for Mechanical Stress Analysis

This chapter explains the fundamental mechanical stress analysis principles and shows the primary methods and formulas necessary for calculating mechanical stresses, safety factors, and margins of safety associated with electromechanical designs. These calculations are used in the mechanical stress analysis in two ways: (1) They ensure that the structural part has sufficient strength to operate in its service environment and under the loads specified, and (2) to a lesser extent, they ensure that there is no appreciable excess of material or over-design resulting in higher costs and burdening the program with excessive weight, mass, volume, and so forth.

Mechanical stress analysis is a detailed and complex engineering discipline. However, for our purposes simplifying assumptions will be made which provide equations for evaluating the approximate values of the stress, loads, margins of safety, and safety factors.

Several important factors must be considered before performing a mechanical analysis:

1. Important parameters are the loads, the material properties, and the actual calculated stresses.
2. Factors to be considered include the size, material joining techniques, welding, bonding, loads, material properties, moisture, thermal environment, and thermal limitations of the material.
3. Environmental factors such as corrosion and temperature and their resultant stresses must be considered.
4. Actual stress values must be calculated under steady-state loading conditions.

Symbols and Abbreviations

Symbols and abbreviations used in this chapter are defined as per US MIL-HDBK-5E. These symbols are abbreviations will be used throughout this section. with the exception that special statistical symbols are presented as necessary. To go further than this information, the reader should be familiar with the symbols and abbreviations used in mechanical structural analysis.

STANDARD DEFINITIONS, NOMENCLATURE, AND FUNDAMENTAL EQUATIONS

All electromechanical systems, while in operation, are subjected to external loads. These supplied loads must be transmitted through components and between components to the supports, which provide the necessary reactions to maintain equilibrium. In the process, forces and moments are developed in each component of the system to resist the externally applied loads; providing equilibrium for the components. The internal forces and moments at any point within the system are called *stress resultants*.

Normal Force. If a uniform bar is subjected to a longitudinal force P , the force must be transmitted to its base. Under this loading the bar will increase in length and produce internal stress resultants called *normal forces*, denoted by P . Normal forces are associated with electromechanical components that lengthen under tensile loads and shorten under applied compression loads.

Shear Force. If a uniform square plate is subjected to a uniformly distributed force f on three edges of the plate, then these forces must be transmitted to the base edge. This form of deformation is called *shear deformation* and is associated with an internal stress resultant called *shear force*, denoted by S .

Bending Moment. If a uniform beam is subjected to a couple C , the beam is no longer straight, but has become bent. Deformations that bend electromechanical components are associated with internal stress resultants called *bending moments*, denoted by M .

Torque. If a uniform circular shaft is subjected to a couple, the shaft must twist as the couple is transmitted to the base support. Deformations that twist electromechanical components are associated with internal stress resultants called *torque*, denoted by the vector C .

Fundamental Stress Equations

Internal stress resultants represent the total force or moment acting at any point within a electromechanical system. In reality these stress resultants are distributed over surfaces within the components, and their magnitudes per unit area are called *stress*. Stress is defined by force per unit area. Therefore, bending moments and torques must be described by statically equivalent force systems made up of distributed normal or shear forces in order to evaluate their effect in terms of stress.

Normal and Shear Stress. Stresses acting perpendicular or normal to a surface are called *normal stresses*, while stresses acting in the plane of the surface are called *shear stresses*. Internal stress resultants do not necessarily act normal or in the plane of the surface in question. For convenience, in mechanical stress analysis, internal force resultants are always represented in component form so that stresses are either normal stresses or shear stresses.

Consider an incremental internal force resultant ΔR acting on an incremental surface area ΔA . The vector sum of ΔP (normal force) and ΔS (shear force) may be used to replace ΔR . The normal force per unit area and the shear force per unit area are then called normal stress f_n and shear stress f_s , respectively. Therefore, average values are defined by

$$f_{n(\text{avg})} = \frac{\Delta P}{\Delta A} \quad f_{s(\text{avg})} = \frac{\Delta S}{\Delta A} \quad (1)$$

Notice that the correct stress involves more than magnitude and area, but also direction, sense, and location.

Fundamental Strain Equations

All electromechanical components deform under load. They may change size, shape, or both.

3.62 RELIABILITY

Normal Strain. Normal strain e_n is defined as a change in length per unit of original length. The uniform bar increased in length by δ when subjected to the normal force P . Therefore, average values for normal strain are defined by

$$e_{s(\text{avg})} = \frac{\delta}{L} = \frac{L_{\text{final}} - L_{\text{initial}}}{L_{\text{initial}}} \quad (2)$$

Shear Strain. Shear strain e_s is defined as change in angle between any two originally perpendicular lengths, measured in radians. A uniform square plate changes in shape when subjected to the shear force S . The square plate becomes a trapezoid under load and forms an interior angle α of less than 90° . Therefore, average values for shear strain are defined in radians by

$$e_{s(\text{avg})} = \frac{\pi}{2} - \alpha \quad (3)$$

When the deformations are small and the angle change is also small, average shear strain can be defined in terms of the shear deformation δ_s ,

$$e_{s(\text{avg})} \geq \tan(e_{s(\text{avg})}) = \frac{\delta_s}{L} \quad (4)$$

COMMONLY USED FORMULAS

Formulas and equations related to tensile and compressive action are given in US MIL-HDBK-5E. Formulas extracted from that handbook are provided on the accompanying CD-ROM, under the heading "Commonly Used Formulas in Electromechanical Reliability Studies."

MECHANICAL FAILURE MODES

This section presents mechanical failure modes that might occur and should be evaluated to ensure that the design has sufficient material strength and adequate margins of safety.

Tensile yield strength failure. This type of failure occurs under pure tension. It occurs when the applied stress exceeds the yield strength of the material. The result is permanent set or permanent deformation in the structural part. This is not generally a catastrophic condition.

Ultimate tensile strength failure. This type of failure occurs when the applied stress exceeds the ultimate tensile strength and causes total failure of the structural part at this cross-sectional point. This is a catastrophic condition.

Compressive failures. Compressive failures are similar to the preceding tensile failures only under compressive loads. They result in permanent deformation or total compressive failure causing cracking or rupturing of the material.

Failures due to shear loading. Yield and ultimate failures occur when the shear stress exceeds the strengths of the material when applying high torsion or shear loads. These failures generally occur on a 45° axis with respect to the principal axis.

Bearing failures. Bearing failures are similar to compressive failures. However, they are generally caused by a round, cylindrical surface bearing on either a flat or a concave surface like roller bearings in a race. Both yield and ultimate bearing stresses should be determined.

Creep and stress rupture failures. Long-term loads generally measured in years cause elastic materials to stretch even though they are below the normal yield strength of the material. If the load is maintained continuously and the material stretches (creeps), it will generally terminate in a rupture. Creep accelerates at elevated temperatures. This results in plastic strain because of creep even though the load is in the elastic region. Creep should always be checked under conditions where high loading for long periods of time are anticipated.

Fatigue failures. Fatigue failures result from repeated loading and unloading of a component. This is a major cause for reducing the design allowable stresses below those listed in the various design tables for static properties. The amount of reduction in the design load is based on complex curves and test data. The amount of load cycling with respect to the maximum load and the number of cycles are the predominant variables. These variables are generally described in Moody diagrams (which relate stress to number of life cycles, $S-N$ curves).

Metallurgical failures. Metallurgical failures are the failures of materials because of extreme oxidation or operation in corrosive environments. Certain environmental conditions accelerate these metallurgical failures. The environmental conditions are: (1) heat, (2) erosion, (3) corrosive media, and (4) nuclear radiation. Therefore, depending on the environment, these conditions should be considered.

Brittle fracture. Certain materials that have little capacity for plastic flow and are generally brittle, such as glass, ceramics and semiconductor materials, are extremely susceptible to surface flaws and imperfections. The material is elastic until the fracture stress is reached. Then the crack propagates rapidly and completely through the component. These fractures can be analysed using fracture mechanics.

Bending failures. A bending failure is a combined failure where an outer surface is in tension and the other outer surface is in compression. The failure can be represented by tensile rupture of the outer material.

Failures from stress concentration. This occurs when there is an uneven stress “flow” through a mechanical design. This stress concentration generally takes place at abrupt transitions from thick gauges to thin gauges, at abrupt changes in loading along a structure, at right angle joints or at various attachment conditions.

Failures from flaws in materials. This is generally because of poor quality assurance or improper inspection of materials, weld and bond defects, fatigue cracks or small cracks and flaws. These reduce the allowable strength of the material and result in premature failure at the flawed location.

Instability failures. Instability failures occur in structural members, such as beams and columns particularly those made from thin material and where the loading is generally in compression. The failure may also be caused by torsion or by combined loading including bending and compression. The failure condition is generally a crippling or complete failure of the structural part.

All of the preceding failure modes should be analyzed as necessary to confirm the adequacy of the mechanical design. It should be noted that some of the analysis is very involved, particularly in the case of combined loads or complex structures. These may require the use of a finite-element computer program.

SAFETY FACTORS AND MARGINS OF SAFETY

In order to design an electromechanical component or system to perform a given function in a reliable manner, the designer must understand all the possible ways the component or system could lose its ability to perform that given function. This requires a complete understanding of how the system or component responds to externally applied loads. With the aforementioned modes of failure established, reasonable limits on load can be defined.

The *safety factor* (SF) is a strength design factor defined by the ratio of a critical design strength parameter (tensile, yield, and so forth) to the anticipated operating stress under normal operating conditions. For example, let F be the strength of the material and f_{mw} be the maximum allowable working stress. Then the factor of safety becomes

$$SF = \frac{F}{f_{mw}} \quad (5)$$

The *margin of safety* (MS) is usually expressed as the maximum allowable working stress (f_{mw}) divided by the applied stress (f) minus 1, as shown in the following equation:

$$MS = \frac{f_{mw}}{f} - 1.0 = \frac{F/SF}{f} - 1.0 \quad (6)$$

This is for a simple unidirectional stress. Any negative value indicates that the structural part will fail because the applied stress is in excess of the allowable material strength.

RELIABILITY PREDICTION TECHNIQUES

With electronic hardware, manufacturers produce millions of similar parts that are then incorporated into thousands of different types of electronic equipment. Billions of hours of operation are accumulated which are used to guess at electronic part failure rates. Because of the many different uses, it is possible to accumulate extensive data, with respect to failure rate, under various environmental, temperature, and electrical stress conditions.

With the exception of nuts and bolts type hardware, electromechanical equipment is designed for a specific configuration and use. There is insufficient quantity of any specific device to accumulate the hours necessary to establish a basic failure rate, or variations caused by different stress levels, environments, and temperature extremes.

A “Probabilistic Stress and Strength Analysis” (p. 3.71) provides techniques for determining structural reliability through the computation of the probability of failure. Although this technique provides a good reliability estimate based on stress and strength, it will be found that to use this method for every electromechanical part of a system would be a long and costly effort.

An alternative approach is failure mode, effects and criticality analysis (FEMCA). This procedure does not consider any failure mechanisms that are not critical to equipment performance, or will not otherwise affect the performance of a prescribed mission. Another method is to establish a reasonable safety factor to minimize the risk of part failure.

There are several methods that can be used to determine the reliability of a electromechanical system. These methods may vary from precise to simple estimates. The precise methods require extensive computations for each element that is used in the electromechanical system. The simple approach uses generic data for each of the parts to obtain an estimated reliability, and as such, does not consider stress levels, temperature extremes, and material strengths. Also, one might use accelerated life testing.

Basic Reliability Definition

In order to use standard exponential reliability formulas, it is necessary to assume that the failure rates of all parts within a given unit are constant, that is, they do not increase or decrease with time. Further, those parts that exhibit a wearout mechanism or otherwise have a limited life are replaced at regular intervals prior to any appreciable increase in failure rate.

As an example, an electronic valve has a constant failure rate of 6.5 failures per 1 million cycles. The mean life is 90,000 cycles. The valve is used in equipment that is to have a 10-year life. On an average, the valve will be activated 10 times per hour throughout the equipment’s life. Therefore, wearout will occur at 9000 h. In order for the 6.5 failures per 1 million cycles for this device to be valid over the 10-year life of the equipment, this device must be scheduled for replacement every year (8760 h), or more frequently, depending on the consequences of its failure.

Methods of Determining Electromechanical System Reliability

To date, no single method or technique has been accepted as the standard for computing the reliability of electromechanical systems. The following paragraphs briefly describe procedures that are used for computing electromechanical systems reliability.

Generic Failure Rate Data

The easiest and most direct approach to computing the reliability of electromechanical hardware is to use the failure rates of generic parts. As an example, it is possible to find the generic failure rate of an electronically activated valve from several sources. There may be many different valve configurations that fit this general or generic description. However, this valve is probably only one part in a much larger electromechanical system. Therefore, by using generic failure rates for all the parts that make up the system, it is possible to determine

which parts will probably be the highest contributors to the system's unreliability. This directs emphasis and design attention to the weak link in the system.

There are several sources of failure rate information with respect to electromechanical hardware. Data sources include:

GIDEP: Government Industry Data Exchange Program

NPRD-95: "Nonelectronic Parts Reliability Data," 1995, Reliability Analysis Center

MIL-HDBK-217F: "Reliability Prediction of Electronic Equipment," Feb. 1995, U.S. Military Handbook

A description of these data source is as follows:

GIDEP Failure Rate Source. GIDEP (<http://www.gidep.org/gidep.htm>) publishes many documents that are continually being updated to provide government and industry with an in-depth perspective of what is currently taking place in practically every technology. Members contribute test data, reports, and other nonrestricted research data and reports.

A GIDEP summary is issued on a yearly basis. The primary drawback to using GIDEP as a source of failure rate data for a part in a specific environment is the lengthy search through computer databases to obtain needed backup data. This is required when environmental conditions differ from the listed environment, or there is an appreciable difference in part application.

NPRD-95. NPRD-95, "Nonelectronic Parts Reliability Data Notebook" (<http://www.rac.iitri.org>), published in 1995 by the Reliability Analysis Center, is a report that is organized into four major sections. It presents reliability information based on field operation, dormant state, and test data for more than 250 major nonelectronic part types. The four sections are Background, Generic Data, Detailed Data, and Failure Modes and Mechanisms. Each device type contains reliability information in relation to specific operational environments. The data presented in this reliability publication are intended to be used as failure rate data, not part replacement data (scheduled maintenance). Only verified failures were used in the calculations of the failure rates.

It is noteworthy that: (1) no attempt has been made to develop environmental factors that allow the use of these failure rates for environmental conditions other than those indicated, (2) no attempt has been made to develop temperature history, (3) no attempt has been made to modify these failure rates for various safety factors or materials.

MIL-HDBK-217F. MIL-HDBK-217F, "Reliability Prediction of Electronic Equipment," Feb. 1995, is a U.S. Military Handbook. It includes 19 sections of various types of electronic parts including seven sections on electromechanical devices. These include: Rotating Devices, Relays, Switches, Connectors, Interconnection Assemblies, Connections, and Meters.

Example Reliability Calculation

Note. To convert failure rate per million cycles to failure rate per million hours, multiply the number of cycles per hour that the device operates times the cycle failure rate.

A pressure regulator failure rate is 34.0 failures/million cycles. It will operate at 200 cycles per hour. Therefore,

$$3.40 \text{ failures}/1,000,000 \text{ cycles} \times 200 \text{ cycles}/\text{hour}$$

$$\text{Failure rate} = 680.0 \text{ failures}/\text{million hours}$$

$$\text{MTBF} = 1/0.000680 = 1470 \text{ h}$$

For a mission time of 500 h, the probability of success (P_s) is

$$P_s = \exp(-500 \times 0.000680) = 0.712 = 71.2 \text{ percent}$$

Remember, generic failure rate sources assume that parts display a constant failure rate.

Computing Electromechanical Systems Reliability

The method of computing the reliability of a electromechanical system, either MTBF or probability of success, will depend on the situation. The reliability can normally be determined, in descending order of preference by:

1. Failure rate models (product multipliers)
2. Probabilistic stress and strength analysis for each part
3. Probabilistic stress and strength analysis for each critical part, with generic data for all others
4. Accelerated life testing
5. Parts count techniques for all parts using NPRD-95 data, GIDEP data, and/or MIL-HDBK-217F

Because of costs and time constraints, technique number 2 is rarely imposed. For critical electromechanical equipment, technique 1 should be required. For the majority of electromechanical systems, technique 1 or 3 is usually acceptable.

The use of the Parts Count Technique greatly simplifies the reliability computations of electromechanical systems. This technique, basically, is to list all electromechanical parts used, determine the generic failure rate for each part in a specific environment, add up the failure rates, and then compute the reliability, either MTBF or probability of success.

The computed value may not be within a factor of 10 of the actual test results. But the exercise will provide trend data and show which are the critical parts.

RELIABILITY PREDICTION USING PRODUCT MULTIPLIERS

Introduction

The accuracy of a reliability prediction using the generic failure rate data bank approach cannot be determined because of the wide dispersion of failure rates that occur for apparently similar components. A better method for predicting the reliability of electromechanical equipment is to use the product multiplier approach.

Variations in failure rates for electromechanical equipment are the result of the following:

Multiple Functions. Individual electromechanical components may perform more than one function.

Nonconstant Failure Rate. Failure rates of electromechanical components are not usually described by a constant failure rate because of wear, fatigue, and other stress-related failure mechanisms resulting in equipment degradation.

Stress History. Electromechanical equipment reliability is more sensitive to loading, operating mode, and utilization rate than electronic equipment reliability.

Criticality of Failure. Definition of failure for electromechanical equipment depends on its application. For example, failure owing excessive noise or leakage cannot be universally established.

The above-listed variables associated with acquiring failure rate data for electromechanical components demonstrates the need for reliability prediction models that do not rely solely on existing failure rate data banks.

Models have been developed that consider the operating environment, the effects of wear and other potential causes of degradation. The models are based on failure modes and their causes. Equations were developed for each failure mode from design information and experimental data. Failure rate models were developed from the resulting parameters in the equations and modification factors were compiled for each variable to reflect its effect on the failure rate of individual electromechanical parts.

Failure rate equations for each part, the methods used to generate the models in terms of failures per hour or failures per cycle and the limitations of the models are presented in the *Navy Handbook of Reliability Prediction Procedures for Mechanical Equipment* (NSWC-92/L01, May 1992).

Failure rate models have been developed for the following categories of electromechanical components and parts. The following are the basis for the fundamental part failures. Each of these are relatively simple. The complex equations should be simplified by holding constant the less important parameters. This will provide ease of calculation.

- Beam: Based on standard beam stress equations
- Shaft: Based on standard shaft stress equations
- Plate: Based on standard plate stress equations
- Spring: Based on standard spring stress equations
- Connector, fitting: Based on standard fitting stress equations
- Structural joint: Based on standard fitting stress equations
- Bearing: As described on p. 3.69
- Gear, spline: Based on standard gear stress equations
- Seal, gasket: As described below
- Solenoid: Based on standard failure rate data
- Motor, pump, compressor, transducer, sensor: Based on standard failure rate data

Failure Rate Model for Seals

A seal is a device placed between two surfaces to restrict the flow of a fluid or gas from one region to another. Static seals, such as gaskets and O-rings, are used to prevent leakage through a mechanical joint when there is no relative motion of mating surfaces other than that induced by environmental changes. The effectiveness of a seal design is determined by the capability of the seal interfaces to maintain good mating over the seal operating environment.

Since the primary failure mode of a seal is leakage, the first step in determining the failure rate of a seal is to isolate each leakage path. In many cases backup seals are used in a valve design and the failure rate is not necessarily proportional to the total number of seals in the valve. Each seal design must be evaluated as a potential internal or external leakage path.

A review of failure rate data suggest the following characteristics be included in the failure rate model for seals:

- Leakage requirements
- Material characteristics
- Amount of seal compression
- Surface irregularities
- Extent of pressure pulses
- Fluid viscosity
- Fluid/material compatibility
- Static versus dynamic conditions
- Fluid pressure
- Seal size
- Quality control/manufacturing processes
- Contamination level

The failure rate of a seal or gasket material will be proportional to the ratio of actual leakage to that allowable under conditions of usage. This rate can be expressed as follows:

$$\lambda_1 = \lambda_{b1} \frac{Q_a}{Q_f} \quad (7)$$

3.68 RELIABILITY

where λ_1 = failure rate of seal or gasket, failures per million cycles
 λ_{b1} = base failure rate of seal or gasket, failures per million cycles
 Q_a = actual leakage rate tendency, in³/min
 Q_f = leakage rate considered to be a device failure, in³/min

The allowable leakage Q_f is determined from design drawings, specifications or knowledge of component applications. The actual leakage rate Q_a for a flat seal or gasket the leakage can be determined from the following equations:

$$Q_a = \frac{2\pi r_1 (P_s^2 - P_o^2)}{24 \nu L P_o} (H^3) \quad (8)$$

where P_s = system pressure, lb/in²
 P_o = standard atmospheric pressure or downstream pressure, lb/in²
 ν = absolute fluid viscosity lb—min/in²
 r_1 = inside radius
 H = conduction parameter, in
 L = contact length

The conduction parameter H is dependent on contact stress, material properties and surface finish. The conduction parameter is computed from the empirically devised formula:

$$H^3 = 10^{-1.1(C/M)} \times f^{1.5} \quad (9)$$

where M = Meyer hardness (or) Young's modulus for rubber resilient materials
 C = apparent contact stress (psi)
 f = surface finish (in)

The surface finish will deteriorate at a rate dependent on the rate of fluid flow and the number of contaminants according to the following relationship:

$$Z \geq f(\alpha \eta Q d t) \quad (10)$$

where Z = seal degradation
 α = contaminant wear coefficient (in³/particle)²
 η = number of contaminant particles per/in³
 Q = flow rate, in³/min
 d = ratio of time the seal is subjected to contaminants under pressure
 t = temperature of operation, °F

The contaminant wear coefficient is a sensitivity factor for the valve assembly based on performance requirements. The number of contaminants includes those produced by wear in upstream components after the filter and those ingested by the system. Combining and simplifying terms provides the following equation for the failure rate of a seal or gasket:

$$\lambda_1 = \lambda_{b1} X_f \left\{ \frac{(P_s^2 - P_o^2) r_1}{Q_f \nu L P_o} (H^3) (\alpha \eta d t) \right\} \quad (11)$$

where λ_b is the base failure rate of a seal owing to random cuts, installation errors, and so forth, based on field experience data.

$$\lambda_1 = \lambda_{b1} \cdot C_P \cdot C_Q \cdot C_D \cdot C_H \cdot C_f \cdot C_V \cdot C_T \cdot C_N \cdot C_W \quad (12)$$

where λ_1 = failure rate of a seal in failures/million cycles

λ_{b1} = base failure rate of seal

C_p = multiplying factor, which considers the effect of fluid pressure on the base failure rate

C_Q = multiplying factor, which considers the effect of allowable leakage on the base failure rate

C_D = multiplying factor, which considers seal size

C_H = multiplying factor, which considers the effect of surface hardness and other conductance parameters on the base failure rate

C_f = multiplying factor, which considers seal smoothness

C_V = multiplying factor, which considers the effect of fluid viscosity on the base failure rate

C_T = multiplying factor, which considers the effect of temperature on the base failure rate

C_N = multiplying factor, which considers the effect of contaminants on the base failure rate

C_W = multiplying factor, which considers the effect of flow rate on base failure rate

Many of the parameters in the failure rate equation can be located on an engineering drawing, by knowledge of design standards or by actual measurement. Other parameters which have a minor effect on reliability are included in the base failure rate as determined from field performance data.

Reliability Prediction of Bearings

From the standpoint of reliability, bearings are by far the most important gear train components, since they are among the few components that are designed for a finite life. Bearing life is usually calculated using the Lundberg-Palmgren method. This method is a statistical technique based on the subsurface initiation of fatigue cracks through hardened air-melt bearing material. Bearing life is generally expressed as the L_{10} life, which is the number of hours at a given load that 90 percent of a set of apparently identical bearings will complete or exceed (10 percent will fail). There are a number of other factors that can be applied to the L_{10} life so that it more accurately correlates with the observed life. These factors include material, processing, lubrication film thickness, and misalignment.

The mean time to failure (MTTF) of a system of bearings can be expressed as

$$\text{MTTF}_B = \frac{L_{10}(5.45)}{N^{0.9}} \quad (13)$$

where MTTF_B = design MTTF for the system of bearings

L_{10} = design life for each individual bearing

N = number of bearings in system

Most handbooks express the L_{10} life of a bearing to be a Weibull distribution as follows (reference "Marks' Handbook," 8th ed., pp. 8–138):

$$L_{10} = \frac{16,700}{\text{RPM}} \left(\frac{C}{P} \right)^k \quad (14)$$

where L_{10} = rated life in revolutions

C = basic load rating, lb (look up value from handbooks)

P = equivalent radial, load, lb

K = constant, 3 for ball bearings, 10/3 for roller bearings

RPM = shaft rotating velocity, rev/min

The above expression assumes a Weibull failure distribution with the shape parameter equal to 10/9, the value generally used for the number N of rolling element applicable bearings. The life (L_{10}) given in Eq. (14) includes the effects of lubrication, material, and misalignment under design conditions in addition to the common parameters. This value will usually suffice during early design. Typical material processing factors used for vacuum-melt aircraft quality bearings are 6.0 for ball bearings and 4.0 for roller and tapered bearings.

3.70 RELIABILITY

These material processing factors should be incorporated into the basic $MTTF_B$ to determine a representative life of these type bearings. These factors should be multiplied times the $MTTF_B$ to get the expected MTTF.

If the bearings being considered are low-speed (under 100 RPM), the $MTTF_B$ should be multiplied by 2 to account for the fact that the lubrication factor is very low.

MEMS Bearings. The bearings used in a MEMS application are likely to have metal on metal sliding friction with little or no lubricant. Wear at the bearing surface should be determined by test. These bearings are, however, often used on lightly loaded gear trains. Higher bearing life is easily achieved in these applications if the loads are balanced by using dual gears or a planetary gear train.

The shaft should be a relatively hard material with the gear or armature having a low coefficient of sliding friction with the shaft. The following is a comparison of friction coefficient for different materials (reference "Marks' Handbook," 8th ed. pp. 3–27):

Nickel on nickel	0.53
Zinc on iron	0.21
Lead on iron	0.43
Aluminum on aluminum	1.40

These numbers are reduced by a factor of 3 (approximately) when a lubricant is used.

Reliability Prediction of Other Wearout Parts

Mathematical models provide the capability of predicting the reliability of all types of electromechanical components.

One can also incorporate time-varying parameters such as wear and wearout. To do this it is necessary to quantify the wear rate. This will provide a time to wearout and a probability failure rate about that wearout failure. This same technique works for fatigue life. The only difference is that strength of the material is changing as a function of stress cycles (time and magnitude of load fluctuation). This can be factored into the equation for determining the fatigue life.

Computer Programs for Determining Failure Rate of Parts

Programs for IBM-compatible PCs are available that will generate failure rate data for various electro-mechanical hardware as described using the product multipliers method.

Mechanical prediction programs are as follows:

MECHREL (mechanical reliability prediction program)

MRP (mechanical reliability prediction program)

RAM commander for Windows

Relex mechanical

MECHREL. Mechanical reliability prediction program performs a mechanical reliability prediction to the component level using the established reliability parameters of electromechanical parts. Environmental and material factors are used in the calculation of base failure rates for the parts. The component failure rates are then summed to give an overall system reliability prediction.

Hard/Software Re.: IBM PC

Supplier: Eagle Technology, Inc. 2300 S. Ninth St., Arlington, VA 22204; Phone: (703) 221-2154

Prices: Public Domain

MRP. Mechanical reliability prediction program addresses the increasing need for predicting failure rates of mechanical equipment. Part of PSI's family of PC-based R&M software. MRP performs reliability prediction

analyses in accordance with the "Handbook of Reliability Prediction Procedures for Mechanical Equipment," Document DTRC-90/010, prepared by the U.S. Navy David Taylor Research Center under sponsorship of agencies of the DoD. In addition to the mechanical handbook, PSI supports the Reliability Analysis Center document NPRD-95, nonelectronic parts reliability data LIB-91, available as an optional library. The computer program enhances your mechanical reliability predictions by including failure rate data published in NPRD-95.

Hard/Software Req.: DOS 3.0 or higher, 512 kb free RAM, 3 MB hard disk space, any printer/132 column

Interface Capabilities: Interfaces with RPP, FME, SRP, LSA, and other forms

Supplier: Powertronic Systems, Inc., 13700 Chef Menteur Hwy., New Orleans, LA 70129; Phone: (504) 254-0383

RAM Commander for Windows. It is a Windows-based reliability, availability, and maintainability (RAM) tool set that implements a wide variety of electronic, electromechanical, and nonelectronic prediction and analysis methods. Robust reliability analysis tools are based on many predictive methods, including graphics engine, large parts library, block diagram modeling, and reliability growth analysis.

Hard/Software Req.: IBM PC or Comp. Intel Pentium, Microsoft Windows

Interface Capabilities: CAD and other RAM packages

Supplier: Advanced Logistics Developments (ALD) Advanced Automation Corp., P.O. Box 4644, Rome NY 13442-4644; Phone: (800) 292-4519

Relex Mechanical. Available for Windows, Mac, and MS-DOS, Relex Mechanical performs reliability analyses on MEMS systems per the "Handbook of Reliability Prediction Procedures for Mechanical Equipment." Its main purpose is to aid the user in evaluating and improving his products' reliability. It provides a state-of-the-art user interface with extensive hypertext help, CAD interface, defaults and derating analysis, system modeling and redundancy capabilities, and much more.

Hard/Software Req.: IBM PC with Windows or Mac

Interface Capabilities: CAD, Text, ASCII, dBase, Lotus, WordPerfect, Paradox

Supplier: Innovating Software Designs, Inc., One Country Drive, Greensburg, PA 15601; Phone: (412) 836-8800

PROBABILISTIC STRESS AND STRENGTH ANALYSIS

Introduction

Probabilistic design can be determined for each type of part. This is determined by taking the basic equation that describes the stresses in the part and performing a Taylor's series expansion on the basic equation. For example, bending stress in a beam would be calculated using the equation MY/I . However, since I and Y are related (not statistically independent) one must use the section modulus (Z). It is very important to use statistically independent variables.

Probabilistic design can be a very important evaluation tool for predicting the probability of failure of an electromechanical system operating in a random loading environment. Ships, airplanes, missiles, and so forth experience random forces that must be considered by the designer during the conceptual phases of the design.

The ultimate design goal would be to manufacture a product that never fails. This, however, is usually not achievable because of other considerations, such as cost and weight, which must be integral parts of any design. However, it may be possible to design a product (or system) that has a low probability of failure and not appreciably impact other design constraints.

Conventional stress analysis does not recognize that material properties, design specifications, and applied loads can be characterized as having a nominal value and some variation. Knowledge of the variables, as well as their statistical properties, will enable the designer to estimate the probability that the part will not fail.

3.72 RELIABILITY

The assumption is made in electromechanical stress and strength analysis that all random variables are statistically independent and are normally distributed. Dependent variables and distributions other than normality are complex to analyze and they usually do not enhance the validity of the analysis.

Statistical Concepts and Principles

Concepts and principles that must be understood to effectively address probabilistic design with respect to the stress-strength relationship are given on the accompanying CD-ROM. See "Concepts and Principles Useful in Electromechanical Stress/Strength Analysis."

CHAPTER 3.5

RELIABLE SYSTEM DESIGN AND MODELING

Ronald T. Anderson, Richard L. Doyle, Stanislaw Kus,

SYSTEM DESIGN

System reliability can be enhanced in several ways. A primary technique is through the application of *redundancy*. Other methods include *design simplification*, *degradation analysis*, *worst-case design*, *overstress analysis*, and *transient analysis*.

Redundancy

Depending on the specific applications a number of approaches are available to improve reliability through redundant design. They can be classified on the basis of how the redundant elements are introduced into the circuit to provide a parallel signal path. There are two major classes of redundancy.

In *active redundancy* external components are not required to perform the function of detection, decision, or switching when an element or path in the structure fails. In *standby redundancy* external elements are required to detect, make a decision, and switch to another element or path as a replacement for a failed element or path.

Techniques related to each of these two classes are depicted in the simplified tree structure of Fig. 3.5.1 Table 3.5.1 further defines each of the eight techniques.

Redundancy does not lend itself to categorization exclusively by element complexity. Although certain of the configurations in Table 3.5.1 are more applicable at the part or circuit level than at the equipment level, this occurs not because of inherent limitations of the particular configuration but because of such factors as cost, weight, and complexity.

Another form of redundancy can exist within normal nonredundant design configurations. Parallel paths within a network often are capable of carrying an added load when elements fail. This can result in a degraded but tolerable output. The allowable degree of degradation depends on the number of alternate paths available. Where a mission can still be accomplished using an equipment whose output is degraded, the definition of failure can be relaxed to accommodate degradation. Limiting values of degradation must be included in the new definition of failure. This slow approach to failure, *graceful degradation*, is exemplified by an array of elements configured to an antenna or an array of detectors configured to a receiver. In either case, individual elements may fail, reducing resolution, but if a minimum number operate, resolution remains good enough to identify a target.

The decision to use redundant design techniques must be based on a careful analysis of the tradeoffs involved. Redundancy may prove the only available method when other techniques of improving reliability have been exhausted or when methods of part improvement are shown to be more costly than duplications. Its use may offer an advantage when preventive maintenance is planned. The existence of a redundant element can

FIGURE 3.5.1 Redundancy techniques.

allow for repair with no system downtime. Occasionally, situations exist in which equipment cannot be maintained, e.g., spacecraft. In such cases, redundant elements may prolong operating time significantly.

The application of redundancy is not without penalties. It increases weight, space, complexity, design, cost, time to design, and maintenance cost. The increase in complexity results in an increase of unscheduled maintenance actions; safety and mission reliability is gained at the expense of logistics mean time between failures (MTBF).

In general, the reliability gain may be minimal for additional redundant elements beyond a few parallel elements. As illustrated in Fig. 3.5.2 for simple parallel redundancy, there is a diminishing gain in reliability and MTBF as the number of redundant elements is increased. As seen for the simple parallel case, the greatest gain, achieved through addition of the first redundant element, is equivalent to a 50 percent or more increase in the system MTBF. In addition to maintenance-cost increases because of the additional elements, reliability of certain redundant configurations may actually be less. This is a result of the serial reliability of switching or other peripheral devices needed to implement the particular redundancy configuration (see Table 3.5.1).

The effectiveness of certain redundancy techniques, especially standby redundancy, can be enhanced by repair. Standby redundancy allows repair of the failed unit (while operation of the unfailed unit continues uninterrupted) by virtue of the switching function built into the standby redundant configuration. The switchover function can also provide an indication that failure has occurred and that operation is continuing on the alternate channel. With a positive failure indication, delays in repair are minimized. A further advantage of switching is related to built-in test (BIT) objectives. Built-in test can be readily incorporated into a sensing and switchover network. Also, the hot swapping of redundant boards or modules minimizes system downtime.

An illustration of the enhancement of redundancy with repair is shown in Fig 3.5.3. The achievement of increased reliability through redundancy depends on effective isolation of redundant elements. Isolation is necessary to prevent failures from affecting other parts of the redundant network. The susceptibility of a particular design to failure propagation can be assessed by application of failure-mode-effects analysis.

Interdependence is most successfully achieved through standby redundancy, as represented by configurations classified as *decision with switching*, where the redundant element is disconnected until a failure is sensed. However, design based on such techniques must provide protection against switching transients and must consider the effects of switching interruptions on system performance.

Furthermore, care must be exercised to ensure that reliability gains from redundancy are not offset by increased failure rates because of switching devices, error detectors, and other peripheral devices needed to implement the redundancy configurations.

Design Simplification

Many complex electronic systems have subsystems or assemblies that operate serially. Many of their parts and circuits are in series so that only one need fail to stop the system. This characteristic, along with the increasing trend of complexity in new designs, tends to add more and more links to the chain, thus greatly increasing the statistical probability of failure.

Therefore, one of the steps in achieving reliability is to simplify the system and its circuits as much as possible without sacrificing performance. However, because of the general tendency to increase the loads on the components that remain, there is a limiting point to circuit simplification. This limit is the value of electrical stress that must not be exceeded for a given type of electrical component. Limit values can be established for

TABLE 3.5.1 Redundancy Techniques

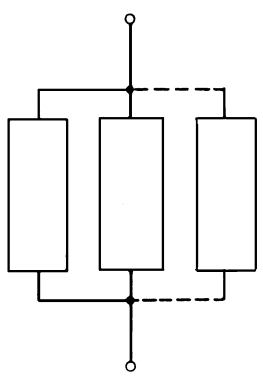

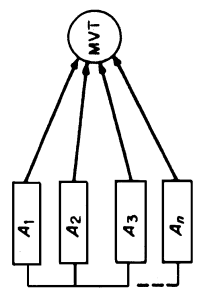

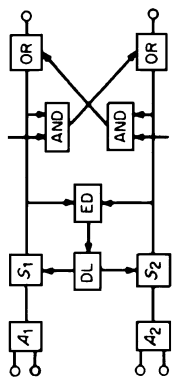

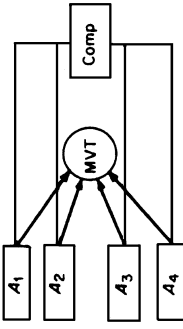

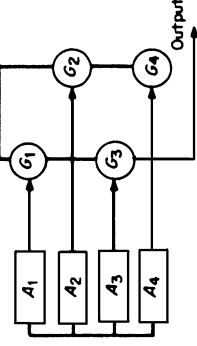

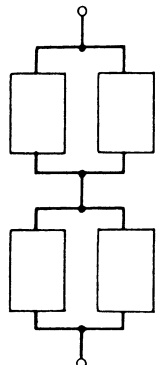

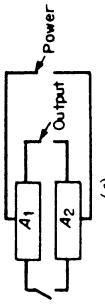

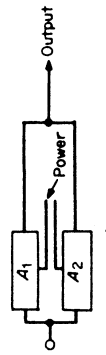

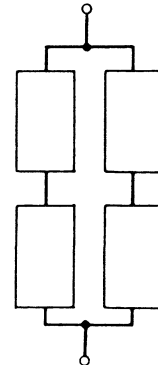

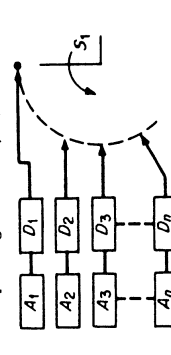

<p>In its simplest form, redundancy consists of a simple parallel combination of elements; if any element fails open, identical paths exist through parallel redundant elements</p> 	<p>Decision can be built into the basic parallel redundant model by inputting signals from parallel elements into a voter to compare each signal with remaining signals; valid decisions are made only if the number of useful elements exceeds the failed elements</p> 
<p>This technique is applied to redundant logic sections, such as A_1 and A_2 operating in parallel; it is primarily used in computer applications where A_1 and A_2 can be used in duplex or active redundant modes or as a separate element; an error detector at the output of each logic section detects noncoincident outputs and starts a diagnostic routine to determine and disable the faulty element</p> 	<p>This technique exemplifies the majority logic configuration with a comparator and switching network to switch out or inhibit failed redundant elements</p> 
<p>Similar to majority voting; redundant elements are generally binary circuits; outputs of the binary elements are fed to switchlike gates, which perform the voting function; the gates contain no components whose failure would cause the redundant circuit to fail; any failures in the gate connector act as though the binary element were at fault</p> 	<p>(Continued)</p>

TABLE 3.5.1 Redundancy Techniques (Continued)

<p>Bimodal parallel-series redundancy</p>  <p>(a)</p>	<p>A series connection of parallel redundant elements provides protection against shorts and opens; direct short across the network because of a single element's shorting is prevented by a redundant element in series; an open across the network is prevented by the parallel element; network (a) is useful when the primary element-failure mode is open; network (b) is useful when the primary element-failure mode is short</p>	<p>Standby redundancy</p>  <p>(a)</p>  <p>(b)</p>	<p>A particular redundant element of a parallel configuration can be switched into an active circuit by connecting outputs of each element to switch poles; two switching configurations are possible: (a) the element may be isolated by the switch until switching is completed and power applied to the element in the switching operation; (b) all redundant elements are continuously connected to the circuit and a single redundant element activated by switching power to it</p>
<p>Bimodal series-parallel redundancy</p>  <p>(a)</p>	<p>In this application, all redundant units operate simultaneously; a sensor on each unit detects failures; when a unit fails, a switch at the output transfers to the next unit and remains there until failure</p>	<p>Operating redundancy</p> 	<p>In this application, all redundant units operate simultaneously; a sensor on each unit detects failures; when a unit fails, a switch at the output transfers to the next unit and remains there until failure</p>

FIGURE 3.5.2 Decreasing gain in reliability as number of active elements increases: (a) simple active redundancy for one of n elements required and (b) incremental increase in system MTBF for n active elements.

various types of components as determined by their failure rates. In addition, it is also clear that the simplified circuit must meet performance criteria under application conditions, e.g., worst-case conditions.

Design simplification and substitution involves several techniques: the use of proved circuits with known reliability, the substitution of highly reliable digital circuitry where feasible, the use of high-reliability integrated circuits to replace discrete lumped-constant circuitry, the use of highly reliable components wherever individual discrete components are called for, and the use of designs that minimize the effects of catastrophic failure modes.

The most obvious way to eliminate the failure modes and mechanisms of a part is to eliminate the part itself. For instance, a digital design may incorporate extraneous logic elements. Minimization techniques, e.g., boolean reduction, are well established and can be powerful tools for incorporating reliability in a design through simplification. Simplification can also include the identification and removal of items that have no functional significance.

In addition, efforts should also be directed toward the reduction of the critical effects of component failures. The aim here is to reduce the result of catastrophic failures until a degradation in performance occurs. As an example, consider Fig. 3.5.4, which illustrates the design of filter circuits. A low-pass design, shown in

FIGURE 3.5.3 Reliability gain for repair of simple parallel redundant elements on failure.

FIGURE 3.5.4 Alternative filter designs: (a) low-pass, (b) high-pass.

Fig. 3.5.4a, can involve either series inductances or shunt capacitances. The latter are to be avoided if shorting is the predominant failure mode peculiar to the applicable capacitor types, e.g., solid tantalum, since a catastrophic failure of the filter could result. Similarly, in the high-pass filter of Fig. 3.5.4b, using a shunt inductor is superior to using a series ceramic capacitor, for which an open is the expected failure mode. Here, the solid-tantalum capacitor, if applicable to the electrical design, could be the better risk, since its failure would result only in noise and incorrect frequency, not a complete loss of signal.

Degradation Analysis

There are basically two approaches to reduce part variation because of aging: control of device changes to hold them within limits for a specified time under stipulated conditions and the use of tolerant circuit design to accommodate drifts and degradation time. In the first category, a standard technique is to precondition the component by burn-in. In addition, there is detailed testing and control of the materials going into the part, along with strict control of fabrication processes.

In the second category, the objective is to design circuits that are inherently tolerant to part parameter change. Two different techniques are the use of feedback to compensate electrically for parameter variations and thus provide for performance stability and the design of circuits that provide the minimum required performance, even though the performance may vary somewhat because of aging. The latter approach makes use of analyses procedures such as worst-case analysis, parameter variation, statistical design, transient design, and stability analysis.

In the design of electronic circuits there are two ways to proceed. One is to view the overall circuit specification as a fixed requirement and to determine the allowable limits of each part parameter variation. Each part is then selected accordingly. The alternative approach is to examine the amount of parameter variation

expected in each part (including the input) and to determine the output under worst-case combination, or other types of combination, e.g., rms or average deviation. The result can be appraised with regard to determining the probability of surviving degradation for some specified period of time. Optimization programs are helpful in both types of design approach.

Worst-Case Analysis

In worst-case analysis, direct physical dependence must be taken into account. For example, if a voltage bus feeds several different points, the voltages at each of the several points should not be treated as variables independent of each other. Likewise, if temperature coefficients are taken into account, one part of the system should not be assumed to be at the hot limit and the other at the cold limit simultaneously unless it is physically reasonable for this condition to occur. A general boundary condition for the analysis is that the circuit or system should be constructed according to its specifications and that the analysis proceeds from there.

In the *absolute worst-case analysis*, the limits for each independent parameter are set without regard to other parameters or to its importance to the system. The position of the limits is usually set by engineering judgment or circuit analysis. In some cases, the designer may perform several analysis with different limits for each case to assess the result before fixing the limits.

Modified worst-case analyses are less pessimistic than absolute worst-case analysis. Typically, the method for setting the limits is to give limits to critical items as in absolute worst-case analysis and to give the rest of the items limits of the purchase tolerance.

In any worst-case analysis, the values of the parameters are adjusted (within the limits) so that circuit performance is as high as possible and then readjusted so it is as low as possible. The values of the parameters are not necessarily set at the limits; the criterion for their values is to drive the circuit performance to either extreme. The probability of this occurring in practice depends on the limits selected by the engineer at the outset, on the probability functions of the parameters, and on the complexity of the system being considered.

Computer Analyses. Computer routines are available for performing these analyses on electronic circuits. Generally speaking, the curve of circuit performance versus each independent parameter is assumed to be monotonic, and a numerical differentiation is performed at the nominal values to see in which direction the parameter should be moved to make circuit performance higher or lower. It is also assumed that this direction is independent of the values of any of the other parameters as long as they are within their limits. If these assumptions are not true, a much more detailed analysis of the equations is necessary before worst-case analysis can be performed. This involves generation of a response surface for the circuit performance which accounts for all circuit parameters.

Overstress and Transient Analysis

Semiconductor circuit malfunctions generally arise from two sources: *transient circuit disturbances* and *component burnout*. Transient upsets are generally overriding because they can occur at much lower energy levels.

Transient Malfunctions. Transients in circuits may prove troublesome in many ways. Flip-flops and Schmitt triggers may be triggered inadvertently, counters may change count, memory may be altered owing to driving current or direct magnetic field effect, one-shot multivibrators may pulse, the transient may be amplified and interpreted as a control signal, switches may change state, and semi-conductors may latch-up in undesired conducting states and require reset. The effect may be caused by transients at the input, output, or supply terminals or combination of these. Transient upset effects can be generally characterized as follows:

1. Circuit threshold regions for upset are very narrow; i.e., there is a very small voltage-amplitude difference between the largest signals which have no probability of causing upset and the smallest signals that will certainly cause upset.
2. The dc threshold for response to a very slow input swing is calculable from the basic circuit schematic. This can establish an accurate bound for transients that exceed the dc threshold for times longer than the circuit propagation delay (a manufacturer's specification).

FIGURE 3.5.5 Square-pulse trigger voltage for typical low-level integrated circuit.

FIGURE 3.5.6 Latch-up response.

3. Transient upsets are remarkably independent in the exact waveshape, depending largely on the peak value of the transient and the length of time over which the transient exceeds the dc threshold. This waveform independence allows relatively easy experimental determination of circuit behavior with simple waveforms such as a square pulse.
4. The input leads or signal reference leads are generally the ones most susceptible to transient upset.

Standard circuit handbook data can often be used to gauge transient upset susceptibility. For example, square-pulse triggering voltage is sometimes given as a function of pulse duration. A typical plot for a low-level integrated circuit is shown in Fig 3.5.5.

Latch-up. There are various ways in which semiconductors may latch-up in undesired conducting states that require reset (power removal). One common situation is shown in Fig. 3.5.6, which shows an open-base transistor circuit with collector current as a function of collector-emitter voltage and the load line for a particular collector resistance. The collector current is normally low (operating point *a*), but a transient can move the operating level to point *b*, where the circuit becomes latched up at a high current level. The signal required to cause this event can be determined by noting that the collector-emitter voltage must be driven above the V_{CEO} (collector-emitter breakdown) voltage.

Another mode of latch-up can occur when a transistor is grown in a semiconductor substrate, e.g., an *npn* transistor in a doped *p*-substrate. Under usual voltage or gamma-radiation stress, the device can act like an SCR device, latching into conduction.

Transient Overstress. Although various system components are susceptible to stress damage, the most sensitive tend to be semiconductor components.

Transient Suppression. There are many techniques available for transient suppression; however, most involve zener diode clamps. Others include some of transistors, SCRs, CMOS, ITL, and diode protection. These techniques are representative of generally applicable methods and are not intended as an exhaustive list.

SYSTEM MODELING

The probability of survival or the reliability function denoted by $R(t)$ is the probability that no failures occur during the time interval $(0, t)$. The most commonly used reliability function is the exponential given by

$$R(t) = e^{-\lambda t} \quad \begin{array}{l} \lambda > 0 \\ t \geq 0 \end{array} \quad (1)$$

The failure density is the negative of the reliability function. For the exponential case the failure density is

$$f(t) = -R'(t) = \lambda e^{-\lambda t} \quad \begin{array}{l} \lambda > 0 \\ t \geq 0 \end{array} \quad (2)$$

The cumulative distribution $F(t)$ is the probability of failure up to time t and is simply given by $1 - R(t)$. For the exponential case where the density exists we have

$$F(t) = 1 - R(t) = \int_0^t f(z) dz = 1 - e^{-\lambda t} \quad \begin{array}{l} \lambda > 0 \\ t \geq 0 \end{array} \quad (3)$$

Thus for the exponential case we have the unique property of having a constant failure function.

In describing the reliability of a complex system the exponential function is rarely appropriate. The reliability function is generally nonexponential because (1) the system is composed of redundant elements (even if each element were itself exponential, the system is no longer exponential), and (2) the system experiences burn-in and wearout properties so that the failure rate is nonconstant. During burn-in the hazard function generally decreases, and during wearout the hazard function generally increases.

For systems formulated as (1), one is given the element reliabilities so that the system reliability can be obtained as a function of them. The particular function obtained depends on the type of redundancy used.

For systems formulated as (2), one is given the hazard function so that reliability is obtained as the solution of the linear differential equation

$$R(t) = -h(t)R(t) \quad \begin{array}{l} R(0) = 1 \\ t \geq 0 \end{array} \quad (4)$$

The solution of Eq. (4) is

$$R(t) = \exp\left(-\int_0^t h(z) dz\right) \quad t \geq 0 \quad (5)$$

In general, $h(t)$ need only be piecewise continuous. If failure time is truncated at $t = L$, then $R(t)$ is continuous in the half-open interval $(0, L)$ and the hazard function is not defined at $t = L$.

Reliability for a system is defined here as the product of individual module or branch reliabilities, where each module or branch reliability is made up of reliability functions described in categories (1) and/or (2).

Module-Reliability Models

This section describes various reliability models currently available. The models are developed at the module level, and the system reliability is the product of these module and branch reliabilities. Branch reliabilities are described later. The set of module reliabilities is not exhaustive; others may be developed.

Model 1: Active Exponential Redundant Reliability. There are n elements in parallel, each element is active with an identical exponential reliability. The module reliability is then

$$R(t) = 1 - (1 - e^{-\lambda t})^n \quad (6)$$

Equation 6 is simply 1 minus the probability that all n elements fail. The symbol λ is the failure rate of the exponential reliability model and is used in the models that follow whenever the exponential reliability model is assumed.

Model 2: Standby Exponential Redundant Reliability. There are n elements in parallel, each element in standby until called upon to operate. Each element has an identical exponential reliability and does not experience any degradation while on standby. The module reliability is then

$$R(t) = \sum_{x=0}^{n-1} \frac{e^{-\lambda t} (\lambda t)^x}{x!} \quad (7)$$

Model 3: Binomial Exponential (Active) Redundancy Reliability. There are n elements of which c are required to function properly for the module. Each element is assumed active with an identical exponential reliability. The module reliability is given by the binomial sum

$$R(t) = \sum_{x=c}^n \binom{n}{x} (e^{-\lambda t})^x (1 - e^{-\lambda t})^{n-x} \tag{8}$$

In Eq. (8) the variable x is interpreted as the number of successes. If we define N ($N = c, c + 1, \dots$) as the number of trials until c successes occur, we have the negative binomial sum for module reliability

$$R(t) = \sum_{N=c}^n \binom{N-1}{c-1} (e^{-\lambda t})^c (1 - e^{-\lambda t})^{N-c} \tag{9}$$

If we further define $y = N - c$ ($y = 0, 1, 2, \dots$) as the number of failures until c successes occur, we have an alternate form of the negative binomial sum for module reliability

$$R(t) = \sum_{y=0}^{n-c} \binom{c+y-1}{y} (e^{-\lambda t})^c (1 - e^{-\lambda t})^y \tag{10}$$

Model 4: Standby Exponential Redundant Reliability with Exponential Standby Failure. There are n elements in parallel standby as in model 2, but it is further assumed that the elements in standby have an exponential standby reliability with failure rate λ . Thus, each element has in addition to an identical exponential operational reliability an identical exponential standby reliability. The module reliability is then

$$R(t) = e^{-\lambda t} \sum_{x=1}^n \frac{(1 - e^{-\mu t})^{x-1} \Gamma(\beta + x - 1)}{\Gamma(x)\Gamma(\beta)} \tag{11}$$

where $\beta = \lambda/\mu$.

The special case for $\mu = 0$ (no standby failure) given as Eq. (7) is obtained from Eq. (11) by taking its limit as $1/\beta \rightarrow 0$.

Model 5: Open-Close Failure-Mode Exponential Redundant Reliability. There are n elements in series in each of m parallel lines, as shown in Fig 3.5.7. The reliability of the module illustrated is

$$R(t) = (1 - Q_b^m)^n - (1 - R_a^m)^n \tag{12}$$

where $Q_b = (1 - R_b) = q_b(1 - e^{-\rho t})$ $Q_a = (1 - R_a) = q_a(1 - e^{-\rho t})$

and where q_b = conditional probability of failure to close (valve) or failure to open (switch) given system failure = μ/ρ , q_a = conditional probability of failure to open (valve) or failure to close (switch) given system failure = λ/ρ , and $\rho = \lambda + \mu$. There is a total of nm elements in the module A configuration dual to the module illustrated in Fig. 3.5.7 is the “bridged” module, which is the same as that in Fig. 3.5.7 except that the dashed vertical lines are now made solid so that the module units are bridged. For this dual module the reliability is

$$R(t) = (1 - Q_a^m)^n - (1 - R_b^m)^n \quad R_b \geq Q_a \tag{13}$$

FIGURE 3.5.7 General open-close failure system.

Model 6: Gaussian Redundant Reliability. There are n identical Gaussian elements in standby redundancy, so that if t_i is the failure time of the i th elements, the module failure time is

$$t = \sum_{i=1}^n t_i \tag{14}$$

The individual elements are independent Gaussian with mean μ_0 and variance σ_0^2 . The module then is also Gaussian with mean and variance

$$\mu = n\mu_0 \quad \sigma^2 = n\sigma_0^2$$

The module reliability is therefore given by

$$R(t) = \frac{c}{\sqrt{2\pi\sigma}} \int_t^\infty e^{-(1/2)\sigma^2(x-\mu)^2} dx \quad t \geq 0 \tag{15}$$

where $c = 1/R(0)$

Model 7: Bayes Reliability for Inverted Gamma Function. The module reliability for a single standby element is given by

$$R(t) = R_1(t) + \int_0^t f_1(t_1)R_2(t-t_1)R_{2s}(t_1)dt_1 \tag{16}$$

- where $R_i(t)$ = reliability of i th element, $i = 1, 2$
- t_1 = failure time of first element ($i = 1$)
- $f_1(t)$ = failure density of first element [$= -R_1'(t)$]
- $R_{2s}(t)$ = reliability of second element in standby mode

Equation (16) is a general formulation of the two-element standby reliability in the sense that the element reliabilities are general. In particular, for the case where the reliabilities are exponential, Eq. (16) reduces to Eq. (11) for $n = 2$. For the case considered here it is assumed that the reliabilities are Bayesian estimates of

3.84 RELIABILITY

reliability where the mean-time-to-failure parameter of the exponential has an inverted gamma density. The reliabilities are given by

$$R_j(t) = \left(1 + \frac{t}{T + \mu}\right)^{-(r+v)} \quad j = 1, 2 \quad (17)$$

and

$$R_{2s}(t) = \left(1 + \frac{t}{T + \mu'}\right)^{-(r+v')} \quad (18)$$

where T = test time

r = number of failures in time T

μ , v , μ' , and v' = inverted gamma parameters

It is noted in Eqs. (17) and (18) that both elements have the same active reliability. In the application of this model the parameters are modeled as follows:

$$\mu = K\theta_A \left(1 + \frac{1}{W^2}\right) \quad v = \left(2 + \frac{1}{W^2}\right) \quad \text{or} \quad \mu' = \mu/K_1 \quad v' = v \quad (19)$$

where K and W are the scale factors on the mean and standard deviation of the a priori mean time to failure (inverted-gamma) variable and K_1 is the ratio between the means for the active and standby reliabilities. when $K = 1$, the mean is equal to θ_A , and when $W = 1$, the standard deviation is equal to $K\theta_A$. The relations of Eqs. (17) and (18) define a specific application of Eq. (16).

Model 8: Reliability Model for Weibull Distribution. The Weibull reliability model is presented in Chap. 3.3 (see "Failure Time Distributions"). Also related to the Weibull distribution is "Specific Hazard Rate Model," also in Chap. 3.3.

Model 9: Accelerated Life Model for all Distribution. The accelerated life model is presented in Chap. 3.3. This model is a function of temperature and time.

Model 10: Reliability Model for Hazard Function Compound of Three Piecewise Continuous Functions. The general reliability model considered here is for the hazard function described in Chap. 3.3.

$$\lambda(t) = \begin{cases} h_1(t) & 0 \leq t < t_1 \\ h_2(t) & t_1 \leq t < t_2 \\ h_3(t) & t_2 \leq t < \infty \end{cases} \quad (20)$$

The particular case considered here is where h_1 and h_3 are Weibull hazard functions and h_2 is the exponential hazard function. Further, it is assumed that the hazard function is continuous at the transit t_1 and t_2 so that we have

$$\begin{aligned} h_1(t) &= \alpha_1 \lambda_1 t^{\alpha_1 - 1} & 0 \leq t < t_1 \\ h_2(t) &= \lambda & t_1 \leq t < t_2 \\ h_3(t) &= \lambda_2 \lambda_2 t^{\alpha_2 - 1} & t_2 \leq t < \infty \end{aligned} \quad (21)$$

FIGURE 3.5.8 Branch system *a* consisting of a model 3 module.

FIGURE 3.5.9 Branch system *b* consisting of models 3, 4, and 8.

where

$\alpha_1, \alpha_2, t_1, t_2,$ and λ are input parameters

$$\lambda_i = \frac{\lambda}{\alpha_i t_i^{\alpha_i - 1}} \quad i = 1, 2$$

Model 11: Tabular Reliability Model. An arbitrary reliability function can be evaluated as an input table of reliability versus time. For each output time, reliability is obtained by interpolation of the input table. This capability is useful as an approximation to a complex reliability model and is also useful in evaluating a reliability function that is available as a plot or a table for which no mathematical model is available.

Model 12: Active Exponential Redundant Reliability with Different Redundant Failure Rate. There are n elements in parallel. The original c elements are exponential each with failure rate λ . The $n - c$ remaining exponential elements in active parallel with the original elements each have failure rate μ . The module reliability is

$$R_s(t) = 1 - (1 - e^{-\lambda t})^c (1 - e^{-\mu t})^{n-c} \tag{22}$$

Branch-Reliability Models

A branch-reliability model is a model that evaluates reliability (at each instant in time) for a set of modules arranged in branches. Each branch individually consists of a set of modules. In particular, a branch may be a module itself. Some typical branches are shown in Figs. 3.5.8 to 3.5.10 and are identified as branches *a*, *b*, and *c*, respectively.

FIGURE 3.5.10 Branch system *c* consisting of models 1 and 6.

Branch system *a* is simply a module. Branch system *c* is a branch consisting of two modules in series and can be evaluated as two separate modules. Branch system *b* is made up of two subbranches in parallel.

A more complex branch system consisting of subbranch systems *a*, *b*, and *c* is shown in Fig. 3.5.11. Branches *a* and *b* are in series in active redundancy to branch system *c*.

Although the reliability functions for particular branch models are not developed here, clearly it is possible, and a generalized computer program based on both module and branch models can be developed.

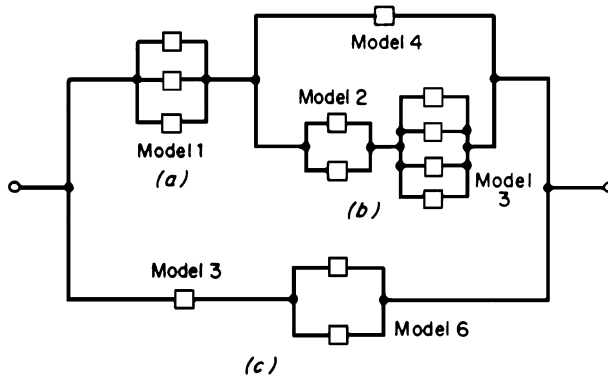

FIGURE 3.5.11 System consisting of branch systems shown in Figs.

The Systems Model

The system reliability model is obtained as the product of the individual branch reliabilities. In addition, the branch reliabilities are multiplied by a system exponential reliability factor and a constant factor; thus

$$R_s(t) = P_0 e^{-\lambda_s t} \prod_{i=1}^{K'} R_i(t) \quad (23)$$

where λ_s = exponential hazard function for system elements not included in branches

P_0 = system reliability factor

$R_i(t)$ = i th branch reliability, $i = 1, 2, \dots, K'$

K' = number of branches in series

CHAPTER 3.6

SOFTWARE RELIABILITY

Samuel Keene, Allen Nikora

INTRODUCTION AND BACKGROUND PERSPECTIVE

This chapter describes software reliability, how it can be measured, and how it can be improved. Software is a script written by a programmer dictating how a system will behave under its anticipated operating conditions (called its *main line* function). These conditions are sometimes referred to as “sunny day operations.” This part of the software has been tested extensively by the time it is shipped. Problems typically arise in handling program exceptions or branching conditions when these were not properly accounted for in its original design. For example, a planetary probe satellite was programmed to switch over to its backup power system if it did not receive any communications from the ground for a 7-day period. It was assumed that such lack of communication would imply a disruption in the satellite communications power system. The strategy was to switch over to the backup power supply. This switching algorithm was built into the software. In the second decade following launch, the ground crews inadvertently went 7 days without communicating to the probe. The satellite followed its preprogrammed instructions and switched the system over to backup power, even though the main-line system was still functioning. Unfortunately the standby system was not. So the logical error led to switching the satellite into a failed state. The satellite program was just doing what it had been told to do more than 10 years earlier.

There are many everyday analogies to software faults and failures. Any transaction having residual risks and uncertainties has a counterpart in software reliability. A real estate contract could include a flaw in the title: the house might encroach on an easement, be in a floodplain, or be flawed in its construction. Prudent parties seek to avoid such faults or their likelihood and build defenses against their occurrences. Likewise, a prudent programmer will think proactively to deal with contingent conditions and thereby mitigate any adverse effects.

Managing the programming consistencies problem is exacerbated in developing large programs. This might be considered analogous to achieving a consistent script with 200 people simultaneously writing a novel. There are many opportunities for disconnects or potential faults.

Twenty years ago, software was typically assumed to be flawless. Its reliability was considered to be 1.0. Nothing was thought to break or wear out. Hardware problems dominated systems reliability concerns. Software (and firmware) has now become ubiquitous in our systems and is most often seen as the dominant failure contributor to our systems. For example, the infamous Y2K bug has come and passed. This bug came about because programmers’ thought-horizon did not properly extend into the new millenium. When the clock rolled over into the twenty-first century, software that thought the date was 1900 could disastrously fail. Fortunately, its impact was less than forecasted. Problem prevention has cost about \$100B worldwide, which is significantly less than many forecasters predicted (<http://www.businessweek.com/1999/02/b3611168.htm>). Hopefully programmers, or information technology (IT) people, have learned from this traumatic experience. Y2K has sensitized the general public to the greater potential impact of software failures.

Imagine what might have happened if this problem caught us unawares and took its toll. Life as we know it could have been shocked. For example, disruptions could impact supermarket scanners and cash registers. Our commerce could have been foiled by credit cards not functioning.

The use of embedded dates in software is pervasive. There are five exposure areas related to the Y2K or date related type of problem:

1. Operating system embedded dates
2. Application code embedded dates
3. Dates in the embedded software
4. Data (with potential command codes such as 9999 used as a program stop)
5. Dates embedded in interfacing commercial off the shelf (COTS) software

The Y2K software audits had to examine all the above five potential fault areas to ensure that the software was free of the date fault. This type of problem can only be avoided by fully developing the program requirements; this means defining what the program *should not do* as well as what it *should do*. The program requirements should also specify system desired behavior in the face of operational contingencies and potential anomalous program conditions. A good way to accomplish this is by performing failure modes and effects analysis (FMEA) on the high-level design (<http://www.fmeainfocentre.com>). This will systematically examine the program responses to aberrant input conditions.

Good program logic will execute the desired function without introducing any logical ambiguities and uncertainties. For example, some different C compilers use different order of precedence in mathematical operations. To ensure proper compiling, it is best to use nested parentheses to ensure the proper order of mathematical execution.

We now have an IT layer that surrounds our life and which we depend on. Internet use is pervasive and growing. Our offices, businesses, and personal lives depend on computer communications. We feel stranded when that service is not available, even for short periods. The most notorious outage was the 18-h outage experienced by AOL users in August 1996 (<http://www.cnn.com/TECH/9608/08/aol.resumes>). This resulted from an undetected operator error occurring during a software upgrade. The cause of failure was thought to be solely because of the upgrade. This confounding problem misled the analysts tracking the problem. Thus, 18 h were required to isolate and correct the problem.

More importantly, many of our common services depend on computer controllers and communications. This includes power distribution, telephone, water supply, sewage disposal, financial transactions, as well as web communications. Shocks to these services disrupt our way of life in our global economy. We are dependent on these services being up and functioning. The most critical and intertwining IT services that envelop our lives, either directly or indirectly are:

1. Nuclear power
2. Medical equipment and devices
3. Traffic control (air, train, drive-by-wire automobiles, traffic control lights)
4. Environmental impact areas (smoke stack filtration)
5. Business enterprise (paperless systems)
6. Financial systems
7. Common services (water, sewer, communications)
8. Missile and weapons systems
9. Remote systems (space, undersea, polar cap, mountain top)
10. Transportation (autos, planes, subways, elevators, trains, and so forth)

SOFTWARE RELIABILITY DEFINITIONS AND BASIC CONCEPTS

Failures can be defined as the termination of the ability of a functional unit to perform its required function. The user sees failures as a deviation of performance from the customer's requirements, expectations, and needs. For example, when a word-processing system locks up and doesn't respond, that is a failure in the eyes

of the customer. This is a failure of commission. A second type of failure occurs when the software is incapable of performing a needed function (failure of omission). This usually results from a “breakdown” in defining software requirements, which often is the dominant source of software and system problems. The customer makes the call as to what constitutes a failure. A failure signals the presence of an underlying fault. Faults are a logical construct (omission or commission) that leads to the software failure. Hardware faults can sometimes be corrected or averted by making software changes on a fielded system. The system software changes are made when they can be done faster and cheaper than changing the hardware.

Faults are in correct system states that lead to failure. They result from *latent defects* (these defects are hidden defects, whereas *patent* defects can be directly observed). The first time the newly developed F-16 fighter plane flew south of the equator, the navigational system of the plane caused it to flip over. This part of the navigational software had never been exercised prior to this trial. In the Northern Hemisphere, there was no problem. A fault is merely a susceptibility to failure, it may never be triggered and thus a failure may never occur.

Fault triggers are those program conditions or inputs that activate a fault and instigate a failure. These failures typically result from untested branch, exception, or system conditions. Such triggers often result from unexpected inputs made to the system by the user, operator, or maintainer. For example, The user might inadvertently direct the system to do two opposing things at once such as to go up and go down simultaneously. These aberrant or off-nominal input conditions stress the code robustness. The *exception-handling* aspects of the code are more complex than the operational code since there are a greater number of possible operational scenarios. Properly managing exception conditions is critical to achieving reliable software.

Failures can also arise from a program navigating untested operational paths or sequences that prove stressful for the code. For example, some paths are susceptible to program timing failures. In these instances the desired sequence of program input conditions may violate the operational premise of the software and lead to erroneous output conditions. Timing failures are typically sensitive to the executable path taken. There are so many sequences of paths through a program that they are said to be *combinatory-explosive*. For example, 10 paths taken in random sequence lead to 2^{10} or 1024 combinations of possible paths. Practical testing considerations limit the number of path combinations that can be tested. There will always be a residual failure risk posed by the untested path combinations.

Errors are the inadvertent omissions or commissions of the programmer that allow the software to misbehave, relative to the user’s needs and requirements. The relationship between errors, faults, and failures is shown in Fig. 3.6.1.

Ideally, a good software design should correctly handle all inputs under all environmental conditions. It should also correctly handle any errant or off-nominal input conditions. An example of this is can be demonstrated in the following simple arithmetic expression:

$$A + B = C \quad (1)$$

This operation is deterministic when the inputs A and B are real numbers. However, what program response is desired when one of the inputs is unbounded, missing, imaginary, or textural? That is, how should the program handle erroneous inputs? Equation (1) would function best if the program recognized the aberrant condition. Then the software would not attempt to execute the program statement shown above but it would report the errant input condition back to the user. Then this code would be handling the off-nominal condition in a robust manner. It would behave in the manner that the user would desire.

The main line code usually does its job very well. Most often, the main line code is sufficiently refined by the extensive testing it has undergone. The software failures or code breakdowns occur when the software exception code does not properly handle a rarely experienced and untested condition. More frequently the failure driver or trigger is an abnormal input or environmental conditions. An example of a rarely occurring or unanticipated condition was the potential problems posed for programs, failing to gracefully handle the millennium clock rollover. A classic example of improperly handling an off-nominal condition was the infamous

FIGURE 3.6.1 The logical path to software failures.

3.90 RELIABILITY

“Malfunction 54” of the Therac 25 radiation therapy machine. It allowed patients to be exposed to potentially lethal radiation levels because the software controls did not satisfactorily interlock the high-energy operating system mode following a system malfunction. The operator had a work-around that allowed the radiation therapy machine to function but unknown to the operator; the work-around defeated the software interlock.

There is a software development discipline that directly addresses the proper handling of branching and exception conditions. That is the so-called “Clean Room” software design (<http://www.dacs.dtic.mil/databases/url/key.hts?keycode=64>). It directly ensures validating the branches and exception conditions by routinely checking the exception conditions before it performs the main line operational function. It does these checks at each operational step throughout the program.

System Management Failures

Murphy reports that the biggest cause of problems for modern software stem from either requirements’ deficiencies or improperly understood system interfaces [Murp95]. These are communications-based problems, which he labels as *system management* failures. An example of this occurred when the Martian probe failed in the fall of 1999 (<http://mars.jpl.nasa.gov/msp98/orbiter/>). This failure was because of at least a couple of system management problems. First, there was a reported break down in communications between the propulsion engineers and the navigation scientists, at a critical point in the design cycle. They were working under different assumptions that compromised design reliability. Second, the newspaper headlines publicized another program communication problem. NASA and its contractor had unconsciously been mixing metric and British dimensional units. The resulting tower of Babel situation helped misguide the \$125 million dollar space probe.

System management problems are truly communication problems. This author has been a life-long student of system failures (and successes). Today, for the most part, hardware is reliable and capable. Almost all significant system problems are traceable to a communications break down or too limited design perspective on the programmer or designer’s part. Also, it needs to be recognized that programmers typically lack the “domain knowledge” of the application area for which they are designing the controlling software. For example, the programmers know the C language or JAVA but they are challenged when it comes to understanding the engineering aspects of a rocket control system. The system development people need to recognize these limitations and be proactive supporting program requirements development.

Failure Modes and Effects Analysis

A FMEA on the new software can also help to refine requirements. This analysis will help focus what the software is expected or desired to do as well as what behaviors are not desired. The software developer is first asked to explain the software’s designed functionality. Then the person performing the FMEA will pose a set of abnormal input conditions that the software should handle. The software designer has been focusing on the positive path and now FMEA rounds out the remainder of the conditions that the software must accommodate. Dr. Keene has found design FMEA analysis, nominally takes two hours working directly with the software developer. This analysis has always led to the developer making changes to make the design more robust.

Code Checking and Revision

Designers must consider the possibility of off-nominal conditions that their codes must successfully handle. This is a proactive or defensive design approach. For example, in numeric intensive algorithms, there is always the possibility of divide-by-zero situations where the formula would go unbounded. When many calculations are involved or when one is dealing with inverting matrices, a divide-by-zero happens too frequently. The code can defend itself by checking the denominator to ensure that it is nonzero before dividing. There is a performance cost to do this operation. It is best when the designer is aware of the exposures and

TABLE 3.6.1 Some Typical Fault Tolerance Programming Considerations

-
1. How will you detect a failure in your module? Programmed exception handling or abort with default exception handling?
 2. Will you detect out-of-range data?
 3. How will you detect invalid commands?
 4. How will you detect invalid addresses?
 5. What happens if bad data are delivered to your module?
 6. What will prevent a divide-by-zero from causing an abort?
 7. Will there be sufficient data in a log to trace a problem with the module?
 8. Will the module catch all its own faults? (What percentage detection and unambiguous isolation?)
 9. Do you have dependencies for fault detection and recovery on other modules or the operating system?
 10. What is the probability of isolating faults to the module? Line of code?
 11. Does your module handle “exceptions” by providing meaningful messages to allow operator-assisted recovery without total restart?
-

the tradeoffs. A sample list of fault-tolerance considerations that can be applied to the design process is shown in Table 3.6.1.

Code changes are best made at planned intervals to ensure proper review, inspection, integration, and testing to ensure the new code fits seamlessly into the architecture. This practice precludes “rushed” changes being forced into the code. The new code changes will be regression tested through the same waterfall development process (requirements validation, high-level code inspection, low-level code inspection, unit test, software integration and test, and system test) as the base code. This change process preserves the original code development quality and maintains traceability to the design requirements. Using prototype releases and incremental releases helps reveal and refine program requirements. The spiral development model promotes progressive software validation and requirements refinement.

SOFTWARE RELIABILITY DESIGN CONSIDERATIONS

Software reliability is determined by the quality of the development process that produced it. Reliable code is exemplified by its greater understandability. Software understandability impacts the software maintainability (and thus its reliability). The architecture will be more maintainable with reliable, fault-free code requiring minimal revision. The software developer is continually refining (maintaining) the code during development and then the field support programmer maintains the code in the field.

Code reliability is augmented by:

1. Increased cohesion of the code modules
2. Lowered coupling between modules, minimizing their interaction
3. Self describing, longer variable, mnemonic names
4. Uniform conventions, structures, naming conventions and data descriptions
5. Code modularity optimized for understandability while minimizing overall complexity
6. Software documentation formatted for greatest clarity and understanding
7. Adding code commenting to explain any extraordinary programming structures
8. Modular system architecture to provide configuration flexibility and future growth
9. Restricting a single line of code to contain only a single function or operation
10. Avoiding negative logic; especially double negative logic in the design
11. Storing any configuration parameters expected to change in a database to minimize the impacts of any changes on the design
12. Ensuring consistency of the design, source code, notation, terminology, and documentation

13. Maintaining the software documentation (including flow charts) to reflect the current software design level
14. Harmonizing the code after each modification to ensure all the above rules are maintained

There are also aging conditions in software that make it prone to failure. This occurs as its operating environment entropy increases. Consider the case of a distributed architecture air defense system, which had reconnaissance satellite receivers distributed across the country. These receivers experienced random failures in time. On one occasion the entire countrywide system was powered down and reset at one time. This system synchronization revealed an amazing thing. When the satellite receivers failed, they all failed simultaneously. Synchronizing the computer applications revealed and underlying common fault. A data buffer was tracking some particular rare transactions. It processed them and then passed them along. This register maintained a stack of all its input data, never clearing out the incoming data. So its overflow was inevitable. This overflow was a rare event but the fault was strongly revealed once the system was synchronized.

Computer System Environment

Software reliability is strongly affected by the computer system environment (e.g., the length of buffer queues, memory leaks, and resource contention). There are two lessons learned from software-aging considerations. First, software testing is most effective (likely to reveal bugs) when the distributed software are synchronously aged, i.e., restarted at the same time. To the other extreme, the distributed assets in the operational system will be more reliable if they are asynchronously restarted. Then processors are proactively restarted at advantageous intervals to reset the operating environment and restore the system entropy. This is called “software rejuvenation,” or averting system “state accretion failures” (<http://www.software-rejuvenation.com>). The system assets will naturally age asynchronously as the software assets are restarted following random hardware maintenance activities. The software running asynchronously helps preserve the architectural redundancy of system structure where one system asset can backup others. No redundancy exists if the backup asset concurrently succumbs to the same failure as the primary asset. Diversity of the backup asset helps preclude common-mode failures.

Software and system reliability will be improved by:

1. Strong and systematic focus on requirements development, validation, and traceability with particular emphasis on system management aspects. Full requirements development also requires specifying things the system should not do as well as those desired actions. For example, heat-seeking missiles should not boomerang and return to the installation that fired them. Quality Functional Development (QFD) is one tool that helps ensure requirement completeness, as well as fully documenting the requirements development process (<http://www.shef.ac.uk/~ibberson/QFD-Introduction.html>).
2. Institutionalizing a “Lessons Learned” database and using it to avoid past problems and mitigating potential failures during the design process, thinking defensively, examining how the code handles off-nominal program inputs, designing to mitigate these conditions.
3. Prototype software releases are most helpful in clarifying the software’s requirements. The user can see what the software will do and what it will not do. This operational prototype helps to clarify the user’s needs and the developer’s understanding of the user’s requirements. Prototypes help the user and the developer gather experience and promote better operational and functional definition of the code. Prototypes also help clarify the environmental and system exception conditions that the code must handle. To paraphrase an old saying, “a prototype (picture) is worth a thousand words of a requirements statement,” the spiral model advocates a series of prototypes to recursively refine the design requirements (<http://www.sei.cmu.edu/cbs/spiral2000/february2000/Boehm>).
4. Building in diagnostic capability. Systems’ vulnerability is an evidence of omissions in our designs and implementation. Often we fail to include error detection and correction (EDAC) capability as high-level requirements. The U.S. electrical power system, which is managed over a grid system, is able to use its atomic clocks for EDAC. These clocks monitor time to better than a billionth of a second. This timing capability’s primary purpose is for proper cost accounting of power consumption. This timing capability

provides a significant EDAC tool to disaggregate failure events that used to appear simultaneous. These precise clocks can also time reflections in long transmission lines to locate the break in the line to within 100 m. The time stamps can also reveal which switch was the first to fail over, helping to isolate the root failure cause.

5. Performing a potential failure modes and effects analysis to harden the system response to properly deal with abnormal input conditions.
6. Failures should always be analyzed down to their root cause for repair and prevention of their reoccurrence. To be the most proactive, the system software should be parsed to see if other instances exist where this same type failure could result. The space shuttle designers did an excellent job of leveraging their failures to remove software faults. In one instance, during testing, they found a problem when system operations were suspended and then the system failed upon restarting the system. Their restart operation, in this instance, somehow violated the original design conception. The system could not handle this restart mode variation and it “crashed.” This failure revealed an underlying fault structure. The space shuttle program parsed all 450 KSLOC of operational on board code. Then two other similar fault instances were identified and removed. So, in this instance, a single failure led to the removal of three design faults. This proactive fault avoidance and removal process is called the “Defect Prevention Process (DPP).” DPP was the cornerstone of the highly reliable space shuttle program (<http://www.engin.umd.umich.edu/CIS/course.des.cis565/lectures/sep15.html>).
7. Every common mode failure needs to be treated as critical, even if its system consequence is somehow not critical. Every thread that breaks the independence of redundant assets needs to be resolved to its root cause the remedied.
8. Studying and profiling the most significant failures. Understanding the constructs that allowed the failure to happen. Y2K is an example of a date defect. One should then ask if other potential date roll over problems existed. The answer is yes. For example, the global positioning system (GPS) clock rolled over August 22, 1999. On February 29, 2000, the Leap Year exception had to be dealt with. Here one failure can result in identifying and removing multiple faults of the same type.
9. Performing fault injection into systems, as part of system development, to speed the maturity of the software diagnostic and fault-handling capability.

Change Management

Operational reliability requires effective change management: Beware small changes can have grave consequence. All too often, small changes are not treated seriously enough. Consequently, there is significant error proneness in making small code changes.

Defect rate:	1 line	50 percent
	5 lines	75 percent
	20 lines	35 percent

The defects here are any code change that results in anomalous code behavior, i.e., changes causing the code to fail. Often, small changes are not given enough respect. They are not sufficiently analyzed or tested. For example, DSC Communications Corp., the Plano Texas Company, signaling systems were at the heart of an unusual cluster of phone outages over a two-month period of time. These disruptions followed a minor software modification. The Wall Street Journal reported, “Three tiny bits of information in a huge program that ran several million lines were set incorrectly, omitting algorithms—computation procedures—that would have stopped the communication system from becoming congested, with messages. . . . Engineers decided that because the change was minor, the massive program would not have to undergo the rigorous 13-week (regression) test that most software is put through before it is shipped to the customer.” Mistake!

Post-release program changes increase the software’s failure likelihood. Such changes can increase the program complexity and degrade its architectural consistency. Because credit card companies have most of their volume between November 15 and January 15 each year, they have placed restrictions on telephony changes during that time period, to limit interruptions to their business during the holiday period.

EXECUTION-TIME SOFTWARE RELIABILITY MODELS

After the source code for a software system has been written, it undergoes testing to identify and remove defects before it is released to the customer. During this time, the failure history of the system can be used to estimate and forecast its reliability software reliability. The system's failure history as input to one or more statistical models, which produce as their output quantities related to the software's reliability. The failure history takes one of the two following forms:

- Time between subsequent failures
- Number of failures observed during each test interval, and the length of that interval

The models return a probability density function (pdf) for either the time to the next failure, or the number of failures in the next test interval. This pdf is then used to estimate and forecast the reliability of the software being tested. A brief description of three of the more widely used execution time models is given in the following sections. Further details on these and additional models may be found in [Lyu96].

Jelinski-Moranda/Shooman Model

This model, generally regarded as the first software reliability model, was published in 1972 by Jelinski and Moranda (Jeli72). This model takes input in the form of times between successive failures. The model was developed for use on a Navy software development program as well as a number of modules of the *Apollo* program. Working independently of Jelinski and Moranda, Shooman (Shoo72) published an identical model in 1972. The Jelinski-Moranda model makes the following assumptions about the software and the development process:

1. The number of defects in the code is fixed.
2. No new defects are introduced into the code through the defect correction process ("perfect debugging").
3. The number of machine instructions is essentially constant.
4. Detections of defects are independent.
5. During testing, the software is used in a similar manner as the anticipated operational usage.
6. The defect detection rate is proportional to the number of defects remaining in the software.

From the sixth assumption, the hazard rate $z(t)$ can be written as

$$z(t) = KE_r(t)$$

- K is a proportionality constant.
- $E_r(t)$ is the number of defects remaining in the program after a testing interval of length t has elapsed, normalized with respect to the total number of instructions in the code.

The failure rate $E_r(t)$ in turn is written as

$$E_r(t) = \frac{E_T}{I_T} - E_C(t) \quad (2)$$

- E_T is the number of defects initially in the program
- I_T is the number of machine instructions in the program
- $E_C(t)$ is the cumulative number of defects repaired in the interval 0 to t , normalized by the number of machine instructions in the program.

The simple form of the hazard rate (exponentially decreasing with time, linearly decreasing with the number of defects discovered) makes reliability estimation and prediction using this model a relatively easy task.

The only unknown parameters are K and E_T ; these can be found using maximum likelihood estimation techniques.

Schneidewind Model

The idea behind the Schneidewind model [Schn75, Schn93, Schn97] is that more recent failure rates might be a better predictor of future behavior than failure rates observed in the more distant past. The failure process may be changing over time, so more recent observation of failure behavior may better model the system's present reliability. This idea is implemented as three distinct forms of the model, each form reflecting the analyst's view of the importance of the failure data as a function of time. The data used for this model are the number of observed failures per test interval, where all test intervals are of the same length. If there are n test intervals, the three forms of the model are:

1. Use all of the failure counts from the n intervals. This reflects the analyst's opinion that all of the data points are of equal importance in predicting future failure behavior.
2. Ignore completely the failures from the first $s-1$ test intervals. This reflects the opinion that the early test intervals contribute little or nothing in predicting future behavior. For instance, this form of the model may be used to eliminate a learning curve effect by ignoring the first few test intervals. This form of the model may also be used to eliminate the effects of changing test methods. For instance, if path coverage testing is used for the first $s-1$ intervals, and the testing method for the remaining intervals is chosen to maximize the coverage of data definition/usage pairs, the failure counts from the first $s-1$ intervals might not be relevant. In this case, the analyst might choose to use this form of the model to eliminate the failure counts from the first $s-1$ test intervals.
3. The cumulative failure counts from the first $s-1$ intervals may be used as the first data point, and the individual failure counts from the remaining test intervals are then used for the remaining data points. This approach, intermediate between the first two forms of the model, reflects the analyst's belief that a combination of the first $s-1$ intervals and the remaining intervals is indicative of the failure rate during the later stages of testing. For instance, this form of the model may be used in the case where the testing method remains the same during all intervals, and failure counts are available for all intervals, but the lengths of the test intervals for the first $s-1$ intervals are not known as accurately as for the remaining intervals.

The assumptions specific to the Schneidewind model are as follows:

1. The cumulative number of failures by time t , $M(t)$, follows a Poisson process with mean value function $\mu(t)$. This mean value function is such that the expected number of failure occurrences for any time period is proportional to the expected number of undetected failures at that time. It is also assumed to be a bounded, non-decreasing function of time with $\lim_{t \rightarrow \infty} \mu(t) = \alpha/\beta < \infty$ where α and β are parameters of the model. The parameter α represents the failure rate at the beginning of interval s , and the parameter β represents the negative of the derivative of the failure rate, divided by the failure rate.
2. The failure intensity function is assumed to be an exponentially decreasing function of time.
3. The number of failures detected in each of the respective intervals are independent.
4. The defect correction rate is proportional to the number of defects remaining to be corrected.
5. The intervals over which the software is observed are all taken to be the same length. The equations for cumulative number of failures and time to the next N failures are given below.

Cumulative Number of Failures. Using maximum likelihood estimates for the model parameters a and b , with s being the starting interval for using observed failure data, the cumulative number of failures between and including intervals s and t , $F_{s,t}$ is given by

$$F_{s,t} = \frac{\alpha}{\beta} (1 - e^{-\beta(t-s+1)}) \quad (3)$$

If the cumulative number of failures between intervals 1 and s , $X_{s,t}$, is added, the cumulative number of failures between intervals 1 and t is

$$F_{s,t} = \frac{\alpha}{\beta} \left(1 - e^{-\beta(t-s+1)} \right) \quad (4)$$

Time to Next N Failures and Remaining Failures. At time t , the amount of execution time, $T_F(\Delta r, t)$, required to reduce the number of remaining failures by Δr is given by

$$T_F(\Delta r, t) = \frac{-1}{\beta} \log \left(1 - \left(\frac{\beta \Delta r}{\alpha} \right) e^{\beta(t-s+1)} \right) \quad (5)$$

Conversely, the reduction in remaining failure, Δr , that would be achieved by executing the software for an additional amount of time T_F is

$$\Delta r(T_F, t) = \frac{\alpha}{\beta} e^{-\beta(t-s+1)} (1 - e^{-\beta T_F}) \quad (6)$$

The Schneidewind model provides a method of determining the optimal value of the starting interval s . The first step in identifying the optimal value of s (s^*) is to estimate the parameters α and β for each value of s in the range $[1, t]$ where convergence can be obtained [Schn93]. Then the *mean square error* (MSE) criterion is used to select s^* , the failure count interval that corresponds to the minimum MSE between predicted and actual failure counts (MSE_p), *time to next failure* (MSE_T), or *remaining failures* (MSE_r), depending on the type of prediction. The first two were reported in [Schn93]—for brevity, they are not shown here. MSE_r , developed in [Schn97], is described below. MSE_r is also the criterion for *maximum failures* ($F(\infty)$) and *total test time* (t_t) because the two are functionally related to *remaining failures* ($r(t)$); see Eqs. (9) and (13) in [Schn97] for details. Once α , β , and s are estimated from observed counts of failures, the foregoing predictions can be made. The reason MSE is used to evaluate which triple (α, β, s) is best in the range $[1, t]$ is that research has shown that because the product and process change over the life of the software, old failure data (i.e., $s = 1$) are not as representative of the current state of the product and process as the more recent failure data (i.e., $s > 1$) [Schn93].

Although we can never know whether additional failures may occur, nevertheless we can form the difference between the following two equations for $r(t)$, the number of failures remaining at time t :

$$r(t) = \frac{\alpha}{\beta} - X_{s,t} \quad (7)$$

where $X_{s,t}$ is the cumulative number of failures observed between the including intervals s and t .

$$r(t_t) = \frac{\alpha}{\beta} e^{-\beta(t_t-s+1)} \quad (8)$$

where t_t represents the cumulative test time for the system.

We form the difference between Eq. (7), which is a function of predicted *maximum failures* and the observed failures, and Eq. (8), which is a function of *total test time*, and apply the MSE criterion. This yields the following MSE_r criterion for number of *remaining failures*:

$$MSE_r = \frac{\sum_{i=s}^t [F(i) - X_i]^2}{t - s + 1} \quad (9)$$

The Schneidewind model has been used extensively to evaluate the Primary Avionics Software System (PASS) for the Space Transportation System [Schn92] with very good success, especially employing the procedure for determining the optimal starting interval to obtain better fits to the data.

Musa-Okumoto Logarithmic Poisson Model

The Musa-Okumoto model has been found to be especially applicable when the testing is done according to a nonuniform operational profile. This model takes input in the form of time between successive failures. In this model, early defect corrections have a larger impact on the failure intensity than latter corrections. The failure intensity function tends to be convex with decreasing slope for this situation. The assumptions of this model are:

1. The software is operated in a similar manner as the anticipated operational usage.
2. The detections of defects are independent.
3. The expected number of defects is a logarithmic function of time.
4. The failure intensity decreases exponentially with the expected failures experienced.
5. The number of software failures has no upper bound.

In this model, the failure intensity $\lambda(\tau)$ is an exponentially decreasing function of time:

$$\lambda(\tau) = \lambda_0 e^{-\theta\mu(\tau)} \quad (10)$$

- τ = execution time elapsed since the start of test
- λ_0 = initial failure intensity
- $\lambda(\tau)$ = failure intensity at time τ
- θ = failure intensity decay parameter
- $\mu(\tau)$ = expected number of failures at time τ

The expected cumulative number of failures at time τ , $\mu(\tau)$, can be derived from the expression for failure intensity. Recalling that the failure intensity is the time derivative of the expected number of failures, the following differential equation relating these two quantities can be written as

$$\frac{d\mu(\tau)}{d\tau} = \lambda_0 e^{-\theta\mu(\tau)} \quad (11)$$

Nothing that the mean number of defects at $\tau = 0$ is zero, the solution to this differential equation is

$$\mu(\tau) = \frac{1}{\theta} \ln(\lambda_0 \theta \tau + 1) \quad (12)$$

The reliability of the program, $R(\tau_i' | \tau_{i-1})$ is written as

$$R(\tau_i' | \tau_{i-1}) = \left[\frac{\lambda_0 \theta \tau_{i-1} + 1}{\lambda_0 \theta (\tau_{i-1} + \tau_i')} \right]^{1/\theta} \quad (13)$$

- τ_{i-1} is the cumulative time elapsed by the time the $(i - 1)$ th failure is observed
- τ_i' is the cumulative time by which the i th failure would be observed

The mean time of failure (MTTF) is defined only if the decay parameter is greater than 1. According to [Musa87], this is generally the case for actual development efforts. The MTTF, $\Theta[\tau_{i-1}]$, is given by

$$\Theta[\tau_{i-1}] = \frac{\theta}{1-\theta} (\lambda_0 \theta \tau_{i-1} + 1)^{1-1/\theta} \quad (14)$$

Further details of this model can be found in [Musa87] and [Lyu96].

Benefits of Execution Time Models. There are three major areas in which advantage can be gained by the use of software reliability models. These are planning and scheduling, risk assessment, and technology evaluation. These areas are briefly discussed below.

Planning and Scheduling

- *Determine when a reliability goal has been achieved.* If a reliability requirement has been set earlier in the development process, the outputs of a reliability model can be used to produce an estimate of the system's current reliability. This estimate can then be compared to the reliability requirement to determine whether or not that requirement has been met to within a specified confidence interval. This presupposes that reliability requirements have been set during the design and implementation phases of the development.
- *Control application of test resources.* Since reliability models allow predictions of future reliability as well as estimates of current reliability to be made, practitioners can use the modeling results to determine the amount of time that will be needed to achieve a specific reliability requirement. This is done by determining the difference between the current reliability estimate and the required reliability, and using the selected model to compute the amount of additional testing time required to achieve the requirement. This amount of time can then be translated into the amount of testing resources that will be needed.
- *Determine a release date for the software.* Since reliability models can be used to predict the additional amount of testing time that will be required to achieve a reliability goal, a release date for the system can be easily determined.
- *Evaluate status during the test phase.* Obviously, reliability measurement can be used to determine whether the testing activities are increasing the reliability of the software by monitoring the failure/hazard rates. If the time between failures or failure frequency starts deviating significantly from predictions made by the model after a large enough number of failures have been observed (empirical evidence suggests that this often occurs one-third of the way through the testing effort), this can be used to identify problems in the testing effort. For instance, if the decrease in failure intensity has been continuous over a sustained period of time, and then suddenly decreases in a discontinuous manner, this would indicate that for some reason, the efficiency of the testing staff in detecting defects has decreased. Possible causes would include decreased performance in or unavailability of test equipment, large-scale staff changes, test staff reduction, or unplanned absences of experienced test staff. It would then be up to line and project management to determine the cause(s) of the change in failure behavior and determine proper corrective action.

Likewise, if the failure intensity were to suddenly rise after a period of consistent decrease, this could indicate either an increase in testing efficiency or other problems with the development effort. Possible causes would include large-scale changes to the software after testing had started, replacement of less experienced testing staff with more experienced personnel, higher testing equipment throughput, greater availability of test equipment, or changes in the testing approach. As above, the cause(s) of the change in failure behavior would have to be identified and proper corrective action determined by more detailed investigation. Changes to the failure rate would only indicate that one or more of these causes might be operating.

Risk Assessment. Software reliability models can be used to assess the risk of releasing the system at a chosen time during the test phase. As noted, reliability models can predict the additional testing time required to achieve a reliability requirement. This testing time can be compared to the actual resources (schedule and budget) available. If the available resources are not sufficient to achieve the reliability requirement, the reliability model can be used to determine to what extent the predicted reliability will differ from the reliability requirement if no further resources are allocated. These results can then be used to decide whether further testing resources should be allocated, or whether the system can be released to operational usage with a lower reliability.

Technology Evaluation. Finally, software reliability models can be used to assess the impact of new technologies on the development process. To do this, however, it is first necessary to have a well-documented history of previous projects and their reliability behavior during test. The idea of assessing the impact of new technology is quite simple—a project incorporating new technology is monitored through the testing and operational phases using software reliability modeling techniques. The results of the modeling effort are then compared to the failure behavior of similar historical projects. By comparing the reliability measurements, it is possible to see if the new technology results in higher or lower failure rates, makes it easier or more difficult to detect failures in the software, and requires more or fewer testing resources to achieve the same reliability as the historical projects. This analysis can be performed for different types of development efforts to identify

those for which the new technology appears to be particularly well or particularly badly suited. The results of this analysis can then be used to determine whether the technology being evaluated should be incorporated into future projects.

Execution Time Model Limitations

The limitations of execution time models are discussed below. Briefly, these limitations have to do with:

1. Applicability of the model assumptions
2. Availability of required data
3. Determining the most appropriate model
4. The life-cycle phases during which the models can be applied.

Applicability of Assumptions

Generally, the assumptions made by execution time models are made to cast the models into a mathematically tractable form. However, there may be situations in which the assumptions for a particular model or models do not apply to a development effort. In the following paragraphs, specific model assumptions are listed and the effects they may have on the accuracy of reliability estimates are described.

- *During testing, the software is executed in a manner similar to the anticipated operational usage.* This assumption is often made to establish a relationship between the reliability behavior during testing and the operational reliability of the software. In practice, the usage pattern during testing can vary significantly from the operational usage. For instance, functionality that is not expected to be frequently used during operations (e.g., system fault protection) will be extensively tested to ensure that it functions as required when it is invoked.

One way of dealing with this issue is the concept of the testing compression factor [Musa87]. The testing compression factor is simply the ratio of the time it would take to cover the equivalence classes of the input space of a software system in normal operations to the amount of time it would take to cover those equivalence classes by testing. If the testing compression factor can be established, it can be used to predict reliability and reliability-related measures during operations. For instance, with a testing compression factor of 10, a failure intensity of one failure per 10 h measured during testing is equivalent to one failure for every 100 h during operations. Since test cases are usually designed to cover the input space as efficiently as possible, it will usually be the case that the testing compression factor is greater than 1. To determine the testing compression factor, of course, it is necessary to have a good estimate of the system's operational profile (the frequency distribution of the different input equivalence classes) from which the expected amount of time to cover the input space during the operational phase can be computed.

- *There is an upper limit to the number of failures that will be observed during testing.* Many of the more widely used execution time models make this assumption. Models making this assumption should not be applied to development efforts during which the software version being tested is simultaneously undergoing significant changes (e.g., 20 percent or more of the existing code is being changed, or the amount of code is increasing by 20 percent or more). However, if the major source of change to the software during test is the correction process, and if the corrections made do not add a significant amount of the new functionality or behavior, it is generally safe to make this assumption. This would tend to limit application of models making this assumption to subsystem-level integration or later testing phases.
- *No new defects are introduced into the code during the correction process.* Although there is always the possibility of introducing new defects during the defect removal process, many models make this assumption to simplify the reliability calculations. In many development efforts, the introduction of new defects during correction tends to be a minor effect, and is often reflected in a small readjustment of the values of the model parameters. In [Lyu91], several models making this assumption performed quite well over the data sets used for model evaluation. If the volume of software, measured in source lines of code, being

changed during correction is not a significant fraction of the volume of the entire program, and if the effects of repairs tend to be limited to the areas in which the corrections are made, it is generally safe to make this assumption.

- *Detections of defects are independent of one another.* All execution time models make this assumption, although it is not necessarily valid. Indeed, there is evidence that detections of defects occur in groups, and that there are some dependencies in detecting defects. The reason for this assumption is that it enormously simplifies the estimation of model parameters. Determining the maximum likelihood estimator for a model parameter requires the computation of a joint probability density function (pdf) involving all of the observed events. The assumption of independence allows this joint pdf to be computed as the product of the individual pdfs for each observation, keeping the computational requirements for parameter estimation within practical limits.

Availability of Required Data

Most software reliability models require input in the form of time between successive failures. These data are often difficult to collect accurately. Inaccurate data collection reduces the usefulness of model predictions. For instance, the noise may be great enough that the model predictions do not fit the data well as measured by traditional goodness-of-fit tests. In some cases, the data may be so noisy that it is impossible to obtain estimates for the model's parameters. Although more accurate predictions can be obtained using data in this form [Musa87], many software development efforts do not track these data accurately.

As previously mentioned, some models have been formulated to take input in the form of a sequence of pairs, in which each pair has the form of (number of failures per test interval, test interval length). For the study reported in [Lyu91, Lyu91a, Lyu91b], all of the failure data was available in this form. The authors' experience indicates that more software development efforts would have this type of information readily available, since they have tended to track the following data during testing:

1. Date and time at which a failure was observed.
2. Starting and ending times for each test interval, found in test logs that each tester is required to maintain.
3. Identity of the software component tested during each test interval.

With these three data items, the number of failures per test interval and the length of each test interval can be determined. Using the third data item, the reliability of each software component can be modeled separately, and the overall reliability of the system can be determined by constructing a reliability block diagram. Of these three items, the starting and ending times of test intervals may not be systematically recorded, although there is often a project requirement that such logs be maintained. Under schedule pressures, however, the test staff may not always maintain the test logs, and a project's enforcement of this requirement may not be sufficiently rigorous to ensure accurate test log entries.

Even if a rigorous data collection mechanism is set up to collect the required information, there appear to be two other limitations to failure history data.

- It is not always possible to determine when a failure has occurred. There may be a chain of events such that a particular component of the system fails, causing others to fail at a later time (perhaps hours or even days later), finally resulting in a user's observation that the system is no longer operating as expected. Individuals responsible for the maintenance of the Space Transportation System (STS) and Primary Avionics Software System have reported in private discussions with colleagues of the authors several occurrences of this type of latency. This raises the possibility that even the most carefully collected set of failure history has a noise component of unknown, and possibly large, magnitude.
- Not all failures are observed. Again, discussions with individuals associated with maintaining the STS flight software have included reports of failures that occurred and were not observed because none of the STS crew was looking at the display on which the failure behavior occurred. Only extensive analysis of post-flight telemetry revealed these previously unobserved failures. There is no reason to expect that this would not occur in the operation of other software systems. This describes another possible source of noise in even the most carefully collected set of failure data.

Identifying the Most Appropriate Model

At the time the first software reliability models were published, it was thought that there would be a refinement process leading to at most a few models that would be applicable to most software development efforts [Abde86]. Unfortunately, this has not happened—since that time, several dozen models have appeared in the literature, and we appear to be no closer to producing a generally applicable model. For any given development effort, it does not appear to be possible to determine a priori which model will be the most applicable. Fortunately, this difficulty can be mitigated by applying several different models to a single set of failure history data, and then using the methods described in [Abd86] to choose the most appropriate model results. The methods include:

1. *Determination of how much more likely it is that one model will produce more accurate results than another.* *Prequential likelihood* functions are formed for each model. Unlike likelihood functions, these are not used to find model parameters—rather, the values of the model parameters are substituted into the prequential likelihood functions, as are the observed times between failures, to provide numerical values that can be used to compare two or more models. The larger the value, the more likely it is that the model will provide accurate predictions. Given two models, A and B, the ratio of the prequential likelihood values, PL_A/PL_B , specifies how much more likely it is that model A will produce accurate predictions than model B.
2. *Determination of whether a model makes biased predictions.* A model may exhibit bias by making predictions of times between failures that are consistently longer than those that are actually observed, or making predictions that are shorter than what's observed. In either case, [Abde86] describes how to draw a *u-plot* that will identify those models making biased predictions. Given two models that have the same prequential likelihood value, the model exhibiting the most bias should be discarded.
3. *Determination of whether a model's bias changes over time.* If a model exhibits bias, that bias may change over time. For instance, early in a testing effort, a model may consistently predict times between failures that are longer than what is actually observed. As testing progresses, the model's bias may change to making predicting shorter times between failures than those actually observed. Such a change in a model's bias may not show up in a *u-plot*, since the computations involved in producing *u-plot* does not preserve temporal information associated with the failure history. However, a series of further transformations allow the construction of a *y-plot*, which identifies models whose bias changes over time. Given two models with identical prequential likelihood values and identical *u-plots*, the model exhibiting a change in bias over time should be rejected over the one that shows no change in its bias.

Applicable Development Phases

Perhaps the greatest limitation of the execution time software reliability models is that they can only be used during the testing phases of a development effort. In addition, they usually cannot be used during unit test, since the number of failures found in each unit will not be large enough to make meaningful estimates for model parameters. These techniques, then, are useful as a management tool for estimating and controlling the resources for the testing phases. However, the models do not include any product or process characteristics that could be used to make tradeoffs between development methods, budget, and reliability.

PREDICTING SOFTWARE RELIABILITY

Software's design reliability is typically measured in terms of faults per thousand lines of source code (KSLOC). The lines of code are the executable lines of code, excluding the commentary lines of source code. Typical fault density levels, as a function of the development process, are shown in Table 3.6.2.

Code is necessarily released with faults in it. These are only estimated faults and not known faults. If they were known faults, the developer would remove them. This author has heard a hardware developer decry the notion of releasing code with faults. This critic claimed that a hardware developer would never do that. The truth is, with software one cannot test or anticipate all the scenarios that the software will have to handle. Some of these bugs

TABLE 3.6.2 Code Defect Rates (Faults/KSLOC)

	Total development	At delivery
Traditional development Bottom-up design, unstructured code, removal through testing	50–60	15–18
Modern practice Top-down design, structured code, design and code inspections, incremental releases	20–40	2–4
Future improvements Advanced software engineering, verification practice, reliability measurement	6–20	<1
Space shuttle code	6–12	0.5*

*The defect density of the space shuttle code is often shown as 0.1 defects/KSLOC. From private correspondence with the software quality lead engineer on the space shuttle, the author has learned that the estimated defect rate is 0.5 at turnover to the NASA customer. The space shuttle code only gets to 0.1 defects/KSLOC after eight additional months of NASA testing.

(another name for faults) will never affect a particular user. Bugs are potential problems in the code that have to be triggered by a set of special conditions. For instance, there could be a calculation in the software having a term of $1/(Z-225)$ that “explodes” or goes to infinity if $Z = 225$. For all other values this term is well behaved.

There was a lot of hype over the thousands of bugs released with Windows 2000 (<http://home.rochester.rr.com/seamans>). That article states, “Well, it’s been 2 months since the release of Windows 2000. Where are we now? After the hype of 63,000 bugs, we’ve seen a few bugs creep up here and there. Many argue over whether the current bugs out there are major or minor in nature. It seems that a vast amount of the bugs found to date are minor in nature and the ones that may be major (i.e., Windows 2000 doesn’t support more than 51 IP addresses) affect only a very few IT operations. In all, I think Windows 2000 has fared rather well considering what has taken place over the last year.”

Keene Process Based Reliability Model

It is often required to estimate the software’s reliability before the code is even developed. The Keene software reliability model projects fault density based on empirical data correlating fault density to the process capability of the underlying development process. Process capability measurement is most conveniently accomplished using the development organization’s Capability Maturity Model (CMM) level, which is explained in the next paragraph. The fault density is projected based on the measured process capability. The Keene model next transforms the latent fault density into an exponential reliability growth curve over time, as failures surface and the underlying faults are found and removed. Thus, failures are traced to the underlying faults and removed. Failures occur and these are the outward manifestation of the underlying fault. The faults are removed over time through software maintenance actions and the corresponding software failure rate diminishes accordingly.

The Software Engineering Institute (SEI) has developed a CMM that is a framework describing the key elements of an effective software development process. It covers key practices for planning, engineering, management, development, assurance, and maintenance that, when followed, should improve the ability of an organization to meet cost, schedule, and quality goals. They also provide five levels of grading which permits good differentiation among process capabilities.

- SEI Level 1 (Initial): Ad hoc process development dependent on individuals. Cost, schedule, and quality are unpredictable. Most companies fall into this category.
- SEI Level 2 (Repeatable): Policies for managing software are in place. Planning is based on prior experience. Planning and tracking can be repeated. Seventy percent of companies are rated at SEI level II or I.

FIGURE 3.6.2 Mapping of the SEI CMM levels versus fault density distributions.

- SEI Level 3 (Defined): The process for developing the software is documented and integrated coherently. The process is stable and repeatable and the activities of the process are understood organization wide.
- SEI Level 4 (Managed): The process is measured and operates within measured limits. The organization is able to predict trends and produce products with predictable quality.
- SEI Level 5 (Optimization): The focus is on continuous improvement. The organization can identify weaknesses in the process and is proactive in preventing faults. The organization is also innovative throughout. It demonstrates a passion to find and eliminate bugs. This organization also is continually improving its development process to reduce the likelihood of bug recurrence. It learns from the errors it finds. It is dedicated to continuous measurable improvement, sometimes referred to as CMI.

Figure 3.6.2 illustrates how the SEI's CMM levels correlate with the design fault density at product shipment as shown below.

The higher capability levels are expected to exhibit lower fault density than the lower capability levels. The higher SEI process levels are indeed more capable. The higher levels are also shown to have less variability, i.e., they are a more consistent predictor of fault density. The figure above depicts that the SEI level is a good predictor (causative factor) of fault density.

The process capability level is a good predictor of the latent fault content shipped with the code. The better the process, the better the process capability ratings and the better the code developed under that process. The projection of fault density according to the corresponding SEI level is now shown in Table 3.6.3. Keene bases these fault density settings on information compiled over a variety of programs. This information is proprietary and is not included in this paper. The SEI Level 5 experience is the most publicized on the space shuttle program of 0.5 defects/KSLOC. The table shows the posited relationship between the development organization's SEI's CMM level and the projected latent fault density of the code it ships.

The software reliability model Eq. (15), shows that the fault content decreasing exponentially over time. The exponential fault reduction model follows from assuming that the number of faults being discovered and removed from the code is proportional to the total number of faults existing in the code, at any point in time. This premise is intuitively appealing and supported by empirical evidence. This relationship expressed mathematically is

$$F(t) = F_0 e^{-kt} \quad (15)$$

where $F(t)$ = current number of faults remaining in the code after calendar time t

F_0 = initial number of faults in the code at delivery, which is a function of the developer's SEI development capability

k = constant of proportionality

t = calendar time in months

TABLE 3.6.3 Software's Projected Latent Fault Density as a Function of CMM Level

SEI'S CMM Level	Maturity profile June 2001 1018 Organizations*	Latent fault density (Faults/KSLOC- all severities)	Defect plateau level for 48 months after initial delivery or 24 months following subsequent deliveries
5	Optimizing: 4.8 percent	0.5	1.5 percent
4	Managed: 5.6 percent	1.0	3.0 percent
3	Defined: 23.4 percent	2.0	5.0 percent
2	Repeatable: 39.1 percent	3.0	7.0 percent
1	Initial: 27.1 percent	5.0	10.0 percent
unrated	The remainder of companies	>5.0	not estimated

*<http://www.sei.cmu.edu/sema/pdf/2001aug.pdf>

The proportionality constant k is set so the latent fault content drops to a certain percentage of the initial fault discovery rate after a code-stabilizing period of time. One analysis showed field data to stabilize at a 10 percent F_0 level after 48 months [Keen94]. This 10 percent level is appropriate for a CMM Level 1 process. The higher level processes drive the stabilization level lower than 10 percent that is used here. The constant k is determined by solving Eq. (15) for $F(t)$ dropping to 10 percent at 48 months. That analysis shows to be equal 0.048 per months.

Faults are revealed by failures. The failures are then traced to root cause, removed and the fault count goes down correspondingly. So failure the software failure rate goes down in proportion to the number of faults remaining in the code.

For purposes of estimating the operational failure rate of the fielded code, one can apply a linear, piecewise approximation to the exponential fault removal profile. This simplifies calculation of an average failure rate over the time interval. The number of faults found and removed is indicative of the failure rate of the software. That is, it usually takes a failure to reveal an underlying fault in the software. The more failures that occur, the more underlying faults there are uncovered in the code. The software failure rate λ is related to the number of underlying fault removal over time as follows:

$$\lambda(t) \approx \frac{F(t_2) - F(t_1)}{t_2 - t_1} \quad (16)$$

Adding a constant of proportionality ρ ,

$$\lambda(t) = \rho \frac{F(t_2) - F(t_1)}{t_2 - t_1} \quad (17)$$

where ρ represents a coverage factor. This is the total number of failure occurrences that a fault manifests before it is removed versus fielded population of systems. The coverage factor is made up of three components:

1. Percentage fault activation is that percent of the population likely to experience a given fault on the average. This factor is a small percentage when there are many copies in a widely distributed system such as an operating system.
2. Fault latency is measured in terms of the number of times that a unit in the failing subpopulation is likely to experience a failure before the failure is analyzed to root cause level and the corrective software patch installed.
3. Percentage critical faults that will cause the system to fail for the user.

The coverage factor is illustrated by considering 10 fielded copies of a software package, where five of the users experience problems. On average these five users experience three failures each before the problem is resolved and the underlying fault removed. The user in this example considers all failures critical. Then the

coverage factor would be (5 failures/10 fielded software instances) \times (3 repeats) \times (100 percent critical failures) over the install base of 10 users. Thus, $\rho = 1.5$. This number is based on the developer's history or by direct estimation of field performance parameters. "Measurement is important, otherwise you are just practicing."

Sometimes a single failure can lead to the removal of several faults. On the space shuttle for instance, a particular problem was experienced when reentering the code, having once exited it. This problem was called the "multi-pass problem." The problem was discovered and resolved. The entire shuttle code was searched looking for other instances of this problem. A single failure led to the correction of three different faults in the code. More often, it takes several failure occurrences before the underlying fault is found and removed.

The failure replication of the same problem will be somewhat offset by failures not being experienced across all systems. That is, the early adopters will first experience the software faults. There is also a subset of all users that stress their systems harder with greater job loads or more diverse applications. Some problems will be found and corrected before the majority of the remaining users have experienced it. This reduces the ρ factor or fault coverage. Chillarege's data show software improvement over time that was slightly steeper than an exponential growth profile (Ram Chillarege, Shriram Biyani, Jeanette Rosenthal, "Measurement of Failure Rate in Widely Distributed Software," Fault Tolerant Computing Symposium, 1995, pp. 424-433). The customer base he reported approached a million users, so there would be plenty of early adapters to find and fix the problems before the majority of users would see them.

Rayleigh Development Model

The defect rates found in the various development phases will successfully predict the latent defects shipped with the product. (from "Metrics and Models in Software Quality Engineering," Chap. 7, by Stephen H. Kan, Addison-Wesley, 1995).

The Rayleigh model is shown below:

- CDF: $F(t) = 1 - e^{-(t/c)^2}$
- PDF: $f(t) = (2/t)(t/c)^2 e^{-(t/c)^2}$

The Rayleigh model is the best tool to predict software reliability during development, prior to system testing. The Rayleigh model is a member of the Weibull distribution with its shape parameter, $m = 2$. The Rayleigh prediction model forward chains all the defect discovery data, collected throughout the development phases, to predict the software's latent fault density. (Latent errors are those errors that are not apparent at delivery but manifest themselves during subsequent operations. This is contrasted to patent errors, which are obvious by inspection.) The inputs to the Rayleigh model are the defect discovery rates found in the following design phases: high level design, low level design, code and unit test, software integration and test, unit test, and system test.

There are two basic assumptions associated with the Rayleigh model. First is that the defect rate observed during the development process is positively correlated with the defect rate in the field. The higher the Rayleigh curve of defects observed during development, the higher the expected latent defect rate of the released code. This is related to the concept of error injection. Second is that given the same error injection rate, if more defects are discovered and removed earlier, fewer will remain in later stages. The output of the Rayleigh model is the expected latent fault density in the code when it is released.

The following are priority definitions used for quantifying development defects. The Rayleigh analysis can be used to project any or all of these priority defects itemized below:

- Critical (Priority 1): An error which prevents the accomplishment of an operational or mission essential function in accordance with specification requirements (e.g., causes a computer program stop), which interferes with use of the system to the extent that it prevents the accomplishment of a mission essential function, or which jeopardizes personnel safety.
- Major (Priority 2): An error which adversely affects the accomplishment of a mission essential function in accordance with specification requirements so as to degrade performance of the system and for which no alternative is provided. Rebooting or restarting the application is not an acceptable alternative, as it constitutes unacceptable interference with use of the system.

FIGURE 3.6.3 Rayleigh defect removal profile curve.

- Minor (Priority 3): An error which adversely affects the accomplishment of an operational or mission essential function in accordance with specification requirements so as to degrade performance and for which there is a reasonable alternative provided. Rebooting or restarting the application is not an acceptable alternative, as it constitutes unacceptable interference with use of the system.
- Annoyance (Priority 4): An error, which is an operator inconvenience or annoyance and does not affect an operational or mission essential function.
- Other (Priority 5): All others errors.

The difference between the amount of faults injected into the code and those that escape detection and end up being shipped to the field reflects the goodness of the development process. Defects are removed by a number of development quality processes such as inspections, reviews, and tests. Eight-five percent of all the injected faults were removed during the development phase prior, to the system test, on the highly successful space shuttle program. The better the development process, the sooner the defects are removed during the development process and the fewer defects that escape (detection and removal) and go to the field as latent defects. Once the code is in operational test or the field, the computer aided software reliability estimation (CASRE) tool can be applied to measure its operational reliability.

CASRE

Computer aided software reliability estimation, developed with funding from the U.S. Air Force Operational Test and Evaluation Center (AFOTEC), is a stand-alone Windows-based tool that implements 10 of the more widely used execution time software reliability models. CASRE's goal was to make it easier for nonspecialists in software reliability to apply models to a set of failure history data, and make predictions of what the software's reliability will be in the future. In 1992, when the first version was released, it was the first software reliability modeling tool that displayed its results as high-resolution plots and employed pull-down menus in its user interface—other tools at that time interacted with the user via command lines or batch files, and displayed their results in tabular form. It also allows users to define combination models [Lyu91a] to increase the predictive accuracy of the models. In addition, it implements the model selection criteria described in [Abde86] to allow user to choose the most appropriate model results from a set of results. Finally, it implements trend tests that can be applied to the failure data to help the user determine whether it's even appropriate to apply reliability models to the data.

The modeling and model applicability analysis capabilities of CASRE are provided by Statistical Modeling and Estimation of Reliability Functions for Software (SMERFS), a software reliability modeling tool developed by Dr. William H. Farr at the Naval Surface Warfare Center, Dahlgren, Virginia. In implementing CASRE, the

original SMERFS user interface and the SMERFS modeling libraries were linked into the user interface developed for CASRE. The combination modeling and trend test capabilities, however, are new for CASRE, as are the model ranking capabilities.

Version 3.0 of CASRE is available from the Open Channel Foundation at <http://www.openchannelfoundation.org>.

The following steps illustrate a typical application of CASRE to a set of failure data:

1. When a set of failure data is first opened with CASRE, the data are displayed both in text and graphical form. One window displays the text of the failure data, and the other displays a high-resolution plot of the data. CASRE can use two types of failure data—either time between subsequent failures, or the number of failures observed in a test interval of a given length. If the data are in the form of times between subsequent failures, the window displaying text shows the failure number, the elapsed time since the previous failure, and the failure's severity on an arbitrary scale of 0 to 9. The initial plot shows the times between subsequent failures as a function of failure number. For interval data, the text display shows the interval number, the number of failures observed in that test interval, the length of the interval, and the severity of the failures in that interval. The initial plot for this type of data shows the number of failures per test interval as a function of test interval number.
2. Whether the reliability of the software being analyzed is increasing depends on many factors, such as the type of testing being performed, and whether substantial amounts of the software's functionality are being added or modified. To determine the advisability of applying reliability models to the failure data, trend tests should be applied to determine whether the failure data are exhibiting reliability growth. If these trend tests indicate that the failure data exhibit reliability growth, then the user can be confident in applying a software reliability model to the data. However, it may be the case that failures are detected at a nondecreasing, or even an increasing rate, in which case the reliability of the software being analyzed would actually be decreasing. As mentioned above, this could happen if significant amounts of additional functionality are being added while testing is taking place. In this case, application of a reliability model would not be advisable, since all of the models assume that the reliability of the software increases as testing progresses. CASRE implements two trend tests to help users determine whether the data are exhibiting reliability growth—a running arithmetic average, and the Laplace test [Lyu96].
3. If the trend tests indicate it is advisable to apply reliability models to the failure data, the next step is the selection of the models to be used. Because it is generally not possible to determine a priori the most appropriate model for a set of data, it is recommended that several different models be applied to the same set of data and the methods described in [Abde86] be applied to the results to select the most appropriate model. CASRE allows users to apply more than one model to the current set of failure data. Once the models have completed, users can select up to three sets of model results, and plot them in several different ways. Among these are displays of including failure intensity (number of failures per unit time) versus failure number, actual and predicted cumulative number of failures versus time, and software reliability versus time.
4. After the models have been applied to a set of failure data, the next step is determining which model's results are the most appropriate to the data. CASRE provides a facility to help rank the models according to goodness of fit and four criteria described in [Abde86]—prequential likelihood, bias, bias trend, and model noise. The default ordering and weighting of these criteria is based on a study of how to rank software reliability model results [Niko95]. First, CASRE uses the goodness-of-fit tests to screen out those model results that don't fit at a specified significance level—those results are excluded from further consideration in the ranking. Next, CASRE compares the prequential likelihood values for the models—models with higher prequential likelihood values are ranked higher than those having lower values. For those models having the same prequential likelihood value, CASRE uses the extent to which the models are biased to break the tie—models having lower values of bias are ranked higher than models with higher bias values. For those models exhibiting the same amount of bias, CASRE uses the value of the bias-trend criterion to break the tie—ranking with respect to bias trend is the same as it is for bias. There is an additional criterion, “prediction noisiness,” or “model noise,” which is also available, but its meaning is not as well understood as that of the other three [Abde86]. The default use of this criterion is to break ties among models exhibiting identical values of bias trend—models having lower values of model noise are ranked higher than models having higher values. Model ranks are displayed in a tabular form—the overall rank for each model is displayed, as well as the ranks with respect to each individual criterion.

SECTION 4

COMPUTER-ASSISTED DIGITAL SYSTEM DESIGN

Computer-assisted design continues to become a more powerful tool in digital and analog circuit design, especially using programmable integrated circuits. The different types and manufacturers of such devices fall into two main classes—field programmable gate arrays (FPGAs) and field programmable analog arrays (FPAAs).

We will focus on digital circuits (FPGAs) using the most general process of design. However, the approach works well on all of the rest of the commercial CAD tools and can be applied to the analog devices (FPAAs) as well. C.A.

CHAPTER 4.1

DESIGN OF DIGITAL SYSTEMS USING CAD TOOLS

Brian R. Fast

OVERVIEW

The use of CAD tools for programming digital circuits has dramatically increased the reusability, processing power, and reliability of digitally designed components. Currently field programmable gate array (FPGA) chips use very high-speed integrated circuits hardware description language (VHDL) to take advantage of these CAD tools in the programming of chips at the lowest gate level. VHDL has become an industry standard language, which is regulated by the Institute of Electrical and Electronic Engineers (IEEE). It is similar, with many conceptual changes described later in this section, to any other programming language (e.g., C, C++, visual basic). The companies that manufacture FPGA devices have software packages that can compile VHDL code that can be simulated or burned to a chip.

One of the potential benefits to VHDL over chip-dependent software is the capability to migrate from one chip manufacturer to another. VHDL is an industrial standard language, therefore the software for each chip manufacture should be capable of compiling code designed for another manufacturer's chip. Of course this is dependent on the code not using functions that are proprietary to a specific chip manufacturer.

The increase in processing power is another major advantage of FPGA devices over the standard microprocessor. There are two avenues in which this can be seen. First, the capability of performing concurrent operations is a major advantage of FPGA devices. One chip can be broken into subsystems that perform the processes in parallel. If this was to be implemented with microprocessors there would need to be an independent processor for each subsystem. This would considerably increase the overall design cost and add complexity to system integration. Second, the capability of designing the number of busses to the desired size increases the efficiency and optimizes the design. For example, standard microprocessors have a fixed number of busses and register sizes. FPGA devices are programmed at the gate level, which gives the designer the added freedom to optimize the size and the number of registers throughout the design.

The added reliability of the design can be seen through improved CAD tools and the ease of reusability. CAD tools now provide powerful simulation packages that enable the designer to thoroughly test the components. These simulation packages are typically not as usable in microprocessor packages. For example, the simulation packages for FPGA devices produce waveforms that can be included with testing documentation. Microprocessor-based design can be simulated to show the desired input-output response; however, all of the intermediate details are typically negated. The ease of reusability also increases the reliability of the design, as the component can be used again and again, the confidence level in the component improves. This is also easier to do in an FPGA-based design over a microprocessor design, because integration of the designed component is easier in an FPGA-based design.

There are, however, some disadvantages to the more powerful FPGA-based chip design. Designing with VHDL requires the designer to think in terms of hardware instead of software. This is a major change in programming

philosophy, which will take some time for the new designer to become accustomed to. It requires the designer to think of the design as a high-level system, and as signals moving throughout the system. The designer must design all of the overhead tasks that are required (internal interrupts, external interrupts, watchdog timers). The FPGA-based chips do not typically have preconfigured devices on the chip (analog-to-digital converter, pulse-width modulator, communication routines). However, the newer devices are beginning to add a standard microprocessor within FPGA device, which would ease some of the implementation burdens of standard tasks.

ALTERNATIVE PROGRAMMING PHILOSOPHY (BASIC)

One of the major difficulties in working with VHDL/FPGA devices is the alternative programming philosophy. Typically programmers are used to thinking in a linear fashion where variables are thought to contain specific information. The information that is held at a specific moment is dependent on where the program is operating. VHDL requires the programmer to change their method of thinking to become a designer. It requires the designer to think of the variables as wires, which move signals throughout the design rather than moving information. Let us take a look at the design philosophy for a microprocessor and compare it to the VHDL design for a simple problem shown in Eq. (1).

$$F <= (a \text{ AND } b) \text{ AND } (c \text{ AND } d) \quad (1)$$

A typical microprocessor design would begin by loading the contents of a to a register, loading the contents of b to another register, and the two registers together, and then store that value in a designated area 1. It would then load the contents of c to a register, load the contents of b to another register, and the two registers together, and then store that value in a designated area 2. It would then load the contents of the designated area 1 to a register, load the contents of the designated area 2 to the register, and the two registers together, and then there is the output. The program would then be repeated over and over to update the changes as a , b , c , or d change. From this process it is seen that programming of a microprocessor occurs, like many programming languages, linearly throughout the appropriate steps.

The implementation of Eq. (1) in VHDL is rather straightforward. However, with this comparison, the difference in the design process is very apparent. For now, the implementation of the VHDL code will be done in a concurrent manner. Later on, the design can be modified to simulate a linear operation. The VHDL designer would first decide if this function is the minimum design needed to generate the appropriate output. This function is of the minimum design, therefore the function will be directly implemented in VHDL. Basically the circuit requires that there be three AND gates. The signals a and b are input to one of the AND gates. The signals c and d are input to the second AND gate. The output of the first and second AND gates are run to the third AND gate that provides the final result. The specific syntax of VHDL will be discussed in the subsequent sections; however, Eq. (1) is also the VHDL code for the desired function. Basically, when sequential statements are not used, in VHDL code the output will change immediately (within a small time delay) following a change in a , b , c , or d . The code would not need a repeating loop to update the output of the function as the values of a , b , c , or d change. The VHDL code would provide the result in an order of magnitude faster than the microprocessor design, and it would also be capable of performing other operations simultaneously. The change from a linear programming to concurrent programming sounds easy; however, it takes a little more effort than would be anticipated.

The most important part of programming in this type of environment is having a good picture of the high-level objective. Having a good high-level diagram is a must for designing VHDL code. An example of the

FIGURE 4.1.1 High-level diagram for Eq. (1).

high-level code for Eq. (1) is shown in Fig. 4.1.1. The high-level diagram shown in Fig. 4.1.1 is rather simple for this problem, but as systems become more complicated with multiplexers and other functions, the high-level diagram will make it possible to keep track of what each signal is. This will be seen in the alternative programming section as the high-level diagrams become more complicated, which requires sequential and concurrent processing.

```

FIGURE 4.1.2 VHDL code for include libraries.

VHDL/FPGA Program Configuration

This will be the first formal introduction to the syntax of VHDL. There are three major components to the syntax. There are the included libraries, there is the entity that defines the inputs and outputs of the component, and there is the architecture that is the main body of the code.

The included libraries provide standard functions, which are available within the architecture. While deciding which libraries to include, one may want to consider what other chip manufactures support these libraries, in case in the future, a decision is made to use another chip manufacture. The syntax for the libraries is shown in Fig. 4.1.2. Note that two dashes (--) indicates a comment.

The entity section tells the system what inputs and outputs will be coming into and out of the component and how they will be defined. A comparison to a standard programming language would be the type of variable (int, double, float). The syntax for the entity is shown in Fig. 4.1.3.

The main purpose of the entity declaration is to define the signals as input or output and define the size of the signals. For example, number is defined as a vector that is 8 bits wide. In the CAD software the input and output signals will be referenced to a specific I/O port. Take note that an output cannot be feedback to a defined input signal. An input must be set by a signal external to the device. The input and output signals that are declared as STD_LOGIC means that these are only a single bit.

The architecture section defines the actual function of the chip. Within the architecture, there are a few more important declarations. These declarations are known as signals (intermediate locations to store signals), constants, and variables. Variables are only allowed to be used within a sequential statement, which will be covered in subsequent sections. The syntax of the architecture is shown in Fig. 4.1.4.

VHDL/FPGA Concurrent Programming

Very high-speed integrated circuits hardware description language is capable of performing concurrent and sequential operations. This section will focus on concurrent processing; in a later section sequential operations will be introduced. The concurrent processing methodology is the main difference from microprocessor-type design. Concurrent processing means that if one of the inputs changes its value then the output will, nearly, immediately change as well. There isn't a sense of looping or linear programming. Essentially the entire program acts in a parallel manner.

FIGURE 4.1.4 VHDL code for architecture.

Within this section the designer has access to multiplexers, basic bit operations (AND, OR, NOT, and so forth), and some other general commands. A few of the multiplexer techniques are the WITH and WHEN statement and will be shown in Figs. 4.1.5 and 4.1.6.

In Fig. 4.1.5 the WITH statement is implemented. The actual purpose of the program is not important. It is only shown to illustrate the syntax. Within the figure there is another command that is implemented and that is the "&." The & command enables the designer to append static or dynamic signals within another signal. Another application of the & is a shift operation.

In Fig. 4.1.6 the WHEN statement is implemented. The actual purpose of the program is not important. It is only shown to illustrate the syntax. Another important aspect to all of the multiplexer commands is to remember to include all possible combinations of the select signal. If all possible combinations are not represented, undesirable results could occur.

ALTERNATIVE PROGRAMMING PHILOSOPHY (ADVANCED)

One of the major difficulties of working with FPGA devices is having to design circuits in a concurrent manner. This section will present a method of removing that limitation. There is a method of designing sequential circuits, essentially creating a circuit that functions in a linear fashion. This type of program is called a *process(sel)*. The process function also has a list of signals that are evaluated by the process. There are no fixed number of signals that can be evaluated by the process. The process will be ignored until the *sel* signal changes. Once the signal changes, the process will be entered and the appropriate code will be evaluated.

              "010000000" WHEN (button = "0100") ELSE
              "001000000" WHEN (button = "0010") ELSE
              "000100000" WHEN (button = "0001") ELSE
              "000000000";
END arch;
-- *****

```

FIGURE 4.1.6 VHDL code for WHEN.

When designing with a process the designer gains access to a new type of command. This new command is a variable. A variable can only be accessed within a process. This new type of command is needed because of the limitation of working with signals within a process. Within a process the signal will not be updated until the process is left, which means if the signal is changed many times within one process, only the last value of the signal will take effect. The change in the signal will not take place until the process is left. The use of a variable creates difficulty because of the lack of knowledge of how the gate-level design will be configured. This causes the size of the design to grow larger than the use of a typical signal. The added advantage of using a variable will allow the designer to make changes to the variable within the process many times before the process is completed.

There are many advantages to designing a sequential circuit. The most obvious is the capability of taking advantage of a looping statement and an “if” statement, however, the most important addition would be the way the high-level design could be reformulated to create a finite state machine. Essentially being able to break a task into multiple states will enable the designer to systematically solve the problem. During the implementation of a finite state machine a state and a next state need to be known at all times. Another key importance of this type of design is the ability to perform multiple operations on a signal. Remember typically a signal cannot write to itself. However, using a current and next state vector for the signal will enable the designer to get around this limitation. The high-level diagram is shown in Fig. 4.1.7.

Figure 4.1.7 shows how to visualize the state update components. The system begins with two separate processes that depend on two different signals. The first process is dependent on a change in the state_reg register. The second process is dependent on a change in the clock. The first process keeps track of the current state and monitors other signals, not shown, to determine when and what state to post to the state_next register. The second process takes into account a clock signal, which waits for the rising edge of the clock to update the state_reg with the state_next register.

The configuration of the state update component is used to streamline the design in order to reduce the amount of spaghetti code. This configuration also provides a method of performing multiple instances of a function to a signal.

There are a few major drawbacks to this type of design. First, when designing a circuit sequentially the way the circuit is compiled at the gate-level becomes less obvious. This causes the circuit to take up more space within the chip. Second, sequential design runs the possibility of not being able to compile even if the syntax is correct. The resulting sequential design might be too complex.

FIGURE 4.1.7 High-level diagram of state update philosophy.

FIGURE 4.1.8 VHDL code for a process and performing multiple instances of a function on a signal.

VHDL/FPGA Sequential Programming

This section will focus on presenting a sequential programming syntax for VHDL. The main illustrations will show how to set up a process, read the rising edge of the clock signal, and how to perform multiple instances of a function on one signal.

Figure 4.1.8 shows the typical syntax for a process and how to determine the rising edge of the clk signal. The implementation of the architecture shown in Fig. 4.1.8 also shows how to perform multiple instances of a function to a signal. This method is done by creating a current signal (defined as count_now) and by creating a next signal (defined as count_next).

Creating a process to implement the state update component shown in Fig. 4.1.7 would follow the same methodology of the process shown in Fig. 4.1.8. Instead of updating the next state by evaluating a function, the output would be the next state, which is dependent on the current state and the inputs to the component.

Timing Considerations

Timing considerations are the most critical components to any embedded system design. This is true with FPGA-based designs as well. The requirements that are standard to any embedded system still remain; however, there is a new timing requirement that must be considered in order to optimize the system. In the development of the states of the system, the designer must consider whether to have fewer states with more packed into the function or to have more states with less packed into the function. The key trade-off is throughput versus clock speed. Within the process that updates the current state based on the clock frequency, the max clock frequency would be dependent on the longest cycle through the process. Therefore, it is typically more desirable to have more states that implement less than to have less states that implement more. The timing considerations and max clock frequency can be determined using the CAD tools.

Simulation with CAD Tools

A key advantage to using the new CAD tools is the powerful set of simulation packages. Windows can be created, which show the waveform for any signal throughout the system. The simulations can show the final value and any intermediate value throughout the design. This is a major advantage for debugging and system verification.

VHDL/FPGA Component Integration and Configuration

Integrating many VHDL components together into a big design is much easier than implementing functions within a typical microprocessor. The overall design can be broken into components and each component can be independently designed and compiled. The final product can link the components together to form the overall design.

In order to illustrate this concept, a kitchen timer example will be shown. The actual function of the design is not as important as how the system is integrated together. However, for clarity, a brief explanation will be given. The system begins by placing the initial value to begin counting from LSreg (seconds) and MSreg (tens of seconds). There will be a clock divider, which will create a 1-s pulse for the counter circuit to count in order to update the clock every second. The counter component will take the initial values of LSreg and MSreg and decrement the value every second until the timer reaches zero. The updated counter will be output to the seven seg display component, which will display the appropriate number on the display. This process will stop when the counter reaches zero or it will reset when the Reset_Switch is initiated. The high-level design is shown in Fig. 4.1.9.

Within Fig. 4.1.9 it is seen that there are four major subsystems for the kitchen timer example—complete system, clkdivider, counter, and the seven seg display. Each of these subsystems is an individual component, individual file, in the design of the overall system. The inputs and outputs of each block are declared and the function of each block is declared within the architecture. The clkdivider, counter, and seven seg display are the core functions, which dictate what is actually happening in the circuit. The complete system component links all of the subsystems together.

Within the complete system component the design will define the inputs and outputs to the entire system and link the inputs and outputs of each component together. There is one more function of the complete system component, which will complete the design. When there is a signal, which is an output from one component and an input to another component (not an output for the system), there needs to be an intermediate signal defined, which will be used to link the signal. Figure 4.1.10 shows the code that was designed for the complete system component.

CONCLUSION

In conclusion this chapter has gone through the process for designing integrated digital systems using VHDL. Details were provided for the appropriate syntax and for design philosophies, which will help a designer get started. This chapter was intended for someone who has a familiarity with digital and embedded system design.

SECTION 5

ELECTRONIC AND FIBER OPTIC COMPONENTS

This section reviews the basic components in their discrete form that make up electronic circuits and systems. The first two chapters cover fundamental passive and active discrete components, respectively. Another chapter is devoted to batteries and fuel cells. While batteries convert chemical energy into electric energy via an oxidation-reduction electrochemical reaction, the reactants are contained within the cell, whereas in a fuel cell, one or both of the reactants are not embedded, but fed from an external supply when power is needed. A chapter on relays and switches compares the characteristics of solid-state and electromechanical versions. Another on connectors describes various types of connectors along with design, application, and reliability issues. Finally, a completely new chapter explores the characteristics and applications of optical fiber components, ranging from the optical fiber itself to connectors, couplers, fiber gratings, circulators, switches, and amplifiers.

Since the selection of materials to fabricate electronic components is fundamental to their operational characteristics and expected lifetimes, valuable background information covering a broad range of electronic materials is provided on the accompanying CD-ROM.

The treatment of specialized components is covered in separate sections of the handbook: Section 6, Integrated Circuits and Microprocessors; Section 7, UHF and Microwave Devices; Section 8, Transducers and Sensors; and Section 9, Radiant Energy Sources and Sensors. D.C.

RESISTORS

Carrington H. Greenidge

Introduction

The resistive function is a fundamental element of electronics. It results from the characteristic of a material to impede the flow of electrons through that material in a measured or calibrated manner. Resistors are devices that exhibit this primary characteristic along with secondary characteristics. The primary characteristic, which is measured in ohms, is derived from the resistivity (ρ) of the material and the geometry of the resistance element. The basic relationships between resistance, voltage (volts), current (amps), and power (watts) are defined by Ohm's law relationships: $I = E/R$ and $P = I * E$.

In general, resistive devices have an equivalent circuit as shown in Fig. 5.1.1, where series inductance (L) and shunt capacitance (C) are secondary (reactance) characteristics that affect device response at high frequencies. The use of different materials and geometries results in a wide range of secondary characteristics and capabilities that provides an expanding portfolio of resistor products to meet new application requirements.

Resistor Terminology

Resistance value. The primary characteristic of the device measured in ohms (Ω).

Nominal resistance value. The ohmic value attributed to a resistor and identified by color coding or some other identification technique.

Resistance tolerance. The allowed variation of resistance value from the nominal value; it is marked on the resistor or identified by some other technique.

Resistance stability. The estimate of the variation of resistance value over time when operated within ratings.

Power rating. The maximum value of steady-state power that can be dissipated by a resistor, over long periods of time without significant change in resistance value.

Voltage rating. The maximum voltage that may be applied across the element without significant change in resistance value.

Temperature rating. The temperature at which the resistor will operate at full rated power. Operation of the resistor at temperatures above the established rating is possible at reduced power levels up to a temperature called the zero power level or zero derating. This temperature usually reflects the hot-spot temperature of the resistor.

FIGURE 5.1.1 Equivalent circuit of a resistor.

Temperature coefficient of resistance (TCR). The variation of resistance value as a function of temperature expressed in parts per million/degree Celsius or as a percentage per degree Celsius. TCR is usually retraceable.

Voltage coefficient of resistance (VCR). The variation of resistance value as a function of applied voltage expressed in parts per million (PPM) or percent per volt. VCR is usually retraceable.

Noise. The instantaneous voltage instability that occurs in a resistor owing to thermal excitation of the structure (Johnson noise) or current effects (current noise). Most resistors have basal noise index and third harmonic (THI) levels. Significant deviation from these indices suggests the presence of structural abnormalities.

High-frequency effects (see Fig. 5.1.1). The application of ac voltages produces inductive and capacitance reactance in many resistors. Series inductance increases the overall impedance of the resistor while parallel capacitance decreases the impedance.

Fixed resistors. Resistors that in the completed state cannot be adjusted.

Adjustable resistors. Resistors that in the completed state can have the resistance value changed by some external technique that is nonreversible.

Variable resistors. Resistors that in the completed state can be changed by some technique (usually mechanical) that is reversible.

Precision resistors. Precision resistors are used in applications requiring tight tolerance (less than ± 1 percent), tight TCR (less than ± 100 PPM), long-term resistance stability (less than ± 1 percent drift), and low noise.

Semiprecision resistors. Semiprecision resistors are used in applications in which long-term stability (up to ± 5 percent) is important but initial tolerance (± 1 percent) and TCR (± 100 PPM) requirements are not as critical.

General-purpose resistors. These devices are used in applications where wide resistance tolerances and resistance shifts (± 5 , 10, and 20 percent) are acceptable.

Fixed Resistors for Thru-Hole Applications

Fixed wirewound resistors are constructed using an appropriate length and diameter of resistance wire that is wound around a mandrel or core to achieve a specific resistance. Leads, lugs, or other terminals (including solderable terminations for surface mount applications) are provided at each end of the resistance wire, mechanically secured and protected in an appropriate package. Wirewound resistors provide very tight tolerance, excellent long stability, high temperature capability, and very low noise. They have poor high-frequency response because of inductive properties and high-resistance value limitations because of thin wire fragility. Wirewound resistors are used in precision and power applications.

Fixed carbon composition resistors consist of a slug of inert binder mixed with measured amounts carbon particles to give the desired nominal resistance. Axial lead terminations are embedded in each end of the slug during a formation process. The entire assembly is molded into a plastic housing that provides mechanical stability. Alternatively, a carbon particle/binder slurry is established on the outside wall of a glass tube,

terminal leads are mounted at each end using a conductive cement and the assembly is molded into a protective case.

Carbon composition resistors are in the general purpose category and provide a wide resistance range. The slug construction provides exceptional transient overload protection and these devices have exceptional reliability. The high-frequency response of these resistors is diminished because of capacitive reactance.

Fixed film resistors (carbon film, cermet, and metal films) are constructed by establishing the appropriate film on an insulating substrate. Terminations, usually cap and lead assemblies, are provided at each end. The film resistance element is adjusted to value using a mechanical or a laser spiraling technique that cuts a helix path into the film or by the mechanical removal of film from the surface (unlike the unadjusted glass tube carbon comp device described previously). A protective coating is usually established over the entire structure to provide mechanical and environmental protection.

Carbon film resistors are available primarily as general-purpose resistors but can fit into semiprecision applications where ± 1 percent tolerances are needed but looser TCRs are acceptable.

They are available over a wide resistance value range (in some specialty areas going into the teraohm range) and they have a good high-frequency response. Their environmental performance, however, is not equal to the metal film and cermet devices described as follows.

Metal film (thin film, thin metal film, or metal oxide) resistors are used in precision ($< \pm 1$ percent) and semiprecision (± 1 percent) applications. They are the most stable film devices with TCRs ± 25 and ± 50 PPM/ $^{\circ}\text{C}$ generally available at reasonable cost. Tighter tolerances and TCRs are available at higher cost. Metal films are selected over precision wirewound devices because of lower cost, better high-frequency response and wider resistance range.

Cermet films are used primarily in semiprecision applications, but are also available for some precision ($< \pm 1$ percent) and general purpose ($> \pm 1$ percent) use. The element structure (different ratios of insulating CERamic and conductive METal particles, fused together on a substrate) provides a wider resistance range than metal film or wirewound resistors. The long-term stability is not as good and tighter tolerances and TCRs are not available.

Resistor networks are structures with multiple fixed elements established on one substrate. The elements are usually Cermet films but precision devices are available in thin film technologies. There are two basic packages, the single in-line package (SIP) and the dual in-line package (DIP) with three standard circuits or interconnections (isolated element, pull-up, and terminator) as shown in Fig. 5.1.2.

Custom circuits, both simple and complex, can be designed for special applications. The termination (pin) count for SIPs ranges from 2 to 20 or more while DIPs are usually 14 or 16 pins. Pin spacing is usually 0.100 in.

Resistor networks in general have a higher per element cost than discrete devices. However, savings in assembly cost, improved circuit board real estate usage and more uniform electrical characteristics (stability, TCR, and high-frequency response) drive the selection of resistor networks.

Fixed Resistors for Surface Mount Applications

Film chip resistors are constructed by establishing a resistive element on the top surface of a rectangular ceramic chip. Solderable terminations are created at each end and short extensions of the terminations are also created on the underside of the chip to enhance the bond strength after solder attachment. A glassy or plastic passivation layer is usually formed over the resistive element for environmental protection. Resistance value is established using laser trim techniques. Film chip resistors have excellent power handling capability because of the thermally efficient mounting technique. This allows for improved board component density compared to axial devices. As new, more accurate placement equipment is developed, the physical size of the parts is shrinking. The size, XXYY, in millimeters, is defined by XX the approximate length and YY the approximate width. The size trend, from 1206 to 0805 to 0603 to 0402, is clear. Larger sizes, 1210, 2012, and 2520 are used when higher power levels are required.

Cermet and metal film film chips have similar electrical and performance characteristics as the axial designs from which they were derived. Because of size standardization, the electrical performance is more uniform and assembly operations are simplified. Film chip resistors are now the workhorse resistive component.

FIGURE 5.1.2 Standard SIP and DIP circuits.

The *metal electrode face-bonding (MELF) resistor* is the surface mount technology (SMT) equivalent of the axial designs described previously. Modifications to the protective coating process leave the endcap back-walls exposed, which provides the solderable surfaces required for surface mounting. MELFs are not as popular as the rectangular chip because of more difficult assembly routines but are used because they are the lowest cost tight tolerance, tight TCR SMT device.

Wirewound chips have been developed to satisfy the needs for precision wirewound performance in the 100 percent SMT assembly environment (as opposed to the mixed through-hole and SMT environment). The performance characteristics of wirewound chips and fixed wirewound resistors are similar.

Surface mount networks are multiple element devices derived from the DIP concept with either standard or custom internal circuitry. “Gull”-shaped or “J”-shaped terminations (which sit on the solder pads of an SMT board) are molded into the completed device body. Lead spacing can be 0.100 to 0.50 in. and can be placed on opposing or on all four sides.

Chip arrays are the true SMT derivatives or resistor networks and are essentially sets of chip resistors integrated into a monolithic structure (although internal circuitry can be much more complex, including film capacitors, than just isolated elements). Chip arrays use termination constructions similar to chip resistors with pitch down to 0.025 in.

Variable Resistors

Potentiometers are precision devices designed with either film, wirewound, or conductive plastic elements and are available in single or multiturn and single multisection units. The electrical output in terms of voltage applied across the element is linear or follows a predetermined curve (taper) with respect to the angular position contact arm. *Precision potentiometers* can provide superior resolution (tracking of the actual resistance to the theoretical resistance defined by the taper) where precise electrical and mechanical output and quality performance are required. *General purpose potentiometers* are used as gain or volume controls, voltage dividers or current controls in lower precision circuits. These devices can be ganged together and/or provided with rear-mounted switches. *Trimmer potentiometers* are lead-screw actuated, multiturn devices principally used as “set and forget” devices to control low current or bias voltages or to balance circuit variables.

Rheostats are larger, variable resistors, usually wirewound, for power applications. They are used for controls for motor speed, ovens, heaters, and other applications where higher current levels are present.

CAPACITORS

Thomas S. Gore, Jr.

Introduction

A capacitor consists basically of two conductors separated by a dielectric or vacuum so as to store a large electric charge in a small volume. The capacitance is expressed as a ratio of electric charge to the voltage applied $C = Q/V$, where Q = charge (C), V = voltage (V), C = capacitance (F). A capacitor has a capacitance of one farad when it receives a charge of 1C at a potential of 1V. The electrostatic energy in watt-seconds or joules stored in the capacitor is given by

$$J = 1/2 CV^2$$

FIGURE 5.1.3 Equivalent circuit of a capacitor; R_s = series resistance owing to wire leads, contact terminations, and electrodes; R_p = shunt resistance owing to resistivity of dielectric and case material, and to dielectric losses; and L = stray inductance owing to leads and electrodes.

Dielectric. Depending on the application, the capacitor dielectric may be air, gas, paper (impregnated), organic film, mica, glass, or ceramic, each having a different dielectric constant, temperature range, and thickness.

Equivalent Circuit. In addition to capacitance, a practical capacitor has an inductance and resistance. An equivalent circuit useful in determining the performance characteristics of the capacitor is shown in Fig. 5.1.3.

Equivalent Series Resistance (ESR). The ESR is the ac resistance of a capacitor reflecting both the series resistance R_s and the parallel resistance R_p at a given frequency so that the loss of these elements can be expressed as a loss in a single resistor R in the equivalent circuit.

Capacitive Reactance. The reactance of a capacitor is given by

$$X_c = 1/2\pi fC = 1/\omega C \quad (\Omega)$$

where $f = \omega/2\pi$ is the frequency in hertz.

Impedance (Z). In practical capacitors operating at high frequency, the inductance of the leads must be considered in calculating impedance. Specifically,

$$Z = \sqrt{R^2 + (X_L - X_C)^2}$$

where R is the ESR, and X_L reflects the inductive reactance.

The effects illustrated in Fig. 5.1.3 are particularly important at radio frequencies where a capacitor may exhibit spurious behavior because of these equivalent elements. For example, in many high-frequency tuned circuits the inductance of the leads may be sufficient to detune the circuit.

Power Factor (PF). The term PF defines the electrical losses in a capacitor operating under an ac voltage. In an ideal device the current will lead the applied voltage by 90°. A practical capacitor, owing to its dielectric, electrode, and contact termination losses, exhibits a phase angle of less than 90°. The PF is defined as the ratio of the effective series resistance R to the impedance Z of the capacitor and is usually expressed as a percentage.

Dissipation Factor (DF). The DF is the ratio of effective series resistance R to capacitive reactance X_C and is normally expressed as a percentage. The DF and PF are essentially equal when the PF is 10 percent or less.

Quality Factor Q. The Q is a figure of merit and is the reciprocal of the dissipation factor. It usually applies to capacitors used in tuned circuits.

Leakage Current, DC. Leakage current is the current flowing through the capacitor when a dc voltage is applied.

5.10 ELECTRONIC AND FIBER OPTIC COMPONENTS

Insulation Resistance. The insulation resistance is the ratio of the applied voltage to the leakage current and is normally expressed in megohms. For electrolytic capacitors, the maximum leakage current is normally specified.

Ripple Current or Voltage. The ripple current or voltage is the rms value of the maximum allowable alternating current or voltage (superimposed on any dc level) at a specified frequency at which the capacitor may be operated continuously at a specified temperature.

Surge Voltage. The surge voltage applicable to electrolytic capacitors is a voltage in excess of the rated voltage, which the capacitor will withstand for a specified limited period at any temperature.

Fixed Capacitors

Precision Capacitors. Capacitors falling into the precision category are generally those having exceptional capacitance stability with respect to temperature, voltage, frequency, and life. They are available in close capacitance tolerances and have low-loss (high- Q) dielectric properties. These capacitors are generally used at radio frequencies in tuner, rf filter, coupling, bypass, and temperature-compensation applications. Typical capacitor types in this category are mica, ceramic, glass, and polystyrene. The polystyrene capacitor has exceptionally high insulation resistance, low losses, low dielectric absorption, and a controlled temperature coefficient for film capacitors.

Semiprecision Units. Paper- and plastic-film capacitors with foil or metallized dielectric are nonpolar and generally fall between the low-capacitance precision types, such as mica and ceramic, and the high-capacitance electrolytics.

General Purpose. Electrolytic aluminum and tantalum capacitors and the large-usage general-purpose (high-K) ceramic capacitors both have broad capacitance tolerances, are temperature-sensitive, and have high volumetric efficiencies (capacitance-volume ratio). They are primarily used as bypass and filter capacitors where high capacitance is needed in small volumes, and with guaranteed minimum values. These applications do not require low dissipation factors, stability, or high insulation resistance found in precision and semiprecision capacitors. On a performance versus cost basis, the general-purpose capacitors are the least expensive of the groups. High-capacitance aluminum electrolytic capacitors have been designed for computer applications featuring low equivalent series resistance and long life.

Suppression Capacitors. The feed-through capacitors are three-terminal devices designed to minimize effective inductance and to suppress rf interference over a wide frequency range. For heavy feed-through currents, applications in 60- and 400-Hz power supplies, paper or film dielectrics are normally used. For small low-capacitance, low-current units, the ceramic and button-mica feed-through high-frequency styles are used.

Capacitors for Microelectronic Circuits. Table 5.1.1 lists representative styles of discrete miniature capacitors electrically and physically suitable for microelectronic circuit use (filtering, coupling, tuning, bypass, and so forth). The chip capacitor, widely used in hybrid circuits, is available in single-wafer or multilayer (monolithic) ceramic, or in tantalum constructions, both offering reliable performance, very high volumetric efficiency, and a wide variety of capacitance ranges at moderate cost. Temperature-compensating ceramic chips are used where maximum capacitance stability or predictable changes in capacitance with temperature are required.

General-purpose ceramic and solid electrolytic tantalum chips are used for coupling and bypass applications where very high capacitance and small size are necessary. The ceramic chips are unencapsulated and leadless, with suitable electrodes for soldering in microcircuits. The beam-leaded tantalum chips are attached by pressure bonding. The tantalum chip is also available in a multiple-unit assembly in the dual-in-line package for use on printed-circuit boards.

Transmitter Capacitors. The principal requirements for transmitter capacitors are high rf power-handling capability, high rf current and voltage rating, high Q , low internal inductance, and very low effective series resistance. Mica, glass, ceramic, and vacuum- or gas-filled capacitors are used primarily for transmitter applications. Glass dielectric transmitter capacitors have a higher self-resonating frequency and current rating than comparable mica styles. The ceramic capacitors offer moderately high rf current ratings, operating temperatures to

TABLE 5.1.1 Characteristics of Typical Capacitors for Microelectronic Circuits

Type of capacitor	Typical capacitance range	Typical working voltage range, V, dc	Temperature range, °C	Dissipation factor, %	Minimum insulation resistance, MΩ at 25°C	Temp. coeff., ppm/°C	Max. capacitance change over temp. range, %	Termination
Chip: Ceramic, temperature-compensating	1 pF to 0.027 mF	50–200	–55 to +125	0.1 at 1 MHz	50,000	0 to –750	...	Metallized
Ceramic, general-purpose	390 pF to 0.47 μF	25–200	–55 to +125	3.0 at 1 kHz	10,000	...	±15	Metallized
Tantalum oxide (beam-lead), dry	100–3000 pF	12–50	–55 to +85	0.6 at 1 kHz	10,000	+200	...	Beam lead
Tantalum oxide Polar, solid electrolyte	0.1–47 μF	3–35	–55 to +85	4.0 at 120 Hz	±10	Metallized

5.12 ELECTRONIC AND FIBER OPTIC COMPONENTS

105°C, and high self-resonant frequencies. The gas or vacuum capacitor is available in a wide range of capacitance and power ratings and is used where very-high-power, high-voltage, and high-frequency circuit conditions exist. These units are also smaller than other transmitting types for comparable ratings. The circuit performance of the transmitter capacitor is highly dependent on the method of mounting, lead connections, operating temperatures, air circulation, and cooling, which must be considered for specific applications.

Variable Capacitors

Variable capacitors are used for tuning and for trimming or adjusting circuit capacitance to a desired value.

Tuning Capacitor (Air-, Vacuum-, or Gas-Filled). The parallel plate (single or multisection style) is used for tuning receivers and transmitters. In receiver applications, one section of a multisection capacitor is normally used as the oscillator section, which must be temperature-stable and follow prescribed capacitance-rotation characteristics. The remaining capacitor sections are mechanically coupled and must track to the oscillator section. The three most commonly used plate shapes are semi-circular (straight-line capacitance with rotation), midline (between straight-line capacity and straight-line frequency), and straight-line frequency (which are logarithmically shaped). For transmitter applications, variable vacuum- or gas-filled capacitors of cylindrical construction are used. These capacitors are available in assorted sizes and mounting methods.

Special Capacitors

High-Energy Storage Capacitors. Oil-impregnated paper and/or film dielectric capacitors have been designed for voltages of 1000 V or higher of pulse-forming networks. For lower voltages, special electrolytic capacitors can be used which have a low inductance and equivalent-series resistance.

Commutation Capacitors. The widespread use of SCR devices has led to the development of a family of oil-impregnated paper and film dielectric capacitors for use in triggering circuits. The capacitor is subjected to a very fast rise time (0.1 ms) and high current transients and peak voltages associated with the switching.

Reference Specifications. Established reliability (ER) specifications are a series of military (MIL) specifications that define the failure-rate levels for selected styles of capacitors. The predicted failure rate is based on qualification-approval life testing and continuous-production life testing by the capacitor manufacturer.

INDUCTORS AND TRANSFORMERS

Emanuel Gikow

Introduction

Inductive components are generally unique in that they must be designed for a specific application. Whereas resistors, capacitors, meters, switches, and so forth, are available as standard or stock items, inductors and transformers have not usually been available as off-the-shelf items with established characteristics. With recent emphasis on miniaturization, however, wide varieties of chokes have become available as stock items. Low inductance values are wound on a nonmagnetic form, powdered iron cores are used for the intermediate values of inductance, and ferrites are used for the higher-inductance chokes. High-value inductors use both a ferrite core and sleeve of the same magnetic material. Wide varieties of inductors are made in tubular, disk, and rectangular shapes. Direct-current ratings are limited by the wire size or magnetic saturation of the core material.

Distributed Capacitance

The distributed capacitance between turns and windings has an important effect on the characteristics of the coil at high frequencies. At a frequency determined by the inductance and distributed capacitance, the coil

becomes a parallel resonant circuit. At frequencies above self-resonance, the coil is predominantly capacitive. For large-valued inductors the distributed capacitance can be reduced by winding the coil in several sections so that the distributed capacitances of the several sections are in series.

Toroids

The toroidal inductor using magnetic-core material has a number of advantages. Using ungapped core material, the maximum inductance per unit volume can be obtained with the toroid. It has the additional advantages that leakage flux tends to be minimized and shielding requirements are reduced. The inductance of the toroid and its temperature stability are directly related to the average incremental permeability of the core material. For a single-layer toroid of rectangular cross section without air gap,

$$L = 0.0020N^2b\mu_d \ln (r_2/r_1)$$

where L = inductance (μH)

b = core width (cm)

μ_d = average incremental permeability

r_1 = inside radius (cm)

r_2 = outside radius (cm)

N = total number of turns

Incremental permeability is the apparent ac permeability of a magnetic core in the presence of a dc magnetizing field. As the dc magnetization is increased to the point of saturating the magnetic core, the effective permeability decreases. This effect is commonly used to control inductance in electronically variable inductors.

Inductors with magnetic cores are often gapped to control certain characteristics. In magnetic-cored coils the gap can reduce nonlinearity, prevent saturation, lower the temperature coefficient, and increase the Q .

Adjustable Inductors

The variable inductor is used in a number of circuits: timing, tuning, calibration, and so forth. The most common form of adjustment involves the variation of the effective permeability of the magnetic path. In a circuit comprising an inductor and capacitor, the slug-tuned coil may be preferred over capacitive tuning in an environment with high humidity. Whereas the conventional variable capacitor is difficult and expensive to seal against the entry of humidity, the inductor lends itself to sealing without seriously inhibiting its adjustability. For example, a slug-tuned solenoid can be encapsulated, with a cavity left in the center to permit adjustment of the inductance with a magnetic core. Moisture will have little or no effect on the electrical performance of the core. The solenoid inductor using a variable magnetic core is the most common form of adjustable inductor. The closer the magnetic material is to the coil (the thinner the coil form), the greater the adjustment range will be. Simultaneous adjustment of both a magnetic core and magnetic sleeve will increase the tuning range and provide magnetic shielding. In another form, the air gap at the center post of a cup core can be varied to control inductance. Not only is the result a variable inductor, but also the introduction of the air gap provides a means for improving the temperature coefficient of the magnetic core by reducing its effective permeability.

Power Transformers

Electronic power transformers normally operate at a fixed frequency. Popular frequencies are 50, 60, and 400 Hz. Characteristics and designs are usually determined by the voltampere (VA) rating and the load. For example, when used with a rectifier, the peak inverse voltage across the rectifier will dictate the insulation requirements. With capacitor input filters, the secondary must be capable of carrying higher currents than with choke input filters. There are a number of ways by which the size and weight of power transformers can be reduced, as follows:

Operating frequency. For a given voltampere rating, size and weight can be reduced as some inverse function of the operating frequency.

FIGURE 5.1.4 Equivalent circuit of a broadband transformer; E_g = generator voltage, R_g = generator impedance, C_p = primary shunt and distributed capacitance, L_p = primary leakage inductance, L_s = secondary leakage inductance, C_s = secondary shunt and distributed capacitance, R_p = primary winding resistance, R_e = equivalent resistance corresponding to core losses, L_e = equivalent magnetizing (open-circuit) inductance of primary, n = ideal transformer primary-to-secondary turns ratio, C_{ps} = primary-to-secondary capacitance (interwinding capacitance), R_s = secondary winding resistance, R_L = load impedance.

Maximum operating temperature. By the use of high-temperature materials and at a given VA rating and ambient temperature, considerable size reduction can be realized by designing for an increased temperature rise.

Ambient temperature. With a given temperature rise and for a fixed VA rating, transformer size can be reduced if the ambient temperature is lowered.

Regulation. If the regulation requirements are made less stringent, the wire size of the windings can be reduced, with a consequent reduction in the size of the transformer.

Audio Transformers

These transformers are used for voltage, current, and impedance transformation over a nominal frequency range of 20 to 20,000 Hz. The equivalent circuit (Fig. 5.1.4) is the starting point for the basic analysis of the transformer frequency response.

A prime consideration in the design, size, and cost of audio transformers is the span of the frequency response. In wide-band audio transformers the frequency coverage can be separated into three nearly independent ranges for the purpose of analysis. Thus, in the high-frequency range leakage inductance and distributed capacitance are most significant. In the low-frequency region the open-circuit inductance is important. At the medium-frequency range, approximately 1000 Hz, the effect of the transformer on the frequency response can be neglected. In the above discussion, the transformation is assumed to be that of an ideal transformer.

Miniaturized Audio Transformers

Frequency Response. The high-frequency response is dependent on the magnitude of the leakage inductance and distributed capacitance of the windings. These parameters decrease as the transformer size decreases. Consequently, miniaturized audio transformers generally have an excellent high-frequency response. On the other hand, the small size of these transformers results in increased loss and in a degradation of the low-frequency response, which is dependent on the primary open-circuit inductance.

Air Gap. The primary open-circuit inductance is proportional to the product of the square of the turns and the core area, and inversely proportional to the width of the gap. As the transformer size is reduced, both the core area and number of turns must be reduced. Consequently, if the open-circuit inductance is to be maintained, the air gap must be reduced. A butt joint has of necessity a finite air gap; as a result the full ungapped inductance is not realized. An interlaced structure of the core, where the butt joints for each lamination are staggered, most closely approximates an ungapped core. A substantially higher inductance, 120 H, is possible.

FIGURE 5.1.5 Pulse waveform.

The problem with taking advantage of this effect is that as the air gap is reduced, the allowable amount of unbalanced direct current flowing in the transformer winding must be lowered to prevent core saturation.

Pulse Transformers

Pulse transformers for high-voltage or high-power applications, above 300 W peak, are used in modulators for radar sets. Their function is to provide impedance matching between the pulse-forming network and the magnetron. Prime concern is transformation of the pulse with a minimum of distortion. Lower-power pulse transformers fall into two categories: those used for coupling or impedance matching similar to the high-power pulse transformers, and blocking oscillator transformers used in pulse-generating circuits. Pulse widths for such transformers most commonly range from about 0.1 to 20 μs .

Assuming the pulse transformer is properly matched and the source is delivering an ideal rectangular pulse, a well-designed transformer should have small values of leakage inductance and distributed capacitance. Within limits dictated by pulse decay time the open-circuit inductance should be high. Figure 5.1.5 shows the pulse waveform with the various types of distortions that may be introduced by the transformer.

Broadband RF Transformers

At the higher frequencies, transformers provide a simple, low-cost, and compact means for impedance transformation. Bifilar windings and powdered-iron or ferrite cores provide optimum coupling. The use of cores with high permeabilities at the lower frequencies reduces the number of turns and distributed capacitance. At the upper frequencies the reactance increases, even though the permeability of the core may fall off.

Inductive Coupling

There are a variety of ways to use inductive elements for impedance-matching or coupling one circuit to another. Autotransformers and multiwinding transformers that have no common metallic connections are a common method of inductive coupling. In a unity-coupled transformer, N_1 = number of primary turns, N_2 = number of

FIGURE 5.1.6 Response of a staggered pair, geometric symmetry.

secondary turns, k = coefficient of coupling, M = mutual inductance, n = turns ratio, L_1 = primary open-circuit inductance, L_2 = secondary open-circuit inductance, I_1 = primary current, I_2 = secondary current, E_1 = primary voltage, E_2 = secondary voltage, Z_1 = primary impedance with matched secondary, Z_2 = secondary impedance with matched primary. Transformer relationships for unity-coupled transformer, $k = 1$, assuming losses are negligible:

$$n = N_2/N_1 = E_2/E_1 = I_2/I_1 = Z_2/Z_1 \quad M = \sqrt{L_1 L_2}$$

Single-Tuned Circuits

Single-tuned circuits are most commonly used in both wide-band and narrow-band amplifiers. Multiple stages that are cascaded and tuned to the same frequency are synchronously tuned. The result is that the overall bandwidth of the cascaded amplifiers is always narrower than the single-stage bandwidth. The shrinkage of bandwidth can be avoided by stagger tuning. A stagger-tuned system is a grouping of single-tuned circuits where each circuit is tuned to a different frequency. For a flat-topped response the individual stages are geometrically balanced from the center frequency. In Fig. 5.1.6, which illustrates the response of a staggered pair, f_0 = center frequency of overall response, and f_1, f_2 = resonant frequency of each stage. The frequencies are related as follows:

$$f_0/f_1 = f_2/f_0 = \alpha$$

Double-Tuned Transformers

One of the most widely used circuit configurations for i.f. systems in the frequency range of 250 kHz to 50 MHz is the double-tuned transformer. It consists of a primary and secondary tuned to the same frequency and coupled inductively to a degree dependent on the desired shape of the selectivity curve. Figure 5.1.7 shows the variation of secondary current versus frequency.

Bandwidth

A comparison of the relative 3-dB bandwidth of multistage single- and double-tuned circuits is shown in Table 5.1.2. Most significant is the lower skirt ratio of the double-tuned circuit, i.e., relative value of the ratio of the bandwidth at 60 dB (BW_{60}) to the bandwidth at 6 dB (BW_6).

POLED FERROELECTRIC CERAMIC DEVICES

Joseph M. Giannotti

Introduction

The usefulness of ferroelectrics rests on two important characteristics, asymmetry and high dielectric constant. Poled ferroelectric devices are capable of doing electric work when driven mechanically or mechanical work

FIGURE 5.1.7 Variation of secondary current and gain with frequency and with degree of coupling: 1 = under-coupled; 2 = critically coupled; 3 = overcoupled.

when driven electrically. In poled ferroelectrics, the piezoelectric effect is particularly strong. From the design standpoint, they are especially versatile because they can be used in a variety of ceramic shapes. Piezoelectricity is the phenomenon of coupling between elastic and dielectric energy. Piezoelectric ceramics have gained wide use in the low-frequency range up to a few megahertz over the strongly piezoelectric nonferroelectric single crystals such as quartz, lithium sulfate, lithium niobate, lithium tantalate, and zinc oxide. High dielectric strength and low manufacturing cost are prime factors for their usefulness.

The magnitude and character of the piezoelectric effect in a ferroelectric material depend on orientation of applied force or electric field with respect to the axis of the material. With piezoelectric ceramics, the polar axis is parallel to the original dc polarizing field. In all cases the deformations are small when amplification by mechanical resonance is not involved. Maximum strains with the best

piezoelectric ceramics are in the range of 10^{-3} . Figure 5.1.8 illustrates the basic deformations of piezoelectric ceramics and typical applications.

Transducers

The use of barium titanate as a piezoelectric transducer material has been increasingly replaced by lead titanate zirconate solid-solution ceramics since the latter offer higher piezoelectric coupling, wider operating temperature range, and a choice of useful variations in engineering parameters. Table 5.1.3 gives the characteristics of different compositions.

The high piezoelectric coupling and permittivity of PZT-5H have led to its use in acoustic devices where its high electric and dielectric losses can be tolerated. For hydrophones or instrument applications PZT-5A is a better choice, since its higher Curie point leads to better temperature stability. The low elastic and dielectric losses of PZT-8 composition at high drive level point to its use in high-power sonic or ultrasonic transducers. The very low mechanical Q of lead metaniobate has encouraged its use in ultrasonic flaw detection, where the low Q helps the suppression of ringing. The high acoustic velocity of sodium potassium niobate is of advantage in high-frequency thickness-extensional thickness-shear transducers, since this allows greater thickness and therefore lower capacitance.

Since ceramic materials can be fabricated in a wide range of sizes and shapes, they lend themselves to designs for applications that would be difficult to achieve with single crystals. Figure 5.1.9 illustrates the use

TABLE 5.1.2 Relative Values of 3-dB Bandwidth for Single- and Double-Tuned Circuits

No. of stages	Relative values of 3-dB bandwidth		Relative values of BW_{60}/BW_6

5.18 ELECTRONIC AND FIBER OPTIC COMPONENTS

of simple piezoelectric elements in a high-voltage source capable of generating an open-circuit voltage of approximately 40 kV. Piezoelectric accelerometers suitable for measuring vibrating accelerations over a wide frequency range are readily available in numerous shapes and sizes. Figure 5.1.10 shows a typical underwater transducer, which uses a hollow ceramic cylinder polarized through the wall thickness. Flexing-type piezoelectric elements can handle larger motions and smaller forces than single plates.

Resonators and Filters

The development of temperature-stable filter ceramics has spurred the development of ceramic resonators and filters. These devices include simple resonators, multielectrode resonators, and cascaded combinations thereof,

FIGURE 5.1.8 Basic piezoelectric action depends on the type of material used and the geometry. Generally, two or more of these actions are present simultaneously. TE and TS are high-frequency (greater than 1 MHz) modes and FS, LE_T , LE_P , and PE_T are low-frequency (less than 1 MHz) modes. The thickness controls the resonant frequency for the TE and TS modes, the diameter for PE_T , and the length for the LE_T and LE_P modes.

FIGURE 5.1.9 High-voltage generator.

mechanically coupled pairs of resonators, and ceramic ladder filters, covering a frequency range from 50 Hz to 10 MHz.

Two lead titanate-zirconate compositions, PZT-6A and PZT-6B ceramics, are most widely used for resonator and filter applications. PZT-6A, having high electromechanical coupling coefficient (45 percent) and moderate mechanical Q (400), is used for medium to wide bandwidth applications, while PZT-6B, with moderate coupling (21 percent) and higher Q (1500), is used for narrow bandwidths. The compositions exhibit a frequency constant stable to within ± 0.1 percent over a temperature range from -40 to $+85^\circ\text{C}$. The frequency characteristics increase slowly with time at less than 0.1 percent per decade of time.

Ceramic Resonators

A thin ceramic disk with fully electroded faces, polarized in its thickness direction, has its lowest excitable resonance in the fundamental radial mode. The impedance response of such a disk and its equivalent circuit are shown in Fig. 5.1.11.

FIGURE 5.1.11 Impedance response of a fundamental radial resonator.

 N_1 = frequency constant (resonance frequency \times length).

Ceramic resonators can be used in various configurations for single-frequency applications or combined in basic L-sections to form complete bandpass filter networks.

QUARTZ CRYSTAL DEVICES

John R. Vig

Introduction

Piezoelectric crystal devices are used primarily for frequency control, timing, transducers, and delay lines. The piezoelectric material used for most applications is quartz. A quartz crystal acts as a stable mechanical resonator, which, by its piezoelectric behavior and high Q , determines the frequency generated in an oscillator circuit. Bulk-wave resonators are available in the frequency range from about 1 kHz to 300 MHz. Surface-acoustic-wave (SAW) and shallow-bulk-acoustic-wave devices can be made to operate at well above 1 GHz.

In the manufacture of the different types of quartz resonators, wafers are cut from the mother crystal along precisely controlled directions with respect to the crystallographic axes. The properties of the device depend strongly on the angles of cut. After shaping to required dimensions, metal electrodes are applied to the quartz wafer, which is mounted in a holder structure. The assembly, called a *crystal unit* (or *crystal* or *resonator*) is usually sealed hermetically in partial- to ultrahigh-vacuum.

To cover the wide range of frequencies, different cuts, vibrating in a variety of modes, are used. Above 1 MHz, the AT cut is commonly used. For high-precision applications, the SC cut has important advantages over the AT and the occasionally used BT cuts. AT-, BT-, and SC-cut crystals can be manufactured for fundamental-mode operation at frequencies up to about 100 MHz. Above 40 MHz, *overtone* crystals are generally used. Such crystals operate at a selected odd harmonic mode of vibration. AT-, BT-, and SC-cut crystals vibrate in the thickness shear mode. Below 1 MHz, tuning forks, X-Y and NT bars (flexure mode), $+5^\circ$ X cuts (extensional mode), or CT and DT cuts (face shear mode) can be used. Over 200 million 32.8-kHz tuning-fork crystals are produced annually for the world watch market.

Equivalent Circuit

The circuit designer treats the behavior of a quartz crystal unit by considering its equivalent circuit (Fig. 5.1.12). The mechanical resonance in the crystal is represented by L_1 , C_1 , and R_1 . Because it is a dielectric with electrodes, the device also displays an electrical capacitance C_0 . The parallel combination of C_0 and the motional arm, C_1 - L_1 - R_1 , represents the equivalent circuit to a good approximation. As shown in Fig. 5.1.12b, the reactance of this circuit varies with frequency.

The Q values ($Q^{-1} = 2\pi f_s R_1 C_1$) of quartz-crystal units are much higher than those attainable with other circuit elements. In general-purpose units, the Q is usually in the range of 10^4 to 10^6 . The intrinsic Q of quartz is limited by internal losses. For AT-cut crystals, the intrinsic Q has been experimentally determined to be 16×10^6 at 1 MHz; it is inversely proportional to frequency. At 5 MHz, for example, the intrinsic Q is 3.2×10^6 .

Oscillators

The commonly used crystal oscillator circuits fall into two broad categories. In series-resonance oscillators, the crystal operates at series resonance, i.e., at f_s . In parallel-resonance or antiresonance oscillators, the crystal is used as a positive reactance; i.e., the frequency is between f_s and f_A . In this latter mode of operation the oscillator circuit provides a load capacity to the crystal unit. The oscillator then operates at the frequency where the crystal unit's reactance cancels the reactance of the load capacitor. When the load capacitance is changed, the oscillator frequency changes. An important parameter in this connection is the capacitance ratio $r = C_0/C_1$. Typically, the value of r is a few hundred for fundamental-mode crystals. It is larger by a factor of n^2 for n th-overtone crystals.

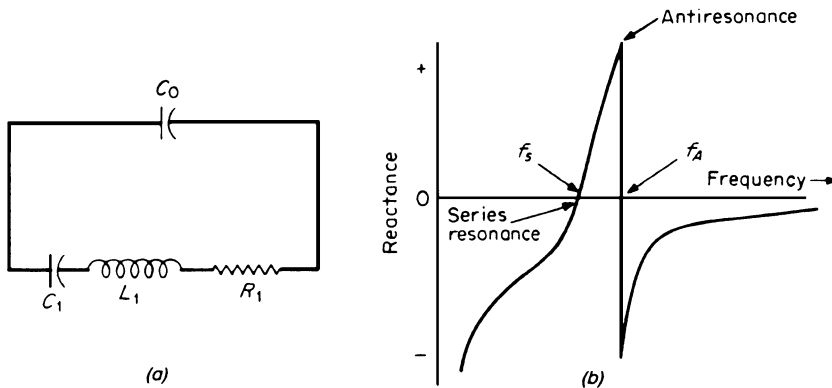

FIGURE 5.1.12 (a) Equivalent circuit and (b) frequency-reactance relationship.

When a load capacitor C_L is connected in series with a crystal, the series-resonance frequency of the combination is shifted from f_s by Δf , which is related to the other parameters by

$$\frac{\Delta f}{f_s} \approx \frac{C_0}{2r(C_0 + C_L)}$$

For a typical fundamental-mode AT-cut crystal unit with $r = 250$, $C_0 = 5$ pF, and $C_L = 30$ pF, the shift is 286 ppm. If such a crystal unit is to remain stable to, for example, 1×10^{-9} , the load reactance owing to C_L and the other circuit components must remain stable to within 1.2×10^{-4} pF. The frequency can also be “tuned” by intentionally changing C_L . For the above example, a change of 1 pF in C_L shifts the frequency by nearly 10 ppm.

Filters

Quartz crystals are used as selective components in crystal filters. With the constraint imposed by the equivalent circuit of Fig. 5.1.12a, filter design techniques can provide bandpass or bandstop filters with prescribed characteristics. Crystal filters exhibit low insertion loss, high selectivity, and excellent temperature stability.

Filter crystals are designed to have only one strong resonance in the region of operation, with all other responses (unwanted modes) attenuated as much as possible. The application of energy-trapping theory can provide such a response. If electrode size and thickness are selected in accordance with that theory, the energy of the main response is trapped between the electrodes, whereas the unwanted modes are untrapped and propagate toward the edge of the crystal resonator, where their energy is dissipated. It is possible to manufacture AT-cut filter crystals with greater than 40-dB attenuation of the unwanted modes relative to the main response.

Transducers

Whereas in frequency control and timing applications of quartz-crystal devices the devices are designed to be as insensitive to the environment as possible, quartz crystals can also be designed intentionally to be highly sensitive to environmental parameters such as temperature, mass changes, pressure, force, and acceleration. Quartz-crystal transducers can exhibit unsurpassed resolution and dynamic range. For example, one commercial “quartz pressure gage” exhibits a 1 ppm resolution, i.e., 60 Pa at 76 MPa (0.01 lb/in² at 11,000 lb/in²), and a 0.025 percent full-scale accuracy. Quartz thermometers can provide millidegrees of absolute accuracy over

5.22 ELECTRONIC AND FIBER OPTIC COMPONENTS

wide temperature ranges. Quartz sorption detectors can detect a change in mass of 10^{-12} g. Quartz accelerometer/force sensors are capable of resolving 10^{-7} to 10^{-8} of full scale.

Standardization

Standardization exists concerning dimensions and performance characteristics of crystal units and oscillators. The principal documents are the U.S. military standards, the standards issued by the Electronics Industry Association (EIA) and by the International Electrotechnical Commission (IEC).

Temperature

The frequency versus temperature characteristics are determined primarily by the angles of cut of the crystal plates with respect to the crystallographic axes of quartz. Typical characteristics are shown in Figs. 5.1.13 and 5.1.14. The points of zero temperature coefficient, the *turnover points*, can be varied over a wide range by varying the angles of cut.

The frequency-temperature characteristic of AT- and SC-cut crystals follow a third-order law, as shown in Fig. 5.1.13 for the AT cut. A slight change in the orientation angle (7 min in the example shown in Fig. 5.1.13) greatly changes the frequency-temperature characteristic. Curve 1 is optimal for a wide temperature range (-55 to 105°C). Curve 2 gives minimum frequency deviation over a narrow range near the inflection temperature T_i . The frequency versus temperature characteristics of SC-cut crystals is similar to the curves shown in Fig. 5.1.13 except that T_i is shifted to about 95°C. The SC cut is a doubly rotated cut; i.e., two angles must be specified and precisely controlled during the manufacturing process. The SC cut is more difficult to manufacture with predictable frequency versus temperature characteristics than are the singly rotated cuts, such as AT and BT

FIGURE 5.1.13 Frequency-temperature characteristics of AT-cut crystals.

FIGURE 5.1.14 Parabolic frequency-temperature characteristic of some crystal cuts.

cuts. Many of the crystal cuts have a parabolic frequency versus temperature characteristic, as shown in Fig. 5.1.14 for the BT, CT, and DT cuts. The turnover temperatures of these cuts can also be shifted up or down by changing the angles of cut.

To achieve the highest stability, oven-controlled crystal oscillators (OCXO) are used. In such oscillators, the crystal unit and the temperature-sensitive components of the oscillator are placed in a stable oven the temperature of which is set to the crystal's turnover temperature. OCXOs are bulkier and consume more power than other types. In addition, when an oven-controlled oscillator is turned on, one must wait several minutes for the oscillator to stabilize. During warm-up, the thermal stresses in the crystal can produce significant frequency shifts. This thermal-transient effect causes the typical warm-up time of an oscillator to be several minutes longer than the time it takes for the oven to stabilize. The thermal-transient effect is absent in SC-cut crystals. In oscillators which use SC-cut crystals, the warm-up time can be much shorter.

In temperature-compensated crystal oscillators (TCXOs) the crystal's frequency versus temperature behavior is compensated by varying a load capacitor. The output signal from a temperature sensor, e.g., a thermistor network, is used to generate the correction voltage applied to a varactor. Digital techniques are capable of providing better than 1×10^{-7} frequency stability from -55 to $+85^\circ\text{C}$. TCXOs are smaller, consume less power than OCXOs and require no lengthy warm-up times. A major limitation on the stabilities achievable with TCXOs is the thermal hysteresis exhibited by crystal units.

Aging

Aging, the gradual change in a crystal's frequency with time, can be a result of several causes. The main causes are mass transfer to or from the resonator surfaces (owing to adsorption and desorption of contamination) and stress relief within the mounting structure or at the interface between the quartz and the electrodes. The observed aging is the sum of the aging produced by the various mechanisms and may be positive or negative. Aging is also sometimes referred to as *drift* or *long-term stability*.

The aging rate of a crystal unit is highest when it is new. As time elapses, stabilization occurs within the unit and the aging rate decreases. The aging observed at constant temperature usually follows an approximately logarithmic dependence on time. When the temperature of a crystal is changed, a new aging cycle starts.

A major reason for the aging of low-frequency units (below 1 MHz) is that mechanical changes take place in the mounting structure. Properly made units may age several ppm/year, half that aging occurring within the first 30 days. Crystal units for frequencies of 1 MHz and above age primarily because of mass transfer. General-purpose crystal units are usually housed in solder-sealed or resistance-welded material enclosures of the HC-6 or HC-18 configuration that are filled with dry nitrogen. The aging rate of such units is typically specified as 5 ppm for the first month; over a year's time their aging may be from 10 to 60 ppm. Higher-quality general-purpose crystals may age as little as 1 ppm per year. If a lower aging rate is desired, overtone crystals in clean glass, metal, or ceramic enclosures should be used. Advanced surface-cleaning, packaging, and ultrahigh-vacuum fabrication techniques have resulted in units that age less than 5×10^{-11} per day after a few days of stabilization, or $<1 \times 10^{-8}$ per year.

Short-Term Stability

Short-term stability, or "noise," in the time domain $\sigma(\tau)$ is usually expressed as the 2-sample deviation of the fractional frequency fluctuations for a specified averaging time. The averaging times τ over which $\sigma(\tau)$ is

5.24 ELECTRONIC AND FIBER OPTIC COMPONENTS

specified generally range from 10^{-3} to 10^3 s. For a good oscillator, $\sigma(\tau)$ may range from 1×10^{-9} for $\tau = 10^{-3}$ s to 5×10^{-13} for $\tau = 1$ s to 1×10^{-12} for up to 10^3 s. For $\tau > 10^3$ s, the stability is usually referred to as *long-term stability* or aging. For $\tau < 1$ s, the short-term instabilities are generally attributed to noise in the oscillator circuitry although the crystal itself can also be a significant contributor.

When measured in the frequency domain, short-term stability is denoted by $S_\phi(f)$ or $S_y(f)$, the spectral density of phase fluctuations and frequency fluctuations, respectively, at a frequency separation f from the carrier frequency ν . $\mathcal{L}(f)$, the single-sideband phase noise, is also used in reporting the frequency-domain stability. The three quantities are related by $f^2 S_\phi(f) = \nu^2 S_y(f) = 2f^2 \mathcal{L}(f)$. For a low-noise 5-MHz oscillator, $\mathcal{L}(f)$ may be -115 dB(c) at 1 Hz from the carrier, and -160 dB(c) at 1 kHz from the carrier.

Thermal Hysteresis

When the temperature of a crystal unit is changed and then returned to its original value, the frequency will generally not return to its original value. This phenomenon, called *thermal hysteresis* or lack of *retrace*, can be caused by the same mechanisms as aging, i.e., mass transfer because of contamination and stress relief.

For a given crystal unit, the magnitude of the effect depends on the magnitude and direction of the temperature excursion, on the thermal history of the unit, and on the design and construction of both the crystal unit and the oscillator circuit. The effect tends to be smaller in OXCOs, where the operating temperature of the crystal is always approached from below, than in TCXOs, where the operating temperature can be approached from either direction. Thermal hysteresis can be minimized through the use of clean, ultrahigh-vacuum fabrication techniques (which minimize the mass-transfer contribution) and through the use of properly mounted SC-cut crystals (which minimize the stress-relief contributions). The magnitude of the effect typically ranges from several ppm in general-purpose crystals to less than 1×10^{-9} in high-stability crystals operated in OXCOs.

Drive Level

The amplitude of vibration is proportional to the current through a crystal. Because of the nonlinearities of quartz, the frequency of a crystal and the incidence of interfering modes are functions of the drive level. The drive level must be stated when a crystal's parameters are specified. The oscillator designer's ability to improve signal-to-noise ratios by using a higher drive level is limited. In SC-cut crystals, the drive level effects are significantly below those observed in AT- and BT-cut units. When the drive level is increased, the frequency of AT- and SC-cut crystals increases and the frequency of the BT-cut crystal decreases.

Acceleration, Vibration, and Shock

The frequency of a crystal unit is affected by stresses. Even the acceleration owing to gravity produces measurable effects. When an oscillator using an AT-cut crystal is turned upside down, the frequency typically shifts about 4×10^{-9} because the acceleration sensitivity of the crystal is typically $2 \times 10^{-9} g^{-1}$. The sensitivity is the same when the crystal is subjected to vibration; i.e., the time-varying acceleration owing to the vibration modulates the frequency at the vibration frequency with an amplitude of $2 \times 10^{-9} g^{-1}$. In the frequency domain, the vibration sensitivity manifests itself as vibration-induced sidebands that appear at plus and minus the vibration frequency away from the carrier frequency. The acceleration sensitivity of SC-cut crystals can be made to be less than that of comparably fabricated AT- or BT-cut crystals.

Shock places a sudden stress on the crystal. During shock, the crystal's frequency changes because of the crystal's acceleration sensitivity. If during shock the elastic limits in the crystal's support structure or in its electrodes are exceeded, the shock can produce a permanent frequency change. Crystal units made with chemically polished crystal plates can withstand shocks in excess of 20,000g (11 ms, $1/2$ sine). Such crystals have been successfully fired from howitzers.

Radiation

The degree to which high levels of ionizing radiation affect the frequency of a crystal unit depends primarily on the quality of quartz used to fabricate the device and on the dose. When crystals made of natural quartz are subjected to steady-state ionizing radiation, their frequencies are changed permanently by approximately a few

parts in 10^{11} per rad at a 1 Mrad dose. To minimize the effect of such radiation, high-purity cultured quartz should be used. The frequency change per rad is higher at lower doses. Pulse irradiation produces a transient frequency shift because of the thermal-transient effect. This effect can be minimized by using SC-cut crystals. Energetic neutrons change a crystal's frequency by about 6×10^{-21} per neutron per cm^2 .

INSULATORS

Sam Di Vita

Introduction

Ceramics and plastics are the principal materials for electronics insulation and mounting parts. Ceramic materials are outstanding in their resistance to high temperature, mechanical deformation, abrasion, chemical attack, electrical arc, and fungus attack. Ceramics also possess excellent electrical insulating properties and good thermal conductivity and are impervious to moisture and gases. These properties of ceramics are retained throughout a wide temperature range and are of particular importance in high-power applications such as vacuum-tube envelopes and spacers, rotor and end-plate supports for variable air capacitors, rf coil forms, cores for wire-wound resistors, ceramic-to-metal seals, and feed-through bushings for transformers.

The properties of plastics differ rather markedly from ceramics over a broad range. In a number of properties, plastics are more desirable than ceramics. These include lighter weight; better resistance to impact, shock, and vibration; higher transparency; and easier fabrication with molded-metal inserts (however, glass-bonded-mica ceramic material may be comparable with plastic in this latter respect).

Ceramic Linear Dielectric Insulators

Ceramic insulators are linear dielectrics having low loss characteristics, that are used primarily for coil forms, tube envelopes and bases, and bushings, which all require loss factors less than 0.035 when measured at standard laboratory conditions. Dielectric loss factor is the product of power factor and dielectric constant of a given ceramic. Military Specification MIL-I-10B, Insulating Compound Electrical, Ceramic Class L, covers low-dielectric-constant (12 or under) ceramic electrical insulating materials, for use over the spectrum of radio frequencies used in electronic communications and in allied electronic equipments. In this specification the "grade designators" are identified by three numbers, the first representing dielectric loss factor at 1MHz, the second dielectric strength, and the third flexural strength (modulus of rupture).

Table 5.1.4 lists the various types of ceramics and their grade designators approved for use in the fabrication of military standard ceramic radio insulators specified in MIL-I-23264A, insulators—ceramic, electrical and electronic, general specification for. This specification covers only those insulators characterized by combining the specific designators required for the appropriate military standard insulators used as standoff, feed-through, bushing, bowl, strain, pin, spreader, and other types of insulators.

Currently, Grade L-242 is typical of porcelain, L-422 of steatite, L-523 of glass, L-746 of alumina, L-442 of glass-bonded mica, and L-834 of beryllia.

High-Thermal-Shock-Resistant Ceramics

Lithia porcelain is the best thermal-shock-resistant ceramic because of its low (close to zero) coefficient of thermal expansion. It is followed in order by fused quartz, cordierite, high-silica glass, porcelain, steatite beryllium oxide, alumina, and glass-bonded mica. Those materials find wide use for rf coil forms, cores for wire-wound resistors, stator supports for air dielectric capacitors, coaxial cable insulators, standoff insulators, capacitor trimmer bases, tube sockets, relay spacers, and base plates for printed radio circuits.

High Thermal Conductivity

High-purity beryllium oxide is unique among homogeneous materials in possessing high thermal conductivity comparable with metal, together with excellent electrical insulating properties.

TABLE 5.1.4 Property Chart of Insulating Ceramic Materials Qualified under MIL-I-10

Class L ceramics	Grade designators	Power factor, 1 MHz	Dielectric constant, 1 MHz	Dielectric loss factor, 1 MHz	Dielectric strength, V/mil
Steatite: Unglazed Glazed	L-523	0.00069-0.0010	6.42+	0.0041-0.0063	230
	L-543	0.0008-0.0014		0.005-0.008	330
Porcelain: Glazed	L-232	0.0076-0.0099	5.42-6.01	0.041-0.059	249
	L-433 L-413	0.0012-0.0014 0.00119	8.14-8.22 8.92	0.010-0.012 0.011	259 191
Zircon: Unglazed Glazed	L-746	0.0001-0.0008	8.14+	0.0009	500
	L-622 L-541	0.00074 0.0017	4.19 3.78	0.0031 0.0065	226 363

	L-723	0.0003	6.37	0.002	200
Forsterite: Glazed	L-321	0.0049	4.57	0.022	245
	L-621	0.0004	6.49	0.003	293
Wallastonite: Unglazed	L-834	0.00015	6	0.0009	295

Care must be exercised in the use of beryllium oxide because its dust is highly toxic. Although it is completely safe in dense ceramic form, any operation that generates dust, fumes, or vapors is potentially very dangerous.

Some typical uses of beryllium oxide are:

1. Heat sinks for high-power rf amplifying tubes, transistors, and other semiconductors
2. Printed-circuit bases
3. Antenna windows and tube envelopes
4. Substrates for vapor deposition of metals
5. Heat sinks for electronic chassis or subassemblies

Polycrystalline sintered diamond powder is also an excellent dielectric. It has the advantage of a thermal conductivity twice as good as copper and three to four times that of beryllia. It provides a cost-effective solution for critical heat sinks for high-power diodes and similar solid-state devices.

Plastic Insulators

The term *plastics* usually refers to a class of synthetic organic materials (resins) that are sold in finished form but at some stage in their processing are fluid enough to be shaped by application of heat and pressure. The two basic types of plastics are *thermoplastic resins*, which, like wax or tar, can be softened and resoftened repeatedly without undergoing a change in chemical composition, and *thermosetting resins*, which undergo a chemical change with application of heat and pressure and cannot be resoftened.

Choice of Plastics

Some of the differences between plastics that should be considered when defining specific needs are degree of stiffness or flexibility; useful temperature range; tensile, flexural, and impact strength; intensity, frequency, and duration of loads; electrical strength and dielectric losses; color retention under environment; stress-crack resistance over time; wear and scratch resistance; moisture and chemical resistance at high temperature; gas permeability; weather and sunlight resistance over time; odor, taste, and toxicity; and long-term creep properties under critical loads.

Reinforced Plastics

These comprise a distinct family of plastic materials that consist of superimposed layers of synthetic resin-impregnated or resin-coated filler. Fillers such as paper, cotton fabric, glass fabric or fiber, glass mats, nylon fabric—either in the form of sheets or macerated—are impregnated with a thermosetting resin (phenolic, melamine, polyester, epoxy, silicone). Heat and pressure fuse these materials into a dense, insoluble solid and nearly homogeneous mass, which may be fabricated in the form of sheets or rods or in molded form.

POWER AND RECEIVING TUBES

George W. Taylor, Bernard Smith

Introduction

Power and receiving tubes are active devices using either the flow of free electrons in a vacuum or electrons and ions combined in a gas medium. The vast majority of uses for low-power electron tubes are found in the area of high vacuum with controlled free electrons. The source of free electrons is a heated material that is a thermionic emitter (cathode). The control element regulating the flow of electrons is called a *grid*. The collector element for the electron flow is the *anode*, or *plate*. Power tubes, in contrast to receiving-type tubes, handle relatively large amounts of power, and for reasons of economy, a major emphasis is placed on efficiency. The traditional division between the two tube categories is at the 25-W plate-dissipation rating level.

Receiving tubes traditionally provided essential active-device functions in electronic applications. Most receiving-type tubes produced at the present time are for replacement use in existing equipments. Electronic functions of new equipment designs are being handled by solid-state devices.

Power tubes are widely used as high-power-level generators and converters in radio and television transmitters, radar, sonar, manufacturing-process operations, and medical and industrial x-ray equipment.

Classification of Types

Power and receiving-type tubes can be separated into groups according to their circuit function or by the number of electrodes they contain. Table 5.2.1 illustrates these factors and compares some of the related features. The physical shape and location of the grid relative to the plate and cathode are the main factors that determine the amplification factor μ of the triode. The μ values of triodes generally range from about 5 to over 200. The mathematical relationships between the three important dynamic tube factors are

$$\text{Amplification factor } \mu = \Delta e_b / \Delta e_{c1}$$

$$\text{Dynamic plate resistance } r_p = \Delta e_b / \Delta i_b \quad e_b, e_{c1}, i_b = \text{const}$$

$$\text{Transconductance } S_m \text{ or } G_m = \Delta i_b / \Delta e_{c1}$$

TABLE 5.2.1 Tube Classification by Construction and Use

Tube type	No. of active electrodes	Typical use	Relative features and advantages
Diode	2	Rectifier	High back resistance
Triode	3	Low- and high-power amplifier, oscillator, and pulse modulator	Low cost, circuit simplicity
Tetrode	4	High-power amplifier and pulse modulator	Low drive power, low feedback
Pentode	5	Low-power amplifier	High gain, low drive, low feedback, low anode voltage
Hexode, etc.	6 or more	Special applications	Multiple-input mixers, converters

where e_b = total instantaneous plate voltage

e_{c1} = total instantaneous control grid voltage

i_b = total instantaneous plate current

Note that $\mu = Gm_r/p$. Figure 5.2.1 shows the curves of plate and grid current as a function of plate voltage at various grid voltages for a typical triode with a μ value of 30.

The tetrode, a four-element tube, is formed when a second grid (screen grid) is mounted between grid 1 (control grid) and the anode (plate). The plate current is almost independent of plate voltage. Figure 5.2.2 shows the curves of plate current as a function of plate voltage at a fixed screen voltage and various grid voltages for a typical power tetrode.

Cooling Methods

Cooling of the tube envelope, seals, and anode, if external, is a major factor affecting tube life. The data sheets provided by tube manufacturers include with the cooling requirements a maximum safe temperature for the various external surfaces. The temperature of these surfaces should be measured in the operating equipment. The temperature can be measured with thermocouples, optical pyrometers, a temperature-sensitive paint such as Tempilaq, or temperature-sensitive tapes.

The envelopes and seals of most tubes are cooled by convection of air around the tube or by using forced air. The four principal methods used for cooling external anodes of tubes are by air, water, vapor, and heat

**FIGURE 5.2.1** Typical triode plate characteristics.

FIGURE 5.2.2 Typical tetrode plate characteristics.

sinks. Other cooling methods occasionally used are oil, heat pipes, refrigerants, such as Freon, and gases, such as sulfahexafluoride.

Protective Circuits

Arcs can damage or destroy electron tubes, which may significantly increase the equipment operating cost. In low- or medium-power operation, the energy stored in the circuit is relatively small and the series impedance is high, which limits the tube damage. In these circuits, the tube will usually continue to work after the fault is removed; however, the life of the tube will be reduced. Since these tubes are normally low in cost, economics dictates that inexpensive slow-acting devices, e.g., circuit breakers and common fuses, be used to protect the circuit components.

FIGURE 5.2.3 Energy-diverter circuit.

High-power equipment has large stored energy, and the series impedance is usually low. Arcs in this type of equipment will often destroy expensive tubes, and slow-acting protective devices offer insufficient protection. The two basic techniques used to protect tubes are *energy diverters* and special *fast-blow fuses*. The term *crowbar* is commonly used for energy diverters. The typical circuit for a crowbar is shown in Fig. 5.2.3. In the event of a tube arc, the trigger-fault sensor unit “fires” to a crowbar, which is a very-low-impedance gas-discharge device. The firing time can be less than $2 \mu\text{s}$. The low impedance in the crowbar arm is in shunt with the Z_2 and tube arm and diverts current from the tube during arcs. The impedance Z_2 , which is in series with the tube, is used to ensure that most of the current is diverted through the crowbar. The value of Z_2 is primarily limited by efficiency considerations during normal operation. The impedance Z_1 is required to limit the fault current in the storage condenser to the maximum current rating of the condenser. The impedance Z_g is the internal power-supply impedance. Devices used as crowbars are thyratrons, ignitrons, triggered spark gaps and plasmoid-triggered vacuum gaps.

Fast Fuses

Two types of fast-blow fuses are used to protect power tubes. They are *exploding-wire* and *exothermic* fuses. Exploding-wire fuses require milliseconds to operate and are limited in their ability to protect the tube. Exothermic fuses, although faster-acting than exploding wires, are significantly slower than crowbars in clearing the fault current in the tube. A second disadvantage of fuses is that after each fault the power supply must be turned off and the fuse replaced. For this reason, fuses are limited to applications where the tubes seldom arc. The major advantage of fuses is low cost.

CATHODE-RAY STORAGE AND CONVERSION DEVICES

I. Reingold, Munsey E. Crost

Storage Tubes

Electronic charge-storage tubes are divided into four broad classes: electrical-input-electrical-output types, electrical-input-visual-output types, visual-input-electrical-output types, and visual-input-visual-output types. An example of each class is cited in Table 5.2.2.

Tubes under these classes in which storage is merely incidental, such as camera tubes and image converters, are classed under conversion devices.

Electrical-Input Devices

Electrical-Output Types. The *radechon*, or *barrier-grid storage tube*, is a single-electron-gun storage tube with a fine-mesh screen in contact with a mica storage surface. The metal screen, called the *barrier grid*, acts as a very-close-spaced collector electrode, and essentially confines the secondary electrons to the apertures of the grid in which they were generated. The very thin mica sheet is pressed in contact with a solid metal backplate. A later model was developed with a concave copper bowl-shaped backplate and a fritted-glass dielectric storage surface. A similarly shaped fine-mesh barrier grid was welded to the partially melted glass layer. The tube is operated with backplate modulation; i.e., the input electrical signal is applied to the backplate while the constant-current electron beam scans the mica storage surface. The capacitively induced voltage on the beam side of the mica dielectric is neutralized to the barrier-grid potential at each scanned elemental area by collection of electrons from the beam and/or by secondary electron emission (equilibrium writing). The current involved in recharging the storage surface generates the output signal.

In a single-electron-gun *image-recording storage tube* (Fig. 5.2.4) information can be recorded and read out later. The intended application is the storage of complete halftone images, such as a television picture, for later readout. In this application, write-in of information is accomplished by electron-beam modulation, in time-sharing sequence with the readout mode. Reading is accomplished nondestructively, i.e., without intentionally changing the stored pattern, by not permitting the beam to impinge upon the storage surface. The electron-gun potentials are readjusted for readout so that none of the electrons in the constant-current beam can reach the storage surface, but divide their current between the storage mesh and the collector in proportion to the stored charge. This process is called *signal division*.

One type of double-ended, multiple-electron-gun *recording storage tube* with nondestructive readout operates by recording halftone information on an insulating coating on the bars of a metal mesh grid, which can be penetrated in both directions by the appropriate electron beams. Very high resolution and long storage time with multiple readouts, including simultaneous writing and reading, are available with this type of tube. Radio-frequency separation or signal cancellation must be used to suppress the writing signal in the readout during simultaneous operation.

Figure 5.2.5 is a representative schematic drawing of a double-ended, multiple-electron-gun *membrane-target storage tube* with nondestructive readout, in which the writing beam and the reading beam are separated by

TABLE 5.2.2 Storage-Tube Classes

Type of input	Type of output	Subclass	Representative example
Electrical	Electrical	Single-gun	Radechon
		Multiple-gun	Graphchon
	Visual	Bistable	Memotron
		Halftone	Tonotron
Visual	Electrical	Nonscanned	Correlatron
	Visual	Time-sharing	Storage image tube

FIGURE 5.2.4 Electrical-signal storage tube, basic structure. (Hughes Aircraft Corp.)

the thin insulating film of the storage target. In this case there is a minimal interference of the writing signal with the readout signal in simultaneous operation, except for capacitive feed-through, which can readily be canceled. Writing is accomplished by beam modulation, while reading is accomplished by signal division. Very high resolution and long storage time with multiple readouts are available with this group of tubes.

The *grapechcon* differs from the two groups of tubes just described in that its storage target operates by means of electron-bombardment-induced conduction (EBIC). Halftones are not available from tubes of this type in normal operation. The readout is of the destructive type, but since a large quantity of charge is transferred through the storage insulator during writing, a multitude of readout copies can be made before the signal displays noticeable degradation. In simultaneous writing and reading, signal cancellation of the writing signal in the readout is generally accomplished at video frequencies.

Visual-Output Types. This class comprises the *display storage tubes (DSTs)* or *direct-view storage tubes (DVSTs)*. Figure 5.2.6 shows a schematic diagram of a typical DVST with one electrostatic focus-and-deflection writing gun (other types may have electromagnetic focus and/or deflection) and one flood gun, which is used to provide a continuously bright display and may also establish bistable equilibrium levels. The storage surface is an insulating layer deposited on the bars of the metal-mesh backing electrode. The view screen is an aluminum-film-backed phosphor layer.

The *memotron* is a DST that operates in the bistable mode; i.e., areas of the storage surface may be in either the cutoff condition (flood-gun-cathode potential) or in the transmitting condition (collector potential), either of which is stable. The focusing and deflection are electrostatic. Normally, the phosphor remains in the unexcited

FIGURE 5.2.5 Typical double-ended scan converter, basic structure. (Hughes Aircraft Corp.)

FIGURE 5.2.6 Cross-sectioned view of direct-view storage tube. (Westinghouse Electric Corp.)

condition until a trace to be displayed is written into storage; then this trace is displayed continuously until erased, so long as the flood beam is maintained in operation.

The *tonotron* is typical of a large number of halftone DSTs. These operate in the nondestructive readout mode, with the storage surface at or below flood-cathode potential. Writing is accomplished by depositing halftone charge patterns by electron-beam modulation.

Visual-Input Devices

Electrical-Output Types. The *correlatron* is a storage tube that receives a visual input to a photoemissive film, focuses the photoelectron image upon a transmission-grid type of storage target, where it is stored, and later compares the original image with a similar image. A single total output current is read out for the entire image, with no positional reference. The purpose of this comparison is to ascertain whether the first and second images correlate.

Visual-Output Types. In the *storage image tube*, a positive electron image can be stored upon the insulated bars of the storage mesh. Then, if the photocathode is uniformly flooded with light to produce a flood electron cloud, a continuously bright image of the stored charge pattern can be obtained on the phosphor screen in the following section of the tube. A high degree of brightness gain can be achieved with this type of tube, or a single snapshot picture of a continuous action can be “frozen” for protracted study.

Conversion Devices

The conversion devices discussed receive images in visible or infrared radiation and convert them by internal electronic processes into a sequence of electrical signals or into a visible output image. Some of these devices may employ an internal storage mechanism, but this is generally not the primary function in their operation. These tubes are characterized by a photosensitive layer at their input ends that converts a certain region of the quantum electromagnetic spectrum into electron-hole pairs. Some of these layers are photoemissive; i.e., they emit electrons into the vacuum if the energy of the incoming quantum is high enough to impart at least enough energy to the electron to overcome the work function at the photosurface-vacuum interface. Others do not emit electrons into the vacuum but conduct current between the opposite surfaces of the layer by means of the electron-hole pairs; i.e., they are photoconductive. The transmission characteristics of the material of the entrance window of the tube can greatly modify the effective characteristics of any photosurface. If the material is photoemissive, the total active area is called a *photocathode*.

The types of conversion devices discussed are divided into visual-input devices, electrical-output and visual-output types. An example of each type is cited in Table 5.2.3.

TABLE 5.2.3 Conversion Devices

Type of input	Type of output	Subclass	Representative example
Visual	Electrical	Photoemissive Photoconductive	Image orthicon Vidicon
	Visual	Photoemissive	Image amplifier

Visual-Input Conversion Devices

Electrical-Output Types. This class covers the large group of devices designated camera tubes. The defining attributes of the *vidicon* are a photoconductive rather than photoemissive image surface or target, a direct read-out from the photosensitive target rather than by means of a return beam, and a much smaller size than the above camera tubes. The original vidicons used coincident electromagnetic deflection and focusing. Many later versions employ either or both electrostatic focusing and deflection.

A very important group of tubes is the *semiconductor diode-array vidicons*. In place of the usual photoconductive target, these tubes include a very thin monolithic wafer of the semiconductor, usually single-crystal silicon. On the beam side of this wafer a dense array of junction photodiodes has been generated by semiconductor diffusion technology. These targets are very sensitive compared with the photoconductors, and they have very low leakage, low image lag, and low blooming from saturation.

Visual-Output Types. The *image tube*, or *image amplifier*, with input in the visible spectrum is used principally to increase the light level and dynamic range of a very low light-level image to a level and contrast acceptable to a human observer, a photographic plate, or a camera tube. The image tube consists basically of a photoemissive cathode, a focusing and accelerating electron-optical system, and a phosphor screen.

Since the photocathode would be illuminated by light returning from the phosphor screen, the internal surface of the phosphor is covered with a very thin film of aluminum that can be penetrated by the high-energy image electrons. The aluminum film also serves as the tube anode and as a reflector for the light that would otherwise be emitted back into the tube.

SEMICONDUCTOR DIODES AND CONTROLLED RECTIFIERS

Gregory J. Malinowski, John F. Donlon

Semiconductor Materials and Junctions

Diodes and controlled rectifiers are fabricated from semiconductor materials, a form of matter situated between metals and insulators in their ability to conduct electricity. Typical values of electrical resistivity of conductors, semiconductors, and insulators are 10^{-6} to 10^{-5} , 10 to 10^4 , and 10^{12} to 10^{16} $\Omega \cdot \text{cm}$, respectively. Silicon is the most widely used semiconductor material. Other semiconductor materials such as germanium, gallium arsenide, selenium, cadmium sulfide, copper oxide, and silicon carbide have electrical properties that make them useful in special applications.

Semiconductor devices develop current flow from the motion of *charge carriers* within a crystalline solid. The conduction process in semiconductors is most easily visualized in terms of silicon. The silicon atoms have four electrons in the outer shell (valence shell). These electrons are normally bound in the crystalline lattice structure. Some of these valence electrons are free at room temperature, and hence can move through the crystal; the higher the temperature, the more electrons are free to move. Each vacancy, or hole, left in the lattice can be filled by an adjacent valence electron. Since a hole moves in a direction opposite to that of an electron, a hole may be considered as a positive-charge carrier. Electrical conduction is a result of the motion of holes and electrons under the influence of an applied field.

Intrinsic (pure) semiconductors exhibit a negative coefficient of resistivity, since the number of carriers increases with temperature. Conduction owing to thermally generated carriers, however, is usually an undesirable effect, because it limits the operating temperature of the semiconductor device.

At a given temperature, the concentration of thermally generated carriers is related to the energy gap of the material. This is the minimum energy (stated in electron volts) required to free a valence electron (1.1 eV for silicon and 0.7 eV for germanium). Silicon devices perform at higher temperatures because of the wider energy gap.

The conductivity of the semiconductor material can be altered radically by doping with minute quantities of *donor* or *acceptor impurities*. Donor (*n*-type) impurity atoms have five valence electrons, whereas only four are accommodated in the lattice structure of the semiconductor. The extra electron is free to conduct at normal operating temperatures. Common donor impurities include phosphorus, arsenic, and antimony. Conversely, acceptor (*p*-type) atoms have three valence electrons; a surplus of holes is created when a semiconductor is doped with them. Typical acceptor dopants include boron, gallium, and indium.

In an *extrinsic (doped) semiconductor*, the current-carrier type introduced by doping predominates. These carriers, electrons in *n*-type material and holes in *p*-type, are called *majority carriers*. Thermally generated carriers of the opposite type are also present in small quantities and are referred to as *minority carriers*. Resistivity is determined by the concentration of majority carriers.

Lifetime is the average time required for excess minority carriers to recombine with majority carriers. Recombination occurs at “traps” caused by impurities and imperfections in the semiconductor crystal. Semiconductor junctions are formed in material grown as a single continuous crystal to obtain the lattice perfection required, and extreme precautions are taken to ensure exclusion of unwanted impurities during processing. However, in some applications the characteristics associated with short lifetime are desirable. In these cases electron and/or proton irradiation and/or heavy metal doping such as gold are used to create recombination sites and lower the life time.

Carrier mobility is the property of a charge carrier that determines its velocity in an electric field. Mobility also determines the velocity of a minority carrier in the diffusion process. High mobility yields a short transit time and good frequency response.

pn Junctions

If *p*- and *n*-type materials are formed together, a unique interaction takes place between the two materials, and a *pn* junction is formed. In the immediate vicinity of this junction (in the *depletion region*), some of the excess electrons of the *n*-type material diffuse into the *p* region, and likewise holes diffuse into the *n*-type region. During this process of recombination of holes and electrons, the *n* material in the depletion region acquires a slightly positive charge and the *p* material becomes slightly negative. The space-charged region thus formed repels further flow of electrons and holes, and the system comes into equilibrium. Figure 5.2.7 shows a typical *pn* junction.

To keep the system in equilibrium, two related phenomena constantly occur. Because of thermal energy, electrons and holes diffuse from one side of the *pn* junction to the other side. This flow of carriers is called *diffusion current*. When a current flows between two points, a potential gradient is produced. This potential gradient across the depletion region causes a flow of charge carriers; drift current, in the opposite direction to the diffusion current. As a result, the two currents cancel at equilibrium, and the net current flow is zero through the region. An energy barrier is erected such that further diffusion of charge carriers becomes impossible without the addition of some external energy source. This energy barrier formed at the interface of the *p*- and *n*-type materials provides the basic characteristics of all junction semiconductor devices.

pn Junction Characteristics

When a dc power source is connected across a *pn* junction, the quantity of current flowing in the circuit is determined by the polarity of the applied voltage and its effect on the depletion layer of the diode. Figure 5.2.8 shows the classical condition for a reverse-biased *pn* junction. The negative terminal of the power supply is connected to the *p*-type material, and the positive terminal to the *n*-type material. When a *pn* junction is reverse-biased, the

FIGURE 5.2.7 *pn* junction.

FIGURE 5.2.8 Reversed-biased diode.

free electrons in the *n*-type material are attracted toward the positive terminal of the power supply and away from the junction. At the same time, holes from the *p*-type material are attracted toward the negative terminal of the supply and away from the junction. As a result, the depletion layer becomes effectively wider, and the potential gradient increases to the value of the supply. Under these conditions the current flow is very small because no electric field exists across either the *p* or *n* region.

Figure 5.2.9 shows the positive terminal of the supply connected to the *p* region and the negative terminal to the *n* region. In this arrangement, electrons in the *p* region near the positive terminal of the supply break their electron-pair bonds and enter the supply, thereby creating new holes. Concurrently, electrons from the negative terminal of the supply enter the *n* region and diffuse toward the junction. This condition effectively decreases the depletion layer, and the energy barrier decreases to a small value. Free electrons from the *n* region can then penetrate the depletion layer, flow across the junction, and move by way of the holes in the *p* region toward the positive terminal of the supply. Under these conditions, the *pn* junction is said to be *forward-biased*.

A general plot of voltage and current for a *pn* junction is shown in Fig. 5.2.10. Here both the forward- and reverse-biased conditions are shown. In the forward-biased region, current rises rapidly as the voltage is increased and is quite high. Current in the reverse-biased region is usually much smaller and remains low until the breakdown voltage of the diode is reached. Thereupon the current increases rapidly. If the current is not limited, it will increase until the device is destroyed.

Junction Capacitance. Since each side of the depletion layer is at an opposite charge with respect to each other, each side can be viewed as the plate of a capacitor. Therefore a *pn* junction has capacitance. As shown in Fig. 5.2.11, junction capacitance changes with applied voltage.

DC Parameters of Diodes. The most important of these parameters are as follows:

FIGURE 5.2.9 Forward-biased diode.

FIGURE 5.2.10 Voltage-current characteristics for a *pn* junction.

FIGURE 5.2.11 Diode junction capacitance vs. reverse voltage.

Forward voltage V_F is the voltage drop at a particular current level across a diode when it is forward-biased.

Breakdown voltage BV is the voltage drop across the diode at a particular current level when the device is reverse-biased to such an extent that heavy current flows. This is known as *avalanche*.

Reverse current I_R is the leakage current specified at a voltage less than BV when the diode is reverse-biased.

AC Parameters of Diodes. The most important of these parameters are as follows:

Capacitance C_0 is the total capacitance of the device, which includes junction and package capacitance. It is measured at a particular frequency and bias level.

Rectification efficiency R_E is defined as the ratio of dc output (load) voltage to the peak of the input voltage, in a detector circuit. This provides an indication of the capabilities of the device as a high-frequency detector.

Forward recovery time t_{fr} is the time required for the diode voltage to drop to a specified value after the application of a given forward current.

Reverse recovery time t_{rr} is the time required for the diode principle current to recover to a specified value after switching from the on state to the reverse blocking state. **Reverse Recovery Charge Q_{rr}** and **recovery softness factor RSF** are also characteristics of the diode turn-off process that are important to the proper application of a rectifier diode.

Transient thermal impedance provides data on the instantaneous junction temperature rise above a specified reference point such as the device case as a function of time with constant power applied. This parameter is essential in ensuring reliable operation of diodes in pulse applications.

Small-Signal Diodes

Small-signal diodes are the most widely used discrete semiconductor devices. The capabilities of the general-purpose diode as a switch, demodulator, rectifier, limiter, capacitor, and nonlinear resistor suit it to many low power applications.

The most important characteristics of all small-signal diodes are forward voltage, reverse breakdown voltage, reverse leakage current, junction capacitance, and recovery time.

Silicon Rectifier Diodes

Silicon rectifier diodes are *pn* junction devices that have average forward current carrying capability ratings upward of 8000A and reverse blocking voltage ratings upward of 10,000 V. An ideal rectifier has an infinite reverse resistance, infinite breakdown voltage, and zero forward resistance. The silicon rectifier approaches these ideal specifications in that the forward resistance can be on the order of a few thousandths of an ohm, while the reverse resistance is in the megohm range.

Since silicon rectifiers are primarily used in power supplies, thermal dissipation must be adequate. To avoid excessive heating of the junction, the heat generated must be efficiently transferred to a heat sink. The relative efficiency of this heat transfer is expressed in terms of the thermal resistance of the device. The thermal-resistance range is typically 0.1 to 1°C/W for stud mount diodes and 0.009 to 0.1°C/W for double side cooled disc diodes.

Zener Diodes

Zener diodes are primarily used as voltage reference or regulator elements. This performance is based on the avalanche characteristics of the *pn* junction. When a source of voltage is applied to the diode in the reverse direction (anode negative), a reverse current I_r is observed. As the reverse potential is increased beyond the knee

5.38 ELECTRONIC AND FIBER OPTIC COMPONENTS

of the current-voltage curve, avalanche-breakdown current becomes well developed. This occurs at the zener voltage V_z . Since the resistance of the device drastically drops at this point, it is necessary to limit the current flow by means of an external resistor. Avalanche breakdown of the operating zener diode is not destructive as long as the rated power dissipation of the junction is not exceeded. The ability of the zener diode to maintain a desired operating voltage is limited by its temperature coefficient and impedance. The design of zener diodes permits them to absorb overload surges and thereby serve as transient voltage protection.

Varactor Diodes

The varactor diode is a pn junction device that has useful nonlinear voltage-dependent variable-capacitance characteristics. Varactor diodes are useful in microwave amplifiers and oscillators when employed with the proper filter and impedance-matching circuitry. The voltage-dependent capacitance effect in the diode permits its use as an electrically controlled tuning capacitor in radio and television receivers.

Tunnel Diodes

The tunnel diode is a semiconductor device whose primary use arises from its negative conductance characteristic. In a pn junction, a *tunnel* effect is obtained when the depletion layer is made extremely thin. Such a depletion layer is obtained by heavily doping both the p and n regions of the device. In this situation it is possible for an electron in the conduction band on the n side to penetrate, or tunnel, into the valence band of the p side. This gives rise to an additional current in the diode at a very small forward bias, which disappears when the bias is increased. It is this additional current that produces the negative resistance of the tunnel diode.

Typical applications of tunnel diodes include oscillators, amplifiers, converters, and detectors.

Schottky Barrier Diodes

This diode (also known as the surface-barrier diode, metal-semiconductor diode, and hot-carrier diode) consists of a rectifying metal-semiconductor junction in which majority carriers carry the current flow. When the diode is forward-biased, the carriers are injected into the metal side of the junction, where they remain majority carriers at some energy greater than the Fermi energy in the metal; this gives rise to the name *hot carriers*. The diode can be switched to the OFF state in an extremely short time (in the order of picoseconds). No stored minority-carrier charge exists.

The reverse dc current-voltage characteristics of the device are very similar to those of conventional pn -junction diodes. The reverse leakage current increases with reverse voltage gradually, until avalanche breakdown is reached.

Schottky barrier diodes used in detector applications have several advantages over conventional pn -junction diodes. They have a lower noise and better conversion efficiency, and hence have greater overall detection sensitivity.

Light Sensors (Photodiodes)

When a semiconductor junction is exposed to light, photons generate hole-electron pairs. When these charges diffuse across the junction, they constitute a photocurrent. Junction light sensors are normally operated with a load resistance and a battery that reverse-biases the junction. The device acts as a source of current that increases with light intensity.

Silicon sensors are used for sensing light in the visible and near-infrared spectra. They can be fabricated as phototransistors in which the collector-base junction is light-sensitive. Phototransistors are more sensitive than photodiodes because the photon-generated current is amplified by the current gain of the transistor.

Light-Emitting Diodes (LEDs)

These devices have found wide use in visual displays, isolators, and as digital storage elements.

LEDs are principally manufactured from gallium arsenide. When biased in the avalanche-breakdown region, pn junctions emit visible light at relatively low power levels. LEDs are capable of providing light of different wavelengths by varying their construction.

FIGURE 5.2.12 (a) SCR junction diagram; (b) typical SCR voltage-current characteristics. Curve *a* applies for zero-gate current; curve *b* applies when minimum gate current to trigger is present and the off-state voltage is V_1 . (Electronic Industries Association)

Silicon Controlled Rectifiers (SCRs)

A silicon controlled rectifier is basically a four-layer *pnpn* device that has three electrodes (a cathode, an anode, and a control electrode called the *gate*). Figure 5.2.12 shows the junction diagram and voltage-current characteristics for an SCR.

When an SCR is reverse-biased (anode negative with respect to the cathode), it is similar in characteristics to that of a reverse-biased silicon rectifier or other semiconductor diode. In this bias mode, the SCR exhibits a very high internal impedance, and only a very low reverse current flows through the *pnpn* device. This current remains small until the reverse voltage exceeds the reverse breakdown voltage; beyond this point, the reverse current increases rapidly.

During forward-bias operation (anode positive with respect to the cathode), the *pnpn* structure of the SCR is electrically bistable and may exhibit either a very high impedance (*OFF state*) or a very low impedance (*ON state*). In the forward-blocking state (*OFF*), a small forward current, called the *forward OFF-state or leakage current*, flows through the SCR. The magnitude of this current is approximately the same as that of the reverse-blocking current that flows under reverse-bias conditions. As the forward bias is increased, a voltage point is reached at

which the forward current increases rapidly, and the SCR switches to the ON state. This voltage is called the *forward breakover voltage*.

When the forward voltage exceeds the breakover value, the voltage drop across the SCR abruptly decreases to a very low value, the forward ON-state voltage. When the SCR is in the ON state, the forward current is limited primarily by the load impedance. The SCR will remain in this state until the current through the SCR decreases below the holding current and then reverts back to the OFF state.

The breakover voltage of an SCR can be varied or controlled by injection of a signal at the gate. When the gate current is zero, the principal voltage must reach the breakover value of the device before breakover occurs. As the gate current is increased, however, the value of breakover voltage becomes less until the device goes to the ON state. This enables an SCR to control a high-power load with a very-low-power signal and makes it suitable for such applications as phase control and high power conversion.

The most important SCR parameters are forward or ON-state voltage V_T , OFF-state and reverse breakover voltage V_{BO} and $V_{(BR)R}$, gate trigger current I_{GT} , rate of application of OFF-state voltage dv/dt , circuit commutated turn-off time t_q , and transient thermal impedance.

Gate-turn-off thyristors (GTOs) are basically SCRs that are specially fabricated so that the gate does not completely lose control when the GTO is in the latched conducting state. It can be restored to the blocking state by the application of reverse bias to the gate. The GTO finds application in dc control, dc-to-dc converters, and self-commutated ac-to-dc, dc-to-ac, and ac-to-ac converters where the fact that it does not need an external force-commutating circuit is an advantage. The GTO finds primary application in very high power circuits where the other turn-off devices (bipolar transistors, IGBTs, MOSFETs, and so forth) do not have the necessary current and/or voltage ratings.

TRANSISTORS

Edward B. Hakim

Introduction

A bipolar transistor consists of two junctions in close proximity within a single crystal. An *npn* transistor is shown in Fig. 5.2.13. In normal bias conditions, the emitter-base junction is forward-biased and the collector-base junction is reversed-biased.

FIGURE 5.2.13 An *npn* junction transistor.

Forward bias of the emitter-base junction causes electrons to be injected into the base region, producing an excess concentration of minority carriers there. These carriers move by diffusion to the collector junction, where they are accelerated into the collector region by the field in the depletion region of the reverse-biased collector junction. Some of the electrons recombine before reaching the collector. Current flows from the base terminal to supply the holes for this recombination process. Another component of current flows in the emitter-base circuit because of the injection of holes from the base into the emitter.

Practical transistors have narrow bases and high lifetimes in the base to minimize recombination. Injection of holes from the base into the emitter is made negligible by doping the emitter much more heavily than the base. Thus the collector current is less than, but almost equal to, the emitter current.

In terms of the emitter current I_E , the collector current I_C is

$$I_C = \alpha I_E + I_{CBO}$$

where α is the fraction of the emitter current that is collected and I_{CBO} is a result of the reverse-current characteristic of the collector-base junction. Increase of I_{CBO} with temperature sets the maximum temperature of operation.

High-frequency transistors are fabricated with very narrow bases to minimize the transit time of minority carriers across the base region. Although germanium has a higher carrier mobility, silicon is the preferred material because of its availability and superior processing characteristics.

FIGURE 5.2.14 Common-base T-equivalent circuit.

FIGURE 5.2.15 Transistor symbols.

Circuit Models of the Transistor

Performance of the transistor as an active circuit element is analyzed in terms of various small-signal equivalent circuits. The low-frequency T-equivalent circuit (Fig. 5.2.14) is closely related to the physical structure. This circuit model is used here to illustrate the principle of transistor action. Carriers are injected into the base region by forward current through the emitter-base junction. A fraction α (near unity) of this current is collected. The incremental change in collector current is determined essentially by the current generator αi_e , where i_e is the incremental change of emitter current. The collector resistance r_c in parallel with the current generator accounts for the finite resistance of the reverse-biased collector-base junction. The input impedance is a result of the dynamic resistance r_e of the forward-biased emitter-base junction and the ohmic resistance r_b of the base region.

The room temperature value of r_e is about $26/I_E \Omega$, where I_E is the dc value of emitter current in milliamperes. Typical ranges of the other parameters are as follows: r_b varies from tens of ohms to several hundred ohms; α varies from 0.9 to 0.999; and r_c ranges from a few hundred ohms to several megohms. The symbolic representations of an *npn* and *pnp* transistor are shown in Fig. 5.2.15. The direction of conventional current flow and terminal voltage for normal operation as an active device are indicated for each. The voltage polarities and current for the *pnp* are reversed from those of the *npn*, since the conductivity types are interchanged.

Transistors may be operated with any one of the three terminals as the common, or grounded, element, i.e., common base, common emitter, or common collector. These configurations are shown in Fig. 5.2.16 for an *npn* transistor.

FIGURE 5.2.16 Circuit connections for *npn* transistor.

Common Base. The transistor action shown at the left in Fig. 5.2.16 is that of the common-base connection whose current gain (approximately equal to α) is slightly less than 1. Even with less than unity current gain, voltage and power amplification can be achieved, since the output impedance is much higher than the input impedance.

Common Emitter. For the common-emitter connection, only base current is supplied by the source. Base current is the difference between emitter and collector currents and is much smaller than either; hence current gain I_c/I_b is high. Input impedance of the common-emitter state is correspondingly higher than it is in the common-base connection.

Common Collector. In the common-collector connection, the source voltage and the output voltage are in series and have opposing polarities. This is a negative-feedback arrangement, which gives a high input impedance and approximately unity voltage gain. Current gain is about the same as that of the common-emitter connection. The common-base, common-emitter, and common-collector connections are roughly analogous to the grounded-grid, grounded-cathode, and grounded-plate (cathode-follower) connections, respectively, of the vacuum tube.

***h* Parameters.** Low-frequency performance of transistors is commonly specified in terms of the small-signal *h* parameters listed in Table 5.2.4. In the notation system used, the second subscript designates the circuit connection (*b* for common-base and *e* for common-emitter). The forward-transfer parameters (h_{fb} and h_{fe}) are current gains measured with the output short-circuited. The current gains for practical load conditions are not greatly different. The input parameters h_{ib} and h_{ie} , although measured for short-circuit load, approximate the input impedance of practical circuits. The output parameters h_{ob} and h_{oe} are the output admittances.

TABLE 5.2.4 Transistor Small-Signal h Parameters

	Input parameter	Transfer parameter	Output parameter
Common-base	$h_{ib} \approx r_e + (1 - \alpha)r_b$	$h_{fb} \approx \alpha$	$h_{ob} \approx 1/r_c$
Common-emitter	$h_{ie} \approx r_e/(1 - \alpha) + r_b$	$h_{fe} \approx \alpha/(1 - \alpha)$	$h_{oe} \approx 1/r_c(1 - \alpha)$

The current gain of the common-base stage is slightly less than unity; common-emitter current gains may vary from ten to several hundred. Input impedance and output admittance of the common-emitter stage are higher than those of the common-base circuit by approximately h_{fe} . Nomenclature and units for h parameters are given in Table 5.2.5.

Although matched power gains of the common-base and common-emitter connections are about the same, the higher input impedance and lower output impedance of the common-emitter stage are desirable for most applications. For these reasons, the common-emitter stage is more commonly used. For example, the voltage gain of cascaded common-base stages cannot exceed unity unless transformer coupling is used.

The common-collector circuit has a higher input impedance and lower output impedance than either of the other connections. It is used primarily for impedance transformation.

**FIGURE 5.2.17** High-frequency common-emitter equivalent circuit.

High-Frequency Limit. The current gain of a transistor decreases with frequency, principally because of the transit time of minority carriers across the base region. The frequency f_T at which h_{fe} decreases to unity is a measure of high-frequency performance. Parasitic capacitances of junctions and leads also limit high-frequency capabilities. These high-frequency effects are shown in the modified equivalent circuit of Fig. 5.2.17. The maximum frequency f_{max} at which the device can amplify power is limited by f_T and the time constant $r_b C_C$, where r_b is the ohmic base resistance and C_C is that portion of the collector-base junction capacitance which is under the emitter stripe. Values of f_T greater than 2 GHz and f_{max} exceeding 10 GHz are obtained by maintaining very thin bases ($<30 \mu\text{m}$) and narrow emitters ($<3 \mu\text{m}$).

Transistor Voltampere Characteristics

The performance of a transistor over wide ranges of current and voltage is determined from static characteristic curves, e.g., the common-emitter output characteristics of Fig. 5.2.18. Collector current I_C is plotted as a function of collector-to-emitter voltage V_C for constant values of base current I_B . Maximum collector voltage for grounded emitter is limited by either punch-through or avalanche breakdown, whichever is lower, depending on the base resistivity and thickness. When a critical electric field is reached, avalanche occurs because of intensive current multiplication. At this point current increases rapidly with little increase in voltage. The common-emitter breakdown voltage BV_{CEO} is always less than the collector-junction breakdown voltage BV_{CBO} . Another

TABLE 5.2.5 h -Parameter Nomenclature

Parameter	Nomenclature	Unit
h_{ib}	Input impedance (common-base)	Ω
h_{ie}	Input impedance (common-emitter)	Ω
h_{fb}	Forward-current transfer ratio (common-base)	Dimensionless
h_{fe}	Forward-current transfer ratio (common-emitter)	Dimensionless

h_{oe}	Output admittance (common-emitter)	S

FIGURE 5.2.18 V_C - I_C characteristic for grounded-emitter junction transistor.

FIGURE 5.2.19 Load line for linear-transistor-amplifier circuit.

characteristic evident from Fig. 5.2.18 is the grounded-emitter saturation voltage $V_{CE,sat}$. This parameter is especially important in grounded-emitter switching applications.

Two additional parameters, both related to the emitter junction, are BV_{EBO} and V_{BE} . The breakdown voltage emitter to base with the collector open-circuited BV_{EBO} is the avalanche-breakdown voltage of the emitter junction. The base-to-emitter forward voltage of the emitter junction V_{BE} is simply the junction voltage necessary to maintain the forward-bias emitter current.

The leakage current I_{CBO} in the common-base connection is the reverse current of the collector-base junction; common-emitter leakage is higher by the factor $1/(1 - \alpha)$ because of transistor amplification. In either case, the leakage current increases exponentially with temperature. Maximum junction temperatures are limited to about 100°C in germanium and 250°C in silicon. The locus of maximum power dissipation is a hyperbola on the voltampere characteristic curve. Power dissipation must be decreased when higher ambient temperatures exist. Large-area devices and physical heat sinks of high thermal dissipation are used to extend power ratings.

FIGURE 5.2.20 Switching states for common-emitter circuit.

Dynamic variations of voltage and current are analyzed by a load line on the characteristic curves, as in vacuum tubes. For a linear transistor amplifier with load resistance R_L , the output varies along a load line of slope $-1/R_L$ about the dc operating point (Fig. 5.2.19). Since the minimum voltage $V_{CE,sat}$ is quite low, good efficiencies can be obtained with low values of supply voltage. The operating point on the V_{CE} - I_C coordinates is established by a dc bias current in the input circuit. Transistor circuits should be biased for a fixed emitter current rather than a fixed base current to maintain a stable operating point, since the lines of constant base current are variable between devices of a given type and with temperature.

The common-emitter circuit can also be used as an effective switch, as shown by the load line of Fig. 5.2.20. When the base current is zero, the collector circuit is effectively open-circuited

and only leakage current flows in the collector circuit. The device is turned on by applying base current I_{BI} , which decreases the collector voltage to the saturation value.

Field-Effect (Unipolar) Transistors

There are two general types of field-effect transistors (FET): junction (JFET) and insulated-gate (IGFET). The IGFET has a variety of structures, known as the metal-insulator-semiconductor (MISFET) and the metal-oxide-semiconductor (MOSFET).

The cross section of a p -channel JFET is shown in Fig. 5.2.21. Channel current is controlled by reverse-biasing the gate-to-channel junction so that the depletion region reduces the effective channel width. The input

5.44 ELECTRONIC AND FIBER OPTIC COMPONENTS

FIGURE 5.2.21 A p -channel junction field-effect transistor.

FIGURE 5.2.22 A p -channel MOS transistor.

impedance of these devices is high because of the reverse-biased diode in the input channel. In fact, the volt-ampere characteristics are quite similar to those of a vacuum tube. Another important feature of the junction FET is the excellent low-frequency noise characteristics, which surpass those of either the vacuum tube or conventional (bipolar) transistor.

The cross section of the p -channel MOSFET (or MOS transistor) is shown in Fig. 5.2.22. This device operates in the depletion mode. For zero gate voltage, there is no channel, and the drain current is small. A negative voltage on the gate repels the electrons from the surface and produces a p -type conduction region under the gate. Compared with the JFET, the MOS transistor has a wider gain-bandwidth product and a higher input impedance ($>100\text{ G}\Omega$).

Power MOSFETs offer the major advantage over bipolar transistors in that they do not suffer from second breakdown. Their safe dc operating areas are determined by their rated power dissipation over the entire drain-to-source voltage range up to a rated voltage. This is not the case for bipolar transistors. The superiority in power handling capability of MOSFETs is also true for the pulsed-power operating mode.

Further operational and reliability advantages of FETs over bipolar devices are obtained by the use of gallium arsenide (GaAs) in place of silicon (Si). The advantages include enhanced switching speeds resulting from electron velocity twice that of Si; lower operating voltages and lower ON resistance resulting from a five-fold greater electron mobility; and 350°C maximum operating temperature versus 175°C .

FIGURE 5.2.23 Unijunction transistor.

Unijunction Transistors

A unijunction transistor is shown in Fig. 5.2.23. The input diode is reverse-biased at low voltages owing to IR drop in the bulk resistance of the n -type region. When V_E exceeds this drop, carriers are injected and the resistance is lowered. As a result, the IR drop and V_E decrease abruptly. The negative-resistance characteristic is useful in such applications as oscillators and as trigger devices for silicon controlled rectifiers.

CHAPTER 5.3

BATTERIES AND FUEL CELLS*

David Linden

BATTERIES

A battery is a device that converts the chemical energy contained in its active materials directly into electric energy by means of an oxidation-reduction electrochemical reaction. This type of reaction involves the transfer of electrons from one material to another. In a nonelectrochemical reaction this transfer of electrons occurs directly, and only heat is involved. In a battery (Fig. 5.3.1) the negative electrode or anode is the component capable of giving up electrons, being oxidized during the discharge reaction. It is separated from the oxidizing material, which is the positive electrode or cathode, the component capable of accepting electrons. The transfer of electrons takes place in the external electric circuit connecting the two materials and in the electrolyte, which serves to complete the electric circuit in the battery by providing an ionic medium for the electron transfer.

Components of Batteries

The basic unit of the battery is the cell. A battery consists of one or more cells, connected in series or parallel, depending on the desired output voltage or capacity. The cell consists of three major components: the anode (the reducing material or fuel), the cathode or oxidizing agent, and the electrolyte, which provides the necessary internal ionic conductivity. Electrolytes are usually liquid, but some batteries employ solid electrolytes that are ionic conductors at their operating temperatures. In addition, practical cell design requires a separator material, which serves to separate the anode and cathode electrodes mechanically. Electrically conducting grid structures or materials are often added to each electrode to reduce internal resistance. The containers are of many types, depending on the application and its environment.

Theoretical Cell Voltage and Capacity

The theoretical energy delivered by a battery is determined by its active materials; the maximum electric energy (watt-hours) corresponds to the free-energy change of the reaction. The theoretical voltage and ampere-hour capacities of a number of electrochemical systems are given in Table 5.3.1. The voltage is determined by the active materials selected; the ampere-hour capacity is determined by the amount (weight) of available reactants. One gram-equivalent weight of material will supply 96,500 C, or 26.8 Ah, of electric energy.

*Material for this chapter has been abstracted from the "Handbook of Batteries," 3rd ed., D. Linden and T. B. Reddy, (eds.), McGraw-Hill, 2001.

FIGURE 5.3.1 Electrochemical operation of a cell or battery during discharge.

FIGURE 5.3.2 Battery discharge characteristics.

Factors Influencing Battery Voltage and Capacity

In actual practice, only a small fraction of the theoretical capacity is realized. This is a result not only of the presence of nonreactive components (containers, separators, electrolyte) that add to the weight and size of the battery but also of many other factors that prevent the battery from performing at its theoretical level. Factors influencing the voltage and capacity of a battery are as follows.

Voltage Level. When a battery is discharged in use, its voltage is lower than the theoretical voltage. The difference is caused by IR losses because of cell resistance and polarization of the active materials during discharge. This is illustrated in Fig. 5.3.2. The theoretical discharge curve of a battery is shown as curve 1. In this case, the discharge of the battery proceeds at the theoretical voltage until the active materials are consumed and the capacity fully utilized. The voltage then drops to zero. Under load conditions, the discharge curve is similar to curve 2. The initial voltage is lower than theoretical, and it drops off as the discharge progresses.

Current Drain of the Discharge. As the current drain of the battery is increased, the IR loss increases, the discharge is at a lower voltage, and the service life of the battery is reduced (curve 5). At extremely low current drains it is possible to approach the theoretical capacities (in the direction of curve 3). In a very long discharge period, chemical self-deterioration during the discharge becomes a factor and causes a reduction of capacity.

Voltage Regulation. The voltage regulation required by the equipment is most important. As is apparent by the curves in Fig 5.3.2 design of equipment to operate to the lowest possible end voltage results in the highest capacity and longest service life. Similarly, the upper voltage limit of the equipment should be established to take full advantage of the battery characteristics. In some applications, where only a narrow voltage range can be tolerated, voltage regulators may have to be employed to take full advantage of the battery's capacity. If a storage battery is used in conjunction with another energy source, which is permanently connected in the operating circuit, allowances must be made for the voltage required to charge the battery, as illustrated in curve 7, Fig. 5.3.2. The voltage of the charging source must just exceed the maximum voltage on charge.

Type of Discharge (Continuous, Intermittent, and so Forth). When a battery stands idle after a discharge, certain chemical and physical changes take place, which can result in voltage recovery. Thus the voltage of a battery that has dropped during a heavy discharge will rise after rest period, giving a sawtooth discharge. Curve 6 of Fig. 5.3.2 shows the characteristic of a battery discharged intermittently at the same drain in curve 2. The improvement resulting from the intermittent discharge depends on the current drain, length of the recovery period, discharge temperature, end voltage, and the particular battery system and design employed. Some battery systems, during inactive stand, develop a protective film on the active-material surface. These batteries, instead of showing a recovery voltage, may momentarily demonstrate a lower voltage after stand until this film is broken by the discharge. This is known as a *voltage delay*.

TABLE 5.3.1 Voltage, Capacity, and Specific Energy of Major Battery and Several Fuel Cell Systems—Theoretical and Practical Values

Battery type	Anode	Cathode	Reaction mechanism	Theoretical values [†]			Practical battery [‡]			
				V	g/Ah	Ah/kg	Specific energy Wh/kg	Nominal voltage V	Specific energy Wh/kg	Energy density Wh/L

Temperature During Discharge. The temperature at which the battery is discharged has a pronounced effect on its service and voltage characteristics. This is because of the reduction in chemical activity and the increase in battery internal resistance at lower temperatures. Curves 3, 2, 4, and 5 of Fig. 5.3.2, can also represent discharges at the same current drawn but at progressively reduced temperatures. The specific characteristics vary for each battery system and discharge rate, but generally best performance is obtained between 20 and 40°C. At higher temperatures, chemical deterioration may be rapid enough during discharge to cause a loss in capacity.

Size. Battery size influences the voltage characteristics by its effect on current density. A given current drain may be a severe load on a small battery, giving a discharge similar to curve 4 or 5 (Fig. 5.3.2), but be a mild load to a larger battery and give a discharge similar to curve 3. It is often possible to obtain more than a proportional increase in the service life by increasing the size of the battery. The absolute value of current, therefore, is not the key influence, although its relation to the size of the battery, i.e., the current density, is important.

Age and Storage Condition. Batteries are a perishable product and deteriorate as a result of chemical action that proceeds during storage. The type of battery, design, temperature, and length of storage period are factors that affect the shelf life of the battery. Since shelf-discharge proceeds at a lower rate at reduced temperatures, refrigerated storage extends the shelf life. Refrigerated batteries should be warmed before discharge to obtain maximum capacity.

General Characteristics

The many and varied requirements for battery power and the multitude of environmental and electrical conditions under which they must operate necessitate the use of a number of different battery types and designs, each having superior performance under certain discharge conditions. In addition to the theoretical values, the practical performance characteristics of the major primary and secondary batteries are listed in Table 5.3.1. A comparison of the performance of some typical batteries is given in Fig. 5.3.3.

FIGURE 5.3.3 Comparative performance of battery system; primary (P), secondary (S).

TYPES OF BATTERIES

Batteries are generally identified as primary or secondary.

Primary batteries are not capable of being easily recharged electrically and hence are used or discharged a single time and discarded. Many of the primary batteries, in which the electrolyte is contained by absorbent or separator materials (i.e., there is no free or liquid electrolyte), are termed *dry cells*.

Secondary or rechargeable batteries are those that are capable of being recharged electrically, after discharge, to their original condition by passing current through them in the opposite direction to that of the discharge current. They are electric-energy storage devices and are also known as storage batteries or accumulators.

Reserve batteries are primary types in which a key component is separated from the rest of the battery. In the inert condition, the battery is capable of long-term storage. Usually, the electrolyte is the component that is isolated. The battery is activated by introducing this component into the cell structure. In other systems, such as the thermal battery, the battery is inactive until it is heated, melting a solid electrolyte, which then becomes conductive.

PRIMARY BATTERIES

The general advantages of primary batteries are reasonably good shelf life; high energy densities at low to moderate rates; little, if any, maintenance; and ease of use. Typical theoretical and practical characteristics of these batteries are shown in Table 5.3.1 and applications in Table 5.3.2.

Leclanché Battery (Zn/MnO₂)

The Leclanché dry cell, known for over 100 years, is still one of the more widely used worldwide but has given way to the popular alkaline cell in the United States and Europe.

The most common construction uses a cylindrical zinc container as the negative electrode and manganese dioxide as the positive element, with electrical connection through a carbon electrode. A paste or paper separator separates the two electrodes. Another common design is the flat cell, used only in multicell batteries, which offers better volume utilization. The Leclanché cell is fabricated in a number of sizes of varying diameter (or cross section) and height.

The capacity varies with different discharge conditions (higher capacities are available at lower current or power densities) to the point where shelf deterioration during the long discharge causes a loss of capacity. Performance is usually better under intermittent discharge, as the cell is given an opportunity to recover. This effect is particularly noticeable at the heavier discharge loads.

Leclanché cells operate best at normal temperatures (20°C). The energy output of the cell increases with higher operating temperatures, but prolonged exposure to high temperatures (50°C) will cause rapid deterioration. The capacity of the Leclanché cell falls off rapidly with decreasing temperature and is essentially zero below -20°C. The effects are more pronounced at heavier current drains. For best operation at low ambient temperatures, the Leclanché cell should be kept warm by some appropriate means. On the other hand there is an advantage in storing batteries at low temperatures for preserving their capacity.

Zinc Chloride Battery

A modification of the Leclanché battery is the zinc chloride battery. The construction is similar to the conventional carbon-zinc cell but the electrolyte contains only zinc chloride, without the saturated solution of ammonium chloride. The zinc chloride battery is a high-performance battery with improved high-rate and low-temperature performance and a reduced incidence of leakage.

TABLE 5.3.2 Major Characteristics and Applications of Primary Batteries

System	Characteristics	Applications
Zinc-carbon (Leclanché) Zinc/MnO ₂	Common, low-cost primary battery, available in a variety of sizes	Flashlight, portable radios, toys, novelties, instruments
Magnesium (Mg/MnO ₂)	High-capacity primary battery, long shelf life	Military receiver-transmitters, aircraft emergency transmitters
Mercury (Zn/HgO)	Highest capacity (by volume) of conventional types, flat discharge, good shelf life	Hearing aids, medical devices (pacemakers), photography, detectors, military equipment but in limited use due to environmental hazard of mercury
Mercad (Cd/HgO)	Long shelf life, good low- and high-temperature performance, low energy density	Special applications requiring operation under extreme temperature conditions and long life, in limited use
Alkaline (Zn/alkaline/MnO ₂)	Most popular general-purpose premium battery, good low-temperature and high-rate performance, moderate cost	Most popular primary-battery, used in a variety of portable battery operated equipments
Silver/zinc (Zn/Ag ₂ O)	Highest capacity (by weight) of conventional types, flat discharge, good shelf life, costly	Hearing aids, photography, electric watches, missiles, underwater, and space application (larger sizes)
Zinc/air (Zn/O ₂)	Highest energy density, low cost, not independent of environmental conditions	Special applications, hearing aids, pagers, medical devices, portable electronics
Lithium/soluble cathode	High energy density, long shelf life, good performance over wide temperature range	Wide range of applications (capacity from 1 to 10,000 Ah) requiring high energy density, long shelf life, e.g., from utility meters to military power applications
Lithium/solid cathode	High energy density, good rate capability and low-temperature performance, long shelf life, competitive cost	Replacement for conventional button and cylindrical cell applications
Lithium/solid electrolyte	Extremely long shelf life, low-power battery	Medical electronics, memory circuits, fusing

Source: D. Linden and T. B. Reddy (eds.) "Handbook of Batteries," 3rd ed., McGraw-Hill, 2001.

Magnesium Primary Batteries (Mg/MnO₂)

The magnesium battery was developed for military use and has two principal advantages over the zinc dry cell: (1) it has twice the capacity or service life of an equivalently sized zinc cell, and (2) it can retain this capacity during storage in an undischarged condition. The construction of the magnesium dry cell is similar to that of the cylindrical zinc cell, except that a magnesium can is used instead of the zinc container. The magnesium cell has a mechanical vent for the escape of hydrogen gas, which forms as a result of a parasitic reaction during the discharge of the battery. Magnesium batteries have not been fabricated successfully in flat-cell designs.

The good shelf life of the magnesium battery results from a film that forms on the inside of the magnesium can, preventing corrosion. This film, however, is responsible for a delay in the battery's ability to deliver full output voltage after it is placed under load. Nevertheless, there has been little commercial interest in this battery because of the generation of hydrogen and the relatively poor storageability of a partially discharged cell.

Zinc/Mercuric Oxide Battery (Zn/HgO)

The zinc/mercuric oxide battery was another important zinc anode primary system. This battery was developed during World War II for military communication applications because of its good shelf life and high volumetric energy density. In the postwar period, it was used in small button, flat, or cylindrical configurations as the power source in electronic watches, calculators, hearing aids, photographic equipment, and similar applications requiring a reliable long-life miniature power source. In the past decade, the use of the mercuric oxide battery has about ended mainly because of environmental problems associated with mercury and with its replacement by other battery systems, such as the zinc/air and lithium batteries, which have superior performance for many applications.

Alkaline-MnO₂ Cell (Zn/MnO₂)

In the past decade, an increasing portion of the primary battery market has shifted to the Zn/alkaline/MnO₂ battery. This system has become the battery of choice because of its superior performance at the higher current drains and low temperatures and its better shelf life. While more expensive than the Leclanché battery on a unit basis, it is more cost-effective for those applications requiring the high-rate or low-temperature capability, where the alkaline battery can outperform the Leclanché battery by a factor of 2 to 10. In addition, because of the advantageous shelf life of the alkaline cell, it is often selected for applications in which the battery is used intermittently and exposed to uncontrolled storage conditions (such as consumer flashlights and smoke alarms), but must perform dependably when required. Most recent advances have been the design of batteries providing improved high rate performance for use in cameras and other consumer electronics requiring this high power capability.

Cadmium/Mercuric Oxide Battery (Cd/HgO)

The substitution of cadmium for the zinc anode (the cadmium/mercuric oxide cell) results in a lower-voltage but very stable system, with a shelf life of up to 10 years as well as performance at high and low temperatures. Because of the lower voltage, the watt-hour capacity of this battery is about 60 percent of the zinc/mercuric oxide battery capacity. Again, because of the hazardous characteristics of mercury and cadmium, the use of this battery is limited.

Zinc/Silver Oxide Battery (Zn/AgO)

The primary zinc/silver oxide battery is similar in design to the small zinc/mercuric oxide button cell, but it has a higher energy density (on a weight basis) and performs better at low temperatures. These characteristics make this battery system desirable for use in hearing aids, photographic applications, and electronic watches. However, because of its high cost and the development of other battery systems, the use of this battery system, as a primary battery, has been limited mainly to small button battery applications where the higher cost is justified.

Lithium Primary Batteries

The lithium battery is the most recent development with a number of advantages over other primary-battery systems. Lithium is an attractive anode because of its reactivity, light weight, and high voltage; cell voltages range between 2 and 3.6 V, depending on the cathode material.

The advantages of the lithium battery include high energy density (see Fig. 5.3.3), high power density, flat discharge characteristics; excellent service over a wide temperature range, down to -40°C or below. Excellent shelf life of 5 to 10 years at normal room temperatures is expected.

Nonaqueous solvents must be used as the electrolyte because of the solubility of lithium in aqueous solutions. Organic solvents, such as acetonitrile and propylene carbonate, and inorganic solvents, such as thionyl chloride, are typical. A compatible solute is added to provide the necessary electrolyte conductivity. A number of different materials (sulfur dioxide, carbon mono-fluoride, vanadium pentoxide, copper sulfide) are used as the active cathode material. Hence the name lithium battery refers to a family of battery systems, ranging in size from 100 mAh to 10,000 Ah; they all use lithium as the anode but differ widely in design and chemical action.

The lithium primary batteries can be classified into three categories. The smallest are the low-power solid-state batteries with excellent shelf life, and are used in applications such as cardiac pacemakers and battery backup for volatile computer memory, where reliability and long shelf life are paramount requirements. In the second category are the solid-cathode batteries, which are designed in coin or small cylindrical configurations. These batteries have replaced the conventional primary batteries in watches, calculators, memory circuits, photographic equipment, communication devices, and other such applications where its high energy density and long shelf life are critical. The soluble-cathode batteries (using gases or liquid cathode materials) constitute the third category. These batteries are typically constructed in a cylindrical configuration, as flat disks, or in prismatic containers using flat plates. These batteries, up to about 35 Ah in size, are used in military and industrial applications, lighting products, and other devices where small size, low weight, and operation over a wide temperature range are important. The larger batteries have been used in special military applications or as standby emergency power sources.

Air Depolarized Batteries

These batteries, particularly the zinc/air battery system, are noted for their high energy density, but they had been used only in large low-power batteries for signaling and navigational-aid applications. With the development of improved air electrodes, the high-rate capability of the system was improved and small button-type batteries are now used widely in hearing aids, electronics, and similar applications. These batteries have a very high energy density as no active cathode material is needed. Wider use of this system and the development of larger batteries have been slow because of some of their performance limitations (sensitivity to extreme temperatures, humidity and other environmental factors, as well as poor activated shelf life and low power density). Nevertheless, because of their attractive energy density, zinc/air and other metal/air batteries are now being seriously considered for a number of applications from portable consumer electronics and eventually for larger devices such as electric vehicles, possibly in a reserve or mechanically rechargeable configuration.

Solid Electrolyte Batteries

Most batteries depend on the ionic conductivity of liquid electrolytes for their operation. The solid electrolyte batteries depend on the ionic conductivity of an electronically nonconductive salt in the solid state, for example, Li^+ ion mobility in lithium iodide. Cells using these solid electrolytes are low-power (microwatt) devices but have an extremely long shelf life and can operate over a wide temperature range. The absence of liquid eliminates corrosion and gassing and permits the use of a hermetically sealed cell. The solid electrolyte batteries are used in medical electronics (in devices such as heart pacemakers), for memory circuits, and other such applications requiring a long-life, low-power battery.

SECONDARY (STORAGE) BATTERIES

Secondary batteries are characterized, in addition to their ability to be recharged, by high-power density, high discharge rate, flat discharge curves, and good low-temperature performance. Their energy densities are usually lower than those of primary batteries. Tables 5.3.1 and 5.3.3 list the characteristics and applications of secondary batteries.

The applications of secondary batteries fall into two major categories: (1) applications where the secondary battery is used essentially as a primary battery but recharged after use; secondary batteries are used in this manner for convenience (as in portable electronic devices), for cost savings (as they can be recharged rather than

5.54 ELECTRONIC AND FIBER OPTIC COMPONENTS

TABLE 5.3.3 Major Characteristics and Applications of Secondary Batteries

System	Characteristics	Applications
Lead-acid:		
Automotive	Popular, low-cost secondary battery, moderate specific-energy, high-rate, and low-temperature performance, maintenance-free designs	Automotive SLI, golf carts, lawn mowers, tractors, aircraft, marine
Traction (motive power)	Designed for deep 6–9 h discharge, cycling service	Industrial trucks, materials handling, electric and hybrid electric vehicles, special types for submarine power
Stationary	Designed for standby float service, long life, VRLA designs	Emergency power, utilities, telephone, UPS, load leveling, energy storage, emergency lighting
Portable	Sealed, maintenance-free, low cost, good float capability, moderate cycle life	Portable tools, small appliances and devices, TV and portable electronic equipment
Nickel-cadmium:		
Industrial and FNC	Good high-rate, low-temperature capability, flat voltage, excellent cycle life	Aircraft batteries, industrial and emergency power applications, communication equipment
Portable	Sealed, maintenance-free, good high-rate low-temperature performance, excellent cycle life	Railroad equipment, consumer electronics, portable tools, pagers, appliances, and photographic equipment, standby power, memory backup
Nickel-metal hydride	Sealed, maintenance-free, higher capacity than nickel-cadmium batteries	Consumer electronics and other portable applications, electric and hybrid electric vehicles
Nickel-iron	Durable, rugged construction, long life, low specific energy	Materials handling, stationary applications, railroad cars
Nickel-zinc	High specific energy, extended cycle life and rate capability	Bicycles, scooters, trolling motors
Silver-zinc	Highest specific energy, very good high-rate capability, low cycle life, high cost	Lightweight portable electronic and other equipment, training targets, drones, submarines, other military equipment, launch vehicles and space probes
Silver-cadmium	High specific energy, good charge retention, moderate cycle life, high cost	Portable equipment requiring a lightweight, high-capacity battery, space satellites
Nickel-hydrogen	Long cycle life under shallow discharge, long life	Primarily for aerospace applications such as LEO and GEO satellites
Ambient-temperature rechargeable “primary” types [Zn/MnO ₂]	Low cost, good capacity retention, sealed and maintenance-free, limited cycle life and rate capability	Cylindrical cell applications, rechargeable replacement for zinc-carbon and alkaline primary batteries, consumer electronics (ambient-temperature systems)
Lithium ion	High specific energy and energy density, long cycle life	Portable and consumer electronic equipment, electric vehicles, and space applications

Source: D. Linden and T. B. Reddy (eds.), “Handbook of Batteries,” 3rd ed., McGraw-Hill, 2001.

replaced), or for power drains beyond the level of primary batteries; (2) applications where the secondary battery is used as an energy-storage device, being charged by primary energy source and delivering its energy to the load on demand. Examples are automotive and aircraft systems, emergency and standby power sources, and hybrid electric vehicles.

Lead-Acid Batteries

This is the most widely used and economical secondary battery. It uses sponge lead for the negative electrode, lead oxide for the positive, and a sulfuric acid solution for the electrolyte. As the cell discharges, the active materials are converted into lead sulfate and the sulfuric acid solution is diluted; i.e., its specific gravity decreases. On charge the reverse actions take place. A key factor is its low cost, good performance, and cycle life.

The lead-acid battery is designed in many configurations, from small sealed cells with a capacity of 1 Ah to large cells, up to 12,000 Ah. The automotive SLI battery is by far the most popular and the one in widest use. Most significant of the advances in SLI battery design are the use of lighter-weight plastic containers, the improvement in shelf life, the “dry-charge” process, and the “maintenance-free” design. The latter, using calcium-lead or low-antimony grids, has greatly reduced water loss during charging (minimizing the need to add water) and has reduced the self-discharge rate so that batteries can be shipped or stored in a wet, charged state for relatively long periods.

The lead-acid industrial storage batteries are generally larger than the SLI batteries, with a stronger, higher-quality construction. Applications of the industrial batteries fall in several categories. The motive power traction types are used in materials-handling trucks, tractors, mining vehicles, and, to a limited extent, golf carts and personnel carriers, although the majority in use are automotive-type batteries. A second category is diesel locomotive engine starting and the rapid-transit batteries, replacing the nickel-iron battery in the latter application. Significant advances are the use of lighter-weight plastic containers in place of the hard-rubber containers, better seals, and changes in the tubular positive-plate designs. Another category is stationary service: telecommunication systems, electric utilities for operating power distribution controls, emergency and standby power systems, uninterruptible power systems (UPS), and in railroads, signaling and car power systems.

The industrial batteries use three different types of positive plates: tubular and pasted flat plates for motive power, diesel engine cranking, and stationary applications, and Planté designs, forming the active materials from pure lead, mainly in the stationary batteries. The flat-plate batteries use either lead-antimony or lead-calcium grid alloys. A relatively recent development for the telephone industry has been the “round cell,” designed for trouble-free long-life service. This battery uses plates, conical in shape with pure lead grids, which are stacked one above the other in a cylindrical cell container, rather than the normal prismatic structure with flat, parallel plates.

An important development in lead-acid battery technology is the valve-regulated lead-acid (VRLA) battery. These batteries operate on the principle of oxygen recombination, using a “starved” or immobilized electrolyte. The oxygen generated at the positive electrode during charge can, in these battery designs, diffuse to the negative electrode, where it can react, in the presence of sulfuric acid, with the freshly formed lead. The VRLA design reduces gas emission by over 95 percent as the generation of hydrogen is also suppressed. Oxygen recombination is facilitated by the use of a pressure-relief valve, which is closed during normal operation. When pressure builds up, the valve opens at a predetermined value, venting the gases. The valve reseals before the cell pressure decreases to atmospheric pressure. The VRLA battery is now used in about 70 percent of the telecommunication batteries and in about 80 percent of the uninterrupted power source (UPS) applications.

Smaller sealed lead-acid cells are used in emergency lighting and similar devices requiring backup power in the event of a utility power failure, portable instruments and tools, and various consumer-type applications. These small sealed lead-acid batteries are constructed in two configurations, prismatic cells with parallel plates, ranging in capacity from 1 to 30 Ah, and cylindrical cells similar in appearance to the popular primary alkaline cells and ranging in capacity up to 25 Ah. The acid electrolyte in these cells is either gelled or absorbed in the plates and in highly porous separators so they can be operated virtually in any position without the danger of leakage. The grids generally are of lead-calcium-tin alloy; some use grids of pure lead or a lead-tin alloy. The cells also include the features for oxygen recombination and are considered to be VRLA batteries.

Lead-acid batteries also are used in other types of applications, such as in submarine service, for reserve power in marine applications, and in areas where engine-generators cannot be used, such as indoors and in mining equipment. New applications, to take advantage of the cost-effectiveness of this battery, include load leveling for utilities and solar photovoltaic systems. These applications will require improvements in the energy and power density of the lead-acid battery.

A lead-acid battery can be charged at any rate that does not produce excessive gassing or high temperatures. The most common practice for recharging a fully discharged battery is to start the charge at the $C/5$ rate (amperes, corresponding to one-fifth the rated capacity of the battery) for 5 h, which will return about 80 to 85 percent of the battery's capacity. The charging current is then tapered to about one-half to complete the charge. In an emergency, fast or boost charging is used. In this type of charge, the current should not exceed the C rate or the battery can suffer damage.

The battery can also be *float-* or *trickle-*charged when it is continuously connected to an electrical system. The current should be regulated at a low level to maintain the battery in a charged condition (sufficient just to replace capacity loss because of stand) and to prevent overcharging. The battery manufacturers can supply detailed charging instructions.

Alkaline Secondary Batteries

Most of the other conventional types of secondary batteries use an aqueous alkaline solution (KOH or NaOH) as the electrolyte. Electrode materials are less reactive with alkaline electrolytes than with acid electrolytes. Furthermore, the charge-discharge mechanism in the alkaline electrolyte involves only the transport of oxygen or hydroxyl ions from one electrode to the other; hence the composition or concentration of the electrolyte does not change during charge and discharge.

Nickel-Cadmium Batteries. The nickel-cadmium secondary battery is the most popular alkaline secondary battery and is available in several cell designs and in a wide range of sizes. The original cell design used the pocket-plate construction. The vented pocket-type cells are very rugged and can withstand both electrical and mechanical abuse. They have very long lives and require little maintenance beyond occasional topping with water. This type of battery is used in heavy-duty industrial applications such as materials-handling trucks, mining vehicles, railway signaling, emergency or standby power, and diesel engine starting. The sintered-plate construction is a more recent development, having higher energy density. It gives better performance than the pocket-plate type at high discharge rates and low temperatures but is more expensive. It is used in applications, such as aircraft engine starting and communications and electronics equipment, where the lighter weight and superior performance are required. Higher energy and power densities can be obtained by using nickel foam, nickel fiber, or plastic-bonded (pressed-plate) electrodes. The sealed cell is a third design. It uses an oxygen-recombination feature similar to the one used in sealed lead-acid batteries to prevent the buildup of pressure caused by gassing during charge. Sealed cells are available in prismatic, button, and cylindrical configurations and are used in consumer and small industrial applications.

Nickel-Iron Batteries. The nickel-iron battery was important from its introduction in 1908 until the 1970s, when it lost its market share to the industrial lead-acid battery. It was used in materials-handling trucks, mining and underground vehicles, railroad and rapid-transit cars, and in stationary applications. The main advantages of the nickel-iron battery, with major cell components of nickel-plated steel, are extremely rugged construction, long life, and durability. Its limitations, namely, low specific energy, poor charge retention, and poor low-temperature performance, and its high cost of manufacture compared with the lead-acid battery led to a decline in usage.

Silver Oxide Batteries. The silver-zinc (zinc/silver oxide) battery is noted for its high energy density, low internal resistance desirable for high-rate discharge, and a flat second discharge plateau. This battery system is useful in applications where high energy density is a prime requisite, such as electronic news gathering equipment, submarine and training target propulsion, and other military and space uses. It is not employed for general storage battery applications because its cost is high, its cycle life and activated life are limited, and its performance at low temperatures falls off more markedly than with other secondary battery systems.

The silver-cadmium (cadmium/silver oxide) battery has significantly longer cycle life and better low-temperature performance than the silver-zinc battery but is inferior in these characteristics compared with the

nickel-cadmium battery. Its energy density, too, is between that of the nickel-cadmium and the silver-zinc batteries. The battery is also very expensive, using two of the more costly electrode materials. As a result, the silver-cadmium battery was never developed commercially but is used in special applications, such as nonmagnetic batteries and space applications. Other silver battery systems, such as silver-hydrogen and silver-metal hydride couples, have been the subject of development activity but have not reached commercial viability.

Nickel-Zinc Batteries. The nickel-zinc (zinc/nickel oxide) battery has characteristics midway between those of the nickel-cadmium and the silver-zinc battery systems. Its energy density is about twice that of the nickel-cadmium battery, but the cycle life previously has been limited because of the tendency of the zinc electrode toward shape change, which reduces capacity and dendrite formations, which cause internal short-circuiting.

Recent development work has extended the cycle life of nickel-zinc batteries through the use of additives in the negative electrode in conjunction with the use of a reduced concentration of KOH to repress zinc solubility in the electrolyte. Both of these modifications have extended the cycle life of this system so that it is now being marketed for use in electric bicycles, scooters, and trolling motors in the United States and Asia.

Hydrogen Electrode Batteries. Another secondary battery system uses hydrogen for the active negative material (with a fuel-cell-type electrode) and a conventional positive electrode such as nickel oxide. These batteries are being used exclusively for the aerospace programs, which require long cycle life at low depth of discharge. The high cost of these batteries is a disadvantage, which limits their application. A further extension is the sealed nickel/metal hydride battery where the hydrogen is absorbed, during charge, by a metal alloy forming a metal hydride. This metal alloy is capable of undergoing a reversible hydrogen absorption-desorption reaction as the battery is charged and discharged, respectively. The advantage of this battery is that its specific energy and energy density are significantly higher than that of the nickel-cadmium battery. The sealed nickel-metal hydride battery, manufactured in small prismatic and cylindrical cells, is being used for portable electronic applications and are being employed for other applications including hybrid electric vehicles. Larger sizes are finding use in electric vehicles.

Zinc/Manganese Dioxide Batteries. Several of the conventional primary battery systems have been manufactured as rechargeable batteries, but the only one currently being manufactured is the cylindrical cell using the zinc/alkaline-manganese dioxide chemistry. Its major advantage is a higher capacity than the conventional secondary batteries and a lower initial cost, but its cycle life and rate capability are limited.

Advanced Secondary Batteries

A number of battery systems are being studied for such applications as electric vehicles and utility power which require a high specific energy (in the order of 200 Wh/kg), high power density and low cost. These include: (1) high temperature systems using molten salt electrolytes, (2) high temperature systems using ceramic or glass electrolytes, (3) aqueous zinc halogen batteries. Some of this work, particularly for electric vehicles, has been deemphasized in favor of lithium-ion and other conventional batteries operating at ambient temperatures, which are now demonstrating energy and power capabilities approaching those of high temperature batteries.

Rechargeable Lithium Batteries

Rechargeable lithium batteries operating at room temperature offer several advantages compared to conventional aqueous technologies, including: (1) Higher energy density (up to 150 Wh/kg, 300 Wh/L), (2) Higher cell voltage (up to about 4 V per cell), and (3) Longer charge retention or shelf life (up to 5 to 10 years).

These advantageous characteristics result in part from the high standard potential and low electrochemical equivalent weight of lithium.

Ambient-temperature lithium rechargeable batteries, on the other hand, do not have the high-rate capability (because of the relatively poor conductivity of the aprotic organic or inorganic electrolytes that must be used because of the reactivity of lithium in aqueous electrolytes) nor, in some instances, the cycle life of conventional rechargeable batteries. In addition, the rechargeable lithium cells that use lithium metal as the negative electrode present potential safety problems, which are more challenging than those with primary lithium batteries.

This is because of a three- to fivefold excess of lithium that is required for these types of cells in order to obtain a reasonable cycle life and to the reactivity of the porous high surface area lithium that is formed during cycling with the electrolyte. For these reasons, these types of batteries have had little commercial success except for small, low energy coin batteries where an aluminum lithium alloy is generally used.

Another type of rechargeable lithium battery that has been recently developed and is achieving commercial success, is the "lithium-ion" battery. This battery does not use metallic lithium and thus should minimize the safety concerns. The lithium-ion battery uses lithium intercalation compounds as the positive and negative materials. As the battery is cycled, lithium ions exchange between the positive and negative electrodes. The negative electrode material is typically a graphite carbon, a layered material. The positive material is typically a metal oxide, also with a layered structure, such as lithium cobalt oxide or lithium manganese dioxide. In the charge/discharge process, lithium ions are inserted or extracted from the interstitial space between atomic layers within the active material. Liquid electrolytes, using lithium salts in organic solvents, are the most common electrolytes. There is increasing interest and activity with polymer electrolytes as these allow for a greater flexibility in cell design and better safety characteristics.

Lithium-ion batteries are presently manufactured in a variety of designs in sizes as small as 0.1 Ah to large units of about 100 Ah but with the major emphasis on consumer electronic applications such as laptop computers, camcorders, and cell phones. Various cell designs have been developed including cylindrical, wound prismatic, and flat plate prismatic configurations. The lithium-ion batteries have a number of advantages, including a high cell voltage, a high specific energy and energy density, a competitive specific power, long cycle life, and a broad operating temperature range. Lithium-ion batteries should not be overcharged nor overdischarged. Electronic management circuits or mechanical disconnect devices are usually used with lithium-ion batteries to provide protection from overcharge, overdischarge, and over temperature conditions.

It is expected that the market share enjoyed by the lithium rechargeable battery will increase significantly during the next decade because of its high energy density and its ability to meet consumer demands for lighter weight and longer service more adequately than the conventional aqueous rechargeable batteries. Larger cells also are being considered for a number of military and commercial applications, including underwater propulsion and electric vehicles.

RESERVE BATTERIES

Batteries that use highly active component materials to obtain the required high energy, high power, and/or low-temperature performance, are often designed in a reserve construction to withstand deterioration in storage and to eliminate self-discharge prior to use. These batteries are used primarily to deliver high power for relatively short periods of time after activation in such applications as radiosondes, fuzes, missiles, torpedoes, and other weapon systems. The reserve design also is used for batteries required to meet extremely long or environmentally severe storage requirements.

In the reserve structure, one of the key components of the cells is separated from the remainder of the cell until activation. In this inert condition, chemical reaction between the cell components (self-discharge) is prevented, and the battery is capable of long-term storage. The electrolyte is the component that is usually isolated, although in some water-activated batteries the electrolyte solute is contained in the cell and only water is added.

The reserve batteries can be classified by the type of activating medium or mechanism that is involved in the activation:

Water-activated batteries: Activation by fresh or seawater.

Electrolyte-activated batteries: Activation by the complete electrolyte or with the electrolyte solvent. The electrolyte solute is contained in or formed in the cell.

Gas-activated batteries: Activation by introducing a gas into the cell. The gas can be either the active cathode material or part of the electrolyte.

Heat-activated batteries: A solid salt electrolyte is heated to the molten condition and becomes ionically conductive, thus activating the cell. These are known as thermal batteries.

Activation of the reserve battery is accomplished by adding the missing component just prior to use. In the simplest designs, this is done by manually pouring or adding the electrolyte into the cell or placing the battery in the electrolyte (as in the case of seawater-activated batteries). In more sophisticated applications the electrolyte storage and the activation mechanism are contained within the overall battery structure, and the electrolyte is brought automatically to the active electrochemical components by remotely activating the activation mechanism. Thermal batteries are activated by igniting a heat source that is contained within the battery.

FUEL CELLS

Fuel cells, such as batteries, are electrochemical galvanic cells that convert chemical energy directly into electrical energy and are not subject to the Carnot cycle limitations of heat engines. Fuel cells are similar to batteries except that the active materials are not an integral part of the device (as in a battery), but are fed into the fuel cell from an external source when power is desired. The fuel cell differs from a battery in that it has the capability of producing electrical energy as long as the active materials are fed to the electrodes (assuming the electrodes do not fail). The battery will cease to produce electrical energy when the limiting reactant stored within the battery is consumed.

The electrode materials of the fuel cell are inert in that they are not consumed during the cell reaction, but have catalytic properties that enhance the electroreduction or electrooxidation of the reactants (the active materials).

The anode active materials used in fuel cells are generally gaseous or liquid (compared with the metal anodes generally used in most batteries) and are fed into the anode side of the fuel cell. As these materials are more like the conventional fuels used in heat engines, the term "fuel cell" has become popular to describe these devices. Oxygen or air is the predominant oxidant and is fed into the cathode side of the fuel cell.

TABLE 5.3.4 Types of Fuel Cells

1. Solid Oxide (SOFC): These cells use a solid oxygen-ion-conducting metal oxide electrolyte. They operate at about 1000°C, with an efficiency of up to 60 percent. They are slow to start up, but once running, provide high grade waste heat that can be used to heat buildings. They may find application in industrial and large-scale applications.
2. Molten Carbonate (MCFC): These cells use a mixed alkali-carbonate molten salt electrolyte and operate at about 600°C. They are being developed for continuously operating facilities, and can use coal-based or marine diesel fuels.
3. Phosphoric Acid (PAFC): This is the most commonly used type of fuel cell for stationary commercial sites such as hospitals, hotels, and office buildings. The electrolyte is concentrated phosphoric acid. The fuel cell operates at about 200°C. It is highly efficient and can generate energy at up to 85 percent (40 percent as electricity and another 45 percent if the heat given off is also used).
4. Alkaline (AFC): These are used by NASA on the manned space missions, and operate well at about 200°C. They use alkaline potassium hydroxide as the electrolyte and can generate electricity up to 70 percent efficiency. A disadvantage of this system is that it is restricted to fuels and oxidants that do not contain carbon dioxide.
5. Proton Exchange Membrane (PEM): These cells use a perfluorinated ionomer polymer membrane electrolyte that passes protons from the anode to the cathode. They operate at a relatively low temperature (70 to 85°C), and are especially notable for their rapid start-up time. These are being developed for use in transportation applications and for portable and small fuel cells.
6. Direct Methanol (DMFC): These fuel cells directly convert liquid methanol (methyl alcohol) in an aqueous solution that is oxidized at the anode. Like PEMs, these also use a membrane electrolyte, and operate at similar temperatures. This fuel cell is still in the development stage.
7. Regenerative (RFC): These are closed-loop generators. A powered electrolyzer separates water into hydrogen and oxygen, which are then used by the fuel cell to produce electricity and exhaust (water). That water can then be recycled into the powered electrolyzer for another cycle.

5.60 ELECTRONIC AND FIBER OPTIC COMPONENTS

Fuel cells have been of interest for over 150 years as a potentially more efficient and less polluting means for converting hydrogen and carbonaceous or fossil fuels to electricity compared to conventional engines. A well-known application of the fuel cell has been the use of the hydrogen/oxygen fuel cell, using cryogenic fuels, in space vehicles for over 40 years. Use of the fuel cell in terrestrial applications has been developing slowly, but recent advances has revitalized interest in air-breathing systems for a variety of applications, including utility power, load leveling, dispersed or on-site electric generators and electric vehicles.

Fuel cell technology can be classified into two categories:

1. Direct systems where fuels, such as hydrogen, methanol and hydrazine, can react directly in the fuel cell
2. Indirect systems in which the fuel, such as natural gas or other fossil fuel, is first converted by reforming to a hydrogen-rich gas that is then fed into the fuel cell

Fuel cell systems can take a number of configurations depending on the combinations of fuel and oxidant, the type of electrolyte, the temperature of operation, and the application, and so forth. Table 5.3.4 lists the various types of fuel cells distinguished by the electrolyte and operating temperature.

More recently, fuel cell technology has moved toward portable applications, historically the domain of batteries, with power levels from less than 1 to about 100 W, blurring the distinction between batteries and fuel cells. Metal/air batteries, particularly those in which the metal is periodically replaced, can be considered a "fuel cell" with the metal being the fuel. Similarly, small fuel cells, now under development, which are "refueled" by replacing an ampule of fuel can be considered a "battery."

Table 5.3.1 gives both theoretical and practical values of voltage, capacity, and specific energy for several fuel cell systems.

CHAPTER 5.4

RELAYS AND SWITCHES

J. Spergel, John M. Kikta

INTRODUCTION

The primary function of switches and relays is the transmission and control of electric current accomplished by mechanical contacting and actuating devices. In recent years, solid-state (nonmechanical) switching devices have come into wide use and their applications are extending rapidly.

ELECTROMAGNETIC RELAYS

The simplified diagram of a relay shown in Fig. 5.4.1a illustrates the basic elements that constitute an electromagnetic relay (EMR). In simplest terms, it operates through the use of a coil which, when energized, attracts the spring-loaded armature; this, in turn, moves a set of contacts to or from a set of stationary contacts. The most common EMR types are as follows:

General-purpose. Design, construction, operational characteristics, and ratings are adaptable to a wide variety of uses.

Latch-in. Contacts lock in either the energized or deenergized position until reset either manually or electrically.

Polarized (or polar). Operation is dependent on the polarity of the energizing current. A permanent magnet provides the magnetic bias.

Differential. Functions when the voltage, current, or power difference between its multiple windings reaches a predetermined value.

Telephone. An armature relay with an end-mounted coil and spring-pickup contacts mounted parallel to the long axis of the relay coil. Ferreeds are also widely used for telephone cross-point switches.

Stepping. Contacts are stepped to successive positions as the coil is energized in pulses; they may be stepped in either direction.

Interlock. Coils, armature, and contact assemblies are arranged so that the movement of one armature is dependent on the position of the other.

Sequence. Operates two or more sets of contacts in a predetermined sequence. (Motor-driven cams are used to open and close the contacts.)

Time-delay. A synchronous motor is used for accurate long time delay in opening and closing contacts. Armature-type relay uses a conducting slug or sleeve on the core to obtain delay.

Marginal. Operation is based on a predetermined value of coil current or voltage.

FIGURE 5.4.1 (a) Simplified diagram of a single-pole, double-throw, normally open relay; (b) structure of conventional relay (from NARM Engineers Relay Handbook, 4th ed.).

Performance Criteria

The design or selection of a relay should be based on the following circuit-performance criteria:

Operating frequency. Electrical operating frequency of relay coil

Rated coil voltage. Nominal operating voltage of relay coil

Rated coil current. Nominal operating current for relay

Nonoperate current (or voltage). Maximum value of coil current (or voltage) at which relay will not operate

Operate voltage (or current). Minimum value of coil voltage (or current) at which switching function is completed

Release voltage (or current). Value of coil voltage (or current) at which contacts return to the deenergized position

Operate time. Time interval between application of power to coil and completion of relay-switching function

Release time. Time interval between removal of power from coil and return of contacts to deenergized position

Contact bounce. Uncontrolled opening and closing of contacts due to forces within the relay

Contact chatter. Uncontrolled opening and closing of contacts due to external forces such as shock or vibration

Contact rating. Electrical load on the contacts in terms of closing surge current, steady-state voltage and current, and induced breaking voltage

Figure 5.4.2. illustrates some of the contacting characteristics during energization and deenergization.

General Design and Application Considerations

The dynamic characteristics of the moving system, i.e., armature and contact assembly, are primarily determined by the mass of the armature and depend on the magnet design and flux linkage. Typical armature configurations are clapper or balanced armature, hinged or pivoted lever about a fixed fulcrum; rotary armature; solenoid armature; and reed armature. Contact and restoring-force springs are attached or linked to the armature to achieve the desired make and/or break characteristics. The types of springs used for the contact assembly and restoring force are generally of the cantilever, coil, or helically wound spring type. Primary characteristics for spring materials are modulus of elasticity, fatigue strength, conductivity, and corrosion resistance. They should also lend themselves to ease of manufacture and low cost. Typical materials for springs are spring brass, phosphor bronze, beryllium copper, nickel silver, and spring steel.

Contacts. These include stationary and moving conducting surfaces that make and/or break the electric circuit. The materials used depend on the application; the most common are palladium, silver, gold, mercury, and various alloys. Plated and overlaid surfaces of other metals such as nickel or rhodium are used to impart special characteristics such as long wear and arc resistance or to limit corrosion.

The heart of the relay is the contact system that is typically required to make and/or break millions of times and provide a low, stable electrical resistance. The mechanical design of the relay is aimed principally at achieving good contact performance. Because of the numerous operations and arcing often occurring during operation, the contacts are subject to a wide variety of hazards that may cause failure, such as:

Film formation. Effect of inorganic and organic corrosion, causing excessive resistance, particularly at dry-circuit conditions.

Wear erosion. Particles in contact area, which can cause bridging between small contact gaps.

Gap erosion. Metal transfer and welding of contacts.

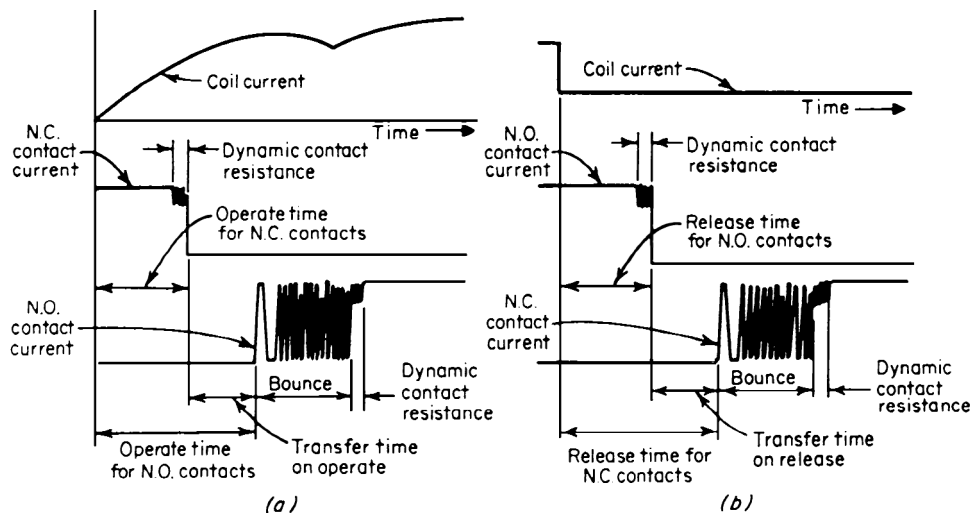

FIGURE 5.4.2 Typical oscillograph depictions of contacting characteristics during (a) energization and (b) deenergization of a relay. (Automatic Electric, Northlake, IL.)

5.64 ELECTRONIC AND FIBER OPTIC COMPONENTS

Surface contamination. Dirt and dust particles on contact surfaces can prevent achievement of low resistance between contacts and may actually cause an open circuit.

Cold welding. Clean contacts in a dry environment will self-adhere or cold-weld.

One of the major factors in determining relay-contact life is the arcing that occurs at the contact surface during the period in which the contacts are breaking the circuit. Contact life (and hence relay reliability) can be greatly enhanced by the addition of appropriate contact-protection circuits. Such circuitry can reduce the effects of load transients, which are especially deleterious. A variety of circuits may be employed using bifilar coil windings, RC networks, diodes, varistors, and so forth. As a rule of thumb, for compact relays with operating speeds of 5 to 10 ms, the approximate parameters for suitable RC networks are approximately R , as low as possible but sufficient to limit the capacitor discharge current to the resistive load rating of the contacts, and C , a value in microfarads approximately equal to the steady-state load current in amperes.

Details on the effects of various methods of suppression are given in the *19th Relay Conference Proceedings*.

Packaging

Relays are packaged in a wide variety of contact arrangements (see Table 5.4.1) and in many package configurations ranging from T05 cans and crystal cans to relatively large enclosures, as well as plastic encapsulation, and open construction with plastic dust covers. The packaging adopted depends on the environment and reliability requirements. If the environment is controlled, as in a telephone exchange, a relatively inexpensive and simple package can be used. In a military or aerospace environment, hermetically sealed or plastic-encapsulated packages are essential, to prevent corrosion of contacts. In this regard the reed switch has had great impact on relay design since it provides a sealed-contact enclosure in a relatively simple and inexpensive package. It has become widely used in the telephone and electronics industry because it has been able to extend relay life to millions of cycles. A comparison between the reed and typical conventional relays is given in Table 5.4.2. Solid-state relays (SSRs) are also used extensively. Table 5.4.3 compares SSRs with electromagnetic relays.

SOLID-STATE RELAYS

An SSR performs a switching function using semiconductor devices and technologies to provide electrical isolation between the control circuit (input) and the load circuit (output) without electromechanical moving parts or contacts, thus ensuring long life and high reliability. It should be noted, however, that SSRs can be very unforgiving when encountering overloads, voltage and current spikes, and other conditions that can “destroy” solid-state devices.

SSRs are used in commercial, industrial, and military applications throughout the world including sophisticated avionics and microprocessor-based systems applications. Increased functional integration and miniaturization are yielding SSRs with greater reliability, reduced system complexity, and improved performance characteristics. The modern SSR has become a complete electronic subsystem, which greatly aids the electronics engineer in connecting the world of the microprocessor to the world of motors and solenoids. See Table 5.4.3.

The primary advantages to the use of SSRs are

- (a) Improved system reliability
- (b) State of the art technical performance
- (c) Improved system life cycle costs

Improved System Reliability

This advantage is related to the long-life characteristics of semiconductor devices. An SSR has no moving parts and suffers no contact degradation from arcing, erosion, or contamination. The absence of moving parts and contact chatter coupled with the low mass of semiconductor devices and proper construction and packaging techniques results in a virtual immunity to shock and vibration effects.

TABLE 5.4.1 Symbols for Relay Contact Combinations Established by American National Standards Institute (ANSI)

Form	Description	ANSI symbol	Form	Description	ANSI symbol
A	Make or SPSTNO		L	Break, Make, Make, or SPDT (B-M-M)	
B	Break or SPSTNC		M	Single pole, Double throw, Closed Neutral SP DT NC (This is peculiar to MIL-SPECS)	
C	Break, Make, or SPOT (B-M), or Transfer		U	Double make, Contact on Arm. SP ST NO DM

The heavy arrow indicates the direction of operation. Contact chatter may cause some electrical discontinuity in forms D and E.

TABLE 5.4.2 Estimated Load-Life Capability of Two-Pole Miniature Relays

	Dry reed. 0.125 A	Conventional crystal can. 5 A	Miniature power, 10 A
λ at 1×10^6 (%/10 ⁴)	0.002	1.2	0.80
$R_{(0.999)}$ (10 ³ operation)	700	2.8	6.0
$R_{(0.90)}$ (10 ³ operation)	10,000	60	120.0

λ = failure rate in percent/10,000 h operation; $R_{(0.999)}$ = operating life with 99.9 percent probability;
 $R_{(0.90)}$ = operating life with 90 percent probability.

The technical characteristics of an SSR can reduce system complexity. Isolation techniques can prevent a series of secondary system failures from rippling through a system when a primary failure occurs. The lower power requirements can also contribute to reduced system power consumption, reduced thermal effects, and downsizing of system power supplies.

State-of-the-Art Performance

Many SSRs can be driven by either CMOS or TTL logic with no need for buffers or relay driver stages. Constant current input circuitry allows a wide control voltage range without need for external current limiting resistors or sources. They also allow a wide range of switching speeds to match user needs. Absence of moving parts provides clean bounce-free switching. This characteristic, coupled with zero-voltage turn-on and zero-current turn-off techniques, results in low EMI/RFI levels that are far below FCC and VDE specifications. The introduction of solid-state power FET relays has provided a quantum leap in switching technology with low “on” resistance with virtually no bipolar offset voltage. This allows them to switch low-level microvolt analog signals that have always been beyond the capability of bipolar solid-state devices, as well as high power levels with significantly reduced power dissipation.

TABLE 5.4.3 Relative Comparison of Electromagnetic Relays (EMRs) vs. Solid-State Relays (SSRs)

Characteristic	EMRs	SSRs	Advantage
Life	From 100,000 to millions of cycles. Reed contacts are outstanding.	No moving parts. When properly designed should last life of equipment.	SSR
Isolation	Infinite dielectric isolation.	Not dielectrically isolated; however, several techniques are available to achieve up to 10 kM Ω .	EMR
EMI (RFI)	Can generate EMI by switching of its coil, thereby requiring special isolation (i.e., shielding).	Noise generated is negligible compared with EMR.	SSR
Speed	Order of milliseconds.	Up to nanoseconds.	SSR
Operate power	Uses more power than SSR.	Lower power requirements but requires continuous standby power.	SSR
Contact voltage drop	Relatively low voltage drop because of low contact resistance.	High voltage drop which is dissipated into heat.	EMR
Thermal power dissipation	Primarily concerned with dissipating coil power.	Higher voltage drop develops appreciable heat to be dissipated.	EMR

Improved System Life Cycle Costs. This aspect stems from the SSRs' greater reliability and reduced failure rate, which yields lower production costs, lower system acquisition costs, and reduced field repair costs.

Anatomy of an SSR. Every SSR consists of at least three parts: (1) input or control circuitry, (2) isolation, and (3) output or load circuitry.

Input. The input circuitry is classified as dc, ac, or ac–dc, depending on the control requirements. Input control circuitry may also include such features as TTL/CMOS compatibility, positive or negative logic control, series/parallel digital interface, and so forth.

Isolation. The isolation between the input and output may be accomplished optically, magnetically (transformer), or, in special applications, using a mechanical relay (typically a reed relay) to drive the output device.

Output. Output circuitry is also classified as dc, ac, or ac–dc, and may use a variety of output devices, depending on the application. For ac operation a thyristor (2 SCRs or triac) is generally used. For dc applications a bipolar device or power FET transistor may be used. For ac–dc operation power FETs are used, although bipolar transistors may be used for currents up to 100 mA. Additionally, the output may be single or multiple pole, single or double throw, and may incorporate such features as time delay, latching, break-before-make logic, and so forth.

SWITCHES

Switches are electromechanical devices used to make and break, or select, an electrical circuit by manual or mechanical operation.

An examination of manufacturers' and distributors' catalogs makes it obvious that switches come in a bewildering array of types, shapes, sizes, actuator styles, ratings, and quality levels.

Beside the basic ability of a switch to make, break, and carry the required electrical load (including the inductive or capacitive, low level or logic level effects), switches can be characterized in additional ways, usually dependent on the sensitivities of the application, such as electrical noise, capacitance, frequency, contact make or break speed, contact bounce, and ability to withstand various environmental conditions.

Contact Make/Break Time and Bounce Time. Make time is the time required by a switch contact to travel from an open position to a closed position. Break time is the time required by a switch contact to travel from a closed position to a fully open position. Bounce time is the interval between an initial contact and steady contact during which the moving contact bounces or makes intermittent contact as a result of its impact on a stationary contact.

Electrical Noise and Capacitance. Electromagnetic radiations may occur during make and break, causing noise interference in sensitive circuits or high-gain amplifiers. Arc suppression may be necessary to reduce such noise to acceptable levels.

Selection Considerations. Once the basic switch type, size, and rating has been selected, the exact configuration must be considered and tailored for the application. Each particular switch type, and sometimes each manufacturer, has its own list of options and peculiarities, so manufacturers should be consulted at an early stage.

For rotary switches, the number of decks (sections), poles per deck, positions per pole, shorting and/or non-shortening contacts, and coding need to be considered, as well as, on the mechanical side, factors such as shaft and mounting bushing configuration, push-to-turn, pull-to-turn, and spring return features.

For toggle switches, contact configuration (single pole normally open, single pole normally closed, double throw, multiple poles, and so forth), the desirability of the bathandle configuration, and whether a lock is required, are among the factors to be considered.

Rocker switches are similar to toggles so similar factors apply. They also provide the option of illumination. Keypads and keyboards offer such a wide range of options that manufacturers should be consulted at the outset of the selection process.

For a simple on-off situation, a two-position rotary or two-position toggle, a push-push, or a push-pull switch are good choices. For data input applications, a numerical keypad and/or a keyboard is an obvious choice.

Application Notes. Switch selection must not overlook the ergonomic factors of the application. When a rotary switch is among the options, its choice will help minimize the panel space required.

Pushbutton switches often require the operator to view them in order to operate them, whereas toggle and rocker switches can be operated by feel. Rotary switches can sometimes be operated by feel, with the practiced operator counting clicks to position the knob correctly. Numerical keypads can be operated by touch, but special keyboards, notably the flush type, require eye contact for correct operation.

Switches designed to carry high electrical loads are physically large in order to accommodate the larger contacts to handle the load and dissipate heat, while switches designed for low and logic level loads can be very small, like subminiature toggles and DIP switches.

Standards. Switches used in appliances and equipment that handle line power will require a UL (Underwriters Laboratories) listing for use in the United States, a CSA listing for use in Canada, and other listings for use in other countries. These listings require the listing agency to run or observe special tests of the product to be listed, and continuous follow-up testing to prove that they can meet the necessary safety requirements. There are no universal tests or listing agencies although there are efforts being made in that direction.

Many switch standards are available from the Electronic Industries Association, the U.S. Department of Defense, Underwriters Laboratories, and others.

Ratings. Switch manufacturers publish one or more ratings for their products. Each represents a point on a load versus life curve, usually developed from testing at room conditions unless otherwise noted. Although not always stated, each load-life curve represents a given set of life limiting criteria: typically a certain maximum allowable value of contact resistance, a minimum value of insulation resistance between adjacent contacts or between contacts and ground (mounting bushing, case, or similar reference point), and a minimum value of dielectric strength (breakdown voltage across insulation). Increasing the ambient temperature during the test will generally result in higher values of contact resistance and reduced insulation resistance, which can equate to shorter life. These should be weighed against the application requirements. Typically the use conditions are more lenient than the test conditions for the load-life curve. For instance, many electronic circuits are of the high impedance variety where contact resistances of 20 or 50 milliohms are insignificant, but where insulation resistance can be important.

Arcing. Typical power loads will cause an arc to be drawn when a circuit is broken, which causes electrical erosion of the contacts. The erosion products are conductive, and if deposited on insulating surfaces, can result in a reduction of insulation resistance and dielectric strength. Higher currents produce hotter arcs and more erosion. Inductive loads also increase arcing. Fast making and breaking of contacts, as in snap-acting switch types, reduce the effect of arcing. Reduced barometric pressure, as in high altitudes, reduces the dielectric strength of air, which enhances the effect of arcing, so a switch should be derated for high-altitude operation.

Life tests for rating purposes are usually run on a continuous basis. This gives the contacts little time to cool between carrying high loads and breaking arcs, whereas typical applications require switches to operate infrequently, giving the contacts plenty of cooling time, and resulting in an application life that is longer than the test life.

Many switch applications in electronics do not switch power loads; they are more likely to handle low level or logic level loads. Typical low level tests are run at 30 mV and 10 mA, while logic level tests are run at 2 to 5 Vdc and 10 mA or less. Low levels can be troublesome because they are run below the melting voltage of the contact material and below the breakdown voltage of contact contaminants.

Contact pairs will be of the butt type, wiping type, or a combination of these basic types. Even small amounts of lateral wiping action between contact pairs can provide significant cleaning of the contact faces, thus minimizing contact resistance but creating some mechanical wear of the contact surfaces. Butt contacts will exhibit less wear but have higher contact resistance. Most rotary switches used in electronics have a considerable amount of wiping action, while sensitive or snap action switches and some types of toggle/rocker switches are closer to pure butt types (although most have a slight amount of wipe).

CHAPTER 5.5

CONNECTORS

Robert S. Mroczkowski

INTRODUCTION

This chapter provides an overview of the structure and function of electronic connectors. Because of space limitations a limited number of topics will be discussed. References are given to provide additional detail for interested readers.

Defining a Connector

A connector can be defined in terms of its structure or its function. A functional definition describes what the connector is expected to do, such as carry a signal or distribute power, and the requirements it must meet, such as the number of mating cycles and electrical requirements. A structural definition describes the materials of manufacture and design of the connector. The discussion will begin with a functional definition.

A connector provides a *separable* connection between two functional units of an electronic system without *unacceptable* effects on signal integrity or power transmission.

A few comments on the highlighted elements in the definition are in order. The *separable* interface is the reason for using a connector. Separability may be required for manufacturing, maintenance/upgrading or portability/multifunction capability. The number of mating cycles a connector must support without degradation in performance depends on the reason for the separability requirement. A manufacturing application may require only a few matings while portability/multifunctional capability may require hundreds or thousands of mating cycles. Once in place, however, the connector must not introduce any *unacceptable* effects on the electrical/electronic function. The effects of connectors on signal degradation is becoming increasingly important as pulse rise times fall to a nanosecond and below.

To understand how these requirements are considered in connector design and selection, a short discussion of connector structure follows.

CONNECTOR STRUCTURE

A connector consists of four basic elements as outlined by Mroczkowski (Ref. 1).

1. The contact interface
2. The contact finish
3. The contact spring element
4. The connector housing

FIGURE 5.5.1 The structural components of a connector: (a) the contact spring and connector housing, (b) the contact finish, and (c) the contact interface.

A schematic illustration of these components is provided in Fig. 5.5.1. Each of these components will be briefly considered.

Contact Interface(s)

There are two contact interfaces of interest. The separable, or mating, interface has already been mentioned as the major reason for using a connector. In addition to the separable interface, it is also necessary to attach the connector to the subsystems that are to be connected. Such connections are generally “permanent,” such as solder joints or crimped connections. A wide variety of separable and permanent connection designs are used in connectors as will be discussed in the section on connector applications.

At this point it is sufficient to say that contact interfaces, whether separable or permanent, are established by generating metallic interfaces between the two halves of the connector or between the connector and the subunit to which it is connected. Williamson (Ref. 2) provides an informative discussion of the fundamental structure of contact interfaces. Design considerations for establishing contact interfaces are discussed in Whitley and Mroczkowski (Ref. 3).

TABLE 5.5.1 Selected Contact Finish Properties

	Hardness (Knoop@25g)	Durability	Coefficient of friction
Gold (soft)	90	Fair	0.4/0.7
(hard)	130/200	Good	0.3/0.5
Palladium	200/300	Very good*	0.3/0.5
Palladium (80)- Nickel (20)	300/450	Very good*	0.2/0.5
Tin	9/20	Poor	0.5/1.0
Silver	80/120	Fair	0.5/0.8
Nickel	300/500	Very good	0.3/0.6

*with gold flash.

Contact Finish

The contact finish consists of a metallic coating intended to provide mating surfaces that optimize the ability to establish and maintain a metallic contact interface. Optimization of the mating surfaces can be simply described as meeting the need to avoid the formation of, or facilitate displacement of, surface films at the mating interface. The dominant contact finishes are noble metals and tin. Noble metal finishes include gold, palladium, and alloys of these two metals. Noble metal finishes “optimize” performance by being corrosion resistant which minimizes film formation. Tin, on the other hand, has a surface oxide that is readily disrupted on mating of the connector. Tin finishes are, however, subject to reoxidation during use, a failure mechanism called *fretting corrosion* (Bock and Whitley, Ref. 4). For additional discussion of contact finishes, see Antler (Refs. 5, 6, 7) and Mroczkowski (Ref. 8).

A brief descriptive compilation of contact finish characteristics of importance for connectors is provided in Table 5.5.1. The values realized depend strongly on the processing of the finish and the state of lubrication of the surface in the case of durability and coefficient of friction. Selection of the appropriate finish for a given application depends on mechanical, electrical, and environmental requirements.

Mechanical requirements include the following.

Mating durability. The number of mating cycles the connector can support without degradation of the finish. Mating durability depends on the hardness of finish system, the contact normal force and the contact geometry.

Connector mating force. The force required to mate the connector depends on the contact normal force, the coefficient of friction of the finish system, the contact geometry, and the number of positions in the connector.

The dominant electrical requirement is a low and stable value of connector resistance. From a contact finish viewpoint the contact resistance is dependent on the film formation and displacement characteristics of the finish. It is in the respect that noble and non-noble finishes display significant differences a previously mentioned.

The environmental characteristics of the operating environment, in particular the temperature, humidity, and corrosive species, determine the type and structure of films, which will form on contact interfaces. Films on noble metal finishes generally result from corrosion of exposed copper. Tin shows good environmental stability in most environments because of the self-limiting oxide film. The degradation of tin is primarily related to small motions, called *fretting* of the contact interface leading to a fretting corrosion (Bock and Whitley, Ref. 4). Such motions can arise from mechanical disturbances or differential thermal expansion mismatch stresses.

Noble metal finishes are generally considered as more forgiving and versatile in connector applications. Evaluation of the sensitivity of an application to fretting susceptibility is the major consideration limiting the use of tin finishes.

TABLE 5.5.2 Selected Properties of Commonly Used Contact Spring Materials

	Young's modulus, (E) (10^6 kg/mm ²)	Electrical conductivity (% IACS)	0.2 percent Offset yield strength (10^3 kg/mm ²)	Stress relaxation
Brass (C26000)	11.2	28	40/60	Poor
Phosphor bronze (C51000)	11.2	20	50/70	Good
Beryllium-copper (C17200)	13.3	20/26	55/95	Excellent

Contact Spring System

The contact spring system has two functions, mechanical and electrical. There are two different mechanical considerations, those for the separable interface and those for the permanent connection. In most separable connections the contact spring system consists of a spring member and a supporting surface. As indicated in Fig. 5.5.1 the deflection of the receptacle contact spring as it mates to the post provides the contact normal force, which establishes and maintains the integrity of the separable contact interface. The contact normal force is a major design consideration for connectors as discussed and Whitley and Mroczkowski (Ref. 3). Establishing a mechanical permanent connection, as opposed to a metallurgical connection such as a soldered or welded joint, involves controlled deformation and force considerations as discussed in Ref. 1. A balance of strength, for spring forces, and ductility, for manufacturing and formation of permanent connections, is required from a contact spring material. Most connector contact springs are copper alloys because such alloys have a good combination of strength, ductility, and electrical conductivity.

For a discussion of contact spring material selection issues see Bersett (Ref. 9), Spiegelberg (Ref. 10) and Lowenthal et al. (Ref. 11). Table 5.5.2 provides a limited selection of materials characteristics of importance for three of the more commonly used contact spring materials. A range of yield strength data is shown since different temper alloys may be used. From a user viewpoint, selection of an appropriate spring material for a given application depends primarily on the application temperature and the stress relaxation characteristics of the spring material. Stress relaxation resistance is important because it results in a reduction in the contact normal force as a function of time and temperature.

Electrically, the contact spring sections provide the conducting path between the permanent connection to the subsystems and the separable interface. The conductivity and geometry of the contact spring elements determine the resistance introduced by the connector. Figure 5.5.2 illustrates the sources of resistance in a connector. Three different resistances are indicated, the connection resistances of the permanent connections, R_{conn} , the bulk resistances of the receptacle spring and the post, R_b , and the resistance of the separable interface, R_c . In a typical connector the permanent connection resistances will be of the order of tens or hundreds of microohms, the bulk resistances of the order of a few to a few tens of milliohms, and the separable interface resistance of the order of milliohms. The resistivity of the contact spring material is a factor in all these resistances and is, therefore, a material selection parameter. As indicated in Table 5.5.2 however, the resistivity of the copper alloys used in connectors varies over a limited range. For power applications the bulk resistance becomes increasingly important and low resistivity alloys may be required.

Although the bulk resistance dominates the overall connector resistance, it is the contact and permanent connection resistances that are variable and can degrade during the application lifetime of a connector. An understanding of connector degradation mechanisms and how they can be controlled is a major element of connector design and selection. For an overview of connector design/degradation issues see Mroczkowski (Ref. 12).

Connector Housing

The connector housing also performs electrical and mechanical functions. There are two levels of electrical function, one at low frequencies and another for high frequencies. For low frequencies, the primary electrical function is insulation. The dielectric material of the housing insulates and isolates the individual contacts electrically, to allow

FIGURE 5.5.2 The contribution of various connector components to connector resistance: the connector resistance, R_{conn} ; the bulk resistance of the contact spring, R_b ; and the interface (contact) resistance R_c .

multiposition connectors. For high-frequency connectors in addition to insulation, the dielectric properties and geometry of the housing significantly impact on the characteristics of the connector as a transmission line. With the increasing processing speed capability of microelectronics, connector transmission line parameters such as characteristic impedance, propagation delay, and cross talk become major system design considerations. For additional discussion of these issues, see Southard (Ref. 13) and Aujia and Lord (Ref. 14).

Mechanically the connector housing latches and supports the contact springs within the housing and locates them mechanically. Control of mechanical location is critical to both mating characteristics of the connector separable interface and to proper permanent connections to the subunits to which the connector is attached.

Most connector housings are made from thermoplastic resins for cost and performance reasons. The electrical and, in most cases, mechanical properties of engineering thermoplastics are generally satisfactory for typical connector applications. Selection of a housing material is typically dependent on a particular manufacturing or application related requirement, such as molding of a long high pin count connector, high-temperature applications (greater than 100°C) or surface mount soldering requirements. For additional discussion on housing functions and material selection criteria see Walezak et al. (Ref. 15).

Table 5.5.3 contains a selection of housing material characteristics of importance in connector housings. The values shown are nominal values indicative of the resin families. For details the manufactures literature should be consulted because a wide variation in properties can be realized within a resin family depending on reinforcement and other additives. In most cases it is the stability of these characteristics through processing and in application that dictates the appropriate housing material for a connector. Surface mounting requirements are arguably the most demanding on connector housings.

One other housing function merits mention. The connector housing provides an environmental shield for the contacts and contact interfaces to decrease corrosion susceptibility in severe operating environments. This function is, of course, dependent on the housing design and independent of the housing material.

CONNECTOR DESIGN

As has been implied, the performance and reliability of electronic connectors depends on the design and material of manufacture of these connector components. Important design parameters for separable interfaces include selection of the contact finish, establishment of an appropriate contact normal force, and attention to

TABLE 5.5.3 Selected Properties of Commonly Used Polymers

	Flexural modulus (10 ⁶ kg/mm ²)	Heat deflection temperature @264 psi(°F)	UL temperature Index (°C)	Dielectric strength (V/M)
Polyamide	0.7	666	130	17.4
Polybutylene Terephthalate	0.8	400	130/140	24.4
Polyethylene Terephthalate	1.0	435	150	26.0
Polycyclohexane Terephthalate	0.9	480	130	25.4
Polyphenylene Sulfide	1.2	500	200/230	18.0
Liquid crystal Polymers	1.5	650	220/240	38.0

the mating interface geometry all of which interact to determine mating mechanics, durability, and susceptibility to degradation of the separable interface. For a permanent interface minimizing the contact resistance and maximizing resistance stability, by control of the permanent connection process, are the dominant parameters of design. Housing performance characteristics of importance include the stability of the housing through the required assembly process, particularly surface mount, and its temperature and environmental stability relative to the application operating environment.

With this overview of connector structure as a context, attention now turns to connector applications and the functional requirements a connector is expected to meet.

CONNECTOR FUNCTION

As stated earlier, functionally, a connector is intended to provide a separable interface between two elements or subsystems of an electronic system without an unacceptable effect on the integrity of the signal, or power, being transmitted.

The requirement on separability is usually defined in terms of the number of mating cycles a connector must provide without an impact on performance, a number that will vary with the application.

For the purposes of this discussion, unacceptable refers to limits on the resistance that the connector introduces into the circuit or system. Both the magnitude of the resistance and the allowed change in resistance depend on the application. For signal applications the most important requirement is often resistance stability. However, the magnitude of the resistance is also important and may be dominant in power distribution applications.

A brief review of classes of connector applications is in order at this point. In this discussion, connector types are considered in terms of the structure of the connector and the medium to which the permanent connection is made. Connector applications are discussed in terms of the system architecture, a “levels of inter-connection” approach, and the connector function, signal, or power applications.

CONNECTOR STRUCTURE/TYPE

With respect to connector structure or type, categorization in terms of the circuit elements being connected is useful. There are three such categories:

1. Board to board
2. Wire to board
3. Wire to wire

FIGURE 5.5.3 Printed circuit board connectors: (a) card edge (one piece) and (b) two piece.

It should be mentioned that the term *wire* also includes cables. In addition to the discussion of connector type, this section also includes a discussion of the classes of permanent connections, both mechanical and metallurgical.

Board-to-Board Connectors

It is in board-to-board connectors that the impact of the tremendous advances in speed of microprocessor chip technology are most apparent. These connectors are closest to the chip and, therefore, face the greatest requirements on maintaining the speed capability of the chip. In many cases board-to-board connectors must be considered as transmission lines with the accompanying requirements on controlled impedance, cross talk and shielding (EMI/RFI). Transmission line requirements have led to the development of connectors with intrinsic ground planes to provide improved high-speed performance with minimal effects on density. For a discussion of such connectors, see Sucheski and Glover (Ref. 16) and Aujla and Lord (Ref. 14). In addition to the transmission line requirements the increased functionality of microprocessor technology has led to a need for high input/output (I/O) connectors. Board-to-board connectors in pin counts in excess of 1000 are available.

There are two basic types of board-to-board connectors, one piece, or card edge, which mate to pads on the board, and two piece, which have an independent separable interface. Examples of each are shown in Fig 5.5.3.

Two-piece connectors are available in higher pin counts and densities because of greater multirow capability (up to eight rows), improved tolerance control, and the possibility of integral ground planes. In addition, they can be placed anywhere on the board. Centerline spacings in two-piece connectors include 0.100 and 0.050 in. and 1 mm with smaller spacings coming online.

Wire-to-Board Connectors

In some cases wire-to-board, or cable-to-board, connectors also face high speed requirements, which impacts on both the connector and the cable design. However, many wire-to-board connectors are used in applications

where speed is not as important. The I/O densities also tend to be lower, but connectors with over 100 positions are not uncommon. There are a wide variety of connector styles and configurations in wire-to-board connectors. Connectors using 25-square technology, square posts 0.025 in. on a side, are one of the dominant wire-to-board technologies with connector systems using 1 mm and 15-square (0.015 in on a side) posts coming on line. Pin and socket connectors are also common.

Wire-to-Wire Connectors

Wire-to-wire connectors are generally located at a distance from the chip and may not face high-speed requirements, with the exception of coax connectors where controlled impedance and cross talk remain important parameters. Many wire-to-wire connectors are used external to the enclosure or equipment so ruggedness, grounding, and shielding become important design considerations. Wire-to-wire connectors are often variations on wire-to-board design, differing only in the media to which the permanent connections are made, to a wire or cable instead of a board.

Types of Permanent Connections

Because these connector types are discussed in terms of their permanent connections to the circuit elements or subsystems being interconnected, a brief discussion of permanent connection types is in order. There are two basic types of permanent connections: mechanical and metallurgical.

Mechanical Permanent Connections. The dominant mechanical permanent connection technologies include:

- Crimped connections
- Insulation displacement connections (IDC)
- Press-in or compliant connections
- Wrapped connections

Crimped and ID connections are wire/cable connections. Press-in connections are made to plated through holes in printed wiring boards. Wrapped connections are made to square posts. A brief description of the mechanisms of contact generation and maintenance for each of these technologies is in order. Illustrations of each permanent connection technology are provided in Fig. 5.5.4.

Crimped connections. The permanent interface in crimped connections is established when the striped wire and crimp barrel are deformed in a controlled fashion by the crimp tooling. The deformation process displaces surface films and creates the contact interface. Residual stresses in the wire and wire barrel provide a restraining force that maintains the permanent connection interface integrity.

Insulation displacement connections. Insulation displacement connections are made by insertion of a wire into a properly designed IDC terminal. The wire insulation is displaced and the conductors deformed in a controlled fashion during the insertion process, which disrupts surface films and generates the contact interface. Elastic restoring forces resulting from the deflection of the terminal contact beams maintain the interface integrity. A wide variety of IDC terminal designs are used depending on the application requirements.

Press-in connections. Press-in connections are made by insertion of pins with controlled geometry compliant sections into a plated through hole (PTH) in a printed wiring boards. The contact interface is generated as the pin is inserted into the PTH, disrupting surface films and creating elastic restoring forces in the compliant section of the pin. The pin restoring force maintains the interface integrity. A wide variety of IDC terminal designs are available.

Wrapped connections. Wrapped connections are made to square posts with controlled radii on the post corners. The contact interface is generated by wrapping a stripped wire section around the post several times under controlled tension. The contact interface is generated as the post corners penetrate the wire. Residual tensile forces in the wire after wrapping maintain the interface integrity.

FIGURE 5.5.4 Permanent connection technologies.

For additional discussion of these technologies, see Ref. 1.

Metallurgical Permanent Connections. Metallurgical permanent connections include soldered and welded connections. Soldered connections are generally to printed wiring boards and welded connections to wire and cable. There are two basic soldering technologies used today, through hole technology (THT) and surface mount technology (SMT). In most cases, THT consists of leads inserted into plated through holes and wave soldered. SMT connections are made to pads on the printed wiring board surface. SMT processing generally involves secondary source of solder applied to the leads or the board and a solder reflow process. Several different reflow processes are used, but the technology appears to be trending toward conduction reflow in inert gas with an infrared assist. For a discussion of soldering technologies, see Manko (Ref. 17).

From this structural discussion of connectors, attention now turns to a more application related categorization.

APPLICATION FACTORS

As mentioned previously, connector applications will be considered from two viewpoints, where the connector is used (levels of interconnection), and how the connector is used (signal/power).

Levels of Interconnection

The level of interconnection is defined by the points in the system that are being connected, not the connector type, as discussed by Granitz (Ref. 18). In brief, the six levels of packaging, and an associated connection or connector type, are:

1. Chip pad to package leads, e.g., wire bonds
2. Component to circuit board, e.g., DIP socket

FIGURE 5.5.5 Levels of packaging in a typical electronic system.

3. Circuit board to circuit board, e.g., card edge connector
4. Subassembly to subassembly, e.g., ribbon cable assembly
5. Subassembly to input/output, e.g., D subcable assembly
6. System to system, e.g., coax cable assembly

A schematic illustration of these levels of packaging is provided in Fig. 5.5.5.

Level-1 connections are intended to be permanent connections and will not be discussed. Level-2 connections, generally accomplished through sockets, share many of the design features and requirements of connectors, but generally are subjected to only a few mating cycles. The separability requirement that has been used as a defining characteristic of a connector becomes important at levels 3 and above.

These levels of interconnection differ primarily in the application environment, but also in the durability requirements on the connector. Levels 3 through 5, being inside the enclosure, are expected to be benign with respect to corrosion and mechanical disturbances, but possibly more demanding with respect to temperature than level 6. In general, the number of mating cycles the connector must support increases, and the level of training of the user decreases, from level 3 to level 6. These differences impact on the ruggedness and “user friendliness” required of the connector. Electrically, performance requirements, particularly in terms of signal speed, are more stringent the closer the connection is to the chip level. Cables and cable connectors, however, may face more demanding electrical requirements even at higher levels of interconnection. It should also be noted that many connector types see usage in more than one level of interconnection.

Signal Connectors

Signal connectors are those that carry relatively small currents, milliamps to a few amperes. The functional requirements the connector must meet, however, depend primarily on the frequencies of signals that the connector must conduct. Signal connectors to be used at high frequencies, hundreds of megahertz or rise times less than 1 ns, conditions, which are increasingly common, must be considered as transmission lines. For such connector systems, characteristic impedance, propagation delay, and cross talk become critical performance

parameters. For connectors, control of characteristic impedance is of particular interest. Controlled impedance requires constancy of materials and geometries, both of which are difficult to realize in connectors. Impedance control in connectors can be addressed, however, by signal/ground ratios in open pin field connectors or by added ground planes to the connector. Both approaches are used with intrinsic ground planes receiving increased attention. For cables and printed wiring boards, characteristic impedance control is more readily attained, but propagation delay and cross talk become more important because of the longer length of the associated transmission lines. Electromagnetic compatibility (EMC) also becomes important for high-speed connectors. EMC includes consideration of the impact of both external and internal electromagnetic radiation on system performance. Shielding and grounding considerations take on increased importance. For additional discussion of these issues, see Southard; Aujla & Lord; Sucheski & Glover; and Katyl & Simed (Refs. 13, 14, 16, and 19).

Power Contacts/Connectors

Contacts and connectors for power applications face different requirements. For power contacts/connectors two effects become important. The first is the loss of voltage arising from the resistance the connector introduces in the system. Systems have a millivolt drop budget to ensure that sufficient driving voltage is available to the chips. Excessive losses in the connector, whether bulk or interface related, can disrupt system performance. Second, the Joule, or I^2R , heating, which accompanies high current flow becomes a factor in system operating temperature. Increasing system temperature generally results in degraded performance or system life. Reduction and control of connector resistance addresses both these issues. From a bulk resistance perspective, selection of high conductivity spring materials is imperative. From a control perspective, ensuring the stability of connector interface resistance takes on new significance. For additional discussion of power contact/connector considerations see Corman and Mroczkowski (Ref. 20).

There are two approaches to power distribution, discrete power contacts and the use of multiple signal contacts in parallel. Discrete power contacts are generally large, to reduce bulk resistance and allow for higher normal forces to ensure interface stability. The size becomes a limiting factor and leads to the parallel signal contact approach. With the development of high pin count connectors allocation of some of the pins to current distribution becomes a viable option. Parallel signal contact consideration include:

- Ensuring an equal distribution of current through the contacts
- Accounting for thermal interactions between the contacts
- Appropriate derating of the contact current capacity for multiple contact applications

For additional discussion of parallel contact application considerations, see Ref. 2.

CHAPTER 5.6

OPTICAL FIBER COMPONENTS

Gordon W. Day

INTRODUCTION

Optical fibers are thin ($\sim 100 \mu\text{m}$ diameter), normally cylindrical, strands of optically transparent material (usually glass or plastic) that are capable of guiding light over long distances with low loss. The basic principles by which optical fibers guide light were discovered in the nineteenth century, applied to the transmission of images in the first part of the twentieth century, and to telephony and data communications in the last part of the twentieth century.

Optical fiber communications systems provide many advantages over their predecessors, the greatest of which is their ability to transmit information at incredibly high rates. In laboratory demonstrations, rates of over 10 Tb/s, or the equivalent of roughly 150 million simultaneous telephone calls, have been achieved in a single fiber. In theory, much higher rates are possible. Optical fiber communications is the key enabling technology of the Internet.

Bundles of optical fibers with their relative positions fixed (imaging bundles) continue to be used to transmit images, and optical fibers have other applications in medicine, sensing, and illumination.

This section covers some of the most important properties of optical fiber and the components used with fiber, especially in communications systems.

Transparency

Glass, especially with very high silica content, can be highly transparent. Early optical fiber used for imaging bundles typically attenuated visible light by factors in the range of 0.1 dB/m (2.3 percent/m) to 1 dB/m (21 percent/m), low enough to permit useful transmission of images over distances of meters. Analyses performed in the 1960s indicated that much lower levels of attenuation could be achieved, perhaps lower than 10 dB/km, making it possible to consider the use of optical fiber as a communications medium over distances of kilometers. In the 1970s, these predictions were fulfilled, and levels of attenuation continued to be reduced until they now approach what is considered to be the fundamental limit in silica glass, approximately 0.15 dB/km at wavelengths near 1550 nm.

Attenuation mechanisms include intrinsic absorption, which in glass generally occurs in the ultraviolet and mid-infrared regions, absorption by impurities, losses associated with waveguide properties, and Rayleigh scattering.

In the spectral region from the visible through about 1700 nm, absorption by the OH^- ion and Rayleigh scattering dominate. Absorption arises from the overtones of the fundamental $2.7 \mu\text{m}$ OH^- lines at 1390 and 950 nm. In most fiber intended for telecommunication applications, manufacturing techniques eliminate the absorption at 950 nm, and the absorption at 1390 nm is no more than a few tenths of a dB (Fig. 5.6.1), and, in some cases, is almost completely eliminated.

FIGURE 5.6.1 Spectral attenuation of a typical silica optical fiber.
Source: R. B. Kummer, Lucent.

The fundamental mechanism limiting attenuation in glass in the visible and near infrared regions is thus Rayleigh scattering, which varies inversely with the fourth power of wavelength. In this case, the attenuation of power in the fiber is given by

$$P(z) = P(0)e^{-\alpha_R z}$$

where $P(0)$ and $P(z)$ are the power in the fiber at the input and at position z along the direction of propagation, respectively, and α_R is the attenuation coefficient associated with Rayleigh scattering. Expressed in dB, the attenuation is given by

$$\text{Attenuation (dB)} = -10 \log \frac{P(z)}{P(0)} \propto \lambda^{-4}$$

Three spectral regions have become important in communications, because fiber properties are favorable and, in some cases, because other components are available for those regions. The first to be exploited was the region around 850 nm, away from the 950 nm OH^- absorption, and where GaAs lasers and LEDs, as well as Si detectors, were readily available. This region continues to be used for short distance systems such as local area and premise networks.

TABLE 5.6.1 Optical Communication Bands

Name	Wavelength range, nm
O-band	1260–1360
E-band	1360–1460
S-band	1460–1530
C-band	1530–1565
L-band	1565–1625
U-band	1625–1675

The second is the region around 1300 nm, where Rayleigh scattering is about a factor of 5 lower and, as discussed below, chromatic dispersion is very small. While this region also remains of interest, for high-performance systems it has been superseded by systems operating around 1550 nm, where Rayleigh scattering losses in the fiber are still lower and, more importantly, high-performance optical fiber amplifiers have been developed. These longer wavelength regions are commonly divided for convenience into “bands.” While the terminology has not been formally standardized, common usage is approximately as shown in Table 5.6.1.

In order to facilitate communications using many wavelengths simultaneously, a technique known as wavelength division multiplexing (WDM), the International Telecommunications Union (ITU) has established a standard frequency grid (Recommendation G.694.1) defined by

$$f_n = 193.1 + n\Delta \quad (\text{THz})$$

Where n is any integer, including zero, and Δ may be 12.5, 25, 50, or 100 GHz. Using the defined value for the speed of light in vacuum ($c = 2.99792458 \times 10^8$ m/s), the corresponding vacuum wavelengths can be computed, as shown in Table 5.6.2.

TYPES OF OPTICAL FIBER

A simple optical fiber consists of long thin concentric cylinders of transparent material—an inner *core* having a slightly higher index of refraction than that of the surrounding *cladding*. The difference in index between the two regions is usually 1 percent or less; in glass, both values are typically near 1.5. While glass, and some other materials from which optical fibers are made, is inherently strong, it must be protected from surface abrasion that can cause it to fracture easily. And its performance can be degraded by certain types of bending, especially small quasiperiodic bends, known as microbends.

Most optical fibers are therefore protected with one or more additional polymeric coatings, sometimes called *buffers*, or *buffer layers*.

In a simple, ray-optics, view, a structure of this sort guides light because light incident at high angles (relative to normal) on a region of lower index of refraction is completely reflected. This is the principle of total internal reflection, discovered in the nineteenth century. A more complete electromagnetic analysis allows the structure to be characterized as a waveguide, guiding a finite number of spatial modes, not unlike those of typical microwave waveguides (see Fig. 5.6.2).

Step-Index Multimode Optical Fibers

The optical fibers used in imaging bundles, and those used in the earliest experimental optical communications systems, are known as step-index optical fibers, meaning that the transition from the index of refraction of the core to that of the cladding is abrupt. Generally, the indices of refraction in the core and cladding are fairly uniform.

In a fiber that is used in an imaging bundle, or in illumination, the difference in index of refraction between the core and the cladding is one of the most important parameters, in that it governs the angular field of view for which light can be collected and guided. In an imprecise analogy to microscope systems, the *numerical aperture* of a step-index multimode fiber is given by

$$NA = \sqrt{n_1^2 - n_2^2} = \sin \theta_{\max}$$

where n_1 and n_2 are the indices of refraction of the core and cladding, respectively, and θ_{\max} is the half-cone acceptance angle for rays that intersect the axis of the fiber.

Numerical aperture, along with the size of the core and the wavelength of the light, also determines how many modes can propagate in the fiber.

Step-index multimode fibers rarely find application in communications, because the different modes propagate at significantly different velocities. Pulses of light that propagate in more than one spatial mode are broadened in time through this process, which is known as intermodal distortion, or sometimes intermodal dispersion. A step-index multimode fiber with a core diameter of $50\ \mu\text{m}$, and an index of refraction difference ($n_1 - n_2$) of about 1 percent may have an effective bandwidth of only about 20 MHz in 1-km length.

Graded-Index Multimode Optical Fiber

To reduce intermodal distortion, the refractive index of the core can be tailored so that all modes propagate at approximately the same velocity. The variation in refractive index with radius (the “refractive index profile”) that minimizes intermodal distortion (maximizes bandwidth) is roughly parabolic with the highest refractive index on the axis. Sometimes the refractive index profile is specified by fitting index data to an equation of the form

$$n(r) = n_1 \sqrt{1 - 2\Delta \left(\frac{r}{a}\right)^g} \quad \text{for } r \leq a$$

$$\text{and} \quad n(r) = n_1 \sqrt{1 - 2\Delta} \equiv n_2 \quad \text{for } r \geq a$$

$$\text{where } \Delta \equiv \frac{n_1^2 - n_2^2}{2n_1^2}$$

$n(r)$ = refractive index as a function of radius

n_1 = refractive index on axis

n_2 = refractive index of the cladding

a = core radius

FIGURE 5.6.2 Modes of an optical fiber: Top, the lowest order, HE_{11} or LP_{01} mode; Middle, several low-order modes; Bottom, a high-order mode.

Sources: E. Snitzer and H. Osterberg, *J. Opt. Soc. Am.* 51 499 (1961); W. J. Stewart, Plessey.

The parameter g defines the shape of the index profile and is used in some specifications (e.g., Telecommunications Industry Association specifications TIA-4920000-B, TIA-492AAAB).

Because the refractive indices of glass vary with wavelength, the maximum bandwidth is achieved at a specific wavelength, and may vary dramatically over the wavelength range in which the fiber may be used.

In fibers that are not optimized for maximum bandwidth at the wavelength of operation, the actual bandwidth will depend on the excitation conditions, that is, the manner in which light is coupled into the fiber. Light coupled into a fiber from a light emitting diode (LED) will typically excite most of the modes of the fiber, and often results in the maximum intermodal distortion (minimum bandwidth) for a given length. This specification of bandwidth

is sometimes called the *effective modal bandwidth* or the bandwidth with an “overfilled launch.” Light coupled into a fiber from a laser will typically excite fewer modes, and may yield a lower intermodal distortion (higher bandwidth), but the bandwidth, in this case, may depend strongly on the specific range of modes excited. Another specification that may be used to describe these effects is *differential mode delay*,

which is generally measured by focusing a laser on the core of a multimode fiber and determining the difference in group delay (the propagation time of a short pulse through a specified length of fiber) as a function of the transverse position of the focused spot. Details of various methods of specifying the bandwidth of graded-index multimode fiber can be found in TIA standards TIA-455-220 and TIA-455-204.

The attenuation of multimode optical fiber may also vary among different modes. This effect is sometimes known as differential mode attenuation. As a result, the specification of attenuation is also dependent on the manner in which light is launched into the fiber and, further, the attenuation coefficient may vary with length as modes with higher attenuation disappear. Differential mode attenuation can also cause the bandwidth of the fiber to vary nonlinearly with length. Commonly, an overfilled launch is used for attenuation specifications, but that is the measurement condition for which these effects are usually the greatest. The measurement of attenuation in multimode fiber is specified in TIA-455-46-A and TIA/EIA-455-50-B.

Graded-index multimode fibers are most commonly used in data networks of under 1 km in length, such as access networks and local area networks. Standards for Gigabit Ethernet and 10 Gigabit Ethernet produced by the Institute of Electrical and Electronics Engineers (IEEE), IEEE 802.3z and IEEE 802.3ae, respectively, are based on these fibers.

Single-Mode Optical Fiber

When, for a given difference in index of refraction between the core and cladding, the ratio of the core radius to wavelength is sufficiently small, the fiber will only support one spatial mode, which is commonly designated the HE_{11} (alternatively the LP_{01}) mode. For a step-index fiber, this occurs when

$$\lambda \geq \frac{2\pi a}{2.405} \sqrt{n_1^2 - n_2^2}$$

where a is the core radius.

The value of λ for which this expression is an equality is usually designated λ_c and is known as the cut-off wavelength. The cut-off wavelength is generally determined by observing the apparent change in attenuation that occurs when the wavelength of light passing through the fiber is scanned through the cut-off wavelength (TIA standard TIA/EIA-455-80B). The cut-off wavelength may vary depending on the configuration (such as bends) of the fiber when measured. Manufacturers thus sometimes specify the change in cut-off wavelength that occurs when a fiber is cabled.

The size of the HE_{11} mode is generally specified through a single-dimensional parameter, known as the mode-field diameter (MFD), which varies with wavelength as well as the physical and optical properties of the fiber. The most commonly used definition of MFD is one known as Petermann II. Several measurement methods for MFD are described in TIA standard TIA/EIA-455-191A. Knowing the MFD permits the calculation of loss when fibers with different MFDs are joined; and, for a given optical power level, the larger the MFD, the lower the irradiance in the fiber, which usually leads to a reduction in nonlinear optical effects. Typical single-mode fibers have mode-field diameters in a range of 10 μm .

For purposes of predicting the magnitude of nonlinear optical effects, it is important to know the effective area A_{eff} of an optical fiber. The TIA (TIA/EIA-455-132A) defines the effective area as

$$A_{\text{eff}} = \frac{2\pi \left[\int_0^\infty I(r) r dr \right]^2}{\int_0^\infty I(r)^2 r dr}$$

which, for a given class of fibers, can usually be estimated by

$$A_{\text{eff}} = k\pi \left(\frac{\text{MFD}}{2} \right)^2$$

where k is a constant specific to that fiber class.

Pulses of light propagating in a single-mode fiber increase in duration because of several dispersive effects—the variation of the index of refraction of the glass with wavelength, which leads to variation of the group velocity with wavelength (chromatic dispersion), the variation of group velocity resulting from the parameters of the optical waveguide (waveguide dispersion), and differences in group velocity with polarization (polarization mode dispersion).

Generally, chromatic dispersion and waveguide dispersion are not distinguished in specifications, and sometimes the term *chromatic dispersion* is used to include both effects. Though specifying dispersion versus wavelength might be useful, it is more common to specify two dispersion parameters, the *zero dispersion wavelength* λ_0 , and the *zero dispersion slope* S_0 , which is the slope of the dispersion near λ_0 , and has units of ps/(nm² km). For a typical step-index single-mode fiber, sometimes called a *conventional* or *nondispersion-shifted fiber*, the dispersion is dominated by chromatic dispersion, and increases with increasing wavelength, exhibiting zero dispersion at a wavelength between 1310 and 1320 nm. For such fibers, S_0 is typically in the range of 0.1 ps/(nm² km), and it is possible to estimate the dispersion at nearby wavelengths $D(\lambda)$ using the expression

$$D(\lambda) = \frac{S_0}{4} \left(\lambda - \frac{\lambda_0^4}{\lambda^3} \right)$$

More complex refractive index profiles can provide waveguide dispersion that differs substantially from that of a step-index profile. This can be exploited to shift the zero dispersion wavelength to another, typically longer, wavelength, or to change the variation of dispersion with wavelength. Fibers in which the dispersion has been shifted to the region around 1550 nm are commonly called *dispersion-shifted fibers*. Fibers that are designed to maintain a low level of dispersion over an extended wavelength range are commonly called *dispersion flattened fibers*. Fibers in which dispersion *decreases* with increasing wavelength are called *dispersion compensating fibers* and can be inserted into a system to reduce the total dispersion.

In WDM systems, nonlinear optical effects can lead to cross talk between channels. Most nonlinear effects are strongest when dispersion is near zero and all wavelengths involved in the process propagate at the same velocity. Maintaining a small but nonzero dispersion over the range of wavelengths used can thus be useful in minimizing cross talk. This has led to the development of various types of “nonzero-dispersion-shifted” fibers, which typically have a zero dispersion wavelength just shorter or just longer than the band in which they will be used. Figure 5.6.3 shows dispersion curves for a variety of fibers.

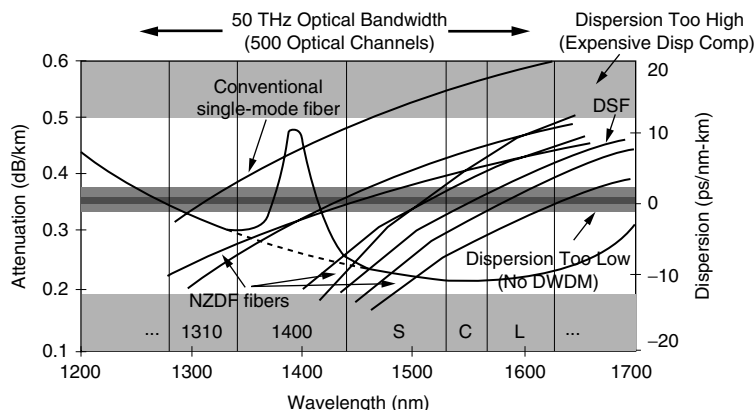

FIGURE 5.6.3 Spectral attenuation of a typical fiber and dispersion characteristics of several types of fiber.

Source: R. B. Kummer, Lucent.

The third source of dispersion in a single-mode fiber arises from the fact that different polarizations within the single spatial mode propagate with slightly different phase and group velocities. These polarization effects arise from stress, either inherent to the fiber or induced mechanically, and imperfections in its cylindrical symmetry. The result is a fiber property known as polarization-mode dispersion (PMD), which, like chromatic dispersion and waveguide dispersion, causes the duration of a pulse to increase as it propagates.

If the polarization properties of the fiber were stable and light did not couple between polarization states, it would be relatively easy to measure and specify PMD. The fiber could be modeled as a combination of a single retarder (a linearly birefringent element) and a single rotator (a circularly birefringent element) and would exhibit an orthogonal pair of stable eigen-polarizations (polarizations for which the output polarization state is the same as the input state). The PMD would be relatively easy to determine and would scale linearly with length.

Instead, the fiber parameters change with the temperature of the fiber and with handling, so PMD can only be specified statistically. Normally, the measurement is of the differential group delay (DGD) between principal polarization states, which are polarization states that, over an appropriate range of wavelengths, represent the fastest and slowest propagation velocities. Theoretically, and well observed in practice, the DGD measured over a range of wavelengths, or over time, follows a Maxwellian distribution, as shown in Fig. 5.6.4. The mean of the distribution is usually called the PMD or mean DGD. Several measurement methods are used, as specified, for example, in TIA standards TIA/EIA-455-113, TIA-455-122-A, TIA/EIA-455-124, and TIA/EIA-455-196.

To further complicate PMD measurements, in long lengths of fiber, light is coupled between polarization states, which tends to decrease the observed DGD. For lengths of fiber long enough for the coupling to be in equilibrium (longer than the “coupling length”) the differential group delay between principal states will increase with the square root of length rather than the length. Similar effects are observed when fibers are concatenated. Methods of addressing these effects, which generally lead to the specification of a *link value* or *link design value* of PMD, are discussed in International Electrotechnical Commission (IEC) Technical Report TR 61282-3.

Single-Mode Fibers with Special Polarization Properties

In certain applications, it may be desirable to use an optical fiber with a very large linear birefringence, that is, a fiber in which orthogonal linear polarizations have significantly different phase velocities. One way to achieve this is to design and manufacture the fiber to have an elliptical core. Another is by incorporating, into the cladding, regions that apply a transverse stress to the core. In either case, the resulting, stress-induced, birefringence can be in the range of 10^{-3} .

Though they may have additional applications, fibers with a large linear birefringence are commonly called *polarization-maintaining fibers*. Linearly polarized light, launched into the fiber with its direction of polarization along one of the axes of birefringence, will tend to remain linearly polarized along that axis, even when the fiber is bent or twisted.

Several methods are used to specify the properties of polarization-maintaining fibers. The beat length, L_B is the propagation distance over which a phase difference between light in the two polarizations of 2π radians

FIGURE 5.6.4 Statistical distribution of differential group delay between principal states showing Maxwellian distribution. PMD is the average DGD.

Source: YAFO Networks.

accumulates. It is given by $L_B = \lambda/\Delta n$, where Δn is the difference in effective (phase) refractive index between the two polarizations and λ is the wavelength. For a typical polarization maintaining fiber, L_B may be in the range of a few millimeters.

Another common specification is *cross talk*, which is generally given for a specific length. This is the fraction of light coupled into the orthogonal polarization when the polarization of the input light is aligned with one of the polarization axes. It is generally given in decibels as

$$\text{Polarization cross talk (dB)} = 10 \log \frac{P_{\min}}{P_{\max}}$$

where, P_{\min} and P_{\max} are the minimum and maximum power levels observed as a polarizer is rotated in the output.

Sometimes, a coupling parameter, commonly known as the *h-parameter* and defined, for a given length L , by

$$hL = \tanh^{-1} \left(\frac{P_{\min}}{P_{\max}} \right) \\ \approx \left(\frac{P_{\min}}{P_{\max}} \right) \quad \text{for} \quad \left(\frac{P_{\min}}{P_{\max}} \right) \leq 0.1$$

is also specified. A typical value for h in a high-quality polarization-maintaining fiber is between 10^{-5} and 10^{-4} .

Fibers Manufactured from Other Glass Systems

Optical fibers made from various fluoride compounds can transmit light in the 2- to 5- μm region. Mixtures of zirconium, barium, lanthium, aluminium, and sodium fluoride have been studied, including a combination of all of these compounds known as ZBLAN. Because the fundamental Rayleigh scattering in that wavelength range would be very small, it was once thought that these fibers could provide levels of attenuation much lower than those of silica fiber. That possibility has not been demonstrated, but fluoride fibers have become useful as hosts for a wide variety of rare-earth dopants, enabling optical amplifiers and lasers to be developed for wavelength ranges where they were not previously available.

Glasses with a high lead content (e.g., SF-57) can have very low stress-optical coefficients, that is, the index of refraction in these glasses is less affected by applied stress than in other glasses. Optical fiber manufactured from these glasses exhibits less birefringence when bent or twisted than ordinary fiber. Because the attenuation in such fiber is relatively high, they are not useful for telecommunications applications, but they may be very useful in certain optical fiber sensor applications.

Plastic Optical Fiber

Optical fiber can also be produced from plastic material, most commonly the acrylic PMMA. Typical plastic optical fibers (POF) are much larger in diameter than silica fibers, often as large as 1 mm, and have a thin cladding. Both step-index and graded-index multimode fibers are available. Generally POF is intended for short-distance applications, perhaps up to 100 m, sometimes within buildings or vehicles.

PMMA fibers have a characteristic spectral attenuation shown in Fig. 5.6.5. Commonly, they are used at a wavelength of about 650 nm, where the attenuation is a local minimum and inexpensive lasers are available.

OPTICAL FIBER CONNECTORS

A wide range of connectors is available for connecting optical fiber; some of the more common designs for single fibers are shown in Fig. 5.6.6. The two key specifications for a connector are the insertion loss and the return loss. For most high-quality connectors, insertion loss is often specified as a maximum value, typically in the range of a few tenths of a dB. The return loss is the fraction of light reflected by the connector. It is usually specified as a positive value in dB (a return loss of 40 dB meaning that the reflected signal is four orders

FIGURE 5.6.5 Attenuation of typical PMMA plastic optical fiber.
Source: Mitsubishi Rayon.

of magnitude smaller than the incident signal). Depending on design, connectors are commonly specified to have return loss values between 20 and 60 dB.

Most connectors rely on ceramic ferrules to hold the fibers and align them transversely. In most high-quality connectors, the ferrule and the fiber are polished together and the connectors are designed to bring the two fibers into contact. This is commonly known as a physical contact (PC) design. In some types of connectors the fiber and ferrule is polished at an angle to the axis, which decreases the return loss. This is known as an angled physical contact (APC) design. Connectors are often available factory installed on short lengths of cabled fiber (fiber pigtailed) for splicing to a longer length, and on patch cords, with connectors, sometimes with a different connector type on each end.

FIBER COUPLERS

If the cores of two or more fibers can be brought into close enough proximity that the modes overlap to some degree, light will be coupled between or among the fibers. This is most readily achieved by twisting the fibers

FIGURE 5.6.6 Common types of optical fiber connectors.
Source: Furukawa Electric Co.

together, heating them until they are soft, and pulling until cores reach the desired separation. The degree of coupling will depend on the wavelength, the separation and size of the cores in the interaction region, and the length of the interaction region.

The simplest device based on this principle is a 2×2 coupler that can be used to tap a portion of the light propagating in fiber (Fig. 5.6.7). Couplers of this sort are usually designed for a specific wavelength, and are commonly available in tap ratios (ratio of power output from the secondary output port to the total power from both output ports) of 1 (20 dB), 10 (10 dB), and 50 percent (3 dB), among others. Typically the wavelength range over which the tap ratio is maintained within a stated range is specified. Another important parameter is insertion loss, which is typically defined as the total decrease in power in the through-port. For example, a 3-dB coupler may have an *insertion loss* of 3.3 dB, meaning that 50 percent (3 dB) of the light is coupled to the secondary port and 0.3 dB is lost to absorption, scattering, or other effects.

FIGURE 5.6.7 Schematic of a 2×2 fiber coupler.

Depending on design and manufacturing processes, the coupling ratio may be strongly wavelength-dependent, and this effect can be used to produce couplers for combining or separating wavelengths. Common applications include separating or combining signals at 1300 and 1550 nm in local networks and coupling pump wavelengths into fiber amplifiers.

FIBER GRATINGS

The refractive index of glass containing germanium can be increased slightly by exposing it to intense ultraviolet light. When this effect is exploited to produce a periodic variation in refractive index along the direction of propagation (a grating), several useful devices can be created. Usually, the manufacturing method involves illuminating the fiber transversely with a laser operating in the 200 to 300 nm spectral range. Periodic variations in the laser intensity can be achieved either by interference of two beams or by using a mask, similar to those used in lithography.

Fiber Bragg Gratings (Short-Period Gratings)

When the spatial periodicity Λ of the variation in refractive index is half the wavelength of light in the fiber, that is, when

$$\lambda_0 = 2n_{co}\Lambda$$

where λ_0 is the vacuum wavelength, and n_{co} is the effective (phase) refractive index of the LP_{01} mode in the fiber, light will be strongly reflected.

Depending on the details of the grating configuration, very high levels of reflection can be achieved over very narrow spectral ranges, in some cases sufficiently narrow to reflect one wavelength of the ITU WDM grid while transmitting adjacent wavelengths. When combined with other components (e.g., Fig. 5.6.12) this permits the removal of a single channel from a WDM system.

If the periodicity of the grating is chirped, that is, the periodicity varies from one end of the grating to the other, the reflection spectrum is broadened. More importantly, chromatic dispersion is created because light reflected from the far end of the grating is delayed relative to light reflected from the near end. Further, by apodizing the refractive index variation, that is, varying the degree of index modulation along the grating, the delay versus wavelength can be a smooth, quasi-linear, function of wavelength suitable for compensating for dispersion in a fiber. These grating characteristics are illustrated in Fig. 5.6.8.

Because their periodicity is affected by temperature and strain, fiber Bragg gratings can also be used as sensors for those measurands, or for other measurands that can lead to changes in strain or temperature. And

FIGURE 5.6.8 Reflection and dispersion characteristics of several types of fiber Bragg gratings.

Source: Southampton University.

because many fiber Bragg gratings can be incorporated into a fiber or network of fibers, quasi-distributed sensor networks can be developed.

Long-Period Gratings

In addition to coupling light from a forward propagating LP_{01} mode to a reverse propagating LP_{01} mode, gratings can be used to couple light from the LP_{01} mode to either forward or reverse propagating cladding modes. This occurs when the following phase matching condition is met:

$$\lambda_0 = \Lambda(n_{co} \pm n_{cl})$$

where n_{cl} is the effective (phase) refractive index of a cladding mode. The positive sign applies to the coupling between modes propagating in opposite directions, in which the spatial period will be similar to that satisfying the Bragg condition described above. In fact, many fiber Bragg gratings will exhibit transmission minima at wavelengths somewhat shorter than the Bragg condition. The negative sign applies to guided and cladding modes propagating in the same direction. In this case, the spatial period Λ will typically be in the range of several hundred micrometers, hence the term *long-period grating*. Figure 5.6.9 shows the transmission spectrum of a grating with a period of $198 \mu\text{m}$, in which the transmission minima correspond to coupling of light into individual cladding modes.

FIGURE 5.6.9 Spectral transmission of a long-period grating.

Source: A. Vengsarkar et al. *J. Lightwave Tech.*, 14, 58–65 (1996).

The principal application of long-period gratings is as nonreflective band-rejection filters. They are sometimes used to reject wavelengths in WDM systems, to attenuate amplified spontaneous emission or adjust gain flatness in erbium-doped fiber amplifiers, and to reject Stokes wavelengths in Raman amplifiers.

OPTICAL FIBER ISOLATORS

Isolators are nonreciprocal two-port devices that have a low attenuation in one direction and a high attenuation in the other direction. They are frequently used in optical systems, usually to block light from reflecting back into a laser and damaging it or causing it to become unstable.

Most isolators are based on the Faraday effect, which is a magnetically induced circular birefringence usually observed as a rotation of the plane of polarization of linearly polarized light as it passes through the device. The magnetic field is parallel to the direction of propagation and the plane of polarization is rotated clockwise or counterclockwise depending on the material and whether the light is propagating in the same or opposite direction as the magnetic field.

In a simple isolator, the material, the magnitude of the magnetic field, and the length of propagation in the material are chosen so that the plane of polarization is rotated by exactly 45° , and the rotating element is placed between polarizers that are oriented at 45° to each other. Light entering the device polarized so that it is transmitted through the input polarizer is rotated so that it also passes through the second polarizer. However, light propagating through the device in the opposite direction is rotated so that it is blocked by the input polarizer.

As described, the isolator works well for linearly polarized light, polarized so that it is transmitted by the input polarizer. However, for arbitrary states of polarization, the attenuation in the forward direction is variable and can be high.

A polarization-independent isolator can be built by dividing the input polarization state into orthogonal polarizations, rotating them separately, and recombining them at the output. One implementation of this approach is shown in Fig. 5.6.10. A wedged birefringent plate causes one linear polarization to be refracted while the other is undeviated. After the plane of polarization of each polarization is rotated 45° by a Faraday rotator, a second wedged birefringent plate, rotated 45° to the first, causes the two polarizations to again propagate in parallel directions, so they can be coupled into fiber. However, for light propagating in the reverse direction, the axial and refracted polarizations are orthogonally polarized, respectively, relative to the forward propagating beam, and are thus refracted at angles that will not be coupled into the fiber.

Optical fiber isolators can usually provide isolation (ratio of the forward to reverse transmittance) in the range of 40 dB, with an insertion loss of less than 1 dB. In multistage, higher performance devices, the isolation can exceed 70 dB.

OPTICAL FIBER CIRCULATORS

Optical fiber circulators, like their microwave counterparts, are multiport devices that use the Faraday effect to direct light from one port to another. In a 3-port circulator, the most common form (Fig. 5.6.11), light entering

FIGURE 5.6.10 Design of polarization insensitive optical fiber isolator.

FIGURE 5.6.11 Schematic of a circulator.

FIGURE 5.6.12 Add-drop multiplexer.

port A is directed to port B; light entering port B is directed to port C, and light entering port C is directed to port A. Most circulators employ Faraday rotation and other technologies similar to those used in isolators.

Circulators are versatile components for manipulating optical signals, as illustrated with the two examples below. Figure 5.6.12 shows how two circulators with a Bragg grating between them can be used to drop and add signals at a particular wavelength. Figure 5.6.13 shows how a single circulator can be used with a chirped fiber Bragg grating to compensate for chromatic dispersion.

WDM MULTIPLEXERS AND WAVELENGTH ROUTERS

In a WDM system, it is necessary to combine and separate (multiplex and demultiplex) different wavelength channels, often large numbers of channels with very small wavelength separations. This can be done with bulk optics and diffraction gratings or thin-film filters, or with combinations of fiber Bragg gratings and wavelength dependent couplers, but most such systems become complex when large numbers of channels are required. An alternative is a planar waveguide device, known (among other names) as an “arrayed waveguide grating (AWG),” and depicted in Fig. 5.6.14.

The AWG is a phased array device, usually produced in silica. Light from each of N input waveguides is divided equally, in an input coupler, among an array of waveguides in which adjacent guides differ in length by a precisely fixed amount. The device is designed so that, for light from a specific input fiber, constructive interference of light from the arrayed waveguides occurs at a specific output port. Thus, one use of the device is as a demultiplexer, as shown in Fig. 5.6.15, which is the superposition of the outputs of an AWG for broadband input light. The AWG is reciprocal, so it can similarly be used as a multiplexer.

The AWG can also be used as a router. If, as illustrated in Fig. 5.6.16, the device is designed so that N wavelengths ($\lambda_1, \dots, \lambda_N$) from input port 3 are directed to output ports $N, N-1, \dots, 1$, respectively, then the same N wavelengths entering input port 2 will be directed to output ports $1, N, N-1, \dots, 2$, respectively. The device is thus a router, permitting one wavelength channel from each input channel to be directed to each output channel.

FIGURE 5.6.13 Dispersion compensator.

SWITCHES

Switches permit networks to be reconfigured, and channels to be rerouted, without conversion from optics to electronics, permitting all-optical networks. For some applications, switching times must be fast, comparable to

FIGURE 5.6.15 Demultiplexing properties of a 16 channel, 100 GHz spacing AWG.

Source: K. Okamoto, NTT.

switching combinations are possible. For example, in Fig. 5.6.17, if input port 1 connected to output port 1, then input port 2 cannot be connected to output ports 2, 3, or 4. This is known as *blocking*.

Figure 5.6.18 shows two approaches to the construction of $N \times N$ nonblocking switches based on MEMS technology. In Fig. 5.6.18a, a two-dimensional array of N^2 MEMS mirrors, which can be independently positioned either in or out of the beam, provide the switching. In Fig. 5.6.18b, two arrays of N MEMS mirrors are used. This approach uses fewer mirrors, but the mirrors require greater positioning control.

a data period, but for most applications relatively slow switching is adequate. These slower switches are often called optical cross-connect switches and usually provide the ability to switch the light from any of N input fibers to any of N output fibers. Several switching technologies have been developed—optomechanical designs, including those based on microelectromechanical structures (MEMS); thermo- and electro-optic effects in planar waveguides; and liquid/bubble filled waveguides. Some approaches are wavelength selective and others are wavelength independent.

One common switch structure is based on 2×2 switches in which the two input ports are either connected to the two corresponding output ports (1→1, 2→2) or to the opposite output ports (1→2, 2→1). Arrays of these switches can provide $N \times N$ switching, as shown in Fig. 5.6.17. Note, however, that not all

FIBER AMPLIFIERS

Optical amplifiers permit an optical signal to be amplified, preserving whatever modulation may be present, and allow designers to compensate for attenuation in fiber, losses in other components, and coupling between components. Perhaps most importantly, they can simultaneously amplify many different wavelengths and they are thus the principal enabler of WDM technology.

Three principal types of optical amplifiers are available: semiconductor optical amplifiers (SOAs), which are based on the same compound semiconductor technologies used in semiconductor lasers (SOAs are outside

of the scope of this section); rare-earth-doped fiber amplifiers, in which the gain is provided by any of several rare-earth ions, incorporated into a fiber and pumped by an appropriate laser source; and Raman fiber amplifiers, in which the gain is provided by the Raman effect in ordinary transmission fiber.

Rare-Earth-Doped Fiber Amplifiers

At least eight of the rare-earth lanthanide ions have been shown to provide optical gain when incorporated into silica or other glass hosts—praseodymium (Pr), neodymium (Nd), terbium (Tb), holmium (Ho), erbium (Er), thulium (Tm), ytterbium (Yb)—alone or in combination. In principle, these ions provide the possibility of gain through most of the spectral region from less than 1300 nm to greater than 1600 nm.

Erbium-Doped Fiber Amplifiers. Of the rare-earth-doped fiber amplifiers, the most successful have been those based on erbium-doped silica fiber. The erbium-doped fiber amplifier (EDFA) is important because it provides gain in the 1535- to 1565-nm region, spanning the region of lowest attenuation in a silica fiber, and it has proven effective and reliable. Alternate host glasses, including tellurium-oxide-containing glass can extend the spectral region to wavelengths greater than 1600 nm.

Figure 5.6.19 shows a diagram of the basic elements of an EDFA. At the center is a length of Er-doped fiber, perhaps 10 to 20 m long, which is pumped with the light of one or two pump lasers, usually operating at either

FIGURE 5.6.19 Schematic of an erbium-doped fiber amplifier (EDFA).

FIGURE 5.6.20 Energy levels and frequencies corresponding to Stokes and anti-Stokes amplification.

980 or 1480 nm, and coupled into the amplifying fiber through WDM couplers. Pumping at 980 nm generally provides lower noise, but may have a lower efficiency. Isolators before and after the amplifier suppress retroreflections.

The small-signal gain typically exhibits a peak at around 1530 nm and a broad shoulder on the longer-wavelength side of the peak. In WDM systems where it is desirable that each channel experience the same gain, filters may be incorporated into the design to flatten the gain spectrum; gain flatness of ± 0.5 dB or better is often achieved in this way.

Depending on doping levels, fiber length, and pump power, the amplifier may provide a peak gain of 20 dB to more than 30 dB. When the input power level is such that the upper level of the amplification transition in Er is depleted, the gain saturates. Corresponding output powers may be as high as 100 mW or more.

Noise in EDFAs arises principally from amplified spontaneous emission (ASE), which depends on fiber properties and on pump power and wavelength. Noise figures in the range of 4 to 6 dB are typical.

The ITU, which provides several recommendations on the description of optical fiber amplifiers (Recommendations G.661, G.662, and G.663), categorizes EDFAs into three types: *booster power amplifiers*, which are high saturation power devices intended to be used with a transmitter to increase signal power level; *preamplifiers*, which are low noise devices intended to be used with an optical receiver to improve sensitivity; and *line amplifiers*, which are used between passive fiber sections to compensate for fiber attenuation and other component losses.

Other Rare-Earth-Doped Fiber Amplifiers. Praseodymium-doped fiber amplifiers, usually pumped around 1017 nm, provide high gain and high saturation power in the 1280- to 1340-nm region, spanning the wavelength of zero-chromatic dispersion. Unfortunately, amplification in the Praseodymium ion works best when the host is fluoride fiber, which is not as well developed as silica fiber.

Thulium, or thulium-ytterbium co-doping, in fluoride fibers has been shown to provide useful gain at wavelengths generally in the S-band, when pumped with a Nd:YAG laser at 1064 nm, and neodymium-doped fibers can provide amplification in the 1320-nm region.

Raman Fiber Amplifiers

In some respects, optical fiber amplifiers based on the Raman effect provide an attractive alternative to rare-earth-doped fiber amplifiers. For a given gain, they require a higher pump power, but Raman fiber amplifiers can provide amplification in any transmission fiber and, when a suitable pump source is available, provide gain at any wavelength where the fiber is transparent. When the pump and signal propagate in opposite directions, the Raman amplifier can provide very low effective noise.

The Raman effect is based on the coupling of light among an intense pump, a low-level signal, and optical phonons, which are mechanical oscillations that have frequencies characteristic of the material and are strongly damped. As shown in Fig. 5.6.20, gain can be achieved at frequencies corresponding to both the difference and sum of the pump and phonon frequencies. These are known as the “Stokes” and “anti-Stokes”

FIGURE 5.6.21 Raman spectrum of a germano-silicate fiber.

Source: R. Stolen, *Proc. IEEE* 68, 1232 (1980).

frequencies, respectively. In silica, the phonon spectra peaks roughly 12 THz (~90 nm) away from the pump frequency (Fig. 5.6.21).

Raman amplifier products are generally pump modules that consist of an ensemble of high power lasers, often four but experimentally as many as 20 or more, with control electronics to control the power of each laser independently. This permits tailoring the gain spectrum to acceptable flatness. Usually the amplifiers are designed to use Stokes amplification, which is more stable than anti-Stokes amplification. Raman amplification is polarization sensitive, so it is common to incorporate polarization diversity into optical systems associated with the pump.

It is also common to insert the Raman pump module into a system so that the pump propagates in the opposite direction from the signal. Thus, the greatest amplification is achieved where the signal would otherwise have been attenuated to its minimum level. This improves overall noise performance.

SECTION 6

INTEGRATED CIRCUITS AND MICROPROCESSORS

Digital and analog integrated circuits are the fundamental building blocks of today's electronic systems, digital ICs being dominant. They can emulate many functions for which analog circuitry was previously required. Nevertheless, because the real world is largely analog in nature, the analog IC remains the primary interface.

The extraordinary rate of progress in making dynamic random-access memories (DRAM) smaller and more powerful is reflected in their wide use, and, for example, in the rapid obsolescence of lesser-performing computer models.

The microprocessor, over its 30-some-year life span, has become a powerful tool for the design engineer, who embeds it in a broad range of intelligent digital devices.

Finally, Chap. 6.5 in this section covers nanotechnologies. The rapid developments in nanofabrication techniques have spawned a new era in microcomponent developments, including microelectromechanical components (see Chap. 8.5). C.A.

CHAPTER 6.1

DIGITAL INTEGRATED CIRCUITS*

P. K. Vasudev, S. Tewksbury

INTRODUCTION

This and the following two sections will discuss the design and application of two major classes of integrated circuits (ICs): digital and analog and their application to both memory and logic circuits, which are shown for both bipolar and complementary MOS (CMOS) technologies.

Digital circuits are the most widespread and commonly used integrated circuits today. They process signals in binary bits. They are distinguished by their function and their performance. Analog circuits are less common and process signals as waveforms.

Analog circuits play a critical role intrinsic to the connection of electronic systems to the physical world and analog electronics have a rich and long history. More recently, digital electronics have become sufficiently sophisticated that computations on numerical values (representing the value of analog signals at regularly spaced intervals in time) can often be used to perform several traditional signal processing functions that previously required analog circuits. This transition of several traditional analog circuit functions into the digital world has accelerated, providing the capability of “programming” the digital computations to perform different traditional analog circuit functions or “reconfiguring” the digital components of an integrated circuit to change the operations performed. However, the analog circuits usually are required for the interface between the physical world (where things are usually analog) and the digital world. The combination of both analog and digital circuitry on the same VLSI circuit has allowed a wide range of applications to develop. Such “mixed signal” ICs are seen in various “embedded systems” such as those used in automobiles (sensors and computers measuring and controlling ignitions, and so forth).

In this section, the basic parameters used to measure the performance of digital circuits are first introduced. This is followed by a description of the different digital integrated circuit technologies, and their function in systems.

Logic Performance Parameters

Although there are a wide variety of parameters of interest, such as environmental, operating speed, voltage range, availability and cost, five key parameters are generally used in comparing digital circuit families.

Speed

This indicates how fast a digital circuit can operate. It is usually specified in terms of gate propagation delay, or as a maximum operating speed such as the maximum clock rate of a shift register or a flip-flop.

Gate propagation delay is defined as the time between the transition of an input signal between two states and the resulting response of the output signal.

*The contents of this chapter have been extracted and significantly updated from “Integrated Circuits” by F. F. Mazda, Butterworth, 1983.

Power Dissipation

This gives a measure of the power which the digital circuit draws from the supply. It is measured as the product of the supply voltage and the mean supply current for given operating conditions such as speed and output loading. Low power dissipation is an obvious advantage for portable equipment. However, since the amount of power which can be dissipated from an integrated circuit package is limited, the lower the dissipation, the greater the amount of circuit which can be built into a silicon die.

Speed-Power Product

The “power-delay” product is obtained by multiplying the power dissipation of a component by the delay between the input signal change and the output response. The product represents the energy associated with the functional operation of the component. The concept of power-delay product extends well beyond its use with simple devices or logic functions to larger scale systems. In general, a given component will be characterized by an energy (power-delay product) but allow trade-offs between the delay (or speed—reciprocal of the delay) and the power dissipation with the constraint that the power-delay product remain constant. This conforms to our intuitive expectation that if we are willing to accept higher power dissipation in a component we can achieve higher speed operation. Figure 6.1.1 illustrates the general theme. Here, three different circuits are characterized by different energies (i.e., representing different energies associated with different VLSI technologies) but each of these circuits can be adjusted either for high-speed operation at high-power dissipation or for low-power dissipation operation at lower speeds).

Current Source and Sink

This measures the amount of current which the digital circuit can interchange with an external load. Generally digital circuits interconnect with others of the same family and this parameter is defined as a *fan-out*, which is the number of similar gates which can be driven simultaneously from one output. The *fan-in* of a circuit is the number of its parallel inputs.

Noise Susceptibility and Generation

Digital circuits can misoperate if there is noise in the system. This may be a slowly changing noise, such as a drift in the power supplies, or high-energy spikes of noise caused by switching transients. Some types of logic

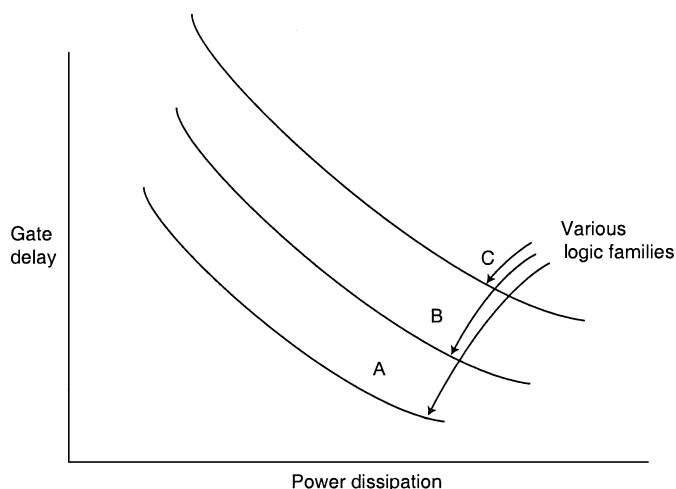

FIGURE 6.1.1 Speed vs. power curves.

families can tolerate more noise than others, and generally the faster the inherent speed of the logic, the more it is likely to be affected by transient noise.

Digital circuits also generate noise when they switch and this can affect adjacent circuits. Noise generation is a direct function of the current being switched in the circuit and the speed with which it is changed.

Comparisons of Various Digital Circuit Families

Today's advanced VLSI circuits draw upon several advantages of silicon CMOS circuits over earlier technologies. During the era of lower density digital circuits, eras of small-scale integration (SSI) and large-scale integration (LSI), bipolar circuit technologies were dominant. Fabricated vertically, small distances were more easily obtained than laterally, an advantage leading to higher performance bipolar circuits than found in MOS circuits. The table below shows the relative advantages of those earlier versions of digital technology. As the number of transistors in an IC increased and as technologies evolved to provide very small lateral distances, MOS circuits became increasingly competitive. The initial NMOS logic (using an NMOS pull-down circuit in combination with a pull-up resistor) was quickly replaced by CMOS technologies, once fabrication techniques had advanced to allow fabrication of both NMOS and PMOS transistors in the same substrate (essentially by creating "wells" deeply doped opposite to the substrate doping to create the other type of MOSFET). Today, CMOS is clearly the dominant technology and each successive generation of microfabrication technology increases the relative advantages of CMOS over the earlier bipolar forms of digital logic. Some of the principles of these earlier bipolar circuits are described later, providing an understanding of the various ways in which basic devices could be arranged to yield the basic digital functions of logic. In contrast to analog circuits which require a very linear response to input analog signals, digital logic circuits are deliberately nonlinear—switching between one state and another in response to the input signal and producing a fundamental regeneration of the binary logic states at the output of the circuit.

Comparison of Logic Families (1 = best, 6 = worst)

Logic family	Speed	Power	Fan out	Noise
DTL	4	4	3	3
TTL	3	4	3	3
ECL	1	6	2	2
NMOS	5	2	2	2
CMOS	3	1	1	1

BIPOLAR LOGIC CIRCUITS

This section discusses digital circuits using bipolar technology.

Saturating Bipolar Logic Circuits

One of the earliest digital circuit families was the resistor-transistor logic (RTL) family. Figure 6.1.2a shows a 3-input NAND gate. When the three transistors are OFF, R_4 pulls up the output voltage D toward V_{cc} . If any of the three transistors turns ON (base voltage high), that transistor pulls down the output voltage toward 0 V. To provide full output voltage swings, the ON (OFF) state resistance of a transistor must be small (large) compared to R_4 . Diode-transistor logic (DTL), Fig. 6.1.2b, was another early bipolar logic technology, using pull-down diodes in combination with a pull-up resistor to drive the base of the output transistor. Replacing the multiple input resistors with simpler diodes leads to smaller gate areas. In addition, the dependence of the output resistance of the RTL circuit on inputs A to C is eliminated.

FIGURE 6.1.2 Resistor-transistor logic and diode-transistor logic.

The RTL and DTL logic families were quickly replaced by transistor-transistor logic (TTL) (Fig. 6.1.3), further simplifying the input configuration (here three emitters placed in the same transistor structure) while adding an active pull-up transistor TR₁ in combination with the pull-down transistor to achieve faster outputs. The TTL logic family developed into a variety of subfamilies, each optimized for different performance objectives and remained the mainstream digital logic technology through the evolution from SSI through MSI to LSI. The increasing number of gates per IC required a decrease in power dissipation per gate to avoid a concurrent increase in the power dissipation of the IC. This limited the extension of the TTL logic family into VLSI since the TTL gate's power dissipation could not be decreased sufficiently. CMOS technologies have replaced TTL as the mainstream logic technology in VLSI. However, the TTL circuits continue to see use in BiCMOS, a technology that combines CMOS circuits with bipolar circuits on the same IC to achieve speed and current drive advantages as needed.

FIGURE 6.1.3 Transistor-transistor logic gate.

FIGURE 6.1.4 Emitter-coupled logic gate.

Nonsaturating Bipolar Logic Circuits

When in the saturated ON state, an excess charge density appears within the bipolar transistors. Switching the transistor to the OFF state requires that this excess charge density be removed, limiting the speed of the gates. One method to reduce the charge storage delays is to use Schottky transistors in the TTL gate. The Schottky diode prevents the transistor from saturating, leading to faster switching times. Such Schottky TTL logic circuits, either in low-power versions or high-speed versions, generally replaced the saturating TTL circuits discussed earlier.

Another nonsaturating bipolar logic family was the standard when high speed was a priority. This is the emitter-coupled logic (ECL) family (Fig. 6.1.4) in which separate transistors for each input and optimized designs for the highest possible speed are used. The amplifier consisting of TR4 and the input transistors drives the output transistors providing both noninverted and inverted outputs. The output transistors are designed with low resistance, providing high output current drive and high speed. Current flow into the gate from the power supply is nearly constant, avoiding noise problems seen in other bipolar logic circuits. The ECL logic circuits used supply voltages different from TTL logic and also had smaller output voltage swings, making connection of TTL logic and ECL logic difficult to interface (special interface circuits were available).

MOS LOGIC CIRCUITS

MOS technologies emerged early in the history of digital logic but suffered from poor performance because of the device structures being fabricated as lateral structures (with larger distances) in contrast to the bipolar device structures which took advantage of small distances achieved with vertical structures. As device dimensions decreased, this disadvantage also decreased, with MOS device performance improving with each scaling to smaller device sizes. Initial MOS logic circuits used either NMOS or PMOS transistors (Figs. 6.1.5 and 6.1.6), a fabrication constraint since these different transistors used different type substrates (P-type and N-type, respectively).

Figure 6.1.7 shows a basic three input NMOS gate as the pull-up circuit and a resistor used as the pull-down element. That pull-down resistor is realized as a transistor in the ON-state to achieve a small area resistor. The symbol for the MOS transistor directly illustrates one feature that provides a fundamental advantage over bipolar transistors. In particular, the input is coupled capacitively to the device, with the result that all inputs are to capacitors, rather than to the resistances appearing at bipolar transistor inputs. For this reason, the output current from D need not be a dc current to maintain the output level. Instead, the output current is merely that needed to charge the capacitance of the MOS input being driven, going to zero when that capacitance has been

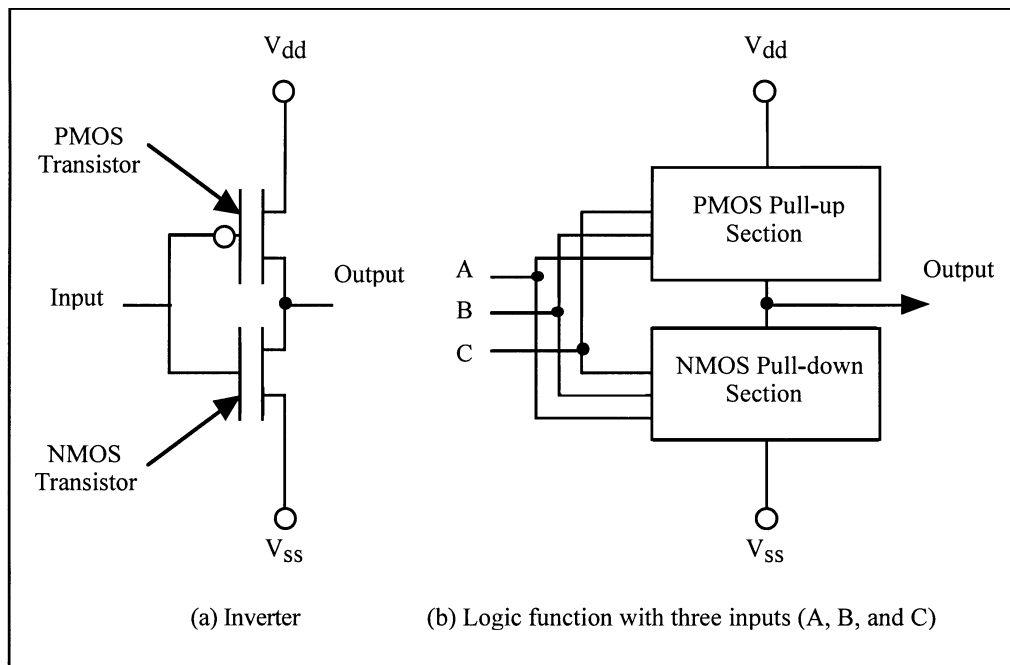

FIGURE 6.1.5 CMOS logic gates.

charged. The result is that, aside from small leakage currents, the dc power dissipation is zero when the pull-up transistors are OFF (output is low). The NMOS circuit does dissipate power when one or more pull-up transistors is in the ON-state since a dc current flows through that transistor through the pull-down resistor.

As technologies advanced, it became possible to efficiently dope selective regions of a substrate in such a manner as to obtain a “well” doped opposite to the substrate. For example, if the substrate is P-type (to create NMOS transistors), a deep well can be doped N-type and PMOS transistors fabricated in that N-type “substrate” region. Being able to fabricate both NMOS and PMOS transistors in the same silicon substrate allows today’s CMOS circuits to be created. Figure 6.1.5a shows a basic inverter using a PMOS transistor for the pull up and an MOS

FIGURE 6.1.6 Noise immunity bands for CMOS logic.

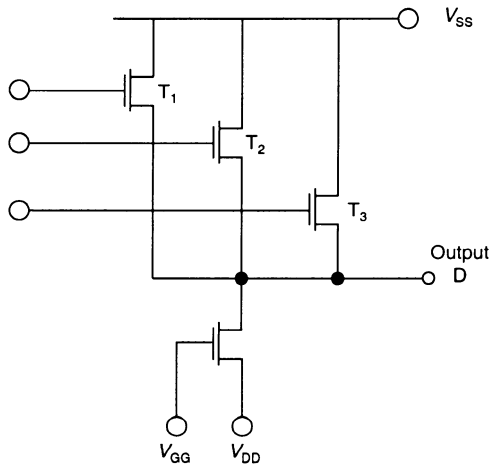

FIGURE 6.1.7 NMOS NOR gate.

Next, the precharge transistor is turned OFF and the pull-down (pull-up) section is activated, either leaving the output unchanged or driving the output capacitance to logic “0” (“1”). Figure 6.1.8 illustrates the general technique for such “dynamic logic,” with the clock signal used to control the activations of the precharge pull-up transistor and of the pull-down section in this example.

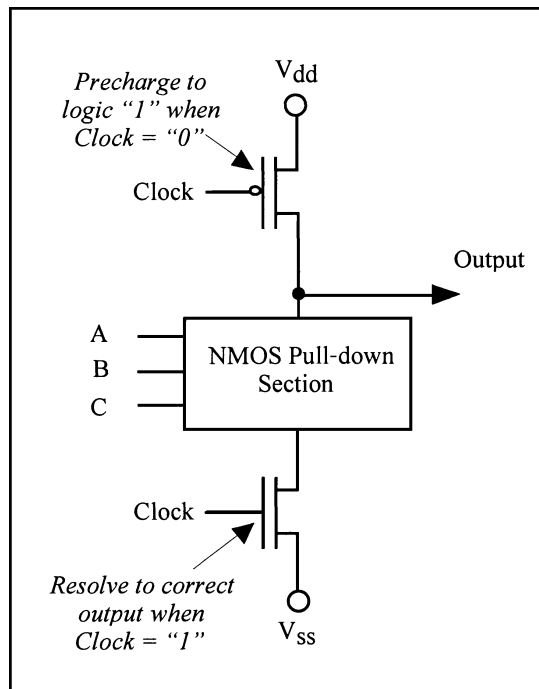

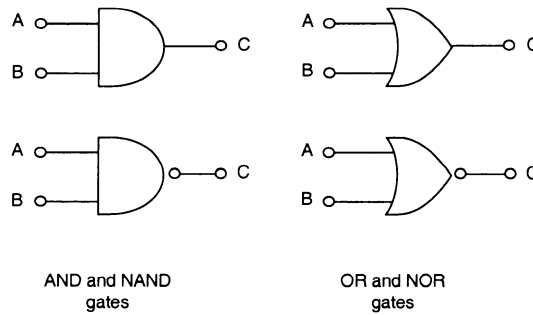

FIGURE 6.1.8 Dynamic CMOS logic gate.

transistor for pull down. Figure 6.1.5b shows the general organization of a CMOS circuit, consisting of a pull-up circuit using PMOS transistors and a pull-down circuit using NMOS transistors. Properly designed, the same set of digital inputs to the pull down are also applied to the pull up, as shown. Noise immunity characteristics of CMOS logic circuits are shown in Fig. 6.1.6.

The CMOS logic circuits using pull-up and pull-down sections such as shown in Fig. 6.1.5b require the same number of transistors in the pull-up section as in the pull-down section but do provide static logic functions (the output is held indefinitely so long as the inputs do not change). Dynamic CMOS logic replaces either the pull-up (pull-down) section with a single transistor used to precharge the capacitive load seen by the output (capacitive since outputs drive the gate of subsequent logic circuits and the gate is essentially a capacitance). When this transistor is turned on and the corresponding pull-down (pull-up) section is OFF, the capacitive load is precharged to logic “1” (“0”).

FIGURE 6.1.9 Commonly used gates and truth table.

DIGITAL LOGIC CIRCUITS

The circuits which are described in this and subsequent sections can be fabricated using any of the bipolar or CMOS logic technologies described earlier. The electrical characteristics such as speed and power consumption will be determined by the logic family but the function will be the same in all cases. The circuits described range from simple to more complex types.

Gates

Figure 6.1.9 shows commonly used gates and a truth table gives the functional performance in logic 1 and 0 states. Gates are usually available as hex inverter, quad two input, treble three input, dual four input, and single eight input. AND-OR-INVERT gates are also available and these are used to connect the outputs of two gates together in a wired-OR connection.

In a CMOS transmission gate a p - and an n -channel transistor are connected together. A gate signal turns on both transistors and so provides an ac path through them, whereas when the transistors are off the gate blocks all signals.

Gates are also made in Schmitt trigger versions. These operate as the discrete component circuits and exhibit an hysteresis between the ON and OFF switching positions.

Flip-flops

Flip-flops are bistable circuits which are mainly used to store a bit of information. The simpler types of flip-flops are also called latches. Figure 6.1.10 shows the symbol for some of the more commonly used flip-flops. There are many variations such as master-slave, J-K, edge-triggered, and gate flip-flops.

In the master-slave set-reset flip-flop, a clock pulse is required. During the rising edge of the clock information is transferred from the S and R inputs to the master part of the flip-flop. The outputs are unchanged at this stage. During the falling edge of the clock the inputs are disabled so that they can change their state without affecting the information stored in the master section. However, during this phase the information is transferred from the master to the slave of the flip-flop is disabled when no clock pulse is present.

FIGURE 6.1.10 Commonly used flip-flops.

J-K flip-flops are triggered on an edge of the clock waveform. Feedback is used internally within the logic such that the undeterminate state, when both inputs are equal to logic 1, is avoided. Now when the inputs are both at 1, the output will continually change state on each clock pulse. This is also known as *toggling*.

D-type flip-flops have a single input. An internal inverter circuit provides two signals to the J and K inputs so that it operates as a J-K flip-flop, having only two inputs modes.

Counters

Flip-flops can be connected together to form counters in a single package. There are primarily two types, asynchronous and synchronous. The synchronous counters may be subdivided into those with ripple enable and those with parallel or look-ahead carry.

In an asynchronous counter the clock for the next stage is obtained from the output of the preceding stage so that the command signal ripples through the chain of flip-flops. This causes a delay so asynchronous counters are relatively slow, especially for large counts. However, since each stage divides the output frequency of the previous stage by two, the counter is useful for frequency division.

In a synchronous counter, the input line simultaneously clocks all the flip-flops so there is no ripple action of the clock signal from one stage to the next. This gives a faster counter, although it is more complex since internal gating circuitry has to be used to enable only the required flip-flops to change state with a clock pulse. The enable signal may be rippled through between stages or parallel (or look-ahead) techniques may be used, which gives a faster count.

Counters are available commercially, having a binary or BCD count, and which are capable of counting up or down.

Shift Registers

When stored data are moved sequentially along a chain of flip-flops, the system is called a shift register. Commercial devices are available in sizes from four bits to many thousands of bits.

The shift register is serial-in, serial-out, but it is possible to have systems that are parallel data input and output. The only limitation is the number of pins available on the package to accommodate the inputs and outputs. Shift registers can also be designed for left or right shift.

In the register, input data ripple through at the clock pulse rate from the first to the last stage. Sometimes it is advantageous to be able to clock the inputs and outputs at different rates. This is achieved in a first-in first-out (FIFO) register. Each data bit has an associated status and input data are automatically moved along until it reaches the last unused bit in the chain. Therefore the first data to come in will be the first to be clocked out. Data can also be clocked into and out of the register at different speeds, using the two independent clocks.

6.12 INTEGRATED CIRCUITS AND MICROPROCESSORS

Data Handling

Several code converter integrated circuits are available commercially. A typical example is a BCD to decimal converter. These converters can also be used as priority encoders. An example may be considered to be a ten-input priority encoder. Several of the lines 0 to 9 may be energized simultaneously but the highest number will generate a BCD output code.

Another example is an eight-channel multiplexer. The channel select lines connect one of the eight data input lines to the output line using BCD code.

Timing

A variety of commercial devices are available to give monostable and astable multivibrators. Most of these incorporate control gates so that they are more versatile when used in digital systems. A gated monostable will trigger when the voltage at the transistor goes to a logic 1.

External resistors and capacitors are used to vary the duration of the monostable pulse. By feeding the output back to the input, this circuit can also be operated as an astable multivibrator.

Drivers and Receivers

Digital integrated circuits have limited current and voltage drive capability. To interface to power loads, driver and receiver circuits are required, which are also available in an integrated circuit package. The simplest circuit in this category is an array of transistors. Usually the emitters or collectors of the transistors are connected together inside the package to limit the package pin requirements.

For digital transmission systems line drivers and receivers are available. The digital input on the line driver controls an output differential amplifier stage, which can operate into low impedance lines. The line receiver can sense low-level signals via a differential input stage and provide a logic output.

Adders

Adders are the basic integrated circuit units used for arithmetic operations such as addition, subtraction, multiplication, and division. A half-adder adds two bits together and generates a sum and carry bit. A full adder has the facility to bring in a carry bit from a previous addition. Figure 6.1.11 shows one bit of the full adder.

The basic single-bit adder can be connected in several ways to add multibit numbers together. In a serial adder the two numbers are stored in shift registers and clocked to the A and B inputs one bit at a time. The carry out is delayed by a clock pulse and fed back to the adder as a carry in.

Serial adders are slow since the numbers are added one bit at a time. A parallel adder is faster. The carry output ripples through from one bit to the next so that the most significant bit cannot show its true value until the carry has rippled right through the system. To overcome this delay, look ahead carry generator may be used. These take in the two numbers in parallel, along with the first carry-in bit, and generate the carry input for all the remaining carry bits.

Adders can be used as subtractors by taking the two's complement of the number being subtracted and then adding. Two's complementing can be obtained by inverting each bit and then adding one to the least significant bit. This can be done within the integrated circuit so that commercial devices are available which can add or subtract, depending on the signal on the control pin.

Adders are used for multiplication by a process of shifting and addition, and division is obtained by subtraction and shifting.

FIGURE 6.1.11 Full adder.

Magnitude Comparators

A magnitude comparator gives an output signal on one of three lines, which indicates which of the two input numbers is larger, or if they are equal. Figure 6.1.12 shows one bit of magnitude comparator. Multibit

FIGURE 6.1.12 Magnitude comparator.

numbers can be compared by storing them in shift registers and clocking them to the input of the single-bit magnitude comparator, one bit at a time, starting from the most significant bit. Alternatively, parallel comparators may be used where each bit of the two numbers is fed in parallel to a separate comparator bit and the outputs are gated together.

Rate Multiplier

Rate multipliers can be connected to give a variety of arithmetic functions. A typical example is an adder for adding the numbers X and Y . The clock input in all cases is produced by splitting a single clock into several phases. For the adder $Z = X + Y$ and for the multiplier $Z = XY$.

CHAPTER 6.2

ANALOG INTEGRATED CIRCUITS

P. K. Vasudev, S. Tewksbury

INTRODUCTION

Digital logic circuits are designed to preserve the concept of binary states (logic “1” and “0”) as voltage levels that are restored to levels defined by the supply voltages at the output of each logic gate. This provides a substantial simplification in the design of complex systems composed of millions of gates—at any point the voltage levels merely reflect the supply voltages at the logic gate driving that point. Analog circuits, on the other hand, must be designed to preserve the concept of a continuum of voltage levels, with the output of an analog component preserving the transformation of an input analog signal into a desired output analog signal. The result is that analog integrated circuits generally do not reach the levels of tens of millions of transistors such as seen in digital logic circuits. The term *analog circuit* has been used somewhat loosely in the past, including circuits such as analog-to-digital converters that convert a continuum of voltage levels into a discrete number corresponding to a set of voltage levels. More recently, the term *mixed signal VLSI* has appeared, representing the placement of both analog circuits and digital circuits on the same integrated circuit. Such mixed signal VLSI merely continues the evolution of the general technology to provide compact and low-cost electronic solutions of practical needs.

One of the developments in digital logic ICs has been the development of *programmable* logic components that can be programmed by the user to implement the logic function desired by the user. Several families of such programmable logic have been developed and present technologies allow not only user programmed logic ICs containing millions of gates but also programmable logic ICs in which the user can embed sophisticated functions such as microprocessors and signal processors. Although not having the efficiency of gate utilization or the speed of fully custom-designed logic ICs, these programmable logic ICs have empowered virtually any user to create low-cost but sophisticated logic circuits through the simple expedient of downloading a configuration file into the IC.

Analog circuits have recently moved also towards such *programmable analog ICs*, providing a set of standard analog circuit functions (operational amplifiers, resistors, and so forth) that can be *programmed* by the user—configuring the interconnections among the analog circuit elements and adjusting the values of some of those elements (e.g., setting the value of a resistor). As these programmable analog IC technologies evolve, programmable VLSI including both digital logic and analog circuit elements will become available, providing the user with powerful components that can be optimized for the specific needs of the user by simply downloading a configuration program to the IC.

There are many distinct types of analog circuit function (operational amplifiers, phase-locked loops, low-noise amplifiers, analog switches, voltage regulators, analog/digital converters, modulators, and so forth). Within each of these analog circuit function types, there are wide ranges of performance specifications. Amplifiers may be intended for lower frequency applications such as audio amplifiers or may be intended for very high frequency applications such as the input amplifier of an RF receiver. Voltage regulators may be required to provide switched local power (generally low current) to subsections of an integrated circuit or may

be required to provide high currents to separate electronic components. Because of the vast differences among the various applications of a particular type of analog circuit, there are corresponding vast differences among the design approaches for those various types. In this chapter, basic analog circuit functions that can be routinely manufactured are reviewed. Specialized techniques for special purpose analog circuits with specialized (and high) performance specifications are not considered. The operational amplifier plays a special role in routine analog circuits and is emphasized here since it demonstrates several of the basic concepts in analog circuit design. Analog-to-digital converters also play a special role, serving as the interface between the analog world and the digital world. Basic analog-to-digital conversions are also discussed. Readers interested in the design and use of analog circuits will find a substantial amount of information (product data sheets, application notes, tutorials, and so forth) available at the websites of the analog IC manufacturers. Although the remarkable evolution of digital ICs is well known (e.g., through the rapid introduction of more powerful personal computers), the equally remarkable advances in analog circuits are far less well known. Although hidden from view within automobiles, cellular telephones, audio equipment, and other consumer products, the miniaturization of analog circuits plays a major role in the rapid expansion of electronics into products of all types, including applications requiring miniaturization of sophisticated analog (and mixed analog/digital) circuit functions.

OPERATIONAL AMPLIFIERS

The operational amplifier, or op amp, was originally developed in response to the needs of the analog computer designer. The object of the device is to provide a gain block whose performance is totally predictable from unit to unit and perfectly defined by the characteristics of an external feedback network. This has been achieved by op amps to varying degrees of accuracy, largely governed by unit cost and complexity. Nevertheless, the accuracy of even low cost units has been refined to a point where it is possible to use an op amp in almost any dc to 1 GHz amplifier/signal processor application.

Ideal Operational Amplifier

The *ideal* operational amplifier of Fig. 6.2.1 is a differential input, single-ended output device that is operated from bipolar supplies. As such, it can easily be used as a virtual earth amplifier. Differential output is possible, although not common, and single supply operation will be discussed later. The ideal op amp has infinite gain, infinite bandwidth, zero bias current to generate a functional response at its inputs, zero offset voltage (essentially a perfect match between the input stages) and infinite input impedance. Because of these characteristics, an infinitesimally small input voltage is required at one input with respect to the other to exercise the amplifier output over its full range.

FIGURE 6.2.1 Ideal operational amplifier.

Hence, if one input is held at earth, the other cannot deviate from it under normal operating conditions and becomes a “virtual earth” of the feedback theory definition. The shortfalls against the ideal of practical op amps are now considered with their application consequences.

Input Offset Current

Op-amp fabrication uses monolithic integrated circuit construction, which can produce very well-matched devices for input stages and so on by using identical geometry for a pair of devices fabricated at the same time on the same chip. Nevertheless, there is always some mismatch, which gives rise to the input offset current. This is defined as the absolute difference in input bias current, i.e.,

$$I_{\text{diff}} = |I_A - I_B|$$

Effect of Input Bias and Offset Current

The effect of input bias current will be to produce an unwanted input voltage, which can be much reduced by arranging for the bias current to each input to be delivered from an identical source resistance. Figure 6.2.2 shows a simple inverting amplifier with a gain defined by R_2/R_1 , in which R_3 is added to achieve to this effect. In this example the effect of amplifier input impedance is ignored, and signal input impedance is assumed to be zero. In order to balance the bias current source resistance, R_3 is made equal to R_2 in parallel with R_1 .

FIGURE 6.2.2 Simple inverting amplifier.

Obviously, the values of the feedback network resistors must be chosen so that, with the typical bias current of the op amp in use, they do not generate voltages that are large in comparison with the supplies and operating output voltage levels. The other sources of error, after balancing source resistances, are the input offset current, and the more insidious effects of the drift of input offset and bias current with temperature, time, and supply voltage, which cannot easily be corrected. Op-amp designers have taken great trouble to minimize the effect of these external factors on the bias and offset current, but, of course, more sophisticated performance is only obtained from progressively more expensive devices. As might be expected, a high precision applications will require an op amp with a high price tag.

Input Offset Voltage and Nulling

As mentioned before a mismatch always exists between the input stages of an op amp, and the input offset voltage (V_{os}) is the magnitude of the voltage that, when applied between the inputs, gives zero output voltage. In bipolar input op amps the major contributor to V_{os} is the bare-emitter voltage mismatch of the differential input stage. General purpose op amps usually have a V_{os} in the region of 1 to 10 mV. This also applies to the modern MOSFET input stage op amps, which achieve an excellent input stage matching with the use of ion implantation. As with the input current parameters, input offset voltage is sensitive to temperature, time, and to a lesser extent input and supply voltages. Offset voltage drift with temperature is often specified as μV per mV of initial offset voltage per $^{\circ}\text{C}$. As a general rule, the lower the offset voltage of an op amp, the lower is temperature coefficient of V_{os} will be.

Enhanced performance low V_{os} op amps are often produced today by correcting or *trimming* the inherent unbalance of the input stage on chip before or after packaging the device. Techniques used are mainly laser trimming of thin film resistor networks in the input stage and a proprietary process known as *zener zapping*.

Other op amps are available with extra pins connected for a function known as *offset null*. Here a potentiometer is used externally by the user with its slider connected to V_+ or V_- to adjust out the unbalance of the device input stage. A note of caution should be sounded here when using an op amp with an offset null feature in precision circuitry; the temperature coefficient of V_{os} can be changed quite significantly in some op-amp types by the nulling process.

Open Loop Gain

This is one parameter where the practical op-amp approaches the infinite gain ideal very closely and typical gains of 250,000 and higher are quite common at zero frequency. However, it is also common for the gain to start to fall off rapidly at low frequencies, e.g., 10 Hz, with many internally compensated op amps (see Fig. 6.2.3). The commercially available $\mu\text{A}741$ op amp, for instance, has its gain reduced to unity at around 1 MHz. The closed loop gain is limited by the open loop gain and feedback theory indicates that the greater the difference between open and closed loop gain, the greater the gain accuracy.

Settling Time

Frequently in op-amp applications, such as digital-to-analog converters, the device output is required to acquire a new level within a certain maximum time from a step input change.

FIGURE 6.2.3 Frequency sensitivity of open loop gain.

The slew rate is obviously a factor in this time, but transient effects will inevitably produce some measure of overshoot and possibly ringing before the final value is achieved. This time, measured to a point where the output voltage is within a specified percentage of the final value, is termed the *settling time*, usually measured in nanoseconds. Careful evaluation of op-amp specifications is required for critical settling time applications, since high-slew-rate op amps may have sufficient ringing to make their settling times worst than medium slew rate devices.

Output Capabilities

As would be expected because of internal design limitations, op amps are unable to achieve an output voltage swing equal to the supply voltages for any significant load resistance. Some devices do achieve a very high output voltage range versus supply, notably those with CMOS FET output stages. All modern op amps have short-circuit protection to ground and either supply built in, with the current limit threshold typically being around $25 \mu\text{A}$. It is thus good practice to design for maximum output currents in the 5- to 10-mA region.

Higher current op amps are available but the development of these devices has been difficult because of the heat generated in the output stage affecting input stage drift. Monolithic devices currently approach 1 A and usually have additional circuitry built in to protect against thermal overload and allow output device protection, in addition to normal short-circuit protection.

Power Supply Parameters

The supply consumption will usually be specified at $\pm 5 \text{ V}$, for example, and possibly other supply voltages additionally. Most performance parameters usually deteriorate with reducing supply voltage. Devices are available with especially low power consumption but their performance is usually a trade-off for reduced slew rate and output capability.

Power supply rejection ratio (PSRR) is a measure of the susceptibility of the op amp to variations of the supply voltage. The definition is expressed as the ratio of the change in input offset voltage to the change in supply voltage ($\mu\text{V}/\text{V}$ or dB). No op amp ever has a PSRR of less than 70 dB. This should not be taken to indicate that supply bypassing/decoupling is unnecessary. It is good practice to decouple the supplies to general purpose op amps at least every five devices. High speed op amps require careful individual supply decoupling on a by-device basis for maximum stability, usually using tantalum and ceramic capacitors.

Common Mode Range and Rejection

The input voltage range of an op amp is usually equal to its supply voltages without any damage occurring. However, it is required that the device should handle small differential changes at its inputs, superimposed on any voltage level in a linear fashion.

Because of design limitations, input device saturation, and so forth, this operational voltage range is less than the supplies and is termed the common mode input voltage range or swing. As a differential amplifier, the op amp should reject changes in its common mode input voltage completely, but in practice they have an effect on input offset and this is specified as the common mode rejection ratio (CMRR) ($\mu\text{V}/\text{V}$ or dB). Note that most general-purpose op amps have a CMRR of at least 70 dB (approximately 300 μV offset change per volt of common mode change) at dc, but this is drastically reduced as the input frequency is raised.

Input Impedance

The differential input resistance of an op amp is usually specified together with its input capacitance. Typical values are 2 M Ω and 1.4 pF for the μA 741.

In practice, the input impedance is usually high enough to be ignored. In inverting amplifiers, the input impedance will be set by the feedback network. In noninverting amplifiers, the input impedance is “bootstrapped” by the op-amp gain, leading to extremely high input impedance for configurations with the feedback case of voltage follower. This bootstrap effect declines as A_{oi} drops off with rising frequency, but it is safe to assume that the circuit input impedance is never worse than that of the op amp itself.

Circuit Stability and Compensation

To simplify design-in and use, many op amps are referred to as “internally” or “fully” compensated. This indicates that they will remain stable for closed loop gains down to unity (100 percent feedback). This almost certainly means that performance has been sacrificed for the sake of convenience from the point of view of users who require higher closed loop gains. To resolve this problem, many op amps are available that require all compensation components to be added externally, according to manufacturers’ data and gain requirements. A compromise to this split has been the so-called undercompensated op amps, which are inherently stable at closed loop gains of 5 to 10 and above.

The aim of the standard compensation to shape the open loop response to cross unity gain before the amplifier phase shift exceeds 180°. Thus unconditional stability for all feedback connections is achieved. A method exists for increasing the bandwidth and slew rate of some uncompensated amplifiers known as feedforward compensation. This relies on the fact that the major contributors of phase shift are around the input stage of the op amp and bypassing these to provide a separate high frequency amplifying path will increase the combined frequency response.

OPERATIONAL AMPLIFIER CONFIGURATIONS

Op amps are available ranging from general purpose to ultraprecision. The low-to-medium specification devices are often available in duals and quads. There is a growing trend to standardize on FET input op amps for general-purpose applications, particularly those involving ac amplifiers because of their much enhanced slew rate and lower noise.

Specific devices are available for high speed and high power output requirements. Additionally, some op amps are available as programmable devices. This means their operating characteristics (usually slew rate, bandwidth, and output capability) can be traded off against power supply consumption by an external setting resistor, for instance, to tailor the device to a particular application. Often these amplifiers can be made to operate in the micropower mode, i.e., at low supply voltage and current.

Single-Supply Operational Amplifiers

It is entirely possible to operate any op amp on a single supply. However, the amplifier is then incompatible with bipolar dc signal conditioning. Single-supply operations is entirely suitable for ac amplifiers.

Most later generation op amps have been designed with single supply operation in mind and frequently use pnp differential input arrangements. They have an extended input voltage range, often including ground-in single-supply mode, and are referred to as single-supply op amps.

Chopper and Auto Zero Operational Amplifiers

Many attempts have been made to circumvent the offset and drift problems in op amps for precision amplifier applications. One classic technique is the chopper amplifier, in which the input dc signal is converted to a proportional ac signal by a controlled switch. It is then applied to a high gain accuracy ac amplifier, removing the inherent drift and offset problems. After amplification, dc restoration takes place using a synchronous switching action at the chopper frequency. This is available on a single monolithic device.

Other approaches have used the fact that the output is now required continually, i.e., as in analog to digital converters, and have used the idle period as a self-correction cycle. This again involves the use of a switch, but in this case it is usually used to ground the input of the op amp. The subsequent output is then stored as a replica of actual device error at that moment in time and subtracted from the resultant output in the measurement part of the cycle.

OPERATIONAL AMPLIFIER APPLICATIONS

Op amps are suitable for amplifiers of all types, both inverting and noninverting, dc, and ac. With capacitors included in the feedback network, integrators and differentiators may be formed. Active filters form an area where the availability of relatively low cost op amps with precisely defined characteristics has stimulated the development of new circuit design techniques. Filter responses are often produced by op amps configured as gyrators to simulate large inductors in a more practical fashion. Current-to-voltage converters are a common application of op amps in such areas as photodiode amplifiers.

Nonlinear circuit may be formed with diodes or transistors in the feedback loop. Using diodes, precision rectifiers may be constructed, for ac to dc converters, overcoming the normal errors involved with forward voltage drops. Using a transistor in common base configuration within the feedback loop is the basic technique used for generating logarithmic amplifiers. These are extensively used for special analog functions, such as division, multiplication, squaring, square rooting, comparing, and linearization. Linearization may also be approached by the *piecewise* technique, whereby an analog function is *fitted* by a series of different slopes (gain) taking effect progressively from adjustable breakpoints.

Signal generation is also an area where op amps are useful for producing square, triangle, and sine wave functions.

Instrumentation Amplifiers

Many applications in precision measurement require precise, high gain differential amplification with very high common mode rejection for transducer signal conditioning, and so forth. To increase the common mode rejection and gain accuracy available from a single op amp in the differential configuration, a three-op-amp circuit is used, which is capable of much improved performance. The standard instrumentation amplifier format, may be assembled from individual op amps or may be available as a complete (often hybrid) integrated circuit. The inputs are assigned one up amp each which may have gain or act as voltage followers. The outputs of these amplifiers are combined into a single output via the differential op-amp stage. Resistor matching and absolute accuracy is highly important to this arrangement. Suitable resistor networks are available in thin film (hybrid) form.

Comparators

The comparator function can be performed quite easily by an op amp, but not with particularly well-optimized parameters. Specific devices are available, essentially modified op amps, to handle the comparator function in a large range of applications. The major changes to the op amp are to enable the output to be compatible with the logic levels of standard logic families (e.g., TTL, ECL, CMOS) and trade off a linear operating characteristic against speed. A wide common mode input range is also useful. Thus, all the usual op-amp parameters are applicable to comparators, although usually in their role as an interface between analog signals and logic circuits, there is no need for compensation.

FIGURE 6.2.4 Voltage comparator using op amps.

A typical comparator application shown in Fig. 6.2.4. The circuit has a separate ground terminal to reference the output swing to ground while maintaining bipolar supply operation for the inputs. The output TTL compatibility is achieved by a pull-up resistor to the TTL supply rail V_{CC} , as this is an open collector type comparator. Higher speed comparators will of necessity employ “totem-pole” output structures to maintain fast output transition times. The circuit produces a digital signal dependent on whether the input voltage is above or below a reference threshold. To clean up the switching action and avoid oscillation at the threshold region,

it is quite often necessary to apply hysteresis. This is usually relatively easy to achieve with a small amount of positive feedback from the output to input.

General-purpose comparators exhibit response time (time from a step input change to output crossing the logic threshold) in order of 200 ns. Their output currents are limited, compared to op amps, being usually sufficient to drive several logic inputs. Often a strobe function is provided to disable the output from any input related response under logic signal control.

Comparator Applications. Voltage comparators are useful in Schmitt triggers and pulse height discriminators. Analog to digital converters of various types all require the comparator function and frequently the devices can be used independently for simple analog threshold detection. Line receivers, RC oscillators, zero crossing detectors, and level shifting circuits are all candidates for comparator use. Comparators are available in precision and high speed versions and as quads, duals, and singles of the general-purpose varieties. These latter are often optimized for single-supply operation.

ANALOG SWITCHES

Most FETs have suitable characteristics to operate as analog switches. As voltage controlled, majority carrier devices, they appear as quite linear low value resistors in their “on” state and as high resistance, low leakage path in the “off” state.

Useful analog switches may be produced with JFETs (junction field effect transistors) or MOSFETs (metal oxide semiconductor FETs). As a general rule, JFET switches are lowest “off” leakage. Either technology can be integrated in single- or multichannel functions, complete with drivers in monolithic form.

The switched element is the channel of a FET or channels of a multiple FET array, hence the gate drive signal must be referred to the source terminal to control the switching of the drain-source resistance. It can be seen that the supply voltages of the gate driver circuit in effect must contain the allowable analog signal input range. The FET switched element has its potential defined in both states by the analog input voltage and additionally in the off stage by the output potential. The gate drive circuit takes as input of a ground refereed, logic compatible (usually TTL) nature and converts it into a suitable gate control signal to be applied to the floating switch element. The configuration will be such that the maximum analog input range is achieved while minimizing any static or dynamic interaction of the switch element and its control signal. Figure 6.2.5 shows a typical analog switch in block diagram form. This is a dual SPST function. Because of their close relationship to mechanical switches in use,

FIGURE 6.2.5 Dual SPST analog switch.

mechanical switch nomenclature is often used, e.g., SPST is single pole, single throw, and DPDT is double pole, double throw, both poles being activated by the same control signal. Break-before-make switching is frequently included to avoid shorting analog signal inputs by a pair of switch elements.

The equivalent of single pole multiway switches in monolithic form is referred to as *analog multiplexers*.

Analog Switch Selection

Selection is based on voltage and current handling requirements, maximum on resistance tolerable, minimum off resistance and operating speed. Precautions have to be taken in limiting input overvoltages and some CMOS switches were prone to latch-up, a destructive SCR effect that occurred if the input signal remained present after the supplies have been removed. Later designs have since eliminated this hazard.

SAMPLE AND HOLD CIRCUITS

A sample and hold takes a *snapshot* of an analog signal at a point in time and holds its voltage level for a period by storing it on a capacitor. It can be made up from two op amps connected as voltage followers and an analog switch.

This configuration block diagram is shown in Fig. 6.2.6. In operations, the input follower acts as an impedance buffer and charges the external hold capacitor when the switch is closed, so that it continually tracks the input voltage (the “sample” mode). With the switch turned off, the output voltage is held at the level of the input voltage at the instant of switch off (the “hold” mode). Eventually, the charge on the hold capacitor will be drained away by the input bias current on the follower. Hence the hold voltage *droops* at a rate controlled by the hold capacitor size and the leakage current, expressed as the droop rate in $\text{mVs}^{-1} \mu\text{F}^{-1}$.

When commanded to sample, the input follower must rapidly achieve a voltage at the hold capacitor equivalent to that present at the input. This action is limited by the slew rate into the hold capacitor and settling time of the input follower and it is referred to as the acquisition time. Dynamic sampling also has other sources of error. The hold capacitor voltage tends to lag behind a moving input voltage, due primarily to the on-chip charge current limiting resistor. Also, there is a logic delay (related to “aperture” time) from the onset of the hold command and the switch actually opening, this being almost constant and independent of hold capacitor value. These two effects tend to be of opposite sign, but rarely will they be completely self-cancelling.

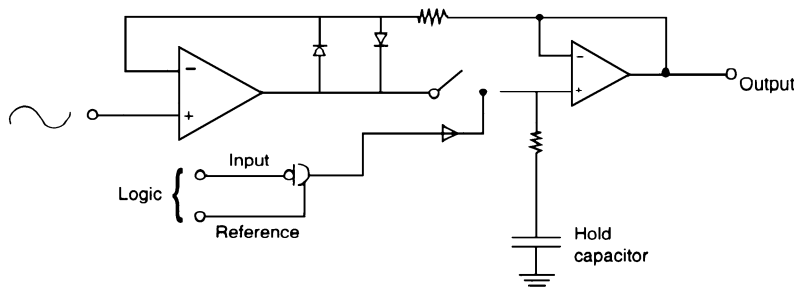

FIGURE 6.2.6 Sample and hold circuit using op amps.

SAMPLE AND HOLD CAPACITOR

For precise applications, the hold capacitor needs more careful selection. To avoid significant errors, capacitors with a dielectric exhibiting very low hysteresis are required. These dielectric absorption effects, are seen as changes in the hold voltage with time after sampling and are not related to leakage. They are much reduced by using capacitors constructed by polystyrene, polypropylene, and PTFE.

The main applications for sample and hold circuits are in analog to digital converters and the effects of dielectric absorption can often be much reduced by performing the digitization rapidly after sampling, i.e., in a period shorter than the dielectric hysteresis relaxation time constant.

DIGITAL-TO-ANALOG CONVERTERS

Digital-to-analog converters (DACs) are an essential interface circuit from the digital world into the analog signal processing area. They are also the key to many analog-to-digital converter techniques that relay on cycling a DAC in some fashion through its operating range until parity is achieved between the DAC output and the analog input signal. All DACs conform to the block diagram of Fig. 6.2.7. The output voltage is a product of the digital input word and an analog reference voltage. The output can only change in discrete steps and the number of steps is immediately defined by the digital inputs. Should this be eight, e.g., an 8-bit DAC, the number of steps will be 256 and the full-scale output will be 256 times voltage increment related to the reference.

Although various techniques can be used to produce the DAC function, the most widely used is variable scaling of the reference by a weighing network switched under digital control. The building blocks of this kind of DAC are (a) reference voltage; (b) weighing network; (c) binary switches; and (d) an output summing amplifier. All may be built in, but usually a minimum functional DAC will combine network and switches.

R-2R Ladders

The weighing network could be binary weighted with voltage switching and summation achieved with a normal inverting op amp. However, even in this simple 4-bit example, there is a wide range of resistor values to implement and speed is likely to suffer due to the charging and discharging of the network input capacitances during conversion. The resistor ladder network employs current switching to develop an output current proportional to the digital word and a reference current. The current switching technique eliminates the transients involving the nodal parasitic capacitances. Significantly, only two resistance values are required and the accuracy of the converter is set by the ratio precision rather than of the absolute value. Analog IC fabrication is capable of accommodating just such resistance value constraints quite conveniently. Monolithic DACs are available in 8- and 12-bit versions and recently in 16 bit. Sixteen-bit and above DACs are also available in hybrid form.

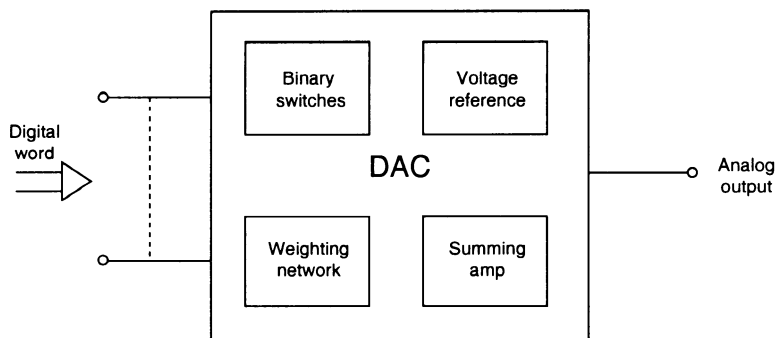

FIGURE 6.2.7 Digital-to-analog converter.

Resolution, Linearity and Monotonicity

Resolution has already been touched upon as being defined by the digital word length and reference voltage increment. However, it is important to note that it is quite possible to have, say, a 12-bit DAC in terms of resolution which is incapable of 12-bit accuracy. This is because of nonlinearities in the transfer function of the DAC. It may well be accurate at full scale but deviate from an ideal straight line response because of variations in step size at other points on the characteristic. Linearity is specified as a worst case percentage of full-scale output over the operating range. To be accurate to n bits, the DAC must have a linearity better than $1/2$ LSB (LSB = least significant bit, equivalent to step size) expressed as a percentage of full scale (full scale = $2 \text{ in.} \times \text{step size}$).

Differential linearity is the error in step size from ideal between adjacent steps and its worst-case level determines whether the converter will be monotonic. A monotonic DAC is one in which, at any point in the characteristic from zero to full scale, an increase in the digital code results in an increase in the absolute value of the output voltage. Nonmonotonic converters may actually “reverse” in some portion of the characteristic, leading to the same output voltage for two different digital inputs. This obviously is a most undesirable characteristic in many applications.

Settling Time

The speed of a DAC is defined in terms of its settling time, very similar to an op amp. The step output voltage change used is the full-scale swing from zero and the rated accuracy band is usually $+1/2$ LSB. Settling times of $100 = 200 \text{ ns}$ are common with 8-bit, 4-2R ladder monolithic DACs. The compensation of the reference op amp will have a bearing on settling time and must be handled with care to maintain a balance of stability and speed.

Other DAC Techniques

There are many other methods that have been proposed and used for the DAC function. There is insufficient space here to make a full coverage. However, mention should be made of the pulse width technique. The digital inputs are assigned time weighing so that in, say, a 6-bit DAC, the LSB corresponds to 1 time unit and the MSB to 32 time units. The time units are derived by variable division from a master clock and usually clocked out at a rate which is some submultiple of the master clock.

The duty cycle will then vary between 0 and $63/64$ in its simplest form. This pulse rate is integrated by an averaging filter (usually RC) to produce a smooth dc output. The full scale is obviously dependent on the pulse height and this must be related back to a voltage reference, albeit only a regulated supply. This type of DAC* is often used for generating control voltages for voltage controlled amplifiers used for volume, brightness, color, and so forth (TV application), and it is possible to combine two 6-bit pulse width ratio outputs for 12-bit resolution (not accuracy) to drive voltage controlled oscillators, i.e., varactor tuners. This is one application (tuning) where nonmonotonicity can be acceptable.

ANALOG-TO-DIGITAL CONVERTERS

Analog-to-digital converters (ADCs) fall into three major categories: (a) direct converters; (b) DAC feedback; and (c) integrating.

Direct or “Flash” Converters

Flash converters have limited resolution but are essential for very high-speed applications. They also have the advantage of providing a continuous stream of the digitized value of the input signal, with no *conversion time*

6.24 INTEGRATED CIRCUITS AND MICROPROCESSORS

waiting period. They consist of a reference voltage which is subdivided by a resistor network and applied to the inputs of a set of comparators. The other inputs of the comparator are common to the input voltage. A digital encoder would then produce, in the case of a 3-bit converter, for example, a weighted 3-bit output from the eight comparator inputs. The method is highly suitable to video digitization and is usually integrated with a high-speed digital logic technology such as ECL or advanced Schottky TTL. Flash converters in monolithic form of up to 9-bit resolution have been built.

Feedback ADCs

Feedback ADCs use a DAC within a self-checking loop, i.e., a DAC is cycled through its operating range until parity is achieved with the input. The digital address of the DAC at that time is the required ADC output. Feedback ADCs are accurate with a reasonably fast conversion time. Their resolution limitations are essentially those of the required DAC cost, performance, and availability.

Feedback ADCs require a special purpose logic function known as a successive approximation register (SAR). The SAR uses an iterative process to arrive at parity with the ADC input voltage in the shortest possible time. It changes the DAC addresses in such a way that the amplitude of the input is checked to determine whether it is greater or smaller than the input on a bit sequential basis, commencing with the MSB. This implies continuous feedback from a comparator on the analog input and DAC output connected to the SAR.

Figure 6.2.8 shows a block diagram of a 10-bit ADC available on a single chip. The 10-bit DAC is controlled by a 10-bit SAR with an internal clock, and the DAC has an on-board reference. The digital output is fed through tristate buffers to ease the problems of moving data onto a bus-structured system. These are high impedance (blank) until the device is commanded to perform a conversion.

After the conversion time, typically $25 \mu\text{s}$ for this type of device, a data ready flag is enabled and correct data presented at the ADC output. An input offset control is provided so that the device can operate with bipolar inputs. Because of the nature of the conversion process, satisfactory operation with rapidly changing analog inputs may not be achieved unless the ADC is preceded by a simple and hold circuit.

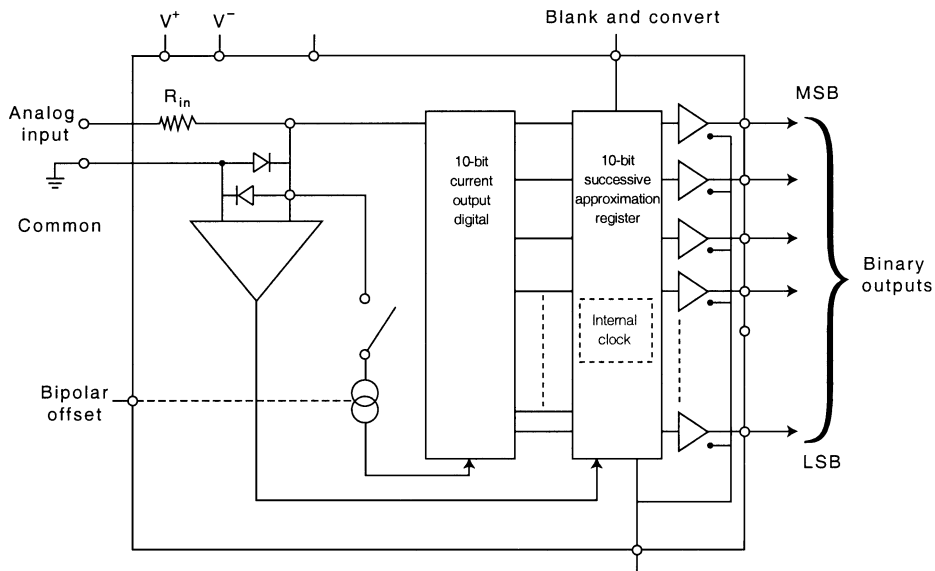

FIGURE 6.2.8 10-bit analog-to-digital converter.

Integrating ADCs

Integrating ADCs use a variety of techniques, but all usually display high resolution and linearity. They also have a much greater ability to reject noise on the analog input than other types of ADC. The penalty that is paid for this is a much longer conversion time which is also variable with actual input voltage. These factors make integrating ADCs very suitable for digital voltmeter, panel meter, and other digital measuring applications.

CHAPTER 6.3

MEMORY CIRCUITS

P. K. Vasudev, S. Tewksbury

DYNAMIC RAM

Dynamic RAM (DRAM) provides the highest density IC memory capacity of the various RAM/ROM technologies. With a market driven by the evolution of computers to higher performance products with increasingly powerful microprocessors (and correspondingly larger and faster main memory), the DRAM technologies are among the most sophisticated of the VLSI technologies. This section reviews the basics of DRAM circuits, drawing on the evolution from the earlier small DRAMs (1 kbit 3-transistor/cell memories to 64 kbit 1-transistor/cell memories) to more advanced DRAMs. Given the sophistication of contemporary DRAM ICs, it is not possible to describe in detail today's advanced technologies. However, it is important to recognize that advances other than the underlying transistor-level design and fabrication technology have played a substantial role in providing fast data transfers between the DRAMs and microprocessors.

DRAMs (like SRAMS and ROMS) are generally organized as an array of cells, each cell holding one bit of data. When an address of a data bit is applied, that address specifies which row (the row address part of the address word) of the array is to be selected and, given the row, which data element of the row is to be selected (according to the column address portion of the address word). Earlier DRAM technologies were designed to access a single data bit cell for a given input address, with a new address applied to access another data bit cell. The data bit is stored as a charge on a capacitor. To read that data bit, the row address is applied and the small output voltage from each cell of the row is connected to individual column lines. Each column line connects through a switch to the corresponding (e.g., N th) bit of each row and only the addressed row's switch is closed. The small signals from each of the selected row's cells are transmitted to a linear array of amplifiers, converting that small signal into a digital signal depending on whether charge was or was not stored on the cell's capacitor. In this sense, an entire row of the DRAM array is read at the same time and that entire row of data is available when the column address is applied. Earlier DRAM architectures selected one of these data bits as the desired output data, discarding the others. The inefficiency of this approach is clear and architectures have advanced to take advantage of the reading of an entire row of data. One approach was to retain the separate row and column addresses but to allow successive column addresses to be applied (without requiring a new read of the row) in order to select successive data bits already placed in the output stage (avoiding the delay time necessary to complete the reading of the row and amplification of the small signals from the cells of the row). However, the data transfer rates between the DRAM module and the microprocessor remained a substantial bottleneck to increased performance. Microprocessor architectures were advancing rapidly, including addition of cache memories to avoid, when possible, having to access the external DRAM to acquire instructions and data. With the advanced microprocessor architectures, a quite different approach became possible, greatly increasing the net data transfer rates between the DRAM module and the microprocessor. In particular, an entire row can be accessed by the row address and then, rather than reading individual bits of that row by applying a new column address each time, the entire row of data can be transferred to the microprocessor. Although somewhat simplified relative to the actual operation, the basic approach is as follows. A row

address is applied and the small signals corresponding to data stored in the cells of that row are passed to the amplifier array, generating digital signals that are loaded into a parallel-load/serial-shift register. Once loaded, the data in the shift register can be clocked out at a high data rate without requiring application of a new address. It is through this process that the very high data rates can be achieved. If the address of the row that will be needed next is known when the current row of data is being shifted out of the DRAM, that address can be applied so that the small signals from that next row are being transferred to the amplifiers and converted to digital signals—ready to be loaded into the register for shifting out as soon as the present data in the register have been shifted out.

This provides a fast transfer of data from the DRAM to the microprocessor. A corresponding approach allows fast data transfer from the microprocessor into the DRAM. To write data, data corresponding to a row are shifted into an input data register. When the register has been filled, its contents are loaded into a parallel data register and are available for writing into the row specified by the write address. While the data in that parallel data register are being written into the DRAM, the next data to be written can be shifted into the serial shift register. The basic approach discussed above has actually been in use for some time, appearing in video RAM. In that case, an entire row of a screen is loaded from memory into a parallel-in/serial-out data register of the read operation to read the row and an entire row of a screen is loaded into the serial-in/parallel-out data register of the write operation. While a row of a data image is being shifted out, another row of the data image can be loaded.

The above example of architectural approaches to relax performance bottlenecks (in this case the data transfers between DRAM and the microprocessor) illustrates an important principle that will increasingly characterize VLSI components. In particular, system-level solutions will increasingly define the functional characteristics of mainstream technologies such as DRAM and microprocessors, providing performance enhancements unachievable through purely technology and circuit design approaches.

Space prohibits detailed discussion of these architectural schemes, or the rather sophisticated techniques that have been used to miniaturize the surface area of the capacitance. However, the underlying principles are similar to earlier memory designs, as summarized below.

DRAM is the lowest-cost, highest-density RAM available. Since the 4k generation DRAM (dynamic RAM) has held a 4 to 1 density advantage over static RAM, its primary competitor. Dynamic RAM also offers low power and a package configuration which easily permits using many devices together to expand memory sizes. Today's computers use DRAM for main memory storage with memory sizes ranging from 16 kbytes to hundreds of megabytes. With these large-size memories, very low failure rates are required. The metal oxide semiconductor (MOS) DRAM has proven itself to be more reliable than previous memory technologies (magnetic core) and capable of meeting the failure rates required to build huge memories. DRAM is the highest volume and highest revenue product in the industry.

Cell Construction

The 1k and early 4k memory devices used the three-transistor (3-T) cell shown in Fig. 6.3.1. The storage of a "1" or a "0" occurred on the parasitic capacitor formed between the gate and source of transistors. Each cell had amplification thus permitting storage on a very small capacitor. Because of junction and other leakage paths the charge on the capacitor had to be replenished at fixed intervals; hence the name dynamic RAM. Typically a *refresh* pulse of a maximum duration was specified.

The next evolution, the 1-T cell, was the breakthrough required to make MOS RAM a major product. The 1-T cell is shown in Fig. 6.3.2. This is the 16k RAM version of the cell. The 4k is similar except that only one level of polysilicon (poly 1) is used. The two-level poly process improves the cell density by about a factor of 2 at the expense of process complexity. The transistor acts as a switch between the capacitor and the bit line. The bit line carries data into and out of the cell. The transistor is enabled by the word line, which is a function of the row address. The row address inputs are decoded such that one out of N word lines is enabled. N is the number of rows which is a function of density and architecture. The 16k RAM has 128 rows and 128 columns. The storage cell transistor is situated such that its source is connected to the capacitor, its drain is connected to the bit line and the gate is connected to the word line. Higher-density DRAMs today have evolved more sophisticated structures, involving trenches and stacked capacitors to continue meeting the requirements of the 1-T cell. By simultaneously driving down the cell size, while maintaining the required storage capacitance of

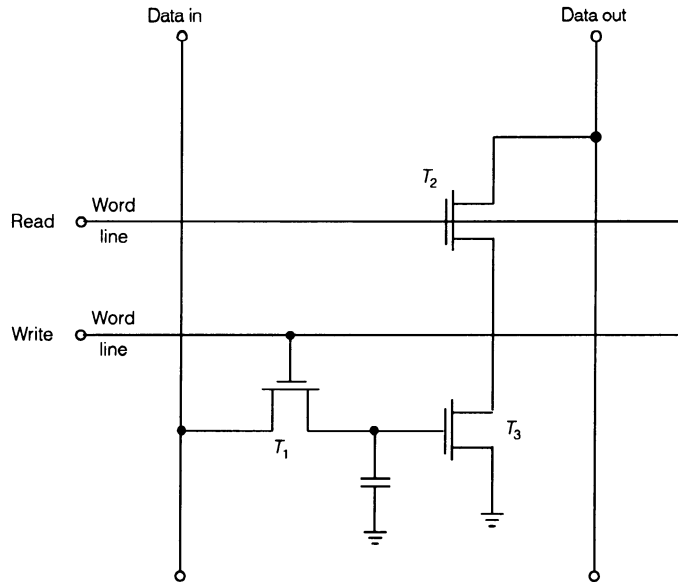

FIGURE 6.3.1 Dynamic RAM cell.

bit line, DRAMs have been able to sustain the steady increase in DRAM capacity, moving beyond the 1 GB level. This steady increase is expected to continue.

Cell Process

The principal process used in early generation DRAMs was the double-level polysilicon gate process. The process uses n -channel devices which rely on electron mobility. The 1k RAM (1103) used a p -channel process which relied on hole mobility. The p -channel process although simpler to manufacture (it is more forgiving to contamination) is by nature slower than the n -channel process (electrons are much faster than holes) and cannot operate a 5-V levels. Therefore once manufacturing technology advanced enough to permit n -channel to yield, it quickly displaced p -channel techniques for memory. Today the DRAM processes are extremely sophisticated, using trenches, stacked capacitors, and high-impedance dielectrics that allow densities in the 100-million gate level to be achieved. They typically use CMOS technology and power supplies as low as 1 V or so.

System Design Consideration Using Dynamic RAMs

Dynamic RAMs provide the advantages of high density, low power, and low cost. These advantages do not come for free; the dynamic RAM is considered to be more difficult to use than static RAMs. This is because dynamic RAMs require periodic refreshing in order to retain the stored data. Furthermore, although not generic to dynamic RAMs, most dynamic RAMs multiplex the address bits which requires more complex edge-activated multi-clock timing relationships. However, once the system techniques to handle refreshing, address multiplexing, and clock timing sequences have been mastered, it becomes obvious that the special care required for dynamic RAMs is only a minor inconvenience.

A synopsis of the primary topics of concern when using dynamic RAMs follows.

Address Multiplexing. The use of address multiplexing reduces the number of address lines and associated address drivers required for memory interfacing by a factor of 2. This scheme, however, requires that the RAM

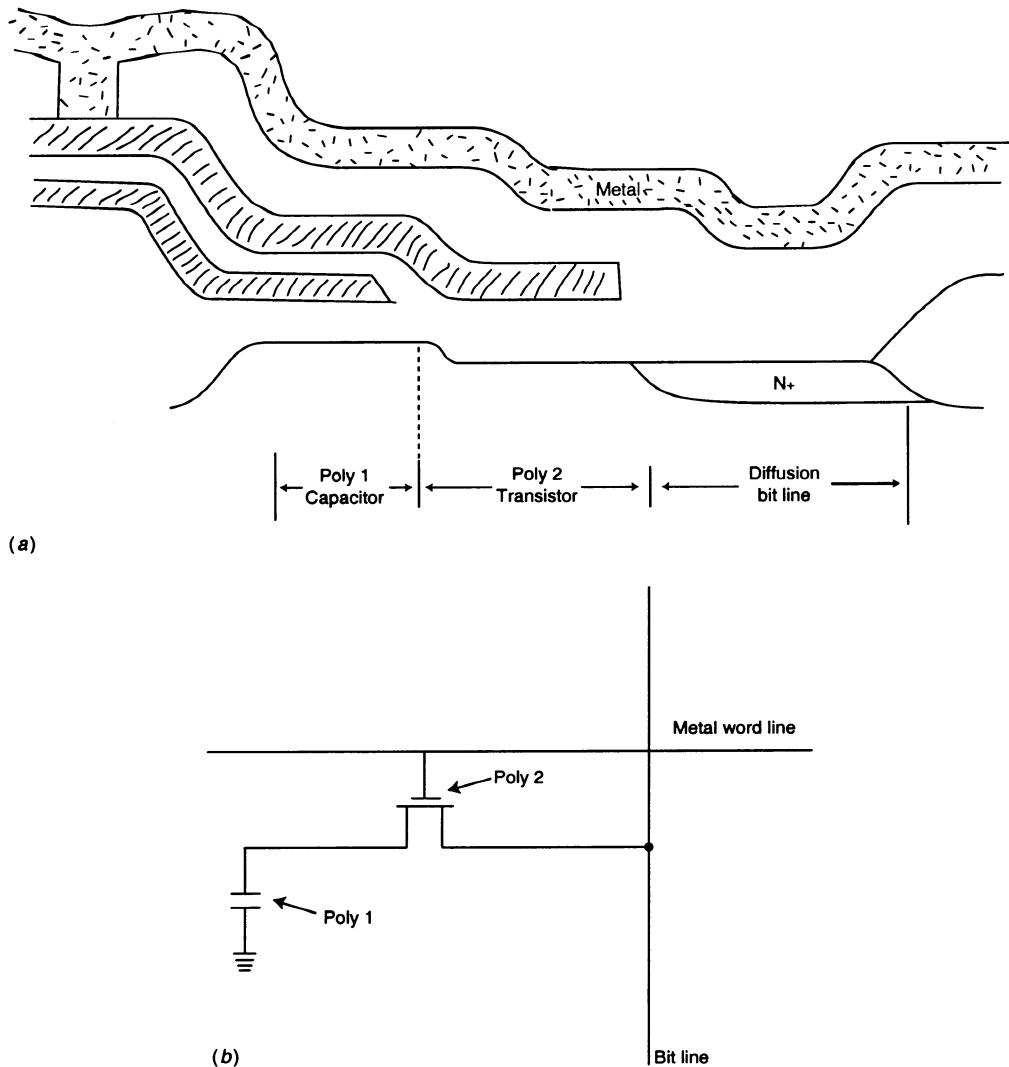

FIGURE 6.3.2 (a) DRAM cross section; (b) schematic of single-transistor cell DRAM.

address space be partitioned into an X - Y matrix with half the addresses selecting X or ROW address field and the other half of the address selecting the Y or column address field. The ROW addresses must be valid during the RAS clock and must remain in order to satisfy the hold requirements of the on-chip address latches. After the ROW address requirements have been met, the addresses are allowed to switch to the second address field, column addresses, a similar process is repeated using CAN (column address strobe) clock to latch the second (column) address field. Note, for RAS-only refreshing the column address field phase is not required.

Error Detection and Error Correction. In a large memory array there is a statistical probability that a soft error(s) or device failure(s) will occur resulting in erroneous data being accessed from the memory system. The larger the system, the greater the probability of a system error.

In memory systems using dynamic RAMs organized N by one configuration, the most common type of error-failure is single-bit oriented. Therefore, error detection and error correction schemes with limited detection/correction capabilities are ideally suited for these applications.

Single-bit detection does little more than give some level of confidence that an error has not occurred. Single-bit detection is accomplished by increasing the word width by 1 bit.

By adding a parity bit and selecting the value of this bit such that the 4-bit word has an even number of "1s" or an odd word number of "1s," complementing any single bit in the word no longer results in a valid binary combination. Notice that it is necessary to complement at least two bit locations across the word in order to achieve new or new valid data word with the proper number of "1s" or "0s" in the word. In order to extract the error information from the stored data word. This concept was introduced by Richard Hamming in 1950. The scheme of defining the number of positions between any two valid word combinations is called the "Hamming distance." The Hamming distance determines the detection/correction capability.

Correction/detection capability can be extended by additional parity bits in such a way that the Hamming distance is increased. Figure 6.3.2 shows how a 16-bit word with five parity bits (commonly referred to as "check bits") can provide single-bit detection and single-bit correction. In this case, a single-bit error in any location across the word, including the check bits, will result in a unique combination of the parity errors when parity is checked during an access.

As indicated above, the ability to tolerate system errors is brought at the expense of using additional memory devices (redundant bits). However, the inclusion of error correction at the system level has been greatly simplified by the availability of error correction chips. These chips provide the logic functions necessary to generate the check bits during a memory write cycle and perform the error detection and correction process during a memory ready cycle.

STATIC RAM

DRAM requires that the charge stored on the capacitance of the data cells be refreshed at a regular interval since the charge slowly leaks off through parasitic diodes. In addition, the signal provided by the cells when accessed is a small analog signal, requiring amplification and noise avoidance. These penalties are compensated by the requirement that only one transistor is needed for each memory cell. Static random access memory (SRAM) holds its data indefinitely, so long as power is applied to the memory. Each cell is essentially a flip-flop, set to logic "1" or "0" when written and providing a full-amplitude logic signal to the output stage. The number of transistors needed for this storage and to connect the flip-flop to the input and output data lines is typically six. With a regular digital signal provided when reading the SRAM, read delays are substantially smaller than in a DRAM, the fast access time justifying the smaller amount of data that can be stored on an SRAM IC (that lower storage capacity resulting from the larger number of cell transistors than needed in the DRAM). Several applications of this faster SRAM appear in a personal computer—including video memory, cache memory, and so forth. Since there is no need for special microfabrication steps to create the minimum area, large capacitance cells of the DRAM ICs, the SRAM can be fabricated on the same IC as standard digital logic. Although there have been demonstrations of the fabrication of microprocessors and DRAM on the same IC, the general need for more DRAM ICs than microprocessor ICs in a personal computer leads to no major advantage of this more complicated technology. On the other hand, the higher capacity of the DRAM memory technology may drive cointegration with logic circuitry for other applications requiring that higher-density RAM.

Just as in the case of the DRAMs discussed earlier, architectural principles are also a significant part of the SRAM IC design. With multiple levels of SRAM cache memory being used in contemporary microprocessor systems, the cache memories connected directly to the DRAM memory can draw upon some of the advantages of reading/writing entire rows of memory in parallel. Cache memories also generally require sophisticated algorithms to place memory from some real DRAM address location into a local RAM accessed with a different address. Translations and other system-level functions related to such needs can be embedded directly within the SRAM IC itself. As in the case of the DRAMs, space here does not permit a discussion of these advanced themes. However, the underlying principles of the basic SRAM cell are captured in the earlier technologies discussed next.

Organization

Static RAMs in the 1k ($k = 1024$) and 4k generations are organized as a square array (number of rows of cells equals the number of columns of cells). For the 1k device there are 32 rows and 32 columns of memory cells. For a 4096 bit RAM there are 64 rows and 64 columns. The RAMs of the seventies and beyond include on-chip decoders to minimize external timing requirements and number of input/output (I/O) pins. Today, much higher-density SRAMs are being built using the same basic array design, but employing scaled silicon structures.

To select a location uniquely in a 4096-bit RAM, 12 address inputs are required. The lower-order 64 addresses decode to select one column. The intersection of the selected row and the selected column locates the desired memory cell.

Static RAMs of the late seventies and early eighties departed from the square array organization in favor of a rectangle. This occurred for primary reasons: performance and packaging considerations.

Static RAM has developed several application niches. These applications often require different organizations and/or performance ranges. Static RAM is currently available in 1-bit I/O, 2-bit I/O, and 8-bit I/O configurations. The 1- and 4-bit configurations are available in a 0.3-in-wide package with densities of 1k, 4k, and 16k bits. The 8-bit configuration is available in a 0.6-in-wide package in densities of 8k and 16k bits. The 8-bit I/O device is pin compatible with ROM (read only memory) and EPROM (electrically programmable ROM) devices. All of the static RAM configurations are offered in two speed ranges. Ten nanoseconds typically are used as the dividing line for part numbering.

Construction

The static RAM uses a six-device storage cell. The cell consists of two cross-coupled transistors, two I/O transistors, and two load devices. There are three techniques that have been successfully employed for implementing the load devices: enhancement transistors, depletion transistors, and high-impedance polysilicon load resistors.

Enhancement transistors are normally off and require a positive gate voltage (relative to the source) to turn the device on. There is a voltage drop across the device equal to the transistors' threshold. Depletion transistors are normally on and require a negative gate voltage (relative to the source) to turn them off. There is no threshold drop across this device. Polysilicon load resistors are passive loads which are always on. Formed in the polylevel of the circuit they are normally undoped and have very high impedances (5000 M Ω typically). They have the advantage of very low current (nanoamperes) and occupy a relatively small area. All present large density, state of the art, static RAMs now use this technique for the cell loads. Further enhancements have been made by manufacturing a two-level polyprocess, thereby further decreasing cell area.

The operation of the polyload SRAM cell is shown in Fig. 6.3.3. The cross-coupled nature of the flip-flop is easily noticed.

Characteristics

Static RAM is typified by ease of use. This comes at the expense of a more complex circuit involving six or more transistors in a cross-coupled array. Thus, the total transistor count or density is four times higher than a DRAM.

The fundamental device is often referred to as a ripple through static RAM. Its design objective is ease of use. This device offers one power dissipation mode "on". Therefore its selected power (active power) is equal to its deselected power (standby power). One need simply present an address to the device and select it (via chip select) to access data. Note that the write signal must be inactive.

The address must be valid before and after read/write active to prevent writing into the wrong cell. Chip select gates the write pulse into the chip and must meet a minimum pulse width which is the same as the read/write minimum pulse width.

Read modify write cycles can be performed by this as well as other static RAMs. Read modify write merely means combining a read and write cycle into one operation. This is accomplished by first performing a read

FIGURE 6.3.3 Polyresistor load static RAM cell.

then activating the read write line. The status of the data out pin during the write operation varies among vendors. The product's data sheet therefore be read carefully.

The device achieves its ease of use by using very simplistic internal circuitry. To permit a nonsynchronous interface (no timing sequence required) all circuitry within the part is active at all times. That static "NOR" row decoder is typical of the circuitry used. For a 4k RAM with 64 rows, this circuit is repeated 64 times with the address lines varying to uniquely identify each row.

In the static row decoder, a row is selected when all address inputs to the decoder are low making the output high. The need to keep the power consumption of this decoder at a minimum is in direct conflict with the desire to make it as fast as possible. The only way to make the decoder fast is to make the pull-up resistance small so that the capacitance of the word line can be changed quickly. However, only one row decoder's output is high; while the output of each of the other 63 decoders is low, causing the resistor current to be shunted to ground. This means that the pull-up resistance must be large in order to reduce power consumption.

Application Areas

Static RAM applications are segmented into two major areas based on performance. Slower devices, greater than 40 ns access time, are generally used with microprocessors. These memories are usually small (several thousands of bytes) with a general preference for wide word organization (by 8 bit). When by 1 organized memories are used, the applications tend to be "deeper" (larger memory) and desire lower power or parity.

The by 4-bit product is an old design which is currently being replaced by $1k \times 8$ and $2k \times 8$ static RAM devices. Statics are used in these applications because of their ease of use and compatibility with other memory types (RAM, EPROM). The by 4 and by 8 devices use a common pin for data in and data out. In this configuration, one must be sure that the data out is turned off prior to enabling the data in circuitry to avoid a bus conflict (two active devices fighting each other drawing unnecessary current). Bus contention can also occur if two devices connected to the same bus are simultaneously on fighting each other for control. The by 8 devices include an additional function called output enable (OE) to avoid this problem. The output enable function controls the output buffer only and can therefore switch it on and off very quickly. The by 4 devices do not have a spare pin to incorporate this function. Therefore, the chip select (CS) function must be used to control the output buffer. Data out turns off a specified delay after CS turn off. One problem with this approach is that it is possible for bus contention to occur if a very fast device is accessed while a slow device is being turned off. During a read/modify/write cycle the leading edge of the read write line (WE) is normally used to turn off the data out buffer to free the bus for writing.

The second segment is high-performance applications. Speeds required here are typically 10–20 ns. This market is best serviced by static RAM because of their simple timing and faster circuit speeds. The requirement of synchronizing two “reads” as required in clocked part typically cost the system designer 10–20 ns. Therefore, fast devices are always designed with a ripple through interface. The by 1 devices have been available longer, and tend to be faster than available by 8 devices. As a result the by 1 device dominates the fast static RAM market today. Applications, such as cache and writable control store, tend to prefer wide word memories. The current device mix should shift over time as more suppliers manufacture faster devices.

Process

The pin-outs and functions tend to be the same for fast and slow static devices. The speed is achieved by added process complexity and the willingness to use more power, for a given process technology.

The key to speed enhancement is increasing the circuit transistor’s gain, minimizing unwanted capacitance, and minimizing circuit interconnect impedance. Advanced process technologies have been developed to achieve these goals. In general, they all reduce geometries (scaling) while pushing the state of the art in manufacturing equipment and process complexity. Figure 6.3.4 shows the key device parameters of MOSFET scaling, one of which is device gain. The speed of the device is proportional to the gain. Because faster switching

FIGURE 6.3.4 Cross section of submicron scaled CMOS gates for high-density SRAMs.

speeds occur with high gain, the gain is maximized for high speed. Device gain is inversely proportional to the gate oxide thickness and device length. Consequently, scaling these dimensions increases the gain of the device.

Another factor that influences performance is unwanted capacitance, which appears in two forms: diffusion and Miller capacitance. Diffusion capacitance is directly proportional to the overlap length of the gate and the source. Capacitance on the input shunts the high-frequency portion of the input signal so that the device can only respond to low frequencies. Second, capacitance from the drain to the gate forms a feedback path creating an integrator or low-pass filter which degrades the high-frequency performance.

One of the limits on device scaling is punch through voltage, which occurs when the field strength is too high, causing current to flow when the device is *turned off*. Punch through voltage is a function of channel length and doping concentration thus channel shortening can be compensated by increasing the doping concentration. This has the additional advantage of balancing the threshold voltage, which was decreased by scaling the oxide thickness for gain.

NONVOLATILE MEMORIES

DRAM and SRAM memories retain their data so long as power is applied but lose their data when the power is disrupted or turned off. In this sense, they are “volatile” memories. Nonvolatile memories retain their data even when the power is turned off. In the case of personal computers, the hard disk drive serves the essential “nonvolatile memory” function, in combination with a nonvolatile IC memory capable of starting the process of loading information from the hard drive into the computer system. The fundamental importance of nonvolatile IC memory can be seen by the rapid trend toward programmable components within many electronics applications not able to handle the inconvenience of an external hard drive. The term *embedded system* reflects this insertion of microprocessors into a vast range of applications. As one example, the microprocessor used to control a refrigerator requires storage of its *program*, a requirement that can be handled by a relatively simple programmable read only memory (PROM). Other applications of embedded systems require memories that can be written as well as read, with the additional requirement that the information written into the memory be preserved when power is removed. If this writing is very modest, then extensions of simple PROM ICs with slow write times is acceptable, as in the case of an electronic address book. But as the embedded systems have become more sophisticated and migrated closer to a personal computer in their general (not detailed) operation, the equivalent of a hard disk drive in IC form with not only fast reads but also fast writes becomes more important. To support such applications, there have been major advances in nonvolatile memory technologies recently, in several cases drawing on storage mechanisms quite different than those used in traditional LSI/VLSI components.

To illustrate the extent to which small embedded systems mimic larger personal computer systems, the example of the Motorola MC680xx 16/32-bit microprocessor can be used. This microprocessor (introduced in its initial version, the MC68000, in 1979 and requiring only about 68,000 transistors) was the processor that drove the early Apple computers. With today’s VLSI able to provide several hundred millions of transistors in a single IC, placing the MC68000 on a VLSI circuit would require only about 0.001 percent of the IC area (assuming 68 million transistors). Equivalently, 1000 MC68000 microprocessors could be placed on a single IC. In this sense, adding a microprocessor to a digital circuit intended for embedded applications is not a major consumer of IC resources. As such embedded systems (particularly those that embed an earlier generation personal computer in its IC) continue to advance into a wider range of applications, the demand for high-performance nonvolatile memories with high-speed read and write capabilities (as well as low-voltage write conditions) will increase. As noted earlier, SRAM (with cells that are basically flip-flops) can be fabricated on the same IC as logic circuits, a major advantage over DRAM in many applications. Nonvolatile memories that can be fabricated on the same IC as logic will also be of major importance as the underlying microfabrication technologies continue to advance, seeking system-on-a-chip or system-on-a-(few) chip (set) capabilities.

The field of advanced technologies for nonvolatile memories is in a state of flux and a variety of quite different technical approaches are under study. Underlying these new technologies and approaches there remains the basic principles of nonvolatile memory seen in the traditional PROM, EPROM, and EEPROM technologies that continue to play a major role in systems designs.

Mask-Programmed ROM

In mask-programmed ROM, the memory bit pattern is produced during fabrication of the chip by the manufacturer using a mask operation. The memory matrix is defined by row (X) and column (Y) bit-selection lines that locate individual memory cell positions.

ROM Process

For many designs, fast manufacturing turnaround time on ROM patterns is essential for fast entry into system production. This is especially true for the consumers' "games" market. Several vendors now advertise turnaround times that vary from 2 to 6 weeks for prototype quantities (typically small quantities) after data verification. Data verification is the time when the user confirms that data have been transferred correctly into ROM in accordance with the input specifications.

Contact programming is one method that allows ROM programming to be accomplished in a shorter period of time than with gate mask programming. In mask programming, most ROMs are programmed with the required data bit pattern by vendors at the first (gate) mask level, which occurs very early in the manufacturing process. In contact programming, actual programming is not done until the fourth (contact) mask step, much later in the manufacturing process. That technique allows wafers to be processed through a significant portion of the manufacturing process, up to "contact mask" and then stored until required for a user pattern. Some vendors go one step further and program at fifth (metal) mask per process. The results in a significantly shorter lead time over the old gate-mask programmable time of 8 to 10 weeks; the net effect is time and cost savings for the end user.

ROM Applications. Typical ROM applications include code converters, look-up tables, character generators, and nonvolatile storage memories. In addition, ROMs are now playing an increasing role in microprocessor-based systems where a minimum parts configuration is the main design objective. The average amount of ROM in present microprocessor systems is in the 10 to 32 kbyte range. In this application, the ROM is often used to store the control program that directs CPU operation. It may also store data that will eventually be output to some peripheral circuitry through the CPU and the peripheral input/output device.

In a microprocessor system development cycle, several types of memory (RAM, ROM, and EPROM or PROM) are normally used to aid in the system design. After system definition, the designer will begin developing the software control program. At this point, RAM is usually used to store the program, because it allows for fast and easy editing of the data. As portions of the program are debugged, the designer may choose to transfer them to PROM or EPROM while continuing to edit in RAM. Thus, he avoids having to reload fixed portions of the program into RAM each time power is applied to the development system.

Electrically Erasable Programmable ROM

The ideal memory is one that can perform read/write cycles at speeds meeting the needs of microprocessors and store data in the absence of power. The EEPROM (electrically erasable PROM) is a device which meets these requirements. The EEPROM can be programmed in circuit and can selectively change a byte of memory instead of all bytes. The process technology to implement the EEPROM is quite complex and the industry is currently on the verge of mastering production.

EEPROM Theory. EEPROMs use a floating gate structure, much like the ultraviolet erasable PROM (EPROM), to achieve nonvolatile operation. To achieve the ability to electrically erase the PROM, a principle known as Fowler-Nordheim tunnelling was implemented. Fowler-Nordheim tunnelling predicts that under a field strength of 10 MV cm^{-1} a certain number of electrons can pass a short distance, from a negative electrode, through the forbidden gap of an insulator entering the conduction band and then flow freely toward a positive electrode. In practice the negative electrode is a polysilicon gate, the insulator is a silicon dioxide and the positive electrode is the silicon substrate.

FIGURE 6.3.5 EEPROM cell using Fowler-Nordheim tunnelings.

Fowler-Nordheim tunnelling is bilateral, in nature, and can be used for charging the floating gate as well as discharging it. To permit the phenomenon to work at reasonable voltages (e.g., 20 V), the oxide insulator needs to be less than 200 Å thick. However, the tunnelling area can be made very small to aid the manufacturability aspects (20-nm oxides are typically one-half the previously used thickness).

Intel Corporation produces an EEPROM based on this principle. Intel named the cell structure FLOTOX. A cross section of the FLOTOX device is shown in Fig. 6.3.5.

The FLOTOX structure resembles the original structure used by Intel for EPROM devices. The primary difference is in the additional tunnel-oxide region over the drain. To charge the floating gate of the FLOTOX structure, a voltage V_G is applied to the top gate and with the drain voltage V_D at 0 V, the floating gate is capacitively coupled to a positive potential. Electrons will then flow to the floating gate. If a positive potential is applied to the drain and the gate is grounded, the process is reversed and the floating gate is discharged.

The EEPROM designs introduced today are configured externally to be compatible with ROM and EPROM standards which already exist. Devices typically use the same 24-pin pin-out as the generic 2716 ($2k \times 8$ EPROM) device. A single 5 V supply is all that is needed for read operations. For the write and clear operations, an additional supply (V_{pp}) of 20 V is necessary. The device reads in the same manner as the EPROM it will eventually replace.

EEPROM Applications. The EEPROM has the nonvolatile storage characteristics of core, magnetic tape, floppy, and Winchester disks but is a rugged low-power solid-state device and occupies much less space. Solid-state nonvolatile devices, such as ROM and EPROM, have a significant disadvantage in that they cannot be deprogrammed (ROM) or reprogrammed in place (EPROM). The nonvolatile bipolar PROM blows fuses inside the device to program. Once set the program cannot be changed, greatly limiting their flexibility. The EEPROM, therefore, has the advantages of program flexibility, small size, and semiconductor memory ruggedness (low voltages and no mechanical parts).

The advantages of the EEPROM create many applications that were not feasible before. The low power supports field programming in portable devices for communication encoding, data formatting and conversion, and program storage. The EEPROM in circuit change capability permits computer systems whose programs can be altered remotely, possible by telephone. It can be changed in circuit to quickly provide branch points or alternate programs in interactive systems.

The EEPROMs nonvolatility permits a system to be immune to power interruptions. Simple fault tolerant multiprocessor systems also become feasible. Programs assigned to a processor that fails can be reassigned to the other processors with a minimum interruption of the system. Since a program can be backed up into EEPROM in a short period of time, key data can be transferred from volatile memory during power interruption and saved. The user will no longer need to either scrap parts or make service calls should a program bug be discovered in fixed memory. With EEPROM this could even be corrected remotely. The EEPROM's flexibility will create further applications as they become available in volume and people become familiar with their capabilities.

Erasable Programmable ROM

The EPROM like the EEPROM satisfies two of our three requirements. It is nonvolatile and can be read at speeds comparable with today's microprocessors. However, its write cycle is significantly slower, like the EEPROM. The EPROM has the additional disadvantage of having to be removed from the circuit to be programmed as contrasted to the EEPROM's ability to be programmed in circuit.

EPROM is electrically programmable, then erasable by ultraviolet (UV) light, and programmable again. Erasability is based on the floating gate structure of n - or p -channel MOSFET. This gate, situated within the silicon dioxide layer, effectively controls the flow of current between the source and drain of the storage device. During programming, a high positive voltage (negative if p -channel) is applied to the source and gate of a selected MOSFET, causing the injection of electrons into the floating silicon gate. After voltage removal, the silicon gate retains its negative charge because it is electrically isolated (within the silicon dioxide layer) with no ground or discharge path. This gate then creates either the presence or absence of a conductive layer in the channel between the source and the drain directly under the gate region. In the case of an n -channel circuit, programming with a high positive voltage depletes the channel region of the cell; thus a higher turn-on voltage is required than on an unprogrammed device. The presence or absence of this conductive layer determines whether the binary 1 bit or the 0 bit is stored. The stored bit is erased by illuminating the chip's surface with UV light. The UV light sets up a photocurrent in the silicon dioxide layer which causes the charge on the floating gate to discharge into the substrate. A transparent window over the chip allows the user to perform erasing, after the chip has been packaged and programmed, in the field.

Programmable ROM

This PROM has a memory matrix in which each storage cell contains a transistor or diode with fusible link in series with one of the electrodes. After the programmer specifies which storage cell position should have a 1 bit or 0 bit, the PROM is placed in a programming toll which addresses the locations designated for a 1 bit. A high current is passed through the associated transistor or diode to destroy (open) the fusible link. A closed fusible link may represent a 0 bit, while an open link may represent a 1 bit (depending on the number of data inversions done in the circuit). A disadvantage of the fusible-link PROM is that its programming is permanent; that is, once the links are opened, the bit pattern produced cannot be changed.

Shadow RAM

A recently introduced RAM concept is called the shadow RAM. This approach to memory yields a nonvolatile RAM (data are retained even in the absence of power), by combining a static RAM cell and an electrically erasable cell into a single cell. The EEPROM shadows the status RAM on a bit-by-bit basis. Hence the name shadow RAM. This permits the device to have read/write cycle times comparable to a static RAM, yet offer nonvolatility.

The nonvolatility has a limit in that the number of write cycles is typically 1000 to 1 million maximum. The device can, however, be read indefinitely. Currently two product types are offered. One permits selectively recalling bits stored in the nonvolatile array, while the other product recalls all bits simultaneously.

Typical memory subsystems used in computers employ a complex combination of dynamic RAMs, static RAMs, and nonvolatile ROMs.

CHAPTER 6.4

MICROPROCESSORS

S. Tewksbury

INTRODUCTION

This chapter reviews microprocessors, ranging in complexity and performance from 8-bit microprocessors widely used in embedded systems applications to very high performance 32- and 64-bit microprocessors used for powerful desktop, server, and higher-level computers. The history of the evolution of microprocessor architectures is rich in the variety of hardware/software environments implemented and the optimization of architectures for general-purpose computation. A variety of simple 8-bit microprocessors introduced over 30 years ago continue to thrive, adding to the basic microprocessor architecture a variety of other analog and digital functions to provide a *system-on-a-chip* solution for basic, intelligent products. These include digital cameras, electronic toys, automotive controls, and many other applications. These applications represent cases in which the programmable capabilities of microprocessors are embedded in products to yield “intelligent modules” capable of performing a rich variety of functions in support of the application. Many of these applications are intended for portable products (such as cameras) where battery operation places a premium on the power dissipated by the electronics.

Starting from the early 8-bit microprocessors, most manufacturers (Intel, Motorola, and so forth) followed a path of evolutionary development driven by the exponentially increasing amount of digital logic and memory that could be placed on a single IC. The class of microprocessor generally called *microcontroller* made use of the additional circuitry available on an IC to integrate earlier external circuitry directly onto the microcontroller IC. For example, 8-bit microcontrollers based on the Motorola 6800 and Intel 8085 8-bit microprocessors have evolved to include substantial nonvolatile memory (able to hold programs without power), significant internal RAM (above to provide storage for data being manipulated), digital ports (e.g., serial ports, parallel ports, and so forth) to the external world, and various analog circuit functions. Among the analog circuit functions are analog-to-digital and digital-to-analog converters, allowing the microcontroller to capture information from sensors and to drive transducers. With increasing circuitry per IC, functions such as the analog-to-digital converters have evolved into more complex components—for example, allowing a multiplicity of different analog input signals to be converted into digital signals using an analog multiplexing circuit and allowing programmable gain to amplify the incoming analog signal to levels minimizing the background noise included in the digital signal.

As the density of VLSI ICs has increased, earlier microprocessors requiring the full IC area have become smaller in area required. The 8- and 16-bit controllers can now be embedded in VLSI ICs to extend many of today’s applications to “intelligent” systems. This embedding of microprocessor cores into other digital circuit functions has extended to the area of programmable logic (general-purpose arrays to logic that can be user programmed to perform a custom function). For example, Altera programmable logic ICs includes IP (Intellectual Property) cores such as a 200 MHz 32-bit ARM9 core processor along with embedded RAM cores. Similar capabilities exist for other manufacturers of programmable logic. Today, the combination of programmable logic allows a user to efficiently implement custom logic functions of considerable complexity (i.e., the Xilinx Virtex family of programmable logic provides 8 million gates and can operate at a 300 MHz clock rate) while

including the familiar functionality of well-established microprocessors for overall control. As the VLSI technologies continue to advance, the more powerful microprocessors of today will eventually migrate into these embedded applications as even more powerful microprocessors emerge for the desktop/laptop computer market.

Another evolutionary path was to create increasingly powerful microprocessors for applications such as desktop computers. Drawing power directly from a plug, minimizing power dissipation is less a priority (aside from the inevitable side issue of heating due to power dissipation). Instead, raw computing performance is the objective. Having to provide connections among integrated circuits to handle different peripheral functions (floating point arithmetic units, modules managing memory access through cache and other techniques, image processing modules, and so forth) can create a substantial performance barrier because of data transfer rate limitations. Migrating such peripheral functions essential to the basic computer operation can greatly improve the performance of the overall computer (microprocessor and peripherals). As an example, the evolution of the Motorola 68000 family starts with the basic MC68000. It then progressed to the MC68010, to the MC68020, to the MC68030, to the MC68040, and beyond not by changing the core microprocessor architecture greatly but rather by moving “onto the chip” such functions as the floating point accelerator, the memory management unit, virtual memory control, cache memory to reuse data/instructions loaded from RAM, and so forth.

The greater computational power of these early 16/32-bit microprocessors (such as the Motorola MC68000) is attractive in many embedded applications. As a result, microcontrollers have evolved beyond the 8-bit microprocessor cores to include these classical 16/32-bit microprocessor cores. At the same time, the microcontrollers retain the integration of other peripherals that support the applications (such as automotive and entertainment) into which they are embedded.

Returning to the microprocessors used for desktop computers, workstations, servers, and so forth, more recent advances have challenged and overcome many limitations that were once considered fundamental. Microprocessors such as the Pentium introduced in 2001–2002 operate at clock rates well above 1 GHz, a clock rate that was deemed unrealizable not long ago. Figure 6.4.1 shows the evolution of clock rates for Intel microprocessors. A high-end microprocessor recently demonstrated by Intel operates with voltages near 1 V

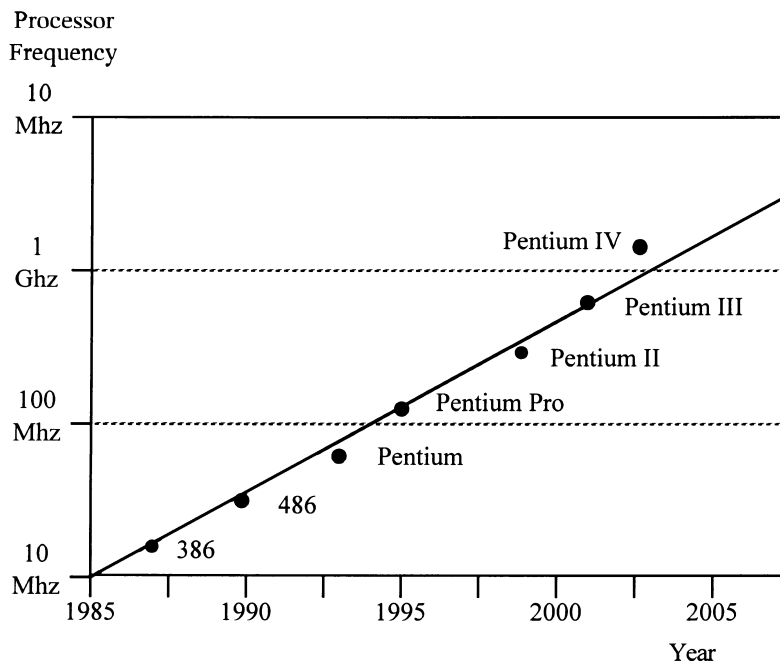

FIGURE 6.4.1 Clock rates of Intel Microprocessors. (From R. Ronen et al., “Coming Challenges in Microarchitectures and Architecture,” 2001.)

and at power levels of over 100 W. That corresponds to currents of 100 A or greater. To respect how large this current is, not that most homes have 100 A or 200 A services to operate the entire house. Today's high-end microprocessors employ well over 100,000,000 transistors on a single integrated circuit not much larger than a few square centimeters. Internally, the architectures have become sufficiently sophisticated that the hardware/firmware providing operating system functions are a fundamental part of the microprocessor. The architectures themselves have become highly refined.

The IBM Power4 microprocessor's basic description illustrates this sophistication. With 170 million transistors, the Power4 microprocessor is a 64-bit microprocessor operating at frequencies greater than 1 GHz, using an eight-instruction-wide design with superscalar operation and out-of-order execution of instructions. More than 200 instructions can be pending completion in each of the two on-chip processor cores.

Programming these contemporary microprocessors requires sophisticated programming support tools and generally require that programs be written in higher-level programming language (such as C++). Programming basic programs in assembly language is virtually impossible.

In a very real sense, microprocessors have become ubiquitous throughout our technologically driven society. Dozens appear in an automobile, invisible to the owner but providing the intelligence and control that are at the heart of the advanced automotive systems. Portable video game players contain some of the most remarkable microprocessors available, supporting advanced visualization in the palm of your hand.

CMOS Technology

Digital circuits today are based on complementary MOS (CMOS), CMOS having emerged as a preferred technology for a variety of reasons, perhaps the most important being the low dc power dissipation provided. Despite the dominance of pure CMOS, a hybrid version of CMOS and bipolar devices (called BiCMOS) has been developed to provide the advantages of low power in CMOS with the capabilities of high speed in bipolar circuits. Such BiCMOS technologies are used, for example, in the Intel Pentium microprocessors.

Digital electronics used a standard +5 V supply voltage over several generations, driven in part by the earlier dominance of bipolar circuits. With the migration to a dominance of CMOS, lower voltage operation has been possible and supply voltages have been decreasing significantly over the past decade. Initially, voltages were decreased to 3.3 V, with subsequent advances leading to further reductions to voltages of about 1 V. These reductions in supply voltage provide substantial performance advantages. For example, the lower voltage leads to a lower power consumption per device, an important reduction for holding overall chip power dissipations within acceptable limits as the number of devices per chip has increased. In addition, the steady decrease in feature sizes leads to cases in which the electric fields within the IC increase if the voltages are not reduced. Reduction of supply voltage in combination with reductions in feature sizes has helped prevent excessive electric fields and their associated effects. Beyond the simple reduction of externally provided supply voltage, contemporary microprocessor chips have evolved to include sophisticated internal power management subsystems—generating internal voltages as needed as well as allowing selective turning off of various sections of the system to reduce power consumption. Although voltage levels have decreased over the past several years, today's advanced, high-performance microprocessors require remarkably high current supplies (several tens of amps up to 100 A or higher). These high currents present complications associated with voltage losses along power interconnections within the IC because of the nonzero resistance of those lines and voltage drops due to that resistance. Such complications have led to specialized metalization layers for distribution of power throughout the IC.

The trends toward very high performance microprocessors are quite visible through their impact on successive generations of personal computers. Less visible have been the dramatic advances in microprocessor based systems intended for embedded applications (e.g., microprocessors embedded in automobiles, in audio equipment, in toys, and so forth). Microprocessor architectures from earlier generations of microprocessors provide the core computing power for these embedded applications while the addition of a wide range of peripheral functions (including analog input and output) have provided essentially single-chip solutions for intelligent embedded systems. In contrast to high-performance desktop computers, which receive power from a wall plug, these embedded applications often receive their power from batteries. Minimization of power dissipation is essential to provide long battery life.

These two application areas have led to two distinct roadmaps for future generation technologies—one roadmap for the high-performance microprocessors and another roadmap for the battery-powered, lower-performance microprocessors. The roadmap generated at regular intervals by the Semiconductor Industry Associates (SIA) organization provides not only a perspective on the current state of the technologies but also on the planned progression of those technologies over the next 10 years. The roadmaps can be viewed at the SIA website.

General Overview

Contemporary microprocessors include many of the functions that in earlier generation computers were implemented on separate integrated circuit chips. In addition, their architectural designs have become highly sophisticated, supporting not only routine user programs but also the underlying operating system associated with the computers. To provide a basic overview of computer architectures, the basic architecture of earlier generation systems implementing the computer on one or more PC boards, rather than on a single integrated circuit, is used here. The reader is advised, however, that far more sophisticated systems have replaced these earlier generation systems.

Figure 6.4.2 illustrates a typical multichip computer based on the earlier generation Intel microprocessors and peripheral chips. The role of the various blocks is as follows.

Processor. The block labeled “processor” was one of the earlier generation microprocessors (e.g., 8088 and higher generations). The internal processor architecture is discussed in the next section. In general, the processor manages the operation of the entire system, communicating with the peripheral functions using a “system bus” shown as the horizontal line. This system bus includes parallel wires (address lines) to select the peripheral and an internal data storage item in the peripheral (or memory), parallel wires (data lines) to transfer data to and from the peripherals and memory, a read/write line to specify whether data are being transferred to or from the microprocessor, and interrupt line(s) allowing external peripherals to “interrupt” the currently

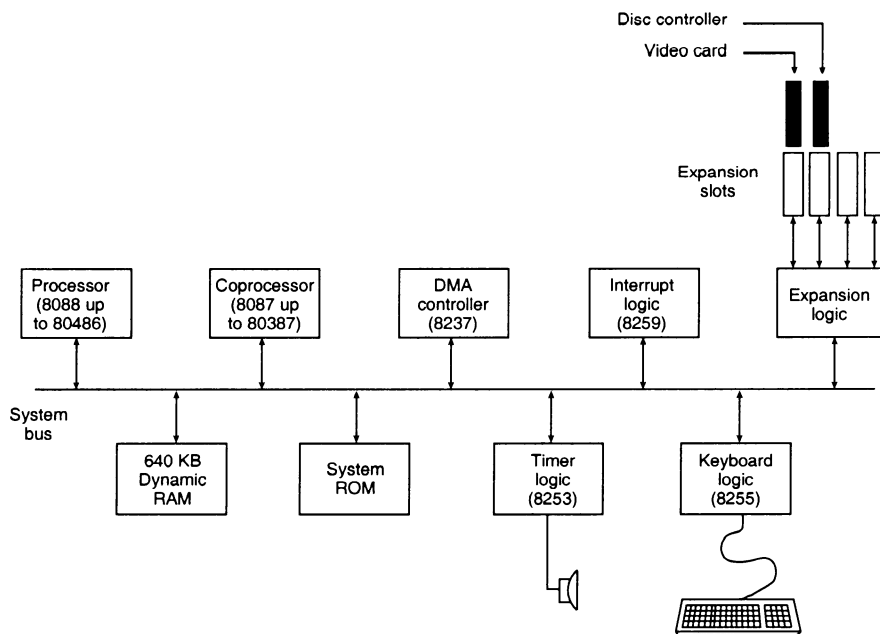

FIGURE 6.4.2 Block diagram of a typical PC motherboard.

executing program to allow the peripheral to communicate at its request with the microprocessor. The bus also includes other lines for functions such as providing resets and clocks.

Dynamic RAM. The dynamic RAM (640k shown, corresponding to the DOS system RAM capacity in those earlier computers) provides storage of both data and instructions. To access a particular item in the RAM, the address lines provide the location of the specific information involved in the data transfer. Today's RAM is far larger than the 640k shown, with standard personal computer memory capacities approaching 1 Gbyte.

System ROM. This nonvolatile memory provides the startup information needed to start the computer in a desired state. During startup, special logic in the processor accesses this startup information.

Disk Controller. The external disk hard drive stores user programs, operating systems, and other information, retained when the power is turned off. The disk controller manages the exchange of data between the microprocessor system (and its RAM) and the disk drive. There has been a substantial evolution in the philosophy and technologies of disk controllers over the past two decades, evolving from manufacturer specific controllers to standardized controller functions and data interfaces. Today's computer systems employ disk drives of substantial capacity (tens to hundreds of Gbyte capacity). The technologies used in contemporary disk drives have advanced dramatically in parallel with the advances in VLSI technologies, providing not only much larger capacities but also smaller and more rugged drives.

Cache Memory. Although the speeds of microprocessors have increased dramatically, memory components have seen a less dramatic increase. Memory access times (DRAMs) are typically several tens of nanoseconds. With microprocessor clock rates having increased to 1GHz and higher, a read or write of external memory can take the microprocessor about 50 to 100 clock cycles. Static RAMs have substantially faster response times, but have lower data storage capacities per IC. This has led to the introduction of "staged" memories, with instructions (and in some cases data) transferred from the slow DRAM into fast SRAM where the instructions (and data) can be retrieved more quickly. If an instruction is reused (and in the case of a loop instruction sequence) or data are reused (as in several computational algorithms), the second use of the instruction (data) is more quickly retrieved from the SRAM. Rather sophisticated algorithms are used to decide when information in a cache can be replaced by new information and to search the cache for instructions (content-addressable memories). Contemporary microprocessors have included one or more stages of cache within the IC. First-level caches are smaller than second-level caches, but significantly faster (two to three cycles for first-level cache versus six to 10 cycles for the second-level cache).

Video Card. The video card provides access to the display of the computer. As in all other components, video displays have seen dramatic improvements over the past 20 years, including not only the transition to high-resolution color displays but also to flat panel displays such as used with laptop computers. The expectations of the display drivers (hardware and software) have increased sufficiently that video cards continue to play a major role in the performance of the overall computer system.

Interrupt Logic. While the processor is in control, it determines to whom it will talk and is oblivious to any needs originating at a peripheral. For example, the serial port of the computer may receive data (e.g., through a modem) and the processor must be made aware that there are data to be read before the next data byte is received by the serial port. Interrupts provide the mechanism through which the peripherals can "interrupt" the processor's current activities and request that it handle requests originating in the peripherals. The "8259" shown for the interrupt logic is a classic integrated circuit included on computer board to interface interrupts from the peripherals for presentation to the processor. The interrupts ask the microprocessor to interrupt its operation and service the peripheral requesting service. The microprocessors allow external inputs to be turned on or off. When an interrupt occurs, the software program branches to a predetermined location where commands determine which peripheral generated the interrupt and then to a location where the program handles the needs of the interrupting peripheral.

Keyboard Logic. The "8255" component shown for interfacing the computer to a keyboard was also an integrated circuit designed specifically for this purpose.

DMA Controller. The direct memory access controller provides a high-speed means of streaming data to and from the computer's RAM. When active, this replaces the normal single word at a time operations provided by the processor across the system bus.

Coprocessor. The capabilities of operations performed by the microprocessor is limited by the number of transistors available, leading to cases in which some desired operations on data that would normally be provided by the processor must be performed instead by an auxiliary integrated circuit. The classic example was floating point computations, since the standard microprocessor's arithmetic unit was designed to operate only on integers. Addition of the coprocessor allowed floating point instructions to be added to the instruction sets, the data being exchanged between the microprocessor and the floating point coprocessor (bypassing the internal arithmetic unit of the microprocessor) for fast hardware execution. The alternative is a slower sequence of instructions executed within the microprocessor to perform the floating point computations as a program. Like many of the other peripherals shown, such floating point coprocessors have migrated into the microprocessor IC. This has led to contemporary architectures with multiple arithmetic units and an ability to execute more than one arithmetic function at a time. This ability is actually employed, and contributes to the ability of microprocessors to execute (on average) one instruction for each clock period.

Timer. The timer function (shown as the earlier 8253 integrated circuit) allows a variety of timing functions to be performed. These include measuring time, generating timing pulses for various peripherals, and so forth.

Not Shown. Not shown in Fig. 6.4.2 are several other peripheral functions such as serial ports for modems and parallel ports for printers. Specialized integrated circuits were also developed to handle these peripheral ports and have evolved over time to include several types of peripheral ports (USB, Firewire, RGB TV, SCSI, and several others). These "standardized" interfaces allow components from different manufacturers to be used in combination with different computers and have played a substantial role in the availability of a rich set of reasonably priced peripherals.

Microprocessor Architecture

Next, the basic internal architecture of the processor shown in Fig. 6.4.2 is discussed. Again, it is necessary to review the general architecture from the perspective of earlier generation microprocessors because of the great complexity of today's high-end microprocessors. Figure 6.4.3 shows the general architecture of an elementary microprocessor. Such architectures are typical of the 8-bit microprocessors used in microcontrollers.

The microprocessor's internal bus is shown as an address bus and a data bus, extending to the external peripherals as shown in Fig. 6.4.2. The data bus "width" (number of parallel wires) defines the size of the data/instruction unit transferred into and out of the microprocessor. Typically, this data bus width also defines the type of microprocessor. An 8-bit microprocessor has an 8-bit data bus, a 16-bit microprocessor has a 16-bit data bus, and so forth. In the case of the microprocessor reading an instruction from the external memory, the data bus width also constrains the number of instructions available. The basic sequence of operations in performing an instruction includes first the reading of the instruction itself, then the reading of any constants associated with the instruction (e.g., numerical constants, address offsets, and so forth) and then, if the data for the instruction is stored in memory, the memory locations where these alterable data items are stored. With an 8-bit data bus, the first instruction item can represent up to 256 instructions, normally setting the limit on the number of instructions in the microprocessor's instruction set. With a 16-bit data bus, the first instruction can represent up to 64,000 instructions (allowing a rich instruction set or an organization of the instruction op code and operand information in a highly efficient manner, as in the Motorola 68000 processor family).

The width of the address bus defines the amount of memory data storage supported. In 8-bit and 16-bit microprocessors, the width of the address bus was twice that of the data bus. For example, an 8-bit microprocessor would have a 16-bit address bus, able to address $2^{16} = 65,536$ (equal to "64K" in computer jargon) memory locations. More memory can be addressed (as in the PC example in Fig. 6.4.2 using "memory banks," essentially an external selection of which set of a multiplicity of 64K memory units is accessible through the address bus. A 16-bit microprocessor with a 32-bit address bus is able to directly address $2^{32} = 4.3$ billion memory locations.

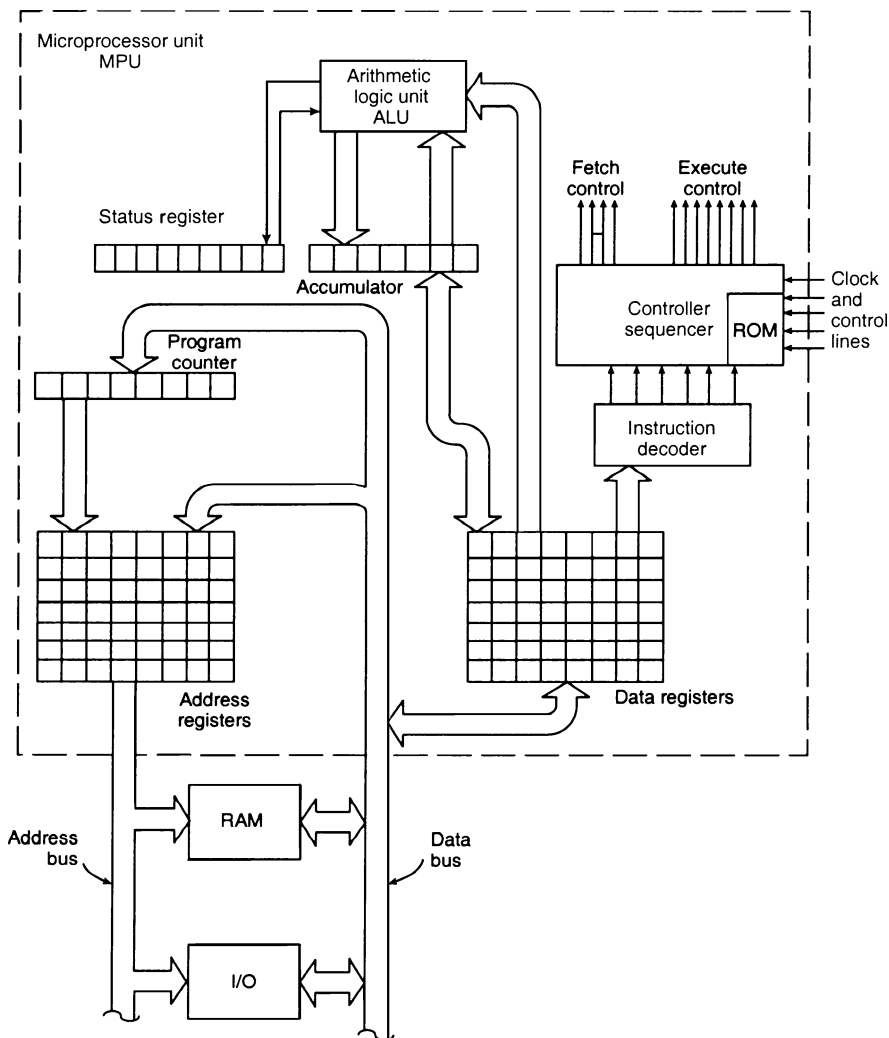

FIGURE 6.4.3 Architecture of an elementary microprocessor.

The internal logic units of the microprocessor shown in Fig. 6.4.3 provide the following functions.

Arithmetic Logic Unit. The arithmetic logic unit (ALU) can perform a variety of arithmetic and logic functions on data inputs (either on two input data items or on a single input data item). Standard arithmetic functions are add, subtract, multiply, and divide. Logic functions include the bit-wise AND, OR, XOR functions. These are also functions allowing the data word to be shifted in position. The specific operation to be performed is determined by input control signals generated by the controller. If a given ALU function requires more than one clock period (e.g., the multiply operation), then the controller/sequencer controls the multiple addition steps to complete the multiplication using a single multiply instruction.

Figure 6.4.3 shows a register receiving the output of the ALU and feeding that output back into the ALU during the next cycle. This provides, for example, an efficient means of adding a long string of numbers—this particular function leading to the name “accumulator” associated with the register.

Microprocessors initially used a single arithmetic unit. However, many programs would allow more than one arithmetic operation to be performed at the same time. By including multiple arithmetic units (perhaps different types of arithmetic units or other functions), more than one execution cycle can be launched at the same time. Such architectures are known as superscalar architectures and have become standard in 32-bit and higher microprocessors. The superscalar architectures, combined with high-performance cache memories and pipelined techniques can execute more than one instruction per clock cycle. For example, the Motorola PowerPC G4 microprocessor supports 1064 MB/s data rates and executes up to 16 simultaneous instructions per clock cycle.

Status Register. The status register is closely associated with the arithmetic logic unit and holds information regarding the data. This information is extracted by analyzing the data, deciding, for example, whether the number is zero, whether the number is negative, whether a carry or borrow state was generated from the high-end of the data in the operation, whether the result is an overflow (larger than the maximum number allowed), and so forth. This information is used most often in establishing the condition in conditional instructions (e.g., the assembly language equivalent of “if the number is negative then do this”).

Instruction Decoder and Controller/Sequencer. The instructions are stored as binary data words (e.g., 8-bit data for an 8-bit microprocessor) in memory, using binary codes to represent the specific task to be performed in completing the reading of the instruction (if a multiword instruction) and carrying out the operation to be performed on the instruction. This binary code must be decoded and then provided to a sequential logic circuit that can generate the various electronic signals to control the various components within the microprocessor. For example, if the instruction says to add the number 10 to the number stored in the accumulator, then the first instruction defines the operation (addition) and the data to be used. The number 10 would be stored in memory along with the instruction so a second read of the memory would be required (for an 8-bit microprocessor). Following the reading of the number 10 into the microprocessor, the controller/sequencer would apply the two data items to the arithmetic unit and tell the ALU to perform an operation. Then, the controller/sequencer would transfer the result to the location specified in the instruction. Although sounding like a complex task, the controller/sequencer can be efficiently implemented using efficient realizations for the basic set of stored information and feedback through registers to sequence the current state to the next state until the entire instruction has been executed.

Data Registers and Address Registers. Figure 6.4.3 shows two banks of registers, one the set of data registers and the other the set of address registers. The distinction between the data and address notations is largely based on the use of address registers to provide part of a memory address (e.g., the base address of a large table). Otherwise, the registers are similar and provide the function of “scratch pad” storage on the microprocessor chip. By taking data inputs to the ALU from these registers (and storing results from the ALU into these registers for later reuse), the delays associated with transferring data to and from external memory are avoided. As an example of the use of this scratch pad data storage, consider the following three instructions: (a) $X = B + C$, (b) $Y = D + E$, and (c) $Z = X * Y$. Upon completion of the first instruction, the value of X could be stored in data register D0. On completion of the second instruction, the value of Y could be stored in data register D1. Then at some later instruction, instruction (c) could be performed by retrieving the values of X and Y stored in the data registers D0 and D1. An example of using the address registers to generate addresses is illustrated by the example of addressing external memory to obtain successive components of a vector $V(j)$. The address (base address) of the first component $V(0)$ could be stored in address register A0. Then, the ALU/accumulator can be used to generate the sequence 0, 1, 2, By using the so-called indexed addressing mode, the address in A0 and the number from the ALU are added without having to perform an explicit addition instruction in the ALU.

Program Counter. The program counter is a counter that is automatically incremented after each instruction has been retrieved from the external RAM so that the number in the counter is the address for the start of the next instruction. This automatic incrementing reflects the typical case of instructions being executed in sequence. In the case when the program jumps to some other place, the offset between the current value of the program counter and the desired value of the program counter is added to the count in the program counter. Since the program counter always points to the next address, this automatically causes program execution to jump to the desired instruction in memory.

Included among the address registers discussed previously (or defined separately) is a specialized register called the “stack.” This register performs a critical function when external interrupts occur or when the program calls a subroutine stored in some area of memory. Once the program jumps to the subroutine (or the “subroutine” used to respond to the interrupt), the microprocessor has lost the value of the next instruction that would have been executed (memory address following the current instruction). When such jumps occur, the location of the *next* instruction in sequence, in particular the address given by the program counter, is stored automatically in the memory location whose address is in the stack register and the contents of the stack pointer is either incremented (or decremented depending on the microprocessor family used). The address in the stack pointer at any time is the memory location in which the last item was stored, allowing that address to be used to retrieve that item. On retrieving an item, the address in the stack pointer is decremented (or incremented) so that the address points to the previous memory location. In this manner, the stack pointer operation implements in memory a “last in, first out” data structure. The memory structure is generally called a *stack*, suggesting a stack of addresses from which you retrieve the address at the top of the stack, exposing the address underneath. Return from the subroutine to the point in the program from which the jump was called is achieved simply by placing the address stored in the stack in the program counter.

Instruction Execution Sequence

The overall execution of an instruction involves a basic sequence of three steps, starting with the reading of the instruction from memory. The three steps are (1) the reading of the instruction, (2) the decoding of the instruction within the microprocessor, and (3) execution of the instruction (including the storage of the result of an instruction). Figure 6.4.4 illustrates this sequence of steps in combination with a clock signal driving the progression. The time from the start of the reading of the instruction (called “fetch” in Fig. 6.4.4) to the completion of the instruction including writing of any results into storage is called the instruction cycle time. The example illustrated in Fig. 6.4.4 is merely representative of several different approaches that can be used to arrange the orderly completion of these three basic steps. For example, in some 8-bit microprocessors, a single clock cycle is used to complete a single basic instruction. When the clock is in one state (e.g., high), the instruction information is fetched and when the clock signal is in the other state (e.g., low) the instruction is decoded and executed. There are also important cases in which a multiplicity of clock cycles are needed for some instructions. For example, a multiply operation in a microprocessor with only a addition-based ALU requires that a sequence of multiplies and adds be performed to complete the overall instruction. In this case, each addition operation will consume one or more clock cycles.

Figure 6.4.4 suggests that only one of the three operations can be performed at any given time. However, the fetch operation involves interfacing to the external memory (setting addresses and reading external data into the microprocessor), whereas the other operations are performed within the microprocessor. It is therefore possible to arrange for the fetching of the next instruction to be started while the decoding/execution stages of the current instruction are being completed. It is also possible to separate the decode and execution operations and perform them in parallel. For example, while executing the current instruction the decoder could be decoding the next instruction while at the same time the microprocessor is fetching still one more instruction. The approach is called “pipelining” (reflecting the output from one step being fed into the next step while a new action is being input to that first step). Pipelining provides a faster throughput of instructions (more instructions per second can be executed) but does not intrinsically reduce the time to execute a given instruction (i.e., pass a single instruction through the pipe). Figure 6.4.5 illustrates the basic principle, here taking the basic instruction cycle as having four phases—fetching an instruction (F), decoding the

FIGURE 6.4.4 Instruction cycle timing.

(a) Sequential completion of each instruction in order.

(b) Pipelined execution (fetching next instruction while executing current instruction).

FIGURE 6.4.5 Instruction step sequencing: (a) nonpipelined; (b) pipelined.

instruction (D), executing the instruction (E), and storing the result (S). Figure 6.4.5a shows the operation without pipelining, each instruction starting after the previous has completed. In Figure 6.4.5b, each of the four steps can be performed in parallel, allowing a higher throughput rate for instructions. Optimizing the performance of a pipeline is complicated by the common use of branch instructions in programs. To handle such cases, sophisticated schemes to manage the pipeline have been developed. Modern high-performance microprocessors are characterized by an increasing number of pipeline stages (e.g., the Pentium Pro has more than 10 pipeline stages).

Serial Data Control

Microprocessors interface with a variety of devices that transmit and receive data in serial streams. The interface logic converts serial data to parallel data and vice versa. A programmable communication interface is used to handle this conversion and samples for data transmission, both synchronous and asynchronous.

Serial protocol involves three possible serial communication techniques. Two of the most widely used are *synchronous* and *asynchronous* serial communication. The third, *isosynchronous*, is a hybrid.

Asynchronous communication is best suited for data transmission between two devices where data are sent at low speed in intermittent, small groupings. A typical application is data entry through a CRT keyboard. Since the receiving device has no way of knowing when data will be sent, the asynchronous format requires *framing information* for each character transmitted. This enables the receiver, such as a universal synchronous-asynchronous receiver-transmitter (USART), to detect a valid data signal properly.

While the receiver waits on a dead line for possible transmission, it constantly samples for the leading edge of the start bit to occur. Sampling is performed by the USART much faster than the transmission baud rate (bit rate). For example, a receiver may sample the signal edge at eight times the baud rate. If the baud rate is 100 (100 bits/s), the USART would sample for the leading edge every $1/800$ s. Once the edge is detected, however, the receiver must ensure that it is receiving a valid signal and not a transmission caused by line noise. Upon detecting a possible start it is receiving a valid signal and not a transmission caused by line noise. Upon detecting a possible start bit, the receiver steps off a half-bit time to see that the bit is a logical 0. Once the start bit is detected, the receiver times a 1-bit time sampling for the remaining data and stop bits. Through this routine, the receiver synchronizes on each character transmitted.

In a synchronous protocol there is clocking between the two systems. The transmitter generates the clock and transmits data on the leading edge of the clock pulse. The receiver uses this clock to read in the serial data stream.

With synchronous protocol, bit synchronization is not necessary, as data are expected continuously. Still, the receiver must establish a reference indicating where data begin and end. With a synchronous protocol, characters are grouped into records, and *framing characters* are added to the record. These framing characters are SYN (or synch) characters. The USART uses the SYN characters to determine the boundaries of the message. SYN characters consist of a synchronization pattern, a pattern not likely to occur during a normal message. They are generated by the transmitter. The receiver samples these SYN characters bit by bit to establish its reference.

The isosynchronous format of serial communication retains the clock interconnect of the synchronous protocol, but it does not generate SYN characters. As with the asynchronous format, a start bit is generated. As the protocol uses clock synchronization, the repetitive samplings of the asynchronous format are eliminated. The hybrid protocol reduces the amount of MPU time devoted to message recognition, eliminates software overhead required by framing characters, and implements a greatly simplified protocol.

In receiving and transmitting the serial protocol in any form, the USART strips (or inserts) the framing characters and bits from the serial data stream and converts the data into a parallel format to be placed on the data bus. Figure 6.4.6 shows the elementary function of a serial I/O interface.

As far as the MPU is concerned, the USART consists of the data bus buffer, a control, and status registers. The receive data and transmit data buffers lie passively in the path of received and transmitted data and do not need direct access. The USART receives the serial-data-in signal and transmits the serial-data-out control signal. The MPU can service the transmissions on an interrupt-driven basis.

The rate of data transfer in serial data communications is stated in bps (bits per second). Another widely used terminology is baud rate. Digital systems normally are based on signals that can take one of two possible values (one corresponding to logic "1" and the other to logic "0"). However, it is also possible to allow a signal to take on a larger number of discrete values. In such cases, each signal value represents more than a single binary bit. For example, if a signal amplitude can assume one of four (eight) different values, each signal amplitude received represents two (three) bits. The baud rate is the number of signal values transmitted per second. If the baud rate is constant, then the number of bits per second transmitted increases as the number of

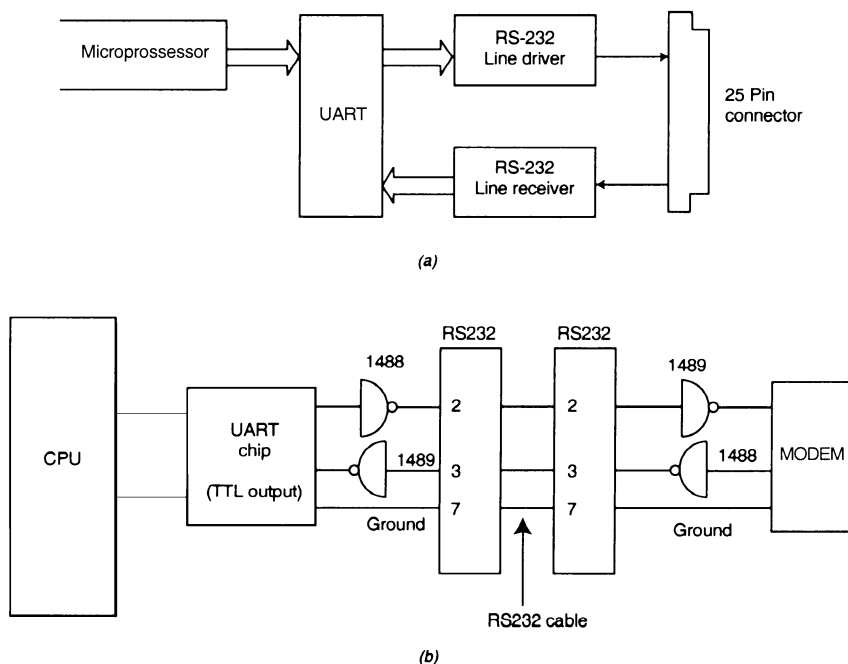

FIGURE 6.4.6 Generalized serial port: (a) using RS-232 interface; (b) using voltage level converters such as MC1488 and MC1489 chips.

TABLE 6.4.1 RS232 Comparison with RS422 and RS423

	RS232	RS422	RS423
Maximum cable length (ft)	50	4000	4000
Maximum speed (baud)	20K	10M/40 ft 1M/400 ft 100K/4000 ft	100K/30 ft 10K/300 ft 1K/4000 ft
Logic 1 voltage level	-3 to -25	A > B	-4 to -6
Logic 0 voltage level	+3 to +25	B > A	+4 to +6

signal levels increases. Serial data communications usually is designed for transmission over as long a distance as possible, with the result that there is significant attenuation (and noise) associated with the received signal level, causing transmission of binary signals to be more robust. This dominance of binary signal transmission has led to the terms *bps* and *baud rate* often being used (though incorrectly) as equivalent.

The serial port of a personal computer is a familiar serial data transmission port. The RS232 standard is common, with characteristics shown in Table 6.4.1. Notice that the voltage levels representing logic 1 and 0 levels are not conventional digital logic levels but rather positive and negative voltages, respectively. These voltage levels are one of the reasons why power supplies for personal computers must provide +/- 12-15 V in addition to the standard digital logic supply voltages. The RS232 standard allows serial data transmission over a modest distance at a modest rate. Table 6.4.1 also shows the characteristics of two extensions of the RS232 standard, both providing substantially higher data rates (or modest data rates over very long distances).

The serial port evolved from peripherals designed to connect a computer to the telephone network through a modem (modulator/demodulator). Table 6.4.2 shows the pins of an RS232 cable using a 25 pin D-type connector. Normally, only a subset of the control signals shown are used, allowing a smaller number of cable pins. Table 6.4.3 shows the pins of a 9-pin serial connector in which the common signals are retained. These tables show that the RS232 connection provides two serial data streams, one transmitted data and the other data being received. In addition, there are a number of control signals that manage the exchange of data between the computer and the peripheral. Because of the origins in connecting computers to telephone networks, terminology related to that connection are still used today. The connectors on opposite ends of an RS232 cable are not equivalent. For example, if one connector is configured according to the connector pins listed in Table 6.4.3, then the other end will require that its transmit data be placed on pin 2 (for reception by the far end) and that its receive data be taken from pin 3 (from transmission by the far end). Control signals also show different pin connections on opposite ends of the cable. The two ends are distinguished by the terminology DTE (Data Terminal Equipment, e.g., the computer) and DCE (Data Communications Equipment, e.g., the connection to the telephone wire). RS232 ports have evolved to provide connections to a wide range of peripherals, well beyond the single example of a modem. Often, the full set of control signals is not required. In cases not requiring end-to-end control signals, only the R x D, T x D, and GND signals shown in Tables 6.4.2 and 6.4.3 are needed.

The RS232 serial port generally transmits ASCII characters. The relationship between the number code (7-bit binary) and the ASCII

characters is shown in Table 6.4.4. There is also an 8-bit code, including several foreign language characters.

The standard printer interface on desktop computers transmits data in parallel, rather than serial. Figure 6.4.7 shows the basic printer cable's connector. There are two data rate links, one an 8-bit data link from the computer to the printer and the other an 8-bit data link from the printer to the computer. Control signals in this case reflect the handshake between the computer and the printer.

Recently, there has been an emphasis on serial data communications technologies capable of handling a far wider range of peripherals than can be handled by the low data rate of RS232 (and its extensions). USB and Firewire are two examples, both allowing connections to not only modems and printers but also to cameras, hard disk drives, and so on. These newer serial data technologies provide

high data rates and allow a single serial data port to be connected to a multiplicity of peripherals. These newer

serial data communication technologies provide significantly smaller connectors and smaller diameter cables, well suited for today's laptop computers but also providing improved performance for desktop computers.

Disk Interfaces

The evolution of interfaces to hard disk drives illustrates the major impact that standardization plays in the area of computer systems. Early computer manufacturers provided both the computer and the hard disk drive, using a proprietary interface requiring that the disk drives be obtained from the same manufacturer as the computer. In those earlier computers, most of the functional tasks required to read data from and write data to a hard disk drive was managed by a disk controller located in the computer itself, the disk drive having little built-in intelligence. As VLSI advanced, it became possible to place much of the functionality needed to manage the reading and writing of data in the hard disk drive unit itself. Once this responsibility was separated from the computer, hard drives could be purchased from a number of manufacturers, so long as the cable connection between the computer and hard drive was satisfied. This drove the evolution to interface and cable standards to connect hard drives to computers, allowing the disk drive market to emerge and provide drives for virtually any computer with the standardized interface.

Standard disk drive interfaces developed to support the Intel-based PC included the ESDI (Enhanced Small Device Interface) and IDE (Integrated Device Electronics). The SCSI (Small Computer System Interface) standard (pronounced "scuzzy") emerged for general computer use, not tied to any particular computer platform. The standards have had to adapt to the remarkable increases in disk drive capacity and data transfer rate,

leading to the highly sophisticated hard disk drives in use today. For example, the SCSI standard has passed through several generations, successive generations providing higher data rates and less bulky connectors. These interfaces are used not only for hard disk drives but also for tape drives, CD drives, and DVD drives.

These disk drive interface standards generally require rather bulky cables, limiting their extension to other peripherals such as digital cameras. The need to support a wide range of external devices has stimulated the development of less bulky but high data rate interfaces such as USB (modest data rate) and Firewire (high data rate), signaling a new generation of standardization of cables and connectors for personal computer use as the variety of peripherals expand.

CHAPTER 6.5

NANOTECHNOLOGIES

Wen H. Ko

INTRODUCTION

As integrated circuit technology and microtechnology progress and expand into all phases of human activities with micron-size devices and systems, we find that materials, devices, and even systems at the nanometer scale are interesting for study and may have great potential for new science, engineering, and industries. The national nanotechnology initiative of National Science Foundation, U.S.A., states “Nanotechnology is concerned with materials and systems whose structures and components exhibit novel and significantly improved physical, chemical, and biological properties, phenomena, and processes because of their small nanoscale size. Structural features in the range of about 10^{-9} to 10^{-7} m (1 to 100 nm) determine important changes as compared to the behavior of isolated molecules (1 nm) or of bulk materials.”

The research and technology on nanoscale materials and some atomic scale biochemical films existed long before the organized initiative. However, only with the recent advances in sciences and technology, it is possible to perform atomic or molecular manipulation and to initiate organized efforts to study and develop all fronts of nanoscale natural world. The flourishing activities under the general topic of nanotechnology now include:

1. Materials with unique or modified properties
 - a. Nanostructured metals, semiconductors, and superconductors
 - b. Nanoparticles—clusters, crystals, and composites
 - c. Hybrid materials—alloys, ceramics, and mono- or multilayer materials
 - d. Supermolecular, dendrimers, polymers
 - e. Nanotubes, nanorods, molecular wires
 - f. Superlattice, quantum wires, and quantum dots
 - g. Nanoporous systems
2. Science of nanomaterials—physical, chemical, and biological analysis; characterization and modeling of surfaces; nanomaterials and nanostructures aimed at understanding of them
3. Nanofabrication and processing—chemical vapor deposition (CVD) and other controlled deposition methods, molecular beam epitaxy growth, surface treatment, and programmable self-assembly techniques
4. Nanomanipulation and instrumentation—Nanoprobes, atomic force microscope (AFM), scanning tunnel current microscope, scanning electrochemical microscope, nanoactuators and controllers, and many other instruments
5. Nanoelectronics, nano-optics, and nanomagnetism—device characteristics and potential application
6. Application to electronics, information technology, robotics, fluidics, communication, and energy research
7. Nanobiotechnology and application in medicine and pharmacology
8. Others

The MEMS has served as a pathway for nanotechnology by providing instruments and tools for nanoresearch such as:

1. Microprobe devices, nanometer actuators, and controllers make these tools available for many researchers
2. Microfluidic systems for biomedical studies and self-assembly instruments with fast, multiple unit parallel process capability
3. Microsensors and actuator for nanofabrication and processes
4. Models and methods to understand nanoscale materials, devices, and properties

From engineering aspect of nanotechnology there are two parallel approaches. One is the bottom-up approach. This is to build materials and devices from atoms or molecules up, starting from the modification of the atomic or molecular structures or composition of material to alter their property. This includes research on self-assembly techniques, nanomaterials, composites, nanotubes, quantum dots ... as well as biochemical and medical related activities. Using these modified materials and nanoassembly techniques applications in biochemical and medicine can be developed. The other is the top-down approach. That is to shrink the microdevices and systems to nanoscale such as the nanotransistors/switches, and 90 nm and smaller integrated circuits, nanoscale sensors and actuators, and thin film and thick film systems. Both approaches are being pursued with great enthusiasm and efforts. The choice depends on which one is more suited for which research activity.

The field of nanotechnology is so broad and is advancing with tremendous speed over many wide fronts; it is not possible for this section to cover it at any depth. Hopefully these few pages will call attention to this field and that the references, particularly the journals and Internet addresses, will serve as beginning steps to understand the scope and potential of this field.

CARBON NANOTUBES

The carbon nanostructures are the most well-known nanostructures, since the discovery of C_{60} in 1985 by Buckminster Fuller. Among all types of carbon nanostructures the carbon nanotubes may be the most studied material. A brief discussion of carbon nanotubes and applications from the electrical engineer's viewpoint is given here as an introduction to the vast world of nanomaterials and nanotechnology.

There are two main types of carbon nanotubes (CNT)—the single-walled nanotubes (SWNTs) and the multi-walled nanotubes (MWNTs). They can be thought of as single or multiple layers of graphite sheets seamlessly wrapped into cylindrical tubes. Depending on the manner the graphite sheet is rolled from the tube, a pair of integers (n, m) is used to denote the nanotube type that defines the direction of rolling and the diameter of the tube. There are three types of CNT: the armchair ($n = m$), zigzag (n or $m = 0$), and chiral (any other n and m). Armchair SWNTs are metals, those $n - m = 3k$ [k is an integer] are semiconductors with small band gap.

Carbon nanotubes can be produced, in small quantity, by several methods, such as laser ablation of carbon, carbon arc discharge, and chemical vapor deposition of hydrocarbon vapor over a dispersed Fe or other catalysts. One method used decomposition of CH_4 or CO over Al_2O_3 supported Mo or Fe:Mo (9:1), at 700 to 850°C.

SECTION 7

UHF AND MICROWAVE COMPONENTS

The three chapters in this section cover passive microwave components, vacuum electronic devices, and microwave semiconductor devices.

A broad range of passive devices (Chap. 7.1) enable the transmission, sampling, filtering, and impedance matching of UHF and microwave power. Rigid rectangular waveguide is widely used for transmission. Flexible coaxial cable is employed for short runs, in cases where its higher attenuation can be tolerated. In lower power applications microstrip technology provides advantages in miniaturization and conformal configurations.

Chapter 7.2 is devoted principally to vacuum electronic devices, both traditional and advanced. Modern materials and design methods have advanced the RF vacuum device orders of magnitude in performance over that of the earlier glass envelope vacuum tube. While magnetrons and klystrons were used in World War II receivers, postwar funding of particle accelerator development resulted in klystrons having a 10^3 increase in peak power. Later developments designed to overcome bandwidth limitations of klystrons include the clustered cavity technique. The klystrode, an advanced version of the inductive output tube (IOT), offers reduced length and weight as a result of prebunching the beam. The traveling-wave tube (TWT) is a linear-beam device that amplifies microwave signals to high power levels over broad bandwidths. It finds diverse applications in communications, radar, and electronic countermeasure systems, and aerospace and avionics where low weight and volume, and minimizing power consumption are required. A further step to miniaturization of RF systems is the microwave power module (MPM), which exploits both vacuum electronics and solid-state technology. In the MPM, a high-gain monolithic integrated circuit drives a miniaturized helix TWT—both powered by a high-density electronic power conditioner. Gyrotrons (or cyclotron resonance masers) are a class of microwave generators that promise applications in the millimeter-wave region. Gyrotron oscillators have been developed that can produce 1 MW for 1 s at frequencies greater than 100 GHz.

Advances in semiconductor materials, particularly compound semiconductors, have enhanced the performance of microwave and millimeter wave devices (Chap. 7.3). Monolithic microwave integrated circuits (MMICs) enable small, lower cost RF and microwave components like amplifiers, oscillators, and switches for use in high speed/high frequency applications like cell phones and optical fiber communication systems. They are used, for example, in microwave power modules (MPMs). D.C.

CHAPTER 7.1

PASSIVE MICROWAVE COMPONENTS

Dwight Caswell, Joseph Feinstein

INTRODUCTION

While the physical concepts and mathematical theory underlying electromagnetic-wave propagation in confined structures were developed at the end of the nineteenth century, the practical utilization of wavelengths shorter than 1 m began during World War II. A wide variety of devices is now available for the transmission, sampling, filtering, and impedance matching of UHF and microwave power. Because of the short wavelengths at these frequencies (10 cm at 3 GHz, 1 cm at 30 GHz), most of these components use distributed elements and obtain specific reactances by judicious use of short-circuited lengths of transmission line. However, the trend toward microcircuitry has led recently to the introduction of lumped elements in some low-power, low- Q applications. In addition, the use of strip and microstrip transmission lines marks a return to open-wire media, with the attendant radiation loss kept low by close spacing and the presence of the dielectric filler.

Except for special applications (such as rotating joints for antenna feeds where a cylindrical member is essential), the use of rectangular waveguide, dimensioned to transmit in the dominant (lowest-order) mode, is standard for high-power transmission. Coaxial cable is used for short-distance runs where the advantage of its flexibility outweighs its higher attenuation. Ridged waveguide is useful for designing matching sections and for providing very-wide-bandwidth single-mode transmission. Oversized cylindrical guide operated in the circular electric mode is finding use in millimeter-wave-carrier telephony, where its extremely low attenuation justifies the special precautions which must be taken to avoid mode conversions.

Reciprocal and Nonreciprocal Components. Of the components which have become standard in this field, perhaps the most unusual are ferrite devices. When biased with the proper magnetic field, ferrites act as non-reciprocal elements with respect to microwave transmission in an appropriate frequency band. This behavior allows isolation of a signal source from reflections and the separation of incident from reflected power along the same transmission line (by means of a ferrite device called a *circulator*). It is also possible to vary the phase of a transmitted wave by adjusting the magnetizing field on the ferrite. Such phase shifters are capable of handling high powers with low loss.

All other types of microwave components, such as hybrid junctions and directional couplers, are reciprocal in their action. The latter are employed for power division and for signal sampling. A wide variety of transmission components such as variable attenuators, matched-load terminations, and slotted lines are used in microwave-measurements and design.

High- Q resonators are formed from completely enclosed short-circuited sections of waveguides with slit or loop coupling. Extremely low loss dielectric cylinders can also be used as high- Q resonators and have the advantages of smaller size and easy coupling to microstrip or other transmission lines. Resonators using lengths of

7.4 UHF AND MICROWAVE COMPONENTS

strip, microstrip or coaxial lines are frequently convenient, but have lower Q 's. Lumped elements, such as varactor diodes or YIG spheres, provide electrically tunable resonators for microwave oscillators and receivers.

Transmission-Line Relationships

The basic transmission-line equations are derived for distributed parameters R (series resistance), G (shunt conductance), L (series inductance), and C (shunt capacitance), all defined per unit length of line. Some useful relations are shown in Table 7.1.1. For zero losses ($R, G = 0$) one obtains the ideal line expression shown on the right. Table 7.1.2 gives some equations that are useful for relating the measured voltage standing wave ratio (VSWR) to wave transmission and reflection.

Matching

A microwave circuit typically consists of several devices connected together or connected through sections of transmission line. Mismatches between the devices decrease transmitted power, increase reflected energy and make the performance of the circuit more frequency dependent. Match between devices may be achieved by using capacitive or inductive elements suitably positioned along the transmission line. Another approach is to

TABLE 7.1.1 Summary of Transmission-Line Equations

Quantity	General line expression	Ideal line expression
Propagation constant	$\gamma = \alpha + j\beta = \sqrt{(R + j\omega L)(G + j\omega C)}$	$\gamma = j\omega\sqrt{LC}$
Phase constant β	Im γ	$\beta = \omega\sqrt{LC} = 2\pi/\lambda$
Attenuation constant α	Re γ	0
Impedance, characteristic	$Z_0 = \sqrt{\frac{R + j\omega L}{G + j\omega C}}$	$Z_0 = \sqrt{\frac{L}{C}}$
Input	$Z_{-1} = Z_0 \frac{Z_r + Z_0 \tanh \gamma l}{Z_0 + Z_r \tanh \gamma l}$	$Z_{-1} = Z_0 \frac{Z_r + jZ_0 \tan \beta l}{Z_0 + jZ_r \tan \beta l}$
Of short-circuited line, $Z_r = 0$	$Z_{oc} = Z_0 \tanh \gamma l$	$Z_{oc} = jZ_0 \tan \beta l$
Of open-circuited line, $Z_r = \infty$	$Z_{oc} = Z_0 \coth \gamma l$	$Z_{oc} = -jZ_0 \cot \beta l$
Of line an odd number of quarter wavelengths long	$Z = Z_0 \frac{Z_r + Z_0 \coth \alpha l}{Z_0 + Z_r \coth \alpha l}$	$Z = \frac{Z_0^2}{Z_r}$
Of line an integral number of half wavelengths long	$Z = Z_0 \frac{Z_r + Z_0 \tanh \alpha l}{Z_0 + Z_r \tanh \alpha l}$	$Z = Z_r$
Voltage along line	$V_{-1} = V_i(1 + \Gamma_0 e^{-2\gamma l})$	$V_{-1} = V_i(1 + \Gamma_0 e^{-2\beta l})$
Current along line	$I_{-1} = I_i(1 - \Gamma_0 e^{-2\gamma l})$	$I_{-1} = I_i(1 - \Gamma_0 e^{-2\beta l})$
Voltage reflection coefficient	$\Gamma = \frac{Z_r - Z_0}{Z_r + Z_0}$	$\Gamma = \frac{Z_r - Z_0}{Z_r + Z_0}$

l = length of transmission line.

TABLE 7.1.2 Some Miscellaneous Relations in Low-Loss Transmission Lines

Equation	Explanation
$r = \frac{1 + \Gamma }{1 - \Gamma }$	$r = \text{VSWR}$
$ \Gamma = \frac{r - 1}{r + 1}$	$ \Gamma = \text{magnitude of reflection coefficient}$
$\Gamma = \frac{R - Z_0}{R + Z_0}$	$\Gamma = \text{reflection coefficient (real) at a point in a line where impedance is real (R)}$
$r = \frac{R}{Z_0}$	$R > Z_0$ (at voltage maximum)
$r = \frac{Z_0}{R}$	$V < Z_0$ (at voltage minimum)
$\frac{P_r}{P_i} = \Gamma ^2 = \left(\frac{r - 1}{r + 1}\right)^2$	$P_r = \text{reflected power}$ $P_i = \text{incident power}$
$\frac{P_t}{P_i} = 1 - \Gamma ^2 = \frac{4r}{(r + 1)^2}$	$P_t = \text{transmitted power}$
$\frac{\alpha_r}{\alpha_m} = \frac{1 + \Gamma^2}{1 - \Gamma^2} = \frac{r^2 + 1}{2r}$	$\alpha_m = \text{attenuation constant when } r = 1, \text{ matched line}$ $\alpha_r = \text{attenuation constant allowing for increased ohmic loss caused by standing waves}$
$r_{\text{max}} = r_1 r_2$	$r_{\text{max}} = \text{maximum VSWR when } r_1 \text{ and } r_2 \text{ combine in worst phase}$
$r_{\text{min}} = \frac{r_2}{r_1} r_2 > r_1$	$r_{\text{min}} = \text{minimum VSWR when } r_1 \text{ and } r_2 \text{ are in best phase}$
$ \Gamma = \frac{ X }{\sqrt{X^2 + 4}}$	Relations for a normalized reactance X in series with resistance Z_0
$ X = \frac{r - 1}{\sqrt{r}}$	
$ \Gamma = \frac{ B }{\sqrt{B^2 + 4}}$	Relations for a normalized susceptance B in shunt with admittance Y_0
$ B = \frac{r - 1}{\sqrt{r}}$	

use transformers in the transmission line, such transformers having an appropriate length and impedance. Yet another approach is to taper from one impedance to another.

Smith Chart. The matching elements or transformers can be calculated graphically using a Smith chart which plots complex impedance. The standing wave pattern in a transmission line repeats itself every half-wavelength. The angular position of the radius of a circle represents the phase along a transmission line. Rotating the radius of a circle a complete revolution corresponds to a phase change of $\frac{1}{2}$ wavelength. Circles of constant resistance are tangent to the circumference of the Smith chart at a single point. These two features are illustrated in Fig. 7.1.1a. The center of the Smith chart has been normalized to a value of 1. To change to a 50-ohm transmission line, all of the resistance values would be multiplied by 50. A constant voltage standing wave

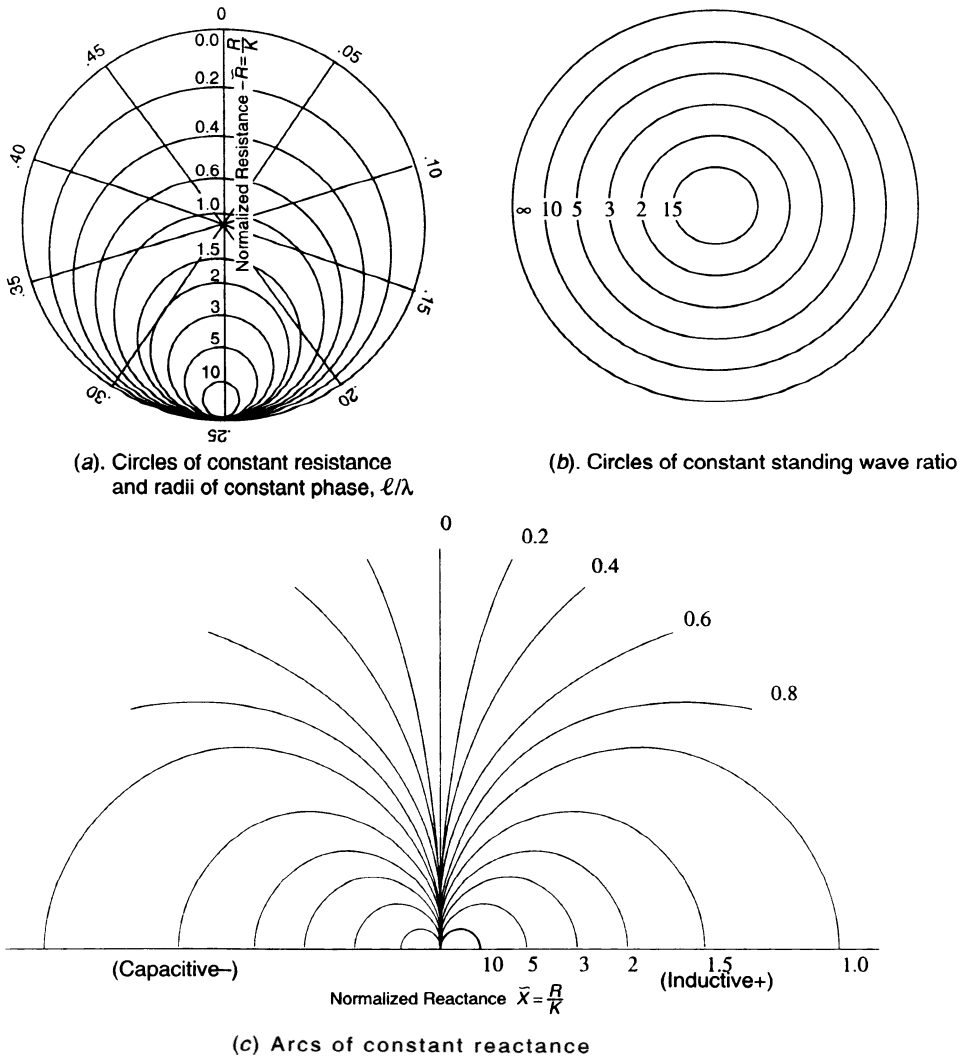

FIGURE 7.1.1 Elements of a Smith chart.

ratio is represented by a circle concentric with the center of the Smith chart. This is illustrated in Fig. 7.1.1b. Circles are not shown on the chart because their value can be determined by measuring the distance from the center of the chart to the point of interest. For the normalized Smith chart, the resistance value along the zero reactance line is numerically equal to the VSWR, varying between 1 and infinity. Normalized reactance is a series of arcs as shown in Fig. 7.1.1c. The actual values of reactance can be obtained by multiplying by the normalizing constant. Figures 7.1.1a and 7.1.1c are superimposed to obtain the Smith chart, Fig. 7.1.2. The impedance of P_1 is 0.6Ω . The impedance of P_2 is $0.5 - j1.0$. The impedance of P_3 is $0.5 + j0.5$. P_3 can be matched by adding a capacitive reactance $-j1.0$ at a distance of 0.72λ toward the generator, as shown.

The Smith chart may also be used to represent admittance Y , where $Y = 1/Z$. For a normalized admittance Smith chart ($Y_0 = 1$ at the center) capacitive reactance ($-jX/Z_0$) is replaced by inductive susceptance ($-jB/Y_0$); inductive reactance ($+jX/Z_0$) is replaced by capacitive susceptance ($+jB/Y_0$).

FIGURE 7.1.2 Smith chart representation of complex impedance. Impedance of P_1 is 0.6 ohm, P_2 is $0.5 - j1.0$, P_3 is $0.5 + j0.5$. P_3 is matched with a capacitive impedance $-j1.0$ with a phase of 0.72λ toward the generator.

Quarter Wavelength Transformers. One or more quarter wavelength sections of transmission line may be used to match from one impedance to another. Table 7.1.3 gives the VSWR which will result when one, two, or three transformer sections are used. R is the ratio of the two impedances to be matched. ω_g is the bandwidth over which match is to be achieved. If a single quarter wavelength section is used, the impedance of the transformer is

$$Z \text{ (impedance of matching transformer)} = \sqrt{Z_L \times Z_H}$$

where Z_L and Z_H are the characteristic impedance of the lower and higher impedance transmission lines, respectively. When two quarter wavelength sections are used and when the impedance of the lower impedance transmission line, Z_L , is normalized to unity, the impedance of the first transformer is the same as Z_1 in Table 7.1.4a. The impedance of the second quarter wavelength section, Z_2 , is R/Z_1 . For three matching transformers, the transformer impedances are

$$Z_1 = Z_1 \quad Z_2 = \sqrt{R} \quad Z_3 = R/Z_1$$

Matching with a Taper. Tapered transitions may be used to match from one transmission line to another. The VSWR is effected by the shape of the taper, i.e., linear or some other shape, and the length of the taper. In general a better match can be achieved using quarter wavelength sections when compared to a taper of the same length. The voltage reflection coefficient Γ is plotted in Fig. 7.1.3 for an impedance ratio of 2:1 for various taper lengths.

Rectangular Waveguide

The electric field pattern of a dominant-mode (TE₁₀) rectangular waveguide is a half sinusoid across the transverse guide dimension with its maximum at the center of the broad wall. Microwave energy cannot be transmitted through a waveguide in frequencies below the cutoff frequency, which has a corresponding cutoff wavelength λ_c . When the inside broad wall width is a , the cutoff wavelength $\lambda_c = 2a$. A different mode (electric field configuration) can be transmitted through the waveguide when the frequency is greater than $c/2b$, where c is the speed of light and b is the narrow dimension of the waveguide. The normal waveguide operating

FIGURE 7.1.3 Use of tapers for impedance matching.

frequency range is significantly higher than the cutoff frequency and significantly lower than the frequency where the second mode can be transmitted.

When higher power must be transmitted than is possible because of breakdown in air with these restrictions on dimensions, pressurization of the air or a sulfur hexafluoride gas fill is generally used.

Unlike the case for the transverse electromagnetic (TEM) mode of a coaxial or parallel-wire line, the guide wavelength λ_g in rectangular waveguide departs from the free-space wavelength λ_0 and varies with frequency, producing phase distortion in a wide-band signal. The relationship is

$$\lambda_g = \lambda_0 / \sqrt{1 - (\lambda_0 / \lambda_c)^2}$$

Ridge Waveguide

To obtain broader bandwidth in a single mode, as well as increased flexibility in the choice of impedance, ridge waveguide is generally employed. The variation of cutoff wavelength with dimensions for single and double ridges (always inserted on the broad wall of a rectangular guide to give capacitive loading) is given in Fig. 7.1.4. A large increase in bandwidth is made possible by this type of guide.

Circular-Mode Transmission

The circular electric (TE_{01}) mode is currently employed in long-distance broadband communications at millimeter wavelengths because of its low-loss transmission property. The electric field pattern and the wall currents form concentric rings in this unusual mode. Conversion to lower-order modes occurs if the cross section is even slightly elliptical or if the guide axis is curved. Various forms of mode suppression are employed; a common technique consists in fabricating the cylindrical wall from a tightly wound helix with loss between the turns to damp out modes with axial components of current. Attenuation as low as a few decibels per mile has been achieved.

Coaxial Line

The attenuation and power handling capabilities of rigid coaxial lines of various outer diameters are shown in Fig. 7.1.5. The frequency scale on this figure extends only to 3 GHz because such high-power transmitting coaxial cable is generally not used at higher frequencies.

7.10 UHF AND MICROWAVE COMPONENTS

FIGURE 7.1.4 Cutoff wavelength of ridged waveguide: (a) single ridge; (b) double ridge.

Care must be taken to avoid operation of a coaxial line at wavelengths where it becomes possible for additional modes to propagate. This occurs when the mean circumference between the inner and outer cylinders forming the transmission path equals a full wavelength; a stable standing wave is then possible in a circumferential direction. The higher attenuation and reduced power-carrying capability which accompany the small dimensions necessary to avoid higher-order modes generally lead to the choice of waveguide as a transmission medium at frequencies above 3 GHz for medium and high-power applications.

Strip Transmission Line

Strip transmission lines consist of a flat conductor between two ground planes. The characteristics are similar to coaxial line; however, they are easier to change by varying the width of the circuit, the proximity of adjacent lines or by the addition of stubs or other circuit elements. Impedance is controlled by the width of the strip; coupling is controlled by the spacing between lines. The circuit is flat and is easily fabricated. The material between the ground planes and the strip can be air or a low-loss dielectric material such as those enumerated in Table 7.1.5. Components such as directional couplers, filters, switches, and isolators are frequently made in stripline. Connectors are usually provided to join one component to another. Characteristic impedance Z_0 of a dielectrically loaded strip line ($\epsilon =$ dielectric constant) is given in Fig. 7.1.6. Figure 7.1.7 illustrates typical attenuation curves. A stripline with 0.125-in. ground plane spacing and teflon fiber glass dielectric will usually handle 25 kW peak power and 500 W average power in C-band. The dielectric material and the ground plane spacing must be chosen so that the line propagates only the TEM mode.

Microstrip Transmission Line

A microstrip transmission line has a conductive circuit on top of a dielectric substrate with a ground plane below the substrate. The advantages of microstrip include low cost production in large volume; the ability

FIGURE 7.1.5 Power rating and attenuation for rigid coaxial line.

to mount components (such as resistors and dielectric cavities) on top of the circuit; and to adjust the circuit which is open so it can be easily worked on. No connectors are required between circuit elements, thereby reducing size. The circuit itself has somewhat higher loss than stripline, but the elimination of connectors and the reduction in size frequently results in surprisingly low loss. Disadvantages include relatively low power capability (satisfactory performance of 100 W average at 2 GHz), tight tolerances, launching difficulty above 15 GHz, and leakage across the open circuit. Absorptive material and grounding screws may be required. Typical substrate materials are shown in Table 7.1.5. Figure 7.1.8 shows characteristic impedance of microstrip. In microstrip, part of the field is above the circuit in air and part below the circuit in dielectric. The resulting effective dielectric constant is less than the dielectric constant of the substrate as shown in Fig. 7.1.9.

Finline

A finline consists of rectangular waveguide with a metallic fin attached along the centerline of the top wall of a waveguide and another fin along the centerline of the bottom wall (Fig. 7.1.10). The fin must have electrical continuity with the waveguide walls. A dielectric substrate is located adjacent to the fin and extends from the bottom to the top wall of the waveguide. This structure has low loss and can operate up to 100 GHz.

Transitions Between Transmission Lines

Waveguide to Coaxial Line. The maximum E field is in the center of the waveguide at a distance $\lambda_g/4$ from a short at the end of the guide. An extension of the center conductor, located at the point of maximum E field, acts like an antenna to couple energy from the coaxial line into the waveguide, Fig. 7.1.11. Typically the diameter of

FIGURE 7.1.8 Characteristic impedance of microstrip line: wide-strip approximation (left); narrow-strip approximation (right).

7.14 UHF AND MICROWAVE COMPONENTS

FIGURE 7.1.9 Plot of the effective dielectric constant vs. w/h for microstrip transmission lines, with the relative dielectric constant as a parameter.

the probe is enlarged and enclosed in a dielectric cylinder to increase bandwidth. Coupling from coaxial line to waveguide may also be achieved by using a loop, as shown in Fig. 7.1.12 which couples to the magnetic fields.

Waveguide to Stripline or Microstrip. The center conductor of a stripline may be extended into a waveguide forming a probe. Increasing the width of the center conductor at the end of the probe may improve bandwidth. Similarly the conductor and substrate of a microstrip circuit, but not the ground plane, may be extended directly into the guide, Fig. 7.1.13.

Coaxial Line to Microstrip. The center conductor of a coaxial line is pressed against or soldered to the strip conductor of microstrip. The outer conductor of the coaxial line is grounded to the microstrip groundplane. At frequencies above 15 GHz, the microstrip substrate thickness may be as little as 0.010 in. which usually requires decreasing the diameter of the coaxial line as illustrated in Fig. 7.1.14. The center conductor must not come so close to the groundplane that it introduces a capacitive discontinuity. It may be necessary to short out unwanted modes with grounded lines or screws near the transition. The exact mechanical configuration and capacitive loading become critical.

Directional Couplers

Waveguide Directional Couplers. Waveguide directional couplers are employed primarily to sample power for measurements. Two waveguides may be located side by side, one above the other, either parallel to each other or crossing each other. Holes are drilled in the common wall to permit coupling power between guides. In Fig. 7.1.15 the coupling = $10 \log P_1/P_4$, while the directivity = $10 \log P_4/P_4'$ (P_1 = power in at port 1, P_4 = power out at port 4 with power P_1 in a port 1, P_4' is the power at port 4 with power P_1 in at port 2). Coupling values range from 3 dB to more than 30 dB with directivity in excess of 40 dB.

Stripline and Microstrip. A stripline or microstrip coupler consists of a main transmission line in close proximity to a secondary line as illustrated in Fig. 7.1.16. The definitions of coupling and directivity are the

FIGURE 7.1.10 Finline configuration.

FIGURE 7.1.11 Electric field coupled waveguide to coax adapter.

FIGURE 7.1.12 Magnetic field coupled waveguide to coax adapter.

FIGURE 7.1.13 Waveguide to microstrip adapter using circuit probe.

FIGURE 7.1.14 Coaxial line to microstrip adapter using constant impedance transformer in coaxial line.

FIGURE 7.1.15 Directional couplers in waveguide: (a) with array of openings, (b) crossguide coupler.

same as for waveguide, but the coupled part is adjacent to the input rather than at the far end. Adding quarter wavelength coupling sections on either side of the center section increases bandwidth and reduces ripple. The added quarter-wave sections are less tightly coupled than the center section and are equally disposed about it. For microstrip, the velocity of propagation is different for even and odd modes. The addition of localized capacitances along the line, Fig. 7.1.17, improves the directivity.

Even and Odd Modes. When two lines are in close proximity and the phase of the energy is the same, there is even-mode symmetry of fields as illustrated in Fig. 7.1.18a. When the fields are 180° out of phase there is odd mode symmetry, Fig. 7.1.18b. The impedance of the two modes are different. In addition, in microstrip, one mode has more field in air than the other, resulting in different propagation velocities.

In-Line Power Dividers. A Wilkinson power divider consists of a single line separated into two quarter wavelength sections as shown in Fig. 7.1.19. The divider can have a VSWR of 1.25:1 or less over an octave. Power division is frequency independent.

FIGURE 7.1.16 Stripline directional coupler.

FIGURE 7.1.17 Microstrip coupler with capacitors to improve the directivity.

FIGURE 7.1.18 Even and odd modes on a homogeneous coupled line.

Resonant Circuits

Resonant circuits are generally formed from a short-circuited length of transmission line. Many modes can exist within the cavity created by the shorted line, as illustrated in Fig. 7.1.20 for a right circular cylinder. The size of the cavity and the quality of resonance, Q , is determined by the mode selected. A resonator with a Q of 100 has poor selectivity, while a resonator with a Q of 5000 will have good selectivity. The Q is defined as

$$Q = \frac{\text{Total energy stored in electric and magnetic fields}}{\text{Energy dissipated per cycle}}$$

The operating frequency can be changed by mechanically changing the cavity geometry, or by introducing a metal or dielectric post.

Dielectric disks and cylinders can be used as cavities. They are most easily coupled to microstrip, but can be used with coaxial line or waveguide, or other types of transmission lines. Materials are available from 0.7 to 30 GHz, with typical dielectric constants of 36, which reduces the dimensions by a factor of 6 when compared to air. Q ($1/\tan \delta$) is typically 30,000/frequency in GHz, where $\tan \delta$ is frequently used as a measure of loss in materials. Tuning of 5 percent or more is achieved by moving metal or dielectric tuning stubs near the dielectric cylinder.

Mechanically tuned resonant cavities are generally used for frequency determination. For a transmission wavemeter, such a cavity is coupled in series into the transmission path, while for an absorptive indication it is coupled in shunt. A dominant-mode (TE_{111}) cylindrical resonator is most widely used for this purpose, but for highest selectivity a circular electric-mode (TE_{011}) resonator is employed. Dielectric resonators are frequently used to tune or stabilize oscillators.

Filters

Frequency filters are used to separate the components of a composite waveform for signal-processing purposes or to suppress RF interference (RFI), which results from the spurious output of transmitters. The latter problem

FIGURE 7.1.19 Compensated and uncompensated in-line three-port power dividers.

FIGURE 7.1.20 Mode chart for right circular cylinder.

has only recently become serious at microwave frequencies, as this area of the spectrum has become congested. High-power capability is required for such filters, leading generally to the use of waveguide structures. A section of waveguide beyond cutoff constitutes a simple high-pass reflective filter. Loading elements in the form of posts, irises, or stubs are employed to supply the reactances required for conventional lumped-constant-filter design.

The desired skirt steepness and stopband attenuation determine the number of sections, as at lower frequencies. A disk-loaded coaxial line is generally used as a low-pass high-power filter. Insertion loss of reflective filters is typically 0.1 to 0.2 dB, with stopband attenuation of the order of 50 dB. Absorption filters avoid the reflection of unwanted energy by incorporating lossy material in secondary guides which are coupled through leaky walls (typically small sections of guide beyond cutoff in the passband). These filters are effective primarily against harmonics.

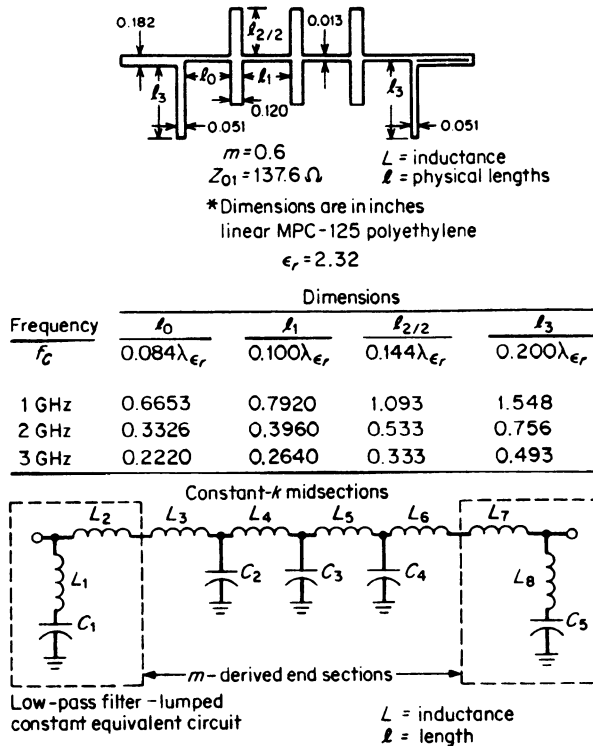

FIGURE 7.1.21 Strip-line filter design.

For low-power applications, strip-line filters are widely used because of their compact sizes and low cost. Typical dimensions for a low-pass filter of this type are shown in Fig. 7.1.21.

Other Components

Among the components useful for measurement purposes are wavemeters, attenuators, and matched terminations. In waveguide, variable attenuators take the form of thin absorptive material introduced tangential to the electric field typically through a slot in the broad wall of rectangular guide to produce minimum reflection. Load terminations are tapered attenuators designed to produce at least 40 dB of return loss, while maintaining a good match (maximum VSWR less than 1.2) through the specified band. For high power, water cooling is provided either around a loaded ceramic or dielectric absorber or by introducing a tube of water directly into the guide to act as the absorber. Calorimetric determination of power is possible with such water loads. A wide range of grounded resistive elements are used as terminations.

Ferrite Components

Isolators. Isolators transmit microwave power in one direction with little attenuation, while power transmitted in the opposite direction is absorbed. Attenuation in the transmit direction may be less than 0.5 dB, while isolation in the opposite direction may exceed 20 dB. Isolators are relatively well matched in both directions, a VSWR less than 1.20:1 is typical. Such an isolator will reduce a mismatch from 2:1 to less than 1.3:1. When used between stages of an amplifier they may eliminate the need for tuning between stages and may improve gain flatness. Isolators are available in waveguide, in stripline with or without coaxial connectors and in microstrip. At 1.0 GHz a differential phase shift type waveguide isolator can handle 4000 kW peak power and

FIGURE 7.1.22 Configuration of microstrip junction circulator.

over 250 kW average power. At higher frequencies, such as Ku-band, a microstrip isolator may handle only a few watts and weigh only a few grams.

Isolators and circulators are based on the interaction of a circularly polarized magnetic component of microwave energy with the magnetic field of a ferromagnetic molecule, usually iron, which has been aligned by the application of a steady dc magnetic field. The ferromagnetic molecules are held in a nonconductive crystalline lattice through which microwave energy can pass with little loss. The interaction between the microwave magnetic field and the magnetic field of the molecule is a vector product interaction which tends to cause the molecule to precess like a gyroscope, and is frequently referred to as gyromagnetic interaction. The direction of the applied dc magnetic field determines the direction for transmission and attenuation of the isolator. Reversing the direction of the applied field reverses the direction of the isolator.

Circulators. The most common type of circulator uses a single junction and can be built in waveguide, stripline or microstrip. Figure 7.1.22 illustrates a single junction microstrip circulator. The stack-up of parts consists of a groundplane (frequently metalized on the ferrite), a ferrite disk, a conductive metal circuit with arms at 120° relative to each other, a spacer to keep the microwave fields out of the magnet, and a magnet to supply the dc magnetic field. Due to the nonreciprocity of the magnetically biased ferrite, the phase shift between ports in the circulation direction is 120° while the phase shift in the opposite direction is 60° . Energy transmitted from port one to port two is shifted 120° , while energy from 1 to 3 is shifted 60° and energy from 2 to 3 is shifted 60° . Energy going either direction is in phase at port 2 and adds together. Energy at port 3 is out of phase and cancels so no energy is transmitted to this port. Due to symmetry, this applies to all ports. Typical characteristics of junction circulators is shown in Table 7.1.6. Placing a termination at port 3 converts the circulator to an isolator.

Differential Phase Shift Circulators. High-power circulators are generally built in waveguide as shown diagrammatically in Fig. 7.1.23. If the phases are added up as shown, it will be seen that power in at 1 goes to 2, power in at 2 goes to 3, and so on. It should be noted that in a folded hybrid Tee, power in at 1 has the same phase in path A and path B. Power in at the vertical arm of the Tee is 180° out of phase for the two paths. A similar phase shift occurs for power traveling in the opposite direction. There is a 90° phase shift across the short slot hybrid as shown. Placing termination at ports 3 and 4 converts the circulator into an isolator.

TABLE 7.1.6 Characteristics of Typical Junction Circulators

Circulator type	Center frequency, GHz	Bandwidth, %	Isolation, dB	Insertion loss, dB	Power capacity	
					Avg, W	Peak kW
Waveguide	12.4–18	20	0.3	20	1
	18–26.5	17	0.5	15	0.5
Strip transmission line	4–8	20	0.4	35	
	12.4–18	18	0.5	25	0.25

Lumped constant	1.2	30	20	0.6		
	0.4–0.5	30	20	0.4		

Source: *Microwave J.*, November 1978.

Circulators may be used to simultaneously connect a transmitter and receiver to a single antenna as shown in Fig. 7.1.24. Transmitted power in at 1 goes to the antenna at 2. Received energy entering the antenna at 2 travels to the receiver at 3. Transmitter energy reflected from the antenna also goes to the receiver. The reflected power must be low enough it does not damage the receiver or a fast-acting switch must be provided to protect the receiver. If the transmitter and the receiver are operating at different frequencies, protection may be provided by a filter.

Phase Shifters. The simplest reciprocal phase shifter uses a thin ferrite rod centered within a rectangular waveguide. An axially directed magnetic field provides a full 180° phase variation at 9 GHz with a change of a few hundred gauss. A more cost-effective approach is the dual-mode reciprocal phase shifter, shown in Fig. 7.1.25, which uses Faraday rotation. Toroidal nonreciprocal phase shifters, in which the ferrite takes the form of a rectangular closed loop in waveguide, switched by means of an axial current-carrying conductor, are also popular. Digital phase shifting is generally obtained by latching ferrites, since the remanent magnetization states of the hysteresis loop require relatively small bias fields.

Limiters. The nonlinear behavior of ferrites at high power levels is used in ferrite limiters. Such limiters have replaced TR gas-discharge tubes in radar. Peak powers of tens of kilowatts at X band can be handled, but with considerable spike-energy leakage, which requires a follow-on solid-state (*pin*) diode stage. Typical insertion loss is

FIGURE 7.1.23 Diagram of differential phase shift waveguide circulator.

FIGURE 7.1.24 A transmitter and receiver connected to same antenna.

about 0.5 dB, with 30 dB of flat limiting and about 6 dB of spike limiting for the ferrite alone. The diode stage increases the insertion loss to about 1 dB but reduces all leakage an additional 30 dB. The recovery time is very short, typically 100 ns, and is determined primarily by the diode section.

Acoustic-Wave Devices

Acoustic waves owe their usefulness to their relatively low velocity, typically 10^{-5} times the electromagnetic velocity, permitting relatively long electric-signal delay times to be obtained in a physically small space. Both bulk-mode propagation and surface waves have been used, the latter gaining in popularity because of the relative ease of access to intermediate points along the propagation path for structure shaping and taping.

Transducers. The transducers designed for the two types of acoustic modes are physically quite different, but both contain electrodes spaced either a quarter or half an acoustic wavelength in a piezoelectric material. Microwave bulk-wave transducers consist of multiple films of ZnO or CdS, each approximately $\lambda/4$ thick, separated by similar films of gold or other nonpiezoelectric material deposited on the bulk medium to provide electric-to-acoustic wave coupling and impedance transformation.

Surface acoustic waves (SAW) are generally excited by interdigital transducers. An interdigital transducer, illustrated in Fig. 7.1.26, consists of two sets of interleaved metal electrodes, called *fingers*, deposited on the piezoelectric substrate. To generate a wave an RF potential is applied between the adjacent sets of fingers, which are spaced by a distance equal to one-half wavelength at the transducer design frequency. A typical 100-MHz transducer on LiNbO_3 has aluminum fingers $0.2 \mu\text{m}$ thick by $9 \mu\text{m}$ wide with $9\text{-}\mu\text{m}$ gaps.

The wave excited by the RF potential between a pair of fingers travels at the surface-wave velocity. By the time the wave arrives midway between the next pair of fingers, the RF excitation potential has reversed sign, and the wave excited by the second pair of fingers will be in phase with the wave from the first pair. Thus the

FIGURE 7.1.25 Dual-mode reciprocal phase shifter.

FIGURE 7.1.26 Piezoelectric surface-wave microwave device with interdigital electrodes.

FIGURE 7.1.27 Coupling between electric port and one acoustic port for transducers with three, five, and seven interdigital periods: (a) theoretical conversion loss; (b) phase dispersion.

FIGURE 7.1.28 Surface-wave attenuation of Y-cut lithium niobate.

excitation due to the second pair is added to the excitation from the first, and so on. The mechanism is reciprocal, and hence the transducer that excites a wave will also detect it.

The transducer has a fractional bandwidth of $1/N$, where N is the number of finger parts. Electrically, the transducer is represented by a capacitance shunted by a radiation resistance which depends on the choice of finger length.

A surface-wave transducer is a three-port device, i.e., with one electric and two elastic ports. Figure 7.1.27 shows the conversion loss as a function of frequency from a 50-Ω source to one of the two acoustic outputs for three different transducers on a lithium niobate surface. These calculated curves show that for this particular case the use of five finger pairs provides the widest bandwidth and smallest conversion loss. The attenuation of the wave, once it has been launched, is given in Fig. 7.1.28 for lithium niobate.

The lowest operating frequency of acoustic surface-wave devices is limited by the allowable size to typically 10 MHz. At present the upper operating frequency is limited by fabrication difficulties to about 1 GHz with possible operation to 3 GHz.

FIGURE 7.1.29 Three-phase unidirectional transducer. Each electrode is 120° out of phase, so that the acoustic waves add in one direction and cancel in the other.

Other Acoustic-Wave Devices. Bandpass filtering is the principal commercial application of SAW technology. Such devices are replacing LC filters in television receiver i.f. circuits. Minimum stop-band rejection of the order of 60 dB with in-band response flat to ± 0.1 dB and phase deviation from linearity of only a few degrees are typical of these filters. The major drawback of SAW devices, their high insertion loss (of the order of 15 dB), can be reduced to less than 3 dB by using a three-phase unidirectional transducer structure, as shown in Fig. 7.1.29. Other acoustic-wave devices include: (a) dispersive filters used primarily for pulse compression; (b) chirp transformers that can be used to obtain a Fourier transform of an input signal; and (c) compact, low-cost SAW resonators, which are useful below 1 GHz.

KLYSTRONS

Robert S. Symons

Introduction

For high frequencies, linear-beam tubes overcome the transit-time limitations of grid-controlled tubes by accelerating the electron stream to high velocity before it is modulated. Modulation is accomplished by varying the velocity, with consequent drifting of electrons into bunches to produce RF space current. The RF circuit for coupling signals to and from the electron beam are generally integral parts of the tube. Two basic types are important today, klystrons and traveling-wave tubes. Different versions of each are used as oscillators and amplifiers.

In a klystron, the RF circuits are resonant cavities which act as transformers to couple the high-impedance beam to low-impedance transmission lines. The frequency response is limited by the impedance-bandwidth product of the cavities but can be increased by stagger tuning and by multiple-resonance filter-type cavities.

Reflex Klystrons

In the reflex klystron a single resonator is used to modulate the beam and extract RF energy from it, making the tube simple and easy to tune. The beam passes through the cavity and is reflected by a negatively charged electrode to pass through again in the reverse direction. With proper phasing determined by applied voltages, oscillating modes occur for $n + \text{three-quarters-cycle}$ transit time between passes through the cavity. The frequency can be modulated by varying voltage on the reflector (which draws no current). Reflex klystrons have been used as test signal sources, receiver local oscillators, pump sources for parametric amplifiers, and low-power transmitters for FM line-of-sight relays. Reflex-tube frequencies cover the entire microwave range from 1 to 140 GHz. In new applications, they have largely been replaced by solid-state devices.

Two-Cavity Klystron Oscillators

In all klystrons except the reflex, the beam goes through each cavity in succession, and so there is no feedback. The tube is a buffered amplifier, with each stage isolated from those upstream. Electromagnetic feedback may be provided to make an oscillator.

7.26 UHF AND MICROWAVE COMPONENTS

The specialized two-cavity oscillator has a coupling iris in the wall between the cavities. This tube is more efficient and more powerful than the reflex klystron. It can be frequency-modulated by varying the cathode voltage around the center of the oscillating mode but requires more modulator power than a reflex klystron.

Two-cavity oscillators have been used where moderate power and stable frequency for low side band noise are needed. Examples are the transmitter source in Doppler navigators, pumps and parametric amplifiers, and master oscillators for cw Doppler radar illuminators.

Again in new applications, most requirements that were met by two-cavity oscillators are now met by solid-state devices unless extremely low noise requirements exist.

Extended-Interaction Oscillators

At millimeter wave frequencies the losses in klystron cavities make it hard to build up the impedance necessary to oscillate with the very small low-current beams required.

If a series of cavities are coupled together and interact sequentially with the beam in the proper phase, the total interaction impedance increases directly with the number of cavities. The circuits of extended-interaction oscillators resemble those of traveling-wave tubes. Since they operate with a complete standing wave (at the cutoff of the traveling-wave passband), the tubes can be classed as klystrons. Various names are used for tubes of this type. The Laddertron uses a ladder-shaped periodic circuit and a flat-ribbon electron beam. Multicavity klystron oscillators use coupled cavities and cylindrical beams. Communication and Power Industries (formerly Varion) makes a number of extended-interaction klystron oscillators with power output ranging from 1 kW at 15 GHz to 1 W at 300 GHz. Most of these oscillators operate with a beam voltage near 10 kV. They provide very low noise characteristics in the order of -120 dB below carrier power in a 1-Hz bandwidth close to the carrier when used with quiet power supplies.

Two-Cavity Amplifiers

In the simplest klystron amplifier, the driving signal is coupled through a transmission line to input cavity. The cavity voltage produces velocity modulation of the beam. After a single drift space, the resultant density modulation induces current in the output resonator, from which power is extracted through another transmission line. As with nearly all klystron amplifiers, for efficiency, the Q of the output cavity is adjusted so the RF voltage almost stops electrons at the center of the bunch. The beam is usually focused electrostatically.

The gain of a two-cavity klystron is about 10 dB. Use is limited because more gain is desired in high-power tubes and solid-state amplifiers are available at low powers.

Multicavity Klystron Amplifiers

Downstream from the input cavity, cascaded intermediate cavities are inserted between the input and output cavities. They usually have no external coupling and are driven by the RF beam current and in turn remodulate the beam velocity. Figure 7.2.1 shows a three-cavity klystron schematically.

Each cavity tuned to the signal frequency adds about 20 dB of gain to the 10 dB of a two-cavity klystron. Net gain of up to about 60 dB is practical. If higher gain is attempted, one must do something to suppress fast secondary electrons traveling in the reverse direction through the tube and creating a feedback path, and one must be careful that one does not create a tube with a high noise figure by exciting a high-power beam with a very low-power drive signal. In klystrons with five or more cavities, they are usually added to increase bandwidth or efficiency rather than gain and consequently are stagger tuned. The characteristics that make the klystron desirable in the various applications in which they are used include fairly linear amplification of the RF input signal and separation of the beam formation, RF interaction and collection functions in different parts of the electron tube. The separation, in turn, allows the designer of

FIGURE 7.2.1 Cross section of cascade klystron amplifier. (Varian Associates)

the tube to optimize it for life, gain, bandwidth, low noise, efficiency or power output. Multicavity klystrons provide the economic solution to many requirements. Air cooling is often used for tubes with output power below 5 kW, and boiling water or forced liquid cooling is used for higher power. Magnetic focusing is used to control the beam in most power amplifier klystrons. Permanent magnets are used if size and required field strength permit, and solenoids or other electromagnets are used for larger and higher-power klystrons.

CW multicavity klystron amplifiers are employed in industrial-heating applications, electron-storage rings and superconducting electron linear accelerators used in high-energy nuclear physics experiments, satellite-ground-station tropospheric-scatter and space-communications transmitters, and UHF television broadcast transmitters. Pulsed multicavity klystrons are used in scientific and medical electron linear accelerators and in proton linear accelerators. They are also used in many radars in which pulse compression, Doppler processing, or spectral purity is an important requirement. A discussion of klystron designs optimized for these various applications follows:

CW klystrons for industrial heating and those used to make up the synchrotron losses of electrons in the storage rings used in nuclear physics experiments must have very large output power and high efficiency. A number of klystrons ranging in operating frequency from 200 to 2450 MHz with continuous output power up

to one-half or 1 MW have been manufactured. At 200 MHz such a klystron is about 6 m in length, but the length scales inversely as frequency and directly as the square root of beam voltage. In such tubes, efficiency is achieved by using enough cavities so that, with the desired drive power, the fundamental component of current in the beam reaches the maximum that can be achieved with synchronously tuned cavities prior to reaching the output cavity. At this distance down the electron beam, the second harmonic content of the current may be used to excite a cavity tuned near the second harmonic in order to sweep electrons located between the electron bunches into the bunches. Alternatively, the beam is allowed to drift for a fairly long distance while the electrons between bunches continue to drift toward the bunches and the bunches deteriorate to some extent. In either approach, following the second-harmonic cavity or the long drift length, usually two cavities tuned to frequencies somewhat above the fundamental frequency (inductively tuned cavities) provide RF electric fields that push most electrons back toward the centers of the bunches and raise the fundamental component of current to a very high level. Using such techniques, together with high beam voltages (V) and low beam currents (I), efficiencies (η) reaching 70 to 80 percent have been achieved. An empirical relationship that fits the experimental data is $\eta = [90 - 20 \times 10^6(I/V^{3/2})]$ for $(I/V^{3/2}) \leq 3 \times 10^{-6}$.

Klystrons for communications applications require bandwidth, and so it is customary to use somewhat lower beam voltages and higher beam currents. Bandwidth scales directly as the dc beam conductance $[I/V]$ so it increases slowly as the power output of the tube is increased by raising beam voltage (because $[I/V^{3/2}]$, the electron beam “perveance,” is a constant of the electron gun design. Bandwidth will increase more rapidly as the perveance, itself, is raised. As discussed above, a perveance increase will reduce efficiency, so there is a trade-off. Nevertheless, the efficiency increasing techniques discussed above remain effective, and bandwidth can be increased further by stagger tuning the input cavity and low-level intermediate cavities. Many tropospheric scatter communications tubes have been designed to operate at frequencies from UHF through 5 GHz at power levels up to several tens of kilowatts, and satellite communications klystrons with power outputs from 800 W to 15 kW have been designed to operate from 5 to 30 GHz. For deep-space communication even higher powers are used ranging from 500 kW at 2450 MHz to 200 kW at X-band. Figure 7.2.2 shows the gain characteristics of a VA-884D, a 14-kW cw broadband klystron designed for ground-to-satellite communication and tunable over the 5.925 to 6.425 GHz band. The klystron is a fairly good linear amplifier from zero signal up to 2 to 3 dB below saturated output, but the curvature of the gain characteristic does introduce some third-order intermodulation products, $(2f_2 - f_1)$ and $(2f_1 - f_2)$. Figure 7.2.3 shows the necessary reduction in the average power of a two-equal-carrier signal relative to the klystron saturation power as a function of the desired third-order intermodulation product level relative to the carrier powers. Another type of distortion in klystrons is am-to-pm conversion. It is caused by the increase in transit angle at the output cavity gap when the tube is operating very efficiently near maximum power and electrons in the bunches are nearly

FIGURE 7.2.2 Typical gain, output power and drive power characteristics.

FIGURE 7.2.3 Third-order intermodulation distortion under two equal carrier conditions.

stopped. The variation in phase amounts to about 20°. Lowering the output cavity Q slightly below that value which gives maximum efficiency will substantially reduce the am-to-pm conversion. Variation of the beam voltage also causes phase modulation, so good filtering of the beam voltage supply is important. The percentage change in phase through a klystron is equal to a maximum of one-half the percentage change in beam voltage because of the square root relationship between beam voltage and electron velocity. At very high beam voltages this is somewhat less because of relativistic effects.

Figure 7.2.4 shows bandwidth curves for the klystron with various levels of drive power. Figure 7.2.5 shows the trade-off between gain and bandwidth as the cavity resonant frequencies are stagger tuned, and Fig. 7.2.6 shows fundamental and harmonic power outputs as a function of drive power. The operating bandwidth of many communications klystrons may be located anywhere within an entire communications band by means of tuners in the cavities. These sometimes take the form of a capacitive paddle which may be moved relative to the cavity gap, or sometimes the form of a moveable copper cavity wall with tungsten spring contacts which can vary the volume or “inductance” of the cavity. In either case, motion is transmitted through the vacuum wall of the klystron by means of a metal bellows. “Channel tuners,” which move all cavities simultaneously to settings appropriate to one of a fixed number of broadband channels, are common on tubes designed for satellite-communication ground stations. A typical power supply schematic for a cw amplifier is shown in Fig. 7.2.7. Protective devices often required for klystron amplifiers include sensors to monitor cooling

air or water flow, collector overtemperature, cathode-heating-time delay, cathode overcurrent, body overcurrent, and output waveguide arcing (photodetector and PIN diode switch).

FIGURE 7.2.4 Gain and output vs. frequency characteristics under saturated and unsaturated RF drive conditions.

FIGURE 7.2.5 Type VA-884 series klystron gain-bandwidth characteristics.

and tuning over the entire 470 to 806 MHz band is accomplished by moving two cavity walls at each end of an air-filled waveguide-like cavity. The synchronizing pulses that are transmitted at the end of each line scan require full output power from the transmitter about 10 percent of the time. White level is 10 percent of the peak RF voltage or 1 percent of the peak power, and black level is about 78 percent of peak voltage or 60 percent of peak power. Thus, for an average gray raster, the average output power is about one-third the peak-of-sync power. Before 1974, when electric power was cheap, it was usual to operate klystrons at constant input power, and the output cavity was heavily loaded to a low Q to improve linearity and reduce am-to-pm conversion at the expense of efficiency. Thus the average efficiency was about 11 or 12 percent. After 1974, as the cost of power rose, it became attractive to operate klystrons at two different beam current levels, a lower current during the visual scan period and a higher current during the synchronizing pulses. To vary the current, a control electrode was incorporated in the electron gun. The Q of the output cavity was also increased. The increased amplitude and phase distortion in the klystron is compensated by predistortion in the exciter at the expense of partially regenerating the lower sideband which is then again eliminated by a high-power filter between the final amplifier and the

UHF television broadcast klystrons are like other communications klystrons except that the designs are optimized to amplify the NTSC signal efficiently. In the NTSC signal, the lower sideband is vestigial and the carrier is suppressed. Typical peak output power of television klystrons is 30 to 60 kW. Operating beam voltages range from 20 to 30 kV. The required bandwidth is 6 MHz. Thus, four or five cavity stagger-tuned klystrons are used to provide gain bandwidth and efficiency. In "internal-cavity" klystrons, the cavity wall is the vacuum wall and tuning is accomplished with a capacitive paddle near the interaction gap of the cavity. The paddle is actuated through a bellows. With this type of construction, tubes with three different cavity sizes are required to cover the 470 to 806 MHz UHF TV band. "External-cavity" klystrons have a ceramic vacuum wall inside each cavity,

FIGURE 7.2.6 Harmonic output of a typical klystron.

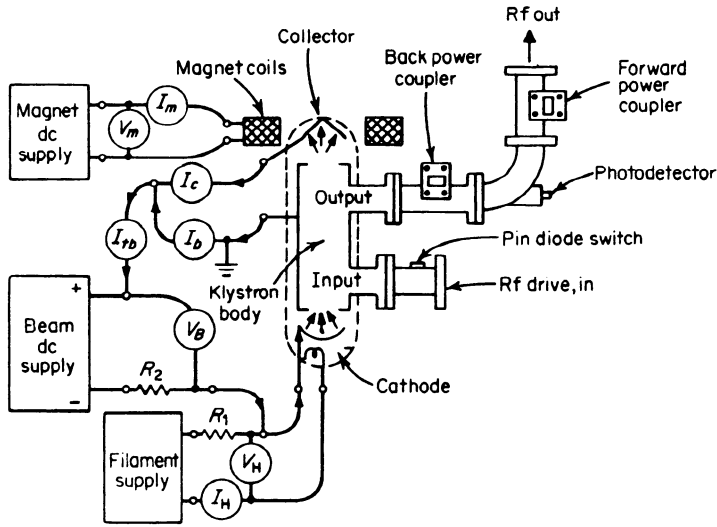

FIGURE 7.2.7 Circuits for a cw klystron amplifier.

antenna. In this way, average efficiency is increased to about 18 percent. More recently, UHF TV klystron efficiency has been increased further by means of multiple electron collector electrodes at reduced potentials, progressively closer to cathode potential. In such “multistage depressed collectors” (MSDC) klystrons, electrons tend to be collected at the lowest possible potential, and the power input goes up and down with drive level and output power in much the same way as it does in a triode or tetrode class-B amplifier. In this way efficiency is further increased by a factor of 2.5 to 3. Figure 7.2.8 shows a simplified schematic diagram of a circuit in which an MSDC klystron might be used.

Klystrons for radar and accelerator applications operate at higher voltages and currents than the cw klystrons described above. Because the electrons are traveling faster, the drift lengths between cavities and the cavity gaps can be longer. Because the gaps can be longer the drift-tube radius can also be larger without excessively lengthening the transit angle for electrons on the axis over that for electrons near the drift-tube wall. For this reason, pulse klystrons can be big enough to handle large average powers. Radar and accelerator klystrons operate at beam potentials and beam currents up to several hundred kilovolts and several hundred amperes. The Stanford Linear Accelerator Center (SLAC) has developed and manufactured many fairly conventional klystrons with peak output power at 2856 MHz ranging from 20 to 60 MW and pulse lengths of several microseconds. A 12 MW peak, 20 kW average power, 115 ms pulse length, 805 MHz klystron is used in the ion injector at the Fermi Laboratory (Fig. 7.2.9). The tube operates at 180 kV and 155 A. Long-pulse (several hundreds of microseconds) klystrons with frequencies between UHF and S-band, peak power of several megawatts and average power of several hundred kilowatts have been used to detect ballistic missiles. The Federal Aviation Agency uses many 2-to-5-MW klystrons in air-route surveillance radars (ARSR) operating in the 1250 to 1350 MHz band, and even more 1-to-2-MW klystrons in airport surveillance radars (ASR) operating in the 2700 to 2900 MHz band. An identical klystron is used in the National Oceanic and Atmospheric Administration’s NEXRAD Doppler weather radar which gives superior tornado and clear-air-turbulence warnings. The coherence and high-peak-power, short-pulse performance of klystrons make them ideal for detecting close-in low-radar-cross-section moving targets such as weather disturbances. It is interesting to note that the ASR/NEXRAD klystron will operate over the voltage range from 60 to 80 kV and produce output from 500 kW to 2 MW with efficiency ranging from 45 to 52 percent over the full range of voltages. This is not atypical; most klystrons will operate from one-half to about twice their design power by varying beam voltage and allowing the current to follow. It is also interesting to note that some of the 5-to-7 MW S-band klystrons used to power 16-to-20 MeV cancer-therapy linear accelerators are made using many of the same parts used in ASR/NEXRAD radar klystrons. The ASR/NEXRAD klystron is air

FIGURE 7.2.8 Simplified schematic for high-efficiency, depressed-collector-klystron UHF-TV final amplifier.

cooled; other radar and accelerator klystrons are liquid cooled. Nearly all are solenoid focused. Because the military, for good reason, places a premium on large instantaneous bandwidth, very few tunable klystrons remain in military service. By raising perveance, by full exploitation of stagger tuning, and by using single-gap, double-tuned output circuits, it is possible to achieve about 4 percent bandwidth at the 1-MW level and 10 percent at the 10-MW level in otherwise conventional klystrons. More modern broadband klystrons usually use some form of extended interaction which will be discussed in the next section.

All klystrons are usually operated with the cavities at ground potential. Short-pulse klystrons are usually “cathode pulsed.” That is, the cathode is connected to the negative going terminal of the secondary of a pulse transformer. The primary is connected by means of a switch (solid-state or gaseous electron tube) to a charged artificial transmission line (pulse-forming network). Longer pulse lengths are usually produced by incorporating a control electrode such as a floating (or “modulating”) anode in the klystron. When such an anode is used, the cathode of the klystron is connected to the negative end of a power supply incorporating a large energy storage capacitor, and electronic switches are connected between the cathode and the modulating anode (the “off switch”) and between the modulating anode and ground (the “on switch”). Sometimes control grids are used in front of the cathodes of pulsed klystrons, but they are fragile and are easily damaged by arcs. When dc power supplies are used either with modulating anodes or grids, it is common to use rapid discharge or “crow bar” circuitry across the power supply to protect the tube if an arc is sensed. These usually operate in less than $1 \mu\text{s}$ and are used in conjunction with an inductor which limits the rate of rise of the fault current.

Extended Interaction Klystrons

Extended interaction klystrons (EIK) use resonant circuits in which a weak electric field interacts with the electron beam over some distance or over several gaps which are so phased that the energy gain or loss of an

Clustered-cavity™ klystron

FIGURE 7.2.9 Conventional and clustered—cavity™ klystrons.

individual electron is cumulative. The advantage of such resonant circuits is that the integral of E^2 over the volume or the stored energy of the circuit is always less than it would be if the same voltage were developed at a single gap. This fact offers several possibilities:

Extended interaction output circuits (EIOC) can develop a greater impedance over a larger bandwidth, or in the highest power accelerator klystrons, the fields in the output circuit can be reduced to prevent RF arcing. Because stagger tuning of the cavities of conventional klystrons can achieve bandwidths which exceed those of single-gap output circuits, EIOCs have sometimes been used on such tubes, which have then been referred to as EIKs. At SLAC double-, triple-, and quadruple-coupled cavity circuits are being used in 150 MW, 3 GHz klystrons and 50 MW, 14 GHz klystrons. The circuits usually have been constant impedance filter circuits which support either a standing wave or a traveling wave. In standing wave resonators, the beam interacts with the forward traveling component of the wave which has been designed to have a phase velocity very nearly the same as the average beam velocity. Most traveling wave circuits are really much like traveling-wave tube output circuits in which the fields grow exponentially toward the output end. Such a circuit is used in the Twystron[®], so called because it uses a klystron buncher and a cloverleaf TWT output circuit. A more sophisticated approach to EIOC design makes use of a tapered impedance output circuit in which the filter circuits which couple the output gaps have image impedances which are progressively reduced in an inverse arithmetic taper (i.e., 1, 1/2, 1/3, . . .). Thus, when used with a current saturated electron beam in which the RF current can be made fairly constant over some distance, the current on the circuit builds up linearly (i.e., 1, 2, 3, . . .) and the voltage at all gaps is the same. This results in lower stored energy and reduces arcing for the same output power.

Extended-interaction buncher circuits have been used to a more limited extent. The first extended interaction klystron built by Wessel-Berg at Stanford about 1960, used three short-circuited helix sections as cavities and gave excellent bandwidth. Several millimeter wavelength klystrons, with power output ranging up to 2 kW at 94 GHz, have been built using ladder circuits to minimize circuit losses. Various manufacturers have proposed klystrons using pairs of cavities coupled together to achieve greater bandwidth. In the mid-1980s during computer simulations of such tubes, it was found that the coupling between the cavities of the pair was largely irrelevant because cavities, so closely spaced that there is little gain between them, are already coupled in the proper phase by the exciting current bunch so they cooperate in forming a new bunch farther downstream. This kind of klystron was named a clustered-cavity[™] klystron, and in a sense, it is a special case of extended interaction which is somewhat easier to design because one does not have to deal with coupling between cavities. Figure 7.2.9 shows a schematic comparison of a conventional klystron and a clustered-cavity klystron of the same power and gain. The clustered-cavity klystron will have twice the bandwidth if the paired cavities are artificially loaded to one-half the Q values of the single cavities they replace. A 13 percent bandwidth, 3 MW, 3 GHz clustered-cavity klystron is being manufactured. Computer simulations indicated that 30 percent bandwidths may be available from megawatt klystrons of this type.

INDUCTIVE OUTPUT TUBES (KLYSTRODES)

Donald H. Preist, M. B. Shrader

Tube and Cavity Configurations

The name *Klystrode* was coined to indicate that the output cavity, load system, and collector are basically as in a klystron. The input cavity and the input part of the tube resemble a triode. In all the UHF/TV amplifiers so far built the output cavity system is the external cavity type using a cylindrical ceramic window concentric with the electron beam. Many klystrons in service use this arrangement and a coupled secondary cavity connected to the output load, to maximize bandwidth (see Fig. 7.2.10). The input cavity is also external in that the major part of the circuitry is outside the vacuum envelope. Two types are in service.

The older type (Fig. 7.2.10) uses a small amount of controlled positive feedback and gives 1 to 3 dB more power gain than the second type (Fig. 7.2.11), but is hard to adjust. The second type is much easier to adjust and gives adequate gain, typically 22 dB. This is the favored approach in new amplifiers. In the very high power amplifiers built for "Big Science" applications the output cavity is in vacuum and the output window is in the coaxial transmission line to the load (Fig. 7.2.11). The input cavity is external as in the TV amplifiers. Both types have been used successfully, but the second type is preferred.

The most significant difference between the IOT/Klystrode and the klystron is the input cavity/tube system. The grid and cathode are at high negative dc potential with respect to ground. The correct RF voltage must appear between grid and cathode, even though the source of the RF drive power must be at dc ground potential. Also the grid to anode RF impedance must be minimized to prevent feedback; if positive this will tend to cause self-oscillation, and if negative it will tend to reduce power gain.

Transmitter Configurations for UHF/TV

Most of the earlier high-power installations used a pair of 60 kW tubes giving 120 kW P. S. visual and a third giving 13 kW CW aural. Later, transmitters featuring combined aural and visual amplification in the same tube were put into service. The exacting NTSC specifications could be met only by a high degree of amplitude and

phase linearity. This was achieved by a combination of careful tube design and a sophisticated precorrection module which allowed the residual nonlinearity of the IOT/Klystron and the solid-state driver amplifier to be reduced to a very low level.

The IOT itself is more linear than the klystron at black level in TV service, and it resembles a tetrode at low level (Fig. 7.2.12).

Properties of the IOT/Klystron as an Electron Device

First, it must be emphasized that the tube, unlike the klystron and the TWT is not a velocity-modulated tube. It uses a density-modulated electron beam as in a triode or tetrode. If the electron transit time through the tube is small in terms of the operating frequency, e.g., 1 rad, the efficiency will be high and may approach the theoretical limit of 78.5 percent. The “Big Science” tubes have shown 70 to 74 percent at output powers of several hundred kW. However, as the frequency is raised and the transit time or angle increases, the efficiency will eventually fall, but it will exceed the triode efficiency because the IOT anode is at high dc potential at the time of maximum current flow.

The tube (Fig. 7.2.10) is a five-electrode device with a spherical cathode and grid and an apertured anode at high dc potential. A reentrant cavity is placed between the anode and the next electrode, the tailpipe. Insulated from this is the final electrode, the collector. The electron beam is guided through the cavity by a magnetic field.

Because of the action of the negatively biased grid and the superimposed RF voltage the beam current flows for about half the RF cycle and is zero for the rest of the cycle. It passes through the aperture in the anode and the first part of the cavity without interception, at constant velocity. Next, it passes through the gap in the cavity where the RF field is decelerating, then through the second field-free region in the tailpipe with minimal interception due to the magnetic field, and finally enters the collector which is usually at ground dc potential. The two field-free regions are field-free because they are cylindrical metal pipes long enough to behave as waveguides beyond cut-off at the operating frequency.

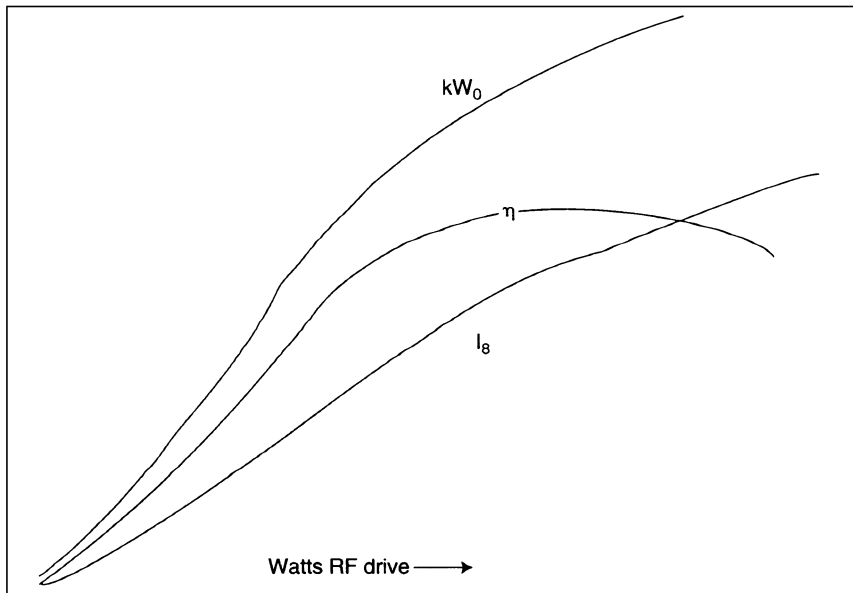

FIGURE 7.2.12 Power output vs. RF drive shows fair linearity. Efficiency stays relatively flat over 2:1 change in drive. Beam current is zero for zero drive.

Reference 2 contains a detailed analysis of the electron field and wave interactions. From the user's viewpoint the outstanding features are: (a) a complete absence of interaction between the output load impedance and the grid-cathode conditions, except when the load impedance approaches infinity; (b) the absence of a "dc blocking capacitor" carrying RF current as in a tetrode; (c) the output cavity system is at dc ground potential; (d) the power dissipated on the tailpipe is small; (e) the power output is not limited by the collector as this can be made indefinitely large and easy to cool, in principle. In practice there may be constructional problems with a very large collector on a super power tube. It should be noted, though, that the collector has to dissipate only the dc beam power minus the RF output power. In a conventional klystron the entire beam power has to be dissipated when the RF drive goes to zero.

Other significant performance characteristics can be seen from Fig. 7.2.12. Because the beam current falls to zero when the RF drive falls to zero, and varies monotonically with drive level, the device resembles the class B linear amplifier well-known to tetrode users. It is this feature that provides high average efficiency with an amplitude-modulated signal such as in TV, compared to a klystron. This is even more important with systems having a high peak-to-average signal ratio such as some digital HDTV systems.

In high power CW or long pulse (10 ms) service the IOT/Klystrode has performed well at 425 MHz (Ref. 5) and at 267 MHz (Ref. 4) as an RF power source for driving proton accelerators (Fig. 7.2.13). Here a set of characteristics become important which do not apply in TV service. Among these are: (1) absence of need for a high level pulser because the RF drive can be pulsed; (2) at VHF the physical size is very much smaller than a Klystron; (3) a high-power ferrite circulator may not be needed between the tube and the accelerator, and (4) the efficiency is higher than that of a klystron or a tetrode (70 to 74 percent measured).

Basis for Output Improvements

There are several reasons why IOT/Klystrodes can produce hundreds of kW compared to the 100 watts of Haeff's developmental tube, described in 1939 (Ref. 1).

1. The evolution of techniques for designing and fabricating electron guns, beam-focusing systems, cooling systems, cavities, and output windows over decades of microwave tube development,

FIGURE 7.2.13 Assumptions made in calculating maximum kW are (a) constant dc perveance 0.3 microperv, (b) maximum usable gun anode voltage 113 kV up to 750 MHz 20 kV at 3 GHz, (c) tube dimensions vary inversely with f above 750 MHz, (d) efficiency 70 percent.

2. The availability of pyrolytic graphite, an excellent material for making grids,
3. The availability of high purity alumina for output windows and coatings for multipactor suppression, and interelectrode insulators, and
4. The invention of the tungsten matrix impregnated cathode.

TRAVELING-WAVE TUBES

Pamela L. Walchli

Introduction

The traveling-wave tube (TWT) is a linear-beam device which amplifies microwave signals to high-power levels over broad bandwidths. It was invented by Rudolf Kompfner in the latter part of World War II and developed into a viable device by J. R. Pierce and L. M. Field at Bell Telephone Laboratories in 1945. Today, the TWT finds diverse application in communications, radar guidance, and electronic countermeasure systems.

Basic structure. All TWTs comprise four basic elements: (1) an electron gun, (2) an RF interaction circuit, (3) an electron-beam magnetic focusing system, and (4) a collector to dissipate the spent beam power.

The major difference between the various types of TWTs lies in the RF interaction structure. A schematic representation of a typical TWT is shown in Fig. 7.2.14. At the left is the electron gun, which forms the beam; at the center are the RF interaction structure (in this case, a helix) and the magnetic beam-focusing system; on the right is the collector that absorbs the spent beam power.

Theory of operation. The purpose of the interaction structure is to slow the RF signal so that it travels at the same speed as the electron beam. Electrons enter the structure during both positive and negative phases of an RF cycle. Those entering during a positive phase are accelerated; those entering during a negative phase are decelerated. The electrons that experience a velocity increase catch up with the electrons that have been slowed down, forming electron bunches. These bunches produce an alternating current superimposed on the dc beam current. The alternating current induces growth of the RF circuit wave, which, in turn, forms tighter electron bunches and thus a larger component of alternating current.

Growth of the wave on the circuit occurs because the velocity at which the beam is traveling forces the electron bunches to enter a decelerating phase of the RF field. In the decelerating field, the electrons are slowed, transferring their energy to the RF wave. This cycle is limited by one or more sever and ultimately by the extraction of the RF power through the output connector. The sever absorbs the RF power that has been built up on the circuit but does not affect the ac component of current in the beam.

The modulated beam drifts through the sever region, and induces a new RF wave in the next circuit section, where the interaction process begins again. The purpose of the sever is to absorb reflected power, which travels in a backward direction on the circuit. The reflected power arises from an imperfect match between the RF circuit and the output connector. Without the sever, regenerative oscillations would be induced.

FIGURE 7.2.14 Basic elements of a typical TWT.

7.40 UHF AND MICROWAVE COMPONENTS

At any given frequency, a certain level of drive power will cause the maximum degree of bunching and thus the greatest amount of output power. This condition is known as *saturation*. For small drive signals, typical TWTs have 40 to 70 dB of gain.

The Electron Gun

The electron gun forms a high-current-density pencil beam of electrons, part of whose energy is converted to RF power through interaction with the wave traveling along the RF circuit. In the typical electron gun, electrons are emitted from a spherical cathode and converged to the required beam size by focusing electrodes. The final converged beam size is maintained through the interaction structure by either permanent magnet or electromagnet focusing.

On-off switching modulation of the electron beam is accomplished by applying a pulse to one of four electrodes: (1) cathode, (2) anode, (3) focus electrode, or (4) grid.

Cathode and anode pulsing. In the first method, the cathode is pulsed negatively with respect to the grounded anode, requiring both the full beam voltage and current to be switched. Alternatively, anode modulation involves switching the full beam voltage between cathode potential and ground, but the current switched is just that intercepted on the anode, usually only a few percent of the full beam current.

Focus-electrode pulsing. The focus electrode, which normally operates at or near cathode potential, can be biased negatively with respect to the cathode to turn the beam off. The voltage swing required is usually one-third or less of the full cathode voltage. Since the focus electrode draws no current, reduction in power requirements is significant.

Grid pulsing. Switching power requirements are minimized with grid modulation. A grid structure, to which the modulating voltage is applied, is placed directly in front of the cathode surface. The amount of voltage swing needed is typically only one-twentieth or less of the full beam voltage.

Some common grid structures in use are shown in Fig. 7.2.15. The grid in Fig. 7.2.15a is a simple, single intercepting grid. To turn the beam on, a voltage positive with respect to the cathode is applied to the grid, drawing current from the full cathode surface. The grid webs intercept the current drawn from the cathode area directly behind the grid. This interception limits the duty cycle at which the tube can operate.

Current drawn by the grid can be minimized by schemes such as those shown in Figs. 7.2.15b and 7.2.15c. The structure in Fig. 7.2.15b is composed of two grids, the one nearest the cathode surface operating at cathode potential and the outer one operating at the modulating voltage. The inner grid, identical in pattern to the outer grid, prevents emission from the cathode surface directly behind it, effectively eliminating intercepted current on the control grid. This inner grid is referred to as a *shadow grid*. The shadow grid may be attached directly to the cathode surface, as in Fig. 7.2.15c. This kind of structure has the trade name Unigridd.

FIGURE 7.2.15 Grid structures used in TWTs: (a) simple intercepting grid; (b) double grid, with shadow grid operated at cathode potential; (c) unigridd type, with shadow grid attached directly to cathode.

A simple grid has application in smaller guns, where high amplification factors are not required. The grid operates at cathode potential and therefore intercepts no current. To turn off the beam, a voltage negative with respect to the cathode is applied to the grid. Amplification factors around 10 are typical for this kind of electron gun.

Magnetic Beam Focusing

Without a focusing system the electron beam would spread due to the mutually repulsive forces on like-charged particles, causing the electrons to strike the RF circuit. A magnetic beam-focusing system is the most widely used and is usually implemented in one of three ways: (1) electromagnetic, (2) permanent magnet, or (3) periodic permanent magnet.

Electromagnet Focusing. Electromagnet focusing is used primarily on very high power coupled-cavity TWTs. Tight beam focusing is required in these tubes because significant interception on the RF circuit is intolerable at the power levels in question. Disadvantages of this kind of focusing are size, weight, and consumption of power, but all can be reduced somewhat by wrapping the windings of the solenoid directly on the tube body. Solenoidal focusing is illustrated in Fig. 7.2.16a.

Permanent-Magnet Focusing. Permanent-magnet focusing is possible where the interaction structure is short, e.g., in low-gain or millimeter-wave tubes. It can be used in place of solenoidal focusing in these kinds of tubes. This focusing system is shown in Fig. 7.2.16b.

Periodic-Permanent-Magnet Focusing. Periodic-permanent-magnet focusing is used on almost all helix TWTs and most coupled-cavity TWTs. A periodic-permanent-magnet (PPM) structure is shown in

FIGURE 7.2.16 Magnetic focusing arrangements: (a) solenoidal type; (b) permanent-magnet type; (c) periodic permanent-magnet structure.

7.42 UHF AND MICROWAVE COMPONENTS

Fig. 7.2.16c. The magnets are arranged with alternate axial polarity in successive cells. In helix TWTs the pole pieces (with nonmagnetic spacers) may form the tube's vacuum envelope, or the pole pieces and spacers may be slipped over a stainless-steel tube that serves the same purpose. In coupled-cavity TWTs the cavity walls themselves are the pole pieces.

This kind of focusing provides a major reduction of tube size and weight, along with the elimination of the magnet power supply. The drawback of this scheme is that the electron beam ripples with a periodicity of the length of one magnet cell. This increases beam interception on the RF circuit and thus generally limits the use of PPM focusing to lower average-power TWTs.

The Interaction Circuit

The fundamental principle of operation of a TWT is that an electron beam moving at approximately the same velocity as an RF wave traveling along a circuit gives up energy to the RF wave. Since the RF wave travels at the speed of light, a method must be found to slow the forward progress of the wave to roughly the same velocity as that of the electron beam. The beam speed in a TWT is typically between 10 and 50 percent of the velocity of light, corresponding to cathode voltages of 4 to 120 kV. The two structures that accomplish the slowing of the RF wave are the helical and coupled-cavity circuits.

Helix circuits. The helix (Fig. 7.2.17) is supported inside the vacuum envelope by three or more ceramic support rods, which also conduct heat away from the helix. A helix interaction structure is used where bandwidths of an octave or more are required, since over this range the velocity of the signal carried by the helix is almost constant with frequency. For greater than octave-bandwidth operation, the variation of velocity with frequency can be modified by the introduction of metal loading segments near the helix, causing the phase velocities of a wider range of frequencies to be more nearly in synchronism with the beam velocity.

The helix provides satisfactory performance over the range of frequencies from 500 MHz to over 40 GHz. However, the typical helix circuit is limited in average power-handling capability to a few hundred watts. Peak power levels above several kilowatts cannot, in general, be achieved because of circuit RF instabilities. Higher peak power levels can be obtained by eliminating these oscillations with a special type of helix circuit consisting of the superposition of a helix wound in a right-hand sense on a helix wound in a left-hand sense. Two practical implementations of this configuration are the ring-loop and ring-bar circuits (Fig. 7.2.18). Peak powers of hundreds of kilowatts are attainable, but average power capability is no better than that of the conventional helix

FIGURE 7.2.17 Helix circuit: (a) end view; (b) side view.

FIGURE 7.2.18 Structures composed of two helices superimposed in opposite sense of rotation: (a) ring-bar circuit; (b) ring-loop circuit.

circuits, since the structures are supported in a like manner. Because the ring-bar and ring-loop circuits are dispersive, the maximum bandwidth of a tube using them is typically only one-third octave.

Coupled-Cavity Circuits. Because of its superior ability to dissipate heat, the coupled-cavity structure is capable of both high peak and average power over moderate bandwidths. Coupled-cavity tubes find applications from 2 GHz up to nearly 100 GHz. Bandwidths of 10 percent are typical, although tubes with 40 percent bandwidth have been developed.

The coupled-cavity circuit consists of resonant cavities coupled through slots cut in the cavity end walls, resembling a folded waveguide. This arrangement results in a bandpass filter network that is highly dispersive, limiting the tube bandwidth. The two most common kinds of coupling schemes are illustrated in Fig. 7.2.19. The structure in Fig. 7.2.19a is a forward fundamental circuit, also called a cloverleaf circuit from the shape of its cavities. It is used primarily on extremely high peak power coupled-cavity tubes or in the output section of a hybrid klystron TWT, known as a Twystron. Typical performance of a tube with a forward fundamental circuit is 3 MW peak and 5 kW average at S band. Figure 7.2.19b illustrates the more commonly used coupled-cavity structure, the single-slot space harmonic circuit. A peak power of 50 kW and an average power of 5 kW at X band are typical for space harmonic TWTs.

FIGURE 7.2.19 Coupled-cavity circuits: (a) forward fundamental circuit ("cloverleaf"); (b) single-slot space harmonic circuit.

The Collector

The function of the collector is to collect the electron beam after it has passed through the interaction structure and dissipate the remaining beam energy. During interaction electrons give up various amounts of energy, and some actually gain energy. Typically, the slowest electrons lose no more than 50 percent of their original energy; the fastest gain at most 20 percent with the remainder distributed between these extremes. If a TWT had an interaction efficiency of 20 percent, the average electron would possess 80 percent of its original energy.

Single-Stage Collectors. The overall efficiency of the TWT can be increased by operating the collector at a voltage lower than the full beam voltage, a practice known as *collector depression*. This introduces a potential difference between the interaction structure and the collector through which the electrons pass. The amount by which a single-stage collector can be depressed is limited by the remaining energy of the slowest electrons; i.e., the potential drop can be no greater than the amount of energy of the slowest electrons or they will be turned around and reenter the interaction structure, causing oscillations.

Multistage Collectors. Efficiency can be increased still more by introducing multiple depressed-collector stages. This method provides for the collection of the slowest electrons on one stage, while allowing those with more energy to be collected on other stages depressed still further. Figures 7.2.20a and b represent the configuration of power supplies (less the heater supply) to operate a gridded TWT with a single-stage and a multi-stage depressed collector, respectively. Calculations of the overall efficiency of such TWTs are shown in the following table, assuming a beam power of 5 kW (10 kV, 0.5 A) and an interaction efficiency of 15 percent:

	Voltage, kV	Current, A	Power, W
Single-stage collector			
Helix supply	10	0.025	250
Collector supply	5	0.475	2,375
Overall efficiency = $\frac{750 \text{ W}}{250 \text{ W} + 2375 \text{ W}} = 29\%$			
	Voltage, kV	Current, A	Power, W
Multistage collector			
Helix supply	10	0.025	250
Collector stage, 1	5	0.23	1,150
2	2.5	0.15	375
3	1	0.085	85
4	0	0.01	0
Overall efficiency = $\frac{750 \text{ W}}{250 \text{ W} + 1150 \text{ W} + 375 \text{ W} + 85 \text{ W}} = 40\%$			

Helix TWTs are cooled conductively by mounting the tube in a metal baseplate, which is in turn attached to an air- or liquid-cooled heat sink. Coupled-cavity tubes below 1 kW average power are cooled convectively by drawing air over the entire tube length. Higher-power coupled-cavity tubes are cooled by circulating liquid over the tube body and collector.

Microwave Power Module

In keeping with the general trend in electronic components toward minimization of system size, the microwave power module (MPM) is a complete microwave power amplifier contained within a volume of less than 20 in³. This system consists of a micro-miniature helix TWT driven by an MMIC preamplifier, and a

FIGURE 7.2.20 Power supplies for TWTs: (a) single collector TWT; (b) multistage depressed collector TWT.

high-density electronic power conditioner that powers both the TWT and the MMIC amplifier. Applications include electronic countermeasures, radar and communications transmitters. These modules may also be combined for use in shared aperture phased arrays.

CROSSED-FIELD TUBES

George K. Farney

Crossed-Field Interaction Mechanism

A crossed-field microwave tube is a device that converts dc electric power into microwave power using an electronic energy-conversion process similar to that used in a magnetron oscillator. These devices differ from beam tubes in that they are potential-energy converters rather than kinetic-energy converters. The term *crossed field* is derived from the orthogonality of the dc electric field supplied by the source of dc electric power and the magnetic field required for beam focusing in the interaction region. Typically, the magnetic field is supplied by a permanent-magnet structure. These tubes are sometimes called *M tubes*.

The electronic interaction is illustrated schematically in Fig. 7.2.21. Electrons moving to the right in the figure experience electric field deflection forces ($f_e = -\epsilon E$) toward the electrically positive anode, while the magnetic deflection forces ($f_m = -\epsilon v \times B$) resulting from the motion of the negatively charged electron in the orthogonal magnetic field cause deflection toward the negative electrode. This electrode is also called the *sole*.

The forces are balanced when an electron is traveling in a parallel direction between the electrodes with a velocity numerically equal to the ratio of the dc electric field to the magnetic field ($v_e = E/B$). Any alteration of the electron velocity leads to an unbalanced condition. Reduction of the electron forward motion causes the magnetic deflection force to become less, and the electron trajectory is deviated toward the positive electrode. Conversely, an increase of velocity causes a greater magnetic deflection force, which causes trajectory deviation toward the negative electrode.

Electronic interaction with a traveling wave occurs when the positive electrode is an RF-guiding slow-wave circuit whose phase velocity for the traveling wave is numerically equal to the ratio of the dc electric field to the magnetic field ($v_p = E/B$). Under these conditions synchronous interaction occurs between the RF fields on the slow-wave circuit and the stream of electrons traveling in the interaction region.

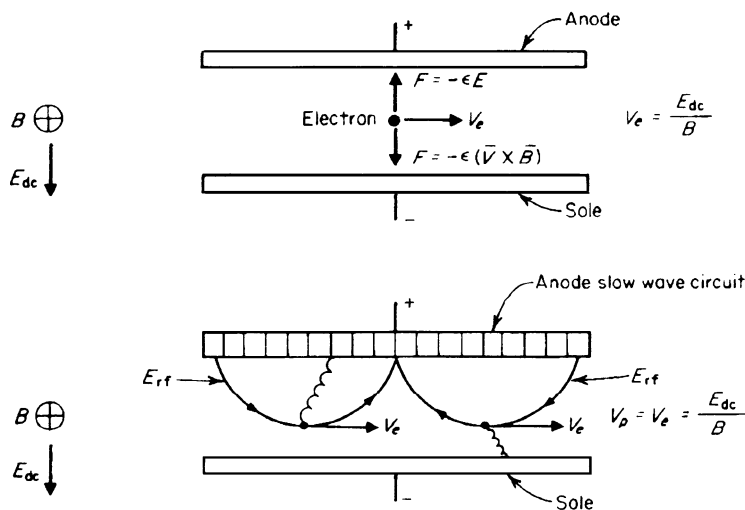

FIGURE 7.2.21 Forces exerted on a moving electron in a crossed-field environment.

Two general kinds of motion result, as illustrated schematically in Fig. 7.2.21, where a moving frame of reference is shown traveling from left to right at a velocity equal to the phase velocity of the circuit wave, so that the instantaneous RF fields are seen as stationary. The electronic motion resulting from interaction with the tangential components of the additional RF electric fields depends on the location of the electron relative to the phase of the RF fields of the slow-wave circuit. Those located so that their forward motion is retarded by the RF electric field are slowed, and the energy they lose is transferred to the RF wave on the circuit. These slower-moving electrons are subsequently accelerated toward the anode by the dc electric field, and their velocity is increased to the synchronous condition. The energy-exchange cycle can then be repeated. Electrons moving in this phase of the RF field pattern transfer energy to the RF wave on the circuit while maintaining nearly constant kinetic energy. The energy transfer results from the loss of potential energy of the electrons as they move to the anode.

Electrons located in the alternate phase of the RF field pattern are accelerated by the RF field and move away from the anode. The intensity of the slow wave decreases exponentially with distance away from the slow-wave circuit so that the magnitude of this interaction decreases. The result is the transfer of dc electric power to microwave power on the slow-wave circuit, with the phase-sorted electrons in the crossed-field interaction region providing the necessary coupling mechanism. Electron current thus flows to the anode only in the region of suitably phased RF electric fields.

The components of the RF field which are perpendicular to the forward motion of the electrons exert forces which phase-lock the electron near the center of the pattern. These regions are called *spokes* because of the similarity, in a magnetron oscillator, to the spokes in a rotating wheel. The phase locking of the sorted space charge relative to the traveling RF wave on the slow-wave circuit reduces the effect of power-supply variations on the electron trajectories. The details of the electron trajectories are extremely complex and have been calculated only approximately, using sophisticated computer techniques.

It is an important fundamental of crossed-field interaction that very high electronic conversion efficiency can be obtained because the kinetic energy of the electrons lost as heat upon ultimate impact with the slow-wave circuit can be designed to be a small fraction of the total potential energy transferred from the power supply. The ideal electronic conversion efficiency is given by $\eta = 1 - V_0/V$, where η is efficiency, V_0 is the synchronous voltage, and V is the cathode-to-anode voltage. Large ratios of V/V_0 lead to high efficiencies.

The crossed-field magnetron oscillator achieved prominence as a source of microwave power for radar applications during World War II. Since that time many kinds of crossed-field devices were investigated. One type of device obtains current from a thermionic cathode, electron gun located external to the crossed-field interaction space similar to that used in electron beam tubes. A second type uses electron current supplied by thermionic and/or secondary emission from a negative electrode facing the slow-wave circuit. This is similar to a cathode in a magnetron. These are called emitting sole tubes. Both types are illustrated schematically in Fig. 7.2.22.

Slow-Wave Circuits for Crossed-Field Tubes

Electron current in crossed-field interaction moves toward the slow-wave circuit rather than through the circuit as in beam tubes. This leads to the use of open circuits that present an RF waveguiding surface to the electron stream. Maximum energy conversion efficiency is usually obtained when the current is intercepted on the slow-wave circuit; so the structures must withstand the thermal stress associated with electron bombardment. Electronic interaction can occur using either forward-wave or backward-wave traveling-wave circuits, as well as with circuits supporting a standing wave. Examples of circuits suitable for use in forward-wave interaction are various *meander lines*, *helix-derived structures*, *bar and vane structures*, which are capacitively loaded by ground planes, and *capacitively strapped-bar circuits*.

A helix-coupled vane circuit and a ceramic-mounted meander line are shown in Fig. 7.2.23a. The most common backward-wave circuits are derivatives of the interdigital line and strapped-bar and vane circuits. Examples of a choke-supported interdigital line and a strapped-bar circuit are shown in Fig. 7.2.23b. Traveling-wave circuits are used mostly in amplifiers. Standing-wave circuits are resonant and used typically in magnetron oscillators. The most commonly used standing-wave circuits are composed of arrays of quarter-wave resonators that may or may not be strapped for improved oscillating-mode stability.

Variations of these circuits include *hole-and-slot resonators* and *rising-sun* anodes. Examples are shown in Fig. 7.2.23c. Cooling of vane structures for high average power is obtained by heat conduction along the vanes to the back wall of the anode to a heat sink, which may be liquid- or forced-air-cooled. Bar structures are cooled by passage of liquid coolant through the tubular bars of the slow-wave circuit.

FIGURE 7.2.22 (a) Linear injected beam and (b) reentrant emitting-sole crossed-field amplifier.

During the time of intense research and development for crossed-field tubes, there were a large number of concepts under investigation. It was common to display a family tree of these to illustrate their similarities and differences. They were separated into two major groupings of injected beam and emitting sole devices. There were subgroups in each dependent on whether the device was an oscillator or amplifier, whether it used reentrant or nonreentrant electron streams and whether it used forward wave, backward wave or standing wave interactions with a slow-wave circuit. Many of these are no longer of general interest since some were not fully developed and others were made obsolete by newer technologies and/or by changes in performance requirements.

Magnetron oscillators are single-port devices. Both the slow-wave circuit and the electron stream are reentrant; i.e., the circular geometry is always used. Traveling-wave crossed-field oscillators are single-port devices but use a nonreentrant electron stream. They use either the linear or circular format.

Injected-beam and emitting-sole amplifiers are two-port devices with RF input and output ports. They are fabricated in both linear and circular format. Linear tubes must use a nonreentrant electron stream. Some circular-format amplifiers use a reentrant electron stream and some do not. Both forward-wave and backward-wave amplifiers have been developed.

Crossed-Field Oscillators

Conventional Magnetrons. The conventional magnetron is an emitting-sole, circular-format, reentrant-stream device with electronic interaction between the circulating current and a π -mode, RF standing wave on the slow-wave circuit. Oscillation builds up from noise contained initially in thermionic-emission current from

FIGURE 7.2.23 Slow-wave circuits for crossed-field tubes.

a heated cathode. During operation interaction current is obtained from a circulating hub of space charge supplied primarily by secondary electron emission from the cathode surface. This is illustrated in Fig. 7.2.24. Large peak currents are obtainable, permitting the generation of high peak power at lower voltages than are used for beam tubes of comparable peak power.

Pulsed magnetrons have been developed covering frequency ranges from a few hundred megahertz to 100 GHz. Peak power from a few kilowatts to several megawatts has been obtained with typical overall efficiencies of 30 to 40 percent, depending on the power level and frequency range. Continuous-wave magnetrons have also been developed with power levels of a few hundred watts, in tunable tubes, at an efficiency of 30 percent. As much as 25 kW cw has been obtained for a 915-MHz fixed-frequency magnetron at efficiency greater than 70 percent.

Pulsed magnetrons are used primarily in radar applications as sources of high peak power. Low-power pulsed magnetrons find applications as beacons. Magnetrons operate electrically as a simple diode, and pulsed modulation is obtained by applying a negative rectangular voltage pulse to the cathode with the anode at ground potential. Voltage values are less critical than for beam tubes, and line-type modulators are often used to supply pulse electric power. Tunable cw magnetrons are used in electronic countermeasure applications. Fixed-frequency magnetrons are used as microwave heating sources.

Mechanical tuning of conventional magnetrons is accomplished by moving capacitive tuners, near the anode straps or capacitive regions of the quarter-wave resonators, or by inserting symmetrical arrays of

FIGURE 7.2.24 Conventional magnetron structure.

plungers into the inductive portions. Tuner motion is produced by a mechanical connection through flexible bellows in the vacuum wall. Tuning ranges of 10 to 12 percent bandwidth are obtained for pulsed tubes and as much as 20 percent for cw tubes.

Coaxial Magnetrons

The frequency stability of conventional magnetrons is affected by variations in the microwave load impedance (frequency pulling) and by cathode current fluctuations (frequency pushing). When the mode control becomes marginal, the tube may occasionally fail to produce a pulse. The coaxial magnetron minimizes these effects by using the anode geometry shown in Fig. 7.2.25. Alternative cavities are slotted to provide coupling to a surrounding coaxial cavity. π -mode operation of the vane structure provides in-phase currents at the coupling slots which excite the TE_{011} circular electric coaxial mode. The unique RF field pattern of the circular electric mode permits effective damping of all other cavity modes with little effect on the TE_{011} mode, and oscillation in other cavity modes is thereby prevented. Additional resistive damping is used adjacent to the slots but removed from the vanes to prevent oscillation in unwanted modes associated with RF energy stored in the vanes and slots that does not couple to the coaxial cavity.

FIGURE 7.2.25 Coaxial magnetron coupling.

The oscillation frequency is controlled by the combined vane system and resonant cavity. Sufficient energy is stored in the TE_{011} cavity to provide a marked frequency-stabilizing effect on the oscillation frequency. Hence the coaxial magnetron is much less subject to frequency pushing and pulling than conventional magnetrons, and it exhibits fewer missed pulses. Tunable versions of this tube type are tuned by a movable end plate in the coaxial cavity similar to a tunable coaxial wavemeter. This is illustrated in Fig. 7.2.26. The larger resonant volume for energy storage leads to a slower buildup time for oscillation than in conventional magnetrons. This causes greater statistical variation in the starting time for oscillation (leading-edge jitter).

These factors are compared in Table 7.2.1 for the SFD-349 coaxial magnetron, which was designed as an improved retrofit for the 7008 conventional magnetron. The operating efficiency of the SFD-349 was deliberately degraded to meet retrofit requirements. Typically, coaxial magnetrons operate with an efficiency of 40 to 50 percent or higher.

Spurious Noise. The circulating space charge in the hub of both conventional and coaxial magnetrons contains wide-band noise-frequency components that can couple to the output. In conventional magnetrons this spurious noise can couple directly to the output waveguide. Spurious noise power measured in a 1-MHz bandwidth is typically greater than 40 to 50 dB below the carrier. The coaxial cavity in the coaxial magnetron provides some isolation between the spurious noise coupled to the vanes and the output waveguide. The spurious-noise power from coaxial magnetrons is typically 10 to 20 dB lower than conventional magnetrons of comparable peak power level.

FIGURE 7.2.26 Schematic of coaxial magnetron.

Frequency-Agile Magnetrons

To improve radar-signal detection and electronic countermeasures, rapid frequency-changing signal sources have been developed. Frequency-agile conventional magnetrons are available with rapidly rotating capacitive tuners (*spin-tuned magnetrons*) or hydraulic-driven, *mechanically tuned* tubes. The operational advantages of the coaxial magnetron are preserved in frequency-agile dither-tuned and gyro-tuned coaxial magnetrons.

Dither-tuned magnetrons use a mechanically tuned coaxial magnetron with an integral motor and *resolver* to provide high-speed, narrow-band frequency-agile operation. Mechanical linkage between the rotating motor and the tuning plunger provides approximately sinusoidal tuning of the magnetron frequency. Mechanical limitations imposed by acceleration forces determine the attainable tuning range and tuning rates. A voltage output from the resolver is made proportional to the magnetron frequency and is used to adjust the receiver local oscillator to track the rapidly tuned frequency of the magnetron. X-band tubes, 200 kW, with narrow-band dither-tuned frequency ranges of 30 to 50 MHz, are tuned at rates of 200 Hz. Wider-band frequency excursions of 250 to 500 MHz are dithered at rates of 25 to 40 Hz. Some of these tubes are equipped with servo motors for tuning. Frequency can be set electronically to provide rapid changes of fixed-frequency operation or can be dither-tuned with various shapes of frequency-tuning curves. These tubes are called *Accutune magnetrons*.

Gyro-tuned coaxial magnetrons use several rotating dielectric ceramic paddles in the stabilizing coaxial cavity, which cause frequency variation as they are rotated in a plane normal to the RF electric field of the TE_{011} mode. The anode vane system of the tube is surrounded by a ceramic cylinder bonded to the ends of the coaxial cavity to form the vacuum wall for the electronic interaction region. The stabilizing cavity, containing the tuning, is outside of this vacuum wall and is pressurized with sulfur hexafluoride, to inhibit arcing or corona caused by high RF fields. The tuner drive motor and frequency readout generator are also located within the pressurized section of the magnetron. The symmetry and inherently low rotational mass of the dielectric paddles result in a mechanism in which tuning speed and RF frequency excursion are essentially independent. It is therefore possible to attain higher tuning rates and relatively broader frequency excursion simultaneously than is achieved currently with dither tuning. K_u band, 60 kW peak power, gyro-tuned magnetrons obtain frequency excursions of 300 MHz at 200-Hz tuning rates.

Crossed-Field Amplifiers (CFAs)

Injected-Beam Types. Extensive development efforts have been devoted to nonreentrant forward-wave amplifiers (*TPOM*) for both cw and pulsed application. Continuous-wave amplifiers with a few hundred watts output have been developed with gain of 20 to 30 dB and with efficiency of 20 to 35 percent. Proper control of the electron stream at large values of gain requires the beam to be physically close to the anode at synchronism. Operation at low values of V/V_0 (3 to 6), together with increased insertion loss for tubes with greater circuit length for greater gain, leads to lower efficiency values. Like TWTs, the attainable bandwidth is dependent on the electron-beam optics and the dispersiveness of the slow-wave circuit. Half-octave bandwidth has been

obtained at constant-voltage settings, and full-octave bandwidth has been obtained with adjustment of the anode-to-sole voltage. Stable operation at gain in excess of 20 dB requires circuit severers or distributed attenuation as in TWTs. Useful gain in excess of 30 dB is difficult because of excessive noise buildup in the electron stream.

Narrow-band (10 percent), pulsed, high-peak-power (5 MW) injected-beam amplifiers, which operate with efficiencies greater than 50 percent, were developed in France for use in radar application. These tubes have gain of 11 to 15 dB. The lower gain values (greater input signal level) permit the use of less critical beam optics, shorter slow-wave circuits, and greater ratios of V/V_0 .

Injected beam CFAs were developed in the United States for electronic countermeasure applications, but the tubes were not widely deployed.

Emitting-Sole Crossed-Field Amplifiers

Electron current for emitting-sole crossed-field amplifiers is obtained from the sole electrode in the interaction space by electron-beam back bombardment, as in the magnetron oscillator. Unlike the magnetron, these amplifiers do not require thermionic emission to initiate current flow. Current flow can be started in an emitting-sole CFA by the admission of an RF signal to the input of the slow-wave circuit when the proper magnetic field and anode-cathode voltage are present in the interaction region. Amplifiers with RF-induced current flow are called *cold-cathode* amplifiers, regardless of cathode temperature, provided there is no thermionic emission from the cathode. In the absence of an RF input signal, these amplifiers remain quiescent even with full operational voltage applied. The details of the starting mechanism of RF-induced current flow are not fully understood, but the phenomenon is reliable in a properly designed amplifier.

Radio-frequency-induced current flow permits several modulation techniques for pulsed emitting-sole CFAs. These include cathode-pulsed CFAs, dc-operated CFAs with combination of dc voltage and a pulsed turn-off voltage, and dc-operated CFAs with only dc voltages applied. Cathode-pulsed amplifiers, as do magnetron oscillators, use pulse modulators to supply the required dc electric power during amplification. Direct-current-operated amplifiers obtain electric input power for amplification from a dc power supply. Electron current flow is initiated by an RF input signal and is terminated at the end of the RF input signal either by a voltage pulse or a dc bias voltage applied to a quench electrode.

Cold-cathode starting for cathode-pulsed amplifiers is assured by correct temporal alignment so that the RF input pulse bridges the cathode voltage pulse. The RF signal is present on the slow-wave circuit as the applied voltage pulse increases to synchronous value. Current flow is initiated, and amplification occurs during the voltage pulse and ceases upon removal.

Both forward-and backward-wave cathode-pulsed CFAs are available. They use the circular-formal reentrant-stream geometry illustrated in Fig. 7.2.27. A reentrant electron stream is advantageous because electrons that have delivered only part of their available potential energy to the circuit wave as they leave the interaction region can reenter for further participation, thereby leading to higher electronic conversion efficiency. (Overall amplifier efficiencies of 45 to 50 percent or more are common.) The leaving phase-sorted electrons contain RF modulation. Some reentrant-stream amplifiers use a circuit geometry with the RF input and output ports spatially separated by a sufficiently long circuit-free region (called the *drift space*) for internal space-charge forces to cause dispersal of the electron spokes. This removes the RF modulation from the reentrant stream while preserving the reentrant-stream efficiency advantage. Other reentrant backward-wave amplifiers (*Amplitrons*) use the modulated electron stream to create a regenerative amplifier. A minimal drift space is used, so that the electron spokes reenter the interaction region before the modulation is dispersed. By suitable design of the shorter drift-space dimensions, the modulated stream reenters with positive phase to enhance the interaction.

Greater electronic conversion efficiency (amplifier efficiency in excess of 70 percent has been obtained) can be obtained at the expense of lower gain-bandwidth product than can be obtained with amplifiers which remove the reentrant modulation. The use of regenerative amplification is not feasible with a forward-wave amplifier because, at a fixed operating voltage, the simultaneous regenerative gain at frequencies other than the drive signal could lead to unwanted auxiliary oscillations or selective peaks in spurious-noise output power. This is avoided with a backward-wave amplifier because the dispersive slow-wave circuits require different voltages to obtain adequate amplification of separated frequencies.

Spurious Noise. Dispersal by space-charge forces of the nonphase-locked electrons in a drifting spoke can lead to a rapid buildup of broadband spurious-noise components in the reentering electron stream. This is

FIGURE 7.2.27 Diagrams of reentrant-stream crossed-field amplifiers: (a) cathode-pulsed; (b) with control electrode turn-off.

prevented from becoming severe by use of a sufficiently large RF input signal to lock out noise-signal growth. CFA power output as a function of RF drive signal is illustrated in Fig. 7.2.28. Reduction of the RF input signal leads to a reduced amplifier output signal at higher values of gain but is accompanied by an increased relative amount of broadband noise-power output. (Reentrant emitting-sole CFAs with terminated input have

FIGURE 7.2.28 Emitting-sole crossed-field power output.

been used for high-efficiency broadband noise generators.) Adequate lockout of the noise power is obtained at reduced signal gain when the amplifier is driven well into saturation. The rapid growth of noise at small drive signals precludes the use of distributed attenuation and of circuit severers for emitting-sole amplifiers.

Relatively short slow-wave circuits are used with the minimum attainable insertion loss between the RF input and output connections. These amplifiers are called *transparent tubes*. Reflected signals from a load mismatch travel backward through the amplifier to the RF input, where they can be reflected, possibly leading to oscillation. Judicious use of ferrite isolators and circulators at the RF input and/or output minimizes this effect. The overall stable gain of emitting-sole CFAs is limited to 20 dB or less (typically 13 to 15 dB) because of the requirement for a sufficiently large RF input signal for adequate lockout of spurious-noise power and the need to limit

gain to avoid oscillations caused by multiple reflected signals. Transparency is often used to advantage in radar systems employing the final amplifier in the transmitter chain in a nonoperating feedthrough mode to provide coarse programming of the output power level.

Bandwidth Characteristics. Cathode-pulsed forward-wave amplifiers offer 10 to 15 percent instantaneous bandwidth at a fixed value of pulsed voltage. Backward-wave amplifiers provide only 1 to 2 percent instantaneous bandwidth under comparable conditions but can accommodate 10 percent bandwidth by adjustment of cathode voltage. The static impedance of both tube types varies as a function of frequency. The constant voltage versus frequency characteristics of forward-wave amplifiers is readily accommodated by a hard-tube cathode modulator, providing nearly constant power output across the frequency band of the amplifier. Constant power output versus frequency for a variable-voltage backward-wave amplifier is nearly achieved

with a constant-current modulator. For restricted bandwidth (4 to 6 percent) this condition is approximated by using a line-type modulator.

Modulation Requirements. A simplification in modulator requirements is obtained with a broadband, dc-operated, RF-triggered CFA. The termination of the RF input signal after RF turn-on leaves uncontrolled circulating space charge that can generate a cw spurious output signals of magnitude as large as half the amplified signal output. To avoid this, a *control electrode* (also called quench electrode) isolated from the cathode is mounted as part of the cathode structure and is located in the drift space. This location minimizes interference with amplifier performance (Fig. 7.2.27b). This electrode is pulsed positive with respect to the cathode, coincident in time with removal of the RF input signal. The circulating space charge in the interaction space is collected upon the control electrode, and the cathode current flow is terminated. Modulator requirements are simplified because the pulse voltage required for the turn-off electrode is typically one-quarter to two-thirds of the anode-cathode voltage and the peak collected current is less than one-half of the peak cathode-current flow during amplification. The duration of the collection time for the circulating current is approximately one transit time for electron flow around the interaction region. Typically, this is a small fraction of the time duration of the amplified signal. Consequently, the modulator energy required for the control electrode per amplifier pulse is much less than that required from the modulator for full-cathode-pulsed amplifiers.

Secondary Emission Cathodes. A variety of materials are used for secondary-electron-emission cathodes in RF-triggered amplifiers. The selection is based on the amplifier drive signal level, peak power output, and the intended operating voltage for the tube. Materials used include pure metals, such as aluminum, beryllium, and platinum, as well as a variety of composite materials, such as dispenser cathodes and cermets. Dispenser cathodes and pure-platinum cathodes are suitable for drive signal levels in excess of 10 kW. Amplifiers with drive signals from a few hundred watts to 10 kW are better accommodated with metals supporting oxide surface layers such as aluminum and beryllium. Oxide layers are susceptible to erosion under electron-beam bombardment, and some CFAs employ a low-level background pressure of pure oxygen supplied from a suitable reservoir to rejuvenate and extend the active cathode life.

Frequency range. Emitting-sole amplifiers have been developed at frequency ranges extending from VHF to K_u band, with experimental models at lower and higher frequencies. Examples of peak power levels available include 100 kW at K_u band, 1 MW at X band, and 3 MW at S band. Average power levels vary from 200 W at K_u band to several kilowatts at lower frequencies. Laboratory models have demonstrated as much as 400 kW of cw power at S band.

Noise Power. Noise-power output from reentrant stream emitting role CFA's with a space charge dispersing drift space measured in a 1-MHz bandwidth far from the carrier frequency is typically greater than 35 dB below the carrier power level. Noise levels greater than 45 dB below the carrier are not uncommon. Many radar applications require very low noise power between spectral lines of a pulsed signal. Much effort has been expended in recent years for further reduction in noise power. Signal-to-noise ratios (S/N) close to the carrier frequency are now exceeding 50 dB/MHz. In some experimental tubes, S/N ratios of greater than 65 dB/MHz have been measured, but this performance is not now obtainable across a full operating band by production tubes. Phase locking of the space charge by the drive signal also minimizes phase variation due to voltage change and drive signal variation. Saturated amplifiers with 12 to 15 dB gain have output phase variations of 3 to 8° for a 1 percent change in anode/cathode voltage. A comparable phase change occurs with a 1 dB variation in drive-signal level.

Applications. The primary use for emitting-sole CFAs is for transmitter tubes in coherent radars. CFAs have been used in pulse compression radars and pulse-coded and phased-coded radars, as well as phased-array radars. Lightweight low-voltage cathode-pulsed amplifiers are attractive for airborne applications. High-power dc-operated CFAs are used in ground-based radars.

CYCLOTRON RESONANCE TUBES (GYROTRONS)

Howard R. Jory

Introduction

Gyrotrons or cyclotron resonance masers are a class of microwave generators that make use of the cyclotron resonance condition to couple energy from an electron beam to a high-frequency electromagnetic (em) field. This type of coupling allows the beam-wave interaction region to be large compared to a wavelength. As a result, gyrotrons can produce orders of magnitude higher power at a given frequency compared to other microwave devices without exceeding power density limits.

The basic equation for cyclotron resonance coupling to an em field stationary in space is given by

$$\omega = \frac{neB}{\gamma m_0}$$

where ω = operating frequency

B = applied dc magnetic field

e/m_0 = charge to mass ratio for the electron

γ = relativistic mass factor

n = an integer

The strongest coupling occurs for the fundamental resonance where $n = 1$. Harmonic interactions where n has larger values are generally progressively weaker unless some special boundary geometry is used to shape the em fields. Second harmonic coupling can be very effective and harmonic interactions as high as $n = 12$ have been demonstrated.

The coupling equation illustrates one of the limitations of gyrotrons in that the required magnetic field is proportional to the frequency of operation. Operation at 30 GHz with fundamental resonance requires a magnetic field of about $1T$, which is near the limit of practical magnets based on room temperature copper technology. Higher-frequency gyrotrons generally employ superconducting magnets that require a supply of liquid nitrogen and liquid helium, but negligible electrical power.

In its simplest form, the cyclotron resonance interaction requires only electrons making circular orbits in a plane perpendicular to a dc magnetic field, and a time-varying electric field also in a direction perpendicular to the magnetic field. In a practical embodiment, the electrons will also have a component of axial velocity and the electric field will have both transverse variations in amplitude and possibly phase. The cyclotron resonance interaction is quite flexible. It can be realized with a single cavity (gyrotron), multiple cavities (gyroklystron), or traveling waves (gyro TWT). It can use simple cylindrical cavities using any TE (transverse electric) modes or quasi-optical cavities formed by mirror reflectors.

Gyrotron Oscillators

Most gyrotron oscillators have been built with the configuration shown in Fig. 7.2.29. The cavity where the interaction with the electron beam takes place is cylindrical with some tapers or steps in diameter to control the axial variation of electric field amplitude. The diameter can range in size from 1 to 20 wavelengths. The axial length is typically in the range of 5 to 10 wavelengths.

In the simplest case, the microwave output from the cavity propagates axially through the beam collector and out through a window at the top of the gyrotron. Since all of the structures are large compared to a wavelength, many waveguide modes could propagate. However, it is generally important to have all of the output power contained in a single waveguide mode. Therefore, care must be taken in designing the tapers in diameter such that mode conversion does not occur. Generally it is possible to achieve an output where 90 to 95 percent of the power is in a single mode.

The beam collector area must be large enough to avoid excessive beam impact density. A typical design value for long pulse or CW operation is 1 kW/cm^2 . Hence a collector for a 1-MW beam should have a beam impact area of 1000 cm^2 or more. Collector magnet coils are often used to help distribute the beam in the collector.

Desirable properties for the output window are low microwave loss, high strength, and high thermal conductivity. Typical materials used are alumina, sapphire, beryllia, and boron nitride. Pulsed gyrotrons generally use single disc windows cooled only at the edges of the disc. CW gyrotrons normally use two discs with a modest axial space between the discs through which a dielectric cooling fluid flows. In this way one face of each window disc is cooled, and the window can transmit much higher CW power without overheating.

The type of electron gun that has been most successful for gyrotrons is the magnetron injection gun. The desired electron beam is one where electrons have helical motion. In the cavity region the electrons should have a transverse to axial velocity ratio of the order of 2. Then about 80 percent of the beam kinetic energy is transverse motion, which can couple in the cyclotron resonance interaction. The axial velocity in this case serves only to determine the transit time of the electrons in the cavity and to keep electron space charge fields to a reasonable value. The magnetron injection gun, combined with magnetic compression of the beam between the cathode and the cavity, effectively provides a good beam for interaction.

Figure 7.2.30 shows a simulation of the electron motion in the gun as well as through the gyrotron to the collector. The cathode (emitting portion) of the gun is a section of a cone. The cathode and its associated support structures operate below ground potential at the full beam voltage desired (typically 20 to 80 kV). The simulation shows the case where the conical anode of the gun is at ground potential along with the body and collector. This provides a large radial component of electric field at the cathode which results in a component of transverse velocity for the electrons. The simulation shows a projection of the electron motion on the R - Z plane. The true motion of the electron is helical. Figure 7.2.29 shows a version of the gun which has an intermediate electrode operated at a potential between cathode and ground. This electrode can be used to control the electric field at the cathode and, therefore, control the ratio of transverse to axial velocity in the final beam at the cavity.

The gyrotron will oscillate when the main magnetic field is adjusted so that the beam cyclotron resonance frequency and a resonant frequency of the cavity are nearly equal and when the electron transverse-to-axial velocity ratio is high enough. Since a cavity that is large compared to a wavelength will have many resonances spaced perhaps a few percent apart in frequency, it is often possible to step tune from one frequency to the next by changing the main magnetic field value. This has been demonstrated at MIT with a pulsed gyrotron covering a 2 to 1 frequency range with steps about 5 percent apart in frequency. High power CW gyrotrons, however, are generally limited to single frequency operation because of bandwidth limitations imposed by double disc windows and collector tapers. As the main magnetic field is varied by a few percent about a normal operating value the oscillator frequency will change slightly and the output power will vary. The frequency variation is related to the Q of the cavity and typically has a value of 0.1 percent. The output power variation can be of the order of 10 to 1.

Output power can also be varied over a range of the order of 10 to 1 by changing the magnetic field at the cathode or by changing the gun anode voltage, if the design includes an intermediate anode. Beam voltage can be used to change power output over a range of about 2 to 1. Beam current can be used to change power output by the order of 10 to 1 also. In the magnetron injection gun beam current is controlled by changing the cathode heating power. The cathode is operated in the mode where emitted current is limited by temperature.

Peak operating efficiencies for gyrotron oscillators are in the range of 30 to 50 percent. When output power is varied by changing beam current the variation of efficiency will be minimized. When one of the other means discussed above is used, the efficiency will be reduced proportionally to the power output.

The high-power levels of gyrotrons require the use of oversize waveguides at the output. Various modes have been used such as TE_{01} or TE_{02} or whispering gallery modes such as $TE_{12,1}$ or $TE_{15,2}$ or $TE_{22,2}$. Waveguide diameters, large compared to a wavelength, are required to avoid breakdown as well as excessive loss. Typical sizes are 1 to 4 in. in diameter. Systems have been built, which transmit power for 50 to 100 m length with losses as low as 5 percent.

As gyrotron frequencies and power levels increase, it becomes particularly advantageous to separate the output waveguide from the beam collector. Figure 7.2.31 shows a technique to accomplish this, which has been used in Russia for about 10 years, and is now also being used in other countries. From the electron gun up through the output taper there are no essential changes. Above that point, the wall of the waveguide is cut in an appropriate way to cause the microwave power to radiate in the direction shown by the arrows. Perturbations in the wall of the waveguide just before the cut can be used to better control the radiation pattern. The radiated power is handled by a number of mirrors to form a Gaussian-like beam which passes through a window on the side of the gyrotron. The electron beam is confined magnetically to pass through the output coupler region and then is allowed to expand to hit a conveniently large collector structure. The output microwave beam can be transmitted further using quasi-optical techniques or by injection into an HE_{11} type of low loss waveguide.

FIGURE 7.2.29 CW gyrotron with an axisymmetric RF output.

FIGURE 7.2.30 Electron trajectories in gyrotron.

Coaxial interaction cavities have produced good results recently as a means of achieving mode separation in very large cavities for higher power output. Coaxial modes such as the $TE_{28,16}$ have been used.

Gyrotrons for Fusion Applications

The gyrotrons used in connection with magnetic fusion have been mainly in the frequency range from 8 to 140 GHz. They have usually been operated under pulsed conditions with pulse lengths of 50 ms to 5 s and duty factors less than 1 percent. The measure of importance in this application is the output power in joules per pulse. Figure 7.2.32 shows the capability of various gyrotrons as a function of frequency. For each data point the first number gives the power output in MW and the second number the pulse length in seconds. Also given

FIGURE 7.2.31 Gyrotron with coupler to separate RF output.

are the year of achievement and group involved. The dotted curves are for constant product of energy \times frequency squared, which is a rough measure of technical difficulty.

Development programs are currently in progress in several countries to produce 1 MW at 110 GHz with pulse lengths of several seconds or CW. There is also development work for 1 MW at 170 GHz which corresponds to the current plan for the International Thermonuclear Experimental Reactor (ITER) project.

Other Gyrotrons

Gyrotrons have been built for operation at frequencies as high as 850 GHz with outputs at watt levels. Near 300 GHz, CW power of tens of watts has been produced and pulsed power of hundreds of kW. Some of these have been developed for plasma diagnostics or spectroscopy applications.

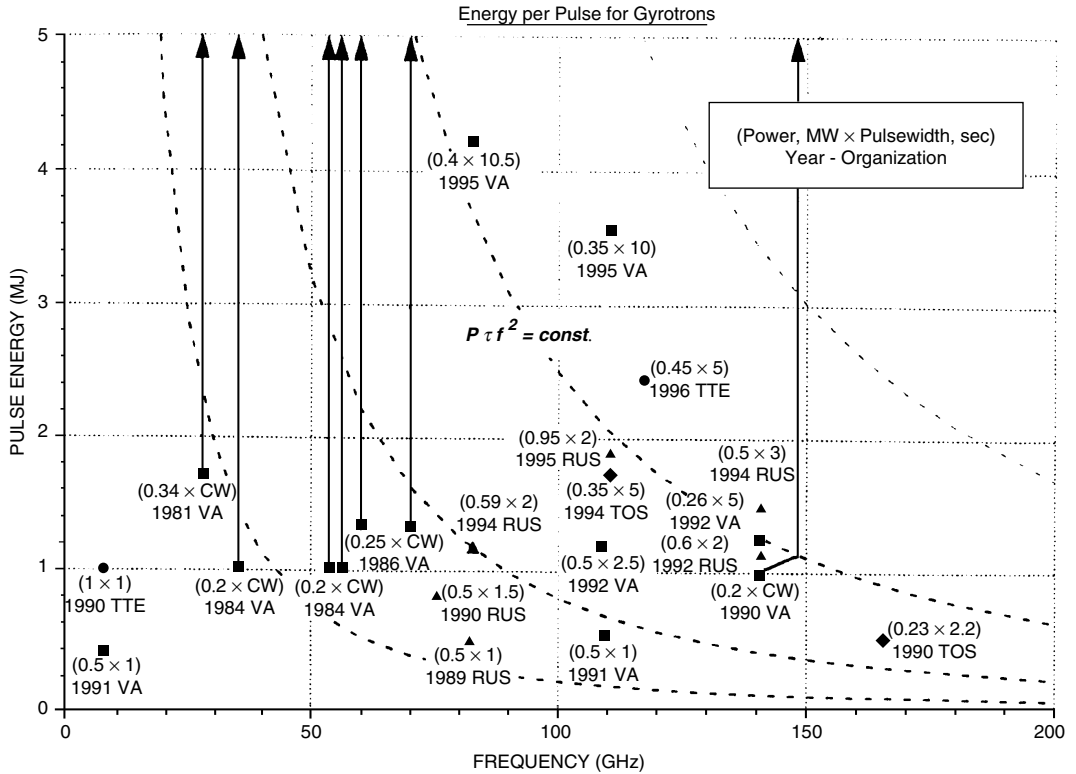

FIGURE 7.2.32 Energy per pulse for gyrotrons “VA = Varian/CPI, Rus = Russia, TTE = Thomson, TOS = Toshiba (data points for CW gyrotrons shown for 5-s pulse).

Gyrotrons using quasi-optical (confocal) resonators have been built near 100 GHz. Pulsed power outputs of hundreds of kW have been achieved but with efficiencies lower than the conventional cavity gyrotrons. Typical values are 10 to 15 percent.

Short-pulse, high-peak-power gyrotrons have been built based on cold-cathode flash x-ray technology. Outputs of hundreds of MW have been achieved at frequencies of 10 to 35 GHz. Lower power levels have been demonstrated up to 100 GHz. Typical pulse lengths are less than 100 ns. Beam voltages up to 1 MV and currents up to 10 kA have been employed. Typical efficiencies are 5 to 10 percent. The cold-cathode technology limits these devices to short pulse length and relatively short life compared to hot cathode devices. Repetitive pulsing has been demonstrated.

Gyroklystrons

The gyrotron can be made into an amplifier by using two or more cavities along the axis of the beam. The cavities are shorter to avoid self-oscillation. As in the conventional linear beam klystron, the RF input to the first cavity modulates the beam. But in this case it is an angular velocity modulation. As the beam drifts, the angular velocity modulation converts to bunching in angle. Intermediate cavities intensify the modulation and the output cavity extracts angular kinetic energy from the beam.

The most impressive results with gyrokystrons have been produced at the University of Maryland where 27 MW output at 9.85 GHz with μs pulse length was achieved. Beam voltage was 440 kV and efficiency 32 percent. This device was also modified to extract power with a second harmonic interaction in the output cavity. The results were 32 MW at 19.7 GHz with 29 percent efficiency.

A gyrokystron built by Varian demonstrated pulsed output of 75 kW at 28 GHz with 41 dB gain and 9 percent efficiency. Gyrokystrons have been built in Russia at XBand and other frequencies. For example, 60 kW pulsed output at 94 GHz with 34 percent efficiency and 40 dB gain is reported.

Major issues with gyrokystrons are stability and efficiency. The beam tunnels between cavities can be non-propagating for the normal cavity modes but will usually propagate for lower-order modes. Mode conversion and reflection back through the beam tunnel can easily result in spurious oscillation. This problem is generally controlled by careful cavity design and the inclusion of absorbing material in the beam tunnels.

Bandwidth of gyrokystron amplifiers is in the range of 0.1 to 1 percent because of the high cavity Q's required. Stagger tuning of cavities might allow small increases.

Gyro Traveling-Wave Tube

The gyro TWT is similar to the gyrokystron except that the resonant cavities are replaced by traveling-wave circuits. Stability in this case is even more difficult. In addition to spurious oscillations caused by reflections at the ends of each circuit, there are potential instabilities at the cutoff frequency of the traveling-wave circuit and with beam interactions with the backward circuit wave.

Nevertheless, reasonable results have been demonstrated for gyro TWTs. An experiment in Taiwan produced pulsed output of 25 kW at 35 GHz with 23 percent efficiency and gain of about 20 dB. Varian pulsed gyro TWTs have operated at 95 GHz with 30 kW output 16 dB gain, 8 percent efficiency and 2 percent bandwidth and at 5 GHz, 120 kW output, 16 dB gain, 26 percent efficiency, and 6 percent bandwidth.

CHAPTER 7.3

MICROWAVE SEMICONDUCTOR DEVICES

George Bechtel, Joseph Feinstein

TYPES OF MICROWAVE SEMICONDUCTOR DEVICES

The number and variety of microwave semiconductor devices have greatly increased as new techniques, materials, and concepts have been applied. Silicon and compound semiconductor materials, such as gallium arsenide (GaAs) and indium phosphide (InP), are used for the fabrication of nearly all devices. The oldest structure is the tungsten-silicon *point-contact diode*, employing a metal-whisker contact, used for signal mixing and detection. The *Schottky barrier diode*, a rectifying metal-semiconductor junction, has supplanted the point contact because of its lower noise figure. These devices display a variable-resistance characteristic.

In contrast, the *variable-reactance (varactor) diode* makes use of the change in capacitance of a reverse-biased *pn* junction as a function of applied voltage. Physically, this capacitance change results from widening the depletion layer as the reverse-bias voltage is increased. By controlling the doping profile at the junction, the functional forms of this relation can be tailored to a specified application. Typical applications of varactor diodes are harmonic generation, parametric amplification, and electronic tuning.

pin diodes employ a wide intrinsic region which permits high-power-handling capability and offers an impedance at microwave frequencies controllable by a lower frequency (or dc) bias. They have proved useful for microwave switches, modulators, and protectors. In changing from reverse to forward bias the *pin* diode changes electrically from a small capacitance to a large conductance, approximating a short circuit.

For microwave power generation or amplification, a negative-resistance characteristic at microwave frequencies can be used. Beginning with the *tunnel diode* in the early 1960s and progressing to the higher-power *IMPATT diodes* and *Gunn diodes*, such negative-resistance devices experienced rapid development in the 1970s. The tunnel diode uses a heavily doped *pn* junction which is sufficiently abrupt for electrons to be able to tunnel through the potential barrier near zero applied voltage. Because this is a majority-carrier effect, the tunnel diode is very fast acting, permitting response in the millimeter-wave region. The very low power at which the tunnel diode saturates has limited its usefulness.

The *transferred-electron oscillator (TEO)*, originally named for its discoverer J. B. Gunn, depends on a specific form of quantum-mechanical band structure for its negative resistance. This band structure is found in gallium arsenide, the semiconductor material generally associated with this class of device, and in a few other III-V compounds. *Gunn oscillators* have power output in the tens to hundreds of milliwatts at low dc operating voltage (9 to 28 V). They have a wide range of tunability and reasonably low AM and FM noise.

The *impact avalanche transit-time (IMPATT) diode* owes its negative resistance to the classical effects of phase shift introduced by the time lag between maximum field and maximum avalanche current multiplication and by the transit time through the device of this current. These effects can occur in all semiconductor

pn junctions under sufficient reverse bias to initiate breakdown. While IMPATT diodes were originally developed as silicon devices (still the predominant type for millimeter waves), gallium arsenide IMPATTs are used because of their higher power (tens of watts). IMPATT diodes find applications in radar and millimeter wave transmitters.

Silicon bipolar transistors have penetrated the microwave region through the refinement of fabrication techniques based on the planar photolithography technology. By reducing the emitter width and base thickness to micrometer dimensions (and by paralleling stripes of structure to maintain power capability), transit times and charging times (resistance-capacitance product) can be kept low enough to provide useful devices with a maximum frequency of oscillation (f_{\max}) of 22 GHz. Such transistors are also used in low-noise preamplifiers up to frequencies of about 4 GHz.

Heterojunction bipolar transistors (HBT) have been developed using GaAs and InP to take advantage of the superior electron transport in these materials. Heterojunction emitters using alloys of GaAs with ternary compound semiconductors such as aluminum gallium arsenide (AlGaAs) are used to improve the emitter injection efficiency for high current gain. Cutoff frequencies of 50 GHz have been achieved, about a factor of 2 better than silicon bipolar transistors.

Field-effect transistors (FETs) are microwave solid-state devices that use the higher mobility and saturated velocity of GaAs. The GaAs FET now dominates low-noise applications in the intermediate microwave region of the spectrum and has now taken over power-amplifier designs from the negative-resistance diodes discussed above. Noise figures less than 1 dB are obtained with low noise GaAs FETs at 10 GHz and below. Cutoff frequencies over 200 GHz have been achieved for new generation FETs, such as the *high electron mobility transistor* (HEMT). Power FETs have delivered power of 12 W at C-band for SATCOM amplifier applications.

Monolithic microwave integrated circuits (MMICs), using the monolithic integration of microwave transistors (both FET and bipolar) onto a single substrate, are now used in many high-frequency or high-speed applications. MMICs reduce the cost and size of RF and microwave components, in the same way as the use of silicon-integrated circuits have revolutionized computer and consumer electronics. GaAs and silicon MMICs provide circuit building blocks such as switches, amplifiers, oscillators, downconverters for such applications as cellular telephones, direct broadcast satellite TV receivers, and high-speed optical fiber communication systems.

Microwave Mixer and Detector Diodes

Mixing is defined as the conversion of a low-power-level signal from one frequency to another by combining it with a higher-power (local-oscillator) signal in a nonlinear device. In general, mixing produces a large number of sum and difference frequencies. Usually, the difference frequency between signal and local oscillator (the intermediate frequency) is of interest and is at a low-power level.

In *microwave detection*, solid-state devices are used as nonlinear elements to accomplish direct rectification of an applied RF signal. The sensitivity of a detector is usually much less than that of a superheterodyne receiver, but the detector circuit is simple and easy to adjust. The sensitivity has been improved considerably by the use of a wide-band low-noise microwave preamplifier preceding the detector.

Tunnel diodes, back diodes, point-contact diodes, and Schottky barrier diodes are majority-carrier devices that have nonlinear resistive characteristics and are useful for mixing and detecting. Noise figures lower than 6 dB are now possible at K_u band using Schottky barrier diodes. These improvements have resulted from better control of epitaxial material to achieve low series resistance and photolithographic techniques to achieve small-area Schottky diodes. Because of greater susceptibility to RF burnout, circuit complications, and fabrication difficulties, tunnel and back diodes have not found as wide acceptance as mixers and detectors at microwave frequencies. The point-contact (pressure contact between metal and semiconductor) and Schottky barrier diodes (formed by deposition of metal on semiconductor surface) are the primary mixer and detector microwave devices. However, back diodes are used in selected applications such as broadband low-level detectors and Doppler mixers.

Point-contact, Schottky barrier, and back diodes are used as mixers and detectors from UHF to millimeter frequencies. The construction and current-voltage characteristics of these diodes are shown in Fig. 7.3.1. The point is contact is fabricated by a metal whisker forming a rectifying junction in contact with the semiconductor. The Schottky is formed generally by an evaporated metal contact, and the back diode by an alloyed junction.

FIGURE 7.3.1 Current-voltage characteristics of back, point-contact, and Schottky barrier diodes. (Proc. IEEE, August 1971.)

FIGURE 7.3.2 Equivalent circuit of microwave diode.

Point-Contact Diodes

The point-contact diode is the oldest structure. Until 1965 point-contact diodes were fabricated using moderately low resistivity material with the rectifying contact established by touching the semiconductor surface with a metal whisker (normally, tungsten for silicon and phosphorus bronze for germanium and GaAs).

Since that time the semiconductor epitaxial deposition has been applied to point-contact diodes (as well as to Schottky diodes) to maximize the frequency cutoff (minimize the $R_s C_j$ product). This is a significant consideration since conversion loss is directly proportional to the product of diode series resistance R_s and junction capacitance C_j , as shown in Fig. 7.3.2.

Such devices are generally used only in the millimeter-wavelength range because of inherent reproducibility problems and because they have poorer noise figures than Schottky diodes. Nevertheless they are more resistant to RF burnout than the Schottky devices.

Schottky Barrier Diodes

The Schottky barrier diode is a rectifying metal-semiconductor junction formed by plating, evaporating, or sputtering a variety of metals on *n*- or *p*-type semiconductor materials. Schottky diodes are fabricated from *n*-on-*n*⁺ epitaxial material (*n* layer 0.5 to 1.0 μm thick), where the *n* layers are optimized in thickness and carrier concentration for minimum conversion loss and maximum RF burnout or power-handling capability. Because of their higher cutoff frequency, GaAs devices are preferred in applications above X-band frequencies. This results from the higher mobility of electrons in GaAs than in silicon. Although in practice this advantage is not as significant as predicted, a conversion-loss improvement of 0.5 dB at K_u band is readily obtainable with GaAs, compared with silicon.

Schottky diodes are fabricated by a planar technique. A SiO_2 layer (1 μm thick) is thermally grown or deposited on the semiconductor wafer, and windows are etched in the SiO_2 by photolithography techniques. Schottky junctions are formed by evaporation, sputtering, or plating techniques. Metal on the oxide is removed by a second photo step. Junction diameters as small as 5 μm are made by this technique. Schottky diodes are also fabricated with attached gold leads, using the beam lead process. After completion of the Schottky contact metallization step, thick gold contact leads are plated on the junction side of the wafer. The backside of the wafer is patterned and etched to form isolated diodes and to expose the gold beams on the frontside of the wafer. Figure 7.3.3a shows a silicon diode intended for operation at X band, and Fig. 7.3.3b shows a beam lead diode for millimeter waves.

Mixer-Diode Parameters

Figure 7.3.4 gives the noise figure for a variety of mixer diodes as a function of local oscillator power at 16 GHz. Below this frequency, silicon Schottky diodes exhibiting a minimum noise figure of 5.5 dB are generally used, while GaAs is preferred at higher frequencies.

FIGURE 7.3.3 Microwave diodes: (a) silicon diode for operation at X band; (b) beam lead diode for stripline and microstrip circuits.

FIGURE 7.3.4 Noise figure vs. local oscillator power for point-contact diodes and *n*-type Schottky barrier diodes.

(After H. A. Watson, "Microwave Semiconductor Devices and Their Circuit Applications," McGraw-Hill, 1969)

The *tangential signal sensitivity* (TSS) is the most widely used criterion for detector performance. It indicates the ability of the detector to detect a signal against a noise background and also includes the noise properties of the diode and video amplifier. This quantity varies with the square root of the amplifier bandwidth, since square-law response is obtained at low signal levels. As a rough basis of comparison, the TSS rating corresponds to a signal-to-noise of about 2.5. Biased silicon Schottky diodes have a typical TSS of -55 dBm at 10 GHz. For RF monitor applications, voltage sensitivity in microvolts per microwatt is important and a typical value of $7 \text{ mV}/\mu\text{W}$ is achieved. Low barrier (or zero bias) detectors provide a higher sensitivity at higher video resistance.

Typical mixer- and detector-diode packages are shown in Fig. 7.3.5. They are designed to be compatible with a particular type of microwave circuitry, waveguide, coaxial, or strip line. The packages shown in Figs. 7.3.5a and b are generally used up to about 12 GHz. The coaxial package in Fig. 7.3.5c permits operation up to about 30 GHz. Stripline or microstrip mixer circuits generally use beam lead diodes, owing the planar lead configuration of the beam lead design. Multiple diodes are fabricated on the same chip, as monolithic pairs or quads for use in balanced or doubly balanced mixers. Balanced mixers provide noise and local oscillator cancellation at the IF port, but at the expense of higher local oscillator power.

Varactor Diodes

The active element of a varactor diode consists of a semiconductor wafer containing a *pn* junction of a well-defined geometry, usually formed by diffusion. Varactor diodes are normally operated under reverse bias, where the junction resistance (ordinarily $10 \text{ M}\Omega$ or more) is negligible in comparison with the microwave capacitive reactance of the junction. The variable capacitance C_j (Fig. 7.3.6) of the varactor diode as a function of applied voltage is used to tune microwave circuits such as voltage-controlled oscillators (VCOs). *Hyperabrupt junction* doping profiles provide a more rapid change in capacitance (and frequency tuning) as a function of voltage than abrupt junction diodes.

For forward bias the diode current increases exponentially with the applied voltage, and for reverse bias a small saturation current I_s flows. When the reverse bias is increased to the avalanche breakdown voltage V_B , the diode reverse current increases very rapidly, since it is limited only by the small diode resistance and any external resistance present in the circuit.

FIGURE 7.3.6 Varactor junction capacitance, series resistance, forward current, and reverse current as functions of bias voltage. (After H. A. Watson, "Microwave Semiconductor Devices and Their Circuit Applications," McGraw-Hill, 1969)

Figure 7.3.7 shows typical dc current-voltage characteristics, microwave series resistance, and 1-MHz capacitance-voltage characteristics.

Varactor Packages. Typical varactor diodes are mounted in hollow dielectric (usually alumina) cylinders with Kovar or copper end caps, as shown in Fig. 7.3.7. A flexible connection is made to the diode mesa from one end cap by means of a thin gold strap.

FIGURE 7.3.7 Low inductance diode construction and equivalent circuit. (Microwave J., November 1970).

The equivalent circuit shown represents the coupling between the diode junction region and the package surface.

Charge-storage effects. In some applications the injected charge-storage capacitance is more important than the capacitance variation associated with the varying width of the depletion region. Charge-storage capacitance is produced by the injection of minority carriers during the forward-biased excursion of the varactor pump voltage and the withdrawal of this charge during the reverse-biased portion of the cycle. The resultant waveform is shown in Fig. 7.3.8. Efforts to maximize charge-storage effects in microwave diodes have led to a class of devices known as *snap-back*, or *step-recovery*, diodes. They feature steep doping profiles and narrow junctions, to give fast recovery of injected charge, typically in a transition period of a few tenths of a nanosecond, yielding a high-harmonic content. However, this design results in lower breakdown voltage, reducing the power capability of the

FIGURE 7.3.8 Current waveform of sinusoidally switched step-recovery diode. (After H. A. Watson, "Microwave Semiconductor Devices and Their Circuit Applications," McGraw-Hill, 1969)

FIGURE 7.3.9 Conversion efficiency and output power of varactors used as frequency triplers, with bias adjusted to maximum output as each point. (After H. A. Watson, "Microwave Semiconductor Devices and Their Circuit Applications," McGraw-Hill, 1969)

diode. Frequency multipliers use these diodes when high-order multiplication (above eight) and circuit simplicity are desired, at the expense of power output.

Varactor Frequency Multipliers

Figure 7.3.9 gives the characteristics of diffused epitaxial GaAs and Si varactor diodes employed in a conventional tripler (4 to 12 GHz) frequency multiplier. Because of its higher cutoff frequency, GaAs gives higher efficiency but lower maximum output power than Si. Frequency triplers with output at 220 GHz have been fabricated for submillimeter wave sources.

pin Diodes

pin diodes consist of heavily doped *p* and *n* regions separated by a layer of high-resistivity intrinsic material. Typical construction of such a diode is shown in Fig. 7.3.10. Under zero and reverse bias this type of diode has a very high impedance, whereas at moderate forward current it has a very low impedance. This permits its use as a switch in microwave transmission lines. Generally, the diode is placed in shunt across a strip line, allowing unimpeded transmission when reverse-biased but short-circuiting the line to produce almost total reflection when forward-biased by as little as 1 V. In attenuator applications the diode behaves like a current-controlled resistance in parallel with the capacitance of the intrinsic region. For stripline or microstrip circuits, beam-leaded *pin* diodes similar to those of Fig. 7.3.3b are used, whereas the low-inductance package of Fig. 7.3.7 is used for high-power applications.

The wide intrinsic layer permits high microwave peak power to be controlled since the breakdown voltage is of the order of 1 kV. Very little power is dissipated by the diode itself because reflection switching is employed. *pin* diodes can be used as limiters, replacing TR tubes for peak powers smaller than 100 kW. At higher peak power, these diodes are useful, following the TR box to eliminate any spike leakage, although if fast response is required (less than 1 μs) a varactor diode is used.

FIGURE 7.3.10 Typical planar *pin* microwave wafer.

Electrically controllable, rapid-acting microwave phase shifters are finding increasing use in phased-array systems. *pin* diodes are employed to switch lengths of transmission line, providing digital increments of phase in individual transmission paths, each capable of carrying many kilowatts of peak power.

Transferred-Electron (Gunn) Devices

The negative resistance that leads to oscillation for this class of device is a consequence of the band structure of certain semiconductors. An upper conduction band must exist in which carriers have lower mobility than in the initially occupied lower band. The transfer of carriers, generally electrons, from the lower to the upper conduction band takes place as a result of lattice collisions as the electric field strength across the material is increased.

FIGURE 7.3.11 Velocity vs. electric field of indium phosphide and gallium arsenide.

The transfer leads to a reduced current as the voltage increases and therefore represents a negative resistance on the v - i curve. The velocity-electric field characteristics of two materials that exhibit this behavior are shown in Fig. 7.3.11. By comparison, silicon has a monotonic characteristic which lies well below the curve for GaAs.

Fabrication of Gunn Devices. The fabrication of these devices requires stringent control over the material. Good electrical performance results from extremely pure and uniform material with a minimum of deep donor levels and traps and the use of very-low-loss contacts. Modern devices use an n -type epitaxial layer of GaAs or InP grown from the vapor phase on n^+ bulk material. Typical carrier concentrations range from 10^{14} to 10^{16} cm^{-3} , while device lengths range from a few to several hundred micrometers.

Noise. One of the more important operating characteristics of the Gunn type of oscillator is its low-noise performance compared with other types of microwave sources at frequencies above 18 GHz. Phase noise for an InP Gunn diode oscillator is typically -87 dBc/Hz measured at 100 kHz offset from the oscillator frequency of 38 GHz.

Electronic Tuning. Electronically tuned Gunn oscillators are available employing YIG spheres, varactor diodes, and *pin* diodes as the tuning element, in addition to mechanically tuned devices. Typical ranges covered are 8 to 12 and 12 to 18 GHz at the rather slow YIG magnetic-tuning speed of 100 Hz and of the order of 10 percent bandwidth at the much faster varactor rate of up to 10 MHz for oscillators up to 40 GHz.

Applications. While Gunn diodes have been used in reflection amplifiers with a ferrite circulator to separate input from output, the advent of the GaAs FET, with its superior noise and power-amplification characteristics, has relegated the transferred-electron devices to oscillator (TEO) use.

The continuing development of indium phosphide (InP) Gunn devices has led to oscillators and reflection amplifiers at wavelengths in the 3- to 5-mm range, a region GaAs devices (TE or FET) cannot reach at present. The performance advantage is a consequence of the superior higher efficiency of InP devices. For example, InP Gunn diode oscillators have achieved a DC-to-RF conversion efficiency of nearly 3 percent at 140 GHz at an output power of 65 mW. Figure 7.3.12 displays the power and efficiency of cw InP Gunn diodes from 35 to 140 GHz.

Microwave Avalanche (IMPATT) Diodes

The power obtainable from IMPATT devices is greater than that available from the Gunn diodes described above but at the expense of higher noise and higher operating voltage. Two fundamental physical processes are pertinent to the operation of avalanche diodes: the drift velocity at which carriers travel under a reverse-biased electric field and the avalanche multiplication which occurs at sufficiently high fields.

FIGURE 7.3.12 Power and efficiency of InP Gunn diodes. (Crowley, Litton Solid State)

Theory of Operation. An understanding of the dynamic operating characteristics of IMPATT diodes can be best obtained by considering the operation of the structure shown in Fig. 7.3.13. The IMPATT diode consists of two regions: a narrow avalanche region (*p* region), in which carrier multiplication by impact ionization occurs, and a drift region (*n* region), in which the carriers drift at saturated or field-independent velocities and where no impact ionization occurs.

The negative resistance or conductance of an IMPATT diode is attributed to phase shift between the current through the diode and the voltage across it. This phase shift consists of two components. There is a phase delay of the current caused by the avalanche multiplication process and by the finite transit time of the holes drifting through the drift region. If the diode is to operate as a stable oscillator, the negative conductance of the diode must decrease with increasing RF voltage. The RF voltage across the diode will grow until the admittance of the diode is balanced by the admittance of the microwave circuit.

At a sufficiently low frequency the phase delay of the transit time plus the phase lag of the avalanche process are not sufficient to have the fundamental component of the external current lag the RF voltage by more than 90°. Therefore, below a certain cutoff frequency, the conductance of the diode becomes positive.

At present the semiconductor materials used in commercial IMPATTs are silicon and gallium arsenide. The latter is operated in this case at much higher electric fields than corresponds to the region of negative differential mobility utilized in the Gunn effect. The basic structure of a typical *pn* junction silicon IMPATT is shown in Fig. 7.3.13. In operation the device is reverse-biased past the point of avalanche breakdown, so that a direct current of 50 to 500 mA flows through the diode.

Significant improvement in performance is obtained, however, by modifying the doping profile so that the

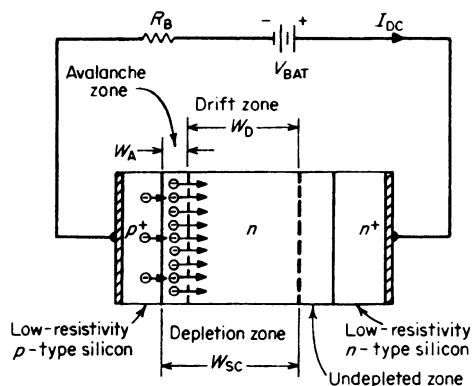

FIGURE 7.3.13 *pn* junction of IMPATT diode under reverse bias. (After Crowley, WESCON, 1971)

high-field avalanche region is narrowly confined and the electric field is optimized separately for the drift region. Such profiles, called high-low, low-high-low, and double-drift, yield efficiencies of 20 to 35 percent compared to 6 to 10 percent and 10 to 15 percent obtained from flat-profile Si and GaAs, respectively.

GaAs IMPATTs are preferred for frequencies up to 30 GHz because of their performance advantages, especially for pulsed radar transmitters at X band. Efficiencies of 20 percent are obtained at output powers of 15 W for low duty cycle RF waveforms. Multiple diodes are combined in an RF cavity to obtain 100 W. Si IMPATTs are used in the millimeter wave range and currently give the highest power available from a solid-state device in this frequency region.

Fabrication. The IMPATT structure is fabricated by first growing a thin epitaxial layer of n -type silicon or GaAs on a heavily doped n -type (n^+) substrate and then adding a p layer by growing an epitaxial layer or by ion implantation. Finally, a thin platinum contact layer is formed by diffusion giving a p^+npn^+ double-drift structure. For 94-GHz operation, the epitaxial-layer thickness is of the order of $0.5 \mu\text{m}$, and the diameter of the diode is of the order of $50 \mu\text{m}$.

Cooling. A difficult technological problem in IMPATT diode packaging is efficient heat removal from the active portion of the device. These diodes operate at high dc power densities, typically 10 to 100 kW/cm^2 , and since only a fraction (6 to 12 percent) is converted to RF power, the remainder must be removed as heat. Inverted mesa thermocompression bonding to a copper heat sink has been employed for this purpose. A better approach electroplates the heat sink at the wafer stage before individual diodes have been fabricated. Diamond has also been employed as a heat sink in experimental devices using inverted chips.

Microwave Bipolar Transistors

To achieve operation at microwave frequencies, individual transistor dimensions must be reduced to the micrometer range. To maintain current and power capability, various forms of internal paralleling on the chip are employed. These geometries fall into three general types, as shown in Fig. 7.3.14, interdigitated fingers forming emitter and base stripes, overlay groupings of emitter and base stripes, and a mesh or matrix of emitter and base spots. All microwave transistors are now planar in form, and almost all are of the silicon npn type.

FIGURE 7.3.14 Typical geometries of bipolar microwave transistors.

Construction and Fabrication. Silicon microwave transistors are built up on an n -type epitaxial layer of the order of $1 \Omega\text{-cm}$ resistivity (deposited on lower-resistivity silicon) to keep the collector depletion layer narrow. Diffusion of p -type dopant (typically boron) is used for the base. More recently ion implantation has replaced diffusion as the means of achieving base widths of less than 0.1 nm .

Following base formation, the emitter is then defined through photomasks, and the appropriate dopant (phosphorus or preferably arsenic) diffused in. Metal contacts are then evaporated or sputtered to interconnect the elements of the device.

Figure 7.3.15 illustrates the steps in the fabrication process. Reduction of strip width to increase frequency response has been made possible by improved lithography and etching, leading to state-of-the-art line definition of 1 nm .

Power Capability. Most power microwave transistors include some form of integral emitter resistors to aid in equalizing the current over the distributed emitter structure.

FIGURE 7.3.15 Cross section of planar transistor, showing (1)–(3) r'_b and (4) contact resistance R_c . (Proc. IEEE, August 1971)

The *overlay transistor* has an integral diffused resistor as part of each emitter stripe, while *thin-film resistors* are deposited as part of the contacts on interdigitated devices. Guard rings are employed to raise the voltage breakdown limit of the collector to about half that of bulk silicon.

A figure of merit can be defined for the transistor in terms of the base resistance r'_b , the collector capacitance C , and the emitter-to-collector signal delay time τ_{ec} :

$$(\text{Power gain})^{1/2}(\text{bandwidth}) \approx 1/4\pi(r'_b C \tau_{ec})^{1/2}$$

τ_{ec} is composed of the transit time of carriers across the base and collector depletion layer plus the charging time of the emitter-base junction capacitance and the collector capacitance. The maximum frequency of oscillation is obtained by setting the gain equal to unity in this expression.

Silicon bipolar transistors provide the highest pulsed output power of any solid-state microwave or RF device, up to 500 W at collector voltages of 50 VDC. In linear amplifier operation, bipolar transistors are used in personal communications network (PCN) and cellular base stations with output power capability of 30 W at 1.9 GHz. Figure 7.3.16 illustrates the output power capability of bipolar transistors from 900 MHz to 20 GHz. The projected maximum frequency of oscillation for silicon bipolar transistors is 22 GHz.

Noise. The principal sources of noise in a microwave transistor are shot noise associated with the emitter and collector current and thermal noise in the base resistance. It is an increase in the latter and reduction in current gain which are responsible for the deterioration of noise figure with frequency. The current state of the art in the bipolar-transistor noise figure is about 2 dB at 4 GHz, increasing to 5 dB at 6 GHz.

Because of the high current gain at low currents, silicon bipolar transistors are used as amplifiers and oscillators in many portable applications up to 2.5 GHz. The transistors are also widely used in VCOs up to 20 GHz, because of their low $1/f$ noise.

FIGURE 7.3.16 Performance of microwave power transistors as of 1979 and projected improvement. (Trans. IEEE, May 1979, Vol. MTT 27, No. 5)

FIGURE 7.3.17 Cross section of GaAs HBT, showing AlGaAs emitter and low collector.

Heterojunction Bipolar Transistors

Heterojunction bipolar transistors (HBTs) fabricated on GaAs take advantage of the high electron mobility for electron transport across the base of the device. A cross section of an HBT is shown in Fig. 7.3.17. The emitter of highly doped, n -type AlGaAs forms a heterojunction with the highly doped GaAs p -type base (called the heterojunction due to different crystalline composition), resulting in favorable electron injection into the base. DC current gains are typically 20 to 200, with cutoff frequencies above 50 GHz. The devices are fabricated with all-epitaxial growth by means of molecular beam epitaxy (MBE) or metallo-organic chemical vapor deposition (MOCVD). HBT base and collector layers are similar in thickness to those for silicon bipolar transistors, but the emitter width can be wider (1 to 3 μm) because of the faster base transit time and lower capacitance per unit area. To achieve high gain, oxygen implantation is used to reduce the base-collector capacitance under the base contact.

The unity current gain figure-of-merit, f_T , and the maximum frequency of oscillation for GaAs HBTs range from 30 to 60 GHz, exceeding the same silicon bipolar transistor figures of merit by over two times. The power capability of the GaAs HBT from 7.5 to 44 GHz is compared to the silicon bipolar transistor in Fig. 7.3.16. Output power of over 10 W has been achieved at 7.5 GHz with 40 percent power-added efficiency.

HBT devices have also been fabricated on InP substrates, using an InAlAs emitter and InGaAs base, with f_{max} over 100 GHz. Silicon-based HBTs, using a silicon-germanium alloy base layer, have also been fabricated, with figures-of-merit over twice those of silicon homojunction devices. SiGe HBTs offer the promise of high performance with the lower cost of silicon processing, compared to GaAs and InP devices.

Field-Effect Transistors

The schematic in Fig. 7.3.18 illustrates the field effect transistor principle of operation. The flow of charge carriers from source to drain is controlled by the potential applied to the gate electrode. This flow takes place in a thin layer of n -type GaAs, called the channel. The gate is generally a Schottky barrier formed by deposition of an appropriate metal, leading to the acronym MESFET. The channel of the MESFET is fabricated by either epitaxy (MBE, MOCVD, VPE) or ion-implantation. The latter is more commonly used for general-purpose MESFETs, while epitaxy is used for low-noise devices.

The electron current from source to drain is determined by the depth of the depletion layer formed under the gate by the negative potential applied to it. The frequency response of this type of amplifier goes up as the gate length is reduced, while its power output increases linearly with gate width. Typical gate lengths range from $1/4$ to 1 μm , while gate widths vary from a fraction of a millimeter for low-noise FETs to tens of millimeters for power devices. About 0.5 W of microwave power per millimeter is a widely used figure of merit.

FIGURE 7.3.18 (a) Schematic and (b) dimensions of a single-gate Schottky barrier GaAs field-effect transistor. (*Microwave J.*, November 1978)

Noise of the MESFET. The GaAs MESFET achieves its low-noise figure from the thermal noise characteristic of the majority carrier (electron) flow in the channel. The typical noise figure of a $0.3\text{-}\mu\text{m}$ gate length MESFET is shown in Fig. 7.3.19. The MESFET is 1.4 dB lower in noise figure at 4 GHz (0.6 vs. 2 dB) with over 14 dB gain, as compared to the silicon bipolar, and is widely used in low-noise amplifiers from 1 to 20 GHz. However, the heterojunction FET is now displacing the MESFET as a low-noise amplifier because of even lower noise figure.

The heterojunction FET has evolved from the earlier high electron mobility transistor (HEMT) to an improved (for lower noise and higher gain) epitaxial layer design called pseudomorphic HEMT (PHEMT). The noise figure of a $0.3\text{-}\mu\text{m}$ gate length PHEMT is also shown in Fig. 7.3.19; note that the noise figure is reduced by 0.7 dB over the MESFET noise figure at 12 GHz. Further improvements in gain have been achieved with the use of $0.1\text{-}\mu\text{m}$ gates and InP epitaxial structures, where f_{max} has exceeded 250 GHz.

Power of the MESFET. A parallel interconnection of MESFET cells is used to increase the power handling capability in accordance with the power figure of merit of 0.5 W/mm of gate width. The number of gates is chosen on the basis of the cell gate length and width; typical cell dimensions are gate length of $0.5\text{ }\mu\text{m}$ by $125\text{ }\mu\text{m}$ width by 12 gates per cell. To achieve 25 W at 5 GHz, four chips of 12 cells each are connected to

FIGURE 7.3.19 Noise figure of MESFET and PHEMT devices.

FIGURE 7.3.20 Gain and noise performance of silicon bipolar RFIC.

yield a total width of 72 mm. The chips are interconnected in a single package, using matching networks internal to the transistor package.

Silicon Bipolar RF and Microwave Integrated Circuits

Integrated circuits using high f_T silicon bipolar transistors are available with complexity ranging from simple single-stage amplifiers to functional blocks, such as vector modulators and downconverters. Resistors and capacitors are integrated onto the same semiconductor chip with a number of transistors and diodes to form microwave integrated circuits for applications from 100 MHz to 3 GHz. The RF gain and noise figure of a typical silicon RFIC, using feedback around a Darlington transistor to obtain a gain greater than 20 dB up to 3 GHz, are shown in Fig. 7.3.20.

More complex circuits have been developed that provide nearly the entire front end of a global positioning satellite receiver, comprising a dual downconversion design. Silicon bipolar integrated circuits have also been designed for new generation cellular telephone transmitters and receivers. Complementary MOS transistors have been combined with bipolar transistors on the same chip (using the *BiCMOS* process) to implement advanced functions for low-power portable telephones.

GaAs Monolithic Microwave Integrated Circuits

Monolithic microwave integrated circuits (MMICs) using GaAs MESFETs as the active elements and monolithically integrated with matching circuits have replaced the discrete circuit implementation in many RF and microwave designs. GaAs MMICs are available for applications from 500 MHz to 40 GHz, with developmental devices having gain to 100 GHz.

The fabrication of GaAs MMICs is facilitated by the use of a semi-insulating substrate as used for MESFETs, permitting the placement of microstrip matching elements and other passive components on the same semiconductor chip with minimum parasitic capacitance and loss. The functional diagram of an amplifier/switch MMIC for 2.4 to 2.5 GHz transmit/receive function is shown in Fig. 7.3.21. The receive path contains

FIGURE 7.3.21 Functional diagram for 2.4 GHz GaAs transceiver. (TriQuint Semiconductor)

a high gain, low-noise amplifier, internally matched to $50\ \Omega$ at both ports. The transmit path contains an internally matched, class-A, medium power amplifier. The circuit also contains fully integrated T/R switches at input and output. The use of GaAs MESFETs as amplifiers provide both low-noise figure (3.5 dB) as well as good linearity for the transmitter in applications such as spread spectrum transceivers.

For millimeter wave amplifiers MESFETs can be replaced by PHEMTs, which have higher gain. A broadband power amplifier MMIC has been fabricated with a nominal gain of 13 dB and output power of +21 dBm from 20 to 50 GHz.

Other GaAs MMICs have been developed with greater complexity that provide an entire downconverter for satellite TV receivers at 12 GHz. Low-power radar transceiver MMICs at 94 GHz have been demonstrated in the laboratory that may provide collision warning sensors for automobiles by the year 2000.

SECTION 8

TRANSDUCERS AND SENSORS

Measurements by direct comparison with a reference standard having the same characteristics as those of the quantity measured are called *direct measurements*, but most measurements yield results in a more indirect way. They are based on knowledge of the relationship between the quantity to be measured and the response of the measuring instrument or system influenced by it. Moving-coil meters are an example: under the influence of the applied voltage or current (or both) a mechanical torque is generated. The pointer attached to the moving coil acquires its final position indicative of the electrical quantity measured, the mechanical torque being balanced by a spring. Thus an electrical quantity is first translated into a torque, which in turn is translated into a position on a scale calibrated in units of the quantity measured.

In this example, the electrical quantities are translated into mechanical ones. In contrast, *transducers* translate primarily nonelectrical quantities into electric signals.

The term transducer has been applied to a variety of devices, including measuring instruments, acoustic-energy transmitters, signal converters, and phonograph cartridges. With the vast increase in the development and use of electronic measuring systems, however, instrumentation engineers found it necessary to devise a more limited definition of transducer as a device used for measurement purposes.

Transducers covered in the first four chapters of this section include those for mechanical, thermal, acoustic, optical, and electrical quantities.

A chapter on microsensors and microactuators based on microfabrication techniques emphasizes physical, chemical, and biomedical sensors. A microelectromechanical (MEMS) instrumentation system can be considered to consist of an input sensor, an output actuator, and a signal processing element. H.N., D.C.

CHAPTER 8.1

TRANSDUCER CHARACTERISTICS AND SYSTEMS

Harry N. Norton

INTRODUCTION

American National Standard, ANSI MC6.1, Electrical Transducer Nomenclature and Terminology (see Ref. 1), defines a *transducer* as “a device which provides a usable output in response to a specified measurand.” The *measurand* is “a physical quantity, property or condition which is measured.” The *output* is “the electrical quantity, produced by a transducer, which is a function of the applied measurand.” Only the last of these three definitions applies specifically to electrical transducers. It could apply equally well to transducers with pneumatic output if the word “electrical” in the definition were omitted. Only electrical transducers are covered in this handbook.

ANSI MC6.1 also applies to the construction of transducer nomenclature (see Table 8.1.1). When used in titles or for indexes, the sequence shown in the table should be used, e.g., “transducer, acceleration, potentiometric, $\pm 5g$.” When the nomenclature is used in the text, the opposite of the sequence shown in the table should be used, e.g., “A 0- to 8-cm dc output relative displacement transducer was installed on the actuator.”

Transducer Classes and Elements

Thermocouples are representatives of a transducer class in which transduction takes place in a single component. An electric signal is generated between the terminals of the two dissimilar wires forming the thermocouple when they are exposed to a temperature difference. This is the simplest class of transducer. It is also *self-generating*, the output signal being produced without an additional power source. Piezoelectric transducers are also of the self-generating type, electric charge or potential being generated when the crystal is exposed to stress.

The thermocouple (or *thermoelectric temperature transducer*) is one of the few transducer types in which the *sensing element* (the element on which the measurand acts directly) also acts as the *transduction element* (the element in which the output of a transducer originates). Most transducer types have separate sensing and transduction elements. For example, in a piezoelectric pressure transducer the pressure acts on a diaphragm (sensing element) which deflects with applied pressure and then stresses the piezoelectric crystal (transduction element) in which the output originates.

The self-generating piezoelectric transducer is an example of a transducer whose transduction element is “active.” In the majority of transducer types the transduction element is “passive,” i.e., it requires the application of *excitation* power from an external source. Some “passive” transduction elements can accept either ac or dc excitation (e.g., strain-gage bridges, potentiometric elements), whereas others can accept only ac excitation (e.g., reluctance, inductive, capacitive elements).

TABLE 8.1.1 Construction of Typical Transducer Nomenclature and Examples of Modifiers

Main noun	First modifier, measurand, examples	Second modifier, restricts measurand, examples	Third modifier, electrical transduction principle, examples	Fourth modifier ^d , sensing element, special features or provisions, examples	Unit, examples
Transducer	Acceleration	Absolute	Capacitive	AC output	A
	Air speed	Angular	Electromagnetic	Amplifying	°C
	Attitude	Biaxial	Inductive	Bellows	cm
	Attitude rate	Differential	Ionizing	Bondable	cm/s
	Current	Gage	Photoconductive	Bonded	deg
	Displacement	Infrared	Photovoltaic	Bourdon tube	°F
	Flow rate	Intensity	Piezoelectric	Capsule ^b	ft/s
	Force	Linear	Potentiometric	DC output	g
	Heat flux	Mass	Reluctive	Diaphragm	Hz
	Humidity	Radiant	Resistive	Digital output	in./s
	Light	Relative	Strain gage	Discrete-increment	in.
	Liquid level	Surface	Thermoelectric	Dual-output	K
	Mach number	Total	Vibrating-element	Exposed-element	kg
	Nuclear radiation	Triaxial		Frequency output	lb/min
	Pressure	Volumetric		Gyro	m
	Speed ^c			Integrating	mmHg
	Sound pressure			Self-generating	N
	Strain			Semiconductor	% RH
	Temperature			Servo ^{d,e}	lb/in. ²
	Torque			Switch	kPa
	Velocity			Toothed-rotor	mbar
				Turbine	rad/s
				Ultrasonic	
				Unbonded	
				Weldable	

^a Nomenclature may include two of these terms.

^b Preferred to "aneroid."

^c Scalar quantity.

^d Preferred to "force balance" or "null balance."

^e When this modifier is used, the third modifier ("transduction principle") may be omitted.

^f Vector quantity.

FIGURE 8.1.1 Output-measurand relationship of ideal linear-output transducer as exemplified for a dc-output transducer. (From Ref. 2 by permission)

Signal Conditioning

The widespread acceptance of industrial standards specific to a particular industry or application demands that the transducer output be in a specific form and within a specific range. Process industry standards, for instance, typically demand a transducer output signal either in the form of a direct current in the range from 4 to 20 mA or a dc voltage between 0 and 5 V. Transducers delivering control signals to microprocessors often require a digital output; this also applies to transducers used in digital data acquisition systems.

The process and the steps involved to provide an output signal in whatever specific form required are referred to as *signal conditioning*. The equipment may include ac or dc amplifiers, rectifiers, demodulators, circuits for square-root extraction, logarithmic amplifiers, and so forth, depending on the laws governing the relationship between the measurand and the desired output signal. For example, the radiation emanating from the surface of a body is an exponential function of its temperature. Thus to obtain a linear temperature scale at the output, logarithmic amplifiers are typically involved in the signal-conditioning process. In addition, excitation voltage or current regulation circuits are used in many instances to ensure accuracy and repeatability.

When a transducer system includes all the above-mentioned elements and circuits and is packaged in a single-housing, it is referred to as an *integrally conditioned transducer*. Recent examples include integrated-circuit semiconductor transducers for temperature-compensated pressure measurements contained in a single miniature housing.

Transfer Function

Every transducer design can be characterized by an ideal or theoretical output-measurand relationship (*transfer function*). This relationship is capable of being described exactly by a prescribed or known *theoretical curve* (see Fig. 8.1.1), stated in terms of an equation, a table of values, or a graphical representation. This applies primarily to the *static characteristics* of a transducer, i.e., the output-measurand relationship for a steady-state or very slowly varying measurand. It can also apply to the transducer's *dynamic characteristics*, i.e., the output-measurand characteristics for a relatively rapidly fluctuating measurand. However, this dynamic behavior is described by relationships other than the transducer's theoretical curve.

Transducer Errors

Because of a variety of factors, the behavior of a real transducer is nonideal. These factors include production variations, as well as the use of nonideal materials, production methods, ambient conditions during manufacture, and testing methods. It must also be recognized that many trade-offs enter into the design of a marketable transducer and that our knowledge (the *state of the art*) is limited with regard to producing an ideal transducer design and then compensating it perfectly for aging effects and a variety of environmental conditions the transducer may be subjected to during its operation.

FIGURE 8.1.2 Static error band referred to terminal line (error scale 10:1).
(From Ref. 2 by permission)

Hence the measurand value indicated by the transducer may often differ from the true measurand value or the specified theoretical value. The algebraic difference between the indicated and the true value is the *error*.

Error Band

A convenient manner of determining or specifying transducer errors is to state them in terms of the band of maximum (or maximum allowable, for a specification) deviations from a specified reference line or curve. This band is defined as the *error band*. The *static error band* (see Fig. 8.1.2) is that error band obtained (or obtainable) by means of a *static calibration*, which is performed under “room conditions” (controlled room temperature, humidity, and atmospheric pressure) and in the absence of any vibration, shock, or acceleration (unless one of these is the measurand) by applying known values of measurand to the transducer and recording corresponding output readings. Other types of error band are applicable under somewhat different (and rigorously specified) conditions. Reference lines for error bands are not limited to the terminal line.

Dynamic Characteristics

When a step change in a measurand is applied to a transducer, the transducer output does not instantaneously indicate the new measurand level. Examples of such step changes are mechanical shock, a sudden pressure rise when a solenoid valve opens, or a temperature transducer is rapidly immersed in a very cold liquid. The lag between the time the measurand reaches its new level and the corresponding steady (final) transducer output reading is defined in various ways. The time required for the output change to reach 63 percent of its final value is the *time constant* of the transducer. The time required to reach a different specified percentage of this final value (say 90 or 98 percent) is the *response time*. The time in which the output changes from a small to a large specified percentage of the final value (usually from 10 to 90 percent) is the *rise time*. The output may rise beyond the final value before it stabilizes at that value. This *overshoot* depends on the *damping* characteristics of the transducer.

When the measurand fluctuates (sinusoidally) over a stated frequency range, the transducer output may not be able to indicate the correct amplitude of the measurand over these excursions. An example is the mechanical vibration (vibratory acceleration) of an engine housing. The output may be somewhat higher at certain measurand frequencies but usually drops off as the frequency increases until the output is essentially zero. The change with measurand frequency of the output-measurand amplitude ratio is the *frequency response* of the transducer, always stated for a specified frequency range. The above characteristics, as well as other transducer dynamic characteristics, are defined in the terminology section of ANSI Standard MC6.1-1975.

Environmental Characteristics

In most applications transducers are used only under the controlled room conditions of the facility where they are calibrated and where various static performance characteristics are determined. The external conditions to which a transducer is exposed not only while operating but also during shipping, storage, and handling can contribute additional errors, such as temperature error, acceleration error, or attitude error. Such environmental conditions (which can also include corrosive atmosphere, salt-water immersion, or nuclear radiation) may even cause a permanent deterioration or malfunction in the transducer.

Transduction Principles

The most essential determinant of any one transducer type is its transduction principle. How the electrical output is originated affects most other characteristics of the transducer. The most frequently used transduction principles are described below and illustrated in Fig. 8.1.3. It should be noted that photovoltaic, piezoelectric, piezoelectric,

8.8 TRANSDUCERS AND SENSORS

and electromagnetic transduction are used in *self-generating* transducers, whereas all other transduction methods illustrated require some sort of external excitation power.

Photovoltaic Transduction. The measurand is converted into a change in the voltage generated when a junction between certain dissimilar materials is illuminated. Used primarily in optical sensors, this principle has also been employed in transducers incorporating mechanical-displacement shutters to vary the intensity of a light beam between a built-in light source and the transduction element.

Piezoelectric Transduction. The measurand is converted into a change in the voltage E or electrostatic charge Q generated by certain crystals when mechanically stressed by compression or tension forces or by bending forces. Either natural or synthetic crystals (usually ceramic mixtures) are used in such transduction elements.

Electromagnetic Transduction. The measurand is converted into a voltage (electromotive force) induced in a conductor by a change in magnetic flux, usually because of a relative motion between a magnetic material and a coil having a ferrous core (electromagnet).

Capacitive Transduction. The measurand is converted into a change of capacitance. This change occurs typically either by having a moving electrode move to or from a stationary electrode or by a change in the dielectric between two fixed electrodes.

Inductive Transduction. The measurand is converted into a change of the self-inductance of a single coil.

Photoconductive Transduction. The measurand is converted into a change in conductance (resistance change) of a semiconductive material because of a change in the illumination incident on the material. This transduction is implemented in a manner similar to that explained for the case of photovoltaic transduction, above.

Reluctive Transduction. The measurand is converted into an ac voltage change by a change in the reluctance path between two or more coils while ac excitation is applied to the coil system. This transduction principle applies to a variety of circuits, including the differential transformer and the inductance bridge.

Potentiometric Transduction. The measurand is converted into a change in the position of a movable contact on a resistance element. The displacement of the contact (wiper arm) causes a change in the ratio between the resistance from one end of the element to the wiper arm and the end-to-end resistance of the element. In its most common applications the resistance ratio is used in the form of a voltage ratio when excitation is applied across the resistance element.

Resistive Transduction. The measurand is converted into a change of resistance. This change is typically effected in a conductor or semiconductor by heating or cooling, by the application of mechanical stresses, by sliding a wiper arm across a rheostat-connected resistive element, or by drying or wetting electrolytic salts.

Strain-Gage Transduction. The measurand is converted into a resistance change, due to strain, usually in two or four arms of a Wheatstone bridge. This principle is a special version of resistive transduction. However, the output is always given by the bridge-output voltage change. In the typical configuration illustrated in Fig. 8.1.3 the upward arrows indicate increasing resistance, and the downward arrows decreasing resistance, in the respective bridge arms for sensing link motion toward the left.

Transducers in Process Control

The availability of an output signal responding to a measurand makes transducers key elements in the many areas of industrial process control. It permits direct comparison of a transducer output with an adjustable electric reference signal, calibrated in units of the measurand. Both the transducer output and the adjustable

reference signal are fed into the input terminals of a differential amplifier. When any deviation of the transducer output from the adjustable reference signal (*set point*) occurs, an error signal is supplied to the controller, which in turn causes the control element to acquire such a position that the measurand again causes the transducer to deliver an output equal to the adjustable reference signal. This control process can be carried out in several alternative modes, e.g., on-off or proportional.

CHAPTER 8.2

TRANSDUCERS FOR MECHANICAL QUANTITIES

Harry N. Norton

TRANSDUCERS FOR SOLID-MECHANICAL QUANTITIES

Transducers for solid-mechanical quantities sense and/or react to acceleration, velocity, vibration, shock, attitude, displacement, and position of a solid element. Transducers can also measure force, torque, weight or mass, and strain (deformation resulting from stress).

Acceleration, Vibration, and Shock

Acceleration, a vector quantity, is the time rate of change of velocity with respect to a reference system. When the term acceleration is used alone, it usually refers to *linear acceleration* a , which is then related to linear (translational) velocity v , and time t by $a = dv/dt$. *Angular acceleration* α is related to angular (rotational) velocity ω and time t by $\alpha = d\omega/dt$. Mechanical *vibration* is an oscillation wherein the quantity, varying in magnitude with time so that this variation is characterized by a number of reversals of direction, is mechanical in nature. This quantity can be stress, force, displacement, or acceleration; however, in measurement technology the term vibration is usually applied to *vibratory acceleration* and sometimes to *vibratory velocity*. Mechanical *shock* is a sudden nonperiodic or transient excitation of a mechanical system.

Acceleration Transducers (Accelerometers). Acceleration transducers (accelerometers) are used to measure acceleration as well as shock and vibration. Their sensing element is the *seismic mass*, restrained by a spring. The motion of the seismic mass in this acceleration-sensing arrangement is usually damped (see Fig. 8.2.1a). Acceleration applied to the transducer case causes motion of the mass relative to the case. When the acceleration stops, the mass is returned to its original position by the spring (see Fig. 8.2.1b). This displacement of the mass is then converted into an electrical output by various types of transduction elements in *steady-state acceleration transducers* whose frequency response extends down to essentially 0 Hz. In piezoelectric accelerometers the mass is restrained from motion by the crystal transduction element, which is thereby mechanically stressed when acceleration is applied to the transducer. Such *dynamic acceleration transducers* do not respond appreciably to acceleration fluctuating at a rate of less than 5 Hz. They are normally used for vibration and shock measurements.

Capacitive and photoelectric accelerometers have been produced at various times, and vibrating-element accelerometers (in which the mass, as it tends to move, applies tension to a wire or ribbon, thereby changing the frequency at which the wire can oscillate) have been used in some aerospace programs. However, the most commonly used steady-state acceleration transducers are the potentiometric, reluctance, strain-gage,

FIGURE 8.2.1 Basic operating principle of an acceleration transducer: (a) spring-mass system; (b) displacement of seismic mass. (From Ref. 1 by permission)

and servo types. For vibration and shock measurement the piezoelectric accelerometers are most frequently used because of their inherently high frequency-response capability; some miniature semiconductor-strain-gage accelerometers are also used for these measurements since they can respond to fairly high acceleration frequencies.

Potentiometric Accelerometers. Potentiometric accelerometers usually employ a mechanical linkage to amplify the motion of the seismic mass so as to produce the necessary extent of wiper-arm travel over the resistance element. The mass is supported by flexural springs or a cantilever spring in some models. In others it slides on a central coaxial shaft, restrained by calibrated coil springs. Magnetic, viscous, or gas damping is normally used in potentiometric accelerometers, primarily to reduce output noise due to wiper-arm whipping and transient wiper-contact resistance changes. Over-load stops keep the wiper arm from moving beyond the resistance-element ends in the presence of acceleration beyond the range of the accelerometer.

Reluctive Accelerometers. Reluctive accelerometers require ac excitation power having a frequency greater than the upper limit of the transducer's frequency response. When moderately high frequency response is needed, the inductance-bridge version has been found most suitable. In a typical design the seismic mass is attached to a spring-restrained ferromagnetic armature plate, pivoted at its middle and placed above two coils so that the small seesaw motion of the plate, due to acceleration action on the mass, causes a decrease of inductance in one coil and an increase of inductance in the other. Since the coils are in opposite bridge arms, these inductance changes are additive and produce a bridge output voltage double that obtainable from having only one coil change its inductance. When a relatively low frequency response is needed, a differential-transformer, synchro or microsyn transduction circuit can be used to convert the seismic-mass displacement into the required electrical output.

Strain-Gage Accelerometers. Strain-gage accelerometers are very popular and exist in several design versions. Some use unbonded metal wire stretched between the seismic mass and a stationary frame or between posts on a cross-shaped spring to whose center the seismic mass is attached and whose four tips are attached to a stationary frame. Other designs use bonded-metal wire, metal foil, or semiconductor gages bonded to one or two elastic members deflected by the displacement of the seismic mass. The recently developed micromachined accelerometers also employ strain-gage transductions.

Servo Accelerometers. Servo accelerometers are closed-loop force-balance, torque-balance, or null-balance transducers. The displacement of the seismic mass is detected by a position-sensing element, usually reluctive

FIGURE 8.2.2 Piezoelectric acceleration transducers: (a) single-ended compression type; (b) shear type. (Endevco, Dynamic Instrument Division)

or capacitive, whose output is the error signal in the servo system. This signal is amplified and fed back to a torquer or restoring coil so that the restoring force is equal and opposite to the acceleration-induced force. The coil or torquer is attached to the seismic mass and returns the mass to its original position, when the feedback current is sufficient, so that the position error signal is reduced to zero. The current, which is proportional to acceleration, passes through a resistor. The IR drop across the resistor is the accelerometer output voltage, proportional to the acceleration.

Piezoelectric Accelerometers. Piezoelectric accelerometers exist in several design versions, two of which are illustrated in Fig. 8.2.2. Both contain a seismic mass that applies a force, due to acceleration, to a piezoelectric crystal. With acceleration acting perpendicular to the base, an output is generated by the crystal due to compression force in one design and to shear force in the other. Crystal materials include quartz and several ceramic mixtures such as titanates, niobates, and zirconates.

Ceramic crystals are used more frequently than natural crystals. They gain their piezoelectric characteristics by exposure to an orienting electric field during cooling after they are fired at a high temperature. If they are subsequently heated, as during transducer operation at elevated temperature, they can lose their piezoelectric qualities if that temperature is above the *Curie point*, which varies between about 100 and 600°C, depending on the materials used in the crystal. Piezoelectric accelerometers almost invariably require some signal-conditioning circuitry to provide a usable output since they have a relatively low output amplitude and a very high output impedance. In many designs, the necessary conditioning circuitry is included in the transducer. For other accelerometers, a separate charge or voltage amplifier is needed, connected to the transducer by a thin shielded coaxial cable of special low-noise construction to avoid noise pickup from within the cable itself.

Criteria for Selection. Criteria for selection of an acceleration transducer are primarily the required acceleration range and frequency response. They are mutually dependent; e.g., a typical $\pm 2g$ potentiometric accelerometer design will have an upper frequency limit for flat response of about 12 Hz, whereas a $\pm 20g$ accelerometer of the same design can have an upper frequency-response limit of about 40 Hz. As frequency-response requirements increase, the relative, servo, metal-strain-gage, semiconductor-strain-gage, and piezoelectric transducers successively become candidates for selection. The best accuracy characteristics are provided by servo accelerometers, which are also most suitable for low-range ($\pm 0.2g$ or lower) applications.

Attitude and Attitude-Rate Transducers

Attitude is the relative orientation of a vehicle or an object represented by its angles of inclination to three orthogonal reference axes. Attitude rate is the time rate of change of attitude.

The sensing methods employed by attitude transducers are best categorized by the kind of reference system to which the orientation to be measured is related. The *inertial* reference system is provided by a *gyroscope* (*gyro*) in which a rotating member will continue turning about a fixed axis as long as no forces are exerted on the member and the member is not accelerated. *Gravity* reference is used to establish a vertical

reference axis. This principle is applied in *pendulum-type transducers*, in which a weight is attached to a wiper arm and a potentiometric or reluctance element is attached to the case, so that an output change is obtained when the object, to which the case is mounted, deflects from a vertical position.

A *magnetic reference axis* can be established by the poles of a magnetic field which remains fixed in position. This reference system is employed by certain navigational transducers related to the compass. *Flow-stream reference* refers to the direction of fluid flow past an object moving within that fluid, a reference system employed in *angle-of-attack* transducers mounted well forward of the nose of high-speed aircraft and rockets, so that the flow stream used is not altered in direction by the vehicle itself.

Optical reference systems are used by electrooptical transducers mounted (in a known attitude) so as to sense a remote light source or a light-dark interface whose position is known. This establishes a reference axis between the object on which the transducer is mounted and the target sensed by the transducer. *Optically referenced* transducers include such aerospace (primarily spacecraft) devices as the sun sensor, star tracker, and horizon sensor, as well as military target-locating equipment.

Gyros. Gyros are the most widely used attitude and attitude-rate transducers. The operating principle of the gyro is illustrated in Fig. 8.2.3. A fast-revolving rotor turns about the *spin axis* of the gyro. This axis, which remains fixed in space as long as the rotor revolves, establishes the inertial reference axis. The rotor shaft ends are supported by a *gimbal* frame which is free to pivot about the gimbal axis. The pivot points are part of the gyro housing structure, which is attached to the object whose changes in attitude about the gimbal axis are to be measured. An angular-displacement transduction element (pick-off) is then used to provide an output proportional to attitude. A simple example of such an element is a wiper arm, attached to the gimbal frame at the pivot point, wiping over a ring-shaped potentiometric resistance element attached to the inside of the case. Potentiometric transduction as well as reluctance (especially synchro) and, occasionally, capacitive and photoconductive transduction are used in most gyros.

Gyro attitude transducers (free gyros) are often designed as two-degree-of-freedom gyros, i.e., those providing an output for each of two of a vehicle's three attitude planes (pitch, yaw, and roll, or *x*, *y*, and *z* axes). The design illustrated in Fig. 8.2.4 provides an inner gimbal for one axis and an outer gimbal for the other axis, with a separate pick-off for each axis. The caging mechanism (symbolized by the hand) is used to lock the inner gimbal to a reference position until the spin axis is to start serving as inertial reference axis. At this point the gyro is uncaged (after the rotor has come up to speed). AC or dc motors are commonly used to turn the rotor. Some gyros use a clock spring, wound before each use, or a pyrotechnic charge which, when activated, forces a stream of combustion gases into a small turbine.

FIGURE 8.2.3 Basic single-degree-of-freedom gyro. (From Ref. 1 by permission)

FIGURE 8.2.4 Two-degree-of-freedom gyro. (Conrac Corp.)

Rate gyros are attitude-rate transducers. They provide an output proportional to angular velocity (time rate of change of attitude). The operating principle of the rate gyro (see Fig. 8.2.5) is similar to that of the single-degree-of-freedom free gyro, except that the gimbal is elastically restrained and its motion is damped. The output is representative of gimbal deflection about the output axis in response to attitude-rate changes about the input axis. The deflection of the gimbal (precession) is caused by the torque T applied to it. The applied torque is the product of the instantaneous attitude rate about the input axis and the angular momentum of the gyro.

FIGURE 8.2.5 Basic-rate gyro. (From Ref. 1 by permission)

The more recently developed *ring laser gyro (RLG)* and *fiber-optic gyro* contain essentially no moving parts; the rotor is replaced by two laser beams traveling in opposite directions many times around a triangular or circular path; attitude rate changes then cause a frequency or phase difference at the optical path terminations.

When selecting a gyro, attention must be paid not only to the usual characteristics (weight, size, range, linearity, repeatability, threshold, and so on, and dynamic characteristics for rate gyros) but also

to *drift*, the amount of precession, per hour, of the spin axis from its intended position because of internal unwanted torques or other instabilities, and the time period (after spin-motor runup or after uncaging) during which measurements must be obtained continuously.

Displacement and Position Transducers

Position is the spatial location of a body or point with respect to a reference point. *Displacement* is the vector representing a change in position of a body or point with respect to a reference point. Displacement transducers are used to measure linear and angular displacements, as well as to establish position from a displacement measurement.

The sensing element of most displacement transducers is the *sensing shaft* with its coupling device, which must be of a design suitable to make the motion of the sensing shaft truly representative of the motion of the measured point (driving point). A spring-loaded sensing shaft (without coupling device) is used for some applications. A number of *noncontacting* transducer designs are also in use. These require no coupling or sensing shaft. Various transduction principles are employed in displacement transducers.

Capacitive Displacement Transducers. In these devices a linear or angular motion of the sensing shaft causes a change in capacitance either by relative motion between one or more moving (*rotor*) electrodes and one or more stationary (*stator*) electrodes or by moving a sleeve of insulating material, having a dielectric constant different from that of air, between two stationary electrodes.

Inductive Displacement Transducers. Inductive displacement transducers can be of the coupled or the non-contacting types. Coupled designs contain a coil whose self-inductance is varied as a nonmagnetic sensing shaft moves a magnetically permeable core gradually into or out of the central hollow portion of the coil. Some designs incorporate an additional coil (balancing coil) having a fixed inductance value equal to the inductance of the transduction coil at a predetermined “zero” position of the sensing shaft. The two coils are connected as two arms of an inductance bridge. This two-coil principle is used in some noncontacting displacement transducers in which the transduction coil has a stationary core but changes its inductance with the distance between itself and a moving ferromagnetic object.

Photoconductive Displacement Transduction. Photoconductive displacement transduction is employed in several nonconducting displacement measuring systems. Pulsed or continuous-wave lasers or light-emitting diodes are typically used as light sources. Noncontacting photoconductive sensors usually require an optical

reflector mounted to the measured object. Various optical configurations are used to obtain an output from the photoconductive element as the intensity, the phase, or the position of the reflected light beam changes. The *laser interferometer* is included in this group of displacement-sensing devices.

Potentiometric Displacement Transducers. Potentiometric displacement transducers are widely used because of their relative simplicity of construction and their ability to provide a high-level output. All these designs use a sensing shaft. The wiper arm is either attached directly to the shaft (but insulated from it) or mechanically connected to it through an amplification linkage. Straight potentiometric resistance elements are used in linear displacement transducers, circular or arc-shaped elements in angular displacement transducers. The elements are usually wire-wound, but conductive plastic, carbon film, metal film, or ceramic-metal mixtures (cermets) are also used. Some transducers have two or more wiper-element combinations moved by the same sensing shaft. A good sliding seal is needed at the point where the sensing shaft enters the transducer case, to protect the internally exposed resistance elements from atmospheric contaminants and moisture.

Reluctive displacement transducers are as commonly used as the potentiometric types. The reductive transduction circuits employed in linear- and angular-displacement transducers are illustrated in Fig. 8.2.6. Only the linear-variable transformer (LVDT) and the inductance-bridge circuits are used for linear-displacement measurements. Many winding configurations exist for the LVDT transducers; one manufacturer offers 12 different “off-the-shelf” configurations, including several with two separate secondary windings. Alternating current excitation is required for all reductive transducers. However, some designs are available with integral ac/dc output conversion and, in some cases, also integral dc/ac excitation conversion. Synchro-type transducers are often connected to a synchro-type receiver, which indicates the measured angle directly, e.g., on a dial.

A few strain-gage displacement transducers have been designed for the measurement of small linear and angular displacement. The gages are usually attached to the top and bottom surfaces of a cantilevered or end-supported beam which is deflected by the displacement.

Digital-Output Displacement Transducers (Encoders). Digital-output displacement transducers (encoders) are frequently referred to as *linear encoders* and *angular* or *shaft-angle encoders*, respectively. These consist essentially of a strip (for linear displacements) or a disk (for angular displacements), coded so as to provide a digital readout for discrete (sometimes very small) displacement increments and a reading head. Two types of encoders are in common use:

1. Photoelectric encoders, in which the reading head consists of a light-source assembly on one side of the disk or strip and a corresponding light-sensor assembly facing it on the other side of the disk or strip; the coded pattern is partly translucent, partly opaque.
2. Magnetic encoders, with a magnetic reading head and a partly magnetized, partly nonmagnetized coded pattern.

Incremental encoders have a simple, alternately ON and OFF coded pattern. They provide an output in the form of number of *counts* between the start and end of the displacement. Hence the start position must be known if the end position is to be determined in absolute terms. *Absolute encoders* have a code pattern such that a unique digital word is formed for each discrete displacement increment. Various codes are used for this purpose, such as the binary, binary-coded-decimal (BCD), and the Gray code.

Among displacement-transducer *selection criteria*, the most critical are range, resolution, starting force, overtravel, and type and magnitude of full-scale output. Accuracy and dynamic characteristics, type of available excitation supply, and freedom from contamination by the ambient atmosphere or other fluids need to be considered as well, for all transducer applications.

Force, Torque, Mass and Weight Transducers

Force is the vector quantity necessary to cause a change in momentum. *Mass* is the inertial property of a body, a measure of the quantity of matter in the body and of its resistance to change in its motion. *Weight* is the gravitational force of attraction; where gravity exists, it is equal to mass times acceleration due to gravity. *Torque* is the moment of force, the product of force, and the perpendicular distance from the line of action of the force to the axis of rotation (lever arm).

(From Ref. 1 by permission)

Force Transducers (Load Cells). Force transducers (load cells) are used for force measurements (compression, tension, or both) as well as for weight determinations in any locality where gravity exists and the gravitational acceleration g is known. The standard g (on earth) is 9.80665 m/s^2 . Mass can be determined from weight, which is expressed in force units. A mass of 1 kg, for example, “weighs” 2.205 lb (pounds force) on earth. Torque is measured by *torque transducers*.

The sensing elements of force and torque transducers usually convert the measured into a mechanical deformation of an elastic element. This deformation, in terms of either local strains or gross deflection, is then converted into a usable output by a suitable transduction element. Bending beams (cantilever, end-supported, or end-restrained), solid rings or frames (*proving rings*), and solid or hollow rectangular or cylindrical columns are the most commonly used force-sensing elements. Special solid or notched shafts are used as torque-sensing elements.

Piezoelectric Force Transducers. Piezoelectric force transducers are used for dynamic compression-force measurements. A typical design has the shape of a thick washer. The annular piezoelectric crystal segments are sandwiched between two hollow cylindrical columns. Bidirectional force measurements can be obtained by preloading this *force washer*. An amplifier is used to boost the low-level output signals.

Reluctive Force Transducers. Reluctive force transducers use proving-ring sensing elements in most design versions. The deflection of the proving ring is converted into an ac output by an inductance-bridge or differential-transformer transduction element. An entirely different design uses the permeability changes because of stresses in a laminated column to vary the voltage induced by a primary winding in a secondary winding.

Strain-Gage Force Transducers. Strain-gage force transducers are the most widely used type. Bonded-metal foil and metal wire gages predominate, but unbonded wire gages and bonded semiconductor gages are used in some designs. Columns and proving rings are the usual sensing elements. The shear-web sensing element of the force transducer shown in Fig. 8.2.7 is related to the column, but is reported to offer greater transduction efficiency.

Torque Transducers. Torque transducers are mostly of the reluctive, photoelectric, or strain-gage type. The last is more widely used than the first two. The metal-foil strain gages in the transducer shown in Fig. 8.2.8 are located on the sensing shaft, which is enclosed in a cylindrical *torque sensor* housing. The leads from the gages are carried through the shaft up to slip rings. Brushes ride on the slip rings to provide stationary external connections. The brush assembly can be lifted off the slip rings to increase brush life during periods when torque is not monitored. In most modern strain-gage torque transducers the slip rings and brushes are replaced by a rotary transformer or by RF coupling.

Other Torque Transducers. Reluctive torque transducers use changes in shaft permeability, resulting from torque-induced stresses in the shaft, to change the voltage coupled from a primary winding to two secondary

FIGURE 8.2.7 Strain-gage force transducer. (Interface, Inc.)

FIGURE 8.2.8 Strain-gage torque transducer. (Lebow Associates, Inc.)

windings. *Photoelectric torque transducers* use two incremental-encoder disks, one on each end of the shaft, to change the illumination on a light sensor when one disk undergoes a small angular deflection, because of torque, relative to the other disk.

Selection criteria include the usual range, accuracy, excitation, and output characteristics, case configuration and dimensional constraints, overload rating, the thermal environment, and, for torque transducers, maximum shaft speed and proximity of any magnetic fields that may cause reading errors. A frequent application of force transducers is in automatic weighing systems.

Speed and Velocity Transducers

Speed (a scalar quantity) is the magnitude of the time rate of change in displacement. *Velocity* (a vector quantity—magnitude and direction) is the time rate of change of displacement with respect to a reference system. *Velocity transducers* are almost invariably linear-velocity transducers, whereas speed transducers are normally angular-speed transducers (*tachometers*).

Velocity Transducers. Velocity transducers are usually of the electromagnetic type, exemplified by a coil in which a permanent-magnet core moves freely. The core has a sensing-shaft extension, and the shaft is attached to the object whose (usually oscillatory) velocity is to be measured. The rate at which lines of magnetic flux from the core are cut by the coil turns determines the amount of electromotive force generated in the coil; hence the output is proportional to the velocity of the measured point. In some designs the coil moves within a fixed magnetic field instead.

Tachometers. Tachometers are also predominantly of the electromagnetic type. Such angular-speed transducers as the *dc tachometer generator*, the *ac induction tachometer*, and the *ac permanent magnet tachometers (ac magneto)* are electric generators. Their output amplitude increases with angular (rotational) speed. In the case of the ac magneto, the output frequency also increases with speed. The output of a *toothed-rotor tachometer*

also varies in both amplitude and frequency, but the frequency variation is much greater than the amplitude variation and represents the angular speed much more accurately.

The speed-sensing gear teeth and sensing coil (pickup) incorporated in the torque transducer of Fig. 8.2.8 constitute a toothed-rotor tachometer. A pulse is generated in the electromagnetic sensing coil every time a ferromagnetic tooth passes by it. Since there are 60 teeth on the gear shown in the illustration, 60 pulses per revolution are provided by the sensing coil. By counting the pulses over a fixed time interval the angular speed can be determined with very close accuracy. *Photoelectric tachometers* provide the same degree of accuracy, typically by chopping a beam between the light source and a light sensor into equidistant pulses by an incremental-encoder disk attached to the sensing shaft. The pulse-frequency output can also be converted into a dc output voltage if the degraded accuracy, resulting from the conversion, can be tolerated.

Selection criteria include, besides range and accuracy characteristics, the mounting position and required frequency response for velocity transducers, and the type of available readout or signal-conditioning and telemetry equipment in the case of tachometers.

Strain Transducers

Strain is the deformation of a solid resulting from *stress*, the force acting on a unit area in a solid. Strain is measured as the ratio of dimensional change to the total value of the dimension in which the change occurs. Essentially all strain transducers are resistive and are referred to as *strain gages*. Their essential characteristic is their sensitivity (*gage factor*), the ratio of the unit change in resistance to the unit change in dimension (length).

Strain Gages. Strain gages employ either a conductor or semiconductor, of small cross-sectional area, suitable for mounting to the measured surface so that it elongates or contracts with that surface and changes its resistance accordingly. Most types of metal gages are made of thin metal foil, die-cut or etched into the required pattern, or they can be deposited on an insulating substrate through a pattern mask by bombardment or evaporative methods. The metals used in strain gages are usually copper-nickel alloys; other alloys such as nickel-chromium, platinum-tungsten, and platinum-iridium are also used. *Semiconductor gages* are usually made from thin doped-silicon wafers or blocks.

Strain gages can be *bare* (*surface-transferable*, free-filament), bonded to an insulating carrier sheet on one side only, or completely *encapsulated* in a bondable (usually plastic) or weldable (metal) carrier, the latter insulated internally from the gage. Bare gages are normally supplied with a strippable insulating substrate (*carrier*). Since two or more gages are normally used to obtain a strain measurement, for temperature-compensation, linearity-compensation, and output-multiplication purposes, strain-gage *rosettes* are sometimes used, combining two, three, or four gages, mutually aligned as to their strain-sensing axes, on one carrier.

Selection criteria involve the desired type and size (always including gage length and width), type, and material of connecting leads and spacing between them on the gage itself, type of carrier or encapsulation, gage resistance, gage factor, transverse sensitivity tolerances, allowable overload (*strain limit*), and maximum excitation current for a given application. Semiconductor gages may have to be shielded from illumination, which can cause reading errors. Proper methods of attachment and of connection into a Wheatstone bridge circuit are very critical for strain gages.

TRANSDUCERS FOR FLUID-MECHANICAL QUANTITIES

Transducers for fluid-mechanical quantities can be used to measure density and flow of a homogeneous fluid. Transducers can also be used to measure humidity, moisture, and dew-point of a homogeneous gas. Liquid level sensors can determine several characteristics of a liquid or slurry within closed vessels.

Density Transducers

Density is the ratio of the mass of a homogeneous substance to a unit volume of that substance. Density transducers (*densitometers*) are used for the determination of the density of fluids (gases, liquids, and slurries).

They are, however, not related to densitometers used to measure optical density, as of a photographic image, or to equipment used to determine spectral density (e.g., power spectral density).

Three methods are primarily used for density sensing:

Sonic density sensing is achieved by an arrangement of piezoelectric sound (usually ultrasound) transmitters and receivers producing outputs proportional to the speed of sound in the fluid and to the acoustic impedance of the fluid. Since acoustic impedance varies with the product of speed of sound and density, a signal proportional to density can be derived from the transducer and signal conditioning system.

Radiation density sensing relies on the attenuation, owing to density, of the radiation passing from a radioisotope source, on one side of the fluid-carrying pipe or vessel, to a radiation detector on the opposite side.

Vibrating-element density sensing employs a simple mechanical structure, such as a cylinder or a plate, electromagnetically set into vibration at its resonant frequency. This frequency changes with density, and an output is produced, proportional to density, which is related directly to the square of the period of vibration.

Additional methods, used to infer density from other measurements, have also been employed in measurement systems.

Flow Transducers

Flow is the motion of a fluid. *Flow rate* is the time rate of motion expressed either as fluid volume per unit time (*volumetric flow rate*) or as fluid mass per unit time (*mass flow rate*). Transducers used for flow measurement (*flowmeters*) generally measure flow rate. Most flowmeters measure volumetric flow rate, which can be converted to mass flow rate by simultaneously measuring density and computing mass flow rate from the two measurements. Some flowmeters measure mass flow rate directly. Flow-sensing elements can be categorized as follows:

FIGURE 8.2.9 Flow measurement using differential pressure-sensing elements: (a) orifice plate; (b) venturi tube; (c) pitot tube; (d) centrifugal section (elbow); (e) centrifugal section (loop); (f) nozzle; (g) measurement of differential pressure due to flow rate. (From Ref. 1 by permission)

1. *Differential-pressure flow-sensing elements.* Sections of pipe provided with a restriction or curvature that produces a pressure differential ΔP proportional to flow rate across two points of the device (see Fig. 8.2.9). The output of a differential pressure transducer whose input ports are connected to these two points is representative of flow rate through the sensing element. Known relationships of ΔP versus flow rate exist for each type of element.

2. *Mechanical flow-sensing elements.* Freely moving elements, e.g., turbine or propeller, or mechanically restrained elements, e.g., a float in a vertical tapered tube, a spring-restrained plug, a hinged or cantilevered vane, whose displacement, deflection, or angular speed is proportional to flow rate.

3. *Flow sensing by fluid characteristics.* Certain transduction elements can be so designed and installed that they will interact with the moving fluid itself and produce an output relative to flow rate. The heated wire of a *hot-wire anemometer* transfers more of its heat to the fluid as the flow rate increases, thereby causing the resistance of the heated wire to decrease. When small amounts of radioisotope tracer material are added to the fluid, a radiation detector close to the moving fluid will respond with increasing output as the flow rate increases (*nucleonic flowmeter*).

FIGURE 8.2.10 Turbine flowmeter. (ITT Barton.)

In the (*fluid-conductor*) *magnetic flowmeter* an increasing electromotive force is induced in an electrically conductive fluid, flowing through a transverse-magnetic field, as the flow rate increases. In the *thermal flowmeter* two thermocouple junctions are immersed in the moving fluid, one upstream, the other downstream, from an electric heater immersed in the same fluid, and the two junctions are connected as a differential thermocouple, the output of the latter increasing with mass flow rate. In a similar device, the *boundary-layer flowmeter*, only the portion of the fluid immediately adjacent to the inside wall of the pipe is heated and thermally sensed.

Turbine Flowmeters. The turbine flowmeter (see Fig. 8.2.10) is among the most widely used flow-rate transducers. Its operating principle is similar to that of the toothed-rotor tachometer. The bladed rotor (turbine) rotates at an angular speed proportional to volumetric flow rate. Rotational friction is reduced as much as possible by special bearing design. As each magnetic rotor blade cuts the magnetic flux of the pickup coil's pole piece, a pulse is induced in the pickup coil (sensing coil). A frequency meter is used to display the frequency output of the flowmeter, or a frequency-to-dc converter can be used to provide a dc voltage increase with flow rate. The rotor blades can be so machined that the variable-frequency ac voltage across the sensing coil terminals is virtually sinusoidal. This permits use of an FM demodulator as a frequency-to-dc converter. The number of turbine blades, the pitch of the blades, and the internal geometry of the flowmeter determine the range of output frequencies for a given flowrate range.

Oscillating-Fluid Flowmeters. In this device the fluid is first forced into a swirling motion, then passes through a venturi-like cavity at a point of which the flow oscillates about the axis of the flowmeter. A fast-response temperature or force transducer at that point provides an output in terms of frequency of resistance changes. This frequency, proportional to flow rate and converted into voltage variations, can then be displayed

8.22 TRANSDUCERS AND SENSORS

on a counter after it has been amplified, filtered, and wave-shaped. Strain or pressure sensors are also used in such flowmeters.

Other Flowmeter Designs. Other flowmeter designs include the *ultrasonic flowmeter*, typically using pairs of piezoelectric transducers to establish sonic paths. Changes in flow rate produce corresponding changes in the propagation velocity of sound along the path. *Strain-gage flowmeters* are cantilevered vanes or beam-supported drag bodies that deflect or displace in response to fluid flow. The strain in the deflecting beam is then transduced by strain gages. A few types of *angular-momentum mass flowmeters* have been developed in which the fluid either imparts angular momentum to a circular tube through which it flows or receives angular momentum by a rotating impeller. The angular momentum is then used to cause an angular displacement or a torque in a mechanical member, either of which can be transduced to provide an output proportional to mass flow.

Selection criteria involve, first, a choice of either a flowmeter alone or a complete flow-rate or flow-measuring system that can include signal conditioning and display equipment and, when required, a flow totalizer. Among the essential flowmeter characteristics are the (mass or volumetric) flow-rate range, the properties and type(s) of the measured fluid (gas, liquid, mixed-phase, slurry), the nominal and maximum pressure and temperature of the fluid, the configuration, mechanical support, weight and provisions for connection of the flowmeter, the required time constant, and the output, as well as accuracy, specifications. The sensitivity of a turbine flowmeter is usually expressed as the *K factor*, stated in hertz (or cycles) per gallon, per liter, per cubic foot, or per cubic meter. Attention must also be paid to the length of straight pipe upstream and downstream of the flowmeter and the necessity for flow straighteners other than those incorporated in the transducer itself.

Humidity and Moisture Transducers

Humidity is a measure of the water vapor present in a gas. It is usually measured as relative humidity or dew-point temperature, sometimes as absolute humidity. *Relative humidity*, which is temperature-dependent, is the ratio of the water-vapor pressure actually present to water-vapor pressure required for saturation at a given temperature; it is expressed in percent (percent RH). The *dew point* is the temperature at which the saturation water-vapor pressure is equal to the partial pressure of the water vapor in the atmosphere. Hence any cooling of the atmosphere, even a slight amount below the dew point, produces water condensation. The relative humidity at the dew point is 100 percent RH. *Moisture* is the amount of liquid adsorbed or absorbed by a solid; it is also the amount of water adsorbed, absorbed, or chemically bound in a nonaqueous liquid. Humidity and moisture measurements are made by one of three methods: hygrometry, psychrometry, and dew-point determination.

Hygrometers. The hygrometer is a device that can measure humidity directly, with a single sensing element; it is usually calibrated in terms of relative humidity. Three types of hygrometric sensing elements are shown in Fig. 8.2.11. In the *resistive* humidity-transducer sensing element a change in ambient relative humidity produces a change in resistance of a conductive film between two electrodes. Carbon powder in a binder material has been used for such films, but hygroscopic salts, also in a binder material, are more common. Lithium chloride was used originally in such elements; more recently, sulfonated polystyrene and *electrolytic* elements (rather than resistive), such as phosphorous pentoxide, have come into use. The *mechanical* hygrometric element is the oldest type. It uses a material, such as human hair or animal membrane, which changes its dimensions with humidity. The resulting displacement on an attaching point on the material is then transduced into an output proportional to humidity. The *oscillating-crystal* hygrometric element consists of a quartz crystal with a hygroscopic coating, so that the total crystal mass changes as water is adsorbed on, or desorbed from, the coating. When the crystal is connected into an oscillator circuit, the oscillator output frequency will change with changes in humidity.

Several other types of hygrometric sensing elements have also been developed. In the *aluminium oxide element* an impedance (resistance and capacitive reactance) change occurs with changes in humidity. The *Brady array* also provides an ac output when excited with alternating current (at about 1 kHz). However, it differs from other devices in that it consists of an array of semiconducting crystal matrices that look electrically neutral to the water molecule. Vapor pressure then allows the molecules to drift in and out of the interstices, creating an exchange of energy within the structure. The *porous-glass-disk* hygrometric element has electrodes

FIGURE 8.2.11 Sensing elements of humidity transducers: (a) resistive; (b) mechanical; (c) oscillating crystal; (d) psychrometric; (e) photoelectric; (f) resistive; (g) nucleonic; (e) to (g) are dew-point sensors. (From Ref. 1 by permission)

plated on the two surfaces of the disk. When water vapors permeate the pores in the glass, it is decomposed electrolytically when a voltage is applied across the electrodes. The current necessary to decompose the water is then a measure of relative humidity.

Psychrometers. Psychrometers use two temperature-sensing elements (see Fig. 8.2.11d). One element, *dry bulb*, measures ambient temperature; the other, *wet bulb*, covered with a water-saturated wick or similar device, measures temperature reduction due to evaporative cooling. Relative humidity can be determined from the dry-bulb temperature reading, the differential temperature between dry-bulb and wet-bulb readings, and knowledge of the barometric pressure by referring to a *psychrometric table* of numbers. Such tables are available from government agencies, e.g., weather service, as well as from manufacturers. The temperature-sensing elements are usually resistive (platinum- or nickel-wire windings or thermistors), sometimes thermoelectric.

Dew-Point Sensing Elements. Dew-point sensing elements are dual elements. The condensation-detection element senses the first occurrence of dew on a surface whose temperature is being lowered. The temperature-sensing element measures the temperature of this surface so that the dew point (the temperature at which condensation first occurs as the temperature is lowered) can be determined by monitoring the output of both elements simultaneously. Typical condensation detectors (see Fig. 8.2.11) include a photoelectric device in which light sensors detect the difference in light, reflected from a mirror that serves as the condensation surface, when the dew point is reached; a resistive element in which a change in conductivity occurs in an inlaid metal grid at the condensation surface when condensation occurs; and a nucleonic device in which a drop in particle flux, emitted from a radiation source at the condensation surface, indicates the dew point.

Auxiliaries. Resistive humidity transducers are generally more popular than other types when a transducer, rather than a complete measurement system, is required. Almost all types require ac excitation. The electrodes are spiral, helical, or loop-shaped to obtain as large a resistance change as feasible for a given element size. Other hygrometric transducers usually require at least an excitation and signal conditioning unit.

Psychrometric transducers are typically complemented by a signal conditioning and readout system. A small blower (*aspirator*) is often included to blow the ambient air over the two sensing elements so that a faster response can be obtained.

Dew-point humidity transducers require, as a minimum, a cooler (thermoelectric coolers are often used), its associated control circuit, and a power conditioning circuit, as well as the two sensing elements. However, several designs are miniaturized and require relatively little signal conditioning.

Selection criteria. Humidity transducer applications should first be examined to see whether relative humidity or dew point is to be measured. Relative humidity can, of course, also be inferred from psychrometric and dew-point readings but not without a look-up table or calculations. Among performance characteristics the measurement range is the most important; measurement accuracy can usually be improved when only a partial range needs to be measured. Other important characteristics include the temperature and the chemical properties of the ambient atmosphere or the measured material.

Liquid-Level Sensing

A large variety of sensing approaches and transducer types have been developed for the determination of the level of liquids and quasi liquids, e.g., slurries and powdered or granular solids, in open or enclosed vessels (such as tanks and ducts). Not only is the knowledge of the *level* itself important, but other measurements can be inferred from level. If the tank geometry and dimensions are additionally known, the *volume* of the liquid can be determined. If, additionally, the density of the liquid is known, its *mass* can be calculated.

Level is generally sensed by one of two methods: obtaining a discrete indication when a predetermined level has been reached (*point sensing*) or obtaining an analog representation of the level as it changes (*continuous sensing*). Point sensing is also used when it is only desired to establish whether a liquid or a gas exists at a certain point, e.g., in a pipe. The different level-sensing methods can be classified into those lending themselves primarily to point sensing, to continuous sensing, or both. It should be understood, of course, that point-sensing systems are usually simpler and cheaper than continuous sensing systems and should be used when only a discrete indication has to be obtained. Even when two or more discrete levels must be established in one vessel, the use of two or more point sensors may be preferable to a continuous sensing system. On the other hand, electronic circuitry can be used to provide one or more discrete level indications from a continuous sensing system.

Point Level-Sensing Methods. Point level-sensing methods are usually aimed at indicating the interface between a liquid and a gas, sometimes the interface between two different liquids. Three methods are illustrated in Fig. 8.2.12. *Heat-transfer sensing* is used by two types of sensors: the resistive sensor (wire-wound or thermistor) is heated to some degree by the current passing through it so that its resistance changes because of cooling when contacted by the liquid; the thermoelectric sensor detects the cooling, upon liquid contact, of a wire-wound heater it is in thermal contact with. *Optical sensing* relies either on the presence or absence of reflection of a light beam from the interface between a prism surface in contact with gas (reflection) or liquid (no reflection) or on the greater attenuation of a light beam when it passes through liquid on its way to a light sensor. In *damped-oscillation sensing* the mechanical vibration of an element, excited into such vibration electrically, is either stopped (in a magnetostrictive or piezoelectric element) or reduced in amplitude (e.g., in an oscillating-paddle element) in response to acoustic damping or viscous damping, respectively, when the measured fluid changes to a liquid.

Continuous Level Sensors. Three classic continuous level-sensing methods are illustrated in Fig. 8.2.13. The level, volume, or mass of a liquid in a tank of known geometry can be determined by *weighing* the tank continuously, as by means of a load cell (force transducer), and subtracting the tare weight of the tank or compensating for the tare weight. *Pressure sensing* relies on the pressure (*head*) developed at the base of a liquid column. This pressure increases with the column height and hence with level above the point at which pressure is sensed. The differential pressure P_D , measured by the differential-pressure transducer, on the tank shown in the illustration, is equal to the difference in pressures between the bottom and top of the tank ($P_L - P_H$). The *level-sensing float* mechanically actuates a transduction element, usually a potentiometer,

FIGURE 8.2.12 Point level-sensing methods: (a) by heat-transfer rate; (b) by optical means; (c) by oscillation damping. (From Ref. 1 by permission)

sometimes a reductive element or one or more magnetic reed switches. A radically different method (not illustrated) is *cavity-resonance sensing*, where electromagnetic oscillations are excited (from a coupling element at the tank top) within the gaseous cavity enclosed by the liquid surface and the upper tank walls, and the change in resonant frequency, as the liquid surface changes in location, becomes a measure of liquid level.

Several methods are equally useful for point and continuous level sensing (see Fig. 8.2.14). *Conductivity level sensing* is usable with even mildly conductive liquids. The resistance between two electrodes (the tank wall may serve as one of the two) changes continuously (or suddenly, in the case of the point-sensor version) as the liquid level rises or falls.

(a)

(b)

(c)

FIGURE 8.2.13 Continuous level-sensing methods: (a) by weighing; (b) by pressure sensing; (c) by float. (From Ref. 1 by permission)

Dielectric-variation (capacitive) sensing is used primarily for nonconductive liquids, which then play the role of dielectric materials between two (sometimes four) concentric electrodes that are used (and electrically connected) as plates of a capacitor. The capacitance changes continuously (or suddenly, for the point sensor) as the vertical distance h of the level changes. If it is necessary to compensate for changes in the liquid's characteristics during measurement, a reference capacitor, always submerged, can be employed so that the ratio of the capacitance change equals the ratio of the measured level to the vertical dimension of the reference capacitor ($\Delta C/\Delta C_R = h/h_R$).

Sonic level sensing uses ultrasound either emitted from a sound projector and detected by a sound receiver or emitted and detected by a single sound transceiver operating alternately in the transmit and receive mode.

FIGURE 8.2.14 Continuous- and point-level sensing: (a) conductivity; (b) dielectric variation; (c) sonic sensing; (d) radiation sensing. (From Ref. 1 by permission)

An echo-ranging technique is commonly used, the liquid-gas interface (the liquid level) acting as the target. The difference in attenuation or travel time of the beam of sound between liquid or gas in its path can also be used for sonic level sensing, especially for point sensing.

Radiation sensing is a nucleonic sensing method employing usually one or more radioisotope sources and radiation detectors to indicate level changes by virtue of the changes in attenuation of the radiation in response to level changes. The attenuation in the liquid is caused mainly by absorption. Such nucleonic methods have also been used to study density profiles and the location and extent of vortices in tanks and of gas bubbles in pipes.

Liquid-Level Transducers. Liquid-level transducers, in their most common configuration, are probes, flange- or boss-mounted through the tank or duct wall. Some pipe-wall-mounted transducers are so designed that their sensing end is flush with the inside of the wall, to prevent obstructions to flow. Nucleonic transducer systems and some ultrasonic designs are attached to the outside of the wall.

The transduction principle of liquid-level transducers is given by the sensing technique employed. Dielectric-variation sensing demands capacitive transducers, using ac excitation having a frequency between 400 Hz and 200 kHz. Magnetostrictive and piezoelectric transducers, whose probe tip oscillates at a frequency in the vicinity of 40 kHz, find their application in the sonic, as well as the damped-oscillation, sensing techniques. Ionization-type, as well as solid-state, transducers are used in nucleonic systems. Photoelectric transducers are used in optical sensing systems. Potentiometric and reluctance transduction elements are found in float-actuated liquid-level transducers. Resistive transducers are used for heat-transfer sensing and, in a somewhat different form, for conductivity sensing. Thermoelectric elements are found in some heat-transfer sensors. Vibrating-element (notably vibrating-paddle) transducers find their use in damped-oscillation sensing systems.

Selection criteria involve, first of all, the choice of one or more point-level sensors or a continuous level sensor. After this choice has been made, together with an evaluation of end-to-end system requirements, the characteristics of the measured liquid are of primary importance. These include its conductivity, viscosity, temperature, chemical properties and, for installation in pipes or ducts, its flow rate and pressure. The transducer must also be designed and installed in such a manner as to prevent false level indications owing to slosh, spray, and splash or to adherence of liquid to the transducer with falling level.

Pressure and Vacuum Transducers

Pressure is force acting on a surface; it is measured as force per unit area, exerted at a given point. *Absolute pressure* is measured relative to zero pressure, *gage pressure* relative to ambient pressure, and *differential pressure* relative to a *reference pressure* or a range of reference pressures. A perfect *vacuum* is zero absolute pressure. Vacuum measurement, however, is the measurement of very low pressures.

Pressure-Sensing Elements. Pressure-sensing elements are almost invariably mechanical in nature (see Fig. 8.2.15). They can be described generally as thin-walled elastic members which deflect when the pressure on one side of their wall is not balanced by a pressure on the opposite side. The former pressure is the measured pressure; the latter is either a vacuum or near vacuum (for absolute-pressure transducers), the ambient atmosphere (for gage-pressure transducers), or some other pressure (for differential-pressure transducers).

The *diaphragm* is a circular plate fastened around its periphery so that its center will deflect when pressure is applied to it. It can be flat or, when a greater deflection is required, contain a number of concentric corrugations that increase the effective area upon which the force (pressure) can act. Two corrugated diaphragms, welded, brazed, or soldered together around their periphery, form a *capsule* sensing element (aneroid). Two or more capsules can be fastened together so that the pressure acts on all. The displacement obtainable at the end of such a multiple-capsule element nearly equals the displacement of one capsule multiplied by the number of capsules in the assembly. The *bellows* sensing element is typically made from a thin-walled tube formed into deep convolutions and sealed at one end, whose displacement can then be made to act on a transduction element. In the *straight-tube* sensing element, again sealed at one end, applied pressure causes an expansion of the tube diameter. This expansion, though slight, can be converted into a usable output by a transduction element.

FIGURE 8.2.15 Pressure-sensing elements: (a) flat diaphragm; (b) corrugated diaphragm; (c) capsule; (d) bellows; (e) straight tube; (f) C-shaped Bourdon tube; (g) twisted Bourdon tube; (h) helical Bourdon tube; (i) spiral Bourdon tube. (From Ref. 1 by permission)

The *Bourdon tube* is one of the most widely used sensing elements, particularly for pressure ranges higher than 2 MPa (about 300 lb/in.²). The Bourdon tube, elliptical in cross section and sealed at its tip, tends to straighten from its curved, twisted, helical, or spiral shape, thus causing the tip to deflect sufficiently to act on a transduction element. The number of turns or twists in a Bourdon tube tends to multiply the tip travel.

Pressure Transducers. Pressure transducers, using the sensing elements described above, provide their outputs by means of a large variety of transduction elements (see Table 8.2.1). Many designs are available with integrally packaged output- and excitation-conditioning circuitry. Certain designs, notably potentiometric, relative, and strain-gage transducers, are more prevalent than other types. Piezoelectric transducers are usable only for dynamic pressure measurements. Inductive transducers can be subject to severe temperature effects and are not used extensively.

A *potentiometric pressure transducer* features a dual-capsule sensing element that transfers its displacement to a lever-type wiper arm by means of a pushrod. The wiper then slides over the curved resistance

element. Capsule elements are commonly used in such transducers for pressure ranges up to 2.5 MPa (about 360 lb/in.²).

Reluctive pressure transducers use either the inductance bridge circuit or, primarily when only the normal ac output is required, the differential-transformer circuit. When inductance bridge transducers use a diaphragm sensing element, the magnetic diaphragm itself, positioned between two coils, acts as the armature which increases the inductance of one coil while decreasing the inductance of the other coil. When inductance bridge transducers use a Bourdon tube sensing element, a flat armature plate, positioned over two coils, tilts more toward one coil than toward the other as the Bourdon tube tip rotates slightly with applied pressure. In differential-transformer transducers the sensing-element displacement is used to move a magnetic core within the transformer.

Most *strain-gage pressure transducers* use a diaphragm sensing element, although at least one good design uses a straight tube. Most designs have a four-active-arm strain-gage bridge, with the gages either on the diaphragm or on a beam actuated by the diaphragm. Included in this category are solid-state pressure transducers, micromachined from a silicon base, with integrally diffused gages.

When the sensing-element displacement is not sufficient for a given transduction element, a mechanical amplification linkage can be inserted between the two elements. Special design considerations apply to differential-pressure transducers when the measured fluid (at one of the two pressure ports) must not come in contact with the transduction element. One solution to this problem has been to fill the affected inside portion of the transducer with a *transfer fluid*, sealed off by a thin *membrane* to which the measured fluid can be applied safely. Gage-pressure transducers have the inside of their case (which usually acts as the *reference cavity*) vented to the outside through a small hole (*gage vent*), equipped with a fine-mesh screen, a porous plug, or another filter to prevent internal contamination.

Flush-diaphragm transducers are designed for high-frequency-response applications where use of tubing, or even the cavity formed by a mounting boss, may reduce response; these transducers are so designed that the diaphragm is flush (when installed) with the inside surface of the pipe wall (or other wall) through which they are mechanically fastened.

Specification characteristics of pressure transducers deserve particular attention since pressure is one of the two most common measurands (the other is temperature). Table 8.2.2 lists those characteristics which should be considered when preparing a specification for a pressure transducer. Not all these characteristics need always be specified; some can be omitted when sufficient knowledge of the application permits.

Vacuum Transducers. Vacuum transducers are an important subgroup of pressure transducers, though bearing little resemblance to them with regard to design and operation. The pressure constituting a practical dividing line between pressure and vacuum measurement is not well defined. Some pressure transducers are usable for very low pressure measurement. Generally, however, pressure measurements extending substantially below 133 Pa (= 1 torr) can be considered as vacuum measurements.

Vacuum transducers (see Table 8.2.3) exist in two major categories, given by their transduction principles.

FIGURE 8.2.16 Thermolectric thermoconductive vacuum transducer; (a) transducer; (b) typical circuit. (From Ref. 1 by permission)

Thermoconductive vacuum transducers measure pressure as a function of heat transfer by the measured gas. As the number of gas molecules within the transducer decreases, the quantity of heat transferred from a heated filament, through the gas, and to the case of the transducer, will decrease proportionally. The *Pirani gage*, as well as the *thermocouple gage* (which may use a thermopile instead of a single junction), both use this principle. A basic thermocouple gage is illustrated in Fig. 8.2.16.

Ionizing vacuum transducers measure pressure as a function of gas density by measuring ion current. Since different gases have different densities, the calibration of such a transducer will usually differ as well. The gas is usually ionized by electrons, except in one type using alpha particles for this purpose.

In thermionic vacuum transducers the electrons are emitted by a filamentary cathode, and positive ions are collected at the anode. Various modifications of the original triode type have helped to extend its lower range limit

from 10^{-8} to 10^{-10} torr (*Bayard-Alpert gage*, by reducing internal x-ray effects) to 10^{-11} torr (*Nottingham gage*, by reducing electrostatic-charge effects) and to 10^{-12} torr (*Schuemann modification*, by virtually eliminating x-ray effects). The ion current, representative of pressure, is in the microampere region.

Several ionizing vacuum transducer types, whose electrons are emitted from either hot or ion-bombarded cold cathodes, use a magnetic field to increase the electron path length by forcing this path to be helical so that the probability of electron collisions with gas molecules is increased (*magnetron gages*). The hot-cathode versions include the *Lafferty gage*. The *Philips* (or *Penning*) *gage* and the *Redhead gage* are examples of the cold-cathode versions.

TABLE 8.2.2 Specification Characteristics for Pressure Transducers

Mechanical design characteristics	
Specified by user and manufacturer	Stated by manufacturer
Configuration and dimensions (shown on drawing)	Sensing element
Mountings (shown on drawing)	Transduction-element details
Type and location of pressure ports (shown on drawing)	Materials in contact with measured fluids
Type and location of electrical connections (shown on drawing)	Dead volume
Nature of pressure to be measured, including range	Type of damping (including type of damping oil if used)
Measured fluids	
Case sealing (explosion proof, burstproof, or waterproof enclosure)	
Isolation of transduction element	
Mounting and coupling torque	
Weight	
Identification	
Nameplate location (shown on drawing)	
Electrical design characteristics	
Excitation (nominal and limits)	
Power rating (optional)	
Input impedance (or element resistance)	
Output impedance	
Insulation resistance (or breakdown-voltage rating)	
Wiper noise (in potentiometric transducers)	
Output noise (in dc output transducers)	
Electrical connections and wiring diagram

	Nuclear radiation
	High-intensity magnetic fields etc.

*Applies to differential-pressure transducers only.

Selection criteria for vacuum transducers (and any necessary ancillary equipment for them) are primarily the required measuring range; secondarily, size, weight, ruggedness, and complexity. Considerations for the selection of a pressure transducer are primarily range, type of excitation and output, accuracy and frequency response; secondarily, the properties of the measured fluid and environmental conditions.

Ranges of Pressure Transducers. Some of the pressure transducers described in this section are available for ranges up to 100 MPa (about 15,000 lb/in.²). Special sensing devices have been designed for pressures up to 7 GPa (about 1 million lb/in.²). Pressure transducers are also used to measure altitude (a known nonlinear relationship exists between atmospheric pressure and altitude above sea level), water depth (pressure increases at the rate of approximately 1 KPa/m (0.44 lb/in.² ft) when descending below the water surface), and air speed (by measuring the difference between impact pressure, obtained from a pitot tube, and static pressure, while in flight).

TABLE 8.2.3 Vacuum Transducers

Sensing element	Common name	Output	Nominal range, torr
Thermoconductive transduction			
Heated filament	Pirani gage	Resistance change	10 ⁻³ -1
	Thermocouple gage	Thermoelectric emf	10 ⁻³ -1
Ionizing transduction			
Thermionic, triode	Bayard-Albert gage	Direct current	10 ⁻¹⁰ -10 ⁻³
Photomultiplier		Direct current	10 ⁻¹⁵ -10 ⁻³
Hot cathode, magnetic field	Hot-cathode magnetron gage (Laffety gage)	Direct current	10 ⁻¹⁴ -10 ⁻⁵
Cold cathode, magnetic field	Cold-cathode magnetron gage (Philips gage, Penning gage)	Direct current	10 ⁻⁷ -10 ⁻³
With flash filament		Direct current	10 ⁻¹² -10 ⁻³
With auxiliary cathode	Redhead gage	Direct current	10 ⁻¹³ -10 ⁻⁴
Radioactive, alpha particles	Alphatron	DC voltage (from amplifier)	10 ⁻⁵ -1000
Beta particles		DC voltage (from amplifier)	10 ⁻⁸ -1000

CHAPTER 8.3

TRANSDUCERS FOR THERMAL QUANTITIES

Harry N. Norton

INTRODUCTION

The *temperature* of a body or substance is (a) its potential of heat flow, (b) a measure of the mean kinetic energy of its molecules, and (c) its thermal state considered with reference to its power of communicating heat to other bodies or substances. *Heat* is energy in transfer, resulting from a difference in temperature between a system and its surroundings or between two systems, substances, or bodies. Heat energy is transferred by one or more of the following methods of *heat transfer*: (a) *conduction*, by diffusion through solid material or stagnant liquids or gases; (b) *convection*, by the movement of a liquid or gas between two points; and (c) *radiation*, by electromagnetic waves.

The sensing elements of temperature transducers typically act as transduction elements as well. The two most commonly used sensing-transduction elements are the *thermoelectric* element (*thermocouple*) and the *resistive* element (*resistance thermometer*). Among other sensing-transduction elements the only one that has found commercial acceptance is the *oscillating-crystal* element, essentially a quartz crystal (connected into an oscillator circuit) which has a substantial and highly linear temperature coefficient of frequency.

Thermocouples

A thermocouple is an electric circuit consisting of a pair of wires of different metals joined together at one end (*sensing junction*) and terminated at their other end in such a manner that the terminals (*reference junction*) are both at the same and known temperature (*reference temperature*). Connecting leads from the reference junction to some sort of load resistance (an indicating meter or the input impedance of other readout or signal-conditioning equipment) complete the thermocouple circuit. Both these connecting leads can be of copper or some other metals different from the metals joined at the sensing junction. Because of the *thermo-electric effect* (*Seebeck effect*), a current is caused to flow through the circuit whenever the sensing junction and the reference junction are at different temperatures. In practice, the reference junction is either held at a known constant temperature (e.g., at 0°C) or is electrically compensated for variations from a preselected temperature.

The electromotive force (*thermoelectric emf*), which causes current flow through the circuit, is dependent in its magnitude on the sensing-junction wire materials, as well as on the temperature difference between the two junctions. Commonly used wire materials are Chromel (CR) and Alumel (AL) (both registered trade names of Hoskins Mfg. Co., Detroit, Michigan), Constantan (CN, an alloy of 53 percent copper and 45 percent nickel), copper (Cu), iron (Fe), platinum (Pt), an alloy of platinum and (either 10 or 13 percent) rhodium (Rh), tungsten (W), tungsten-rhenium (Re) alloys (5 or 26 percent rhenium content is typical), nickel (Ni), and ferrous nickel alloys.

FIGURE 8.3.1 Thermocouple output vs. temperature characteristics (reference junction at 0°C).

The characteristics of certain combinations of wire materials, such as their thermoelectric emf versus temperature characteristics, their accuracy tolerances, and wire-insulation color codes, were standardized by ANSI Standard C96.1 (which is based on ISA Recommended Practice RP1) in such a manner that materials of different brand names can be used as long as the characteristics assigned to a specific type of thermocouple are maintained.

The names of the wire materials constituting, in their combination, a thermocouple sensing junction are now listed only as typical examples. Thus typical materials of a *type K* thermocouple are Chromel and Alumel. The ANSI Standard favors the use of type-letter designations in lieu of the names of the two metals used. Figure 8.3.1 shows the thermoelectric emf obtainable from various types of thermocouples when the reference temperature is held at 0°C.

Thermopiles (see Fig. 8.3.2) consists of several sensing junctions of the same material pairs, in close proximity to each other and connected in series so as to multiply the output obtainable from a single sensing junction.

FIGURE 8.3.2 Thermopile schematic diagram: CR-CN combination shown as example.

The isothermal reference junctions are usually also in close proximity to each other to assure an equal temperature for each reference junction.

Resistive Temperature-Sensing Elements

Resistive temperature-sensing elements are either conductive or semiconductive. Conductive elements are usually wire-wound, sometimes made of metal foil or film. Elements wound of high-purity annealed platinum wire are best suited for most applications. Other metal-wire elements are wound of nickel or nickel alloy. Copper-wire elements are rarely used any more. Tungsten-wire elements have shown some promising characteristics but are generally considered too difficult to manufacture and too brittle to stay reliable.

A platinum-wire element has been used to define the International Practical Temperature Scale from -183 to $+630^{\circ}\text{C}$, and it is expected that this upper limit will be extended to the melting point of gold ($+1063^{\circ}\text{C}$). The resistance versus temperature curve of such an element follows a well-defined theoretical relationship, making most points on the curve calculable within very close tolerances when only a few measured points have been established. Repeatabilities within about 0.01 K have been obtained at temperatures up to the freezing point of gold (1337.58 K). Semiconductive resistive temperature-sensing elements include thermistors, germanium and silicon crystals, carbon resistors, and gallium arsenide diodes. Thermistors have a nonlinear and negative temperature coefficient of resistance and an empirical resistance versus temperature relationship.

Temperature Transducers

Temperature transducers are classified into two general categories: surface-temperature transducers, which are cemented, welded, bolted, or clamped to a surface whose temperature is to be measured, and immersion probes, which are immersed into stagnant or moving fluids to measure their temperature. The fluid can be in a pipe, a duct, a tank, or other enclosed vessel, where the immersion probe is mounted through a pressure-sealed opening. It can also be freely moving, even at almost imperceptible rates of motion, e.g., an open body of water, an outdoor or indoor atmosphere.

Thermoelectric temperature transducers have the same sort of sensing junction, whether they are intended for surface temperature measurement or as immersion probes. The junctions between the two dissimilar-metal wire pairs are made by butt-welding the wire ends, by crossing them and welding them, by coiling one wire end around the other, or twisting the two ends about each other, then welding, brazing, or soldering the junction, or by welding both wire ends, in very close proximity to each other, to a metallic surface or to the metallic inside of an immersion-probe tip.

For surface measurements, the junctions are soldered, brazed, or welded to a surface (if it is metallic) or cemented to it (if it is not). If it is cemented, care must be taken to have the junction in solid thermal contact with the measured surface. Taping a junction to a surface is poor practice, since even a very small gap between junction and surface can introduce considerable errors. For immersion measurements, thermocouples are often produced with an integral sheath or inserted into a sealed immersion sheath (*thermowell*).

Junctions for thermoelectric immersion probes can be grounded (metallic contact from junction to sheath or thermowell) or isolated (ungrounded). In some cases, exposed junctions, at the tip of a probe, are immersed

in the fluid without use of an integral sheath or thermowell. If terminals or connectors must be used between the sensing junction and the reference junctions, the terminals as well as the *extension wires* must be made of the same types of metals as used for the junction.

Thermocouples are usually made from two-conductor insulated cable, rarely from reels of individual bare-wire materials. The cables have a variety of insulation, over each conductor as well as over the conductor pair, and can be shielded or unshielded. Useful for many applications is thin (2 to 10 mm outside diameter) metal-sheathed, ceramic-insulated thermocouple cable.

Differential thermocouples can be used when the measurement objective is to measure the temperature difference between two points. In this case the sensing junction at the other measured point replaces the reference junction. The first wire of the first junction and the second wire of the second junction must still be brought to isothermal terminals; however, it is not necessary that the temperature of these terminals be known.

Resistive Temperature Transducers

Electrically conductive surface-temperature transducers are usually small and flat enough not to be influenced by convective heat transfer but only by conductive transfer from the measured surface. After installation they may be coated or covered to minimize any radiative heat transfer to them. The sensing element is usually a metal wire either wound around a thin insulating “card” or a coiled wire cemented to the base (see Fig. 8.3.3). Some metal-foil transducers (encapsulated or *free-grid*) are in the shape of a zigzag pattern. All designs are aimed at exposing the maximum sensing surface to the conductive heat transfer in an area of minimum size.

Resistive metal-wire *immersion probes*, most commonly with a platinum-wire element but some-times with elements of nickel or nickel-alloy wire, are widely used for industrial and scientific fluid-temperature measurements. The probe-type transducer, illustrated in Fig. 8.3.4, has a ceramic encapsulated (coated) element in a perforated protective sheath so that it is usable for a variety of measured fluids over a wide temperature range. For applications in relatively stagnant fluids an unencapsulated (*exposed*) element is used to provide a shorter time constant. Some fluids require an element completely *enclosed* within a metallic well but with good thermal contact between well and element. The threaded mounting allows for compression sealing by means of a gasket or O ring between the housing and the mounting boss.

FIGURE 8.3.3 Platinum-wire resistive surface-temperature transducer. (Rosemount Inc.)

FIGURE 8.3.4 Platinum-wire resistive immersible-probe temperature transducer. (Rosemount Inc.)

Thermistors

Thermistors are used for surface-temperature as well as fluid measurements. Because of their nonlinear (essentially negative exponential) resistance versus temperature characteristics, they are particularly useful when a large resistance change is needed for a narrow range of temperature. Where a short time constant is required, a glass-coated thermistor bead, as small as 0.3 mm in diameter, can be suspended on its 0.03-mm-diameter precious-metal-alloy leads. Where somewhat more ruggedness is required, a glass-encapsulated bead about 1.5 mm around the tip and 4 mm long can be used. Excitation power must be kept low to avoid errors due to self-heating. Thermistor-type temperature transducers are available in a large variety of configurations.

Semiconductor Thermometers

Germanium thermometers are made of germanium crystals with highly selected and controlled impurities (dopants). They are intended primarily for cryogenic temperature measurements (below -195°C). Carbon resistors have also been used for such applications, as have gallium-arsenide junction diodes, which can be used to somewhat higher temperatures. Silicon-wafer transducers have been used for surface-temperature measurements in the range -50 to 275°C , where their resistance versus temperature characteristics are similar to those of some metal wires.

Quartz-Crystal Temperature Transducers

Quartz-crystal temperature transducers use oscillating-crystal sensing elements in such a manner that the change of oscillator frequency with temperature is nearly linear over a range from about -50 to 250°C . They are usually furnished with associated electronics and readout equipment. This tends to limit their usability for general telemetry application without, however, detracting from their advantages in laboratory applications.

The selection of a temperature transducer is more complex than the selection of most other types of transducers. The objective is to select a design whose sensing element will attain the temperature of the measured material within the time available to make the measurement. Among primary selection criteria are, then, the characteristics and properties of the measured solid or fluid, the measuring-range limits, the required response time (time constant), and the type of excitation and signal conditioning available or intended to be used.

Radiation Pyrometers

Radiation pyrometers are noncontacting temperature transducers which respond to radiative heat transfer from the measured surface or material. This radiation occurs primarily in the infrared portion of the electromagnetic spectrum (wavelengths between 0.75 and $1000\ \mu\text{m}$). Typical radiation pyrometers use an optical lens or mirror system (sensitive in the infrared region) which focuses the radiation on a thermoelectric or resistive (usually photoconductive) sensing element. The output of the sensing element can be correlated, by calibration, to the temperature of the measured surface. Radiation pyrometers are used primarily for high-temperature measurements (up to about 3500°C), but have also been found useful for noncontacting measurements in the medium temperature range (down to about -50°C). Some designs now use optical fibers in place of purely radiative coupling between source and instrument.

Heat-Flux Transducers

Two basic types of transducers have been developed to measure *heat flux*, heat transfer in terms of the total amount of thermal energy (heat flux is commonly expressed in W/cm^2 or $\text{Btu}/\text{ft}^2\cdot\text{s}$). The *calorimeter* provides an output proportional to convective as well as radiant thermal energy (*total heat flux*). The *radiometer* responds to radiant thermal energy (*radiant heat flux*) only. Virtually all heat-flux transducers have thermoelectric sensing elements.

FIGURE 8.3.5 Calorimeters: (a) foil; (b) slug.

Calorimeters

The *foil calorimeter* (*membrane calorimeter*, Gardon gage) acts as a copper-Constantan differential thermocouple. When heat flux is received by the thin Constantan sensing disk (Fig. 8.3.5a), which is metallurgically bonded around its rim to a copper heat sink, the heat absorbed by the membrane is transferred radially to the heat sink. This causes a temperature difference between the center of the disk and its rim. A thin copper wire is attached to the bottom surface of the disk, at its exact center, thus forming one copper-to-Constantan sensing junction. The copper-to-Constantan contact around the rim of the disk forms the other junction. The output of the calorimeter is then proportional to the energy absorbed. When heat flux must be measured over long periods of time, the foil calorimeter can be provided with tubing and an internal flow path so that it can be water-cooled.

The *slug calorimeter* (*slope calorimeter*) uses a relatively thick thermal-mass sensing disk with an external high-emissivity (black) coating, which is thermally insulated from the transducer housing (Fig. 8.3.5b). A thin-wire thermocouple is attached to the bottom of the disk (slug), at its center. When heat flux is received by the slug, an output signal is produced by the thermocouple. The signal is proportional to the temperature rise of the slug.

Radiometers

A typical *radiometer* is essentially a foil calorimeter with a *window* (usually of quartz or synthetic sapphire) mounted over the sensing disk so that a disk can receive radiant heat flux but no convective heat flux. The cavity formed by window, transducer housing, and sensing disk is usually sealed, but provisions for gas purging of this cavity can be made to prevent window clouding when the radiometer is to be used in a contaminating atmosphere. Radiometers can also be water-cooled. The sensitivity of a radiometer can be increased by using a differential (multijunction) thermopile instead of the two-junction differential thermocouple.

CHAPTER 8.4

TRANSDUCERS FOR ACOUSTIC, OPTICAL, AND ELECTRICAL QUANTITIES

Harry N. Norton

TRANSDUCERS FOR ACOUSTIC QUANTITIES

Terminology

Sound is an oscillation in pressure, stress, particle displacement, or other physical characteristics, in an elastic or viscous medium. *Sound sensation* is the auditory sensation evoked by the oscillations associated with sound. *Sound pressure* is the total instantaneous pressure at a given point, in the presence of a sound wave, minus the static pressure at that point. *Sound pressure level* (SPL or L_p) is 20 times the logarithmic ratio of the mean-square sound pressure p to a mean-square reference pressure p_{ref} . It is normally expressed in decibels as $\text{SPL} = 20 \log (p_{\text{rms}}/p_{\text{ref,rms}})$. The reference pressure is usually specified as $2 \times 10^{-4} \mu\text{bar}$, sometimes as $1 \mu\text{bar}$ (0.1 Pa). *Sound level* is a weighted sound-pressure-level reading obtained with a meter complying with a standard, e.g., ANSI Standard S1.4, Specification for General-Purpose Sound Level Meters.

Sound-Pressure Transducers

The sensing element of a sound-pressure transducer is almost invariably a diaphragm. The reference cavity behind the diaphragm is vented to the ambient atmosphere by means of a small hole in the transducer case so that static pressures on both sides of the diaphragm are equalized and only sound pressure is sensed.

A perforated cap over the diaphragm protects the diaphragm mechanically and, by its shape and geometry of perforations, provides some control over the transducer's directivity characteristics.

Sound-pressure transducers can be described, essentially, as special-purpose gage-pressure transducers. *Capacitive sound-pressure transducers* (usually called *condenser microphones*) use the sensing diaphragm as one electrode of a capacitor and a rigidly supported back plate, insulated from the rest of the structure but provided with a connecting lead or terminal, as the other electrode. A dc polarization voltage, applied across the two electrodes through a high-series resistance, maintains a constant charge on them. Capacitance changes due to diaphragm deflection cause changes in the voltage across the electrodes. The transducer output is first fed to an emitter follower so as to reduce the output impedance to a workable value. The output is the amplified. The emitter-follower (or cathode-follower) circuitry is sometimes built into the transducer case to keep the coupling path short. A shielded cable connects the transducer to the amplifier.

8.42 TRANSDUCERS AND SENSORS

Piezoelectric and, to a limited extent, *inductive pressure transducers* have also been designed as sound-pressure transducers. Some piezoelectric designs have sealed cases, primarily to protect the internal components from atmospheric moisture and contaminants. The absence of a gage vent, however, necessitates correction of output readings when the transducer is used at low ambient pressures (e.g., high altitudes). Piezoelectric transducers do not require an excitation power supply but do require an amplifier.

The primary performance characteristics of sound-pressure transducers are range, output, frequency response, and directivity (directional response). Output is usually expressed as sensitivity or sensitivity level, sometimes as full-scale output for a stated range of sound pressures or sound-pressure levels.

Sound-Level Meters

Sound-level meters are complete, self-contained measuring systems, typically battery-operated and portable. A sound-level meter consists of a sound-pressure transducer (microphone), amplifier, standardized weighting networks, a calibrated attenuator, and an indicating meter. The sound-level range is always referred to a sound pressure of 10^{-4} μbar . The weightings denote different frequency-response characteristics of the measuring system. Referred to merely as A, B, or C, they are defined in a national standard as, for the United States, ANSI Standard S1.4.

Underwater Sound Detectors

Underwater sound detectors are used either for listening (*hydrophone*) or, in conjunction with an *underwater sound projector*, in sonar (*sound navigation and ranging*) systems. The transmitting and receiving function in a sonar system are frequently combined in a single device (sound transceiver). In the sonar field, underwater sound detectors, as well as projectors and transceivers, are commonly referred to as *transducers*.

TRANSDUCERS FOR OPTICAL QUANTITIES

Terminology

Light is a form of radiant energy, an electromagnetic radiation whose wavelength is between approximately 100 and 0.01 μm . By strict definition, only visible light (0.4 to 0.76 μm wavelength) can be considered as light, and infrared or ultraviolet light is then termed *radiation*. The light spectrum, in terms of wavelengths, frequency, photon energy, and blackbody temperature (all interrelated by physical laws), is illustrated in Fig. 8.4.1 with the visible-light spectrum (color spectrum) brought out in detail.

The transduction elements of light sensors (photocells, photosensors, *photodetectors*, light detectors) also act as sensing elements since they convert electromagnetic radiation into a usable electrical output. Four transduction principles are commonly used: photovoltaic, photoconductive, photoconductive junction, and photoemissive (see Fig. 8.4.2).

Photovoltaic Light Sensors

Photovoltaic light sensors are self-generating in that their output voltage is a function of the illumination of a junction between two dissimilar materials. These materials are semiconductive, either nonmetallic or metal compounds (Fig. 8.4.2a). Photons (particles of light) first pass through a thin conductive layer, and then impinge on the junction, causing an electron flow across the junction area so that the conductive layer becomes the negative terminal of the sensor. Various materials constitute the conductive and semiconductive portions of a photovoltaic light sensor.

The *silicon cell* (silicon photovoltaic cell, silicon solar cell) uses an arsenic-doped *n*-type silicon wafer. Boron is diffused into the upper (light-receiving) surface to create a thin *p*-type silicon layer. The *pn* junction between the layer and the wafer acts as a permanent electric field. Photons incident upon the junction cause a

FIGURE 8.4.1 The light spectrum. (From Ref. 1 by permission)

flow of positive and negative charges. The *pn* junction, acting as an electric field, directs the positive charges into the *p*-type material (nickel plating around its edge forms the positive connecting terminal) while directing the negative charges into the *n*-type material (solder around the bottom edge of the silicon wafer forms the negative connecting terminal). The third connecting pin serves as a case connection.

Germanium photovoltaic light sensors are similar to silicon types but have a different spectral response (a peak near 1.55 μm , as compared with 0.8 to 0.9 μm for silicon). Special “blue-enhanced” silicon cells have spectral responses with their peak as low as 0.56 μm (the nominal peak of the human eye’s response). *Indium-arsenide* (InAs) and *indium-antimonide* (InSb) photovoltaic sensors have spectral-response peaks near 3.5 and 6.8 μm , respectively, at room temperature. They are single-crystal *pn* junction semiconductors, used primarily for infrared-light sensing. In such applications they are often cooled artificially to increase their sensitivity.

Photoconductive Light Sensors

Photoconductive light sensors are widely used for control functions, such as automatic exposure control in cameras, in addition to their photometric (light-measurement) applications. The photoconductors are polycrystalline films or bulk single-crystal materials which, when contained between two conductive electrodes, act as light-sensitive resistors (Fig. 8.4.2b) whose resistance decreases as incident illumination increases. *Cadmium sulfide* (CdS) and *cadmium selenide* (CdSe) are popular because of their spectral-response peaks in the visible-light region (approximately 0.6 μm for CdS, 0.72 μm for CdSe) and because of their relatively high output without artificial cooling. Some photoconductive sensors use mixed CdS–CdSe crystals to obtain a response peak around 0.66 μm .

Lead sulfide (PbS) and *lead selenide* (PbSe) photoconductive cells are used for infrared-light sensing because their spectral-response peaks are close to 2.2 μm . The spectral-response curve of PbSe, however, is shallow enough to provide good sensitivity between about 1.8 and 3.6 μm , and its time constant is less than

FIGURE 8.4.2 Basic methods of light transduction: (a) photovoltaic; (b) photoconductive; (c) photoconductive junction semiconductor; (d) photoemissive. (From Ref. 1 by permission)

one-tenth that of PbS. *Mercury-doped-germanium* (HgGe) photoconductive sensors have been used for far-infrared measurements while being cooled to cryogenic temperatures. *Lead-tin-telluride* (PbSnTe) sensors are always cooled to 77 K and have a spectral response in the 8- to 12- μm region. *Mercury-cadmium-telluride* sensors operate at 77 to 120 K and have a spectral response within the overall region of 2 to 14 μm adjustable by varying the proportions of the three materials.

Photoconductive Junction Sensors

In these devices the resistance across the junction in a semiconductor device changes as a function of incident light (Fig. 8.4.2c). Increasing incident illumination causes the junction photocurrent to increase. This category of photosensors includes *photodiodes* and *npn* as well as *pnp phototransistors*. They are made of silicon, with a spectral peak near 1.0 μm , except when germanium must be used to raise the spectral peak to about 1.6 μm . Time constants of photodiodes and phototransistors are less than 1 μs (compared with 10 μs for PbSe photoconductive sensors; 100 to 700 μs for PbS photoconductive sensors; 10 ms for CdSe photoconductive cells; and 100 ms for CdS cells but around 20 μs for silicon photovoltaic cells). Transistors also provide some amplification of the light-induced signal. Both types are usually sealed into a standard transistor can, sometimes furnished with a lens or window. A special silicon photodiode design has also been developed for ultraviolet measurements (0.06- to 0.25- μ region).

Photoemissive Sensors

The earliest *photoemissive light sensor* was the phototube, in which electrons are emitted by the cathode of a vacuum (or gas-filled) diode tube when photons impinge on the cathode surface (Fig. 8.4.2d). When a closely

spaced anode is at a positive potential with respect to the cathode, the anode collects some of these electrons, and the resulting anode current can produce an output voltage as an IR drop across a suitable load resistor (R_L).

The photoemissive principle is now employed mostly by *photomultiplier* tubes, in which additional electrodes (*dynodes*) are placed between cathode (*photocathode*) and anode to amplify the electron current by means of secondary emission. An additional dynode is located behind the anode. A voltage divider network is used to apply a successively higher voltage to each of the dynodes as they approach the anode in proximity. Various spectral-response peaks can be obtained, depending on the photocathode material and material of that portion of the sealed envelope directly in front of the cathode (the *window*). Photomultiplier tubes are particularly useful in the visible-light and ultraviolet regions. They can provide very high sensitivities without artificial cooling.

Selection criteria for light sensors are, primarily, spectral-response characteristics and sensitivity and, secondarily, operating temperatures, relative complexity of associated circuitry, ruggedness, and cost. Where the spectral-response must be limited to only a portion of a sensor's basic response capabilities, a window can be placed in front of the sensing surface. Windows are optical filters which have spectral-response characteristics of their own, depending on their material. Typical window spectral responses are 0.2 to 1.4 μm (quartz crystal or fused silica), 0.4 to 1.2 μm (borosilicate glass), 0.15 to 1.6 μm (cultured sapphire), 0.11 to 1.8 μm (lithium fluoride), 0.12 to 11 μm (calcium fluoride), and 0.25 to 50 μm (cesium iodide).

Spectrometers and Colorimeters

Light sensors in conjunction with light sources are used in a number of measuring devices other than for photometry. In optical *spectrometers* the incident light is passed through a *monochromator*, which can be a filter or set of filters, or a grating or prism whose angular displacement relative to the incoming light beam can be closely correlated with the single wavelength (or narrow band of wavelengths) it sends on to the light sensor. The latter, in turn, is selected so that its spectral responses match the wavelength (or wavelengths) of interest. The angular motion of the prism or grating can be mechanized so that a given spectrum is scanned at a known rate over a known time interval. The wavelength of an observed peak can then be determined from the time counted from the start of a scan. Spectrometers can be called *spectrophotometers* when their spectral range extends anywhere between ultraviolet to infrared. They are really a subclass of *spectroradiometers* whose spectra can include any electromagnetic radiation from gamma rays to microwaves. Spectroradiometers are widely used to determine chemical composition from the spectral distribution of electromagnetic energy.

Spectrophotometers exist in the following three basic categories: (1) In an *absorption spectrophotometer* the collimated beam from an artificial light source passes through a monochromator, then through the sample whose composition is to be determined, and finally to the light sensor (photodetector). (2) In an *emission spectrophotometer* the polychromatic light from a hot or heated sample (or body) is collimated and passed through the monochromator to the photodetector. (3) In a *fluorescence spectrophotometer* monochromatic wavelengths are selected from the polychromatic emissions of a light source (or other source of electromagnetic radiation) by the *excitation monochromator*. The collimated monochromatic beam is directed at the sample in which fluorescence will occur. The fluorescent light is then analyzed for spectral content by a second monochromator (*emission monochromator*) in conjunction with the photodetector. Spectroradiometers, including those operating in nonoptical wavelengths, are described in more detail in Ref. 2.

The *colorimeter* is a specialized type of spectrophotometer whose light-source-filter-photodetector combination simulates the tristimulus functions of human visual color perception (*tristimulus colorimeter*). Three filters and either one or three photodetectors are used to obtain three separate outputs which represent (in their simplest form) the amount of "red," "green," and "blue" reflected from a sample.

Interaction of Light with Substances

A light-source-photodetector combination is also used for material characterization in instruments other than colorimeters and spectrophotometers. The most common application of such instruments is in the detection of particulates in gases and liquids. The *turbidimeter*, *opacity sensor*, and *transmittance sensor* all employ the same operating principle: The collimated beam from a light source passes through the sample onto a

8.46 TRANSDUCERS AND SENSORS

photodetector. The latter sees maximum light intensity when the sample is perfectly clear. When the (gaseous or liquid) sample contains solid particles, the amount of light received by the photodetector is attenuated. The attenuation is due primarily to *absorption* or *scattering* or a combination of both. In a *nephelometer* the photodetector is mounted normal to the axis of the light beam entering the sample. Thus, the photodetector responds to light scattered from the sample at 90° , and its output increases with increasing turbidity in the sample. The detection threshold can be improved by adding a second photodetector at 180° to the first one. The transmitted light is either absorbed by a hood or sensed by an additional photodetector for reference purposes. The *fluorimeter* employs a source of ultraviolet light to cause *fluorescence* in a sample; i.e., the light is first absorbed and then is reemitted after a very short time (about 10^{-8} s). When the time of reemission is much longer, the phenomenon is known as *phosphorescence*. The incoming light is first passed through a filter for wavelength selection. The reemitted light is sensed (after filtering to exclude nonfluorescent products) by a photodetector mounted normal to the axis of the incident light beam. A *refractometer* measures the *index of refraction* of a sample, usually by having its photodetector sense the light reflected from the boundary between two media of different density (and, hence, a different index of refraction). As more light is lost because of refraction in the second medium, less light is reflected back to the photodetector. Its output is then typically compared with that of a reference photodetector that receives all the light from the light source. For more details on these, as well as other analysis instruments, see Ref. 2.

TRANSDUCERS FOR ELECTRICAL QUANTITIES

Current Sensors

Current measurements can be made by various devices acting as transducers. A *series resistance*, inserted into the conductor where current is to be measured, provides a usable voltage across it because of the IR drop caused by the resistance. When the series resistance is relatively low, it is referred to as a *shunt*.

If it is necessary to keep the measurement circuit electrically isolated from the measured circuit (which is always desirable), a differential amplifier can be used, with its input terminals closely coupled across the series resistance so that its output terminals can be isolated from the measured circuit, and so that a signal sufficient for telemetry can be provided without inserting too high a series resistance into the measured circuit. This method is usable for both ac and dc currents. Other isolating current transducers are the *saturable reactor*, an adjustable inductor in which the input-current versus output-voltage relationship is adjusted by controlled magnetomotive forces applied to the core, and the *Hall effect* current transducer, in which an output-voltage change is produced by measured-current-originated electromagnetic effects on a semiconductor placed in a magnetic field. The *current transformer* can be used to convert the measured current, with circuit isolation, into an output current or voltage.

Electrometers

Small currents (down to 10^{-15} A) can be measured by means of an *electrometer tube* or by special semiconductor devices such as an amplifier with varactor diodes, metal-oxide semiconductor field-effect transistors (MOSFET), or junction field-effect transistors. All these devices require output amplification to provide signals suitable for remote measurement. When current must be measured on the high-voltage secondary side of a transformer, the current in the low-voltage primary can often be measured instead, and a suitable calibration used to correlate the two currents.

Voltage Sensors

DC and ac voltages can be monitored by means of a voltage divider connected across the two terminals to be measured. A voltage divider consists of two resistors in series, with the output taken across only one of the two resistors when a signal lower than the actual voltage is required by the measurement system. AC voltages are most frequently sensed by a *voltage transformer* or by Hall effect devices.

Frequency Converters and Dividers

Frequency can be converted into a voltage signal by use of a tuned discriminator or of integrating circuitry. When a digital signal is required, the measured frequency can be passed through an electronic “gate” which is “opened” for a fixed period of time. The pulse count over the gated period is then indicative of the frequency. If the measuring system can accept a frequency, but one much lower than the measured frequency, a *frequency divider* circuit can be used to provide an output frequency which is a fixed fraction of the input frequency.

Power Sensors

Power measurements have often been derived from simultaneous but separate voltage and current measurements. *Hall multipliers* are now in common use for power measurements. In these devices voltage changes are transformed into excitation current changes; simultaneously, current changes are used to change the magnetic field applied to the Hall device. Power (especially at microwave frequencies) is also measured by using a portion of the power to raise the temperature of a resistive temperature transducer (e.g., a thermistor), then measuring the temperature change, which can be correlated to measured power by a suitable calibration. Such a sensor is often referred to as a *bolometer*.

CHAPTER 8.5

MICROSENSORS AND MICROACTUATORS

Wen H. Ko, C. C. Liu, M. Mehregany

INTRODUCTION

The term *microelectromechanical systems* (MEMS) was coined around 1987. Besides microfabricated sensors and actuators, the field includes micromechanical components and microassembled systems. The field of microtransducers traditionally has been application driven and technology limited, and has emerged as an interdisciplinary field that involves many areas of science and engineering. MEMS is expected to follow a similar trend.

Microelectromechanical devices and systems are inherently smaller, lighter, faster, and usually more precise than their macroscopic counterparts. However, development of micromechanical systems requires appropriate fabrication technologies that enable the definition of small geometries, precise dimensional control, design flexibility, interfacing with control electronics, repeatability, reliability and high yield, and low cost per device. IC fabrication technology meets all of the above criteria and has been the primary enabling technology for the development of micromechanical systems. Microfabrication provides a powerful tool for batch processing and miniaturization of mechanical systems into a dimensional domain not accessible by conventional (machining) techniques. It provides an opportunity for integration of mechanical systems with electronics to develop high-performance closed-loop functional MEMS. In its most general form, MEMS would consist of mechanical microstructures, microsensors, microactuators, and information processing electronics integrated in the same package. This chapter will emphasize microsensors and microactuators.

MICROMACHINING TECHNOLOGY

Micromachining is a key fabrication technology for solid-state sensors and actuators, as well as MEMS. There are two classifications of micromachining, bulk and surface, both of which are based on silicon IC technology. In surface micromachining, the shaping is done only on one or both surfaces of a substrate material. Bulk and surface micromachining include techniques for selective etching, deposition, bonding, and packaging. The deposition technology is the same as that used in IC fabrication; the packaging is a developing technology that differs with each situation. Therefore, the major discussion on micromachining usually concentrates on etching and bonding and other special processes.

FIGURE 8.5.1 The basic concepts of bulk micromachining. (a) The bottom plan view of an anisotropically etched wafer showing the fabrication of cavities, diaphragms, and holes. (b) The top plan view of an anisotropically etched wafer showing the fabrication of a cantilever beam using etch stop layers. (c) The cross section, A-A', showing the hole, diaphragm, and cavity of (a). (d) The cross section, B-B', showing the cantilever beam of (b).

Bulk Micromachining

There are two techniques that make micromachining of silicon viable: (1) anisotropic etchants of silicon that preferentially etch single crystal silicon along selected crystal planes, and (2) etch masks and etch-stop techniques used in conjunction with silicon anisotropic etchants to selectively prevent regions of silicon from being etched. By appropriately combining etch masks and etch-stop patterns with anisotropic etchants, three-dimensional microstructures in a silicon substrate can be fabricated with high accuracy. Figure 8.5.1 shows two basic concepts of bulk micromachining.

Surface Micromachining

Surface micromachining relies on encasing the structural parts of the device in layers of a sacrificial material during the fabrication process. The sacrificial material (also called spacer material) is then dissolved away in

FIGURE 8.5.2 Schematics demonstrating surface micromachining in its simplest form: (a) cross-sectional view after the sacrificial layer is deposited; (b) cross-sectional view after the structural layer is deposited; (c) top plan view after patterning of the structural layer; (d) cross section AA' of (c); (e) top plan view after release; and (f) cross section AA' of (e).

a chemical etchant that does not attack the structural parts. The final stage of dissolving the sacrificial layer is called “release.” In other words, there are two primary components in a surface micromachining process: (1) *structural* layers of which the final microstructures are made and (2) *sacrificial* layers that separate the structural layers and are dissolved in the final stage of device fabrication. The basic concepts and principles of surface micromachining are given below.

Figure 8.5.2 describes one of the simplest forms of surface micromachining in which only two film depositions (i.e., one sacrificial and one structural) followed by one patterning step (i.e., for the structural layer) are needed for device fabrication. The sacrificial layer is deposited first, followed by the deposition of the structural layer. The structural layer is then patterned, forming the cantilever and the anchor region in our example. At this point, the release step is performed, creating a cantilever suspended over the substrate at a height that is flush with the surface of the silicon.

Bonding

In micromachining, bonding techniques are used to assemble individually micromachined parts to form a complete structure. Usually entire wafers or individual dies are bonded together. Wafer bonding allows the fabrication of three-dimensional structures that are thicker than a single wafer. This is important for micropumps and microvalves where more than one cavity is needed in the thickness direction. Several processes have been developed for bonding silicon wafers. A review of bonding techniques is given by Ko, et al.⁴ and Tong.⁵ Fusion bonding was developed to bond silicon to silicon and to many other materials for MEMS (Kovacs 1998, Wolf 1986).

Dry Etch and Deep Reactive Ion Etch

Dry etch processes replace wet etches for precise pattern transfer and simple operation. There are many types of dry etch techniques developed for IC processes including gas discharge methods and ion beam methods. They are used in micromachining. The deep reactive ion etch can be used to fabricate structures with great depth and controlled wall profile. It is an important process for etching devices with high aspect ratio (ratio of height to width).

LIGA and High Aspect Ratio Processes

LIGA (a German acronym for Lithographie, Galvanoforming, Abformung) process uses lithography of thick photo resist and x-ray exposure to produce a desired structure, then uses metal electroplating to generate a complementary metal mold, and microinjection molding to fabricate multiple replicas of the original. This process is used to fabricate high aspect ratio structures that are difficult to make with conventional MEMS process (Ref. 7). A Synchrotron accelerator provides x-ray exposure. Other high-aspect ratio lithography employs ultraviolet and other techniques (Ref. 8).

Packaging

Hermetic seal, lapping, polishing, and assembly techniques for microsystems as well as protection package processes were developed to bring MEMS from laboratory to market place. However, the technology is developing and each technique is applicable to a small group of applications. There are no universal package methods available and this is a field of intense research.

Micromachining of Other Materials

Micromachining of compound semiconductors, quartz, glass, ceramic, and polymeric materials for optical communication, chemical, biological, and medical applications is possible. Large-scale manufacturing methods for microdevices including injection molding, precision plating, and microassembly are anticipated.

DEFINITIONS

As in the case of other instrumentation systems, MEMS can be deemed to consist of an input block (sensor), output block (actuator), and signal processing block (electronics). A *sensor* is a device that provides a usable electrical output signal in response to a specified measurand. An *actuator*, the reverse of a sensor, is a device that converts an electrical signal to an action, while a *transducer* can be considered as the device that transforms one form of signal or energy into another form. Therefore, the term transducer can be used to include both sensors and actuators. These definitions, though not universal, are used throughout this chapter. A number of criteria can be used to classify sensors, including *transduction principle* (the physical, chemical, or biological effects), *measurands* (e.g., pressure, acceleration, gas concentration, ion concentration), *fabrication*

technology and materials (e.g., thin film, semiconductors, ceramics) *applications* (e.g., automotive, medical, aerospace), and *cost and performance*. In most of the literature, a combination of principle, measurand, and application is used to define sensors and actuators. This chapter will follow the popular approach of classifying sensors into three major groups: *physical, chemical, and biomedical*.

PHYSICAL MICROSENSORS

Integrated, Intelligent (Smart) Sensors

When a microsensor is integrated with signal processing circuits in a single package, it is referred to as an integrated sensor. A monolithic integrated sensor has the signal processing circuit fabricated on the same chip as the sensor, while a hybrid integrated sensor has the signal processing circuit on the same hybrid substrate as the sensor chip. The packaged sensor not only transduces the measurand into electrical signals, but also may have other signal processing and decision-making capabilities. Thus, the term *intelligent sensors* was coined.⁹ In trade journals and popular news articles they are also called smart sensors. Integrated sensors with specific types of on-chip electronic circuits may have the following advantages:

Better signal-to-noise ratio.

Improved characteristics. Signal processing can provide: (a) on-chip feedback system or look-up tables to improve the output linearity, (b) compensation circuits to reduce cross-sensitivity to temperature, strain, or other known interfering effects, (c) on-chip accurate current and voltage sources and associated circuits to provide automatic and periodic self-checking and calibration, and (d) feedback and other circuits to improve or compensate for the frequency response of the sensor.

Signal conditioning and formatting. Signal conditioning can be performed by integrated circuits prior to the output, such as (a) A-to-D conversion, (b) impedance matching, (c) output formatting to a standard, and (d) signal averaging.

Improved signals representing the measurands. Decision-making and computing circuits as well as memory devices may be used with redundant sensors to exclude noisy or failed sensors from the array of devices, thus improving the signal beyond a single sensor's capability. Multiple sensors, each with poor selectivity to a family of measurands, can be used with pattern recognition circuits to obtain accurate signals for each of the measurands. Neural networks may be used to train the sensors to recognize the desired measurands among several interfering effects. Many of the signal processing techniques used so successfully in communications and defense applications may be incorporated with the sensors to improve the quality of the sensor output beyond the individual device's capability. A brief summary of commonly used physical sensors follows.

Thermal Sensors

The best-known thermal sensors are thermistors and thermocouples for measuring the temperature of the environment. Thermistors and resistive temperature detectors (RTDs) are based on the change of mobility and carrier density with temperature. These changes are represented by temperature coefficients that may be constants or nonlinear functions of temperature. The resistance of a thermistor is an exponential function of the temperature. Linearization networks may be used to make the output a linear function of the temperature over a specific range, with some sacrifice in sensitivity.

The thermocouple is based on the Seebeck effect, one of the three thermoelectric effects (Seebeck, Peltier, and Thompson effects). Two different materials (usually metals) are joined at one point to form a thermocouple. Various metal wires can be used as thermocouples for different temperature ranges and sensitivity. Common wire materials are: iron/constantan, chromel/constantan, and platinum/platinum +10 percent rhodium. Semiconductors, including silicon, may also be used with a metal to form a microthermocouple by micromachining techniques. Hundreds of these microthermocouples may be connected in series on a silicon

chip to form a thermopile microsensor that is hundreds of times more sensitive than a single thermocouple. These microthermosensors are sensitive enough to measure the temperature rise in millidegree centigrade as a result of incident infrared radiation (IR), making them useful as IR imaging sensors and remote temperature sensors.¹⁰

If the current through a $p-n$ junction is kept constant, the junction voltage is a linear function of temperature. This principle has been used for many commercial temperature sensors. When two bipolar transistors are operated at a constant ratio of emitter current densities, the difference in base emitter voltages is proportional to the absolute temperature. This principle is the basis of many precise commercial temperature sensor ICs.

The mass flow of fluids can be measured by the temperature difference between two sensors, one on the downstream and one on the upstream of a heating (or cooling) source. This is the principle of microanemometers and is also a good example of how the mechanical measurand (flow) is reduced to thermal parameters that are then transduced to electrical signals.

Electrical Sensors

Electrical signals can be picked up by *ideal* ohmic connections without special sensors. However, most connections and electrical probes are not *ideal* and, sometimes, the magnitude of the charge, current, and voltage may not be convenient to measure directly. For example, Hall effect sensors are used to measure the current and polarity in motor windings where the current value is very large or a contact is difficult to make. Similarly, electrical sensors may be used to measure very high voltages or very large charges.

The flow of electrical currents occurs through the motion of charge carriers that may be electrons (and holes), ions, and charged defects in materials. These different charge carriers can have very different charge-to-mass ratios and mobilities. When a current has to pass from a material with one type of charge carrier (e.g., electrons) through the interface to another material with a different type of charge carrier (e.g., ions), there are complex reactions occurring at the interface associated with the transfer of charges. The charge carriers in metals are electrons, and in semiconductors may be electrons or holes (the collective behavior of electrons). In electrolytes, the movement of ions carries the current. In dielectrics, it is much more complicated because electrons, ions, charged atom groups, and combinations of these can carry the current. The electrodes that are used to measure electrical parameters in electrolytes or dielectrics are electrical sensors. These electrodes are used in electrochemistry, material science, and biology. The equivalent circuit of such electrodes may include several resistance-capacitance (RC) networks to model the several layers of carriers near the interface. The characterization of the electrode may involve many techniques. A commonly used method is to plot the imaginary part of the impedance versus the real part. In all applications, it is important to know the RC equivalent circuit of the electrodes, the contact potential (work function difference) between the materials in contact, and the thermoelectric effects between the materials in the measurement loop. Using specialized computer programs, the equivalent circuit of the electrode may be found. Noble metal (platinum) wires coated with various materials may be used to measure the potential of the electrolyte, or the ionic concentration of the ions in the electrolyte. These chemical sensors are called *ion selective electrodes* and are used in many chemical and biomedical applications.

Microelectrodes were designed for the measurement of electrical potentials on the surfaces of tissues, cells, and other materials. Vibrating microelectrodes can be used to measure the potential or charge the surface without making direct contact to it.

Mechanical Sensors

There are many mechanical sensors described in the literature and commercially available.³ Mechanical parameters may be converted to other energy domains and then sensed or measured directly. For direct sensing, the parameters are related to strain or displacement. Silicon, a brittle material, will fail (break) at a maximum strain of about 2 percent. However, below the elastic limit the strain is related to the stress by a nearly constant Young's modulus, which is less than but close to that of steel. The principles commonly used to sense strain are piezoelectricity, piezoresistivity, and capacitive or inductive impedance.

Piezoelectricity. The piezoelectric effect relates the elastic strain S (or stress T) in one orientation to displacement charge density D (or electric field intensity E) in another orientation that may or may not be the same as the orientation of the strain, through the piezoelectric coefficients. The piezoelectric coefficients are, in general, a $(n \times m)$ matrix, where n is the number of orientations for strain—the mechanical parameter, and m is the number of orientations for D or E —the electrical parameters. The four parameters S , T , D , and E are interrelated by various coefficients or constants. For most applications, simplifying assumptions can be made so that only parallel and perpendicular orientation between the mechanical and electrical parameters are considered. For example, d_{ij} is the strain constant or charge constant of piezoelectricity relating D and T when E is constant, or S and E , when T is constant:

$$D_i = d_{ij}T_j + \epsilon E_i \quad (1)$$

and

$$S_j = YT_j + d_{jt}E_i \quad (2)$$

where ϵ is the dielectric constant or permittivity; and $1/Y$ is the Young's modulus of the material. The coefficient $d_{33} = (\Delta D/\Delta T)_{E=k}$ or $d_{33} = (\Delta S/\Delta E)_{T=k}$, relates D and T or S and T when they are both oriented in the “ $z-3$ ” direction; thus, they are in parallel. d_{31} relates the electrical parameters D_3 and E_3 to the perpendicular mechanical parameters T_1 and S_1 .

These coefficients can be used to estimate the characteristics of sensors and actuators. The piezoelectric effect of sensors is used to measure various forms of strain or stress. Examples are microphones for strains generated by acoustic pressure on a diaphragm; ultrasonic sensors for high-frequency strain waves arriving at or propagating through the sensors; and pressure sensors for AC pressures on a silicon diaphragm coated with piezoelectric materials. The piezoelectric effect can also be used to sense small displacements, bending, rotations, and so forth. These measurements require a high input impedance amplifier to measure the surface charges or voltages generated by the strain or stress. Piezoelectric thin films and micromachining technology are used to fabricate strain or stress microsensors of various types.

Piezoresistivity. The piezoresistive effect in conductors and semiconductors is used for commercial pressure sensors and strain gauges. The strain on the crystal structure deforms the energy band structure and thus changes the mobility and carrier density that changes the resistivity or conductivity of the material. The strain in one orientation may affect the conductivity in another orientation. Therefore, similar to the piezoelectric effect, piezoresistivity can be described by an $n \times n$ matrix. For most applications, the piezoresistive material is a crystal and has symmetry in its structure. For cubic crystals, n is 6 (three for axial strain, three for shear strain, three for voltage, and three for current). Using some simplifying assumptions, the matrix of piezoresistivity coefficients can be reduced to parallel and perpendicular coefficients just as for the piezoelectric coefficients. However, the coefficients are not only orientation dependent, but are also affected by doping and temperature. A practical piezoresistive pressure sensor can be built by fabricating four sensing resistors at the edges or at the center of a thin silicon diaphragm that acts as a mechanical amplifier to increase the stress and strain at the sensor site. Usually, the four sensing resistors are connected in a bridge configuration with push–pull signals to increase the sensitivity. The measurable pressure range for such a sensor can be from 10^{-3} to 10^6 Torr. Bulk and surface micromachined pressure sensors are currently at various stages of commercialization.

Capacitive/Inductive Impedance. Capacitive or inductive impedances can also be used to measure displacements and strains. Capacitive pressure sensors present some advantages over piezoresistive devices.¹¹ Capacitive devices integrate the change of elementary capacitive areas, while piezoresistive devices take the difference of the resistance changes of the bridge arms. Therefore, capacitive sensors are less sensitive to the sideways forces and are more stable. Furthermore, capacitive changes can be much larger as a percentage of the reference value than the 5 percent maximum resistance change found in piezoresistive devices. However, capacitive sensors require a capacitance-to-voltage (C-to-V) converter on or near the chip to avoid the effects of stray capacitances.¹² Therefore, the device operation becomes complicated unless the required C-to-V converter can be fabricated on the chip or packaged in the same encapsulation. The measurement circuit also must be stable and have low noise.

Figure 8.5.3 shows a cross-sectional schematic drawing of pressure sensors based on three principles that can be used to measure acceleration, force, flow, and small displacements. Other sensors that can measure torque, rotation, touch, and so forth have also been reported in the literature.

FIGURE 8.5.3 Schematic drawings of the different types of silicon pressure sensors: (a) piezoelectric; (b) piezoresistive; (c) capacitive; and (d) surface micromachined capacitive.

Optical Sensors

Optical sensors include photoconductors, photovoltaic devices, and fiber-optic sensors. The conductivity of photoconductors changes under optical radiation because of changes in the charge carrier population. Photovoltaic devices involve a p - n junction where radiation-generated carriers may cross the junction to form currents and a self-generated voltage. Photovoltaic devices, such as solar cells, can supply energy to external circuits. However, the current is proportional to the radiation intensity, but the voltage is not (it is very nonlinearly related to the intensity of the radiation). Many micro-optical sensors and imagers are commercial products now.

When strained, a fiber-optic cable changes the intensity or the phase delay of the output optical wave relative to a reference. Using an optical detector and an interference measuring technique, small strains can be measured with high sensitivity. Intensity sensors can detect changes in optical intensity, which is related to an applied measurand. Examples include: underwater acoustic sensors, fiber-microbend sensors, evanescent or coupled waveguide sensors, moving fiber-optic hydrophones, grating sensors, polarization sensors, and total internal reflection sensors.

Optical interference sensors have been developed for interferometer acoustic sensors, fiber-optic magnetic sensors with a magnetostrictive jacket, and fiber-optic gyroscopes. Specially doped or coated optical fibers have been shown to have great versatility for physical sensors of various types and configurations. They have been used for radiation dosimeters, current sensors, accelerometers, temperature sensors, as well as detectors for liquid level, displacement, strain, torque, and fluid flow. Many chemical and biomedical materials can be sensed with fiber-optic devices.¹³

Magnetic Sensors

Magnetic sensors may employ any of the following effects: (1) the magneto-optic effect based on the Faraday rotation of the polarization plane of linearly polarized light owing to the Lorentz force on bound electrons; (2) the magnetostrictive effect where the magnetic field causes strain on the material; (3) the galvanomagnetic effect that shows up as a Hall field and carrier deflection and magnetoresistance with different sample configurations. Sensing devices include: Hall effect devices—bulk Hall plate and magnetic field sensitive field effect transistors (MAGFETS), magnetotransistors, magnetodiodes, and current domain magnetometers. A comprehensive review paper by Baltes¹⁴ is suggested for further reading.

Future Trends of Physical Sensors

Physical microsensors have been developed over the past 25 years and nearly all possible sensors have been explored. Future research and development will be focused on the following: (1) new materials, principles, and technology that push sensors beyond current limitations, such as high temperature devices, submicron devices, self-powered sensors, etc.; (2) sensor arrays and multiple sensors to improve the sensitivity, selectivity, and stability, as well as to sense the distribution of the measurands; (3) integrated sensors with built-in intelligence to recognize desired signals in noise; and (4) integrated sensors with actuators to provide self-checking and self-calibration functions, as a step toward integrated systems.

CHEMICAL AND BIOMEDICAL MICROSENSORS

General

The introduction of microelectrode assembly and the microfabrication of sensor elements are considered the most significant developments in chemical sensor technology in the past few decades. The potential advantages of microelectrodes for chemical sensor development include: (1) the small electrode size requires a small sample volume, even in biological sensing; (2) the very low level of Faradaic current results in the beneficial effect of very small ohmic potential drop, even in samples of very low conductivity; (3) the limiting current density

increases as the electrode size decreases, thus improving the signal-to-noise ratio, since capacitive background currents are proportional to the surface area; (4) the quick response of microelectrodes allows monitoring of the low-frequency fluctuation of signals and rapid recording of steady-state polarization curves; and (5) the current output of ultramicroelectrodes with dimensions in the μm range is practically insensitive to conventional flow in solution.

Microelectronic fabrication techniques provide advantages for producing these microsize chemical sensors. These include reduced size, reduced sample volume, reduced sensor cost, and fast response. Furthermore, microfabrication processing produces identical, highly uniform, and geometrically well-defined sensor elements. This is particularly attractive for chemical sensors based on the amperometric mode of operation.

While the feasibility and advantages of microfabrication of chemical sensors have been well demonstrated, practical microfabricated chemical microsensors remain elusive. The recent advancements in micromachining technology add new dimensions and impetus to sensor development. These techniques permit the formation of three-dimensional structures and other desirable features and will have a significant and revolutionary impact in future chemical sensor development.^{15,16}

Common microfabricated chemical sensors include electrochemical sensors (based on conductivity, potentiometric, and amperometric measurements), tin-oxide based sensors, and calorimetric devices. The operational principles of these sensors are described below.

Electromechanical Sensors

Electromechanical sensors have been used as a whole or as an integral part of many chemical and biosensors. The operational modes of electrochemical sensors are based on traditional laboratory electroanalytical principles. In recent years, the advancement of microelectronic fabrication techniques has provided impetus to the development of new types of electrochemical sensors for chemical and biosensor development. The introduction of solid electrolytes and conductive polymers further enhanced the applicability of electrochemical sensors, particularly in a gaseous environment. A parallel and significant development in sensor technology, though unrelated to conventional electroanalytical principles, is the development of semiconductive chemical sensors, such as the ion-sensitive field effect transistor (ISFET) depicted in Fig. 8.5.4.

FIGURE 8.5.4 A schematic drawing of a typical ISFET.

FIGURE 8.5.5 Typical planar, three-electrode electrochemical sensor. The working electrode is divided into many small cells which are in parallel to reduce the effects of flow on the sensor output.

Principles of Electromechanical Sensors. Electromechanical sensors are essential electrochemical cells consisting of two or more electrodes in contact with a solid or a liquid electrolyte. A typical planar, three-electrode electrochemical sensor is shown in Fig. 8.5.5. Electrochemical sensors can be classified according to their mode of operation, e.g., conductivity/capacitance sensors, potentiometric sensors, voltammetric sensors. Amperometric sensors are considered a specific type of voltammetric sensor in this discussion. Measurements of capacitance or resistance, or potential or current of an electrochemical cell, are all feasible. When the cell is used as a sensor, the choice of a measurement parameter is based on the sensitivity, specificity, and accuracy provided with respect to the species to be sensed. Therefore, understanding the principles and limitations of each operational mode is essential in sensor design and development.

Conductivity and Capacitance Electromechanical Sensors. An electromechanical conductivity sensor measures the change in the conductivity of the electrolyte in an electrochemical cell. It is different from the electrical (physical) sensor that measures the change in electrical resistance of the conductor in the presence of a given concentration of a solute. An electromechanical sensor may also involve a capacitive impedance resulting from the polarization of the electrodes and the Faradaic or charge transfer processes.

In a homogeneous electrolytic solution, the conductance of the electrolyte $G(\Omega^{-1})$ is inversely proportional to L (cm), the segment of the solution along the electrical field and directly proportional to $A(\text{cm}^2)$, the cross-sectional area perpendicular to the electric field.

$$G = \sigma \frac{A}{L} \quad (3)$$

where $\sigma(\Omega^{-1}\text{cm}^{-1})$ is the specific conductivity of the electrolyte and is related quantitatively to the concentration and the magnitude of the charges of the ionic species.

The measurement of electrolytic conductance by an electromechanical conductivity sensor employs a Wheatstone bridge with the electromechanical cell (the sensor) forming one of the resistance arms of the bridge. However, the conductivity measurement is complicated by the polarization of the electrodes at the operating voltage. Charge transfer processes occur at the electrode surfaces and a double layer is formed adjacent to each of the electrodes when a potential is imposed on the cell. Both effects can be minimized by using a high-frequency, low-amplitude alternating current. The higher the frequency and the lower the amplitude of the imposed alternating current, the closer the measured value is to the true conductance of the electrolyte. A better technique would be to balance both the capacitance and the resistance of the cell by connecting a variable capacitor parallel to the resistance of the bridge arm adjacent to the cell. The basic measurement could be performed using an impedance measuring bridge in which the resistive and reactive components of the impedance of the electrochemical cell can be determined by balancing the bridge. Greater measurement precision with fewer demands on the operator can be achieved using special electronic instruments, such as lock-in amplifiers, to determine the magnitude of the cell impedance and its phase angle. One way of using the lock-in amplifier is to drive the conductivity cell with a constant current amplitude sinusoidal signal and measure the resulting potential across the cell and its phase angle with respect to the excitation. The impedance magnitude

can then be found by taking the ratio between this measured voltage amplitude and the amplitude of the excitation current.

Potentiometric Sensors. Potentiometric sensors use the effect of the concentration on the equilibrium of the redox reactions occurring at the electrode-electrolyte interface in an electrochemical cell. A potential may develop at this interface as a result of the redox reaction, $Ox + Ze^- = Red$, taking place at the electrode surface, where Ox denotes the oxidant, Red the reduced product, Z the number of electrons in the redox reaction and e^- an electron.

This reaction occurs at one of the electrodes (cathodic reaction in this case) and is called a half-cell reaction. At thermodynamical quasi-equilibrium conditions, the Nernst equation is applicable and can be expressed as

$$E = E^0 + \frac{RT}{ZF} \ln \left(\frac{a_{Ox}}{a_{Red}} \right) \quad (4)$$

where E and E^0 are the electrode potential and electrode potential at standard state, respectively, a_{Ox} and a_{Red} are the activities of Ox and Red , respectively, Z the number of electrons transferred, F the Faraday constant, R the gas constant, and T the operating temperature in Kelvin. In a potentiometric sensor, two half-cell reactions will take place simultaneously. However, only one of the two half-cell reactions should involve the sensing species of interest, and other half-cell reaction is preferably reversible and noninterfering.

Potentiometric sensors can be classified based on whether the electrode is inert or active. An inert electrode provides the surface for the electron transfer or provides a catalytic surface for the reaction and does not actively participate in the half-cell reaction, whereas an active electrode is either an ion donor or acceptor in the reaction. There are three types of active electrodes: the metal/metal ion, the metal/insoluble salt or oxide, and metal/metal chelate electrodes.

Each electrode type can be involved in a chemical cell or concentration cell. In a chemical cell, the two half-cell redox reactions are different. In a concentration cell, the two half-cell reactions are in redox fashion but with different reactant concentrations or activities.

Voltammetric and Amperometric Sensors. Voltammetric measurement is characterized by the current and potential relationship of the electrochemical system, a technique commonly used by electrochemists. This method is often referred to as amperometric measurement. Amperometric sensors can be considered as a subclass of voltammetric sensors, since they are operated in one of the voltammetric modes. In this case, the current-solute concentration relationship is obtained at a fixed potential or overall cell voltage. On the other hand, voltammetric sensors can be operated in other modes such as linear voltammetric or cyclic voltammetric modes. Figure 8.5.6 shows the three different modes of operation and their respective current-potential responses.

Voltammetric sensors utilize the concentration effect on the current-potential characteristics of the electrochemical system for their sensing operation. The current-potential characteristics depend on the rate by which the components in the electrolyte are brought to the electrode surface (mass transfer) and the kinetics of the Faradaic or charge transfer reaction at the electrode surface. Three different modes of mass transfer can be identified in an electrolyte solution, namely, (a) ionic migration as a result of an electric potential gradient, (b) diffusion under a chemical potential difference or concentration gradient, and (c) convective or bulk transfer by virtue of natural convection (density difference) or forced convection.

Linear sweep voltammetry involves increasing the imposed potential linearly at a constant scanning rate from an initial value to a given upper potential limit. The current-potential curve usually shows a peak at a potential where the rate of reaction equals the mass transfer rate. Cyclic voltammetry is similar to the linear sweep voltammetry except that the electrode potential is returned to its initial value at the same scanning rate as shown in Fig. 8.5.6. The cathodic and anodic sweeps would normally generate two current peaks.

Semiconductive Gas-Sensing Microsensors

SnO_2 -based Semiconductor Gas Sensors. The surface conductance of semiconducting oxides, such as zinc oxide and tin dioxide, can be influenced by the composition of ambient gases. This phenomenon is the basis of many resistive semiconductor gas sensors.

FIGURE 8.5.6 Current-potential relationship of various voltammetric modes of operation.

Among the semiconducting oxides, SnO_2 is the most widely used for gas sensors. Such sensors have roles in the detection of flammable or reducing gases such as carbon monoxide, hydrogen and methane at low-level concentrations. SnO_2 -based sensors are used to detect leaks of flammable and toxic gases, for combustion control and even for detecting odors. Millions of units of tin dioxide-based gas sensors are sold each year, mainly for automobile exhaust emission monitoring and for gas leak detection. Extensive literature on tin dioxide-based sensors can be accessed.^{15,16,21}

As the active sensing part of the gas sensor, tin (IV) oxide (tin dioxide) is nonstoichiometric and is deficient in oxygen atoms. Charge neutrality is maintained by the presence of numbers of tin (II) ions (Sn^{2+}) instead of Sn^{4+} ions, and these Sn^{2+} ions act as electron donors during the process. Thus, the active material of tin dioxide is an *n*-type semiconductor. At elevated temperatures, adsorption of atmospheric oxygen takes place at the face of the tin-oxide film and oxygen accepts electrons that are donated by the *n*-type SnO_2 film and becomes ionic by forming O_2^- , O^- , or O^{2-} anions. If a reducing gas adsorption follows, the reducing gas may react with adsorbed oxygen anions and become a positively charged species or the reducing gas may react with the adsorbed oxygen atom and release bound electrons. As an example, the overall reaction of carbon monoxide on a tin dioxide film can be described by

where e^- represents a conduction band electron. In the absence of reducing gas, electrons are removed from the conduction band via the reduction of molecular oxygen and an O^- species is formed such that in consequence the SnO_2 film becomes highly resistive. When carbon monoxide is introduced, it undergoes oxidation to carbon dioxide by surface oxygen anion (O^-) and electrons are reintroduced into the conductive band which leads to an increase in film conductivity. This example provides a general operation principle for tin dioxide-based gas sensors.

The main advantages of tin dioxide-based gas sensors include high sensitivity, low cost, fast response time and low power consumption. However, there are also significant drawbacks, such as long-term drift, relative low selectivity, and effects of humidity and temperature. Efforts have been made in recent years to improve the performance characteristics of tin dioxide-based gas sensors. For instance, noble metal doping of tin dioxide

improves the catalysis process of the detecting gas, which greatly enhances the selectivity and decreases the operating temperature. Other modifications are described later.

Microfabrication of SnO_2 -Based Gas Sensors. Fabrication techniques for semiconductive gas sensors have been developed over many years. The microfabrication technologies previously described have added impetus to the advancement of semiconductive gas sensors. The use of microfabrication techniques in the production of tin dioxide type gas sensors provide a good illustration of the potential and future trends of this application.

The original Taguchi type tin dioxide gas sensor was adopted by Figaro Gas Sensor Inc. and by many Japanese groups. The tin dioxide layer is a porous thick film formed by tin dioxide powder sintering. The tin dioxide was prepared from stannic acid gel and followed by firing for 1 h at 500°C . A ratio of palladium and alumina was added to the oxide powder to get the resulting 2:1 ratio of Al_2O_3 to SnO_2 . Distilled water was added to the above mixture to yield a paste that was then applied to the surface of an alumina tube with preprinted gold electrodes on the surface. A silica solution was used to cover the paste as a binder. Subsequent low-temperature baking resulted in the formation of a porous sintered thick film. A heater filament was placed inside the tube to provide the required operating temperature.

Thick-Film Technology. Planar thick-film gas sensors have been developed in recent years. The fabrication procedures include sequential screen-printing of thick film gold electrodes, followed by printing a gas-sensitive layer onto an alumina substrate. The paste used for printing of the gas-sensing layer consists of tin dioxide powder along with an organic vehicle and a glass binder. Sometimes a catalytic additive is included. Normally, the thickness of the active film is around several micrometers to tens of micrometers. Schmitte and Wiegleb¹⁷ proposed the composition of tin dioxide paste as 71 percent tin dioxide powder, 5 percent glass powder with solvents and adhesives, and a firing condition of 850°C for 1 hour. A thickness of $15\ \mu\text{m}$ was used for this tin dioxide layer.

The advantages of screen printing technology in the fabrication of thick film gas sensors include the porosity of the sensitive layer, a simple sensor design and a variety of possible geometries for the sensor element (e.g., coplanar, interdigitated, or sandwich form). The heater, located on the back side, is helpful for saving power. The use of thick-film tin dioxide-based gas sensors for the detection of carbon monoxide, hydrogen sulfide, hydrogen, methane, and carbon tetrachloride have been reported.¹⁸

Thin-Film Technology. This is another useful tool for fabricating tin dioxide-based gas sensors. Chemical vapor deposition (CVD) and reactive evaporation or sputtering can both be applied for this purpose.¹⁹ A typical bulk micromachined, thin film tin oxide gas sensor is shown in Fig. 8.5.7.

Chemical vapor deposition technique involves two gaseous compounds that chemically react and form a compound on the substrate. For the tin dioxide gas sensor film, one of the compounds used is a tin-organic compound (e.g., dibutyl tin diacetate). It is dissolved in an organic solvent and then vaporized at a controlled temperature. The vapor is fed into the reacting chamber using nitrogen as the carrier gas. The tin-organic vapor will react with absorbed oxygen on the surface of the substrate (Al_2O_3 or SiO_2 (Si)) forming the tin dioxide film. A tin dioxide sensitive layer is formed after annealing at 500°C for 12 h or longer. The film thickness and the grain

FIGURE 8.5.7 A micromachined tin oxide gas sensor. The tin oxide film is placed on a thin silicon region to reduce the power consumption when the film is heated to its operating temperature.

size of tin dioxide can be controlled by the fabrication conditions and are considered critical for the sensor response. In most cases, the thickness and grain size are in the order of several tens or hundreds of nanometers.

In the reactive evaporation method, the tin dioxide film is fabricated in an evaporator. Pure metallic tin (or tin alloy) is heated to a high temperature (1200–1300°C) and is deposited on a heated substrate on which the sensor heater and gold electrode have already been deposited. After deposition, the sensor unit is annealed in an oxygen-containing atmosphere for several hours at a designated temperature, allowing the tin metal to transform to the oxide. Generally, the resulting thickness of the oxide film is of the order of several hundred nanometers.

Response Characteristics of SnO_2 -Based Gas Sensors. *N*-type semiconductive tin dioxide-based gas sensors can be used to detect low-level concentrations of reducing gases such as hydrogen, carbon monoxide, methane, ethanol, hydrogen sulfide, and other inflammable gases, as well as some anesthetic agents like forane, halothane, and ethrane. This sensor is based on the conductance change through the tin dioxide grain boundaries on its surface in the absence of the detecting gas compared with its presence. The sensitivity S of the sensor is expressed as the ratio of the conductivity G under tested gas flow and ambient air, and is expressed as

$$S = G_g / G_a \quad (7)$$

where G_g is the conductivity of the sensor in the presence of tested gas flow and G_a is that in ambient air. The sensitivity of a tin dioxide sensor may be influenced by the layer composition, grain size, operating temperature, humidity, and various other factors.

Calorimetric Sensors

The calorimetric sensor is essentially a high-temperature resistance thermometer that measures the temperature change caused by the heat evolved during the catalytic oxidation of the combustible gases. The most commonly used calorimetric sensors are in the form of an encapsulated platinum coil, which serves both as a heater and as a resistance thermometer. This is normally referred to as a pellistor type calorimetric sensor, and was first developed in 1962. This type of calorimetric sensor can be used for the detection of combustible gas at low concentration. However, the results were not accurate because of the heat loss, a condition that may not be easy to improve with a conventionally sized sensor.

Microfabrication technology provides a means to fabricate miniature calorimetric sensors with improved characteristics. Recently, a thick-film calorimetric microsensor for combustible gas monitoring was fabricated on an alumina substrate.²⁰ Platinum-thick film was deposited using the screen-printing method. Two types of catalysts were employed, namely, platinum black and palladium. The noncatalytic compensating platinum film was left bare as printed. This microsensor can be used for the detection of hydrogen, carbon monoxide, methane, and ethane. Proper selection of the reaction temperature for catalytic oxidation may lead to possible identification of different gases. Catalytic metallic layer deposition onto silicon wafers or glass plates with the thin-film process has been reported by different groups.^{21–24}

A thin-film thermopile sensor based on a bismuth-antimony junction array has been reported.²³ This thermopile consisted of an alternating junction of bismuth and antimony, with a gold contact between, on a kapton thick-film that was formed on a glass plate. Metal shadow masks were used in intimate contact with a kapton sheet to define the geometry for each of the metal layers. The thickness of the bismuth and antimony layer was around 1 μm or less.

An enzyme microsensor based on this thermopile has also been proposed.²⁴ Glucose oxidase was crosslinked above the active junctions of the thermopile with a thickness of 100 μm . It proved to have a rapid response and good stability when used either intermittently or continuously. Also, catalase and urease were used for immobilization, and both enzyme sensors yield attractive results.

Biosensors

Biosensors are a special class of chemical sensors for molecular detection that take advantage of the high selectivity and sensitivity of biologically sensitive materials. It is a device incorporating a biological sensing element with a traditional sensor, such as physical or chemical sensors. The biological sensing element selectively

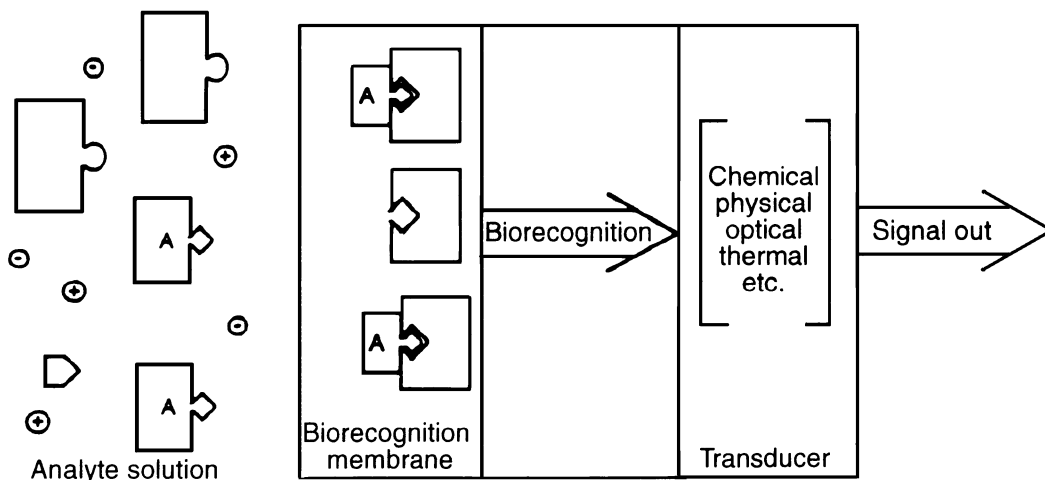

FIGURE 8.5.8 Schematic drawing of the general biosensor. It consists of a traditional transducer with a biological recognition membrane intimately in contact with the transducer. The biologically active material recognizes the analyte molecule, A, through a shape-specific recognition. In affinity-based biosensors, the binding of the analyte and bioactive molecule is the chemical signal that is detected by the transducer. In metabolic biosensors, the biologically active material converts the analyte, and any co-reactants, into product molecules. The transducer converts the result of that reaction into the output signal. The transduction can be through measurement of concentration changes in a product or coreactant concentration, or the heat liberated in the reaction.

recognizes a particular biological material (the measurand) through a reaction, specific adsorption or other physical or chemical process, and the sensor element converts the results of this recognition into a usable signal, usually electrical or optical. Figure 8.5.8 illustrates this definition.

Biosensors represent a specialized field in sensors. A selected reference list is provided.^{23–25}

A biological sensor operates on similar principle of a chemical sensor. A biorecognition reaction with the analyte, through a transduction mechanism, results in a sensor output. This output can be electrical, optical, or as a change in color. The biorecognition reaction often involves biocatalysts such as enzymes. The sensory mechanism of a biological sensor is often based on a chemical sensor. Consequently, the microfabricated chemical sensors serve as the bases of microbiological sensors. For instance, the commercially available i-STAT portable clinical analyzer and the portable blood analysis system by Diametrics Medical Inc. are good examples of microchemical sensors serving as the core for biosensor applications.

Measurements of dissolved blood gases (oxygen and carbon dioxide) and blood electrolyte (pH, Na⁺, K⁺, Ca²⁺, and others) can be accomplished using electrochemical sensors. For instance, the Clark oxygen sensor for measuring dissolved oxygen in biological fluids is based on an electrochemical-based amperometric sensor. In this electrochemical sensor, the reduction of oxygen results in a cathodic current, which can then be used to quantify the oxygen presented. This approach is applicable to measurements of dissolved oxygen in biological samples. Therefore, miniaturization of electrochemical sensors or chemical sensors can lead to the development of microsize biological sensors making portable biological analyzers a reality.

Biological sensors based on enzymatic reactions also frequently use a chemical sensor as the sensing mechanism. For example, a blood glucose sensor employs glucose oxidase to catalytically oxidize the glucose in the presence of oxygen. One of the resulting products is hydrogen peroxide, which can be detected electrochemically. The amount of hydrogen peroxide detected can then be used to quantify the blood glucose presented. Other enzymatic reactions have also been used for extensive biological sensor development, and the detection of a product or a co-reactant with a chemical or electrochemical sensor is then used to quantify the bio-analyte.

As anticipated, the application of MEMS technology to chemical sensors leads to the logical consideration of using MEMS technology in the development of biological sensors.^{20,21} Many attempts in this direction have been made but with only limited success thus far. The fragility and relatively poor biocompatibility of silicon

are concerns. Furthermore, biological sensors often prefer to be disposable or to have a limited number of uses. This is difficult to achieve with expensive MEMS manufacturing processes.

MEMS technology applied to biomedical fields has led to the term BIOMEMS. Major efforts in BIOMEMS are focusing on DNA chips and drug delivery systems. These applications are beyond the scope of biological sensors for in vivo and in vitro applications. Development of biological sensors is a vast scientific endeavor. It is beyond the scope of this chapter to discuss it in detail. We wish only to point out the relationship between chemical and biological sensors, and the issues involved in MEMS technology to both types of microdevices.

Laboratory on a Chip. One of the potential applications of MEMS technology is that of a complete chemical laboratory on a chip (LOC). The functional components of a simple analytical laboratory would be fabricated using silicon-based microfabrication technology. These functional components might include sample pretreatment, transportation, and separation of the sample, introduction of reagents, sensing and detection and data collection and analysis. The advantages of an LOC approach include the requirement of a small sample volume, minimum quantity of expensive reagents, and relatively portability. However, its success depends on many intricate microfabricated components such as microfluidic devices, micropumps, valves, channels, and sensors. *Fundamentals of Microfabrication* by M. Madou provides a summary of the commercial aspects of this technology. The transport properties of fluid in these microstructures can differ significantly from those in a larger-size environment. Fabrication costs are again an issue.

The term “ μ TAS,” meaning “micro total analytical system,” is used in the MEMS field. It is a part of the “system on a chip” when applied to the integrated biochemical analytical systems. The term biochip also is being used in popular science and news media in reference to the biomedical diagnostic systems fabricated on a chip.

Chemical and Biosensor Packaging

Packaging of chemical sensors is a critical issue that needs to be addressed. Differing from the packaging of electronics, that of chemical sensors must provide an area where the sensor is exposed to the environment. This means that on one hand the overall integrity of the sensors must be protected, yet on the other hand, the most critical part of the sensor must be exposed to the sensing environment, which can often be hostile. There is no simple or direct packaging method for chemical sensors, rather, it depends on the environment of the sensor applications, such as high temperature or the presence of corrosive materials.

MICROACTUATORS

Research on design, fabrication, and characterization of new microactuators is accelerating. A critical need is the development of actuation forms that are compatible with the materials and processing technologies of silicon microelectronics. Additionally, actuation is to be powered and controlled electrically, allowing full utilization of integration with on-chip electronics. Despite these stringent requirements, numerous physical phenomena have been demonstrated for microactuator applications.²⁶ However, the most commonly used microactuation methods have so far been either electromagnetic or thermal and are, therefore, the microactuation techniques described in this section as examples. Other microactuation techniques can be found in the journals and proceedings of the conferences in the field (see Bibliography).

Selected microactuators that exemplify the basic microactuator concepts and mechanical designs are described here. Two basic electrostatic microactuator designs, lateral resonant devices and micromotors, are discussed in more detail as examples.

Mechanical Design of Microactuators

The mechanical design of microactuators can be divided into two classes: (1) mechanisms and (2) deformable microstructures. Mechanism-type microactuators (e.g., the micromotor shown in Fig. 8.5.9) provide displacement

FIGURE 8.5.9 A photomicrograph of a salient-pole, variable-capacitance, side-drive micromotor. The rotor rotates in the plane of the motor/substrate.

and force through rigid-body motion while deformable microstructures (e.g., beams, diaphragms, and the lateral resonant microactuator of Fig. 8.5.10) provide displacement and force through mechanical deformation (or straining). The unrestrained, large motion capability of mechanism-type microactuators comes at the cost of friction, which is present in the bearings and joints of such devices. In contrast to the operation of macroscopic mechanical devices in which gravitational and inertial forces are often dominant, friction plays an important role in the operation of micromechanical devices. In micromechanical devices, gravitational forces (i.e., weight of the moving parts) are usually insignificant while inertial forces are often, but not always, negligible. Deformable microstructures eliminate friction since they only use joints and suspensions. Avoiding friction, however, comes at the cost of restrained (and often small) motion.

Electromagnetic and Thermal Microactuation

Most notable among electromagnetic microactuation methods have been electric (often referred to as electrostatic), piezoelectric, and magnetic actuation. Utilization of electrostatic actuation in microfabricated mechanical devices is readily possible since IC processes provide a wide selection of conductive and insulating materials. By using the conductors as electrodes and the insulators for electrical isolation of the electrodes, attractive electrostatic forces can be generated by applying a voltage across a pair of electrodes. To generate repulsive forces, *electrets* (dielectric materials that have a permanent charge) are required; however, electrets are not readily available in the IC industry and, as a result, have not as yet been used in microactuation.

FIGURE 8.5.10 A photomicrograph of a lateral resonant device. The shuttle mass attached to the folded cantilever suspension moves in the plane of the device/substrate in the direction of the comb fingers.

Electrostatic forces can be used in conjunction with conventional deformable microstructures such as beams and diaphragms to generate force or provide motion. For this group of microactuators, the deformation is predominantly in the direction normal to substrate plane. Figure 8.5.11 is a schematic example of an electrostatic diaphragm microactuator. By applying a voltage across the diaphragm/electrode air gap (which is typically a few microns), the diaphragm can be deflected upward. The generated electric force results from the attractive force between the electrical charges of opposite sign on the electrically conductive silicon surfaces across the gap. As in the case of the lateral resonant microactuator in Fig. 8.5.11, electrostatic actuation can also be used in conjunction with deformable microstructures to provide motion in the plane of the substrate.

Electrostatic actuation can also be used in conjunction with a mechanism, for example, in the case of the micromotor in Fig. 8.5.9. In an electric micromotor, the attractive forces generated by electric charge distributions are used to convert electrical to mechanical energy. By proper commutation of these charge distributions (i.e., proper switching of excitation voltage) on a set of stationary electrodes, known as the stator, and a set of moving electrodes, known as the rotor, continuous motion of the rotor can be achieved.

Another form of microactuation has been based on the piezoelectric effect. Figure 8.5.12 is a schematic example of a possible cantilever microactuator design. In this design the piezoelectric thin film, which is sandwiched between two electrodes, is placed on top of a silicon cantilever beam. When a voltage is applied across the piezoelectric film, the film will expand or contract in the lateral direction, resulting in a downward or upward deflection, respectively, of the cantilever. The polarity of the applied voltage determines if the film expands or contracts. Piezoelectric films have been used to provide actuation in a variety of applications such

FIGURE 8.5.11 A schematic drawing of an electrostatic diaphragm microactuator.

as valves, pumps, positioning devices, and ultrasonic micromotors.^{27,28} Typical piezoelectric thin films being used in microactuators are zinc oxide (ZnO), lead zirconate titanate (PZT), and polyvinylidene difluoride (PVDF). Of these materials, PZT has the largest piezoelectric coefficients.

Similar to electrostatic actuation, magnetic actuation can be used in conjunction with both deformable microstructures and mechanisms. Since most macroscopic electromagnetic motors use magnetic actuation, this form of actuation is most familiar. However, its utilization for microfabricated actuators has been limited because it requires magnetic materials and fabrications of windings. Nevertheless, a few studies^{29–31} have addressed the development of magnetic microactuators. For example, magnetic micromotors made of nickel have been demonstrated by using the LIGA fabrication process.³²

While electromagnetic microactuation has been demonstrated in conjunction with both classes of microactuators, thermal microactuation is primarily suitable for deformable microstructures. Most notable among thermal microactuation methods have been bimetallic, shape memory alloy (SMA), and thermopneumatic. Figure 8.5.13 shows a schematic example of a possible bimetallic or SMA cantilever microactuator. Bimetallic microactuators use the thermal coefficient of expansion mismatch between the material components of a sandwich layer to generate force or motion.³³ For example, applying a current through the heating resistor in the device of Fig. 8.5.13 will heat the composite metal/silicon cantilever beam. Since the metal expands more than the silicon, the beam will deflect downward. The downward deflection of the beam can be maintained by supplying power through the heating resistor. Since microfabrication techniques lend themselves more easily to the stacking of the materials on top of rather than beside each other, reported microactuators based on the bimetallic effect provide deformations that are predominantly in the direction normal to the plane of the substrate.

SMAs are metals that have shape-recovery characteristics. When these alloys are plastically deformed at one temperature (martensitic phase), they will completely recover their original shape on being raised to a higher temperature (austenitic phase).³⁴ In recovering their shape, the alloys can produce a displacement or force, or a combination of the two, as a function of temperature. The development of thin-film SMAs provides the potential for development of silicon-based MEMS that incorporate SMA microactuators. The specific SMA that has been studied for microactuator applications is Nitinol or TiNi, an alloy of titanium and nickel.^{35,36} TiNi alloys undergo a martensitic transformation during cooling at a temperature M_s , and the transformation is completed at a lower temperature M_f . In the temperature interval between M_s and M_f , the alloy

FIGURE 8.5.12 Schematic of a piezoelectric cantilever microactuator.

FIGURE 8.5.13 Schematic drawing of a bimetallic or shape-memory-alloy cantilever microactuator.

has a two-phase (austenite and martensite) microstructure; the transformation temperature is relatively narrow and is on the order of 15°C .^{37,38} Therefore, one may speak of a transition temperature, M_t (average of M_s and M_f), below which the alloy shows the shape memory effect and above which the effect is absent. Associated with the martensitic transformation, TiNi shows a shape memory effect.

An SMA cantilever microactuator based on the construction shown in Fig. 8.5.13 would, for example, use TiNi for the metal component. Assume that the cantilever is fabricated such that it is flat (i.e., no deflection) with TiNi in its austenitic phase (well above M_t), and then cooled to below M_t to form the martensitic phase. Since the cantilever is also a bimetallic device, it will deflect upward on cooling (i.e., TiNi contracts more than the silicon). By applying current through the heating resistor, the cantilever will try to recover its flat shape once M_t is reached. Note that there would be some bimetallic contribution to the actuation until M_t is reached. However, the transition at M_t will be sudden and because of the shape memory effect.

In a thermopneumatic microactuator, the volume expansion of a fluid is used for actuation.³⁹ Figure 8.5.14 is a schematic of a possible implementation of a thermopneumatic diaphragm microactuator based on resistive heating of a fluid in a micromachined sealed cavity. As the fluid is heated, its volume expands, increasing the pressure inside the cavity. The increased pressure acts as a load on the thin diaphragm and results in its deflection. The fluid may be a liquid that turns to a gas or simply a gas that expands on heating.

Comparison of Actuation Methods

It is often of interest to compare the various microactuation methods for their relative advantages and disadvantages, but detailed comparisons are only realistic when performed in light of an application. Nevertheless, it is possible to outline some general points. An important point of interest for a microactuation method is the amount of force (or mechanical energy) that can be generated. One approach for general comparison is to estimate the amount of energy, W , available per unit volume. For example, the energy per unit volume, W , available from a TiNi SMA material can be calculated from the area under the operating curve on the stress-strain

FIGURE 8.5.14 Schematic of a thermopneumatic diaphragm microactuator.

diagram. For an austenitic state with a yield strength of 420 MPa and an available shape memory strain of 8 percent, W is $4 \times 10^7 \text{ J/m}^3$. For bimetallic actuators, W would depend on the magnitude of temperature change but can be of comparable magnitude. For an electrostatic microactuator, $W = (1/2)\epsilon_0 E_{\text{max}}^2$ is nearly $4 \times 10^5 \text{ J/m}^3$, assuming an electric field breakdown limit (E_{max}) of $3 \times 10^8 \text{ V/m}$ for microscopic air gaps.⁴⁰ (ϵ_0 is the permittivity of free space.) For piezoelectric microactuators, W may be up to 10^5 J/m^3 , assuming PZT to be the piezoelectric material. For magnetic microactuators, $W = (1/2)(B_{\text{max}}^2/\mu_0)$ is about 10^6 J/m^3 , assuming a magnetic flux density saturation of 1.5T .⁴⁰ (μ_0 is the permeability of free space.)

Other factors must also be considered in comparing different microactuation methods. In general, thermal microactuators have a slow response time (e.g., on the order of tens of milliseconds) and high power consumption (e.g., on the order of tens of milliwatts). Comparatively, electromagnetic microactuators can be much faster (e.g., microsecond response time) and consume far less power, particularly electrostatic microactuators. The construction of thermal microactuators often requires the final freestanding part to be a laminate of layers with very different mechanical properties. This often complicates device design as evidenced by the fact that reported bimetallic actuators exhibit a preset deflection because of the residual stresses in the thin films. Piezoelectric microactuators require deposition of additional films since silicon is not piezoelectric. Furthermore, static operation of piezoelectric microactuators is limited by charge leakage. Electrostatic microactuators can be fabricated using conducting and insulating films that are common to microelectronics technology. Static excitation of electrostatic microactuators requires voltages across insulating gaps and nearly no loss. Magnetic microactuators require magnetic materials that are not common in IC technology and often require some type of manual assembly. Static excitation of magnetic microactuators requires current through windings and persistent conduction losses.

Microactuator Examples

While research and development of microactuators has been rapidly expanding in the last few years, the four classes of microactuators described below are representative of a large segment of the microactuator technology. The examples provide typical performance characteristics of a large cross section of microactuators.

Microvalves. Microactuator technology is being pursued for the development of microvalves for industrial (e.g., electronic pressure regulators) and biomedical applications (e.g., drug delivery and chemical analysis fluidic microsystems). The microvalve in Fig. 8.5.15 is an example of a bimetallic microactuator fabricated by bulk micromachining and bonding of two wafers.⁴¹ Heating of the bimetallic diaphragm by passing a current

FIGURE 8.5.15 Schematic drawing of a bimetallic microvalve.²¹

FIGURE 8.5.16 Schematic drawing of an electrostatic micropump.⁴³

through a heating resistor embedded between the metal and silicon sandwich causes the metal and silicon layers to expand. This expansion results in the downward deflection of the diaphragm because of the mismatch in the thermal expansion coefficients of the metal and silicon. If heated sufficiently, the diaphragm can deflect far enough to close off the valve. The diaphragm in this device is 2.5 mm in diameter and is 10 μm thick. A 5 μm -thick aluminum layer is used as the metal component. Fully proportional control of flows in the range of 0 to 300 cc/min has been demonstrated with this valve for input pressures from zero to 100 psi. On/off flow ratios have been greater than 1000. To close the valve at 20 psig input, 1.5 W of power is required.⁴¹

Electrostatic, shape memory metal (SMA)⁴² and thermopneumatic³⁹ actuations are also being used in the development of microvalves similar in architecture and concept to that described above.

Micropumps. Another application of microactuator technology is the development of micropumps. Such micropumps are of interest, for example, in developing chemical analysis and drug delivery microsystems. The micropump in Fig. 8.5.16 is an example of electric actuation in conjunction with a deformable diaphragm.⁴³ This micropump employs two check valves that are simply cantilever beam flaps covering micromachined holes. When a voltage is applied to the counter electrode, the diaphragm deflects up, increasing the pump chamber volume and reducing its pressure. The inlet check valve then opens as its cantilever flap bends up in response to differential pressure. When the excitation is turned off, the diaphragm returns to its normal position, reducing the pump chamber volume and increasing its pressure. The outlet valve then opens allowing the fluid to exit. In the micropump described, the square diaphragm is $4 \times 4 \text{ mm}^2$ and 25 μm thick; the actuator gap is 4 μm . Pumping has been demonstrated for actuation frequencies of 1 to 100 Hz. At 25 Hz, a pumping rate of 70 $\mu\text{l}/\text{min}$ has been demonstrated when the outlet and inlet pressures are equal. Typical forward to reverse flow rate ratio of the check valves is 5000:1.⁴³

Lateral Resonant Devices. Where the deformable microactuators above were fabricated by bulk micromachining and bonding, many current deformable microactuators rely on (polysilicon) surface micromachining. Lateral resonant microstructures are the newest among these;⁴⁴ they are actuated by electrostatic forces. Figure 8.5.17 shows a plan-view schematic of the lateral resonant microactuator of Fig. 8.5.10. While

FIGURE 8.5.17 Plan view of a lateral resonant microactuator.

polysilicon surface micromachining has thus far been the primary technique for the fabrication of these devices, other fabrication techniques are emerging.⁴⁵ Lateral resonant structures typically consist of a movable plate that is suspended a couple of microns above the substrate by a flexible folded beam support. The folded beam support is anchored to the substrate at one end and attached to the movable plate at the other end. (In Fig. 8.5.17, the light-fill regions indicate parts that are suspended over the substrate and the dark-fill regions indicate the substrate anchor areas.) Electric forces through the use of comb-drive and/or side-drive electrodes are employed to provide actuation. The suspension and actuation are designed for lateral deformation of the suspension and, therefore, lateral movement of the movable plate. In resonant mode, these microactuators can provide lateral deformations near $10\ \mu\text{m}$; tens of kHz is typical of resonant frequencies for the designs reported.⁴⁴

The electrostatic force generated by a single comb finger on the movable plate is

$$F = 2\epsilon_0 V^2 \left(\frac{t}{g} \right) \quad (8)$$

where F = force

ϵ_0 = permittivity of free space

V = applied voltage

t = beam thickness

g = comb finger gap

The factor of 2 accounts for the fact that on the stationary electrode there are always two comb fingers, one on each side of the comb finger on the movable plate. The above formula is based on simple parallel-plate capacitance calculations. For comparable values of t and g (which is often the case in actual devices based on polysilicon surface micromachining), the above formula provides a reasonable approximation. Its accuracy increases as the t to g ratio increases beyond 3 to 4 such that the contribution of the fringing fields becomes negligible. For t to g ratios below 1, the accuracy of the above formula may be quite poor.

This displacement x (along the comb finger direction) of the movable plate as a function of the applied force is

$$x = \frac{F}{K} \quad (9)$$

TABLE 8.5.1 Typical Lateral Resonant Device Parameters

Parameter	Typical values
Comb finger gap (μm)	1–4
Comb finger width (μm)	2–4
Number of fingers	9–11
Finger length (μm)	20–40
Polysilicon thickness (μm)	1.5–3
Beam length (μm)	80–200
Beam width (μm)	1–2

where x is the displacement of the shuttle, and K is the mechanical stiffness of the folded beam suspension. The stiffness of the suspension is given by

$$K = 2Et \left(\frac{w}{l} \right)^3 \quad (10)$$

where E = Young's modulus (near 160 GPa for polysilicon)
 ν = Poisson's ratio (assumed to be near 0.3 for polysilicon)
 l = beam length
 w = beam width

When the l to w ratio is greater than 1, wide beam effect can be accounted for by dividing the modulus by $(1 - \nu^2)$. The resonant frequency of the shuttle is given by

$$f = \frac{1}{2\pi} \sqrt{\frac{K}{M}} \quad (11)$$

where M is the mass of the shuttle.

Typical dimensions of lateral resonant devices are described in Table 8.5.1. Based on these typical dimensions, the generated forces per square volt, for a single comb finger, are usually in the range of 4 to 26 pN/V², while typical stiffness values for the suspension are in the range of 60 mN/m to 15 N/m.

To improve performance by increasing the generated actuation force⁴⁶ and displacement,⁴⁷ other polysilicon deformable microstructure mechanical designs that use electrostatic actuation have been tried. The reader is referred to the proceedings of recent conferences in the field for reported design variations.

Micromotors. In addition to deformable microstructures, MEMS require large-motion actuators (e.g., micromotors) to power linkages. Electrostatic actuation in conjunction with polysilicon surface micromachining has been used to develop variable-capacitance side-drive micromotors⁴⁸ similar to the one shown in Fig. 8.5.9. For variable-capacitance micromotors (which require conductive materials for the rotor and the stator, as well as insulators for electrical isolation), the material requirements are compatible with polysilicon surface micromachining. Heavily-phosphorous-doped polysilicon is used for the rotor and the stator, and silicon nitride is used for electrical isolation. Additionally, since the electric breakdown limit in air increases drastically for microscopic (order of 1 μm) air-gap sizes, high enough torques can be generated to start the motor. The electric field breakdown limit in air is 3×10^6 V/m for macroscopic dimensions and increases to above 10^8 V/m for microscopic, air-gap sizes.^{44,49} For microscopic dimensions, the gap size approaches the mean free path in air. As a result, the field strength increases since avalanche breakdown, which is the field breakdown mechanism, requires a large number of collisions to ionize the air.

Figure 8.5.18 is a plan-view schematic of the micromotor in Fig. 8.5.9 and describes the micromotor operation. At the end of a phase excitation, the rotor is fully aligned with the excited stator phase (e.g., the configuration shown in Fig. 8.5.18 for alignment of rotor pole set 1 with stator phase B). To move the rotor clockwise,

FIGURE 8.5.18 Plan-view schematic of the micromotor shown in Fig. 8.5.9.

stator phase C is excited next. To move the rotor counterclockwise, stator phase A would be excited next. Proper commutation of the excitation signal results in continuous rotation of the rotor. The operation of these micromotors relies on the storage of electrical energy in a variable rotor-stator capacitance. The change in this capacitance in the direction of motion is proportional to the output torque of the micromotor. In terms of design, one strives for optimum torque generation by enhancing the capacitance change in the direction of motion. Very rough estimates of the micromotor motive torque can be calculated by parallel-plate approximations. More accurate calculations of torque have been performed by finite element analysis.⁵⁰

A detailed discussion of the evolution of polysilicon micromotors in terms of design and operational characteristics is documented elsewhere,^{51–55} and a review of the micromotor technology is available in Ref. 49. In sum, the evolution in the design of variable-capacitance micromotors has been motivated by enhanced rotor stability, simpler fabrication processes, and increased torque. The former two are achieved at the cost of sacrificing the latter by using the side-drive architecture shown above. Some of the torque is regained by going from a salient-pole to a wobble (Fig. 8.5.19) micromotor design.^{49,51,52,55} The structural design of a wobble micromotor is identical to that of the salient-pole (see Fig. 8.5.20) showing the micromotor cross-section), except that the rotor and stator designs are different. For the wobble micromotor, the rotor has no poles (or no saliency). The central feature of the wobble micromotor is that the rotor wobbles around the center bearing post as the excitation voltage is moved on the stator poles. Since there is a finite bearing clearance, the rotor's wobbling motion will also result in a rotation of the rotor.

Table 8.5.2 presents typical dimensions of electrostatic polysilicon micromotors. The reader is referred to Refs. 51, 53, and 56 for a detailed discussion of micromotor design and to Ref. 49 for a review of the micromotor technology.

Micromotor operation has been demonstrated in dielectric liquids (e.g., deionized water and silicone oil),⁵⁷ as well as in gaseous environments (e.g., nitrogen, argon, oxygen, and room air).⁵⁸ The performance and

FIGURE 8.5.19 A photomicrograph of a wobble micromotor having a 100- μm diameter.

lifetime of micromotors have been improved significantly over time. Excitation voltages as low as 30 V have been sufficient in operating some current micromotors.^{57,58} Open-loop operational stepping speeds up to 15,000 rpm have been reported for operation in a gaseous environment.⁵¹⁻⁵⁷ The maximum attainable speeds for operation in gaseous environments have been limited by the power supply and not the micromotor. Micromotor lifetime has been extended to many millions of cycles over a period of several days for operation in room air or silicone oil.^{55,57} For these micromotors, a clear failure point has not yet been identified even though some micromotors have been tested for a few hundred million start-stops. Dynamic friction torque is below 10 percent of the micromotor motive torque⁵⁴ and wear is not presently a limiting factor in micromotor operation.⁵⁵ The motive torque of the side-drive micromotors is typically on the order of tens of pico-Newton-meters (pN-m).

FIGURE 8.5.20 Schematic drawing of the cross section of salient-pole and wobble micromotors of Figs. 8.5.9 and 8.5.19.

TABLE 8.5.2 Typical Micromotor Dimensions

Parameter	Value
Rotor/stator gap (μm)	1.5–2.5
Rotor inner radius (μm)	10–20
Rotor outer radius (μm)	50–75
Bearing clearance (μm)	0.3–0.8
Rotor to substrate gap (μm)	2–2.5

SECTION 9

RADIANT ENERGY SOURCES AND SENSORS

Radiant energy sources include both coherent and noncoherent sources. Noncoherent sources are typically traditional light sources for illuminating applications, but also include light-emitting diodes. Lasers, on the other hand, rely on coherent emission that produces a beam that is highly collimated and highly monochromatic.

Semiconductor laser diodes represent a class of lasers especially useful in optical computing applications, optical sensors, optical disc systems, and materials processing. They are small and highly efficient. When the laser diode is forward biased, incoherent light emission takes place until the drive current reaches a threshold value. Below threshold, the device is similar to a light-emitting diode (LED). Above threshold, lasing takes place and the light output increases rapidly with current. A completely new segment on semiconductor laser diodes begins on p. 9.31.

This section also includes a chapter on cathode-ray tubes and electroluminescent displays, with valuable complementary material on the accompanying CD-ROM covering electro-optics and nonlinear optics, phosphor screens, photoemissive electron tubes, and camera tubes.

Four chapters treat radiant energy sensors. Photoconductive and semiconductor junction detectors convert electromagnetic energy to electric energy. Charge-coupled-device and charge-injection-device image sensors are applicable to high- and low-light-level imaging, spatial character recognition, and facsimile reproduction. Infrared detectors include both thermal detectors and quantum detectors, and often require cryogenic cooling to reduce noise. Solar cells may be used in quantity for power generation or individually as light detectors in applications such as cameras. D.C.

INTRODUCTION

Glossary

Generation of light. Light is produced by the transition of electrons from states of higher energies to states of lower energies. The law of conservation of energy is satisfied in these transition processes by the emission of a photon, or quantum of light, whose energy corresponds to the difference in energy of the initial and final energy states of the electron.

Blackbody radiation. A blackbody is defined as a body which, if it existed, would absorb all and reflect none of the radiation incident on it. It is thus a perfect absorber and a perfect emitter. The blackbody curves for several values of T are plotted on a logarithmic scale in Fig. 9.1.1.

The total emissivity ϵ of a thermal radiator at a given temperature is the ratio of the total radiation output of that radiator to that of a blackbody of the same temperature.

The spectral emissivity $\epsilon(\lambda)$ of a thermal radiator is defined as the ratio of the output of the source at the wavelength λ to that of a blackbody at the same wavelength and operating temperature.

Graybody radiation. If the emissivity of a thermal radiator is a constant less than 1 for all wavelengths, the radiator is called a graybody.

Selective radiation. A thermal radiator whose spectral emissivity is not constant but is a function of wavelength is called a selective radiator.

The color temperature of a thermal radiator is the temperature of a blackbody chosen such that its output is the closest possible approximation to a perfect color match with the thermal radiator. Figure 9.1.2 shows the spectral distribution of a tungsten filament operating at a color temperature of 3000 K compared with a blackbody of the same temperature and a graybody whose emissivity is the same as tungsten in the visible spectrum.

The candela (cd) is the unit of luminous intensity. Luminous intensity is the amount of luminous flux per unit solid angle in a given direction. This is measured as the luminous flux on a target normal to the direction of incidence divided by the solid angle (measured in steradians, abbreviated sr) subtended by the target as viewed from the source.

The lumen (lm) is the unit of luminous flux. It is equal to the flux in a unit solid angle from a uniform point source of 1 cd intensity.

FIGURE 9.1.1 Blackbody distribution curves for several values of temperature in kelvins.

FIGURE 9.1.2 Spectral distribution of tungsten at a color temperature compared with blackbody and graybody of the same temperature.

The luminous efficacy of a light source is the measure of light-producing efficiency of the source. It is the ratio of the total luminous flux output to the total input power of the source. Luminous efficacy is measured in lumens per watt.

Radiative efficiency of a light source is the ratio (in percent) of total output power of the source measured in watts to the input power to the source.

Incandescence. Emission of radiation relating to the temperature of the source.

Luminescence. Emission of radiation relating to causes other than temperature of the source.

Fluorescence. Luminescence stimulated by radiation, not continuing more than about 10^{-8} s after the stimulating radiation is cut off.

The most commonly used light sources are the tungsten filament, electric discharge and electroluminescent lamps, and solid-state or light-emitting diodes. The first source is incandescent; the others are luminescent.

Tungsten-Filament Lamps

Filament. The higher the operating temperature of a solid filament, the higher the percentage of its radiation that falls in the visible portion of the electromagnetic spectrum. Tungsten, with its high melting point (3653 K), low vapor pressure, and other favorable characteristics, is the most frequently used filament material. In higher-power incandescent lamps (generally above 40 W) an inert gas instead of vacuum surrounds the filament to reduce the evaporation rate of the tungsten.

Lamp Types. Tungsten filament lamps are divided into the following categories: general-service lamps; high- and low-voltage lamps; series-burning lamps; projector and reflector lamps; showcase lamps; spotlight, floodlight, and projection lamps; halogen-cycle lamps; and infrared lamps.

Tungsten halogen-cycle lamps have a quartz envelope and use a halogen fill, usually iodine, to keep the bulb clean by chemical reaction with sublimated tungsten. This reaction provides a high-lumen maintenance

FIGURE 9.1.3 Interrelation of lamp parameters for large tungsten-filament lamps. (General Electric Co.)

throughout the life of the lamp by redepositing evaporated tungsten on the filament instead of on the bulb. *Infrared lamps* are tungsten-filament lamps that operate at low filament temperature.

Lamp Parameters. The quantities voltage, current, resistance, temperature, watts, light output, efficacy, and life of a filament lamp are interrelated, and one cannot be changed without changing the others. Figure 9.1.3 shows how these quantities change typically as a function of the voltage for large gas-filled lamps.

Some useful exponential relations frequently applied to incandescent filament lamps, where capital letters indicate normal-rated values, are

$$\frac{\text{life}}{\text{LIFE}} = \left(\frac{\text{VOLTS}}{\text{volts}} \right)^d \qquad \frac{\text{lumens}}{\text{LUMENS}} = \left(\frac{\text{volts}}{\text{VOLTS}} \right)^k$$

$$\frac{\text{LM/W}}{\text{lm/w}} = \left(\frac{\text{VOLTS}}{\text{volts}} \right)^g \qquad \frac{\text{watts}}{\text{WATTS}} = \left(\frac{\text{volts}}{\text{VOLTS}} \right)^n$$

For approximate calculations the following average exponents may be used: $d = 13$, $g = 1.9$, $k = 3.4$, and $n = 1.6$.

Electric-Discharge Lamps

Fluorescent Lamps. Fluorescent lamps are electric-discharge lamps in which light is produced through the excitation of phosphors by the ultraviolet energy from a mercury arc. The lamp usually consists of a phosphor-coated tubular bulb with electrodes sealed into each end and containing mercury vapor at low pressure along with an inert starting gas such as argon or an argon-neon mixture. Various colors, grades of white light, and even black light (near ultraviolet) are obtained by the choice of available phosphors. Cool white is the most widely used white-light fluorescent tube.

Lamp types. Fluorescent lamps are classified as *hot-cathode* or *cold-cathode* type. There are three classes of hot-cathode fluorescent lamps: *preheat*, *instant-start*, and *rapid-start*. Preheat lamps allow preheating of the cathodes for a few seconds before striking the mercury arc. Instant-start lamps require no preheat because sufficient voltage is applied between the electrodes to strike the arc very quickly. Rapid-start lamps have continuously heated cathodes requiring a lower voltage than instant-start lamps. This feature also allows dimming and flashing of the lamp.

Mercury Lamps. Mercury vapor discharge lamps of the wall-stabilized variety are used primarily for general lighting. Mercury lamps with additives such as the metal halide lamp and sodium vapor lamp and mercury compact arcs are treated in separate succeeding paragraphs. Most mercury vapor lamps have two bulbs. The inner bulb, called the *arc tube*, contains the arc and the electrodes between which the arc burns. The outer bulb protects the arc tube from drafts and stabilizes the operating temperature. Mercury lamps for general lighting are available in input power sizes from 50 to 3000 W.

In addition to mercury in the arc tube, an easily ionized inert gas such as argon is present to facilitate starting. The arc is generally ignited through use of a starting electrode and current-limiting starting resistor. An arc is first struck between the starting electrode and the adjacent main electrode. The heating and additional ionization resulting from this arc allow the large arc to form between the main electrodes.

Electrical and radiation characteristics. The color-rendering properties of a clear mercury lamp are only fair, owing to the line structure in the blue end of the spectrum. A clear mercury lamp of 1000 W input power has a typical initial luminous efficacy of 56 lm/W.

Metal Halide-Mercury Vapor Lamps. Metal halide-mercury vapor lamps are very nearly the same as regular mercury lamps except that additives such as the iodides of sodium, thallium, and indium are contained in the arc tube for the purpose of improving color rendition and efficiency. The typical initial luminous efficacy of a metal halide-mercury lamp of 1000 W input power is 90 lm/W.

High-Pressure Sodium Vapor Lamps. High-pressure sodium vapor lamps are presently the most efficient source of artificial light. A typical 1000-W high-pressure sodium lamp has an initial luminous efficacy of 140 lm/W. The theoretical efficiency of white light in the visible region, assuming 100 percent conversion of power into a continuum output, is 220 lm/W. Typical life of high-pressure sodium lamps is 12,000 to 20,000 h.

High-pressure sodium lamps require a high-transmission ceramic envelope such as alumina to contain the alkali metal at high temperature and an alkali-resistant high-temperature metal seal. The corrosive effects of sodium at high operating temperature prohibit the use of quartz and other glasses as an arc-tube material. Xenon is used as the readily ionized starting gas. When the xenon starting gas is ionized, the arc is struck, producing heat, and the vapor pressure starts to rise.

Arc-Light Sources. (a) *Short-arc or compact-arc lamps* are of the enclosed-bulb type. Most are made for dc operation, which results in long life and good arc stability. They have high operating pressure, a comparatively short arc gap, and very high luminance (photometric brightness). The arc length may vary from about $1/3$ to 17 mm. Since these lamps have the highest luminance of any continuous-operation light source and provide maintenance-free, clean operation, they have replaced the carbon arc in many applications.

Mercury short-arc lamps contain a low pressure of inert gas such as argon for starting. After the arc is struck, the lamp warms up and the mercury vapor reaches full operating pressure within a few minutes. Warmup time is reduced to approximately one-half of that of the mercury arc if xenon at 1 atm or more pressure is added. The spectra of mercury and mercury-xenon lamps are essentially the same. The luminous efficacy of these lamps is about 50 lm/W for a 1000-W lamp. These lamps are available in a power range from 30 to 5000 W.

Xenon short-arc lamps are filled to a cold pressure of several atmospheres with high-purity xenon gas. Operating pressure is roughly double the cold pressure. These lamps do not have as long a warmup time as the metal vapor types; 80 percent of the light output is obtained within 1 s of startup. Xenon has excellent color-rendering characteristics because of its continuous spectrum in the visible region. Luminous efficacy at 5000 W is approximately 45 lm/W.

(b) *Carbon arcs* are of three basic types: the low-intensity arc, the flame arc, and the high-intensity arc.

The *low-intensity arc* has as its source of light the incandescent tip of the positive carbon, which is maintained near the sublimation point of carbon (3700°C). The heat supplied to the positive carbon is from high-current-density electron bombardment originating from the negative carbon.

The *flame arc* is obtained by enlarging the core of the electrodes of a low-intensity arc and replacing the removed material with compounds of rare-earth elements such as cerium.

The *high-intensity arc* is obtained from the flame arc by increasing the core size and the current density so that the anode spot spreads over the entire tip of the carbon. A crater is formed, and this becomes the primary source of light.

Flashtubes. Flashtubes are designed to produce high-luminance flashes of light of very short duration. They are used in optical pumping of lasers, stroboscopic work, photographic applications, and many other purposes requiring flashing lights.

Lamp construction. The flashtube consists of a glass or quartz tube filled with gas and containing two or more electrodes. The fill gas preferred for most flashtube applications is xenon because of its high output of white light. Other gases, including argon, neon, krypton, and hydrogen, are frequently used.

Driving circuit. Energy for flashing the tube is usually stored in a capacitor. This energy is determined by the equation $E = CV^2/2$, where E = energy (J), C = capacitance (μF), and V = voltage on capacitor (kV). The duration of the flash usually depends on the resistance of the discharge and the capacitance of the storage capacitor, the duration being approximately $3RC$, with R in ohms and C in farads. For short pulses of 1 μs or less duration, frequently the inductance of the tube or circuit is the dominant factor over the resistance in determining pulse length.

Many circuits have been used to flash lamps. One basic method is to hold off a voltage higher than the self-breakdown voltage of the lamp with an electronic switch, such as a thyatron, silicon-controlled rectifier, or spark gap, and trigger the switch when a flash is desired.

Electroluminescent Lamps

An electroluminescent lamp is a thin flat source in which light is produced through excitation of a phosphor by an alternating electric field. The lamp basically consists of a capacitor with a phosphor embedded in the dielectric material sandwiched between two conducting plates. The front plate is a transparent sheet of either plastic, glass, or ceramic with a thin transparent conductive film on it. The back conductive plate may be a metal sheet or film or a transparent material like the front plate.

LIGHT-EMITTING DIODES

Mark Hodapp, David L. Evans, David O'Brien, Jason Yorks

Pn Junction Injection Electroluminescence

The emission of light (photons) from a naturally occurring *pn* junction was first noted by Lassew in 1923. In 1962, studies of GaAs (gallium arsenide) revealed the feasibility of high-level electroluminescent emissions from *pn* junctions (see Holonyak, 1962). The same year, an intensive development program was begun at Hewlett-Packard and elsewhere to produce a useful manufacturable, visible-light-emitting *pn* junction device. The result was the light-emitting diode (LED). LEDs benefit from: (1) useful light output at low currents and voltages; (2) the accuracy with which the light-emitting area can be defined through the use of semiconductor photolithographic processes; (3) the high speed at which the devices can be switched; (4) a lifetime far in excess of an incandescent light source; and (5) the ability to withstand high degrees of shock and vibration.

Operating Mechanism

Light-emitting diode lamps operate much like a silicon or germanium diode. Although they both rectify current, neither silicon nor germanium emits light. When an LED is forward biased, photons are emitted in all directions; however, not all of these photons emerge from the lamps as useful light. The amount of emitted light is dependent upon the material, the geometry of the package, how many photons are absorbed, reflected, refracted, and finally emitted from the lamp.

LED Materials

There are numerous elements and elemental compounds that have bandgap energies capable of producing photon emissions ranging from ultraviolet to infrared. Very few of these materials, however, are practical for LED devices. Some of them are not useful because they cannot be easily doped to form a *pn* junction, some do not emit photons at a useful wavelength, and some have too low a conversion efficiency. Most commercially available LED devices are manufactured from Type 3 elements in the periodic table (Al, Ga, In) and Type 5 elements in the periodic table (N, P, As, Sb); however, a small number of LEDs use Type 4 elements (SiC) and Type 2 (Zn) and Type 6 (Se). Most commercial LED devices use the binary compounds GaAs, GaP, SiC, ternary compounds $\text{GaAs}_{1-x}\text{P}_x$, $\text{Al}_x\text{Ga}_{1-x}\text{As}$, or quaternary compounds $(\text{Al}_x\text{Ga}_{1-x})_{0.5}\text{In}_{0.5}\text{P}$.

Table 9.1.1 lists a few of the materials available for LEDs, their associated bandgaps, emission wavelengths, and transition types. In a direct transition, the electrons in the conduction band and the holes in the valence band both have zero momentum at the point where the energy bandgap between two bands is the smallest. Electrons can easily drop across the bandgap and emit a photon while conserving momentum.

In an indirect transition, the momenta are different at the narrowest point between the bands. To conserve momentum, a phonon (quantum of heat) is either generated or absorbed by the crystal structure. The addition of this extra component reduces the likelihood of recombination, resulting in a less efficient LED. The maximum possible energy of the emitted photon is determined by the bandgap energy of the solid in which the *pn* junction is formed.

Efficiency of LED Devices

The efficiency with which an electroluminescent material converts current flow into detectable photon emission determines whether usable devices can be manufactured from the material. The percentage of current flow, which results in recombination's yielding photons of the desired wavelength, is a measure of the internal conversion efficiency (n_{int}) of the diode, sometimes referred to as internal quantum efficiency (see Craford,

TABLE 9.1.1 LED Semiconductor Materials

Material	Band Gap Energy (eV)	Peak Wavelength (nm)	Transition Type
GaAs	1.43	910	Direct
$\text{GaAs}_{0.6}\text{P}_{0.4}$	1.91	650	Direct
$\text{GaAs}_{0.35}\text{P}_{0.65}$	2.09	635	Indirect

FIGURE 9.1.4 External quantum efficiency of LED materials.

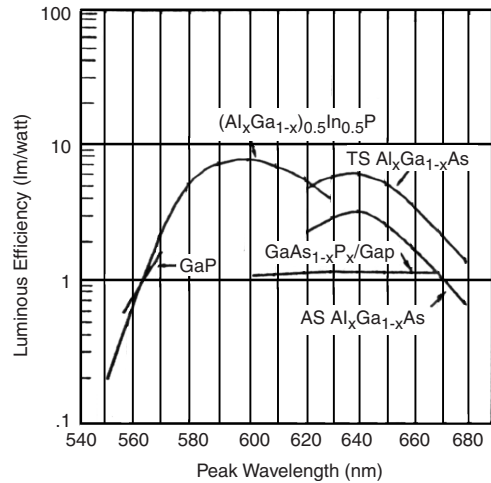

FIGURE 9.1.5 Luminous efficiency of LED materials.

1992). A material that has n_{int} of 100 percent may not be useful if the emitted photons cannot be efficiently coupled from the device.

Two major factors control the internal (n_{int}) to external coupling coefficient (n_{ext}). One factor is direct reabsorption of the emitted photon in the bulk material (basically a measure of the opacity of the material). The other factor is *internal reflection* at the crystal/air interface, causing the photon to be reflected back into the crystal and reabsorbed.

Figure 9.1.4 shows the external quantum efficiency (photons/electron) for a number of LED materials. $GaAs_{1-x}P_x$ grown on a GaP substrate has an external quantum efficiency of about 1 percent. $Al_{0.35}Ga_{0.65}As$ has an external quantum efficiency of 5 to 10 percent depending on whether the substrate is transparent or opaque. $(Al_xGa_{1-x})_{0.5}In_{0.5}P$ has an external quantum efficiency of about 6 percent in the red and orange spectrum.

It is desirable to optimize the total coupling efficiency between the emitting device's input signal and the detecting device's output. A standard emitter is matched to the human eye by picking the wavelength at which the product of the relative response of the eye and the relative efficiency of the diode is largest.

For diodes having shorter peak-emitting wavelengths, such as n -doped GaAsP emitters at 565 nm (green) and 585 nm (yellow), the relative sensitivity of the diode is substantially lower but the relative efficiency of the eye is higher. For visible applications, the efficiency of LEDs is usually specified in terms of lumens per watt or lumens per amp. The numerator, lumens, is a measurement of the total optical flux generated, scaled by the human eye response. The denominator, watts or amps, is the electrical power or current applied to the LED.

Figure 9.1.5 shows the luminous efficiency (lumens per watt) for a number of LED materials. $GaAs_{1-x}P_x$ grown on a GaP substrate has a luminous efficiency of about 1 lm/W. $Al_xGa_{1-x}As$ has a luminous efficiency that peaks at 8 lm/W in the red region. (This corresponds to the wavelength of $Al_{0.35}Ga_{0.65}As$. ($-Al_xGa_{1-x}$) $_{0.5}In_{0.5}P$ has a luminous efficiency of about 8 lm/W in the red and orange regions. (For the sake of comparison, a red filtered incandescent bulb in an auto tail light has a luminous efficiency of about 6 lm/W.)

Real Versus Ideal LEDs

A pn junction in GaAsP material exhibits numerous discrepancies between the ideal and the real. Surface recombination, tunneling phenomena, space charge recombination, current crowding, and bulk recombination because of anomalous impurities tend to reduce the efficiency of an LED. The relative effects of these nonradiative phenomena tend to be dependent on the current density J (amps per square centimeter of junction area),

FIGURE 9.1.6 Cross sections of (a) GaAsP on opaque GaAs substrate; (b) GaAsP or GaP on transparent GaP substrate.

and the perimeter to area ratio of the diode. At low current ($< 1\text{A}/\text{cm}^2$) nearly all the current in a diode may result from one of these nonideal mechanisms.

The net effect of nonideal mechanisms is that an LED has its peak operating efficiency at a current that is dependent on the area and geometry of the junction and the size of the electrical contact. A doubling of current at low current densities may lead to a light output increase of two to three times, whereas a doubling of current at high current densities may result in slightly less than a doubling of light output.

Transparent Versus Opaque Substrates

The photons generated at the junction of a *pn* electroluminescent diode are emitted in all directions. If the diode substrate is opaque, as is the case with GaAs, only those photons that are emitted upward within a critical angle defined by Snell's law will be emitted as useful light. All other photons emitted into or reflected into the crystal will be absorbed. This phenomenon is illustrated in Fig. 9.1.6a.

When compared to GaAs, GaP is nearly transparent. Diodes formed by an epitaxial layer grown on a GaP substrate will exhibit improved efficiency because of the emission of photons that would have been absorbed in the GaAs substrate. The resulting structure is shown in Fig. 9.1.6b.

Similar considerations exist for AlGaAs and AlInGaP LEDs. In the case of DH AlGaAs LEDs, the AlGaAs is grown on an opaque GaAs substrate. For the TS AlGaAs LEDs, the GaAs substrate is removed. The bottom layer of the $\text{Al}_{0.6}\text{Ga}_{0.4}\text{As}$ is transparent to the light emitted in the junction. This is the reason that TS AlGaAs LEDs have twice the luminous efficiency of DH AlGaAs LEDs. The present AlInGaP LEDs use an opaque GaAs substrate. If the substrate was removed, an additional factor of 2 in luminous efficiency could be achieved.

Temperature Effects on LED Parameters

Absolute temperature variation affects an LED's parameters. Those of greatest interest to the user are forward voltage, quantum efficiency, and emitted wavelength. These are discussed in some detail in Hewlett-Packard Application Note, "LED Theory" (see Evans, 1993).

Lamp Packaging

Figure 9.1.7 shows the cross section of a typical LED lamp. The light emitting element consists of a small chip of LED material about 0.010 in. on a side by 0.006 in., mounted in a reflective metal dish. The bottom of the LED is attached to the reflector using an electrically conducting epoxy. The top of the LED is bonded to the second pin of the package with a gold wire. The LED die and lead frame are cast in an epoxy housing. The epoxy package secures the pins of the lamp and contributes to the optical properties of the lamp. A wide range of optical properties can be created by using different lens shapes and positions of the reflector dish in the package, and by adding diffusant to the epoxy.

FIGURE 9.1.7 Cross section showing LED lamp construction.

The mechanical properties of the LED lamp are typically limited by the epoxy package rather than the LED die. The LED die, die attach material, and wire bond are very rugged and can withstand mechanical shock and vibration that would destroy a tungsten filament. However, the epoxy material typically has a higher temperature expansion coefficient than the rest of the lamp, so that temperature cycling at extremely high temperatures can put excessive stresses on the gold wire and wire bond. Today's LEDs are capable of withstanding hundreds of temperature cycles from $-55/100^{\circ}\text{C}$; however, at temperatures above 100°C , the number of survivable temperature cycles is significantly reduced. Consequently most LED lamps recommend a maximum junction temperature of 110°C . The availability of higher temperature epoxies is expected to raise this limit to at least 125°C .

LED Drive Circuits

The LED lamp typically has an electrical characteristic shown in Fig. 9.1.8. Light is generated only when the *pn* junction is forward biased and current flows through the junction. This occurs at the turn-on voltage. At higher voltages, the current increases very quickly. The light output is a function of the current through the LED.

FIGURE 9.1.8 (a) Forward and (b) reverse characteristics of LED lamp.

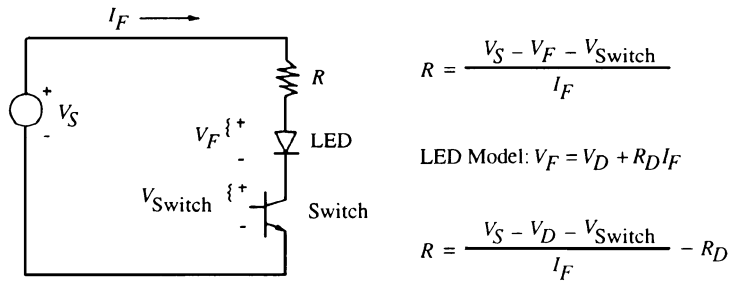

FIGURE 9.1.9 Typical resistive drive circuit for LED.

Under reverse bias conditions, negligible current flows through the LED until the breakdown voltage is exceeded. Higher negative voltages will force a current through the *pn* junction. This breakdown voltage depends on the doping of the *pn* junction and the type of LED materials technology used. Typically, the reverse breakdown voltage is greater than 10 V. If the current is not externally limited, the *pn* junction can be damaged by localized heating within the diode junction.

Most LED drive schemes use a resistor in series with the LED lamp (or string of LED lamps) as shown in Figure 9.1.9. The resistor sets the current to the LED lamp (or string). Most LEDs can be modeled in the forward direction as a resistor in series with a constant voltage, or by the equation described below:

$$V_F = V_D + I_F R_D$$

- where V_F = voltage applied to the LED
- V_D = turn-on voltage of the LED
- R_D = reciprocal of the slope of the I-V characteristics
- I_F = current flowing through the LED

For most LEDs, V_D is in the range of 1.7 to 3.0 V, depending on the color of light generated. R_D typically varies from 1 to 20 Ω , depending on the LED material used.

Then, the current through the LED can be calculated as follows:

$$I_F = (V_S - V_{SWITCH} - nV_F) / R$$

$$= (V_S - V_{SWITCH} - nV_D) / (R + nR_D)$$

- where I_F = current flowing through the LED
- V_S = power supply voltage
- V_{SWITCH} = voltage across transistor switch
- V_F = voltage across the LED
- R = external resistance
- n = number of LED lamps in series

For most LEDs of a given materials technology, V_D is generally very well controlled. This means that the current through the circuit is determined primarily by R and R_D . If R is much larger than nR_D , then the current is controlled primarily by the value of the external resistance R .

LEDs can be driven by a number of other drive circuits including constant current drivers and a variety of pulsed drive circuits (see Hodapp, 1994).

Segmented Displays and Multi-indicator Applications

LED displays and individual lamps are commonly used as information or status indication devices. These products are typically categorized as intelligent or nonintelligent. An intelligent LED display is one that has an

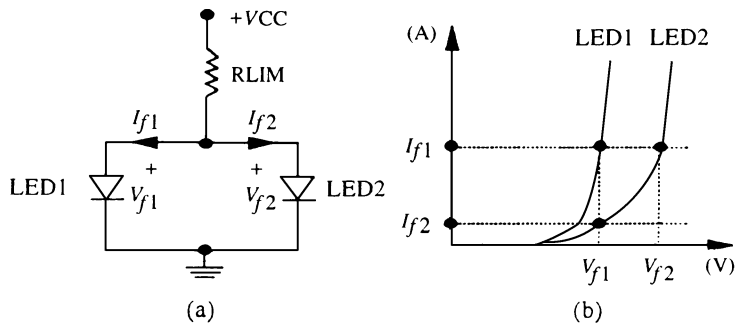

FIGURE 9.1.10 Application circuit: (a) two LEDs in parallel share one current limiting resistor; (b) forward voltage vs. forward current characteristics for the LEDs.

on-board IC integrated with the LEDs, where all the electro-optical biasing of the discrete LEDs has already been provided to the end user. The user varies the brightness of the LEDs by simply changing a combination of 1s and 0s in the control register of the IC. The active semiconductor chips have already been matched by the OEM and thus uniformity is provided. However, a nonintelligent display or individual lamp is made up of semiconductor chip(s), contact wires, and some packaging to provide mechanical stability, environmental protection, and optical lensing. These products are seven and sixteen segment displays, light bars, and discrete lamps. These nonintelligent devices require the designer to determine the electro-optical biasing configuration to achieve a desired brightness and uniformity.

There are important precautions in designing biasing circuits for nonintelligent applications. For example, in an application that requires the use of two or more LEDs of the same color, and luminous uniformity is required, it is recommended that the designer *not* place the LEDs in parallel with each other and in series with the same current limiting resistor (RLIM). Figure 9.1.10 depicts this situation. The mismatched LEDs can result in a discernible difference in brightness between the two. In this case LED 1 will appear to be brighter than LED 2 if the current ratio is greater than 2 to 1. This and other problems related to variations in the V_f versus I_f characteristics of a given LED are treated in the literature (see York, 1994).

LEDs and Light Guides

A light guide is a device designed to transport light from a light source to a point at some distance with minimal loss. Light is transmitted through a light guide by means of total internal reflection. Light guides are usually made of optical grade materials such as acrylic resin, polycarbonate, epoxies, and glass. A light guide can be used to transmit light from an LED lamp on a pc board to a front panel for use as status indication, can be used to collect and direct light to backlight an LCD display or legend, and can be used as the means to illuminate a grid pattern on a see-through window (see Evans, 1993).

Bart H. Verbeek**

LASER FUNDAMENTALS

James E. Miller, Daniel S. Horowitz

Laser Light Versus Nonlaser Light

The main characteristic of laser light is coherence, although laser light is usually more intense, more monochromatic, and more highly collimated than light from other sources.

Coherence is the property wherein corresponding points on the wavefront are in phase. A coherent beam can be visualized as an ideal wave whose spatial and time properties are clearly defined and predictable. Ordinary noncoherent light consists of random and discontinuous phases of varying amplitudes. The noncoherent beam has an average intensity and a predominant wavelength, but it is basically a superposition of different waves. The characteristic grainy appearance of laser light is a result of interference effects that result from coherence.

Intensity of laser light can be very high. For example, power densities of over 1000 MW/cm² can be obtained. A beam of such intensity can cut through and vaporize materials.

A laser beam is often highly *monochromatic* and highly *collimated*, both varying with the type of laser.

Stimulated Versus Spontaneous Emission

The laser operates on the principle of stimulated emission, an effect which is rarely observed except in connection with lasers.

Spontaneous Emission. This is the usual method whereby light is emitted from excited atoms or molecules. Assume that the laser material has energy levels, which can be occupied by electrons, that the lowest level or ground state is occupied, and that the next upper level is unoccupied. An excitation process can then raise an electron from the ground state to this upper state. The electron, after a variable time interval, returns to the ground state and emits a photon whose direction and phase of the associated wave are random and whose energy corresponds to the energy difference between the states. The upper-level lifetime may be comparatively short (less than 10 ps) or it may be long (greater than 1 μ s), in which case the level is referred to as *metastable* and the light emission is *fluorescence*.

Stimulated Emission. When the electron is in the upper level, if a light wave of precisely the wavelength corresponding to the energy difference strikes the electron in the excited state, the light stimulates the electron to transfer down to the lower level and emit a photon. This photon is emitted precisely in the same direction,

9.16 RADIANT ENERGY SOURCES AND SENSORS

and its associated wave is in the same phase as that of the incident photon. Thus a travelling wave of the proper frequency is produced, passing through the excited material and growing in amplitude as it stimulates emission.

Pumping and Population Inversion

The process of exciting the laser material (raising electrons to excited states) is referred to as *pumping*. Pumping can be done optically using a lamp of some kind, by an electric discharge, a chemical reaction, or in the case of the semiconductor laser, by injecting electrons into an upper energy level by means of an electric current.

A *population inversion* is necessary to initiate and sustain laser action. Normally, the ground state is almost entirely occupied and the upper level or levels, assuming they are more than a few tenths of an electron volt above the ground state at room temperature, are essentially unoccupied. When the upper level has a greater electron population than the lower level, a population inversion is said to exist. This inverted population can support lasing, since a traveling wave of the proper frequency can stimulate downward transitions and the associated energy can be amplified.

Optical Resonators

The addition of a positive-feedback mechanism to a lasing medium permits it to serve as an oscillator.

The Fabry-Perot Resonator. The Fabry-Perot resonator that provides optical feedback consists of two parallel mirrors, the rear mirror fully reflecting and the front mirror partly reflecting and partly transmitting at the laser wavelength. The light reflected back from the front and rear mirrors serves as positive feedback to sustain oscillation, and the light transmitted through the front mirror serves as the laser output. Laser action is started by spontaneously emitted light with the proper direction to travel down the axis of the laser rod and be reflected on itself from the end mirrors. The two mirrors form an optical cavity which can be tuned by varying the spacing of the mirrors. The laser can operate only at wavelengths for which a standing-wave pattern can be set up in the cavity, i.e., for which the length of the cavity is an integral number of half wavelengths. Mirrors may be separate from the laser rod or deposited on its end faces.

Spectral Modes. Spectral modes, i.e., a multiplicity of radiation patterns, are permitted within the cavity. Longitudinal modes, determined by the spacing of the mirrors, occur at each wavelength for which a standing-wave pattern can be set up in the cavity. Transverse modes vary not only in wavelength but also in field strength in the plane perpendicular to the cavity axis. The longitudinal, or axial, mode structure determines the spectral characteristics of the laser, i.e., the coherence length and spectral bandwidth, while the transverse-mode structure determines the spatial characteristics, e.g., beam divergence and beam energy distribution.

If no attempt is made to control the mode of the laser, many longitudinal modes will be seen in the output. These modes lie within the natural spectral line width of the laser transition (Fig. 9.2.1). The transverse modes depend on the physical geometry of the cavity and are denoted similarly to waveguide modes at microwave frequencies. The lowest-order mode, characterized by a narrow, diffraction-limited beam spread, is the transverse electromagnetic (TEM_{00}) mode. Higher-order modes have multilobe intensity patterns and wider beams.

Mode control, or selection, is achieved by a variety of methods, e.g., varying the mirror curvatures, restricting the beam by apertures in the cavity, using resonant reflectors that reflect only a narrow band of wavelengths, and using Q -switching techniques.

Generation of Laser Pulses

The typical output of an optical laser consists of a series of spikes occurring during the major portion of the time the laser is pumped (Fig. 9.2.2). These spikes result because the inverted population is being alternately built up and depleted. Q switching (Q spoiling) is a means of obtaining all the energy in a single spike of very high peak power. As an example, an ordinary laser might generate 100 mJ over a time interval of 100 μ s for a peak power (averaged over this time interval) of 1000 W. The same laser Q -switched might emit 80 mJ in a single 10-ns pulse for a peak power of 8 MW. The term Q switching is used by analogy to the Q of an electric circuit. Lowering the Q of the optical cavity means the laser cannot oscillate, and a large inverted population builds up.

FIGURE 9.2.1 Typical spectral modes of an optically pumped laser.

FIGURE 9.2.2 Typical output of an optically pumped laser for Q -switched and non- Q -switched operation.

When the cavity Q is restored, a single “giant pulse” (see Fig. 9.2.2) is generated. This high-peak-power pulse is useful in optical ranging and communication and in producing nonlinear effects in materials.

Q switches use five techniques to inhibit laser action: the mechanical, or movable-optical-element, Q switch; the saturable organic-dye absorber; the electro-optic-effect crystal; the magneto-optic-effect crystal; and the acousto-optic-effect crystal.

All Q switches except the saturable absorber operate by deflecting radiation out of the optical cavity to prevent laser oscillation. The saturable absorber, called a *passive* Q switch because no external signal is required, consists of an organic compound usually in a liquid solution placed between the laser medium and one of the cavity mirrors. The dye is initially very highly absorbing at the laser wavelength, and the laser is isolated from one mirror. The absorbing transition in the dye is saturated as its ground state is depopulated, causing the dye to become transparent, or “bleach.” The rate of bleaching is a strongly nonlinear function of incident radiation, and as the population inversion increases, the dye rapidly switches to a highly transparent state to allow lasing to occur.

Mode locking (phase locking). This technique leads to even shorter pulses. A free-running laser output consists of a time average of many longitudinal and transverse modes with no fixed phase and amplitude relationship. If the laser is constrained to oscillate in only one transverse mode, there are still many longitudinal modes spaced in frequency at intervals of $c/2L$ (L = cavity length), which contribute randomly to the output. The time dependence of the output will be controlled by constraining these modes to maintain a fixed phase and amplitude relationship. A narrow pulse in the time domain requires a wide bandwidth in the frequency domain. The output of a mode-locked laser is a series of pulses, approximately $1/\Delta\nu$ wide, where $\Delta\nu$ is the laser gain bandwidth. These pulses are spaced at intervals of the cavity round-trip transit time.

Frequency Selection

Methods of frequency (or wavelength) selection vary with the type of laser. The following techniques are typical. For solid-state lasers, the output frequencies are limited to a few sharp closely spaced lines. The wavelength of these lines depends on the active ion in the laser, and the specific wavelength is chosen by a highly selective dielectric mirror or a dispersive prism used as part of the optical cavity. Liquid lasers have broad emission bands, several tens of nanometers wide. The output wavelength can be continuously tuned within this band by an intracavity prism or diffraction grating.

Semiconductor lasers have narrow emission bands determined by the constituents. For a given semiconductor, the output wavelength can be varied by changing the temperature. Gas lasers emit discrete lines at wavelengths depending on the gas. Specific lines are chosen by a diffraction grating or prism. Some gas lasers are pumped by a second gas laser. The wavelength of this type of laser is controlled by the wavelength of the pump laser as well as the cavity elements described previously.

CLASSES OF LASERS AND THEIR BASIC APPLICATIONS

Richard R. Shurtz II

Primary Characteristics of the Laser Classes

Lasers can be divided into the four basic categories shown in Table 9.2.1: gas, solid-state optically pumped, liquid dye, and semiconductor. Combined, these lasers cover the spectral region from ultraviolet (0.1 μm) to far infrared (1000 μm), available wavelengths most densely populating the visible to infrared region.

The rapid development of new lasers over the past several years has created a dynamic and continually changing ensemble of devices available to the applications engineer. This set has stabilized as the most useful lasing systems have become known commodities and commercially available. In this section we quantify this established set of commercial devices and outline the primary applications base of each laser type. The reader should be able to identify the laser system best suited for a particular application and then refer to the appropriate paragraph for more specific information.

Gas lasers, shown in the top bar of Table 9.2.1, have the broadest spectral coverage.

The solid-state optically pumped laser category spans the visible to near infrared region. This is the only laser class that can be *Q*-switched or cavity-dumped. The electronic transitions are pumped either by flash lamps or by semiconductor diodes.

The family of *optically pumped organic-dye lasers* extends in wavelength from 0.4 to 1 μm . The major distinction of the category is its continuous tunability over the entire visible spectrum. Because of their

broadband spectral output, these lasers can generate subpicosecond pulses when mode-locked. Their primary use is in spectroscopy and photochemistry.

Semiconductor lasers are pumped by the injection of excess electrons and holes into a thin semiconductor layer. Radiation is produced when the excess carriers recombine, producing photon energies equal to the bandgap energy. Lead salt laser diodes operate from 4 to 30 μm , continuously tunable either by varying the drive current or the temperature. They are used primarily for spectroscopy and must be cooled to nominally 77 K during operation. The shorter-wavelength semiconductor lasers are formed from III-V compounds: gallium arsenide (GaAs), gallium aluminum arsenide (GaAlAs), and gallium indium arsenide phosphide (GaInAsP). These devices, either pulsed or cw, operate at room temperature.

Single III-V compound laser diodes are used for fiber-optic communication, integrated optical processing, and rangefinding. Arrays of diodes are used for low-power infrared illuminators.

Characteristics of commercially available pulsed and cw lasers are summarized in Tables 9.2.2 and 9.2.3. The ranges shown are based on tables published in laser buyers' guides. A few key lasers have been selected to illustrate the essential properties of each laser category, as discussed in the previous paragraphs.

TABLE 9.2.3 Properties of Commercially Available Continuous Wave (cw) Lasers

Laser	Type	Wavelength, μm	Power, W		Beam diam, mm	Beam divergence, mrad

Laser Applications

Laser applications can be divided into several general categories: measurement of spatial parameters, material heating and/or removal, nondestructive probing of resonant phenomena, communications, optical processing, laser-induced chemical reactions, and weapons. Selected laser applications are shown in Table 9.2.4.

SOLID OPTICALLY PUMPED LASERS

Edward J. Sharp

Basic Principles

A solid optically pumped ionic laser consists of a solid material with optical gain, situated inside a resonator formed by two or more mirrors. Spontaneous emission in the material is amplified by stimulated emission. The resonator provides the feedback for the optical amplifier, resulting in a laser oscillator. The optical arrangement for a typical optically pumped laser is shown in Fig. 9.2.3.

These devices generally consist of a pump reflector enclosing the laser rod and optical pump in one of the number of efficient ways which is usually determined by the application or laser property to be exploited. The laser rod is pumped by flash lamp for pulsed operation and usually by arc lamps for cw (continuous-wave) operation, or in some cases an appropriate laser can be selected for the optical pump.

Two important conditions must be met: the wavelength region of the pump emission must overlap a significant portion of the absorption spectrum of the active ion or ions which are incorporated in the laser rod, and the optical pump must not damage the laser rod. Figure 9.2.4 illustrates the overlap of pump emissions and the absorption bands of a typical Nd³⁺ four-level laser scheme where pumping is accomplished by xenon-lamp pumping and LED laser pumping.

FIGURE 9.2.3 Typical optically pumped laser configuration. Component A can represent a Q switch, polarizer, or other optical element.

FIGURE 9.2.4 A typical four-level Nd^{3+} laser, in which the Nd^{3+} ions are optically excited by pumping the absorption bands of the ions with (a) a xenon lamp and (b) an LED laser.

Laser Components

Optical Pumps. The general technique of optical pumping has many uses. To achieve population inversion linear, low-pressure flash lamps are the most common pumping device. Typically they have tungsten electrodes and are filled to a few atmospheres pressure with xenon or krypton. For pulsed operation xenon is commonly used but the lines of krypton radiate at wavelengths more favorable than xenon for pumping a neodymium laser at low input levels. Thus it is a more efficient cw pump. At higher input levels, the blackbody spectrum becomes stronger than the emission lines, and this advantage is lost.

Pulsing Electronics. For pulsed operation the energy to be discharged into a flash lamp is stored in a capacitor and discharged through the lamp via a choke whose value is selected to give the desired pulse width with minimum ringing. The spectrum of the lamp discharge depends on the electrical parameters, pressure, and fill gases, so that it can be tailored to match the absorption bands of the active ion to a certain extent.

Coolants. Lasers that operate cw or at a high repetition rate need to be cooled, since most of the energy expended in the flash lamp is converted into heat and would quickly cause overheating and/or thermal cracking of the laser rod. Air and liquids have been successfully used as coolants, liquids being used when cooling requirements are more severe. Distilled or deionized water is often used, and mixtures of water and ethylene glycol are used for operation below 0°C. The coolant circuit includes a pump for circulation and a radiator, often with a fan, to dissipate the heat.

Pumping Reflectors. To obtain maximum use of the pump light, it must be efficiently collected and coupled into the rod. The reflectors used to do this are usually elliptical in cross section, with a rod at one focus and the lamp at the other. Sometimes two lamps are used, in a double elliptical cavity. Often a round cross section is used, resulting in an afocal system. In general, the smallest cross section is best, and the highest efficiency is obtained with a close-coupled arrangement, where the rod and lamp are almost in contact and the reflector encloses them closely. However, in this close-coupled configuration the thermal distortion of the rod owing to the asymmetrical pumping could be a serious problem.

Mirrors. Multilayer dielectric mirrors can be deposited on the laser-rod ends, which are finished flat and parallel. These mirrors are designed for specific reflectivities at the operating wavelengths and eliminate the problem of alignment. The rear-mirror reflectivity is normally 100 percent, but the front-mirror reflectivity is selected for the best performance, determined by laser-material properties, rod size, and operating power level. Where separate mirrors are used (see Fig. 9.2.3) the rod ends should be antireflection-coated or cut at Brewster's angle. Separate or external mirrors must be mounted in holders that permit fine adjustment about two axes to achieve the required parallelism.

Q-Switched Lasers

Q switching, a technique used for generating large output bursts of radiation from laser devices, is accomplished by effectively blocking the optical path to one of the mirrors for most of the time during which the rod is being pumped, causing the rod to store energy. The *Q* switch then quickly restores the optical path to the mirror and a giant pulse (see Fig. 9.2.2) is generated. The four main types of *Q* switches are the rotating mirror, acousto-optical, electro-optical, and saturable absorber.

Rotating Sector, Prism, or Mirror. The rotating prism or mirror requires careful mechanical design to provide rotation at the required speeds (30,000 r/min is common) and still maintain alignment. They are generally less reliable than other methods of *Q* switching, but the extinction ratio is infinite and the insertion loss is negligible, enabling this type of *Q* switch to attain high efficiencies.

Electro-Optic *Q* Switches. An electro-optical crystal, or liquid Kerr cell, can be placed in the optical resonator, usually between the rear mirror and the laser rod (position A in Fig. 9.2.3) along with an appropriate

9.24 RADIANT ENERGY SOURCES AND SENSORS

polarizer to effect the cavity losses. The polarization of the light passing through the electro-optic medium is changed by the application of an applied electric field and is rejected by the polarizer. When the voltage is removed, the cavity losses are reduced, permitting giant-pulse radiation.

Acousto-optic Q switch. An acousto-optic Bragg scattering switch deflects the beam, which is then used to provide feedback during the buildup time. In these devices a standing-wave pattern of ultrasonic waves is set up in a suitable cell positioned in the resonator. The refraction resulting from the passage of a plane-parallel light beam through this ultrasonic field is sufficient to provide shuttering action for infrared lasers, leading to giant-pulse radiation.

Saturable absorber Q switch. These switches are usually bleachable dyes that undergo decreased absorption at high light intensities. They are known as passive *Q* switches since they do not require any electrical or mechanical control. The material is opaque until the fluorescence of the laser rod bleaches it and the optical path is restored for a *Q*-switched pulse.

Ions and Hosts

The current list of ions which can be incorporated into a solid host and made to lase numbers about 20. The total number of different wavelengths available from these ions is approximately 150. The solid host is any crystal or glass that can accommodate trivalent or divalent rare-earth and iron-group ions. The iron-group ions in which laser oscillation has been achieved are divalent nickel and cobalt and trivalent chromium and vanadium. The rare-earth ions in which laser oscillation has been achieved are divalent samarium and dysprosium and trivalent europium, praseodymium, ytterbium, neodymium, erbium, thulium, and uranium.

Characteristics of the Hosts

The host material to which the active ion (dopant) is incorporated can be either crystalline or glass and should exhibit the following properties:

- High thermal conductivity

- Ease of fabrication

- Hardness (to prevent degradation of optical finishes)

- Resistance to solarization or radiation-induced color centers

- Chemical inertness, i.e., not water soluble

- High optical quality, which implies uniformity of refractive index and absence of voids, inclusions, or other scattering centers

Crystalline Hosts. Crystalline hosts offer as advantages in most cases their hardness, high thermal conductivity, narrow fluorescence line width, and, for some applications, optical anisotropy. Crystalline hosts usually have as disadvantages their poor optical quality, inhomogeneity of doping, and generally narrower absorption lines.

Glass Laser Hosts. Glass laser hosts are optically isotropic and easy to fabricate, possess excellent optical quality, and are hard enough to accept and retain optical finishes. In most cases glasses can be more heavily and more homogeneously doped than crystals, and, in general, glasses have broader absorption bands and exhibit longer fluorescent decay times. The primary disadvantages of glass are its broad fluorescence line widths (leading to higher thresholds), its significantly lower thermal conductivity (a factor of 10 leading to thermally induced birefringence and distortion when operated at high pulse-repetition rates or high average powers), and its susceptibility to solarization (darkening because of color centers that are formed in the glass as a result of the ultraviolet radiation from the flash lamps). These disadvantages limit the use of glass laser rods for cw and high-repetition-rate lasers.

Sensitized Lasers

Laser performance and efficiency can be enhanced through the technique of energy transfer. A second ion (sensitizer) is incorporated into the host in addition to the laser ion (activator) to accomplish this effect. The sensitizer may be a color center. Pump energy is absorbed by the sensitizer and is transferred to the activator, which then emits this energy at the laser wave-length.

Miniature Lasers

Several host materials that incorporate Nd as a constituent rather than a dopant, such as $\text{NdAl}_3(\text{BO}_3)_4$, neodymium aluminum borate (NAB); $\text{LiNdP}_4\text{O}_{12}$, lithium neodymium tetraphosphate (LNP); and $\text{NdP}_5\text{O}_{14}$, neodymium pentaphosphate (NdPP), have been studied recently, and since concentration quenching is not appreciable in these materials, they are excellent candidates for miniaturized lasers.

LIQUID LASERS

Patrick R. Manzo

Laser Media

Liquid Lasers. Liquid lasers use a liquid as the laser medium in place of a large single crystal or a gas (Fig. 9.2.5). Their properties are intermediate between those of gaseous and solid lasers. They are easy to prepare in large samples with excellent optical quality, and for certain types their energy output can be as high as 10^8 W peak and several tens of watts average. The wavelength coverage available for certain types of liquid lasers is considerably greater than that of both the solid and the gaseous lasers. There are two types of liquid lasers in common use.

FIGURE 9.2.5 Typical dye-laser configuration.

The *aprotic liquid laser* consists of a rare-earth salt dissolved in an inorganic solvent that does not contain hydrogen. Energy from the excitation source is absorbed by the solvent and then transferred to the rare-earth ion, which lases. The absence of hydrogen in solution greatly increases the efficiency of this energy-transfer process because it lessens the possibility of this energy being transferred into vibrations of the molecule. The output wave-length is that of the rare-earth salt (see Table 9.2.1). In system gain, in output power levels, and in overall efficiencies, the aprotic liquid lasers are comparable with the solid-state lasers. They are capable of extremely high peak powers (10^8 W) and sustained high average powers (50 to 100 W). The principal aprotic liquid laser materials are Nd^{3+} in SeOCl_3 with SnCl_4 or in PoCl_3 with SnCl_4 .

The *dye laser* uses highly fluorescent organic molecules as the laser medium; unlike the aprotic liquid, these molecules do not contain the rare-earth salts. The radiative transition in the dye laser does not originate at a metastable energy level, as in most other lasers, but takes place instead between two singlet electronic states of the molecule. Consequently it is strongly allowed and extremely short-lived—approximately 10 ns compared with several hundreds of microseconds for the rare-earth ions. This requires quite different excitation techniques to achieve laser action. The first organic dye lasers required Q-switched lasers or flash lamps with extremely fast rise times in order to invert the population fast enough to achieve laser action. However, newer techniques alleviate the necessity for such fast excitation sources. Rhodamine 6G and several other dyes have been made to operate in a continuous mode with average power as high as 10 W.

The organic dyes exhibit excellent optical quality in solution, and they are extremely easy to prepare and handle. The absorption and fluorescent bands of the molecule are extremely broad (several tens of nanometers) because of the large number of vibrational and rotational energy levels associated with each electronic energy level. The laser output can be broadband (30 nm wide) or very narrow (0.001 nm).

The very short lifetime of the excited state means that sources must be of very high intensity to cause the dyes to lase. Therefore, the sources used to pump the dyes include high-intensity flash lamps and other lasers. Distortion in the dye because of thermal inhomogeneities requires that the dye be mixed rapidly and exchanged in order to minimize beam spreading and losses during cw and repetition-rate operation. The line width of typical dye materials is homogeneously broadened, and therefore all the stored energy in the upper laser level can be channeled into a spectrally narrow emission line, which can be tuned over the gain profile of the active medium.

Flashlamp-pumped dye lasers have demonstrated average powers as high as 100 W at high repetition rates. Single pulse energies to 10 J per pulse and peak powers to 10 MW have also been demonstrated. Present flashlamp-pumped systems are limited to approximately 1 percent efficiency while the efficiency of laser-pumped dyes is somewhat lower. Average power from a few milliwatts to over 10 W has been achieved in cw operation of laser dyes using pump laser configurations such as the one shown in Fig. 9.2.6a. Frequency-stabilized cw dyes have achieved a line width of less than 1 MHz and long-term stabilities of a few hundred hertz.

With an appropriate selection of dyes, this type of laser can be directly tuned from 340 to 1200 nm. This wavelength range has been extended into the ultraviolet and the infrared by frequency mixing of dye-laser radiation in nonlinear optical materials. Tunable ultraviolet radiation down to 196 nm has been obtained by second-harmonic and sum-frequency generation in nonlinear crystals. In the long-wavelength range the generation of tunable near and middle infrared, as the difference frequency of two laser oscillators, has been successful out to 12.7 μm . It is also possible to produce multiple wavelengths from the same or combination of dyes. Figure 9.2.6b illustrate one scheme for doing so.

It is possible to produce dye laser pulses with a duration of less than 1 ps. Durations as short as 0.3 ps have been reported. In addition, the broad emission bands of dyes make them the only sources capable of producing mode-locked picosecond pulses at high repetition rates which are wavelength tunable over several tens of nanometers.

FIGURE 9.2.6 (a) Schematic of a continuous-wave dye laser; (b) double-wavelength dye laser. The lower portion of the beam is shifted toward the red by the wedge.

GAS LASERS

Gareth M. Janney

General Characteristics

Gas lasers can best be characterized by their variety. The laser medium may be a very pure, single-component gas or mixture of gases. It may be a permanent gas or a vaporized solid or liquid. The active species in a gas laser may be a neutral atom, an ionized atom, or a molecule (including excimers, which are “stable” molecules only in an excited state). The operating pressures range from a fraction of a torr to atmospheric pressure, and the operating temperature from -196 to 1600°C . Excitation methods include electric discharges (glow, arc, pulsed, rf, dc), chemical reactions, supersonic expansion of heated gases (gas dynamic), and optical pumping. The average output power of useful gas lasers range from a few microwatts to tens of kilowatts (10 orders of magnitude), and the peak power ranges from a fraction of a watt to 100 MW. The range of output wavelengths extends from 0.16 to $744\ \mu\text{m}$ at discrete wavelengths.

Multiple Wavelengths

Most gas laser materials have a number of distinct laser transitions (i.e., different wavelengths). For example, the neon atom has more than 100, and the argon ion has more than 30. Lasers using these materials can operate with a multiwavelength output, or one transition at a time can be selected by a simple adjustment (rotating a prism or diffraction grating in the optical cavity). Table 9.2.5 (bottom) shows several commercially available lasers that provide more than one wavelength of operation.

Electrically Excited Electric-Discharge Gas Lasers

Most gas lasers are excited by electric discharges. Electrons that have been accelerated by an electric field transfer energy to the gas atoms and molecules by collisions. These collisions may excite the upper laser level directly. Indirect excitation is also possible by cascading from higher-energy levels of the same atom (or molecule) or resonant-energy transfer from one atom (or molecule) to another by collision.

Typical configuration (Fig 9.2.7). The gas is contained in a glass tube having an electrode near either end. The ends are sealed by windows mounted at Brewster’s angle to minimize reflections at the windows (for one plane of polarization). An optical cavity is formed by two mirrors (usually both are concave), at least one of which is partially transmitting. When an electric discharge is produced in the tube between the electrodes, the gas atoms or molecules are excited and laser action starts. Listed below are some typical parameters for several common types of electric-discharge gas lasers.

Laser species	Gas mixture	Pressure, torr	Current, density A/cm ²
Ne (neutral atom)	He	1.0	0.05–0.5
	Ne	0.1	
Ar (ion)	Ar	0.3	100–2000
CO ₂	He	5–10	0.01–0.1
	N ₂	1.5	
	CO ₂	1.0	

The Transverse-Electric-Discharge Configuration (Fig. 9.2.8). The transverse-electric-discharge configuration is used for some gas lasers, especially for high-average-power, fast-flowing gas lasers. It provides high electric fields at practical voltages while retaining long paths of excited gas.

TABLE 9.2.5 Representative Gas Lasers*

Continuous-wave (cw)				
λ , μm	Laser type	Power, W		Comment
		Typical	Max

Carbon dioxide		9.1–11.3		Several groups of closely spaced lines in this wavelength region; line separations within groups $\sim 0.02 \mu\text{m}$; rotate diffraction grating to select lines one at a time

*Wavelength ranges are sets of discrete wavelengths and simultaneous output at more than one wavelength may or may not be possible.

A pair of long electrodes (or linear arrays of electrodes) is located parallel to the optical axis, within the envelope that contains the gas. The discharge current flows transverse to the optical axis. Lasers employing this configuration include high peak power, pulsed N_2 , Ne, and CO_2 ; high-average-power, fast-flowing CO_2 lasers; and excimer lasers (e.g., XeF, KrF).

E-Beam Lasers. High-energy high-current electron beams are generated in an evacuated high-voltage electron gun. The electron beam passes through a thin metal foil into a chamber containing the gas mixture. As in electric-discharge lasers, some of the kinetic energy of the electrons is transferred directly or indirectly to the laser species (atom or molecule). Electron beams are sometimes used in conjunction with transverse electric discharges.

Chemical Lasers

Chemical lasers derive their energy from the free-energy change of a chemical reaction. The chemical reaction may be initiated by some other source of energy, such as light or electric discharges. Since the chemical reaction consumes the reactants, a flowing system is necessary for repetitive-pulsed or cw operation. Figure 9.2.9 shows an arrangement used to produce high-power, cw laser output from hydrogen fluoride (HF) and other

FIGURE 9.2.7 Electric-discharge gas laser.

FIGURE 9.2.8 Transverse-electric-discharge gas laser.

9.30 RADIANT ENERGY SOURCES AND SENSORS

FIGURE 9.2.9 Fast-flowing chemical laser.

molecules. A series of chemical reactions is required to sustain the laser operation in practice, but in simplified form the reaction can be expressed as

where F_2 = reactant, 1

H_2 = reactant 2

ΔE = free-energy change, some of which is in the form of vibrationally excited HF molecules

Laser action occurs on vibrational transitions of the HF molecule in the wavelength region 2.6 to 2.9 μm . Chemical lasers of this general type are potential sources of high average power (multikilowatt).

Gas Dynamic Lasers

The expansion of a hot, high-pressure mixture of CO_2 and N_2 through a supersonic nozzle results in a lowering of the gas temperature in a time which is short compared with the vibrational relaxation time of the CO_2 molecule. A differential relaxation time between the upper and lower laser levels results in a population inversion for a short distance downstream from the supersonic nozzle, and laser operation in this region is possible. Average output power of 60 kW at 10.6 μm has been obtained from such a device.

Properties of the Gas-Laser Output Beam

Wavelength and Frequency. It is customary in laser terminology to refer to a laser transition by its wavelength (in micrometers or nanometers) and to discuss the fine structure of the transition in terms of frequency. Wavelength λ and frequency ν are related by $\lambda\nu = c$, where c is the velocity of light. The wavelength of a laser transition, as well as the wavelength interval or width of the transition over which optical gain exists, is a property of the laser atom or molecule. The transition width is also related to gas temperature and pressure. Typical widths of common gas lasers are:

Laser	λ , μm	Line width, MHz
HeNe	0.6328	1700
	1.15	920
	3.39	310
Ion laser	0.5	2500–3000
CO_2 low-pressure	10.6	60
	High-pressure	10.6

Oscillation can occur at discrete frequencies (cavity modes) at frequency spacings of $\Delta\nu = c/2L$, where L is the separation of cavity mirrors. Depending on the nature of the laser medium and the geometry of the optical cavity, oscillation may occur at a number of different modes, within the line width of the transition. For example, for helium-neon at 0.6328 μm , with a cavity-mirror spacing of 100 cm, the mode spacing is 150 MHz, and 11 (axial) modes could oscillate. Single-axial-mode oscillation is generally achieved by reducing L so that only one axial mode lies within the line width of the laser transition. A stable optical cavity is required for both frequency and amplitude stability.

Available Gas Lasers

Of the many commercially available gas lasers (over 35 gas-laser species), four groups are most common: (1) low-power (few milliwatts) visible cw, including helium-neon (He-Ne) and helium-cadmium (He-Cd);

(2) medium-power (few watts), visible cw, including argon-ion (Ar^+) and krypton-ion (Kr^+); (3) medium- to high-power (10 to 10^4 W) infrared, cw, primarily carbon dioxide (CO_2) and ultraviolet wavelengths (rare gas halogen excimers, XeF, KrF, and so forth). These lasers along with a selected listing of other gas lasers are included in Table 9.2.5, which is arranged by wavelength, with cw and pulsed lasers listed separately. For many of the lasers, both the typical and the maximum available power or energy levels are given.

SEMICONDUCTOR LASER DIODES

Bart H. Verbeek

Introduction

Semiconductor laser diodes, or laser diodes in short, represent key components in the field of opto-electronics including optical communication, optical sensor technology, optical disc systems and material processing. They represent the smallest and most efficient of all lasers since it is based on the injection of carriers in a semiconductor *pn*-structure in combination with an optical cavity/resonator formed by the same semiconductor material. The *pn*-junction is operated in the forward direction and the injected carriers recombine at the *pn*-junction giving rise to the emission of photons. If the carrier density reaches a critical value, the light will be amplified and will yield in laser light emission. The injection current at which the laser start lasing is called the threshold current of the laser. The recombination of electrons and holes takes place in the active layer, sandwiched between a *p*-doped and *n*-doped cladding layer as shown in Fig. 9.2.10. These thin layers (= microns) are grown by epitaxial growth techniques on a semiconductor single crystal substrate with low defects. The dimensions of the laser chip are in the order of a few hundred micron (grain of salt size) but the active layer is much smaller (typically $1.5 \times 0.2 \times 250 \mu\text{m}$). Top and bottom of the laserchip are metallized to provide low ohmic contacts to the semiconductor material.

Since the laser diode is a small device and the aperture of the *optical beam* is in the order of the wavelength the light beam is divergent (Fraunhofer Diffraction). Semiconductor lasers require therefore a lens to couple the light from the chip into, e.g., an optical fiber or to generate a parallel beam. These lenses are usually provided in fiber-coupled packages together with a temperature stabilization unit (TEC). If the lens is not provided with the package (like TO-can type), external optics are required.

Laser diodes can be operated in the following modes:

FIGURE 9.2.10 Schematic of semiconductor laser chip. The central area is the active layer surrounded by cladding layers. Top and bottom are metallized to provide electrical current injection. The laser light is a divergent beam because of diffraction emitted from the edge of the crystal. In the inset the definition of the transversal/lateral and longitudinal directions of the laser is given.

Continuous Wave (CW). A DC current flow will generate continuous emission of coherent light.

Amplitude Modulation. By modulation of the injection current, the optical output power can also be modulated. This is called direct modulation of the laser diode. Both analog as well as digital signals can be generated up to frequencies of 15 GHz.

Frequency Modulation. If a small ac injection current is applied to the dc current, the frequency of the emitted light is modulated (typically 100 MHz/mA), which can be employed in, e.g., FM transmission systems or suppressing Stimulated Brillouin Scattering in high-power optical transmission links.

Semiconductor lasers cover a wide spectrum in *emission wavelength* ranging from blue (450 nm) to be used in next-generation optical storage systems, via visible (red 633–650 nm), infrared (780–850 nm), IR (980 nm pump lasers), 1310, 1480, and 1520–1600 nm telecom wavelength) to FIR (>2000 nm for spectroscopy). Different semiconductor materials are used to achieve these wavelengths as will be discussed in the next sections.

Semiconductor Physics Background

Materials. In contrast to other lasers where the radiative transitions occur between atomic or molecular energy levels, semiconductor laser transitions occur between electronic bands, namely, the conduction band and valence bands of the semiconductor crystal. In particular, group III-V and II-VI compounds are *direct* semiconductors with efficient light-emitting characteristics (e.g., Si is an indirect semiconductor and does not radiate efficiently). Various III-V and II-VI materials are available; their ability to form solid solutions opened the possibility to vary the compositions in order to obtain the desired variations in bandgap and in refractive index, while maintaining lattice matching to the substrate. In Fig. 9.2.11 the solid dots represent the relationship between the bandgap E_g and the lattice constant of binary III-V compounds containing Al, Ga, or In and P, As, or Sb, and II-VI materials containing Cd or Zn and S, Se or Te, respectively. Since the photon energy E is approximately equal to the bandgap energy, the lasing wavelength λ can be obtained using $E_g = hc/\lambda$, where h is the Planck constant, and c is the speed of light in vacuum. If E_g is expressed in eV, the lasing wavelength in μm is given by $\lambda = 1.23889/E_g$.

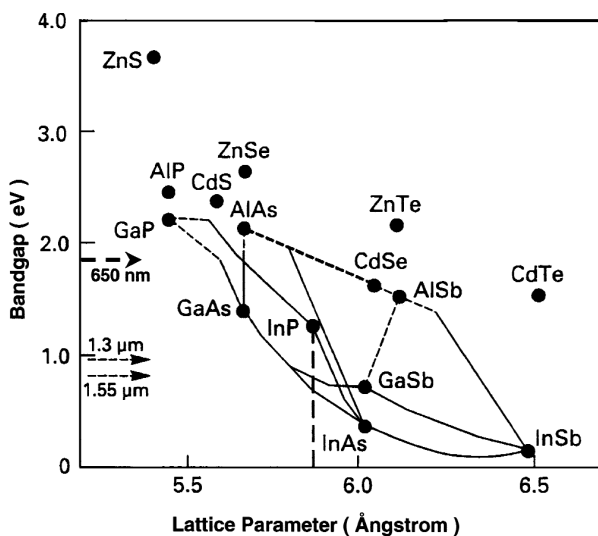

FIGURE 9.2.11 Graph showing the various semiconductor materials for making laser active and cladding layers. For each binary compound the lattice parameter and bandgap energy is given. Lines denote mixed compound solid solutions. As substrate material GaAs and InP are used for most lasers. Arrows indicate bandgap energy for three mostly used wavelength.

TABLE 9.2.6 Semiconductor Materials for Active/Cladding Layers and Their Wavelength Window/Applications

Substrate	Active/cladding layer	Wavelength range (μm)	Applications
GaAs	(Al)GaAs/AlGaAs	0.70–0.88	Optical disc
	(In)GaAs/AlGaAs	0.88–1.1	Pumping
	(In)GaAs/InGaP	0.88–1.1	High power
GaAs	(Al)GaInP/AlGaInP	0.60–0.67	Optical disc
	InGaAsP/AlGaInP	0.65–0.88	Laser printer
	InGaAsP/AlGaAs	0.65–0.88	Barcode/displays
InP	InGaAsP/InP	1.05–1.65	Fiber communication
	(Al)GaInAs/AlGaInAs		
Sapphire/SiC	InGaN/GaN	0.45	Optical disc
GaSb	GaInAsSb/AlGaAsSb	2–5	Spectroscopy laser radar

Figure 9.2.11 shows that the bandgaps and lattice parameters of $\text{In}_x\text{Ga}_{1-x}\text{As}_y\text{P}_{1-y}$ (quaternary) compositions cover the area bound by connecting lines between the binaries InAs, InP, GaP, and GaAs, and can be grown lattice matched to InP and GaAs substrates for certain combinations of x and y . The interrelationships for the ternary $\text{Al}_x\text{Ga}_{1-x}\text{As}$ follow the connecting line between the binary constituents GaAs and AlAs.

Lasers and other optoelectronic devices require a very low defect density in the crystal or else nonradiative processes will dominate over the radiative processes. Therefore, lattice matched crystal growth of the various compound layers on the substrate is essential and is achieved by modern epitaxial growth techniques such as MOVPE, MBE, and CBE. The semiconductor material can be doped with, eg., Zn (Si) to achieve p -type (n -type) doping. All modern semiconductor lasers consist of a double heterostructure in order to achieve high carrier densities at low currents by confining the recombining carriers in a small volume. The active layer is embedded between heterolayers having a larger bandgap—cladding layers. Wavelength ranges and applications for various substrates and active/cladding layers are given in Table 9.2.6. The pn -junction just occurs at the active layer, which has a lower bandgap. By injecting current in the diode, electrons from the n -side and holes from the p -side recombine in the active layer generating photons of the designed wavelength by the bandgap energy E_g (see Figs. 9.2.12a and 9.2.13). In order to reduce the total current, injection only takes place in a stripe of width w (typically 1–2 μm) (see also Fig. 9.2.10). The electrical diode characteristic of the laser is given by

$$I = I_0 \left[e^{(V - IR_s)/nkT} - 1 \right] \quad (1)$$

where R_s is the series resistance of the diode and n is the ideality factor with $1 < n < 2$.

Now that carriers can recombine in the active layer, three processes will occur: (1) spontaneous emission, (2) stimulated emission, and (3) absorption of generated photons. At low injection current processes (1) and (3) dominate and the laser behaves as an LED. Only with sufficient carrier injection, the stimulated emission process will dominate and sufficient amplification of generated photons will occur. If the active layer is placed in an optical cavity preferred directional gain is obtained and laser action is possible. The optical material gain of the active layer is shown in Fig. 9.2.12b versus the wavelength, with increasing injection current as a parameter. With zero injection current, the material absorbs light for shorter wavelengths than λ_g , i.e., this material can be used as a photodetector. With increasing injection current gain is increasing and the maximum of the gain value shifts a little to lower wavelength because of bandfilling effects. For wavelengths beyond the bandgap energy (denoted as arrow) the material is transparent. The 3-dB bandwidth of the gain is typically 80 to 100 nm.

For efficient operation of the laser, the light that is generated in the active layer has to be guided within the laser structure. An optical waveguide is formed by the higher refractive index of the active layer with respect to the surrounding (cladding) layers. For stable laser operation it is required that this waveguide can only support the lowest-order mode (usually the TE_{00} mode) both in the transverse and lateral directions. Design parameters for obtaining a lowest-order mode are: thickness, width, and refractive index of the active layer and

the cladding layers. In Fig. 9.2.13 the transversal index profile and the resulting optical mode are shown. Several numerical tools are available to solve the Maxwell equations for the dielectric waveguide and obtain the optical mode profile in the laser (Near Field), external beam (Far Field), and astigmatism. Usually the optical mode (near Gaussian shape) is larger than the active layer and the fraction of light that travels in the active layer is called the *confinement factor* Γ (see Fig. 9.2.13).

With the gain medium in the active layer and the waveguide description to guide the light in the laser, the next step is the longitudinal *optical cavity*. Since the refractive index of the semiconductor lasers is about 3.3 to 3.4, which is much higher than air ($n \approx 1$), the simplest cavity is formed by cleaving the crystal to form the endfacet-mirrors. The (power) reflection is calculated as $R = [(n - 1)/(n + 1)]^2$ and results in about 30 percent. This value can be modified by applying appropriate dielectric facet coatings like AR or HR coating depending on application. A semiconductor laser based on cleaved facets is referred to as Fabry Perot lasers. Other cavity structures will be discussed later. A FP-cavity allows a set of discrete longitudinal modi which are determined by the condition that in a round-trip an integer number of wavelengths fit within the cavity of length, $n_e L$ where n_e is the effective refractive index. Allowed wavelengths are $\lambda_m = 2n_e L/m$, where m is the mode index. For evaluating the spacing between adjacent modi, $\Delta\lambda$, one must take into account the dispersion of the refractive index and the effective group index $n_{e,g}$ is introduced. The mode distance is given by $\Delta\lambda = \lambda^2/2n_{e,g}L$, which corresponds to the inverse round-trip delay τ_L of the cavity. With an effective group index of 3.5 and a laser cavity of 300 to 400 μm a typical round-trip delay is about 10 ps.

When the semiconductor active medium with gain profile, as shown in Fig. 9.2.12b, is placed in the Fabry Perot cavity to build a laser, this laser will start lasing at a wavelength corresponding to the mode with the highest gain. The spectrum of the FP laser consists then of a set of modi around this highest gain mode to form the spectrum of the FP laser.

Semiconductor Laser Parameters

The threshold for lasing in a Fabry Perot laser can be obtained by considering the intensity of the laserfield in a round-trip within the cavity. If the semiconductor material gain is denoted by G , the mode gain is given by $g = \Gamma G$ where Γ is the confinement factor and internal loss α_i , the reflection coefficients R_1 and R_2 and length L , the net round-trip gain g_r is given by

$$g_r = R_1 R_2 e^{[2(g - \alpha_i)L]} \quad (2)$$

The material gain can be expressed in a linear relation to the current density N by $G = A(N - N_{tr})$, where A is the differential gain ($\partial G/\partial N$) and N_{tr} is the transparency current density, i.e., the value for injecting carriers such that the absorption and gain are equal and the material is transparent. At the lasing threshold, the optical field is sustained after traveling on round-trip in the cavity, thus the net round-trip gain g_r is unity, resulting in the threshold condition given by

$$g_{th} = \alpha_i + \frac{1}{2L} \ln \frac{1}{R_1 R_2} = \alpha_i + \alpha_m \quad (3)$$

where α_m is called the mirror loss.

The current density is related to the carrier density by

$$J = \frac{ed_{act}N}{\tau_n} \quad (4)$$

where d_{act} is the thickness of the active layer, and τ_n the carrier lifetime. The threshold current density J_{th} is now given by

$$J_{th} = \frac{J_{tr}}{\eta_i} + \frac{d_{act}}{\Gamma\beta\eta_i} \left(\alpha_i + \frac{1}{2L} \ln \frac{1}{R_1 R_2} \right) \quad (5)$$

FIGURE 9.2.12 (a) Schematic representation of the conduction band and both valence bands of semiconductor laser crystals. The arrow denotes the bandgap energy determining the wavelength of the laser by $\lambda = 1.23889/E_g$. (b) Calculated gain spectrum of semiconductor materials as function of the wavelength. The vertical arrow indicates the bandgap wavelength, the horizontal arrow shows the transparent region of the material. The curves show the gain/absorption as a function of injection current density. Semiconductor lasers tend to operate near the gain maximum.

Electrons (holes) flow from the n -(p -) doped cladding layer into the active layer with smaller bandgap giving radiative transitions emitting photons. Middle: Corresponding refractive index variation between cladding- and active region for waveguiding. Bottom: Optical intensity profile of the laser beam inside the laser cavity. The grey area is the part of the beam traveling in the active layer and defines the confinement factor Γ .

9.36 RADIANT ENERGY SOURCES AND SENSORS

where J_{tr} is the current density to reach transparency, η_i is the internal efficiency with which electrons and holes recombine radiatively and β is the gain coefficient, which is related to the differential gain A by $\beta = A\tau_n/e$. Equation (5) shows that the threshold current consists of the transparency current density J_{tr} and a contribution to overcome the internal and mirror losses. By further increasing the injection current above threshold, the round-trip gain remains fixed, i.e., clamped to the value of g_{th} and the excess carriers are consumed to build up the laser oscillation intensity. The total optical power generated by stimulated emission in the cavity is given by

$$P = \eta_i \frac{hv}{e} (I - I_{th}) \quad (6)$$

where I and I_{th} are the driving and the threshold current, respectively, and hv the photon energy. Part of this power is dissipated inside the laser cavity, and the remaining is coupled out through the facets. These two powers are proportional to the effective internal and mirror loss. The total output power from both facets is thus given by

$$P = \eta_i hv \frac{(I - I_{th})}{e} \frac{\alpha_m}{\alpha_i - \alpha_m} \quad (7)$$

The external differential efficiency is the ratio of the variation in photon output rate that results from an increase in the injection current and is given by

$$\eta_d = \frac{d(P/hv)}{d[(I - I_{th})/e]} = \eta_i \left[1 + \frac{2\alpha_i L}{\ln \frac{1}{R_1 R_2}} \right]^{-1} \quad (8)$$

In Fig. 9.2.14 the typical optical output power per facet (mW) versus the injection current (mA) (so called L/I curve) of a semiconductor laser is shown for various temperature where a photodetector is placed in front of the output facet of the laser. Up to the threshold current only spontaneous emission is generated but at threshold current the output power increases dramatically by the stimulated photons.

FIGURE 9.2.14 Light output power (mW) vs. injection current (mA)— L/I characteristic—of a semiconductor laser at various temperatures.

Several observations can be made from Fig. 9.2.14. First, the L/I curves are not exactly linear and deviate more at higher output power and high temperatures due to internal heating effects, increased internal losses and increased current (blocking) leakage. Second, the threshold current value increases with temperature owing to active layer temperature rise and additional loss mechanisms. The variation of the threshold current with temperature is expressed by an empirical relation:

$$I_{\text{th}}(T_2) = I_{\text{th}}(T_1)e^{(T_2 - T_1)/T_0} \quad (9)$$

where T_0 is the characteristic temperature and T_1 and T_2 are expressed in Kelvin. T_0 values of 50 to 70 are found for InP-based lasers and >100 for GaAs-based lasers. It should be noted that T_0 is not constant over a wide temperature range.

The single-mode laser has a finite *linewidth* caused by spontaneous emission into the lasing mode adding phase noise. The well-known Shawlow-Townes expression for the linewidth of a semiconductor laser has been modified by Henry to include the dynamics of the carrier density on spontaneous emission events and the linewidth expression for a semiconductor laser is given by

$$\Delta\nu = \frac{h\nu v_g^2 (\alpha_i + \alpha_m) \alpha_m n_{\text{sp}}}{8\pi P} (1 + \alpha_H^2) \quad (10)$$

where $h\nu$ is the photon energy, n_{sp} is the spontaneous emission coefficient and α_H is Henry's parameter. This equation shows that increasing power, reducing internal and mirror losses and low α_H values result in narrow (Lorentzian) linewidth values. The linewidth of the laser is also related to the coherence length L_c that can be measured using a Mach-Zehnder interferometer to obtain the autocorrelation function via $L_c = c/\pi\Delta\nu$. Example: laser with linewidth of 10 MHz has a coherence length of about 10 m.

Optical Waveguiding

The photons generated by stimulated emission in the active layer must be guided in the semiconductor laser structure in order to optimize the gain (high confinement Γ). Guiding is also needed to generate a proper beam from the laser that can be coupled into a fiber with high efficiency or can be handled with bulk optical lenses. Beam profiles that have a Gaussian shape are preferred and these can be obtained when a dielectrical waveguide is designed to support the lowest order mode only. Two-dimensional waveguiding in the laser structure is formed by designing both the transversal direction (x , perpendicular to the active layer) and the lateral directional (y , in plane of active layer).

Transversal Guiding. This is determined by the refractive index difference between the active layer and the cladding layers (see also Fig. 9.2.13) and the thickness of the active layer. The parameter that determines the cutoff condition for higher-order modes is called the normalized frequency or simply the V parameter.

$$V = \frac{\pi d}{\lambda} \sqrt{n_{\text{act}}^2 - n_{\text{cladding}}^2} \quad (11)$$

where d is the thickness of the active layer. In order to obtain single mode operation, the V parameter should obey $V < 2.4$, which is easily met with thin active layers and optimized cladding layers for carrier confinement.

Lateral Guiding. It is less straightforward mainly because of technological constraints. Three classes of lateral guided laser structures can be distinguished (Fig. 9.2.15).

1. **Gain guided structure.** A continuous active layer with no lateral index variation. Current injection in a stripe top contact results in local gain under the stripe and optical losses away from the stripe, hence the name gain guiding. The laser beam shows considerable astigmatism and a non-Gaussian lateral profile at high-power levels. It is used in very high-power lasers with a wide stripe where the beam properties are less

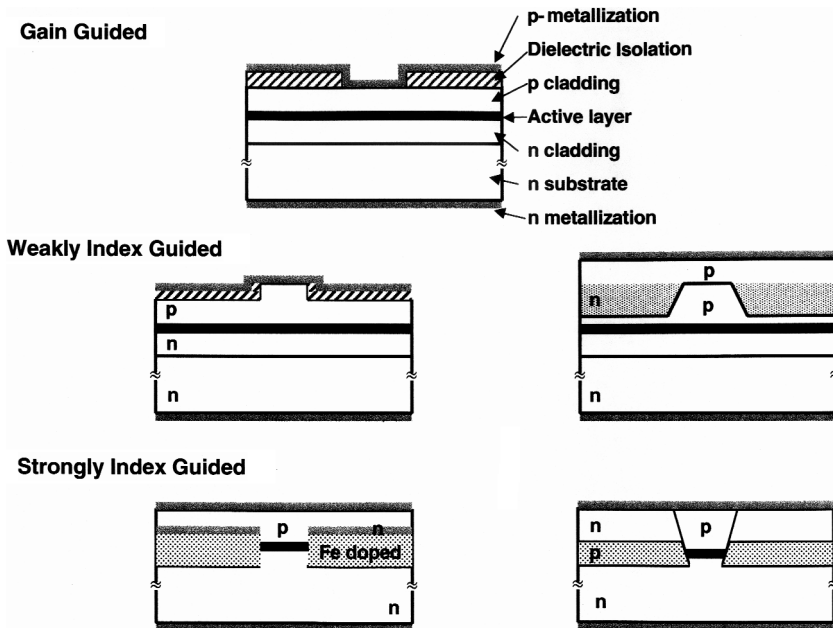

FIGURE 9.2.15 Lateral laser structures for lateral optical guiding. Top: Gain guided laser, Center: Weakly index guided structures (Ridge waveguide and buried Ridge structure). Bottom: Strongly index guided laser structures (SI-PBH, semi-insulating planar buried hetrostructure and n - p - n blocking structure).

important. Many lateral higher-order modes are present but this can be reduced by employing a longitudinal taper structure in the stripe.

2. *Weakly guided structure.* A continuous active layer but with a lateral index variation in the top/bottom cladding layer by processing, e.g., ridge structure or buried ridge structure. The lateral index guiding is small ($\sim 10^{-3}$) compared to the transversal confinement giving rise to elliptical beam profile.
3. *Strongly index guided structure.* The active layer is surrounded by cladding type material giving rise to both lateral and transversal strong index contrast and waveguiding with almost circular beam profiles. Strongly index guided laser structures are fabricated using several epitaxial growth and regrowth and processing steps. These structures have efficient current injection in the active layer of typically 1.5 to 2 mm width.

Longitudinal Laser Structures

Fabry-Perot Laser. The simplest longitudinal structure laser is a chip that is cleaved to form facets with reflectivity R to achieve optical feedback. These facets can be coated to modify the reflection value from low (AR) to high (HR). This structure allows for a discrete set of cavity modes and in combination with the gain profile, which is parabolic in shape, the laser operates in a series of modes around the gain maximum. The associated spectrum is called multilongitudinal mode and is depicted in Fig. 9.2.16. The number of modes (5 to 30) depends on the output power of the laser and decreases with increasing power. These modes operate simultaneously as is proven by the occurrence of frequency doubled components in the spectrum.

DFB Laser. In fiber optic long distance applications the multimode emission spectrum in FP lasers restricts the transmission distance because of the material dispersion of the fiber. To improve the link distance the need

FIGURE 9.2.16 Longitudinal laser structures and corresponding spectral behavior. From top to bottom: Fabry Perot laser, DFB (distributed Bragg reflector) laser, DBR (distributed Bragg reflector) laser, and VCSEL (vertical cavity surface emitting laser).

for a narrow spectral width laser has led to the development of the distributed feedback (DFB) laser emitting a narrow (few MHz) single longitudinal mode. The DFB laser is characterized by a grating near (above or below) the active layer in the longitudinal structure. The analysis of the coupled modes in the DFB laser is too lengthy to be discussed here and can be found in the reference books. The lasing wavelength of the DFB laser is to first approximation determined by the grating pitch Λ and the effective refractive index of the waveguide and is given by $\lambda = 2n_{\text{eff}} \Lambda$. Using $\lambda = 1550 \text{ nm}$ and $n_{\text{eff}} = 3.25$ this results in a submicron grating pitch of $0.2384 \mu\text{m}$. This grating requires an additional transparent guiding layer in which the grating is made using holographic exposure or e-beam pattern generator. The accuracy of the laser wavelength needed in DWDM systems (e.g., 50 GHz spacing) requires a controlled grating pitch fabrication within 30 pm! Since DFB lasers have an internal feedback for laser operation, the facets need to be eliminated by applying AR coatings on both sides. The position of the laser wavelength with respect to the gain maximum is a design parameter and usually the negative detuning of 10 to 30 nm (i.e., laser wavelength is positioned on the short wavelength side of the gain peak) is applied for improved modulation properties. The spontaneous emission spectrum of DFB lasers (i.e., subthreshold) is characterized by a so-called stopband. The width of the stopband is linearly related to the coupling coefficient parameter κ of the grating to the optical mode. Standard DFB lasers have a nonuniform power distribution in the longitudinal cavity, which can be modified/improved by including phase shifts in the grating. Single $\lambda/4$ -phase shift but also multiple $\lambda/8$ or $\lambda/16$ have been introduced to improve the uniform power density that is required for linear L/I characteristics in, e.g., analog transmission. The linewidth of DFB lasers is sub-MHz.

DBR Laser. In a distributed Bragg reflector (DBR) laser one of the facets is replaced by a waveguide structure with grating, which serves as a wavelength selective reflector. In contrast to the DFB laser, the active layer (= gain region) is now separated from the wavelength selection element (Bragg section). This Bragg section consists of a transparent guiding layer with an etched grating and cladding layers. This section is “butt-coupled” to the active section where the active layer provides the waveguiding. In many DBR lasers, an

intermediate section is applied in order to be able to provide round-trip phase matching for the lasing mode. The DBR wavelength is determined by the overlap of one of the cavity modes and mode with highest reflectivity. Since the reflector is positioned at the rear of the laser structure, most power is emitted from the front facet. From a technology point of view, this structure is more complex and requires more regrowth steps than the DFB laser. This structure is also very suited to make wavelength tunable lasers. The optical spectrum shows single frequency with MHz linewidth.

VCSEL. In a vertical cavity surface emitting lasers (VCSELs) the active layer is sandwiched between two highly reflective DBR mirrors (>90 percent) epitaxially grown on the substrate. The first VCSELs were made on GaAs substrate with many pairs of AlAs and GaAs as multistack reflectors operating at wavelength of 850 and 980 nm. Also InP-based VCSEL are available for the 1310 to 1550 nm telecom applications. The laser operates in a single longitudinal mode by virtue of an extremely small cavity length (about 1 μm) for which the mode spacing exceeds the gain bandwidth. Light is emitted in a direction normal to the active layer plane and since the output power has to pass the high reflector, VCSELs are characterized by low output power levels (few mWs). An important advantage of the VCSELs is the beam shape, which can easily be made narrow and symmetrical which allows direct fiber coupling without additional optics. This, along with the possibility of on-wafer testing, is viewed as considerable cost saving. Direct modulation has been achieved up to 2.5 Gb/s. Application areas are optical interconnect and short haul optical data links.

Dynamic Properties of Semiconductor Lasers

Rate Equations. One of the virtues of semiconductor laser diodes is their capability to modulate the optical output power directly with the injection current. To analyze the modulation aspects it is necessary to consider the laser diode dynamics on the basis of the single mode rate equations for the photon density S in the optical mode and the carrier density N in the active medium. These equations can be written as

$$\frac{dS}{dt} = \Gamma v_g g(N, S) S - \frac{S}{\tau_p} + \Gamma \beta \frac{N}{\tau_n} \quad (12)$$

$$\frac{dN}{dt} = \frac{I(t)}{e V_{\text{act}}} - \frac{N}{\tau_n} - v_g g(N, S) S \quad (13)$$

Here v_g is the group velocity, Γ is the optical confinement factor, V_{act} is the volume of the active medium, e is the electronic charge, $I(t)$ is the (modulated) pump current, τ_p is the photon lifetime, τ_n is the carrier lifetime, and β is the fraction of the spontaneous emission that couples into the lasing mode. The first equation represents the photon density variation owing to the photon generation by stimulated and spontaneous emission and the photon loss at the mirrors and by absorption. The second equation describes the carrier density variation resulting from the carrier injection by the pump current $I(t)$ and the carrier annihilation by the stimulated and spontaneous recombination. The material gain $g(N, S)$ (per unit length) depends on both the carrier density and the photon density and is modeled as

$$g(N, S) = \frac{\partial g}{\partial N} (N - N_{\text{tr}}) (1 - \epsilon S) \quad (14)$$

Here the gain is linearized at the transparency carrier density N_{tr} with a gain slope constant $\partial g / \partial N$ (differential gain) and the gain dependency on the photon density S is characterized by the gain suppression parameter ϵ .

The rate equations cannot be solved analytically; however, the small signal response of a laser diode can be derived by linearizing the rate equations and applying a small signal analysis. Then the intensity modulation transfer function normalized to the zero frequency response $M(0)$ is given by

$$\left| \frac{M(j\omega)}{M(0)} \right| = \frac{\omega_0^4}{(\omega^2 - \omega_0^2)^2 + \gamma^2 \omega^2} \quad (15)$$

FIGURE 9.2.17 Calculated small signal laser diode response as function of the output power from 0.25 to 32 mW.

with the circular relaxation oscillation (RO) frequency given as

$$\omega_0^2 = \frac{v_g}{\tau_p} \frac{\partial g}{\partial N} S \quad (16)$$

and the damping factor γ

$$\gamma = \frac{\beta \Gamma N}{S \tau_n} + \frac{1}{\tau_n} + v_g \frac{\partial g}{\partial N} S + \frac{\epsilon S}{\tau_p} \quad (17)$$

As an example the calculated small signal response for a semiconductor laser diode at several output powers is given in Fig. 9.2.17. The intrinsic frequency response of a laser diode is completely described and shows a second-order low pass network nature. The transfer function is characterized by a clear resonance followed by a steep roll-off. The resonance known as the relaxation oscillation results from the interplay between the photon field and the carriers. The resonance frequency ω_0 , obtained from the small signal analysis, increases with the square root of the optical power. The damping of the resonance is determined by the spontaneous emission at low photon densities and by the gain suppression factor ϵ at high photon densities. In view of high frequency modulation an ultimate increase of the relaxation oscillation frequency is desired but will be severely limited at high photon densities by the damping introduced by the gain suppression ϵ .

In addition to the maximum intrinsic modulation frequency, parasitic capacitance in the laser structure and/or mounting are also determining the small signal response of laser diodes. To account for the chip and bonding parasitic capacitance, it should be expanded as

$$R(\omega) \approx \frac{\omega_0^4}{(\omega^2 - \omega_0^2)^2 + \gamma^2 \omega^2} \frac{1}{1 + \omega^2 (RC)^2} \quad (18)$$

In digital modulation schemes the large signal nonlinear modulation response should be taken into account and the small signal approach is not sufficient. A typical response on a rectangular current pulse is schematically given in Fig. 9.2.18. Important parameters here are the turn-on and the turn-off time. Moreover, frequency ringing will occur when the laser diode is switched from the “off” state to the “on” state (and back)

FIGURE 9.2.18 Large signal optical modulation response of a laser diode on rectangular current pulse.

with correspondingly different relaxation oscillation frequencies and damping factors. The turn-on time t_{on} for $I_{\text{off}} > I_{\text{thr}}$ can be calculated as

$$t_{\text{on}} = \frac{0.23}{f_0} \sqrt{\ln\left(\frac{S_{\text{on}}}{S_{\text{off}}}\right)} \quad (19)$$

with $f_0 = \omega_0/2\pi$ is the relaxation oscillation frequency corresponding to the “on” state, S_{on} is the steady-state photon density in the “on” state, and S_{off} in the “off” state. Considering a high-speed laser diode with $f_0 = 10$ GHz and an extinction ratio of 6:1 yields a turn-on time t_{on} of 31 ps. The turn-off time t_{off} can be approximated as $(0.5-2)t_{\text{on}}$. As the relaxation oscillation frequency corresponding to the “off” state with $S_{\text{off}} < S_{\text{on}}$ is several factors lower than f_0 , the turn-off time is larger than the turn-on time.

A powerful tool to predict the performance of laser diodes is given by simulation. By numerical integration of the rate equations the time domain response of the laser output power can be calculated when a time-varying input current $I(t)$ is inserted. The results of simulations are represented as eye patterns (Fig. 9.2.19) obtained with a 10 Gb/s²-1 PRBS data formats. The laser extinction ratio is approximately 6:1.

Optical Frequency Response of Laserdiodes. When a modulated current is injected into a laserdiode, the varying carrier density will affect the refractive index of the active medium because of carrier-induced band-edge shifting. This implies that not only the photon density S will be modulated by the gain variations, but also the lasing resonance frequency by the varying refractive index. This optical frequency response (in intensity modulated direct detection systems regarded as highly undesirable) is denoted as *frequency chirp*. The so-called linewidth enhancement or Henry’s factor α_H describes this coupling between the gain and the refractive index and is given by

$$\alpha_H = -\frac{4\pi}{\lambda} \frac{(\partial n_{\text{eff}}/\partial N)}{\Gamma(\partial g/\partial N)} \quad (20)$$

FIGURE 9.2.19 Simulated 10 Gb/s eye patterns ($I_{\text{off}} = 18$ mA, $I_{\text{on}} = 54$ mA) for SL-MQW active layer laser diode.

With this α_H parameter the expression for the frequency variation under injection current modulation is expressed as follows:

$$\Delta\nu(t) \cong \frac{\alpha_H}{4\pi} \left[\frac{1}{P(t)} \frac{dP(t)}{dt} + \frac{2\Gamma}{h\nu\eta_d V_{\text{act}}} \epsilon P(t) \right] \quad (21)$$

where η_d is the differential efficiency. In this equation, two chirp contributions are present. The first part (*transient chirp*) is associated with the transients and the ringing introduced by the relaxation oscillation when the laser is switched between the “on” and the “off” states. The second contribution is governed by nonlinear gain suppression coefficient ϵ and originates from the imperfect carrier density pinning because of the nonlinear gain. This *adiabatic chirp* depends on the laser structure and causes a frequency offset during modulation between the “on” state and the “off” state. The total chirp is directly proportional to the α_H -factor that highlights the significance of this parameter. Typical α_H -factors range from 2 to 6 depending on the detailed structure of the active layer and laser structure.

The laser frequency variations as function of the time can be calculated by numerical integration of the rate equations. Figure 9.2.20 shows the optical output power (dashed curve) and the corresponding frequency response (solid curve) for a single 2.5 Gb/s pulse (400 ps). The zero chirp value is related to the CW “on” state.

The optical frequency response of laser diodes poses severe problems in intensity modulated direct detection systems employing dispersive fibers. The addition of spectral components by chirp increases the total frequency bandwidth. In combination with fibers showing a substantial dispersion at the operating wavelength (-17 ps/nm/km) (@ 1550 nm), the frequencies that compose the signal travel with a different group velocity along the fiber. This results in a frequency dependent arrival time of the signal components and hence signal distortion at the receiver side. In digital systems information associated with one bit can occur in a neighbor bitslot give rise to intersymbol interference (ISI).

Active Layer Structures

Quantum Well Lasers. The development of advanced crystal growth techniques like metallo-organic chemical vapor phase epitaxy (MOVPE) and molecular beam epitaxy (MBE) allowed the growth of defect-free

FIGURE 9.2.20 Simulation of the frequency response (solid curve) and the large signal response (dashed curve) of a bulk laser diode.

ultrathin layers with sharply defined heterointerfaces. The creation of these layers with a thickness close to the Broglie wavelength of electrons accelerated the development of single quantum well (SQW) and multi-quantum well (MQW) laser diodes. For conventional bulk laser diodes the active layer thickness is about 150 nm or more. The active layer of quantum well lasers consists of one or more thin layers ($L_z < 30$ nm) which are separated by barrier layers with a larger bandgap material. For injected carriers confined to these wells, the energy for motion normal to the well is quantized into discrete energy levels. The motion of electrons/holes in the plane of the quantum well is not quantized and form continuous states. The heterostructure for bulk active layer, as shown in Fig. 9.2.13, is now modified as shown in Fig. 9.2.21. Here the conduction and valence band structure is shown for a MQW laser having four quantum wells. For every quantum number, one conduction band and two valence bands (namely, the heavy and light holes) levels exist. These levels are degenerated. In the z direction the carriers are confined in the well as a particle in a box of width L_z and the calculation of the

FIGURE 9.2.21 Schematic band energy diagram of a four quantum well active layer showing the conduction and valence band. The well width is L_z . The dashed lines indicate the energy corresponding to the material composition and the solid lines show the energy levels for ($n = 1, 0, \dots$) because of the quantum effect ("particle in box"). Arrows show the radiative transitions between electrons (filled balls) and holes (open balls).

allowed energy states is a well-known quantum mechanical problem. The energy levels associated with this “particle-in-box” is given by

$$E_n = \frac{h^2 n^2}{8mL_z^2} \quad (22)$$

which is valid for both electrons and holes. Here n is the quantum number, L_z is the quantum well width (QW layer thickness), m is the effective mass for this level, and h is Planck’s constant. The effective bandgap of quantum wells is given by $E_g = E_g^{\text{bulk}} + E_{n=1}^c + E_{n=1}^v$, and thus is a function of the well thickness L_z ; i.e., by using the same composition in the QW, the emission wavelength can be adjusted by changing the well width. Furthermore, the gain spectrum and the gain current relations lead to improvements for laser operation such as a reduction of the threshold current and its temperature sensitivity, enhancement of the differential quantum efficiency, an increase in modulation bandwidth and a reduction of the spectral linewidth (lower α_H). These improvements have been observed mainly in AlGaAs-based lasers and to a lesser extent in InP-based lasers because of higher intervalence band absorption processes.

Strained Quantum Well Lasers. To further improve the transition efficiency of MQW lasers, in particular for InP-based lasers, mechanical strain in the QWs can be introduced by growing lattice mismatched epitaxial layers on a thick substrate. These layers are subjected to a biaxial in-plane strain. As an example, the growth of $\text{In}_x\text{Ga}_{1-x}\text{As}$ with $x = 0.53$ is lattice-matched to InP substrate. For $x > 0.53$, i.e., large In atom rich, the lattice is compressed in the x - y plane and is called compressive strain. For $x < 0.53$, i.e., smaller Ga atom rich, the strain is tensile. The lattice mismatch is bound by the critical thickness limitation depending on materials (elastic constants), degree of lattice mismatch and substrate orientation, and sets an upper limit to the applied strain before lattice defects such as misfit dislocations occur. Because of the deformation of the unit cell of the crystal, the bandstructure of the semiconductor material is modified. For InGaAs/InP materials the effect is most pronounced in the valence subbands, namely, the removal of the valence subband degeneracy and a larger split of the valence bands. This results in more efficient electron-hole transitions and reduction of the intervalence band absorption leading to much improved laser performance such as threshold current reduction, higher differential gain, lower α_H parameter, less temperature sensitivity, and TE or TM emission control.

Quantum Dot Lasers. Quantum dot (QD) or quantum dash-lasers are characterized by an active layer consisting of small clusters of active material embedded in cladding material. These clusters are made of InAs using the self-assembly property in crystal growth using MBE or MOVPE. Self-assembled QDs form spontaneously on the GaAs surface during growth because of lattice mismatch between InAs and GaAs. The InAs islands are then capped by another GaAs layer. Since the GaAs conduction (valence) band minimum (maximum) has higher (lower) energy than that of InAs, both electrons and holes are trapped by the InAs island (QDs). The shape of these QDs depends on the growth conditions. Typically, the size is strongly asymmetric: the in-plane diameter of the QDs ranges from 20 to 40 nm, whereas the height ranges from 2 to 6 nm. Nevertheless, the electrons and holes are now trapped in three dimensions unlike the quantum well (one-dimensional) or the quantum wire (two-dimensional) giving rise to new physical properties when applied in an optical cavity. The transitions within the QD are now uncoupled from the surrounding QDs modifying the gain dynamics. Also, QD-lasers have been fabricated to obtain 1300-nm-emitting lasers using GaAs as substrate and allowing much higher T_0 values than for InP-based lasers.

Quantum Cascade Lasers. The principle of quantum cascade laser is based on quantum confinement in quantum wells (with associated energy levels) and the tunneling property of electrons through energy barriers. In contrast to usual semiconductor lasers where the emission process is based on transitions between conduction band and valence band, in QCLs the transitions take place between the higher energy state of one QW and a lower energy state of the nearest neighbor QW as schematically depicted in Fig. 9.2.22. By applying many QWs in the active layer with carefully designed barriers, a single electron is able to generate more than one photon, thus allowing high power operation. The wide wavelength range in FIR (3 to 30 μm) can be obtained by properly designed QW and barrier layer thickness. The efficient photon generation allows high output power levels in the watt range. These QCLs are applied in environmental sensing and polluting monitoring, process control, automotive, and medical analysis.

Other Semiconductor Lasers

Analog Lasers. Semiconductor lasers are used as the optical source in fiber optic cable television systems where a large number (up to 200) channels—having independent frequencies in the range between 25 and 301

FIGURE 9.2.22 Schematic conduction band energy diagram of a quantum cascade laser with three QWs of width L_z . In the left well the energy levels corresponding to $n = 1, 2$, and 3 is indicated by the horizontal lines. Tunneling of the electron takes place through the intermediate barrier B and an electron transition between $n = 3$ state to the $n = 2$ state of the nearest QW is shown by the arrow.

tunability and maintaining the prime characteristics of nontunable lasers such as the DFB laser, i.e., high power, low noise, spectral purity, and small footprint. Also the tuning speed is an important differentiator and ranges between several ns for semiconductor solutions to ms to mechanical and thermal solutions. A good overview of all tunable laser concepts can be found in the textbook of Amann and Buus (1998) on this topic. Tunable semiconductor lasers can be classified into four groups:

Temperature tunable lasers (TTLs). The wavelength of the diode laser increases with temperature because the material gain is temperature dependent with $d\lambda/dT = 0.5 \text{ nm/K}$. For DFB lasers with an internal grating the wavelength tunability is much less because only the temperature dependence of the effective mode index has to be taken into account. The $d\lambda/dT$ for DFB lasers is 0.08 nm/K . Using the internal TEC in the laser package, the wavelength can be tuned thermally over typically 3.5 nm .

External cavity lasers (ECL). This concept uses a FP laser chip of which one of the mirrors is AR-coated and the light from this facet is reflected back by an external grating that can rotate. The grating gives wavelength selective feedback and the achievable tuning range is usually determined by the gain bandwidth of the active layer of the FP laser. A tuning range of 100 nm can easily be obtained. The front mirror and the grating form the laser cavity, which is usually long (centimeters) so many “external cavity modes” are present. Laser linewidth is excellent ($<100 \text{ kHz}$). This laser is mainly used in instrumentation applications. Recent developments in microelectromechanical systems (MEMS) have revealed miniature ECLs using a grating. An alternative to the grating is a set of etalons between the AR-coated facet and a retroreflector. If one of the etalons is made variable, then a differential etalon external cavity is obtained.

Multisection lasers. Here the laser chip is split up into a number of electrically separated longitudinal segments where independent injection currents can be applied. The physical mechanism for tuning the wavelength is the free-carrier effect. The refractive index change Δn caused by injection of carriers is proportional to the carrier density, which in turn has a nonlinear relationship with the tuning current resulting from Auger recombination processes. The maximum achievable Δn is about -0.04 , whereas the thermally induced index change is in the order of $+0.01$. Examples of multisection lasers based on tuning current injection only

MHz or even to 860 MHz —are multiplexed on the optical carrier and broadcasted. This amplitude-modulated subcarrier lightwave CATV system requires extremely linear transfer characteristic of the laser, i.e., a linear L - I curve. If not, intermodulation products result from the modulation of the laser current with the frequency channels. If these intermodulation products have frequencies corresponding to one or more of the TV channel frequencies, distortion of the signals arises. A measure of the distortion is the so-called CSO (composite second order) which is the sum of all mix frequencies by f_m and f_k at $|f_m \pm f_k|$ and CTB (composite triple beat; $|f_m \pm f_k \pm f_l|$). CATV lasers are specified by $\text{IM2} < -45 \text{ dBc}$ and $\text{IM3} < -50 \text{ dBc}$. Also low noise in the optical power is important. The relative intensity noise (RIN) should be below -155 dB/Hz in a frequency interval between 100 kHz and 2.5 GHz . CATV lasers are characterized by high optical output power ($>20 \text{ mW}$) allowing a higher split ratio in the broadcast mode.

Tunable Lasers. Semiconductor tunable lasers have the property that the emission wavelength can be tuned by thermal/mechanical/electronic means. This feature makes tunable lasers very attractive in DWDM applications in fiber optical systems, fiber sensor applications, environmental sensing, and instrumentation. A vast variety of technical solutions have been proposed and introduced in the market that offer wavelength

are 2-section DFB, 2- and 3-section DBR laser and tunable twin guide lasers. Maximum achievable tuning range is determined by $\Delta\lambda/\lambda \approx \Delta n/n$ and is typically 15 nm. For increased tuning ranges, so-called *widely tunable lasers*, use is made of the Vernier effect in sampled grating DBR lasers having a comb-like reflection spectrum from sampled gratings in two sections. The sampled grating consists of several sections of interrupted grating. The SG-DBR has four sections with the active and phase control section in between two sampled Bragg reflectors with slightly shifted periods. Tuning range of 50 nm can be achieved with this laser although with moderate output power because the beam has to propagate the SG reflector. Another structure is the superstructure grating DBR using a chirped grating giving more uniform reflection peaks. Tunable multisection lasers using codirectionally coupled waveguides provide an additional internal mode filter to discriminate between cavity modes. An example of this structure is the grating-assisted codirectional coupler with rear sampled grating reflector (GCSR) laser. This laser achieves over 100 nm tuning range. Multisection tunable lasers require sophisticated control loops to adjust the individual wavelengths and is usually delivered with the device.

Vertical cavity lasers. If the top mirror of a VCSEL is made movable by applying MEMS technology, the single longitudinal mode that can exist in the small cavity can be tuned in wavelength. Up to 50 nm tuning range can be achieved with a simple control algorithm. However, the output power is low as a consequence of the VCSEL structure.

Pump Lasers. Semiconductor lasers that can deliver high output power into the optical fiber for erbium-doped fiber amplifiers (EDFAs) and RAMAN amplifiers (for C- and L-band) are called pumplasers. Amplifier designs developed before 2001 incorporate the 14xx (1405 to 1520 nm), 1480 and 980 nm pump lasers with power levels of typically less than 200 mW. The 980-nm-based pumplasers are fabricated using InGaAs/AlGaAs/GaAs materials with a wide spot size to reduce catastrophic optical mirror damage because of facet erosion due to the high optical flux. Ridge waveguide (weakly index guided) laser structures are the common laser design. The other pump sources are based on InGaAs/InP material system where COD is no issue and an optimum fibre chip coupling can be achieved by beam design. Index-guided laser structures are used here. Pump lasers for the next generation of optical networks will typically have more than 300 mW of power. In order to increase the power level, hybrid integration of pump modules by, e.g., polarization multiplexing, allow for power levels up to 1 W.

Optical Storage Lasers. Historically, the first optical disc lasers were made in GaAs/AlGaAs lasers operating at a wavelength of 820 nm. Since the spot size on the disc to read and/or write data is proportional to $\lambda/2NA$ where NA is the numerical aperture of the lens, a higher optical capacity can be obtained by developing semiconductor lasers operating at shorter wavelengths. This has led to weakly guided 780 nm GaAs/AlGaAs-lasers for the CD application and 633 nm lasers based on AlInGaP/InGaP/GaAs materials for DVD. To further increase the density, green lasers have been investigated based on II-VI materials using ZnSe/ZnSSe/GaAs materials but these lasers suffered from reliability problems because of crystal defects. Recent developments of InGaN/GaN/AlN/GaN on sapphire substrate-based lasers, emitting in blue 450 nm, have led to a capacity of 15 Gbyte of digital data on a single layer. Also based on InGaN materials, semiconductor lasers emitting 405 nm, i.e., blue-violet color have been made for optical data-storage systems such as DVD and future systems.

CHAPTER 9.3

DISPLAY TECHNOLOGY

Munsey E. Crost, Irving Reingold, David A. Bosserman

CATHODE-RAY TUBES

Munsey E. Crost, Irving Reingold

Introduction

Generation of Radiation. The cathode-ray tube (CRT) produces visible or ultraviolet radiation by bombardment of a thin layer of phosphor material by an energetic beam of electrons. The great preponderance of applications involves the use of a sharply focused electron beam directed time-sequentially toward relevant locations on the phosphor layer by means of externally controlled electrostatic or electromagnetic fields. In addition, the current in the electron beam can be controlled or modulated in response to an externally applied varying electrical signal.

General Design Principles. The generalized modern CRT consists of an electron-beam-forming system, electron-beam deflecting system, phosphor screen, and evacuated envelope (see Figs. 9.3.1 and 9.3.2).

The electron beam is formed in the electron gun, where it is modulated and focused, and then travels through the deflection region, where it is directed toward a specific spot or sequence of spots on the phosphor screen. At the phosphor screen the electron beam gives up some of the energy of the electrons in producing light or other radiation, some in generating secondary electrons, and the remainder in producing heat.

The magnetic field imparts no kinetic energy to the electron, since it always acts in a direction perpendicular to the velocity.

Electrostatic Deflection. In electrostatic deflection, metallic deflection plates are used in pairs within the neck of the CRT (see Fig. 9.3.2).

The simplest deflection plates are merely flat rectangular parallel plates facing each other, with the electron beam directed along the central plane between them. The deflection plates are located in the field-free space within the second-anode region, and the plates are essentially at second-anode voltage when no deflection signal is applied. Deflection of the electron beam is accomplished by establishing an electrostatic field between the plates.

The well-made modern electrostatic-deflection CRT does not exhibit excessive deflection defocusing until the beam deflection angle off axis exceeds the neighborhood of about 20° . Most electrostatic-deflection CRTs are used to display electric waveforms as a function of time.

To display the electric waveform it is necessary to generate a sweep representing passage of time and to superimpose on this an orthogonal deflection representing signal amplitude. This is most readily accomplished by the use of two pairs of deflection plates. The second pair of deflection plates must have an entrance window large enough to accept the maximum deflection of the beam produced by the first pair. This requires that although the plates may be close enough together at the entrance to afford high deflection sensitivity, they must

FIGURE 9.3.1 Generalized schematic of a cathode-ray tube with electromagnetic focus and deflection.

also have an appreciable width, which results in high capacitance. The plates must also diverge, to accommodate their own deflection of the beam.

To obtain an acceptable deflection sensitivity, the plates must be made long, and consequently the capacitance is increased.

Electrostatic deflection CRTs are particularly suited for the display of arbitrary waveforms, as opposed to electromagnetic-deflection CRTs, because the deflection plates generally have capacitances with reference to each other and to all other electrodes of the order of 10 pF or less.

FIGURE 9.3.2 Generalized schematic of a cathode-ray tube with electrostatic focus and deflection.

Electromagnetic-Deflection Systems. In contrast to electrostatic-deflection systems, the deflection components in electromagnetic-deflection systems are almost universally disposed outside the tube envelope, rather than inside the vacuum. Since the neck of the CRT beyond the electron gun is free of obstructions, a larger-diameter electron beam can be used in the magnetic-deflection CRTs than in the electrostatic-deflection CRTs, which permits a much greater beam current to the phosphor screen and consequently a much brighter picture than if electrostatic deflection were used. In fact, included deflection angles of 110° (55° off axis) are commonly used in television picture tubes without excessive spot defocusing. As is apparent, large deflection angles permit CRTs to be made with shorter bulb sections for any given screen size.

Cathode-Ray-Tube Faceplates. The CRT envelope consists of the faceplate, bulb, funnel, neck, base press, base, faceplate safety panels, shielding, and potting. Not all CRTs will incorporate each of these components, of course.

The *faceplate* is the most critical component of the envelope, since the display on the phosphor must be viewed through it. Most faceplates are now pressed in molds from molten glass and are trimmed and annealed before further processing. Some specialized CRTs for photographic recording of flying-spot scanning use optical-quality glass faceplates sealed to the bulb section in such a way as to produce minimum distortion.

To minimize the return scattering of ambient light from the white phosphor, many CRT types, especially for television applications, use a neutral-gray-tinted faceplate. While the display information will be attenuated as it makes a single pass through this glass, ambient light will be attenuated both going in and coming out, thus squaring the attenuation ratio and increasing contrast.

Certain specialized CRTs have faceplates made wholly or partially of fiber optics, which may have extraordinary characteristics, such as high ultraviolet transmission. A fiber-optic region in the faceplate permits direct-contact exposure of photographic or other sensitive film without the necessity for external lenses or space for optical projection.

Categories of Cathode-Ray Tubes

Oscilloscope Tubes. For oscilloscopic applications the general requirements on a CRT include a sharp, bright, rapidly deflectable, single-line trace with a minimum of deflection defocusing or astigmatism. The rapidity of deflection and the fact that arbitrary waveforms must be displayed dictate the use of ES deflection, at least for the vertical direction. For general use, both horizontal and vertical axes employ ES deflection. Since the included deflection angle must be small, usually less than 45° , to preserve good spot size and shape, these CRTs are relatively long compared with the face diameter.

The phosphors generally used for oscilloscope CRTs are P1 (green, medium persistence) or P2 (yellow-green, medium persistence, but with a much longer, low-level "tail" than P1).

Radar Display Tubes. Except for the *A-scope* radar display, which is essentially the same as an oscilloscope display, most radar displays consist of a two-dimensional coordinate display with beam-intensity modulation. Since the coordinate scans are mathematically regular and at preselected rates, EM deflection is generally used, in as much as this permits greater deflection angles and consequently shorter tubes to be used for a given face diameter.

Especially in filtered radar displays, it is often necessary to include alphanumeric characters, symbols, and vectors in the display along with the radar information. Shaped-beam tubes, such as the Charactron, or a multiple-beam tube, in which one beam is devoted to the tracing of the characters of symbols and the other to the plan-position-indicator (PPI) display, are used for this purpose.

Long-persistence phosphors are generally used in CRTs for radar displays, since it is desirable to be able to see the radar situation in the entire area covered at any given time.

Television Picture Tubes

Monochrome tubes. Since the standards for television transmission in the United States call for 30 frames of two interlaced fields each per second, producing the effect of 60 pictures per second, which is above the flicker fusion frequency for all light levels, there is no stringent limitation on phosphor persistence for monochrome

TV picture tubes so long as the persistence does not cause picture smearing. The white luminescence used for most applications is achieved by a mixture of phosphors rather than any single component. Several white-luminescing combinations, all designated P4, have been in common use, namely, the all-silicates, the silicate-sulfide mixture, and the all-sulfides.

Color tubes. Many types of full-color CRTs have been developed for television use, but the shadow-mask tube is in most widespread use. This type of CRT uses a cluster of three electron guns in a wide neck, one gun for each of the colors red, green, and blue. All the guns are aimed at the same point at the center of the shadow mask, which is an iron-alloy grid with an array of perforations in triangular arrangement, generally spaced 0.025 in between centers for entertainment television. For high-resolution studio-monitor or computer-graphic readout monitor applications, color CRTs with shadow-mask aperture spacing as small as 0.012 in center-to-center are now readily available. This triangular arrangement of electron guns and shadow-mask apertures is known as the *delta-gun configuration*. Phosphor dots on the faceplate just beyond the shadow mask are arranged so that after passing through the perforations, the electron beam from each gun can strike only the dots emitting one color.

Because of the close proximity of the phosphor dots to each other and the strict dependence on angle of penetration of the electrons through the apertures to strike phosphor dots of the desired color, close *attention* must be paid to shielding the CRT from extraneous ambient magnetic fields and to degaussing of the shield and shadow mask, which is usually carried out automatically when the equipment is switched on or off. All three beams are deflected simultaneously by a single large-diameter deflection yoke, which is usually permanently bonded to the CRT envelope by the tube manufacturer. The three phosphors together are designated P22, individual phosphors of each color being denoted by the numbers P22R, P22G, and P22B. Most of the present color CRTs are made with rare-earth-element-activated phosphors, because of the superior colors and brightness compared with previously used phosphors.

Two other classes of multicolor CRTs are those with parallel-stripe phosphors and those with voltage-penetration phosphors. In the *parallel-stripe class* of CRTs, such as the *Trinitron*, sets of very fine stripes of red-, green-, and blue-emitting phosphors are deposited in continuous lines repetitively across the faceplate, generally in a vertical orientation. The Trinitron, unlike conventional color CRTs, has a single electron gun that emits three electron beams across a diameter perpendicular to the orientation of the phosphor stripes. This type of gun, also used by some United States CRT manufacturers, is called the *in-line gun*. Each beam is directed to the proper color stripe by means of the internal beam-aiming structure and a slitted *aperture grille*.

The *Lawrence tube*, or *Chromatron*, is another example of the parallel-stripe-phosphor class of color CRT. It employs a single electron beam, and color selection is accomplished solely by control voltages applied between the integrated combs of wires constituting the grille itself.

In the voltage-penetration type of phosphor screen, two or three unstructured layers of phosphors emitting different colors are deposited on each other, sometimes with a nonluminescing, transparent barrier layer between them for better color differentiation. A second important structure consists of individual phosphor grains built up in layers, called *onionskin phosphors*. The core phosphor is generally green-emitting. This is surrounded by a nonemitting layer which in turn is surrounded by an outer red-emitting layer. With both types of phosphor screen, a single electron beam is employed, and the resultant color of the screen is determined by preselected beam-accelerating voltages, which are changed to control the depth of beam penetration into the phosphor layers.

Intermediate colors are produced by the visual combination of the first color, resulting from the penetration of the first layer by the electron beam, with varying intensities of the second color, as more electrons penetrate into the second color-emitting layer. The range of colors producible is thus limited by the hues of the two phosphor layers, which must lie on the same side of the CIE chromaticity diagram and as close to the spectral locus as possible. A major problem associated with voltage-penetration color CRTs is the change in deflection sensitivity and focus of the electron beam as the screen voltage is changed to change the color displayed. This usually dictates operation at only a few preset screen voltages (and therefore colors) where the deflection amplifications and focus voltages are also preset to correspond. Another type of voltage-penetration CRT features a constant-potential mesh grid very close to the phosphor screen to separate the deflection and focusing space from the color-adjusting space. In this type of CRT a maximum residual deflection error of 1 to 2 percent can be automatically compensated for by means of a large weak electron lens formed between electrode bands deposited on the inside surface of the bulb.

Recording Tubes. Cathode-ray tubes for recording or transcribing information on photographic or otherwise sensitized film are usually of the very-high-resolution (vhr) or ultrahigh resolution (uhr) types. The great majority of these types have nominal faceplate diameters of 4 or 5 in. The spot diameters of the vhr and uhr tubes range from approximately 0.0015 in. down to 0.00033 in.

The displayed information is transferred to the recording medium either by an external focusing optical system or by direct contact with a fiber-optic faceplate, requiring no focusing.

Computer-Terminal Display Tubes. Cathode-ray tubes for computer display are very similar to tubes used in high-resolution video monitors, but since the display is principally alphanumeric and vector-graphical, the linearity of the beam-modulation characteristics is less important. Well-focused round spots with minimum spot growth or deflection aberrations from the center to the useful edges of the display area are required. High legibility is of primary importance, implying high contrast. White-emitting phosphors are not necessary, so that highly efficient, high-visual-response phosphors emitting in the yellow or green spectral regions are applicable. Most of these CRTs are made with rectangular faceplates.

ELECTROLUMINESCENT DISPLAYS

David A. Bosserman

Background

Destriau discovered intrinsic electroluminescence (EL) in ZnS among other materials. Sylvania's powdered SZnS EL panel dominated EL work in the 1950s and early to mid-1960s, when most of the projects were cancelled or deferred because of life and/or crosstalk-contrast problems. Attempts were made to correct crosstalk and contrast problems by placing addressable electronic components at each pixel site to serve as turn-on or threshold devices and to provide address-state memory, needed for bright displays where the addressing duty cycle is a factor. These attempts ran into manufacturing difficulties concerning the uniformity and reproducibility of the pixel circuit-elements.

Thin-Film Display

In 1972, Sigmatron, working on the thin-film EL (TFEL) [also called light-emitting film (LEF) and AC-TFEL], reported an *XY* matrix with inherent threshold and an optical light-absorbing layer in the otherwise transparent thin-film structure which enhanced the display contrast when viewed in bright ambient illumination. Shortly thereafter, Sharp Corporation in Japan achieved a breakthrough with a panel life of over 10,000 h coupled with a continuous ac excitation brightness of over 3500 cd/m² (over 1000 fL). Many laboratories now work on applying the TFEL structure to various types of matrix-addressed displays. Sharp has since reported on a memory phenomena intrinsic to the TFEL structure which can be used to freeze a frame or to increase the brightness of line-at-a-time addressed displays. Rockwell International has reported on a 500-pixel/in TFEL display.

The early successes of TFEL displays are attributable to the thin-film planar sandwich structure, consisting of electrode-dielectric-phosphor-dielectric-electrode, where at least one electrode is transparent. Since the thickness of this structure is less than 1 nm, high field strengths can be achieved with modest voltages across the structure. This high field strength produces hot electrons through tunneling from relatively deep traps. The hot electrons are fired across the ZnS film, exciting the color centers associated with the dopant, usually Mn. This process is relatively temperature-independent, which translates into a wide operational temperature range. The details of the tunneling and subsequent retrapping of activator electrons are being studied in various laboratories to determine the best structure for enhancing the various desirable operational parameters such as threshold, brightness, memory, and uniformity.

9.54 RADIANT ENERGY SOURCES AND SENSORS

The low-cost production processes inherent in the planar TFEL structure make them eminently suitable for the commercial and consumer markets.

CHAPTER 9.4

PHOTOCONDUCTIVE AND SEMICONDUCTOR JUNCTION DETECTORS

William A. Gutierrez

INTRODUCTION

Photoconductors and junction devices constitute an important class of solid-state photodetectors that can operate somewhere within the 0.2- to 2- μm spectral region. These detectors convert electromagnetic energy directly into electric energy via the photoconductivity effect that occurs in semiconductors.

PHOTOCONDUCTORS

Operation

The simplest photoconductor detector is a bar of relatively low conductivity n - or p -type semiconductor (in bulk or thin-film form) with ohmic contacts at its ends (Fig. 9.4.1). The photoconductor varies its electrical resistance in accordance with the light wavelength and intensity it receives. Its operation depends on the photoconductivity that occurs in semiconducting materials. Electrons in bound states in the valence band (intrinsic) or in forbidden-gap levels (extrinsic) absorb the energy of the incident photons and are excited into the free states in the conduction band, where they remain for a characteristic lifetime. Electric conduction may take place either by the electrons in the conduction band or by the positive holes vacated in the valence band. The electrical resistance of the material thus decreases on illumination, and this resistance change can be translated into a change in the current that flows through the output circuit.

Performance

The performance of photoconductor detectors is measured not only in terms of D^* but also in terms of photoconductivity gain, response time, dark current, spectral response, and temperature coefficient. For a photoconductor in which the conductivity is dominated by one carrier (either holes or electrons) the gain is given by the ratio of free-carrier lifetime to the transit time of this carrier. It can also be expressed as

$$\text{Gain} = \tau\mu V/L^2$$

FIGURE 9.4.1 Diagram of a photoconductor detector.

where τ = free-carrier lifetime

μ = mobility

V = applied voltage

L = spacing between ohmic contacts, as shown in

Fig. 9.4.1

The maximum D^* and spectral dependence of commercially available CdS and CdSe photodetectors are shown in Fig. 9.4.2. Table 9.4.1 lists typical gains, response times, and dark current.

Properties of Specific Photoconductors. The long-wavelength threshold for photoconductivity is usually determined by the bandgap of the material according to the relationship

$$\lambda_c = 1.24/E_g$$

where λ_c = threshold wavelength (μm) and E_g = bandgap (eV).

Bandgap values of materials commonly used as photodetectors in the 0.1- to 2- μm region are given in Table 9.4.2. The normalized spectral response of some of them is shown in Fig. 9.4.3.

SEMICONDUCTOR JUNCTION DETECTORS

Semiconductor junction detectors (photodiodes and phototransistors) differ from photoconductive detectors in that their operation depends essentially on a reverse-biased diode whose leakage current is varied by electron-hole pairs generated near or at the depletion region by light absorption. Their response time is characteristically short.

Basic Classes of Photodiode Detectors

Photodiodes fall into two general categories, the *depletion-layer type* and the *avalanche type*. The distinguishing feature between them is the existence of a gain mechanism.

The Depletion-Layer Photodiode. The depletion-layer photodiode family includes the *pn-junction diode*, the *pin diode*, the Schottky barrier (metal-semiconductor) diode, the point-contact diode, and the heterojunction diode.

1. *pn-junction diode.* Figure 9.4.4 is a diagram of a *pn-junction diode*. The junction is reverse-biased, and the diode is illuminated either at the *n* or *p* region, away from the depletion region (Fig. 9.4.4a), or right at the depletion region (Fig. 9.4.4b). Their built-in field enables them to be operated in the photovoltaic mode (i.e., no externally applied bias); however, the photoconductive mode, with a fairly large reverse bias, is usually the more common mode of operation.
2. *pin photodiode.* Figure 9.4.5 shows a cross-sectional diagram of a typical *pin* photodiode. The sensitivity range and frequency response of this type of diode depend principally on the thickness of the intrinsic layer (which defines the depletion layer). Light passes through the *p* region before it arrives at the depletion region, where it excites hole-electron pairs that are very quickly swept out by the large electric field present.
3. *Metal-semiconductor photodiode.* Figure 9.4.6 is a cross-sectional diagram of a metal-semiconductor (Schottky barrier) photodiode. In this case, light passes through a thin (~10 nm) metal film with a suitable antireflection coating to minimize large absorption and reflection losses. As with the *pn* and *pin* diodes, the photogenerated electron-hole pairs in the semiconductor give rise to an output-signal current.

FIGURE 9.4.2 Detectivity vs. wavelength for various photoconductors. PC = photoconductive mode. PM = photomultiplier mode.

Phototransistors

A *npn* or *npn* junction transistor can act as a photodetector, with the possibility of large internal gain. An *npn* structure, for example, is usually operated as a two-terminal device with the base floating and the collector positively biased.

Phototransistors are generally fabricated of Ge or Si in the same manner as conventional transistors, except that a lens or window is provided in the transistor to admit light at the base or base-collector junction. Response time of 10^{-8} and peak sensitivities of 30 A/lm are possible. Gains of several hundred have been attained with dark currents as low as nanoamperes.

4. *Point-contact photodiode.* Figure 9.4.7 shows a diagram of a point-contact detector. Light is incident onto the Schottky barrier through an etched cavity in the semiconductor. This detector is extremely fast because of small dimensions and low capacitance.

5. *Heterojunction photodiode.* A depletion-layer photodiode can be constructed by forming a junction between two semiconductors of different bandgaps. Figure 9.4.8 shows a photodiode made up of n^- GaAs and p^- Ge. Light is absorbed almost completely in the low-bandgap material. Large dark currents could arise owing to spontaneous electron-hole generation in the depletion region from a large density of interface states. This could have deleterious effects on the signal-to-noise ratio at low light levels.

Avalanche Photodiodes. Depletion-layer photodiodes operated at higher-reverse-biased voltages give an increase in output signal. This is because of internal carrier multiplication via the avalanche effect. If the field in the depletion region can impart an energy equal to or greater than the bandgap energy to an electron, this electron can create another hole-electron pair by collision, and this pair can be accelerated to create an additional pair, and so on. This gives rise to carrier multiplication and to internal gain in the photodiode. The avalanche photodiode is therefore the counterpart of the photomultiplier tube, and its multiplication factor M is

$$M = K(1 - V/V_B)^{-1}$$

where K is a constant and V_B is the breakdown voltage.

Figure 9.4.9 shows two types of avalanche photodiodes with guard rings. The guard ring prevents a high-field breakdown region from reaching the surface.

Performance of Photodiodes. The spectral dependence of D^* , gain, speed of response, and dark current of the various photodiodes are shown in Table 9.4.1 and Fig. 9.4.2.

TABLE 9.4.1 Parameters of Various Photoconductive Detectors

Photodetector	Gain	Response time, s	Dark current
Photoconductor	10^5	10^{-3}	1–10 mA
<i>pn</i> junction	1	10^{-11}	1–10 μ A
Metal-semiconductor	1	10^{-11}	
Avalanche diode	10^4	10^{-10}	
Point contact	1	...	1–3 mA
Heterojunction photodiode	1	...	High
Phototransistor	10^2	10^{-8}	1 nA
Photofet	10^2	10^{-7}	1 μ A

TABLE 9.4.2 Bandgap Values for Photoconductor Materials

Material	Threshold λ_c, μ m	Bandgap, eV
CdS	0.52	2.4
CdSe	0.73	1.7
ZnS	0.33	3.7
ZnSe	0.48	2.6
GaAs	0.89	1.4
InP	1.03	1.2

9.60 RADIANT ENERGY SOURCES AND SENSORS**Photofets, SMS Photodetectors, and *pnpn* Devices**

The *photofet*, or *photosensitive field-effect transistor*, combines a photodiode and high-impedance amplifier in one device to achieve photodetection with large gain.

A *semiconductor-metal-semiconductor* (SMS) device is essentially a Schottky barrier device with gain.

A silicon controlled rectifier (SCR), or *pnpn device*, can be used as a photosensitive switch, with photo-generated current taking the place of the usual gate current.

CHAPTER 9.5

CHARGE TRANSFER DEVICE (CTD) IMAGERS

Larry V. Caldwell, Andrew J. Kennedy, John H. Pollard

MONOLITHIC SOLID-STATE SELF-SCANNED IMAGE SENSORS

Monolithic solid-state self-scanned image sensors of the charge-coupled-device (CCD) and charge-injection-device (CID) types are extremely versatile and can be applied to high- and low-light-level imaging, optical character recognition, and facsimile reproduction. Solid-state devices offer advantages over vidicons for imaging applications: they provide lag-free, burn-free imaging and operate at low power in a self-scanned mode; they are lightweight and have high sensitivity. Advanced metal-oxide-semiconductor (MOS) technology is employed to fabricate the closely spaced single- or multiple-capacitor imaging elements, called *pixels*. Linear or area configuration of the pixels, with the appropriate on-chip scanning circuit and low-noise preamplifier, constitute the focal-plane image sensor in a camera system.

CCD IMAGING

The principle of operation is based on the transfer of photogenerated minority-carrier charge packets to adjacent pixels. Sequentially clocked voltage pulses applied to adjacent pixels create potential wells, which transfer charge packets to adjacent positions across the surface. Each charge packet corresponds to a pixel-sized optical image element. Thus, the moving charge packets and transferred to a low-capacitance output diode that has typical values on the order of 0.2 pF to obtain the video signal. This is one of the major advantages of the CCD imagers and produces high signal-to-noise output signals. Two implementations of CCD imagers are possible, one using charge transport in a surface channel and the other in a buried or bulk channel.

In the surface-channel device (SCCD) the conduction channel is at the semiconductor-oxide interface and allows the signal charge packets to interact with interface states. The resultant interface-state trapping can be reduced by introducing a bias charge 5 to 20 percent of full well, referred to as “fat zero.” The performance is limited by temporal noise resulting from interface state trapping and a spatial or fixed pattern noise caused by nonuniform fat-zero insertion.

For a buried-channel device (BCCD) the conduction channel is ion-implanted approximately 0.5 μm into the bulk with respect to the semiconductor-oxide interface. The charge packets interact with low density (of the order of 10^{11} cm^{-3}) bulk states, but the bulk trapping noise is insignificant even for signals as low as approximately 10 electrons per pixel per frame at -20°C . The charge transfer efficiency is also improved over the surface-channel device because of the larger fringing fields between the pixels present in the channel.

CID Imaging

The CID is an XY addressed matrix of MOS capacitor pairs in which each capacitor pair constitutes a pixel. Charge transfer occurs only between the capacitor pairs within a pixel, and the photogenerated charge packets are not transferred to a common output. The charge packets are stored by biasing at least one of the capacitors. When the capacitor pair of a pixel is simultaneously pulsed to zero, the potential well collapses and the stored minority carrier charge is injected into the substrate, where most of the carriers recombine. This injected charge provides the video signal. A reverse-biased epitaxial junction in the substrate collects the unrecombined minority carriers to prevent them from diffusing back into the same pixel or into neighboring pixels, which would degrade the resolution.

An alternative low signal-to-noise readout technique uses an output circuit that senses the relative magnitude of the stored charge in a given pixel by transferring the charge between the capacitor pairs. Even with this improvement, the effective output capacitance of a CID is still approximately an order of magnitude higher than that of a CCD. This is a definite disadvantage for low-light-level imaging, but the superior antiblooming control and the random-access features provided by the CID scheme are useful in many other applications.

CHARGE-TRANSFER-DEVICE ARCHITECTURE

Charge-coupled-device area imagers have been fabricated in two main configurations. One uses a frame-storage mode and the other in interline transfer mode. The former has nearly 100 percent optically sensitive imaging area with transparent electrodes or backside illumination but can suffer from optical transfer smearing effects. For certain applications not requiring TV readout rates, e.g., astronomical observations and space telescopes, full frame imagers can be used.

The frame-storage device is illustrated in Fig. 9.5.1. Charge is integrated in the imaging section and then rapidly moved into the frame-storage section for subsequent readout through the serial shift register. In this mode both frontside and backside illumination is possible. Interlaced readout is obtained by imaging under different electrode sets, giving alternate readout of frame A and frame B. The shaded regions are opaque.

The interline transfer device is shown in Fig. 9.5.2. The charge is integrated in the photosensitive areas and is shifted into opaque columns for subsequent transfer to the readout serial shift register. In this mode only frontside illumination is possible. Interlacing is obtained by integration under different electrodes in subsequent frames (A and B in the figure). Shaded regions are opaque.

In the charge-injection-device area imager (Fig. 9.5.3) a particular column is allowed to float, and the change in potential after a row transfer under that column provides the pixel signal readout. Area imaging is obtained by suitable scanning of the horizontal and vertical registers. The device has the advantage of random access and is also free of optical smearing effects. Transparent electrodes allow about 100 percent optically active areas with a sensitivity that depends on the readout scheme.

FIGURE 9.5.1 Frame-storage charge transfer device.

FIGURE 9.5.2 Interline charge transfer device.

FIGURE 9.5.3 Charge injection area imager.

LOW-LIGHT-LEVEL IMAGING

Image-intensifier technology can be used with charge transfer devices for low-light-level applications, and two methods are available. In the EBS-CCD approach (electron-bombarded silicon-CCD), the phosphor screen, in a proximity-focused and/or inverter-type image intensifier, is replaced by a backside thinned and accumulated silicon CCD. The impinging 8- to 15-kV photoelectrons produce high gains in the approximately 10- μm -thick CCD substrate. The maximum theoretical gain is $V/3.5$, where V is the accelerating voltage of the incident electrons.

In this mode of operation the effective preamplifier noise of a cooled direct-view CCD is reduced by the approximately 1000 to 2500 electron gain in the CCD, and low-light level imaging has been demonstrated under overcast night-sky illuminance levels of 8 μlx . The second method uses image intensifiers, fiber optically coupled directly to either a frontside-illuminated CCD or CID area array. This hybrid approach allows the selection of conventional image intensifiers based on an optimum trade-off between gain, life expectancy, noise figure, and charge-transfer-device noise.

CHAPTER 9.6

INFRARED DETECTORS AND ASSOCIATED CRYOGENICS

Wayne T. Grant, Randolph E. Longshore

DETECTORS

Infrared Detectors

Infrared detectors provide an electrical output, which is a useful measure of the incident infrared radiation. It is usually necessary to cool detectors to cryogenic temperatures to reduce the thermal noise inherent in an electrical transducer. Infrared detectors can be divided into two categories, *thermal detectors* and *quantum detectors*.

Thermal Detectors (Table 9.6.1)

Thermal detectors are of three types. The *bolometer* varies its electrical resistance as a result of temperature changes produced by absorbed infrared radiation.

The *thermocouple* is a junction of two dissimilar metals. When the junction is heated, it produces a voltage across the two open leads. A *thermopile* consists of several thermocouples combined in a single responsive element.

The *pyroelectric detector* produces an observable external electric field when heated by infrared radiation.

Quantum Detectors (Table 9.6.2)

Quantum detectors are of three types. A *photovoltaic detector* is a *pn* semiconductor junction. Absorbed infrared photons produce free charge carriers which, if near the junction, are separated by it, producing an external voltage (open circuit) or an electric current (closed circuit).

A *photoconductor* is a semiconductor in which absorbed infrared photons produce free charge carriers, resulting in a change in the electric conductivity.

A *photoemissive detector* is one in which incident photons impart sufficient energy to surface electrons to free them from the detector surface.

Detector Parameters

The parameters most often used in the description of infrared detectors are as follows.

TABLE 9.6.1 Thermal Detectors

Type	Operating temp, K	Detectivity D^* , $\text{cm} \cdot \text{Hz}^{1/2}/\text{W}$	Wavelength region, μm	Response time, ms	Resistance
Pyroelectric	300	1×10^9	>1	1	10 T Ω
Thermistor	300	5×10^8	1–40	0.1	2 M Ω

Tin bolometer	3.7	7×10^{10}	>10	10	100 Ω
Carbon bolometer	2.0	4×10^{10}	>10	1	100 k Ω

Responsivity R is the ratio of the rms signal voltage (or current) to the rms incident signal power, referred to an infinite load impedance or to the terminals of the detector, $R = V_{s,rms}/P_{s,rms}$. Spectral responsivity R_λ refers to monochromatic input signal, and blackbody responsivity R_{BB} refers to an input signal having a blackbody spectrum. The units of responsivity are volts per watt (or amperes per watt). Responsivity is a function of wavelength λ , signal frequency f , operating temperature T , and bias voltage V_B .

Impedance times area product ZA is a parameter used to characterize a photovoltaic detector. Here A is the area of the detector, and Z is the dynamic impedance taken from the I - V curve of the diode at some operating point; that is, $Z = \delta V/\delta I$. Usually the zero-bias impedance Z_0 is measured to determine the thermal noise and the proper matching to external electric circuits. The unit of ZA is $\Omega \cdot \text{cm}^2$.

[†]Avalanche.

Chopping frequency f_c is the rate at which the blackbody radiation source is mechanically interrupted to provide a strong periodic signal for separating ac components of the instantaneous power from the dc component.

Noise-equivalent power (NEP) is that value of incident rms signal power required to produce an rms signal-to-noise ratio of unity $NEP = V_{n,rms}/R$. Spectral noise-equivalent power $(NEP)_\lambda$ refers to a monochromatic input signal, and blackbody noise-equivalent power $(NEP)_{BB}$ refers to an input signal having a blackbody spectrum. The unit of NEP is the watt, NEP is a function of wavelength λ , detector area A , chopping frequency f_c , electric bandwidth Δf , temperature of blackbody T_{BB} , field of view Ω , and background temperature T_B .

Detectivity D is the reciprocal of the NEP. It can also be expressed as the rms signal-to-noise ratio per unit of rms power incident on the detector. Spectral detectivity D_λ and blackbody detectivity D_{BB} are the reciprocals of NEP and $(NEP)_{BB}$, respectively.

D star (D^*) is a normalization of the reciprocal of the noise-equivalent power to take into account the area and electric-bandwidth dependence, $D^* = \sqrt{A\Delta f}/NEP = \sqrt{A\Delta f}/D$. By using $(NEP)_{BB}$, D_{BB}^* can be determined, and from the definitions of $(NEP)_{BB}$ and R , $D_{BB}^* = \sqrt{A\Delta f}/V_{s,rms}V_{n,rms}P_{BB,rms}$, where $P_{BB,rms}$ is the rms power incident on the detector from a blackbody at temperature T_{BB} . Since D_{BB}^* depends on T_{BB} , f_c , and Δf , it is sometimes written as $D^*(T_{BB}, f_c, \Delta f)$. Similarly, D_λ^* depends on λ , f_c , and Δf and is sometimes written as $D^*(\lambda, f_c, \Delta f)$. It can be determined from $(NEP)_\lambda$, $D_\lambda^* = \sqrt{A\Delta f}/V_{s,rms}V_{n,rms}P_{\lambda,rms}$ where $P_{\lambda,rms}$ is the rms power incident on the detector from a monochromatic source.

These figures of merit can be used to compare detectors of different types since the detector with the greater value of D^* is a better detector when the terms in the parentheses are identical. This does not hold for detectors limited by noise resulting from fluctuations in background photon flux. For such detectors, field of view and background temperature must be specified. The units of D^* are $cm\cdot Hz^{1/2}/W$.

Quantum efficiency (QE or η) is the ratio of countable output events to the number of incident photons.

Time constant τ is a measure of the speed of response of a detector. It is usually defined as $\tau = (2\pi f_c)^{-1}$, where f_c is that signal frequency at which the responsivity has fallen to 0.707 times its maximum value.

Noise Mechanisms in Infrared Detectors

Noise mechanisms in infrared detectors are usually of five types.

Photon Noise (Background Noise). Random fluctuations in the arrival rate of background photons incident on the detector produce random fluctuations in its output signal. Photodetectors whose D^* is limited only by this type of noise are called *background-limited infrared photodetectors* (BLIP detectors). This value of D^* is the theoretical limit for a photon detector.

Figure 9.6.1 is a plot of relative improvement in D^* versus angular field of view for a BLIP detector. Cooled spectral filters also improve the D_λ^* of a BLIP or near-BLIP detector by attenuating radiation at wavelengths which are not of interest.

Johnson Noise (Nyquist or Thermal Noise). The random motion of charge carriers in a resistive element at thermal equilibrium generates a random electric voltage across the element.

Generation-Recombination Noise (GR). Variations in the rate of generation and recombination of charge carriers in the detector create electric noise.

Shot Noise. Since the electric charge is discrete, there is a noise current flowing through the detector as a result of current pulses produced by individual charge carriers.

1/f Noise. The mechanism involved in this type of noise is not well understood. It is characterized by a $1/f^n$ noise-power spectrum, where n varies from 0.8 to 2.

FIGURE 9.6.1 Relative increase in D^* for BLIP detectors obtained by using cold shielding.

FIGURE 9.6.2 Spectral D^* of photodetectors.

Detector Data

Tables 9.6.1 and 9.6.2 list commercially available detectors. They include the operating temperature, cutoff wavelength, and peak D^* .

Figure 9.6.2 is a plot of D^* versus wavelength for selected detectors. Since detector noise is a function of operating temperature, D^* will also vary with temperature. Figure 9.6.3 is a plot of peak D^* versus temperature for selected detectors. All values tabulated are data from above-average single-element detectors.

Charge Transfer Devices for Infrared Detection

In applications requiring many infrared detectors, e.g., thermal imaging, the detectors and signal processors have been integrated into a single structure. The signal processor provides rapid and efficient readout of the

FIGURE 9.6.3 Peak D^* vs. temperature for selected detectors. PC = photoconductive mode, PV = photovoltaic mode.

many detected signals by using charge-coupled devices (CCDs) or charge-injection devices (CIDs). These structures have been fabricated with InSb, extrinsic silicon, and HgCdTe.

Detector Selection

Though no absolute guidelines for the choice of an infrared detector for a specific application are possible, certain criteria can be used to eliminate many of the available detectors. Among them are spectral region of interest, maximum signal frequency, required sensitivity, and available cooling.

COOLERS

Cryogenic Cooling

For BLIP performance, temperatures of 200 K or lower are required for intrinsic infrared detectors, and extrinsic detectors require temperatures of 80 K or less (Table 9.6.2).

The four basic types of cooling systems are:

1. *Open-cycle, expendable systems*, which operate by the transfer of stored cryogens
2. *Mechanical coolers*, which are closed-cycle, expansion engines providing cooling at low temperatures and rejecting heat at high temperatures

3. *Thermoelectric coolers*, which operate by using the Peltier cooling effect
4. *Radiation coolers*, which are passive and cool detectors by radiating heat to the low-temperature deep-space environment.

Cooling Specifications

The particular application and detector type determine the best-suited cooling system. Variables used for cooler specifications include cooling capacity, cooling temperature, cooldown time, temperature stability, reliability, duty cycle, environment, weight, configuration, noise (acoustical, electromagnetic, mechanical), and power (ac, dc, limits).

Open-Cycle Expendable Systems

Open-cycle systems include the use of high-pressure gas combined with a Joule-Thomson (J-T) expansion valve, cryogenic liquids, or solid cryogenics.

Joule-Thomson. The J-T cooling process exploits the cooling effect obtained by the adiabatic expansion of a high-pressure (1000 to 6000 lb/in.²) gas through an orifice. The cooled, expanded gas is used to cool incoming gas. This process of regenerative cooling continues until liquid forms at the orifice. Figure 9.6.4 shows a typical J-T cooler. Self-regulating throttle valves can be placed in the orifice of the J-T cooler to maintain constant temperature, reduce clogging, and improve gas economy. Some gases, e.g., helium, hydrogen, and neon, require precooling before the J-T cooling effect can occur.

Liquid-Cryogen Storage. Cryogenics can be stored as liquids in equilibrium with their vapors (subcritical) or as homogeneous fluids at high pressure and temperatures (supercritical). There are two basic types of storage, direct-contact and liquid-feed. In the direct-contact (or integral) system, the detector is built into a cryogenic dewar which stores the liquid cryogen. In the liquid-feed method, the cryogen is fed to the detector from a remote storage tank. The liquid is transferred by gravity or by gas pressure resulting from the natural pressure buildup in the storage tank.

Solid-Cryogen Storage. Stored solid cryogen sublimates, causing an increase in pressure and temperature. The detector temperature and the dewar pressure are maintained at constant levels by venting the gas through specially designed ducts. Such coolers have operated successfully in space for a year or more.

Mechanical Coolers

Closed-cycle, expansion-engine refrigerators (described below) are used to cool infrared detectors. Cooling is produced by the expansion of a gas from a high pressure to a low pressure, with consequent reduction of working gas temperature. The figure of merit for coolers is the coefficient of performance (COP), the ratio of the produced cooling power to the power supplied. The Carnot cycle is used as a standard of comparison because for given temperature limits its COP is maximum. For a Carnot engine operating between the temperatures T_a and T_c , $\text{COP} = T_c/(T_a - T_c)$, where heat is absorbed at T_c and heat is rejected at a higher temperature T_a .

Stirling. In the Stirling cycle, cooling is obtained by cyclic out-of-phase motion of a compression piston and a displacer-regenerator. The working gas is compressed while occupying the ambient space, at temperature T_a , by an upward motion of the compression piston, reducing the gas volume. Heat of compression is rejected to ambient. The COP for an ideal working gas is equal to that of the Carnot engine. This refrigeration cycle is well developed. Stirling cycle refrigerators have the best COP in practice (10^{-3} to 5×10^{-2}) and the best ratio of total weight per watt refrigeration compared with other refrigerators.

Vuilleumier (VM). This is a heat-driven cycle which is exploited for its long life and low vibration, owing in part to inherently very low dynamic forces on moving parts. Coolers have been built that provide

FIGURE 9.6.4 Single-stage, open-cycle Joule-Thomson cooling system.

refrigeration at 10 K. Cooling is obtained by cyclic out-of-phase motion of two displacer-regenerators. The working gas throughout the entire cooler is compressed by downward motion of the hot displacer-regenerator as it transfers part of the gas at the ambient end into the heated end. COP is equal to that for two Carnot heat engines in series: $COP = (T_c/T_h)(T_h - T_a)/(T_a - T_c)$. Typical COP values of 3×10^{-4} to 2×10^{-2} are obtained.

Gifford-McMahon (GM) and Solvay. By separating the expander from the compressor, a refrigeration system can be constructed that consists of a simple, lightweight cooling unit and a compressor which can be located remotely, connected to the expander with pressure lines. A piston displacer-regenerator is pneumatically moved up and down by timed valving of the high and low working-gas pressure. Cyclic charging and discharging of the expander working-gas pressures with time piston motion will pump heat from the cold to the ambient end. Heat pumped from the cold end using the GM cycle is rejected at the ambient end of the expander. Heat pumped from the cold end using the modified Solvay cycle is rejected along pressure lines and at the compressor. For these coolers COP values of 2×10^{-4} to 10^{-2} are measured.

J-T Closed Cycle. In this system a compressor is used to supply high-pressure gas to the J-T throttling valve. After expansion, the gas is recycled through the compressor. COP values of 3×10^{-3} to 10^{-2} are obtained for this system.

FIGURE 9.6.5 Single-stage thermoelectric refrigeration.

Thermoelectric (TE) Cooler

The basic operating principle of the thermoelectric cooler, the Peltier cooling effect, is the absorption or generation of heat as a current passes through a junction of two dissimilar materials (Fig. 9.6.5). Electrons passing across the junction absorb or give up an amount of energy equal to the transport energy and the energy difference between the dissimilar-materials conduction bands. Cryogenic temperatures are reached using heat rejected from one thermoelectric cooler stage to supply thermal input to the stage below. The maximum temperature difference attainable on a practical basis is about 150°C, which implies a minimum attainable temperature of approximately 150 K.

Radiation Coolers

Radiation coolers are used in spaceborne applications. These systems are passive and cool by radiating heat from the detector into the low-temperature (4-K) sink of deep space. The radiators consist of a suitably sized cold plate of high emissivity connected to the detectors. The high-vacuum in-space environment minimizes convective heating, but the radiator must be shielded from sunlight and (for near-earth orbits) from thermal emission and reflected sunlight from the earth and its atmosphere. Radiation coolers have been designed for cooling milliwatt-level loads at 85 K and 5-W loads at 135 K.

CHAPTER 9.7

SOLAR CELLS*

Kim W. Mitchell

INTRODUCTION

A solar cell is a semiconductor electric-junction device that absorbs the radiant energy of sunlight and converts it directly and efficiently into electric energy. Solar cells may be used individually as light detectors, e.g., in cameras, or connected in series and parallel to obtain the required values of current and voltage for electric-power generation.

Most solar cells are made from single-crystal silicon and have been too expensive for generating electricity, except for space satellites and remote areas where low-cost conventional power sources are unavailable. Recent research has emphasized lowering solar-cell cost by improving performance and by reducing materials and manufacturing costs. One approach is to use optical concentrators such as mirrors or fresnel lenses to focus the sunlight onto solar cells of smaller area. Other approaches replace the high-cost single-crystal silicon with thin films of amorphous or polycrystalline silicon, gallium arsenide, cadmium sulfide, or other compounds.

SOLAR RADIATION

The intensity and quality of sunlight is dramatically different outside the earth's atmosphere and on the surface of the earth, as shown in Fig. 9.7.1. The number of photons at each energy is reduced on entering the earth's atmosphere because of reflection, scattering, or absorption by water vapor and other gases. Thus, while the solar energy at normal incidence outside the earth's atmosphere is 1.36 kW/m^2 , on the surface of the earth at noontime on a clear day the intensity is about 1 kW/m^2 .

PRINCIPLES OF OPERATION

The conversion of sunlight into electric energy in a solar cell involves three major processes: (1) absorption of the sunlight in the semiconductor material; (2) generation and separation of free positive and negative charges which move to different regions of the solar cell, creating a voltage in it; and (3) transfer of these separated charges through electric terminals to the outside application in the form of electric current.

In the first step, the absorption of sunlight by a solar cell depends on the intensity and quality of the sunlight, the amount of light reflected from the front surface of the solar cell, the semiconductor bandgap energy,

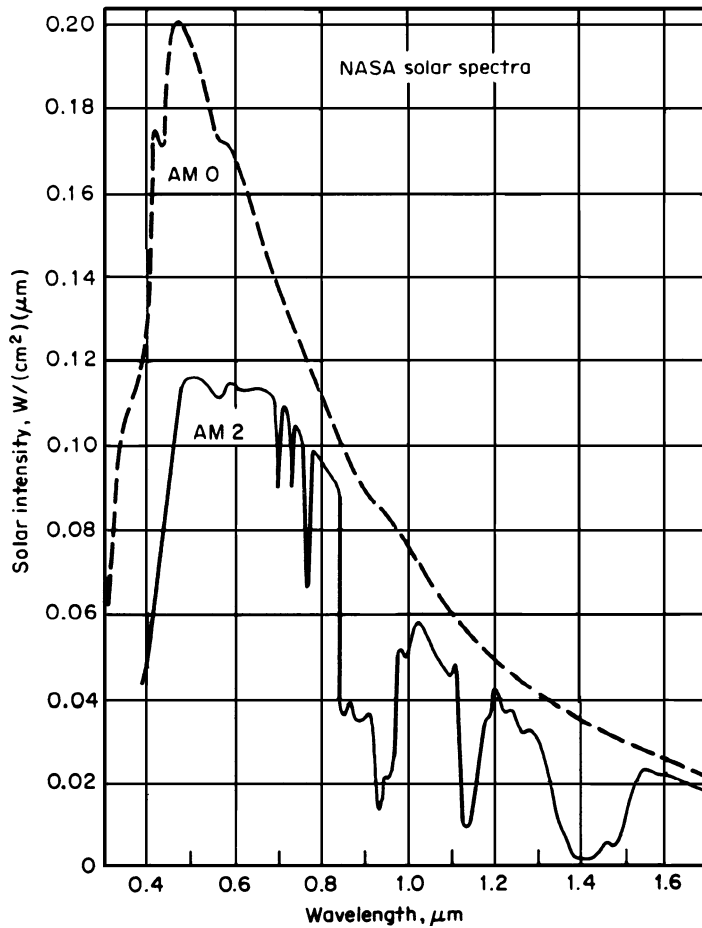

FIGURE 9.7.1 Variation of solar intensity with wavelength of photons for air mass O (AM0) outside the earth's atmosphere and for AM2, a typical spectrum on the surface of the earth.

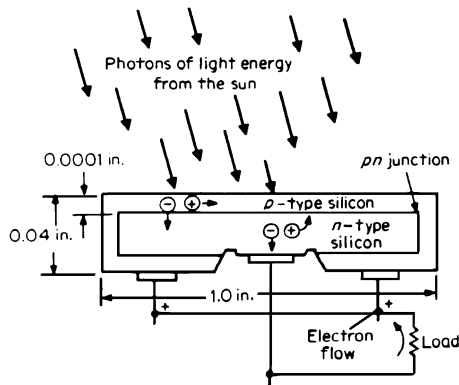

FIGURE 9.7.2 Cross-sectional view of a silicon pn -junction solar cell, illustrating the creation of electron pairs by photons of energy from the sun.

FIGURE 9.7.3 Electrical characteristics of silicon *pn*-junction solar cell at operating temperature of 17°C: (a) variation of open-circuit voltage and short-circuit current with light intensity; (b) variation in power output as load is varied from short to open circuit.

which is the minimum light (photon) energy the material absorbs, and the layer thickness. Some materials, e.g., silicon, require tens of micrometers thickness to absorb most of the sunlight, while others, e.g., gallium arsenide, cadmium telluride, and copper sulfide, require only a few micrometers.

When light is absorbed in the semiconductor, a negatively charged electron and positively charged hole are created. The heart of the solar cell is the electric junction which separates these electrons and holes from each other after they are created by the light. An electric junction can be formed by the contact of (1) a metal to a semiconductor (a Schottky barrier); (2) a liquid to a semiconductor (a photoelectrochemical cell); or (3) two semiconductor regions (a *pn* junction).

The fundamental principles of the electric junction can be illustrated with the silicon *pn* junction. Pure silicon, to which a trace amount of a column V element such as phosphorus has been added, is an *n*-type semiconductor where electric current is carried by free electrons. Each phosphorus atom contributes one free electron, leaving behind the phosphorus atom bound to the crystal structure with a unit positive charge. Similarly, pure silicon to which a trace amount of a column III element such as boron has been added is a *p*-type semiconductor, where the electric current is carried by free holes. Each boron atom contributes one hole, leaving behind the boron atom with a unit negative charge. The interface between the *p*- and *n*-type silicon is called the *pn* junction. The fixed charges at the interface owing to the bound boron and phosphorus atoms create a permanent-dipole charge layer with a high electric field. When photons of light energy from the sun produce electron-hole pairs near the junction, the built-in electric field forces the holes to the *p* side and the electrons to the *n* side, as illustrated in Fig. 9.7.2. This displacement of free charges results in a voltage difference between the two regions of the crystal, the *p* region being plus and the *n* region minus. When a load is connected at the terminals, an electron current flows in the direction shown by the arrow and useful electric power is available at the load.

SOLAR-CELL CHARACTERISTICS

The electrical characteristics of a typical silicon *pn*-junction solar cell are shown in Fig. 9.7.3. Figure 9.7.3a shows open-circuit voltage and short-circuit current as a function of light intensity from total darkness to full sunlight (1000 W/m^2). The short-circuit current is directly proportional to light intensity and amounts to 28 mA/cm^2 at full sunlight. The open-circuit voltage rises sharply under weak light and saturates at about 0.6 V for radiation between 200 and 1000 W/cm^2 . The variation in power output from the solar cell irradiated by full sunlight as its load is varied from short circuit to open circuit is shown in Fig. 9.7.3b. The maximum power output is about 11 mW/cm^2 at an output voltage of 0.45 V .

Under these operating conditions, the overall conversion efficiency from solar to electric energy is 11 percent. The output power as well as the output current is proportional to the irradiated surface area, whereas the output voltage can be increased by connecting cells in series, as in a chemical storage battery. Experimental samples of silicon solar cells have been produced which operate at efficiencies up to 18 percent, but commercial cell efficiency is around 10 to 12 percent under normal operating conditions.

Using optical concentration to intensify the light incident on the solar cell, efficiencies above 20 percent have been achieved with silicon cells and above 25 percent with gallium arsenide cells. New concepts to split the solar spectrum and illuminate two optimized solar cells of different bandgaps have achieved efficiencies above 28 percent with expected efficiencies of 35 percent. Thin-film solar cells currently between 4 and 9 percent efficiency are expected in low-cost arrays to be above 10 percent.

FILTERS AND ATTENUATORS

To make communication systems, radar systems, and the like work, we need filters and attenuators. Filters are basic electronic building blocks that are passive and active, analog and digital. They basically allow us to condition electrical signals in order to accomplish the elements of most of our complex electrical systems in use today.

Active filters have led to the elimination of elements that prohibited miniaturization. Active filters easily fit into today's microcircuits and systems.

Digital filters represent a class of filters that do not have the limitations of analog filters. Although they require much care and attention in how they are designed and how they will be used, they most certainly have given us a significantly larger set of applications some of which could never be handled by analog filters. Because of the nature of digital filters, we need to fully understand the problems with phase.

In this section we look at the basic principles behind all of these filters. In Chap. 10.7, we look at attenuators that are used in matching impedances, critical in high-frequency systems. C.A.

CHAPTER 10.1

IDEAL FILTERS AND APPROXIMATIONS

Edwin C. Jones, Jr., Harry W. Hale

INTRODUCTION

Campbell and Wagner independently developed the concept of an electrical wave filter in 1915. The continuation of this work proceeded along two paths, *image-parameter filter design* and *insertion-loss filter design*. The latter technique is now dominant.

Insertion-loss filter design requires the designer to specify an appropriate network response as a part of a transfer function. The part might be magnitude, phase, or delay. Norton, Foster, Cauer, Bode, and Darlington developed procedures to determine the complete transfer function and to synthesize the network. Digital computers have made the techniques practical, and now the design of these filters is largely a matter of looking up element values in computer-generated tables and modifying them in a routine fashion. Virtually all techniques use a low-pass prototype and derive other filters from this prototype.

This chapter describes insertion loss techniques, develops common transfer functions, and gives structures and element values for passive networks. It also extends use of the transfer functions to several types of active networks.

Throughout, the notation is that of the Laplace transformation. The general frequency variable is $s = \sigma + j\omega$, where ω is the signal frequency in rad/s.

INSERTION-LOSS FILTER DESIGN

Figure 10.1.1 shows two general networks, often called two-ports. One has a current source, the other, a voltage source. The design procedure consists of these steps:

1. Determine filter specifications
2. Approximate the specifications with a network function part that will lead to a realizable circuit. Typical magnitude functions are

$$|G_{LS}(j\omega)| = \left| \frac{V_L}{V_S}(j\omega) \right| \quad (1)$$

Chapters 10.1 to 10.5 and Chap. 10.7 were contributed by Edwin C. Jones Jr. and Harry W. Hale. Portions were adapted from Fink and Beaty (eds.), "Standard Handbook for Electrical Engineers," 13th ed., McGraw-Hill, 1993. Chapter 10.6 was contributed by Arthur B. Williams and Fred J. Taylor, author's of the "Electronic Filter Design Handbook," 3rd ed., McGraw-Hill, 1995, from which portions were adapted.

FIGURE 10.1.1 General form of network: (a) with voltage source; (b) with current source.

$$|Z_{LS}(j\omega)| = \left| \frac{V_L(j\omega)}{I_S} \right| \tag{2}$$

for networks of Fig. 10.1.1a and b, respectively. (For convenience, subsequent references to G_{LS} omit subscripts, and the discussion applies to Z_{LS} except where noted.) The phase function

$$\theta(\omega) = \arg G(j\omega) \tag{3}$$

is often the specification.

3. Synthesize the coupling network of Fig. 10.1.1a or b. Darlington* showed that this network may be lossless, and often that it is a ladder network, an attractive circuit structure.

CLASSIFICATION OF IDEAL FILTERS

It is convenient to have ideal filter characteristics for discussion purposes. Four are ideal magnitude characteristics, and one is for phase. They are:

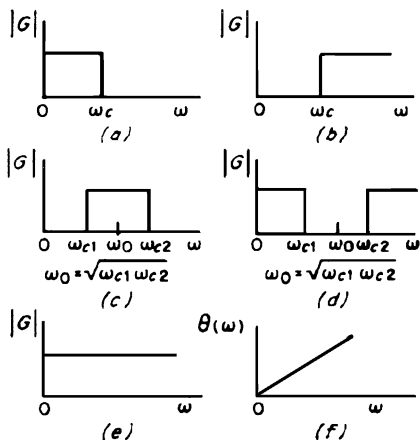

FIGURE 10.1.2 Ideal-filter characteristics: (a) low-pass; (b) high-pass; (c) bandpass; (d) band-elimination; (e) all-pass (magnitude); (f) all-pass (phase).

1. The *low-pass* filter transmits without attenuation or loss signal frequencies from zero to a cutoff frequency and stops all signal frequencies higher than the cutoff.
2. The *high-pass* filter stops all signal frequencies below its cutoff, and transmits without attenuation signal frequencies above the cutoff.
3. The *bandpass* filter passes all signal frequencies between the lower and upper cutoff frequencies, and stops all signal frequencies outside this range.
4. The *bandstop* (or reject) filter stops signal frequencies between its lower and upper cutoff frequencies, and transmits all signal frequencies outside this range.
5. The *all-pass* filter transmits all signal frequencies. It produces a predictable phase shift.

These ideal filter characteristics are shown in Fig. 10.1.2.

*In many cases, explicit bibliographic references are omitted. However, the bibliography entries are in about the same order as the topics that are discussed.

THE LOW-PASS PROTOTYPE

Synthesis techniques lead to low-pass prototypes, for which extensive tables exist. Modifications of these prototypes enable design of the three remaining filters. The technique is to make $R_L = 1$ and $\omega_C = 1$, to transform specifications to the low-pass domain, and to determine the prototype. Transformations of the low-pass prototype to the needed domain lead to the final network.

THE APPROXIMATION PROBLEM

The ideal low-pass filter is not realizable. A basic problem is to select a transfer function magnitude $|G(j\omega)|$ that *approximates* the ideal characteristic and results in a practical network. Figure 10.1.3 illustrates the concept, and defines the limits on the frequency response. The approximation for $|G(j\omega)|$ must lie within the shaded region.

FIGURE 10.1.3 Limits on frequency response.

Often it is easier to work with the magnitude-squared function, which is of the form

$$|G(j\omega)|^2 = K^2 \frac{A(\omega^2)}{D(\omega^2)} \tag{4}$$

The numerator and denominator must be even, nonnegative polynomials, and other restrictions apply. Another form for Eq. (4) is

$$|G(j\omega)|^2 = K^2 \frac{N(\omega^2)}{N(\omega^2) + M(\omega^2)} = K^2 \frac{1}{1 + \frac{M(\omega^2)}{N(\omega^2)}} \tag{5}$$

A common technique is to let $N(\omega^2) = 1$. Equation (5) then becomes

$$|G(j\omega)|^2 = \frac{K^2}{1 + M(\omega^2)} \tag{6}$$

A requirement for the polynomial $M(\omega^2)$ is that

$$|M(\omega^2)| \begin{cases} \ll 1 & \omega \ll 1 \\ \gg 1 & \omega \gg 1 \end{cases}$$

which leads to all-pole approximations.

Low-pass filters based on Eq. (6) are ladder structures with inductors as series elements, and capacitors as shunt. The more general form of Eq. (5) leads to a filter that is a ladder with the series elements having parallel combinations of inductors and capacitors, while the shunt elements are series combinations of inductors and capacitors. The Inverse Chebyshev and elliptic approximations lead to such filters.

K of Eq. (4) is not arbitrary. The requirement is that, in terms of Fig. 10.1.1,

$$|G(0)| = \frac{R_L}{R_S + R_L} \tag{7}$$

10.10 FILTERS AND ATTENUATORS

for a voltage source, and

$$|Z(0)| = \frac{R_s R_L}{R_s + R_L} \quad (8)$$

for a current source. K must satisfy this constraint.

TRANSFER FUNCTION CONSTRUCTION

It is necessary to construct a complete transfer function from the approximation. The complete transfer function allows computation of time-domain responses. Several active realizations require them. The processes show construction of $G(s)$, in terms of Eq. (6). The technique for $Z(s)$ is identical. The Inverse Chebyshev shows an extension for the case of Eq. (5), where the nonconstant numerator imposes additional considerations.

From a suitable $G(\omega^2)$, use analytic continuation to obtain

$$|G(j\omega)|_{\omega^2=-s^2}^2 = G(s)G(-s) = \frac{K^2}{1 + M(-s^2)} \quad (9)$$

Assign the left-half-plane poles of $G(s)G(-s)$ to $G(s)$ and the right-half-plane poles to $G(-s)$, respectively, to ensure stability. The result is

$$G(s) = \frac{K}{\prod_{j=1}^n (s - s_j)} \quad (10)$$

where s_j are the left-half-plane poles.

The following sections describe six different approximations, five to the ideal low-pass filter and one to the ideal all-pass or time delay filter. Two approximations (the Inverse Chebyshev, and elliptic) are examples of Eq. (5), while the others all are examples of Eq. (6). Explicit equations give the poles for some approximations. Examples show use of these equations. Numerical solutions give the poles for other approximations. Tables show the roots, tabulated in terms of linear and quadratic factors.

THE BUTTERWORTH APPROXIMATION

The n th Butterworth approximation is

$$|G(j\omega)| = \frac{K}{(1 + \omega^{2n})^{1/2}} \quad (11)$$

Figure 10.1.4 shows the general form of the function. The first $2n - 1$ derivatives of $|G(j\omega)|$ are zero, and the magnitude of the function decreases monotonically with ω . Figure 10.1.4 also shows that increasing n improves the approximation in both the pass and stop bands, at the price of a more complex network. The appropriate n is the smallest value that will meet frequency domain specifications, as suggested in Fig. 10.1.5.

If the specifications require that

$$|G(j\omega)| \leq A \quad \omega_a \leq \omega < \infty \quad (12)$$

then the value of n required is the smallest integer satisfying the inequality

$$A \geq \frac{K}{(1 + \omega_a^{2n})^{1/2}} \quad (13)$$

FIGURE 10.14 The Butterworth approximation.

FIGURE 10.15 Determination of the minimum value of n for the Butterworth approximation.

In terms of attenuation, the frequency response is

$$\alpha = 20 \log \frac{|G(j\omega)|}{|G(0)|} = 10 \log(1 + \omega^{2n}) \quad \text{dB} \quad (14)$$

At $\omega = 1$,

$$\alpha = 10 \log 2 = 3.0103 \text{ dB} \quad (15)$$

This is a common interpretation of the cutoff frequency, frequently called the half-power or “3-dB” frequency. A more general specification of minimum attenuation α_{\min} (dB) for $\omega \geq \omega_a$ and a maximum attenuation α_{\max} for $\omega \leq \omega_b$ leads to a solution for n of

$$n = \log \frac{(10^{\alpha_{\min}/10} - 1)}{(10^{\alpha_{\max}/10} - 1)} \bigg/ 2 \log \left(\frac{\omega_a}{\omega_b} \right) \quad (16)$$

with the next larger integer being chosen.

The stable poles lie on a unit circle in the left half s -plane, and are given by $s_k = \sigma_k + j\omega_k$, where

$$\sigma_k = -\sin \frac{2k-1}{2n} \pi \quad \omega_k = \cos \frac{2k-1}{2n} \pi \quad k = 1, 2, \dots, n \quad (17)$$

Since complex poles occur in conjugate pairs, it is convenient to combine them into quadratic factors. When $n = 3$, Eq. (17) gives

$$G(s) = (s + 1)(s^2 + s + 1) \quad (18)$$

and for $n = 4$,

$$G(s) = (s^2 + 1.84776s + 1)(s^2 + 0.76537s + 1) \quad (19)$$

THE CHEBYSHEV APPROXIMATION

The n th order Chebyshev approximation is

$$|G(j\omega)| = \frac{K}{[1 + \epsilon^2 C_n^2(\omega)]^{1/2}} \quad (20)$$

FIGURE 10.1.6 The Chebyshev approximation: (a) n even; (b) n odd.

where $C_n(\omega)$ is the n th-order Chebyshev polynomial and ϵ is a real constant less than 1. Specifically,

$$C_n(\omega) = \begin{cases} \cos(n \cos^{-1}(\omega)) & \text{for } 0 < \omega \leq 1 \\ \cosh(n \cosh^{-1}(\omega)) & \text{for } 1 < \omega \end{cases} \quad (21, 22)$$

The polynomials in the form of Eqs. (21) and (22) are convenient for calculations. To show a conventional polynomial appearance, note that $C_0(\omega) = 1$ and $C_1(\omega) = \omega$. Use the recursion formula, which is derived from a trigonometric identity,

$$C_{n+1}(\omega) = 2\omega C_n(\omega) - C_{n-1}(\omega) \quad (23)$$

to develop higher-order polynomials. For example,

$$C_5(\omega) = 16\omega^5 - 20\omega^3 + 5\omega \quad (24)$$

Figure 10.1.6 shows the frequency response for the Chebyshev approximation for n even and odd. In either case there are n half cycles (from maximum to minimum and the reverse) in the interval $0 \leq \omega \leq 1$. One effect of the relative minimum at $\omega = 0$ when n is even is that there are combinations of R_S , R_L , and ϵ that are not realizable. In particular, the even-order Chebyshev approximation is unrealizable for any value of ϵ when $R_S = R_L$. The modified Chebyshev approximation that leads to realizable networks in this case.

FIGURE 10.1.7 Identification of ϵ and n .

Two parameters, ϵ and n , define a particular Chebyshev approximation. Figure 10.1.7 defines the parameters for n odd (the results also apply to n even). The ripple factor ϵ controls the passband limits, while both ϵ and n control the stopband. The ratio of upper to lower passband limits is $(1 + \epsilon^2)^{1/2}$, and the value of this ratio is sufficient to determine ϵ . The logarithmic function

$$10 \log(1 + \epsilon^2) \quad (\text{dB}) \quad (25)$$

describes this ratio. Thus, a Chebyshev approximation with $\epsilon = 0.7648$ has a 2.0 dB ripple. Equation (26) relates the ripple R , in dB, and ϵ , the ripple factor

$$\epsilon = \sqrt{10^{R/10} - 1} \quad (26)$$

With ϵ known and a specification that

$$G(j\omega) \leq A \quad \text{for } \omega_\alpha \leq \omega < \infty \quad (27)$$

The attenuation requirement in the stopband leads to the inequality

$$A \geq \frac{K}{[1 + \epsilon^2 C_n^2(\omega_a)]^{1/2}} \quad (28)$$

From Eq. (28) and the known value of ϵ ,

$$C_n(\omega_a) = \frac{(K^2 - A^2)^{1/2}}{A\epsilon} \quad (29)$$

This leads to the requirement on n , the order of the filter,

$$n = \frac{\cosh^{-1} C_n(\omega_a)}{\cosh^{-1} \omega_a} \quad (30)$$

with the next larger integer value being chosen.

The *half-power frequency* is a commonly used figure of merit for a filter. At this frequency, the power transmission to the load is 50 percent of the maximum, corresponding to a reduction of 3.0103 (or approximately 3) dB. Equation (31) gives the half-power frequency.

$$\omega_{hp} = \omega_{3dB} = \cosh \left(\frac{1}{n} \cosh^{-1} \frac{1}{\epsilon} \right) \quad (31)$$

To find the stable or left-half s -plane poles of $G(s)$, substitute $\omega - sj$ and set the denominator of Eq. (20) to zero. From this,

$$C_n \left(\frac{s}{j} \right) = \cos \left(n \cos^{-1} \frac{s}{j} \right) = \pm \frac{j}{\epsilon} \quad (32)$$

This equation is a complex function, and the complex solution is

$$\sigma_k = -\sin u_k \sinh v \quad (33)$$

$$\omega_k = \cos u_k \cosh v \quad (34)$$

where

$$u_k = \frac{2k-1}{2n} \pi \quad (35)$$

$$k = 1, 2, 3, \dots, n \quad (36)$$

$$v = \frac{1}{n} \sinh^{-1} \frac{1}{\epsilon} \quad (37)$$

Since complex roots occur in conjugate pairs, it is convenient to combine such pairs into quadratic factors. For example, with a ripple of 0.50 dB and third order,

$$G(s) = (s + 0.62646)(s^2 + 0.62646s + 1.14245) \quad (38)$$

while for a ripple of 1.0 dB and fourth order,

$$G(s) = (s^2 + 0.27907s + 0.98650)(s^2 + 0.67374s + 0.27940) \quad (39)$$

COMPARISON OF BUTTERWORTH AND CHEBYSHEV APPROXIMATIONS

A good comparison of the Butterworth and Chebyshev responses is possible when they have the same half-power frequency. In general, this requires a normalization of the Chebyshev approximation to a 3.0103 dB bandwidth before comparison. This occurs naturally when $\epsilon = 1$. Figure 10.1.8 shows the two-frequency responses for third order filters. Analysis shows that:

FIGURE 10.1.8 Butterworth and Chebyshev approximations for $n = 3$ and $\epsilon = 1$.

1. The Butterworth approximation is superior at and near $\omega = 0$. Of all polynomial approximations, it has the highest number of zero derivatives at the origin.
2. The Chebyshev approximation is superior at and near the cutoff frequency or passband edge.
3. The Chebyshev approximation is superior in the stopband.
4. The Chebyshev approximation sacrifices smoothness in the passband.

THE MODIFIED CHEBYSHEV APPROXIMATION

With passive networks, even-ordered Chebyshev networks with equal source and load resistances are unrealizable, because of the relative minimum at zero frequency in the frequency response. Saal has shown a modification of the Chebyshev polynomials that leads to even-ordered polynomials with a zero at $\omega = 0$, relative maxima and minima of $+1$ and -1 within the interval $0 < \omega \leq 1$, and that are monotonically increasing for $\omega > 1$. These polynomials are given in Table 10.1.1.

For a given n , the modified Chebyshev polynomials have the property that

$$C_n(\omega) > \bar{C}_n(\omega) > C_{n-1}(\omega) \tag{40}$$

for $\omega > 1$. Thus a low-pass approximation based on these polynomials for even n will be better in the stopband than that using the Chebyshev polynomial of order $n - 1$, but not as good as that using the regular Chebyshev polynomial of order n . However, it will, in passive networks, permit equal source and load resistances.

Figure 10.1.9 compares $C_n(\omega)$ and $\bar{C}_n(\omega)$ by plotting the ratio as a function of ω .

Table 10.1.2 gives the poles of the transfer function $G(s)$, in terms of quadratic factors, for $n = 2, 4, 6, 8$, and 10, and for ripples of 0.01, 0.10, 0.50, 1.00, and 3.00 dB. These poles assume that the end of the ripple band is the passband edge at $\omega = 1$. Table 10.1.11 gives the corresponding half-power frequencies.

TABLE 10.1.1 Modified Chebyshev Polynomials of Even Order

n	$C_n(\omega)$
2	ω^2
4	$5.82842713\omega^4 - 4.82842713\omega^2$
6	$25.9903811\omega^6 - 36.1865335\omega^4 + 11.1961524\omega^2$
8	$109.597711\omega^8 - 210.522708\omega^6 + 122.034355\omega^4 - 20.109358\omega^2$
10	$452.344415\omega^{10} - 1102.492675\omega^8 + 926.297276\omega^6 - 306.717773\omega^4 + 31.568758\omega^2$

THE LEGENDRE-PAPOULIS APPROXIMATION

Papoulis derived an approximation using Legendre polynomials ($L_n(\omega^2)$) of the first kind. The n th order approximation is

$$|G(j\omega)| = \frac{1}{\sqrt{1 + L_n(\omega^2)}} \tag{41}$$

FIGURE 10.1.9 Ratio of modified Chebyshev polynomial to Chebyshev polynomial. Limiting value as ω approaches infinity is in parentheses for each value of n .

Table 10.1.3 shows the polynomials, and Table 10.1.4 shows the denominator roots (poles) for this function.

This approximation has three important properties:

1. $L_n(\omega^2)$ increases monotonically, and thus $|G(j\omega)|$ decreases monotonically.
2. $L_n(0) = 0$ and $L_n(1) = 1$, which means that $|G(0)| = 1$ and $|G(1)| = 0.50$.
3. Of all polynomials satisfying 1 and 2, $L_n(\omega^2)$ has the largest derivative at $\omega = 1$, and thus this filter has the steepest cutoff characteristic.

Figure 10.1.10 compares the Legendre-Papoulis approximation with the Butterworth, and Chebyshev (3 dB) approximations for $n = 3$.

The selection of n follows the same general procedure as for the Butterworth approximation. To satisfy the specification

$$A \geq |G(j\omega_a)| = 1 / \sqrt{1 + L_n(\omega_a^2)} \tag{42}$$

or

$$L_n(\omega_a^2) \geq (1/A^2) - 1 \tag{43}$$

evaluate successively higher-ordered polynomials of Table 10.1.3 at ω_a .

THE BESSEL APPROXIMATION

The ideal all pass characteristics of Fig. 10.1.2.

$$|G(j\omega)| = K \tag{44}$$

and

$$\theta(j\omega) = -T\omega \tag{45}$$

implies that the output is a scaled (by K) replica of the input, delayed in time by T s. This notion leads to the definition of group delay, which is the negative derivative of the phase function

$$-\frac{\partial}{\partial \omega} \theta(j\omega) = \tau_d(\omega) \tag{46}$$

In the ideal case, the group delay is a constant T .

A series of Bessel polynomials provides a transfer function that yields a maximally flat approximation to the ideal delay. The form of the function that gives a group delay of 1 s at $\omega = 0$ is

$$G(s) = \frac{Kb_0}{s^n + b_{n-1}s^{n-1} + \dots + bs + b_0} \tag{47}$$

A recursion formula relates these polynomials

$$B_n = (2n - 1)B_{n-1} + s^2B_{n-2} \tag{48}$$

and Table 10.1.5 gives the coefficients of the first eight Bessel polynomials. Table 10.1.6 gives the pole locations for $G(s)$ in terms of quadratic factors.

Figure 10.1.11 shows the general forms of the delay and magnitude functions for this approximation. The magnitude behavior is that of a low-pass function, and Table 10.1.11 gives the resulting half-power frequencies.

The parameter n is selected to satisfy either a minimum group delay requirement or a minimum magnitude (or the equivalent maximum attenuation) requirement at some frequency ω_a , that is,

$$\tau_d(\omega_a) \geq T_a \tag{49}$$

or

$$|G(j\omega_a)| \geq A \tag{50}$$

with the more stringent condition being chosen. Figure 10.1.12 shows the attenuation versus ω and the group delay versus ω for $n = 2$ to 8, and can be used to select n .

THE STEP RESPONSE

The primary design consideration for a filter is its frequency response, but often the step response is of interest. Computation of the step response requires computation of the inverse Laplace transform of the transfer function

FIGURE 10.1.11 (a) Magnitude and (b) group delay for maximally flat group-delay approximation.

FIGURE 10.1.12 Group delay and attenuation for the Bessel approximation.

multiplied by $1/s$, readily done with modern computers and suitable software. Three figures of merit commonly characterize the step response. Figure 10.1.13 defines these, which are *overshoot*, *rise time*, and *delay time*. While the general form of Fig. 10.1.13 is common, the odd order, high ripple Chebyshev and modified Chebyshev responses have unusual features, as suggested in Figs. 10.1.14 and 10.1.15. Often several relative maxima occur before the peak value. Tables 10.1.7, 10.1.8, and 10.1.9 give the percent overshoot, rise time, and delay time, respectively, for the all pole approximations described.

THE PROTOTYPE FILTER NETWORKS

Passive networks that realize all pole functions are lossless ladder networks terminated in resistance at both ends. Figure 10.1.16 shows four networks classified by the type of transfer function, Z_{LS} or G_{LS} , being realized

FIGURE 10.1.13 General form of the step response and definitions of figures of merit.

FIGURE 10.1.14 Step response of third-order Chebyshev approximation with a 3-dB ripple.

and whether n is odd or even. The networks of Figs. 10.1.16*c* and *d* are duals of those in Figs. 10.1.16*a* and *b*, respectively. An application of source transformations to the networks of Fig. 10.1.16 yields the four networks of Fig. 10.1.17.

For a given type of source and value of n there are two networks to choose from. When the source is a current source and n is odd, Figs. 10.1.16*b* and 10.1.17*d* apply. In the first case, the first and last lossless elements are capacitors; in the second case, they are inductors.

For a given type of approximation and order of filter, numerical element values apply to four different networks. For example, a Butterworth approximation with $n = 2$ and R_S or $G_S = 1/2$ according to the specific networking being used, yields the four networks of Fig. 10.1.18. Here, the numerical values for the lossless elements are the same when they are taken in order from the source end. This fact makes it possible to construct a table of element values, which uses as parameters for entry (1) the type of approximation, including the ripple width in dB, Eq. (25), for Chebyshev approximations; (2) the value of n ; and (3) the value of R_S or G_S , according to the particular network for Figs. 10.1.16 and 10.1.17 that is being used. Table 10.1.10 is such a table.

THE TABLE OF ELEMENT VALUES

Table 10.1.10 gives element values, numbered in order from the source end as in Figs. 10.1.16 and 10.1.17, for the five all-pole approximations, $n = 2$ to 10, and for R_S or G_S equal to 0 and 1. Five different ripple widths are tabulated for the Chebyshev approximations.

The synthesis process for determining the element values in Table 10.1.10 often involves a choice of location for the zeros of the reflection coefficient. In this table when choices were necessary, the networks have left-half s -plane zeros.

FIGURE 10.1.15 Step response of fifth-order Chebyshev approximation with a 3-dB ripple.

*The Chebyshev filter prototypes have the ripple specified at 1 rad/s. The Bessel filter has a delay of 1 s at very low frequency. The second figure given is the delay at the half-power frequency.

Table 10.1.10 assumes:

1. $R_L = 1$.
2. $\omega_{hp} = 1$ for the Butterworth and Legendre-Papoulis approximations.
3. $\omega = 1$ is the end of the ripple band for the Chebyshev approximations.
4. The group delay at $\omega = 0$ is 1 s for the Bessel approximation.

The half-power frequencies for the (regular) Chebyshev approximation are found from Eq. (31), and, for the modified Chebyshev and Bessel approximations, are tabulated in Table 10.1.11.

FIGURE 10.1.19 The scaling of symmetrical networks to change the value of G_S .

The two values of R_S or G_S , 0 and 1, used in Table 10.1.10, represent the two most commonly encountered situations. Zverev and Weinberg give tables for additional values of R_S or G_S .

When n is odd, $G_S = R_S = 1$, and the approximation is either Butterworth or (regular) Chebyshev, the networks are symmetrical; that is, $C_1 = C_n$, $L_2 = L_{n-1}$, etc. In these cases, there is a technique to realize other values of R_S or G_S . Consider Fig. 10.1.16b with $n = 5$, redrawn as Fig. 10.1.19a to emphasize the symmetry. Scale the half of the network containing G_S , and recombine the two center elements. Making $G_S = 1/2$ leads to the network of Fig. 10.1.19b, where the two parts of the center capacitor are shown separately before recombination. This procedure leads to right-half s -plane zeros of the reflection coefficient.

EXPLICIT BUTTERWORTH AND CHEBYSHEV FORMULAS

Closed-form solutions for doubly terminated Butterworth and Chebyshev filters were derived by Takahasi and restated by Humpherys.⁸ They assume that the zeros of the reflection coefficient lie in the left half plane, and so give different networks than the symmetrical network procedure. This gives the designer a choice in cases where both techniques may be applicable.

The Butterworth formulas make use of the poles of the transfer functions and require also a factor λ that relates the load and source resistances. The source resistance is assumed to be 1.0, and the formulas are

$$s_i = 2 \sin(\pi i / 2\pi) \quad (51)$$

$$c_i = 2 \cos(\pi i / 2\pi) \quad (52)$$

$$\lambda = -\left(\frac{R_L - 1}{R_L + 1}\right)^{1/n} \quad (53)$$

when the first reactive element is a shunt capacitor, and

$$\lambda = -\left(\frac{G_L - 1}{G_L + 1}\right)^{1/n} \quad (54)$$

when the first reactive element is a series inductor. Recursive equations give the element values

$$C_1 = \frac{s_1}{1 - \lambda} \quad (55)$$

$$C_n = \frac{s_1}{(1 + \lambda)R_L} \quad n \text{ odd} \quad (56)$$

$$L_n = \frac{s_1 R_L}{1 + \lambda} \quad n \text{ even} \quad (57)$$

$$C_{2m-1} L_{2m} = \frac{s_{4m-1} s_{4m+1}}{1 - \lambda c_{4m-2} + \lambda^2} \quad (58)$$

$$L_{2m-1} C_{2m+1} = \frac{s_{4m-1} s_{4m+1}}{1 - \lambda c_{4m} + \lambda^2}$$

$$\text{where } m = \begin{cases} 1, 2, \dots, (n-1)/2 & n \text{ odd} \\ 1, 2, \dots, n/2 & n \text{ even} \end{cases}$$

When the first element is a series inductor, the roles of L and C are interchanged. An example follows. Develop the prototype network for third-order Butterworth, $R_L = 3$, $R_s = 1$. It follows that

$$\lambda = -0.7937 \quad (59)$$

$$s_1 = 1.0000 = s_5 \quad (60)$$

$$s_2 = 1.7321 = s_4 \quad (61)$$

$$s_3 = 2.0000 \quad (62)$$

$$c_1 = 1.7321 \quad (63)$$

$$c_2 = 1.0000 \quad (64)$$

$$c_3 = 0.0000 \quad (65)$$

$$c_4 = 1.0000 \quad (66)$$

FIGURE 10.1.20 Prototype Butterworth network, $n = 3, R_s = 1, R_L = 3$.

$$C_1 = \frac{1.0000}{1 - (-0.7937)} = 0.5575 \quad (67)$$

$$L_2 = \frac{s_1 s_3}{1 - (-0.7937)(1.0000) + (0.7937)^2} \frac{1}{C_1} = 1.4802 \quad (68)$$

$$C_3 = \frac{s_3 s_5}{1 - (-0.7937)(-1.0000) + (0.7937)^2} \frac{1}{L_2} = 1.6158 \quad (69)$$

The prototype network thus becomes that of Fig. 10.1.20.

The results are similar if the equation for C_n is used first and the network is developed from the load end; this serves as a check on the work.

The Chebyshev equations are similar. Define the following terms:

$$\epsilon = \sqrt{10^{r/10} - 1} \quad \epsilon = \text{ripple factor} \quad (70)$$

$$r = \text{ripple, dB}$$

$$A = \begin{cases} 4R_L R_s / (R_L + R_s)^2 & n \text{ odd} \\ 4(1 + \epsilon^2) R_L R_s / (R_L + R_s)^2 \leq 1 & n \text{ even} \end{cases} \quad (71a, 71b)$$

$$s_1 = 2 \sin(\pi i / 2n) \quad (72)$$

$$c_1 = 2 \cos(\pi i / 2n) \quad (73)$$

$$k = \left(\frac{1}{\epsilon} + \sqrt{\frac{1}{\epsilon^2} + 1} \right)^{1/n} \quad (74)$$

$$h = - \left(\sqrt{\frac{1-A}{\epsilon^2}} + \sqrt{\frac{1-A}{\epsilon^2} + 1} \right)^{1/n} \quad (75)$$

$$k' = k - 1/k \quad (76)$$

$$h' = h - 1/h \quad (77)$$

Recursive equations give the element values

$$C_1 = \frac{2s_1/R_s}{k' - h'} \quad (78)$$

$$C_n = \frac{2s_1/R_L}{k' + h'} \quad n \text{ odd} \quad (79)$$

$$L_n = \frac{2s_1 R_L}{k' - h'} \quad n \text{ even} \quad (80)$$

$$C_{2m-1} L_{2m} = \frac{4s_{4m-3} s_{4m-1}}{k'^2 - c_{2i} k' h' + h'^2 + s_{2i}^2} \quad (81)$$

10.32 FILTERS AND ATTENUATORS

$$L_{2m} C_{2m+1} = \frac{4S_{4m-1}S_{4m+1}}{k'^2 - c_{2i}k'h' + h'^2 + s_{2i}^2} \tag{82}$$

$$\text{where } m = \begin{cases} 1, 2, \dots, (n-1)/2 & n \text{ odd} \\ 1, 2, \dots, n/2 & n \text{ even} \end{cases}$$

When the first element is a series inductor, the roles of L and C are interchanged, while G_s and G_L are substituted for R_s and R_L . As an example, develop the prototype when $R_s = 3$, $R_L = 1$, 0.5 dB ripple, and a fourth-order network is needed. It follows that

$$\epsilon = \sqrt{10^{0.05} - 1} = 0.3493 \tag{83}$$

$$A = 0.75[1 + (0.3493)^2] = 0.8415 \tag{84}$$

$$s_1 = 0.7654 = s_7 \tag{85}$$

$$s_2 = 1.4142 = s_6 \tag{86}$$

$$s_3 = 1.8478 = s_5 \tag{87}$$

$$s_4 = 2.0000 \tag{88}$$

$$c_0 = 2.0000 \tag{89}$$

$$c_2 = 1.4142 \tag{90}$$

$$c_4 = 0.0000 \tag{91}$$

$$c_6 = -1.4142 \tag{92}$$

$$k = 1.5582 \tag{93}$$

$$h = -1.2766 \tag{94}$$

$$k' = 0.9164 \tag{95}$$

$$h' = -0.4933 \tag{96}$$

$$C_1 = \frac{2(0.7654)}{3[0.9164 - (-0.4933)]} = 0.3620 \tag{97}$$

$$L_2 = \frac{4s_1s_3}{C_1(k'^2 - c_2k'h' + h'^2 + s_2^2)} = 4.1985 \tag{98}$$

$$C_3 = \frac{4s_3s_5}{L_2(k'^2 - c_4k'h' + h'^2 + s_4^2)} = 0.6399 \tag{99}$$

$$L_4 = \frac{4s_5s_7}{C_3(h'^2 - c_6k'h' + h'^2 + s_6^2)} = 3.6172 \tag{100}$$

The prototype network is shown in Fig. 10.1.21.

FIGURE 10.1.21 Prototype Chebyshev network, $R_s = 3$, $R_L = 1$, $n = 4$, 0.5 dB ripple.

THE INVERSE CHEBYSHEV APPROXIMATION

The Inverse Chebyshev approximation uses the Chebyshev polynomials in an approximation that decreases monotonically in the passband, and has ripples in the stopband. Specifically,

$$|G_{IC}(\omega)| = \sqrt{\frac{\epsilon^2 C_n^2(1/\omega)}{1 + \epsilon^2 C_n^2(1/\omega)}} \tag{101}$$

where Eqs. (21) and (22) define C_n . Figure 10.1.22 shows this approximation and defines appropriate design criteria. K_s is the minimum attenuation in the stopband; K_p is the maximum attenuation in the passband, and it occurs at $\omega \geq \omega_p$. The edge of the stopband is at $\omega_a = 1$, which requires scaling of the specifications differently from the previous approximations.

When K_s is expressed in dB,

$$\epsilon = \sqrt{\frac{1}{10^{0.1k_s} - 1}} \tag{102}$$

Equation (103) gives the order n_{IC} required to meet the specifications, with the next larger integer being chosen.

$$n_{IC} = \frac{\cosh^{-1} \sqrt{\frac{(10^{0.1k_s} - 1)}{(10^{0.1k_p} - 1)}}}{\cosh^{-1}(1/\omega_p)} \tag{103}$$

FIGURE 10.1.22 The Inverse Chebyshev low-pass approximation. A fifth-order function is illustrated.

10.34 FILTERS AND ATTENUATORS

In general, the order of inverse Chebyshev filter required to meet a set of specifications is identical with the order required for a conventional Chebyshev filter. It has improved step response and phase response characteristics when compared with the (regular) Chebyshev approximation, and a more complex network realization.

The stopband ripples and the zero magnitudes at finite frequencies in the stopband mean that the Inverse Chebyshev filter is not an *all-pole* approximation as the preceding have been, but rather it has roots in the numerator as well as in the denominator. Explicit formulas for these roots exist.

The numerator roots, or zeros, are

$$z_k = \alpha_k + j\beta_k \quad (104)$$

where

$$\alpha_k = 0 \quad \beta_k = \frac{1}{\cos u_k} \quad k = 1, 2, 3, \dots, n \quad (105)$$

and

$$u_k = \frac{2k-1}{2n} \pi \quad (106)$$

The denominator factors, or poles, are

$$p_k = \frac{1}{\sigma_k + j\omega_k} \quad k = 1, 2, 3, \dots, n \quad (107)$$

where

$$\sigma_k = -\sin u_k \sinh v \quad \omega_k = \cos u_k \cosh v \quad (108)$$

and

$$v = \frac{1}{n} \sinh^{-1} \frac{1}{\epsilon} \quad (109)$$

and Eq. (106) gives u_k .

For example, assume that, using scaled frequency parameters, a designer needs a filter with a maximum passband attenuation K_p of 2.0 dB at frequencies below $\omega_p = 0.58$ rad/s, and a minimum stopband attenuation K_s of 40 dB above 1.0 rad/s. Equation (103) shows that a fifth-order filter is adequate. Application of Eqs. (104) through (109) shows that

$$G(s) = \frac{0.0500(s^2 + 1.1056)(s^2 + 2.8944)}{(s + 0.7878)(s^2 + 1.0496s + 0.5110)(s^2 + 0.3118s + 0.3975)} \quad (110)$$

where the numerator constant makes $G(0) = 1.0000$.

THE ELLIPTIC FILTER

The five approximations thus far described are of a class known as *all-pole approximations* because the magnitude-squared function of Eq. (6) has no finite zeros. This concentration of the zeros at infinity usually gives more attenuation than required at the higher frequencies and less in the vicinity of the cutoff frequency. If the more general form of Eq. (5) is used for the magnitude-squared function, some of the zeros can be placed

FIGURE 10.1.23 The elliptic approximation for (a) $n = 3$ and (b) $n = 4$.

close to the stopband edge frequency, with an improvement in the cutoff rate. Specifically, if

$$|G(j\omega)|^2 = K^2 \frac{1}{1 + \epsilon^2 R_n^2(\omega)} \tag{111}$$

$$R_n(\omega) = \begin{cases} r \frac{\omega \prod_{i=1}^{(n-1)/2} (\omega^2 - \omega_{pi}^2)}{\prod_{i=1}^{(n-1)/2} (\omega^2 - \omega_{si}^2)} & n \text{ odd} \\ r \frac{\prod_{i=1}^{n/2} (\omega^2 - \omega_{pi}^2)}{\prod_{i=1}^{n/2} (\omega^2 - \omega_{si}^2)} & n \text{ even} \end{cases} \tag{112}$$

where

$$R_n(\omega) = \begin{cases} r \frac{\prod_{i=1}^{n/2} (\omega^2 - \omega_{pi}^2)}{\prod_{i=1}^{n/2} (\omega^2 - \omega_{si}^2)} & n \text{ even} \end{cases} \tag{113}$$

r being a multiplicative constant, the approximation can be made equiripple in both the passband and the stopband. Such an approximation is called an *elliptic approximation* because elliptic functions are used in its determination. Figure 10.1.23 shows such an approximation in a plot of attenuation versus frequency for $n = 3$ and $n = 4$, illustrative of the general characteristics for even and odd n , respectively.

Since the even-order elliptic approximation does not have infinite attenuation at infinite frequency, it cannot be realized by an *LC* ladder. A modified even-order elliptic approximation can be obtained by a frequency transformation. This transformation sacrifices some stopband attenuation to shift a pole of attenuation to ∞ . A further modification of the even-order approximation can be used to make the attenuation zero to zero frequency. This permits an *LC* ladder realization to be equally terminated.

The elliptic approximation is characterized by four parameters.

1. The passband ripple A_{\max} or, equivalently, the reflection coefficient ρ , related to A_{\max} by $A_{\max} = -10 \log(1 - \rho^2)$
2. The order n
3. The minimum stopband attenuation A_{\min}
4. The stopband edge frequency ω_s or, equivalently, the modular angle θ^6

Any three of these four parameters can be independently specified.

As for the all-pole approximations, tabulations of pole-zero locations and tables of element values for normalized low-pass filters based on the elliptic approximation are possible. Since three parameters are required to specify in elliptic approximation, these tabulations are voluminous.

DELAY EQUALIZATION

The ideal low-pass filter characteristic would have a constant group delay as well as a constant amplitude throughout the passband so that the various frequency components of a signal would arrive at the output unattenuated and with the proper phase relationship. Deviations from constant amplitude and group delay produce amplitude and phase distortion, respectively. While phase distortion is not a problem in many applications, it is significant when pulse transmission is involved.

With the exception of the Bessel approximation, the various approximations have focused on the amplitude characteristic. While the Bessel approximation has a good group-delay characteristic, it has a significantly poorer amplitude characteristic. One approach to the problem of obtaining filters with good amplitude *and* group-delay characteristics is through the use of delay equalizers. This consists of using one of the approximations with desirable amplitude characteristics in conjunction with an all-pass function that does not affect the amplitude characteristic but modifies the group delay beneficially.

The first-order all-pass function is

$$G(s) = \frac{s - \delta}{s + \delta} \quad (114)$$

This function has an amplitude of 1 for all frequencies and a group-delay function

$$\tau_d(\omega) = \frac{2}{\delta} \frac{1}{1 + (\omega/\delta)^2} \quad (115)$$

The specific properties of the group-delay function are controlled by the selection of δ .

The second-order all-pass function is

$$G(s) = \frac{(s - \delta)^2 + \beta^2}{(s + \delta)^2 + \beta^2} \quad (116)$$

with

$$|G(j\omega)| = 1 \quad (117)$$

and

$$\tau_d(\omega) = \frac{4\delta(\omega^2 + \delta^2 + \beta^2)}{(\delta^2 + \beta^2 - \omega^2)^2 + 4\delta^2\omega^2} \quad (118)$$

The specific properties of this group-delay function are controlled by the selection of δ and β .

Except for some simple situations, the problem of delay equalization is best approached by using a computer to optimize the group delay in some sense. Blinchikoff and Zverev¹¹ give an excellent discussion of a least-squares optimization as well as the basic principles of delay equalization.

TABLES

Many authors have published extensive tables of prototype element values for filters. Table 10.1.12 lists some of the readily available tables, with comments.

TABLE 10.1.12 Books Containing Element Values for Filters

First-named author	Reference number in references and bibliography	Length, pages	Comment

CHAPTER 10.2

FILTER DESIGN

Edwin C. Jones, Jr., Harry W. Hale

PRACTICAL FILTER DESIGN

Table 10.1.10 gives element value for normalized networks. Three general steps lead to practical filters.

1. Statement of the filter specifications
2. Translation of the specifications to equivalent statements for the normalized prototype and their use to determine the parameters necessary to enter Table 10.1.10
3. Application of frequency transformations and impedance-level scaling to the normalized prototype to determine the filter network

This process is described in the following paragraphs for the various types of filters, accompanied by examples.

THE LOW-PASS FILTER

The low-pass filter is related to the normalized prototype by frequency and impedance-level scaling. The frequency in the prototype is related to the frequency in the low-pass filter by

$$\omega = \omega' / \omega'_c \quad (1)$$

where the primed quantities refer to the practical low-pass filter, with ω'_c being its cutoff frequency. The application of the frequency scaling implied by Eq. (1) and the impedance-level scaling required to change the load resistance from 1.0 to R_L results in the elements of the low-pass filter becoming those indicated in Fig. 10.2.1.

Example. A low-pass filter is to be designed to have (a) a maximally flat amplitude-versus-frequency characteristic at $f = 0$, (b) a cutoff (half-power) frequency of 2 kHz, (c) a load resistance of 200 Ω , (d) a voltage source input with zero resistance, and (e) an attenuation of not less than 20 dB at frequencies greater than 3.2 kHz. A Butterworth approximation is indicated. The frequency in the prototype equivalent to 3.2 kHz is

$$\omega = \frac{(3.2 \times 10^3)(2\pi)}{(2 \times 10^3)(2\pi)} = 1.6 \quad (2)$$

FIGURE 10.2.1 Relations between elements of (a) a normalized prototype and those of (b) a practical low-pass filter.

FIGURE 10.2.2 (a) A normalized prototype and (b) resulting low-pass filter.

and the equivalent design specifications for the prototype require that the attenuation be no less than 20 dB for $\omega \geq 1.6$. This, using Eq. (16), results in

$$n \geq \frac{20}{20 \log 1.6} = 4.899 \tag{3}$$

and the next larger integer value of 5 is used. The appropriate prototype appears in Fig. 10.2.2a with element values taken from Table 10.1.10 for the Butterworth approximation with $n = 5$ and $R_s = 0$. The application of frequency and magnitude scaling by means of the relations in Fig. 10.2.1 results in the low-pass filter of Fig. 10.2.2b.

A TIME-DELAY NETWORK

The frequencies in the time-delay network and its normalized prototype are related by

$$\omega = \tau'_d \omega' \tag{4}$$

where the primed quantities again refer to the practical network, τ'_d being the group delay evaluated at $\omega' = 0$. The element values of the practical network are related to those of the normalized prototype by frequency and impedance-level scaling. These relations are shown in Fig. 10.2.3.

FIGURE 10.2.3 Relations between elements for (a) a normalized prototype and those of (b) a time-delay network.

Example. A time-delay network is to be designed to have (a) a time delay of 1 ms, the error being no greater than 5 percent at 500 Hz; (b) a voltage input with a resistance of 500 Ω ; and (c) a load resistance of 500 Ω . The prototype frequency equivalent to 500 Hz is

$$\omega = 10^{-3}(2\pi \times 500) = 3.142 \tag{5}$$

and the equivalent specifications for the prototype require a time delay of 1 s, the error being no greater than 5 percent at $\omega = 3.142$. Figure 10.1.12 is used to determine that $n = 5$ is required to satisfy this requirement. The prototype can be of the form of either Fig. 10.1.16d or Fig. 10.1.17b. The latter is chosen with the element values taken from Table 10.2.1 for

TABLE 10.2.1 Element Choices for GIC Biquadratic Filters

Filter type	Y_0	Y_1	Y_2	Y_3	Y_4	Y_5	Y_A	Y_B
Low-pass	0	$G_1 + sC_1$	G_2	sC_3	G_4	G_5	0	G_B
High-pass	G_0	G_1	sC_2	G_3	G_4	G_5	0	sC_B
Band-pass	sC_0	G_1	sC_2	G_3	G_4	G_5	0	G_B
Band-stop, version 1	0	sC_1	G_2	G_3	G_4	G_5	sC_A	G_B
Version 2	G_0	G_1	G_2	G_3	sC_4	0	G_A	sC_B
All-pass	G_0	G_1	sC_2	G_3	G_4	0	$G_A = G_4$	sC_B

the Bessel approximation with $n = 5$ and $G_5 = 1$. The prototype is shown in Fig. 10.2.4a and the application of the relation is Fig. 10.2.3 results in the time-delay network of Fig. 10.2.4b.

THE HIGH-PASS FILTER

The frequency in the high-pass filter is related to that in the normalized prototype by

$$\omega = \omega'_c / \omega' \tag{6}$$

where the primed quantities refer to the high-pass filter, ω'_c being the cutoff frequency. The relations between the elements of the normalized prototype and those of the high-pass filter are given in Fig. 10.2.5.

Example. A high-pass filter is to be designed to have (a) a cutoff frequency of 7.5 kHz, (b) an equiripple characteristic in the passband with a 0.5-dB ripple ($\epsilon = 0.3493$), (c) an attenuation of at least 35 dB at frequencies below 3 kHz, (d) equal load and source resistance of 2000 Ω , and (e) a voltage source input. The prototype frequency equivalent to 3 kHz is

$$\omega = \frac{2\pi(7.5 \times 10^3)}{2\pi(3 \times 10^3)} = 2.5 \tag{7}$$

Thus the prototype is based on a Chebyshev approximation with a 0.5-dB ripple, equal load and source terminations, voltage source input, and an attenuation of at least 35 dB for frequencies greater than $\omega = 2.5$. The last requirement, used with Eq. (29), results in $C_n(2.5) \approx 161.0$. This result, used in Eq. (30), yields $n = 3.69$, and $n = 4$ is used. Since the regular Chebyshev approximation is not available, the modified Chebyshev approximation is used. The networks of Figs. 10.1.16c and 10.1.17a are possible. The former is chosen, and the

FIGURE 10.2.4 (a) A normalized prototype and (b) resulting time-delay network.

FIGURE 10.2.5 Relations between elements of (a) a normalized prototype and those of (b) a high-pass filter.

FIGURE 10.2.6 (a) A normalized prototype and (b) resulting high-pass filter.

FIGURE 10.2.7 Relations between elements of (a) a normalized prototype and those of (b) a bandpass filter.

resulting prototype is shown in Fig. 10.2.6a. The relations of Fig. 10.2.5 are then used to determine the element values of the high-pass filter of Fig. 10.2.6b.

THE BANDPASS FILTER

The frequency in the bandpass filter is related to that in the normalized prototype by

$$\omega = \frac{\omega'_0}{\beta'} \left(\frac{\omega'}{\omega'_0} - \frac{\omega'_0}{\omega'} \right) \tag{8}$$

where the primed quantities refer to the bandpass filter, ω'_0 being the center frequency and β' the bandwidth, $\omega'_c - \omega'_c$, as defined in Fig. 10.1.2c. The elements of the normalized prototype and those of the bandpass filter are related as shown in Fig. 10.2.7.

Example. A bandpass filter is to be designed to have (a) a center frequency of 4.0 kHz, (b) a bandwidth of 900 Hz, (c) an equiripple characteristic in the passband with a 1-dB ripple ($\epsilon = 0.5088$), (d) an attenuation of at least 18 dB at 4.9 kHz, (e) equal load and source resistances of 200 Ω , and (f) a current source input. The prototype frequency equivalent to 4.9 kHz is, from Eq. (8), 1.816 and the prototype is based on a Chebyshev approximation with a 1-dB ripple, equal load and source terminations, current source input, and an attenuation of at least 18 dB at $\omega = 1.816$. The last requirement, used with Eq. (29), results in $C_n(1.8163) \approx 19.65$. This result, used in Eq. (30), yields $n = 2.86$, and $n = 3$ is used. Two networks, those of Figs. 10.1.16a and 10.1.17d, are possible. The former is chosen, and the resulting prototype is shown in Fig. 10.2.8a. The relations of Fig. 10.2.7 are then used to determine the element values of the bandpass filter of Fig. 10.2.8b.

FIGURE 10.2.8 (a) A normalized prototype and (b) resulting bandpass filter.

The results of the preceding example illustrate a problem in the transformation from prototype to bandpass filter. For even the moderate ratio of center frequency to bandwidth of the example, the ratio of series-arm to shunt-arm inductances in the bandpass filter is large. This creates some practical problems arising from the stray capacitances associated with large inductances. The reader is referred to Humpherys⁸ for an excellent

FIGURE 10.2.9 Relations between elements of (a) a normalized prototype and those of (b) a band-elimination filter.

FIGURE 10.2.10 (a) A normalized prototype and (b) resulting band-elimination filter.

discussion of this problem and possible ways of overcoming the difficulty. A similarly large ratio of shunt-arm to series-arm capacitances is also present, although the practical problems are not so severe.

THE BAND-ELIMINATION FILTER

The frequency in the band-elimination filter is related to that in the normalized prototype by

$$\omega = \frac{1}{(\omega_0'/\beta')[(\omega_0'/\omega') - \omega'/\omega_0']} \tag{9}$$

where the primed quantities refer to the band-elimination filter, ω_0' being the center frequency and β' the bandwidth, $\omega_2' - \omega_1'$, as defined in Fig. 10.1.2d. The elements of the normalized prototype and those of the band-elimination filter are related as shown in Fig. 10.2.9.

Example. A band-elimination filter is to be designed to have (a) a center frequency of 12 kHz, (b) a bandwidth (half-power) of 1.5 kHz, (c) a maximally flat characteristic at $\omega' = 0$, (d) an attenuation of at least 16 dB at 11.6 kHz, (e) a current source input, and (f) $R_I = 800 \Omega$ and $G_S = 0$. Since the prototype frequency equivalent to 11.6 kHz is, from Eq. (9), 1.8432, the prototype is based on a Butterworth approximation with an attenuation of at least 16 dB at this frequency. This requirement, used with Eq. (16), results in $n = 2.99$, and $n = 3$ is used. Since $G_S = 0$, the only network available is that of Fig. 10.2.17b, and the resulting prototype is shown in Fig. 10.2.10a. The relations of Fig. 10.2.9 are then used to determine the element values of the band-elimination filter of Fig. 10.2.10b.

This example illustrates the large ratios of shunt-arm to series-arm inductances and of series-arm to shunt-arm capacitances that result with even a moderate ratio of center frequency to bandwidth. The reader is again referred to Humpherys⁸ for a discussion of this difficulty and steps that can be taken to overcome it.

CHAPTER 10.3

ACTIVE FILTERS

Edwin C. Jones, Jr., Harry W. Hale

INTRODUCTION

Active filters are electronic filter circuits that incorporate one or more electronic devices in their realizations. They include operational amplifiers, operational transconductances amplifiers, and, in some cases, special transistors. Many are available in integrated circuit form. Active filters eliminate inductors and usually provide a voltage or current gain. Three basic techniques are synthetic inductance networks, infinite gain networks, and controlled source (including Sallen and Key) realizations.

The factors computed from Eqs. (17) (Butterworth), (33), and (44) (Chebyshev), or tabulated in Tables 10.1.2 (modified Chebyshev), 10.1.4 (Legendre-Papoulis), or 10.1.6 (Bessel) are all low-pass functions, and are all denominator polynomials. In the functions, the numerators are constants. To transform these functions to high pass, use the change of variable

$$s = 1/p \quad (1)$$

followed by frequency scaling.

To transform to bandpass functions, use the transformation

$$s = (p^2 + \omega_0^2)/Bp \quad (2)$$

on a factor-by-factor basis to avoid later factoring of high-ordered polynomials. Use the quadratic equation on Eq. (2) to transform bandpass variables to equivalent low-pass variables. An n th order, low-pass function is of order $2n$ when this transform is used, and the numerator includes a factor p^n and a constant. In this expression, B = bandwidth, $\omega_{c2} - \omega_{c1}$, and ω_0 = center frequency (Fig. 10.1.2, rad/s).

To transform to a band reject function, use the reciprocal of Eq. (2).

FIRST-ORDER STAGES

Most active network realizations require the cascading of second-order networks, each of which realizes one of the second-order denominator polynomials. To realize a first-order factor (real poles), use either of the networks of Fig. 10.3.1 as the initial or final stage in the cascade. In Fig. 10.3.1,

$$\frac{V_2}{V_1}(s) = -K_1 \left(\frac{s+a}{s+b} \right) \quad (3)$$

FIGURE 10.3.1 (a) Inverting and (b) noninverting amplifiers to realize real poles.

and in Fig. 10.3.1,

$$\frac{V_2}{V_1}(s) = K_2 \left(\frac{s+a}{s+b} \right) \tag{4}$$

In Fig. 10.3.1, $K_2 \geq 1$, and $aK_2 \geq b$.

SYNTHETIC INDUCTANCE FILTERS—GYRATORS

It is possible to build filters with active elements that replace inductors. These realizations use the published tables for passive low-pass networks and the networks that are transformed from them. They also have the low-sensitivity properties of passive networks. One technique is based on the gyrator,²⁴ a two-port with a z-matrix representation

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} 0 & -a \\ a & 0 \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} \tag{5}$$

FIGURE 10.3.2 Gyrator terminated with Z_L .

where a is called the *gyration resistance*. A gyrator terminated in an impedance Z_L is shown in Fig. 10.3.2, and it is possible to show that

$$V_1/I_1 = Z_{IN} = a^2/Z_L \tag{6}$$

when $Z_L = 1/sC$,

$$Z_{IN} = a^2sC \tag{7}$$

which is equivalent to an inductance of a^2C . The problem then becomes one of choosing a and C .

Gyrators are available in integrated-circuit form from several electronics manufacturers; the user simply adds the appropriate capacitor. Gyrators can also be built with operational amplifiers. One useful circuit is the Riordan gyrator, shown in Fig. 10.3.3 with Z_L as one of the five impedances it requires.

FIGURE 10.3.3 Riordan gyrator.

It can be shown that

$$\frac{V_1}{I_1} = Z_{IN} = \frac{Z_1 Z_2 Z_3}{Z_4} \frac{1}{Z_L} \tag{8}$$

When all Z 's are resistors R , and $Z_L = 1/sC$,

$$Z_{IN} = R^2 sC \tag{9}$$

This circuit must be used to replace a grounded inductor, e.g., in a high-pass network. If an ungrounded inductor is needed, the modification shown in Fig. 10.3.4 can be used, for which

$$Z_{IN} = R^2 sC \tag{10}$$

Other circuits, for which one side of the added capacitor C may be grounded, can also be used, though they may be more difficult to align.

FIGURE 10.3.4 Riordan-type back-to-back gyrator for floating inductors.

SYNTHETIC INDUCTANCE FILTERS—FREQUENCY-DEPENDENT NEGATIVE RESISTORS

Bruton²⁵ introduced a new type of circuit, called the *frequency-dependent negative resistor* (FDNR); the symbol is shown in Fig. 10.3.5. To use this idea, consider a new type of impedance scaling, in which passive elements become scaled by A/s ; this does not affect the transfer function:

FIGURE 10.3.5 FDNR representation.

Passive impedance	Scaled impedance	
sL	\rightarrow AL	(11a)
R	\rightarrow AR/s	(11b)
$1/sC$	\rightarrow A/Cs^2	(11c)

FIGURE 10.3.6 Generalized impedance converter.

FIGURE 10.3.7 A multiple-feedback, infinite-gain active realization for low-pass, high-pass, and bandpass filters. Table 10.3.1 indicates the choice of the five active elements for each case.

When $s = j\omega$ or $s^2 = -\omega^2$, the last element becomes

$$Z(j\omega) = -A/D\omega^2 \quad (12)$$

a real, negative, frequency-dependent resistor. Thus, inductors are replaced by resistors, resistors by capacitors, and capacitors by FDNRs.

Bruton also gives a circuit for an FDNR, as a special case of the generalized impedance converter (GIC). It is similar to the gyrator and is shown in Fig. 10.3.6. For this circuit,

$$V_1/I_1 = Z_{\text{IN}} = Z_1 Z_3 Z_5 / Z_2 Z_4 \quad (13)$$

when

$$Z_1 = Z_3 = 1/sC \quad (14)$$

$$Z_2 = Z_4 = Z_5 = R \quad (15)$$

$$Z_{\text{IN}} = 1/s^2 RC^2 \quad (16)$$

which is an FDNR. GICs are available from integrated-electronic-circuit manufacturers, and the user adds resistors and capacitors to make FDNRs. They can also be used to make gyrators. FDNRs are grounded when replacing capacitors in low-pass networks; floating FDNRs can be achieved by back-to-back GICs, as with gyrators.

INFINITE-GAIN, MULTIPLE-FEEDBACK REALIZATION

The circuit of Fig. 10.3.7 shows an operational amplifier with five passive elements, which are either resistors or capacitors. The general voltage transfer function is

$$\frac{V_2}{V_1} = \frac{-Y_1 Y_3}{Y_5 (Y_1 + Y_2 + Y_3 + Y_4) + Y_3 Y_4} \quad (17)$$

TABLE 10.3.1 Element Choices for Active Filter Circuit of Fig. 10.3.7.

Filter desired	Y_1	Y_2	Y_3	Y_4	Y_5
Low-pass	Resistor	Capacitor	Resistor	Resistor	Capacitor
High-pass	Capacitor	Resistor	Capacitor	Capacitor	Resistor
Bandpass	Resistor	Resistor	Capacitor	Capacitor	Resistor

Table 10.3.1 describes how the five passive elements can be chosen to implement a low-pass, high-pass, or bandpass network.

STATE-VARIABLE REALIZATION

This network is a special but important type of infinite-gain realization. It has the advantage that low-pass, high-pass, and bandpass configuration can be realized simultaneously, and it is also easy to adjust and to produce in quantity. The network is shown in Fig. 10.3.8, and the three possible transfer functions are

Low-pass:
$$\frac{V_{lp}}{V_1} = \frac{R_4(R_5 + R_6)}{R_1R_2R_5C_1C_2(R_3 + R_4) \left[s^2 + s \left[\frac{R_3(R_5 + R_6)}{R_1C_1(R_3 + R_4)} \right] + \frac{R_6}{R_1R_2R_5C_1C_2} \right]} \quad (18)$$

**FIGURE 10.3.8** State-variable realization of second-order active filters.

$$\text{High-pass: } \frac{V_{hp}}{V_1} = \frac{\frac{s^2 R_4 (R_5 + R_6)}{R_5 (R_3 + R_4)}}{s^2 + s \left[\frac{R_3 (R_5 + R_6)}{R_1 C_1 (R_3 + R_4)} \right] + \frac{R_6}{R_1 R_2 R_5 C_1 C_2}} \quad (19)$$

$$\text{Bandpass: } \frac{V_{bp}}{V_1} = \frac{\frac{-s R_4 (R_5 + R_6)}{R_1 R_5 C_1 (R_3 + R_4)}}{s^2 + s \left[\frac{R_3 (R_5 + R_6)}{R_1 C_1 (R_3 + R_4)} \right] + \frac{R_6}{R_1 R_2 R_5 C_1 C_2}} \quad (20)$$

The network has a low output impedance at each terminal, so that RC sections can be added for odd-ordered networks. These sections can be cascaded so that networks of order 4 and higher can be built. They have the property that performance variations with parameter changes are comparable with those of strictly passive networks, but the disadvantage of requiring three operational amplifiers.

As with the other networks, design is a matter of choosing the appropriate quadratic factors, matching coefficients with other constraints that arise from technological and economic considerations, and finally, scaling impedance and frequency.

DELYIANNIS BANDPASS CIRCUIT

Daryanani⁴⁴ describes a useful bandpass circuit shown in Fig. 10.3.9. For this circuit

$$\frac{V_2}{V_1}(s) = \frac{-s/[R_1 C_2 (1 - 1/k)]}{s^2 + (\omega_p/Q_p)s + \omega_p^2} \quad (21)$$

$$\text{where } k = 1 + \frac{R_B}{R_A} \quad (22)$$

$$\omega_p^2 = \frac{1}{R_1 R_2 C_1 C_2} \quad (23)$$

$$\frac{\omega_p}{Q_p} = \frac{1}{R_2 C_1} + \frac{1}{R_2 C_2} - \frac{1}{k-1} \frac{1}{R_1 C_2} \quad (24)$$

The circuit can be used with $R_A = 0$; in this case $k \rightarrow \infty$, and Eq. (21) is readily simplified. Here it is necessary to limit Q_p to about 5.

When Q_p greater than 5 is desired, R_A is included and the difference term in the denominator permits a greater Q_p .

FRIEND BIQUADRATIC

Friend²⁶ has described a generalization of the Delyiannis circuit of the preceding section that can be used for high-pass, band-reject, and all-pass networks with proper choice of components. It is shown in Fig. 10.3.10. For this circuit

FIGURE 10.3.9 Delyiannis bandpass circuit.

FIGURE 10.3.10 Friend biquadratic circuit.

$$\frac{V_2(s)}{V_1(s)} = \frac{K_2 s^2 + as + b}{s^2 + (\omega_p / Q_p)s + \omega_p^2} \quad (25)$$

where

$$a = \frac{K_2}{C_2} \left(\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} \right) + \frac{K_2}{C_1} \left(\frac{1}{R_2} + \frac{1}{R_3} \right) - \frac{K_1}{R_1 C_2} \left(1 + \frac{R_A}{R_B} \right) - \frac{K_3}{R_3} \left(\frac{1}{C_1} + \frac{1}{C_2} \right) \left(1 + \frac{R_A}{R_B} \right)$$

$$b = \frac{1}{C_1 C_2} \left[\frac{K_2}{R_1} \left(\frac{1}{R_2} + \frac{1}{R_3} \right) - \frac{K_3}{R_1 R_3} \left(1 + \frac{R_A}{R_B} \right) \right] \quad (26)$$

$$\frac{\omega_p}{Q_p} = \frac{C + C_2}{C_1 C_2} \left(\frac{1}{R_2} - \frac{R_A}{R_B R_3} \right) - \frac{R_A}{R_B R_1 C_2}$$

$$\omega_p^2 = \frac{1}{R_1 C_1 C_2} \left(\frac{1}{R_2} - \frac{R_A}{R_B R_3} \right)$$

and

$$K_1 = \frac{R_5}{R_1 + R_5} \quad K_2 = \frac{R_D}{R_C + R_D} \quad K_3 = \frac{R_7}{R_6 + R_7} \quad (27)$$

$$R_4 = \frac{R_C R_D}{R_C + R_D} \quad R_1 = \frac{R_4 R_5}{R_4 + R_5} \quad R_3 = \frac{R_6 R_7}{R_6 + R_7}$$

With this circuit, normal practice is to make $C_1 = C_2$. If a high-pass network is needed, $a = b = 0$; this leads to constraints on K_1 , K_3 , and the resistors. For band-reject or notch filters, $a = 0$, other constraints follow from Eqs. (26), but it is usually possible to adjust them so that all element values are positive.

BIQUADRATICS WITH GENERALIZED IMPEDANCE CONVERTERS

Temes describes a general method for designing any biquadratic transfer function using two operational amplifiers and eight impedances. The GIC, introduced earlier, can be used. A complete circuit is shown in Fig. 10.3.11. For this circuit,

$$\frac{V_2(s)}{V_1(s)} = \frac{Y_A(Y_1 Y_3 - Y_0 Y_3) + Y_B Y_2(Y_4 + Y_5)}{Y_1 Y_3(Y_A + Y_5) + Y_2 Y_4(Y_B + Y_0)} \quad (28)$$

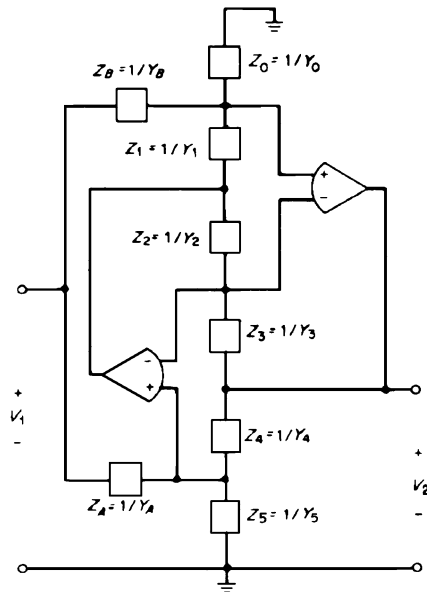

FIGURE 10.3.11 GIC biquadratic filter.

Table 10.2.1 shows to choose the elements for various types of transfer function. In version 1, the notch frequency is greater than the resonant frequency of the circuit, while in version 2, the notch frequency is less than the resonant frequency. In addition, version 2 requires $G_1G_3 > G_0G_2$. These circuits have the property of low sensitivity at the expense of two amplifiers.

SALLEN AND KEY NETWORKS

The circuits of Figs. 10.3.12, 10.3.13, and 10.3.14 are low-pass, high-pass, and bandpass circuits, respectively, having a positive gain K . Design of any of these circuits requires choice of suitable linear and quadratic denominator factors, transformation and frequency scaling, and coefficient matching. Since there are more elements

FIGURE 10.3.12 A low-pass active filter network with gain K greater than 0.FIGURE 10.3.13 A high-pass active filter network with gain K greater than 0.

FIGURE 10.3.14 A bandpass active filter network with gain K greater than 0.

to be specified than there are constraints, two elements may be chosen arbitrarily. Often, $K = 1$ or $K = 2$ leads to a good network. For Fig. 10.3.12,

$$\frac{V_2}{V_1}(s) = \frac{K/(R_1 R_2 C_1 C_2)}{s^2 + \left[(1-K) \frac{1}{R_2 C_2} + \frac{1}{R_1 C_1} + \frac{1}{R_2 C_1} \right] s + \frac{1}{R_1 R_2 C_1 C_2}} \quad (29)$$

For Fig. 10.3.13,

$$\frac{V_2}{V_1}(s) = \frac{Ks^2}{s^2 + \left[(1-K) \frac{1}{R_1 C_1} + \frac{1}{R_2 C_2} + \frac{1}{R_2 C_1} \right] s + \frac{1}{R_1 R_2 C_1 C_2}} \quad (30)$$

For Fig. 10.3.14,

$$\frac{V_2}{V_1}(s) = \frac{\frac{Ks}{R_1 C_2}}{s^2 + \left[\frac{(1-K)}{R_2 C_2} + \frac{1}{R_3 C_2} + \frac{1}{R_1 C_1} + \frac{1}{R_2 C_1} + \frac{1}{R_1 C_2} \right] s + \frac{1}{R_3 C_1 C_2} \left(\frac{1}{R_1} + \frac{1}{R_2} \right)} \quad (31)$$

CHAIN NETWORK

Figure 10.3.15 shows a chain network that realizes low-pass functions and is easily designed. For this circuit,

$$\frac{V_2}{V_1}(s) = \frac{\omega_1 \omega_2 \omega_3 \cdots \omega_n}{s^n + \omega_1 s^{n-1} + \omega_1 \omega_2 s^{n-2} + \cdots + \omega_1 \omega_2 \omega_3 \cdots \omega_n} \quad (32)$$

where

$$\omega_i = 1/R_i C_i \quad (33)$$

As an example, consider a third-order Bessel filter, for which

$$\frac{V_2}{V_1}(s) = \frac{15}{s^3 + 6s^2 + 15s + 15} \quad (34)$$

FIGURE 10.3.15 An RC-unity-gain amplifier realization of an active low-pass filter.

Choose $1/R_1C_1 = 6$, $6(1/R_2C_2) = 15$, and $15(1/R_3C_3) = 15$. If all C 's are set to 1.0, then $R_1 = 1/6$, $R_2 = 2/5$, and $R_3 = 1$. Use frequency and impedance scaling as required.

LEAPFROG FILTERS

Also called active ladders or multiple feedback filters, these circuits use the tabulated element values from Table 10.1.10 to develop a set of active networks that have the sensitivity characteristics of passive ladders. The process may be extended from low-pass to bandpass networks using the transformation from prototype to bandpass filter disc under “Bandpass Filter” and techniques that will be discussed in this paragraph. The term “leapfrog” was suggested by Girling and Good,²⁸ the inventors, because of the topology.

Figure 10.3.16a shows a conventional fourth-order low-pass prototype network, and Fig. 10.3.16b shows a block diagram of a simulation with the same equations, which follow, using Laplace notation. In writing these equations and preparing the block diagram, current terms have been multiplied by an arbitrary constant R so that all variables appear to have the dimensions of voltage. This simplifies the block diagram and later examples.

$$I_1 = (V_1 - V_3)[R/(R_1 + sL_1)]$$

$$V_3 = (RI_1 - RI_3)(1/sC_2R)$$

(a)

(b)

FIGURE 10.3.16 (a) Low-pass prototype ladder filter; (b) block-diagram simulation.

$$RI_3 = (V_3 - V_2)(R/sL_3) \quad (35)$$

$$V_2 = RI_3 \frac{1}{R(1/R_4 + sC_4)}$$

Though shown for a specific case, the technique is general and may be extended for any order of ladder network. In the simulation it should be noted that the algebraic signs of the blocks alternate. This variation is important in the realization.

In Fig. 10.3.16*b*, the currents are simulated by voltages, and this suggests the use of operational amplifiers as realization elements. The blocks in simulation require integrations, which are readily achieved with operational amplifiers, resistors, and capacitors. Figure 10.3.17 shows suitable combinations that will realize integrators, both inverting and noninverting, and also lossy integrators, which have a pole in the left half plane, rather than at the origin. Bruton²⁵ shows that, for integration, the circuit of Fig. 10.3.17*b* has superior performance compared with Fig. 10.3.17*a* when the imperfections of nonideal operational amplifiers are considered.

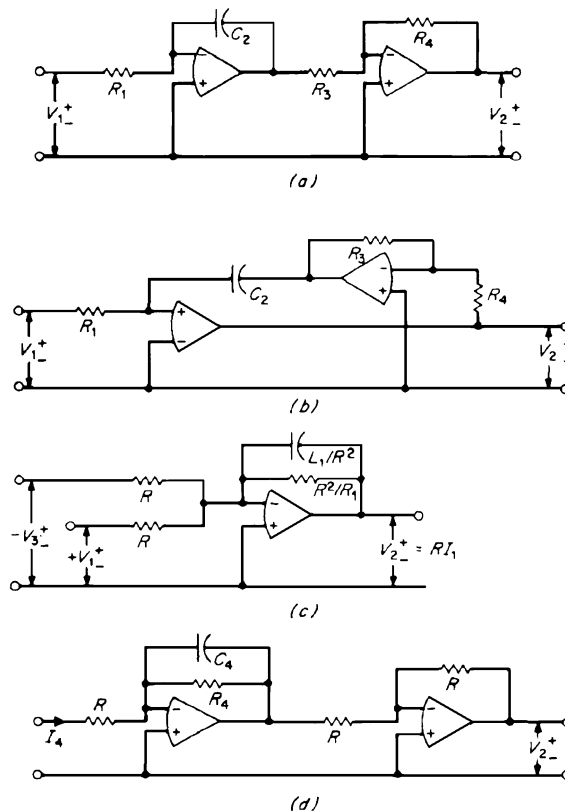

FIGURE 10.3.17 Building blocks for leapfrog filters: (a) noninverting integrator, for which $V_2/V_1 = R_4/sC_2R_1R_3$; (b) noninverting integrator, for which $V_2/V_1 = R_4/sC_2R_1R_3$; (c) lossy, summing integrator to realize $(V_1 - V_3)R/(R_1 + sL_1) = -RI_1$; (d) lossy, noninverting integrator to realize $V_2/RI_4 = 1/R(1/R_4 + sC_4)$.

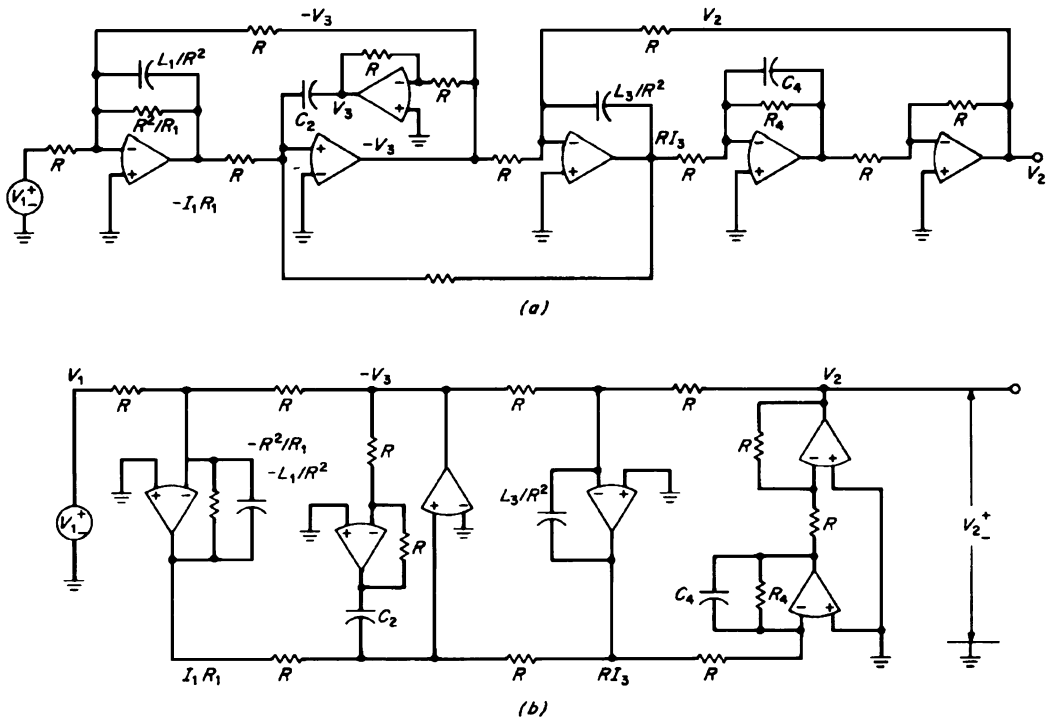

FIGURE 10.3.18 Two arrangements of a leapfrog low-pass circuit: (a) block-diagram arrangement; (b) ladder arrangement.

In Fig. 10.3.18, the combination of these blocks into a circuit is shown. In the preparation of this drawing, the integrator of Fig. 10.3.16b has been used, and the drawing is given in two forms. Figure 10.3.18a follows from the simulation, while Fig. 10.3.18b is a rearrangement that emphasizes the ladder structure.

The design of a low-pass leapfrog ladder may be summarized in these steps.

1. Select a normalized low-pass filter from Table 10.1.10
2. Identify the integrations represented by inductors, capacitors, and series resistor-inductor or parallel resistor-capacitor combinations. For each, determine an appropriate block diagram.
3. Connect together, using inverters, summers, and gain adjustment as needed.
4. Apply techniques of frequency and magnitude scaling to achieve a practical circuit.

BANDPASS LEAPFROG CIRCUITS

The technique of the previous section may be extended to bandpass circuits. The basic idea follows from the low-pass to bandpass transformation introduced in “Bandpass Filters” and from the recognition that it is possible to build second-order resonators from operational amplifiers, capacitors, and resistors. When the transformation is applied to an inductor, the circuit of Fig. 10.3.19a results. The resistor is added to allow for losses or source/load resistors that may be present. Similarly, the transformation applied to a

FIGURE 10.3.19 Passive resonant circuits: (a) series resonator; (b) parallel resonator.

capacitor yields Fig. 10.3.19b. It is to be noted that the forms of the equations are identical, and since the leapfrog technique makes use of simulation, the realizations will be similar. The necessary equations are given by Eq. (36).

Figure 10.3.20 shows an active simulation of a resonant circuit. This circuit is similar to that of Fig. 10.3.8, though the first two stages are interchanged. The new circuit has the advantage that both inverted and noninverted resonant outputs are available. Further, the input allows for summing operations, which may be needed in the leapfrog realization. Appropriate equations are given by Eq. (37).

$$Y_s(s) = \frac{(1/L_s)s}{s^2 + (R_s/L_s)s + 1/L_s C_s} \tag{36}$$

$$Z_p(s) = \frac{(1/C_p)s}{s^2 + (1/R_p C_p)s + 1/L_p C_p}$$

$$V_{o2}(s) = -V_{o1}(s) = \frac{(1/R_3 C_1)s}{s^2 + (1/R_1 C_1)s + 1/R_2 R_4 C_1 C_2} (V_{i1} + V_{i2})(s) \tag{37}$$

The implementation of this circuit is substantially the same as that of Fig. 10.3.18, with the resonators being used as the blocks of the simulation. Since both inverted and noninverted signals are available, the one needed is chosen. Table 10.3.2 gives the parameters of the active resonators in terms of the transformed series or parallel resonant circuits. Frequency and magnitude scaling may be done either before or after the elements of the active resonator are determined, but it generally is more convenient to do it afterward.

An example is given to show this technique. It begins with a third-order Butterworth normalized low-pass filter, Fig. 10.3.21a, which has been taken from Table 10.1.10. The circuit is transformed to a bandpass network

FIGURE 10.3.20 Active resonator.

TABLE 10.3.2 Resonator Design Relationships*

Circuit parameters from Fig. 10.3.20	Series circuit prototype values from Fig. 10.3.19a	Parallel circuit prototype values from Fig. 10.3.19b
$R_2 = R_4 = R$	$(1/C)\sqrt{L_s C_s}$	$(1/C)\sqrt{L_p C_p}$
R_1	$R\sqrt{L_s/C_s}$	$R\sqrt{C_p/L_p}$
R_3	$R\sqrt{L_s/C_s}$	$R\sqrt{C_p/L_p}$
R_5	Choose any convenient value	

*In this table it is presumed that $C_1 = C_2 = C$ and that this is chosen to be some convenient value. It is further presumed that $R_2 = R_4$.

for which the center frequency ω_0 is 1.0 rad/s and the bandwidth β' is 0.45 rad/s, corresponding to upper and lower half-power frequencies of 1.25 and 0.80 rad/s. This result is shown as Fig. 10.3.21b.

For the first and third stages of the circuit, application of the equations from Table 10.3.2 shows that $R_1 = R_3 = 20/9 \Omega$, and that all other components have unit value. For the second stage, R_1 is infinite, as indicated by the table, and $R_3 = 9/40 \Omega$. Other components have unit value. The complete circuit is shown as Fig. 10.3.21c. This circuit has been left in normalized form. Impedance and frequency denormalization techniques must be used to achieve reasonable values.

CHAPTER 10.4

SWITCHED CAPACITOR FILTERS

Edwin C. Jones, Jr., Harry W. Hale

Switched capacitor filters, also known as analog sampled data filters, result from a new technology that builds on the passive network theory of Darlington and implements the circuits in active-network integrated-circuit forms. Essentially, the switched capacitor replaces the resistor in operational-amplifier circuits, including the resonator. Early work was reported by Allstot, Broderson, Fried, Gray, Hosticka, Jacobs, Kuntz, and others. Huelsman¹² and Van Valkenburg¹⁶ give additional information.

Consider the circuit of Fig. 10.4.1*a* and the two-phase clock signal of Fig. 10.4.1*b*. The circuit has two MOS switches and a capacitor C . The clock cycles the MOS switches between their low- and high-resistance states. In the analysis that follows, it is assumed that the clock speed is sufficiently high that a simplified analysis is valid. It is also assumed that the Nyquist sampling theorem is satisfied. It is possible to use discrete circuit analysis and z transforms if some of the approximations are not met.

Let the clock be such that switch A is closed and B is open. This may be modeled by Fig. 10.4.1*c*. The source will charge the capacitor to V_1 . When the clock cycles so that B is closed and A is open, the capacitor will discharge toward V_2 , transferring a charge

$$q_C = C(V_1 - V_2)$$

This will require a time $T_C = 1/f_C$, yielding an average current

$$i_{av} = C(V_1 - V_2)/T_C$$

corresponding to a resistor $R_{eq} = (V_1 - V_2)/i_{av}$, or

$$R_{eq} = T_C/C = 1/(Cf_C) \quad (1)$$

Figure 10.4.2 shows a conventional integrator, a damped integrator, and several sum and difference integrators, along with realizations and transfer functions of circuits implemented with switched capacitors. It is noted that the transfer functions are functions of the ratios of two capacitors, and this fact makes them useful. It is possible in integrated-circuit design to realize the ratio of two capacitors with high precision, leading to accurate designs of filters. With similar techniques it is possible to realize many of the second-order circuits given in earlier sections.

Possibly the most important application is in the realization of leapfrog filters. As discussed in the previous section, leapfrog filters use integrators to realize the resonators that are the basic building blocks. In this technology, the resistors of the resonators are replaced by switched capacitors. In essence, the technique is to realize the circuit with resonators, as was done in Fig. 10.3.21, and then to replace the resistors with switched capacitors. Though slightly less complex, the technique for low-pass filters is similar.

Consider the low-pass prototype filter of Fig. 10.4.3*a*. A simulation is shown in Fig. 10.4.3*b*. This simulation has equations that are identical with those of the prototype. While the simulation is similar to that of Fig. 10.3.16; two important differences may be noted. The first is that the termination resistors are separate,

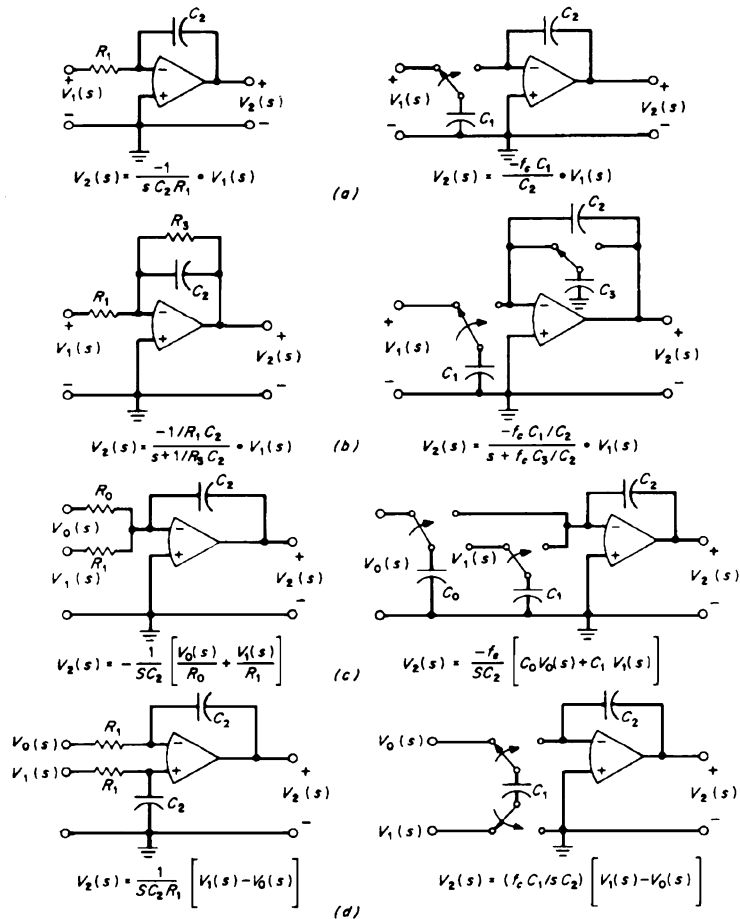

FIGURE 10.4.1 Integrators with switched capacitor realizations: (a) conventional integrator; (b) damped or lossy integrator; (c) summing integrator; (d) difference integrator.

rather than being incorporated with the input and output elements. The second is that all the elements have positive signs, and the amplifiers used are different types. This is more convenient. Figure 10.4.3c shows a switched capacitor equivalent for the low-pass filter. The equations for the simulation and for the development of the switched capacitor version follow.

$$\begin{aligned}
 RI_3 &= (V_1 - V_4)(R/R_1) \\
 V_4 &= I_5(1/sC_3) = (I_3 - I_6)(R)(1/sC_3R) \\
 RI_6 &= (V_4 - V_6)(R/sL_4) \\
 V_2 &= R(I_6 - I_8)(1/sC_5R) \\
 RI_8 &= V_2(R/R_2)
 \end{aligned}
 \tag{2}$$

As was done previously, the current equations have been nominally multiplied by R so that all terms appear to be voltages. In practice, R may be set to 1.0 as scaling will take care of it.

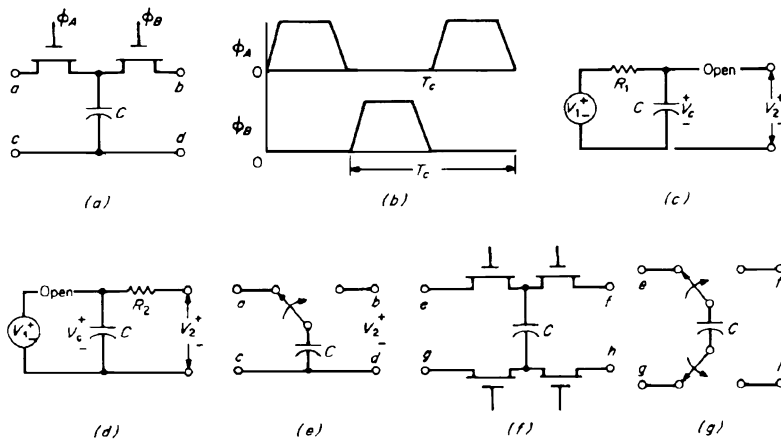

FIGURE 10.4.2 Development of equivalent circuit for a switched capacitor: (a) double MOS switch; (b) two-phase clock; (c) switch A closed; (d) switch B closed; (e) representation; (f) double-pole double-throw switch; and (g) representation.

FIGURE 10.4.3 Low-pass switched capacitor filter development; (a) low-pass prototype and definition of equation symbols; C_3 , L_4 , and C_5 would be obtained from Table 10.1.10; (b) simulation of low-pass prototype; R may be set to 1.0; (c) switched capacitor equivalent network.

10.60 FILTERS AND ATTENUATORS

The next step is to determine the capacitor ratios in the final simulation. From Fig. 10.4.2*d* it may be seen that a typical integrator term is given by

$$\frac{V_2(s)}{V_1(s) - V_0(s)} = \frac{f_c C_1}{s C_2}$$

Similar results are obtained for the remaining integrators. The prototype values were obtained from Table 10.1.10, including C_3 , L_4 , and C_5 for this circuit. The similarity of terms then suggests that

$$\begin{aligned} C_3 &= (1/f_c)(C_{23}/C_{13}) \\ C_5 &= (1/f_c)(C_{25}/C_{15}) \end{aligned} \quad (3)$$

Extension to the inductors shows that

$$L_4 = (1/f_c)(C_{24}/C_{14}) \quad (4)$$

As used here, C_3 , L_4 , and C_5 are prototype values, but they may be magnitude- and frequency-scaled as desired to achieve realistic values. In Eqs. (3) and (4), the ratios C_2/C_1 are computed after the clock speed is known, and the second subscripts on both numerator and denominator denote which prototype the ratio has been derived from. In general they will differ for each element. In design, it is likely that one of these would be fixed and have a common value for all integrators, thus allowing the other capacitor to vary in each case. Figure 10.4.3*c* shows the circuit that results. It uses the difference-type integrator of Fig. 10.4.1*d*. It also shows a method for handling the terminations. It should be noted that the clock phases are adjusted so that alternate integrators have open and closed resistors at a given instant. This is necessary to avoid delay problems.

The extension of this technique to bandpass filters is a matter of combining the principles of leapfrog filters and switched capacitor implementation of resistors. From the specifications, a transformation to equivalent low-pass requirements is made, and the low-pass prototype is chosen. This prototype is transformed to a bandpass network, an appropriate simulation is developed, and the network is developed using integrators. Finally, scaling in frequency and magnitude is needed. It is desirable to test these simulations using computer programs designed for analysis of sampled data networks.

CHAPTER 10.5

CRYSTAL, MECHANICAL, AND ACOUSTIC COUPLED-RESONATOR FILTERS

Edwin C. Jones, Jr., Harry W. Hale

In applications such as single-sideband communications it is often necessary to have a bandpass filter with a bandwidth that is a fractional percentage of the center frequency and in which one or both transition regions are very short. Meeting such requirements usually requires a filter in which the resonators are not electrical. Two types of resonator are quartz crystals and mechanical elements, such as disks or rods. Transducers from the electric signal to the mechanical device, output transducers, and resonator-coupling elements are needed.

Crystal filters include resonators made from piezoelectric quartz crystals. The transducers are plates of a conductor deposited on the appropriate surfaces of the crystal, and coupling from one crystal to the next is electrical. The center frequency depends on the size of the crystal, its manner of cutting, and the choice of frequency determining modes of oscillation. It can vary from about 1.0 kHz to 100 MHz. If extreme care is taken, equivalent quality factors (Q 's) can be greater than 100,000. These filters can also be very stable with regard to temperature and age.

Mechanical filters use rods or disks as resonating elements, which are coupled together mechanically, usually with wires welded to the resonators. The transducers are magnetostrictive. The frequency range varies from as low as 100 Hz to above 500 kHz. Quality factors above 20,000 are possible and, with proper choice of alloys, temperature coefficients of as low as 1.0 ppm/°C are possible.

Acoustic filters use a combination of crystal and mechanical filter principles. The resonators are monolithic quartz crystals; the transducers are similar to those of crystal filters, but the coupling is mechanical (referred to as acoustic coupling). These filters have many of the properties of crystal filters, but the design techniques have much in common with those of mechanical filters.

Coupled-resonator filters are usually described in terms of an electric equivalent circuit. The direct or mobility analogy (mass to capacitance, friction to conductance, and springs to inductance) is more useful, because the "across" variables of velocity and voltage are analogous, as are the "through" variables of force and current. Equivalent capacitances or inductances and center frequencies are among the common parameters specified for filter elements.

The following paragraphs discuss, in general terms, the design procedure used for coupled-resonator filters, the equivalent circuits used, and some network transformations that enable the designer to implement the design procedure. References 6, 8, and 27 give much additional information, and in particular, Ref. 27 contains an extensive discussion and bibliography. Manufacturer's catalogs are a good source of current data.

COUPLED-RESONATOR DESIGN PROCEDURE

The insertion-loss low-pass prototype filters can be used to design coupled-resonator bandpass filters. Five steps can be identified in the process, though in some cases the dividing lines become indistinct.

1. Transform the bandpass specifications to a low-pass prototype, using Eq. (8). This will take the center frequency to $\omega = 0$ and, usually, the band edge to $\omega = 1$.
2. Choose the appropriate low-pass response, e.g., Chebyshev, elliptic, or Butterworth, that meets the transformed specifications. Zeros of transmission are fixed at this time. From this characteristic function determine the transfer function that is needed. The tables presented earlier may be useful.
3. Determine the short-circuit y or open-circuit z parameters from the transfer function.
4. If possible, look up or synthesize the appropriate ladder or lattice network needed. At this point, it is still a low-pass prototype. The technique chosen may depend on the expected form of the final network.
5. Use Fig. 10.2.7 to transform the network into a bandpass network and then use network theorems to adjust the network to a configuration and a set of element values that is practical, i.e., one that matches the resonators.

This process is not one in which success is assured. It may require a variety of attempts before a suitable design is achieved. Equivalent circuits and network theorems are summarized in the following paragraphs.

EQUIVALENT CIRCUITS

The most common equivalent circuit for a piezoelectric crystal shows a series-resonant RLC circuit in parallel with a second capacitor, as shown in Fig. 10.5.1. The parallel capacitor C_p is composed of the mounting hardware and electric plates on the crystal. In practice, the ratio C_p/C cannot be reduced below about 125, but it may be increased if needed. When a filter contains more than one crystal, the coupling is electrical, usually with capacitors.

FIGURE 10.5.1 Equivalent circuit for piezoelectric crystal. Because coupling is electrical, a one-port representation is sufficient.

Mechanical filters have an equivalent circuit, as indicated in Fig. 10.5.2. The resonant circuits L_0, C_R represent the transducer magnetostrictive coils and their tuning capacitances. (In cases of small R_L , it may be more accurate to place C_R in series with L_0 .) The resonant circuit L_1, C_1, R_1 and L_n, C_n, R_n include the motional parameters of the transducers. Elements $L_2, C_2, R_2, \dots, L_{n-1}, C_{n-1}, R_{n-1}$ represent the motional parameters of the resonant elements, and $L_{12}, \dots, L_{n-1,n}$ represent the compliances of the coupling wires.

FIGURE 10.5.2 Equivalent circuit for a mechanical filter. A two-port representation allows an electric equivalent circuit for the entire filter.

FIGURE 10.5.3 Equivalent circuit for a monolithic crystal or acoustic filter. The one-to-one ideal transformer models the 180° phase shift observed in these filters.

The acoustic filter is represented, after substantial development, by the circuit shown in Fig. 10.5.3. The development has made the circuit easy to use, but the association between the electrical elements and the filter elements is less apparent than in the previous circuits. The ideal transformer at the output accounts for the 180° phase shift observed in these filters. In some analyses, it may be omitted.

NETWORK TRANSFORMATIONS

In the process of changing a bandpass circuit to meet the configuration of the equivalent circuit of a coupled resonator a variety of equivalent networks may be useful. At one step negative elements may appear. These can be absorbed later in series or parallel with positive elements so that the overall result is positive.

The impedance inverters of Fig. 10.5.4 can be used to invert an impedance, as indicated. Over a very narrow frequency range they can often be approximated with three capacitors, two of which are negative. An inverter can be used to convert an inductance into a capacitance provided the negative elements can then be absorbed. Other similar reactive configurations can also be used.

Lattice networks (Fig. 10.5.5) are often used in crystal filters. If the condition prevailing in Fig. 10.5.6 exists, the equivalent can be used in either direction to affect a change. In particular, the ladder can be transformed into a lattice, which then has the crystal equivalent circuit.

Two Norton transformations and networks derived from them are shown in Figs. 10.5.7 and 10.5.8. They lead to negative elements, and it is expected that they will later be absorbed into positive elements. Humpherys⁸ gives another derived Norton transformation that can be used to reduce inductance values. It changes the impedance level on one side of the network. When this is applied to a symmetrical network, the new impedance levels will eventually become directly connected, so that no transformer is needed.

CHAPTER 10.6

DIGITAL FILTERS*

Arthur B. Williams, Fred J. Taylor

RELATION TO ANALOG FILTERS

Digital filters provide many of the same frequency selective services (low, high, bandpass) expected of analog filters. In some cases, digital filters are defined in terms of equivalent analog filters. Other digital filters are designed using rules unique to this technology. The hardware required to fabricate a digital filter are basic digital devices such as memory and arithmetic logic units (ALUs). Many of these hardware building blocks provide both high performance and low cost. Coefficients and data are stored as digital computer words and, as a result, provide a precise and noise free (in an analog sense) signal processing medium. Compared to analog filters, digital filters generally enjoy the following advantages:

1. They can be fabricated in high-performance general-purpose digital hardware or with application-specific integrated circuits (ASIC).
2. The stability of certain classes of digital filters can be guaranteed.
3. There are no input or output impedance matching problems.
4. Coefficients can be easily programmed and altered.
5. Digital filters can operate over a wide range of frequencies.
6. Digital filters can operate over a wide dynamic range and with high precision.
7. Some digital filters provide excellent phase linearity.
8. Digital filters do not require periodic alignment and do not drift or degrade because of aging.

DATA REPRESENTATION

In an analog filter, all signals and coefficients are considered to be real or complex numbers. As such, they are defined over an infinite range with infinite precision. In the analog case, filter coefficients are implemented with lumped R , L , C , and amplifier components of assumed absolute precision. Along similar lines, the designs of digital filters typically begin with the manipulation of idealized equations. However, the implementation of a digital filter is accomplished using digital computational elements of finite precision (measured in bits). Therefore, the analysis of a digital filter is not complete until the effects of finite precision arithmetic has been

*This section is based on the author's *Electronic Filter Design Handbook*, 3rd ed., McGraw-Hill, 1995.

determined. As a result, even though there has been a significant sharing of techniques in the area of filter synthesis between analog and digital filters, the analyses of these two classes of filters have developed separate tools and techniques.

Data, in a digital system, are represented as a set of binary-valued digits. The process by which a real signal or number is converted into a digital word is called analog-to-digital conversion (ADC). The most common formats used to represent data are called *fixed* and *floating* point (FXP and FLP). Within the fixed-point family of codes, the most popular are binary-coded decimal sign magnitude (SM) and diminished radix (DR) codes. Any integer X such that $|X| < 2^{n-1}$ has a unique sign-magnitude representation, given by

$$X = X_{n-1} : (2^{n-2} X_{n-2} + \dots + 2X_1 + X_0) \quad (1)$$

where X_i is the i th bit and X_0 is referred to as the least significant bit (LSB). Similarly X_{n-2} is called the most significant bit (MSB) and X_{n-1} is the sign bit. The LSB often corresponds to a physically measurable electrical unit. For example, if a signed 12-bit ADC is used to digitize a signal whose range is ± 15 V, the LSB represents a quantization step size of $Q = 30 \text{ V (range)} / 2^{12} - \text{bits} = 7.32 \text{ mV/bit}$.

Fractional numbers are also possible simply by scaling X by a power of 2. The value of $X' = X/2^m$ has the same binary representation of X except that the m LSBs are considered to be fractional bits.

SIGNAL REPRESENTATION

An analog filter manipulates real signals of assumed infinite precision. In a discrete system, analog signals of assumed infinite precision are periodically sampled at a rate of f samples per second. The same period is therefore given by $t_s = 1/f_s$ second(s). A string of contiguous samples is called a *time series*. If the samples are further processed by an ADC, a digital time series results. A digital filter can be used to manipulate this time series using digital technology. The hardware required to implement such a filter is the product of the microelectronics revolution.

SPECTRAL REPRESENTATION

Besides representing signals in the continuous or discrete time domain, signals can also be modeled in the frequency domain. This condition is called *spectral representation*. The principal tools used to describe a signal in the frequency domain are: (1) Fourier transforms, (2) Fourier series, and (3) discrete Fourier transforms (DFT).

A Fourier transform will map an arbitrary transformable signal into a continuous frequency spectrum consisting of all frequency components from $-\infty$ to $+\infty$. The Fourier transform is defined by an indefinite integral equation whose limits range from $-\infty$ to $+\infty$. The Fourier series will map a continuous but periodic signal of period T [i.e., $x(t) = x(t + kT)$ for all integer values of k] into a discrete but infinite spectrum consisting of frequency harmonics located at multiples of the fundamental frequency $1/T$. The Fourier series is defined by a definite integral equation whose limits are $[0, T]$. The discrete Fourier transform differs from the first two transforms in that it does not accept data continuously but rather from a time series of finite length. Also, unlike the first two transforms, which produce spectra ranging out to $\pm\infty$ Hz, the DFT spectrum consists of a finite number of harmonics.

The DFT is an important and useful tool in the study of digital filters. The DFT can be used to both analyze and design digital filters. One of its principal applications is the analysis of a filter's impulse response. An impulse response database can be directly generated by presenting a one-sample unit pulse to a digital filter that is initially at a zero state (i.e., zero initial conditions). The output is the filter's impulse response, which is observed for N contiguous samples. The N -sample database is then presented to an N -point DFT, transformed, and analyzed. The spectrum produced by the DFT should be a reasonable facsimile of the frequency response of the digital filter under test.

FILTER REPRESENTATION

A transfer function is defined by the ratio of output and input transforms. For digital filters, it is given by $H(z) = Y(z)/U(z)$ where $U(z)$ is the z transform of the input signal $u(n)$ and $Y(z)$ is for the output signal $y(n)$. The frequency response of a filter $H(z)$ can be computed using a DFT of the filter's impulse response.

Another transform tool that also is extensively used to study digital filters is the *bilinear z transform*. While the standard z transform can be related to the simple sample and hold circuit, the bilinear z transform is analogous to a first-order hold. The bilinear z transform is related to the familiar Laplace transform through

$$s = \frac{2(z-1)}{t_s(z+1)} \quad z = \frac{(2/t_s) + s}{(2/t_s) - s} \quad (2)$$

Once an analog filter $H(s)$ is defined, it can be converted into a discrete filter $H(z)$ by using the variable substitution rule.

FINITE IMPULSE-RESPONSE (FIR) FILTERS

Linear constant coefficient filters can be categorized into two broad classes known as finite impulse-response (FIR) or infinite impulse-response (IIR) filters. An FIR filter can be expressed in terms of a simple discrete equation:

$$y(n) = c_0x(n) + c_1x(n-1) + \dots + c_{N-1}x(n-N+1) \quad (3)$$

where the coefficients $\{C_i\}$ are called *filter tap weights*. In terms of a transfer function, Eq. (3) can be restated as

$$H(z) = \sum_{i=0}^{n-1} C_i z^{-i} \quad (4)$$

As an example, a typical $N = 111$ th-order FIR is shown in Fig. 10.6.1. The FIR exhibits several interesting features:

1. The filter's impulse response exists for only $N = 111$ (finite) contiguous samples.
2. The filter's transform function consists of zeros only (i.e., no poles). As a result, an FIR is sometimes referred to as an all-zero, or transversal, filter.
3. The filter has a very simple design consisting of a set of word-wide shift registers, tap-weight multipliers, and adders (accumulators).
4. If the input is bounded by unity (i.e., $|x(i)| \leq 1$ for all i), the maximum value of the output $y(i)$ is $\sum |C_i|$. If all the tap weights C_i are bounded, the filter's output is likewise bounded and, as a result, stability is guaranteed.
5. The phase, when plotted with respect to frequency (plot shown over the principal angles $\pm \pi/2$), is linear with constant slope.

LINEAR PHASE BEHAVIOR

The FIR is basically a shift-register network. Since digital shift registers are precise and easily controlled, the FIR can offer the designer several phase domain attributes that are difficult to achieve with analog filters. The most important of these are: (1) Potential for linear phase versus frequency behavior and (2) potential for constant

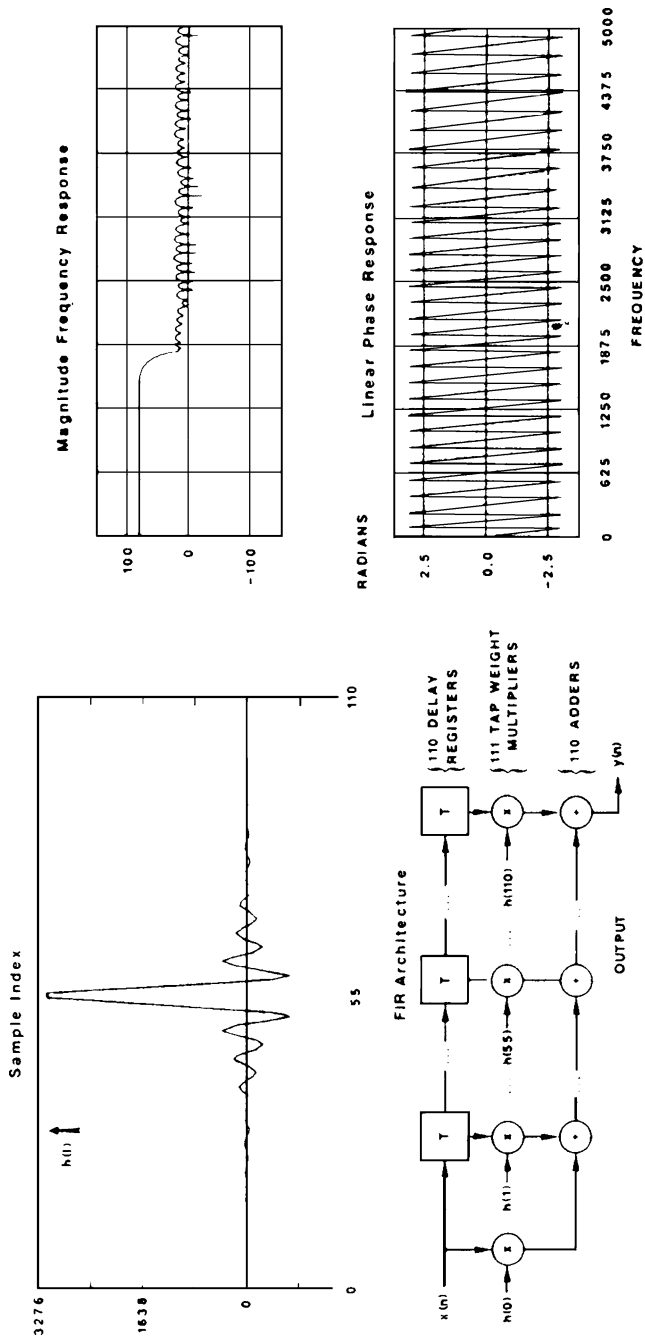

FIGURE 10.6.1 Typical FIR architecture, impulse response, and frequency response.

group-delay behavior. These properties are fundamentally important in the fields of digital communications systems, phase synchronization systems (e.g., phase-locked loops), speech processing, image processing, spectral analysis (e.g., Fourier analysis), and other areas where nonlinear phase distortion cannot be tolerated.

FIR DESIGN METHODS

The design of an FIR entails specifying the filter's impulse response, tap weights $\{C_i\}$. As a result, the design of an FIR can be as simple as prespecifying the desired impulse response. Other acceptable analytical techniques used to synthesize a desired impulse response are the inverse Fourier transform of a given frequency domain filter specification or the use of polynomial approximation techniques. These methods are summarized below.

A simple procedure for designing an FIR is to specify an acceptable frequency domain model, invert the filter's spectral representation using the inverse Fourier transform, and use the resulting time series to represent the filter's impulse response. In general, the inverse Fourier transform of a *desired* spectral waveshape would produce an infinitely long time domain record. However, from a hardware cost or throughput standpoint, it is unreasonable to consider the implementing of an infinitely or extremely long FIR. Therefore, a realizable FIR would be defined in terms of a truncated Fourier series. For example, the Fourier transform of the "nearly ideal" $N = 101$ order low-pass filter has a $\sin(x)/x$ type impulse-response envelope. For a large value of N , the difference between the response of an infinitely long impulse response and its N -sample approximation is small; however, when N is small, large approximation errors can occur.

Optimal Modeling Techniques

Weighted Chebyshev polynomials have been successfully used to design FIRs. In this application, Chebyshev polynomials are combined so that their combined sum minimizes the maximum difference between an ideal and the realized frequency response (i.e., mini-max principle). Because of the nature of these polynomials, they produce a "rippled" magnitude frequency-response envelope of equal minima and maxima in the pass- and stopbands. As a result, this class of filters is often called an *equiripple* filter. Much is known about the synthesis process, which can be traced back to McClellan et al.⁴⁸ Based on these techniques, a number of software-based CAD tools have been developed to support FIR design.

WINDOWS

Digital filters usually are expected to operate over long, constantly changing data records. An FIR, while being capable of offering this service, can only work with a limited number of samples at a time. A similar situation presents itself in the context of a discrete Fourier transform. The quality of the produced spectrum is a function of the number of transformed samples. Ideally, an infinitely long impulse response would be defined by an ideal filter. A *uniform window* of length T will pass N contiguous samples of data. The windowing effect may be modeled as a multiplicative switch that multiplies the presented signal by zero (open) for all time exclusive of the interval $[0, T]$. Over $[0, T]$, the signal is multiplied by unity (closed). In a sampled system, the interval $[0, T]$ is replaced by N samples taken at a sample rate f_s where $T = N/f_s$. When the observation interval (i.e., N) becomes small, the quality of the spectral estimate begins to deteriorate. This consequence is called the *finite aperture effect*.

Windowing is a technique that tends to improve the quality of a spectrum obtained from a limited number of samples. Some of the more popular windows found in contemporary use are the rectangular or uniform window, the Hamming window, the Hann window, the Blackman window, and the Kaiser window.

Windows can be directly applied to FIRs. To window an N -point FIR, simply multiply the tap weight coefficients C_i with the corresponding window weights w_i . Note that all of the standard window functions have even symmetry about the midsample. As a result, the application of such a window will not disturb the linear phase behavior of the original FIR.

MULTIRATE SIGNAL PROCESSING

Digital signal processing systems accept an input time series and produce an output time series. In between, a signal can be modified in terms of its time and/or frequency domain attributes. One of the important functions that a digital signal processing system can serve is that of sample rate conversion. As the name implies, a sample rate converter changes a system's sample rate from a value of f_{in} samples per second to a rate of f_{out} samples per second. Such devices are also called multirate systems since they are defined in terms of two or more sample rates. If $f_{in} > f_{out}$ then the system is said to perform decimation and is said to be decimated by an integer M if

$$M = \frac{f_{out}}{f_{in}} \quad (5)$$

In this case, the decimated time series $x_d[n] = x[Mn]$, or every M th sample of the original time series is retained. Furthermore, the effective sample rate is reduced from f_{in} to $f_{dec} = f_{in}/M$ samples per second.

Applications of decimation include audio and image signal processing involving two or more subsystems having dissimilar sample rates. Other applications occur when a high data rate ADC is placed at the front end of a system and the output is to be processed parameters that are sampled at a very low rate by a general-purpose digital computer. At other times, multirate systems are used simply to reduce the Nyquist rate to facilitate computational intensive algorithms, such as a digital Fourier analyzer, to be performed at a slower arithmetic rate. Another class of applications involves processing signals, sampled at a high data rate, through a limited bandwidth channel.

QUADRATURE MIRROR FILTERS (QMF)

We have stated that multirate systems are often used to reduce the sample rate to a value that can be passed through a band-limited communication channel. Supposedly, the signal can be reconstructed on the receiver side. The amount of allowable decimation has been established by the Nyquist sampling theorem. When the bandwidth of the signal establishes a Nyquist frequency that exceeds the bandwidth of a communication channel, the signal must be decomposed into subbands that can be individually transmitted across band-limited channels. This technique uses a bank of band-limited filters to break the signal down into a collection of subbands that fit within the available channel bandwidths.

Quadrature mirror filters (QMF) are often used in the subband application described in Fig. 10.6.2. The basic architecture shown in that figure defines a QMF system and establishes two input-output paths that have a bandwidth requirement that is half the input or output requirements. Using this technique, the channels can be subdivided over and over, reducing the bandwidth by a factor of 2 each time. The top path consists of low-pass filters and the bottom path is formed by high-pass filters.

FIGURE 10.6.2 Quadrature mirror filter (QMF).

Designing QMF is, unfortunately, not a trivial process. No meaningful flat response linear phase QMF filter exists. Most QMF designs represent some compromise.

INFINITE IMPULSE-RESPONSE FILTER

The FIR filter exhibits superb linear phase behavior; however, in order to achieve a high-quality (steep-skirt) magnitude frequency response, a high-order FIR is required. Compared to the FIR, the IIR filter

1. Generally satisfies a given magnitude frequency-response design objective with a lower-order filter.
2. Does not generally exhibit linear phase or constant group-delay behavior.

If the principal objective of the digital filter design is to satisfy the prespecified magnitude frequency response, an IIR is usually the design of choice. Since the order of an IIR is usually significantly less than that of an FIR, the IIR would require fewer coefficients. This translates into a reduced multiplication budget and an attendant saving in hardware and cost. Since multiplication is time consuming, a reduced multiplication budget also translates into potentially higher sample rates.

From a practical viewpoint, a realizable filter must produce bounded outputs if stimulated by bounded inputs. The magnitude is bounded on an IIR's impulse response, namely,

$$\sum_{n=0}^{\infty} |h(n)| < M \quad (6)$$

If M is finite (bounded), the filter is stable, and if it is infinite (unbounded), the filter is unstable. This condition can also be more conveniently related to the pole locations of the filter under study. It is well known that a causal discrete system with a rational transfer function $H(z)$ is stable (i.e., bounded inputs produce bounded outputs) if and only if its poles are interior to the unit circle in the z domain. This is often referred to as the circle criterion and it can be tested using general-purpose computer root-finding methods. Other algebraic tests—Schur-Cohen, Routh-Hurwitz, and Nyquist—may also be used. The stability condition is implicit to the FIR as long as all N coefficients are finite. Here the finite sum of real bounded coefficients will always be bounded.

DESIGN OBJECTIVES

The design of an IIR begins with a magnitude frequency-response specification of the target filter. The filter's magnitude frequency response is specified as it would be for an analog filter design. In particular, assume that a filter with a magnitude-squared frequency response given by $|H(\omega)|^2$, having passband, transition band, and stopband behavior as suggested by Fig. 10.6.3, is to be synthesized. The frequency response of the desired filter is specified in terms of a cutoff critical frequency ω_p , a stopband critical frequency ω_s and stop- and passband delimiters ϵ and A . The critical frequencies ω_p and ω_s represent the end of the passband and the start of the stopband, respectively, for the low-pass example. In decibels, the gains at these critical frequencies are given by (passband ripple constraint) and $-A_s = -10 \log(A^2)$ (stopband attenuation). For the case where $\epsilon = 1$, the common 3-dB passband filter is realized.

FIR AND IIR FILTERS COMPARED

The principal attributes of FIR are its simplicity, phase linearity, and ability to decimate a signal. The strength of the IIR is its ability to achieve high-quality (steep-skirt) filtering with a limited number order design. Those positive characteristics of the FIR are absent in the IIR and vice versa.

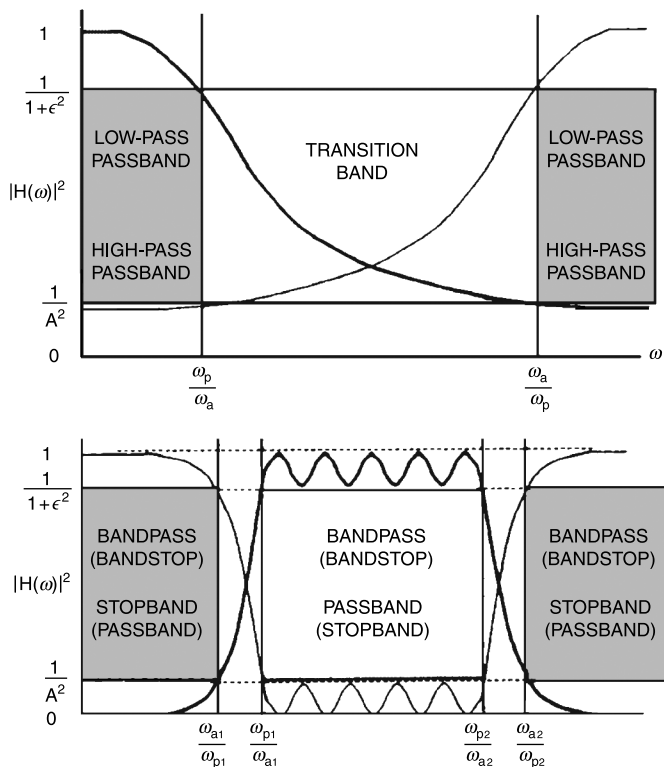

FIGURE 10.6.3 Typical design objective for low-pass, high-pass, and bandstop IIR filters.

The estimated order of an FIR, required to achieve an IIR design specification, was empirically determined by Rabiner. It was found that the approximate order n of an FIR required to meet a design objective

$$\begin{aligned}
 (1 - \delta_1)^2 &= \frac{1}{1 + \epsilon^2} \quad \delta_1 \text{ (passband-ripple)} \\
 \delta_2^2 &= \frac{1}{A^2} \quad \delta_2 \text{ (stopband bound)} \\
 \Delta f &\text{ (transition frequency range/} f_s \text{)}
 \end{aligned}
 \tag{7}$$

is given by

$$n \sim \frac{-10 \log((1 - \delta_1)\delta_2) - 15}{14\Delta f} + 1
 \tag{8}$$

STANDARD FILTER FORMS

The standard filter forms found in common use are: (1) Direct II, (2) Standard, (3) Cascade, and (4) Parallel. These basic filter cases are graphically interpreted in Ref. 52. The direct II and standard architectures are somewhat similar in their structure. Both strategies possess information feedback paths ranging from one

delay to n delays. The transfer function denominator is an n th-order polynomial. The cascade and parallel models are constructed using a system of low-order subsections or subfilters. In the cascade design, the low-order subsections are serially interconnected. In the parallel filter, these sections are simply connected in parallel. The low-order subfilters, in both cases, are the result of factoring the n th-order transfer function polynomial into lower-order polynomials.

The design and analysis of all four classes of filters can be performed using manually manipulated equations or a digital computer. The most efficient method of formulating the filter design problem, whether using tables, calculators, or a computer, is called the *state-variable* technique. A state variable is a parameter that represents the information stored in a system. The set of state variables is called a *state vector*. For an analog system, information is stored on capacitors or in inductors. In earlier chapters, state variables were used to specify and facilitate the manipulation of the R , L , and C components of an analog filter. In these cases, capacitive voltage and inductive current were valid state variables. Since resistors have no memory, they would not be the source of a state variable.

In digital filters, the memory element, which stores the state information, is simply a delay (shift) register. The realization of digital filters is described in Ref. 52.

FIXED-POINT DESIGN

An IIR, once designed and architected, often needs to be implemented in hardware. The choices are fixed- or floating-point. Of the two, fixed-point solutions generally provide the highest real-time bandwidth at the lowest cost. Unfortunately, fixed-point designs also introduce errors that are not found in more expensive floating-point IIR designs. The fixed-point error sources are either low-order inaccuracies, because of finite precision arithmetic and data (coefficient) roundoff effects or potentially large errors because of run-time dynamic range overflow (saturation).

Additional precision can be gained by increasing the number of fractional bits assigned to the data and coefficients fields with an attendant decrease in dynamic range and an increased potential for runtime overflow. On the other hand, the overflow saturation problem can be reduced by enlarging the dynamic range of the system by increasing the integer bit field with an accompanying loss of precision. The problem facing the fixed-point filter design, therefore, is achieving a balance between the competing desire to maximize precision and to simultaneously eliminate (or reduce) run-time overflow errors. This is called the *binary-point assignment problem*.

CHAPTER 10.7

ATTENUATORS

Arthur B. Williams, Fred, J. Taylor

ATTENUATOR NETWORK DESIGN

Attenuators are passive circuits that introduce a fixed power loss between a source and load while matching impedances. The power loss is independent of the direction of power flow. Figure 10.7.1 shows T , Π , and bridged- T networks. The first two are unbalanced and unsymmetrical, unless $Z_L = Z_S$. In this case, $Z_1 = Z_2$, and the network is symmetrical. To build an unbalanced network, divide Z_1 and Z_2 by 2, and put half of each element in each series arm. The bridged- T shown is only for symmetrical networks.

These design equations are valid for resistive and complex impedances.

$$\begin{aligned}
 Z_S &= \text{source impedance} \\
 Z_L &= \text{load impedance} \\
 A &= \text{ratio of available power to desired load power (dB)} = 10^{B/10} \\
 B &= 10 \log A \\
 \theta &= 1/2 \ln A = 1/2 \ln 10^{B/10}
 \end{aligned} \tag{1}$$

As an example, design an attenuator to match a 75- Ω source to a 300- Ω load and to introduce a 14.0-dB loss. Use a T section. In terms of Eq. (1),

$$\begin{aligned}
 Z_s = 75 \Omega & & Z_L = 300 \Omega & & B = 14.0 \text{ dB} & & A = 25.12 \\
 \theta = 1.612 & & Z_3 = 62.34 \Omega & & Z_1 = 18.88 \Omega & & Z_2 = 262.54 \Omega
 \end{aligned}$$

Figure 10.7.2 shows the network.

Circuit name	Circuit diagram	Equations
T-Network		$Z_3 = \sqrt{Z_s Z_L} / \sinh \theta = \frac{2\sqrt{Z_s Z_L} \cdot A}{A-1}$ $Z_1 = Z_s \coth \theta - Z_3 = Z_s \left(\frac{A+1}{A-1} \right) - Z_3$ $Z_2 = Z_L \coth \theta - Z_3 = Z_L \left(\frac{A+1}{A-1} \right) - Z_3$
π-Network		$Y_3 = \frac{1}{\sqrt{Z_s Z_L} \sinh \theta}$ $= \frac{2}{A-1} \sqrt{\frac{A}{Z_s Z_L}}$ $Y_1 = \frac{\tanh \theta}{Z_s} - Y_3 = \frac{1}{Z_s} \left(\frac{A+1}{A-1} \right) - Y_3$ $Y_2 = \frac{\tanh \theta}{Z_L} - Y_3 = \frac{1}{Z_L} \left(\frac{A+1}{A-1} \right) - Y_3$
Bridged-T		$Z_1 = Z$ $Z_2 = Z(A-1)$ $Z_3 = \frac{Z}{A-1}$

SECTION 11

AMPLIFIERS AND OSCILLATORS

Amplifiers serve a number of purposes from allowing us to hear beautiful music to accurately positioning elements of complicated systems using control technologies. Oscillators are found in a number of applications from the watch on your wrist to the transmitter and receiver in your cell phone. We look at audio-frequency amplifiers and oscillators and radio-frequency amplifiers and oscillators.

The most versatile amplifier has to be the operational amplifier (op amp). The key to its success is that it is perhaps the most ideal device in analog electronics. Because of this it is found in a number of amplifier designs.

High-power amplifiers are necessary where significant amounts of power need to be used to accomplish activities such as radio and television broadcasts. Just imagine what a rock concert might sound like without power amplifiers. Microwave amplifiers and oscillators represent a special part of the high-power amplifier and oscillator field. C.A.

CHAPTER 11.1

AMPLIFIER AND OSCILLATOR PRINCIPLES OF OPERATION

G. Burton Harrold

AMPLIFIERS: PRINCIPLES OF OPERATION

Gain

In most amplifier applications the prime concern is gain. A generalized amplifier is shown in Fig. 11.1.1. The most widely applied definitions of gain using the quantities defined there are:

$$\text{Voltage gain } A_v = e_{22}/e_{11} \quad \text{Current gain } A_i = i_2/i_1$$

$$\text{Available power from source } P_{\text{avs}} = \frac{|e_s|^2}{4 \operatorname{Re} Z_s} \quad \text{where Re = real part of complex impedance}$$

$$\text{Output load power } P_L = \frac{|e_{22}|^2}{\operatorname{Re} Z_L} \quad \text{Input power } P_I = \frac{|e_{11}|^2}{\operatorname{Re} Z_{\text{in}}}$$

$$\text{Available power at output } P_{\text{avo}} = \frac{|e_{22}|^2}{4 \operatorname{Re} Z_{\text{out}}} \quad \text{Transducer gain } G_T = P_L/P_{\text{avs}}$$

$$\text{Available power gain } G_A = P_{\text{avo}}/P_{\text{avs}} \quad \text{Power gain } G = P_L/P_I$$

$$\text{Insertion power gain } G_I = \frac{\text{power into load with network inserted}}{\text{power into load with source connected to load}}$$

Bandwidth and Gain-Bandwidth Product

Bandwidth is a measure of the range of frequencies within which an amplifier will respond. The frequency range (passband) is usually measured between the half-power (3-dB) points on the output-response-versus-frequency curve, for constant input. In some cases it is defined at the quarter-power points (6 dB). See Fig. 11.1.2.

The gain-bandwidth product of a device is a commonly used figure of merit. It is defined for a bandpass amplifier as

$$F_a = A_r B$$

11.6 AMPLIFIERS AND OSCILLATORS

FIGURE 11.1.1 Input and output quantities of generalized amplifier.

where F_a = figure of merit (rad/s)
 A_r = reference gain, either the maximum gain or the gain at the frequency where the gain is purely real or purely imaginary
 B = 3-dB bandwidth (rad/s)

For low-pass amplifiers

$$F_a = A_r W_H$$

where F_a = figure of merit (rad/s)
 A_r = reference gain
 W_H = upper cutoff frequency (rad/s)

In the case of vacuum tubes and certain other active devices this definition is reduced to

$$F_a = g_m / C_T$$

where F_a = figure of merit (rad/s)
 g_m = transconductance of active device
 C_T = total output capacitance, plus input capacitance of subsequent stage

Noise

The major types of noise are illustrated in Fig. 11.1.3. Important relations and definitions in noise computations are:

Noise factor

$$F = \frac{S_i / N_i}{S_o / N_o}$$

where S_i = signal power available at input
 S_o = signal power available at output
 N_i = noise power available at input at $T = 290$ K
 N_o = noise power available at output

Available noise power

$$P_{n,av} = \frac{e_n^2}{4R} = KTB \quad \text{for thermal noise}$$

where the quantities are as defined in Fig. 11.1.3.

Excess noise factor

$$F - 1 = N_e / N_i$$

FIGURE 11.1.2 Amplifier response and bandwidth.

FIGURE 11.1.3 Noise-equivalent circuits.

where $F - 1$ = excess noise factor

N_e = total equivalent device noise referred to input

N_i = thermal noise of source at standard temperature

Noise temperature

$$T = P_{n,av} / KB$$

where $P_{n,av}$ is the average noise power available.

At a single input-output frequency in a two-port,

Effective input noise temperature

$$T_e = 290(F - 1)$$

Noise Factor of Transmission Lines and Attenuators. The noise factor of two ports composed entirely of resistive elements at room temperature (290 K) and an impedance matched loss of $L = 1/G_A$ is $F = L$.

Cascaded noise factor

$$F_T = F_1 + (F_2 - 1)/G_A$$

11.8 AMPLIFIERS AND OSCILLATORS

where F_T = overall noise factor
 F_1 = noise factor of first stage
 F_2 = noise factor of second stage
 G_A = available gain of first stage

System Noise Temperature. Space probes and satellite communication systems using low-noise amplifiers and antennas directed toward outer space make use of system noise temperatures. When we define T_A = antenna temperature, L = waveguide numeric loss (greater than 1), T_{E1} = amplifier noise temperature, G_A = amplifier available gain, F = postamplifier noise factor, and B = postamplifier bandwidth, this temperature can be calculated as

$$T_{\text{sys}} = T_A + |L - 1| 290^\circ + LT_{E1} + \frac{(F - 1)(290L)}{G_A}$$

The quantity of interest is the output signal-to-noise ratio where S_A is available signal power at the antenna (assuming the antenna is matched to free space)

$$S/N = S_A / K T_{\text{sys}} B \quad K = 1.38 \times 10^{-23}$$

Generalized Noise Factor. A general representation of noise performances can be expressed in terms of Fig. 11.1.4. This is the representation of a noisy two-port in terms of external voltage and current noise sources with a correlation admittance. In this case the noise factor becomes

$$F = 1 + \frac{G_u}{G_s} - \frac{R_N}{G_s} [(G_s + G_\gamma)^2 + (B_s + B_\gamma)^2]$$

where F = noise factor
 G_s = real part of Y_s
 B_s = imaginary part of Y_s
 G_u = conductance owing to the uncorrelated part of the noise current
 Y_γ = correlation admittance between cross product of current and voltage noise sources
 G_γ = real part of Y_γ
 B_γ = imaginary part of Y_γ
 R_N = equivalent noise resistance of the noise voltage

The optimum source admittance is $Y_{\text{opt}} = G_{\text{opt}} + jB_{\text{opt}}$

$$G_{\text{opt}} = \left(\frac{G_u + R_N G_\gamma^2}{R_N} \right)^{1/2}$$

FIGURE 11.1.4 Noise representation using correlation admittance.

where $B_{\text{opt}} = -B_{\text{gg}}$ and the value of the optimum noise factor F_{opt} is

$$F_{\text{opt}} = 1 + 2R_N(G_\gamma + G_0)$$

The noise factor for an arbitrary source impedance is

$$F = F_{\text{opt}} + \frac{R_N}{G_s} [(G_s - G_0)^2 + (B_s - B_0)^2]$$

The values of the parameters of Fig. 11.1.4 can be determined by measurement of (1) noise figure versus B_s with G_s constant and (2) noise figure versus G_s with B_s at its optimum value.

Dynamic Characteristic, Load Lines, and Class of Operation

Most active devices have two considerations involved in their operation. The first is the dc bias condition that establishes the operating point (the *quiescent point*). The choice of operating point is determined by such considerations as signal level, uniformity of the device, and temperature of operation.

The second consideration is the ac operating performance, related to the slope of the dc characteristic and to the parasitic reactances of the device. These ac variations give rise to the *small-signal parameters*. The ac parameters may also influence the choice of dc bias point when basic constraints, such as gain and noise performance, are considered.

For frequencies of operation where these parasites are not significant, the use of a load line is valuable. The class of amplifier operation is dependent on its quiescent point, its load line, and input signal level. The types of operation are shown in Fig. 11.1.5.

Distortion

Distortion takes many forms, most of them undesirable. The basic causes of distortion are nonlinearity in amplitude response and nonuniformity of phase response. The most commonly encountered types of distortion are as follows:

Harmonic distortion is a result of nonlinearity in the amplitude transfer characteristics. The typical output contains not only the fundamental frequency but integer multiples of it.

Crossover distortion is a result of the nonlinear characteristics of a device when changing operating modes (e.g., in a push-pull amplifier). It occurs when one device is cut off and the second turned on if the crossover is not smooth between the two modes.

Intermodulation distortion is a spurious output resulting from the mixing of two or more signals of different frequencies. The spurious output occurs at the sum or difference of integer multiples of the original frequencies.

Cross-modulation distortion occurs when two signals pass through an amplifier and the modulation of one is transferred to the other.

Phase distortion results from the deviation from a constant slope of the output-phase-versus-frequency response of an amplifier. This deviation gives rise to echo responses in the output that precede and follow the main response, and a distortion of the output signal when an input signal having a large number of frequency components is applied.

Feedback Amplifiers

Feedback amplifiers fall into two categories: those having positive feedback (usually oscillators) and those having negative feedback. The positive-feedback case is discussed under oscillators. The following discussion is concerned with negative-feedback amplifiers.

FIGURE 11.1.5 Classes of amplifier operation. Class S operation is a switching mode in which a square-wave output is produced by a sine-wave input.

Negative Feedback

A simple representation of a feedback network is shown in Fig. 11.1.6. The closed-loop gain is given by

$$e_2/e_1 = A/(1 - BA)$$

where A is the forward gain with feedback removed and B is the fraction of output returned to input.

For negative feedback, A provides a 180° phase shift in mid-band, so that

FIGURE 11.1.6 Amplifier with feedback loop.

$$1 - AB > 1 \quad \text{in this frequency range}$$

The quantity $1 - AB$ is called the *feedback factor*, and if the circuit is cut at any X point in Fig. 11.1.6, the open-loop gain is AB .

It can be shown that for large loop gain AB the closed-loop transfer function reduces to

$$e_2/e_1 \approx 1/B$$

The gain then becomes essentially independent of variations in A . In particular, if B is passive, the closed-loop gain is controlled only by passive components. Feedback has no beneficial effect in reducing unwanted signals

at the input of the amplifier, e.g., input noise, but does reduce unwanted signals generated in the amplifier chain (e.g., output distortion).

The return ratio can be found if the circuit is opened at any point X (Fig. 11.1.6) and a unit signal P is injected at that X point. The return signal P' is equal to the return ratio, since the input P is unity. In this case the return ratio T is the same at any point X and is

$$T = -AB$$

The minus sign is chosen because the typical amplifier has an odd number of phase reversals and T is then a positive quantity. The return difference is by definition

$$F = 1 + T$$

It has been shown by Bode that

$$F = \Delta / \Delta^0$$

where Δ is the network determinant with XX point connected and Δ^0 is the network determinant of amplifier when gain of active device is set to zero.

Stability

The stability of the network can be analyzed by several techniques. Of prime interest are the Nyquist, Bode, Routh, and root-locus techniques of analyzing stability.

Nyquist Method. The basic technique of Nyquist involves plotting T on a polar plot as shown in Fig. 11.1.7 for all values $s = j\omega$ for ω between minus and plus infinity. Stability is then determined by the following method:

FIGURE 11.1.7 Nyquist diagram for determining stability.

1. Draw a vector from the $-1 + j0$ point to the plotted curve and observe the rotation of this vector as ω varies from $-\infty$ to $+\infty$. Let R be the net number of counterclockwise revolutions of this vector.
2. Determine the number of roots of the denominator of $T = -AB$ which have positive real parts. Call this number P .
3. The system is stable if and only if $P = R$. Note that in many systems A and B are stable by themselves, so that P becomes zero and the net counterclockwise revolution N becomes zero for stability.

Bode's Technique. A technique that has historically found wide use in determining stability and performance, especially in control systems, is the Bode diagram. The assumptions used here for this method are that $T = -AB$, where A and B are stable when the system is open-circuited and consists of minimum-phase networks. It is also necessary to define a phase margin γ such that $\gamma = 180 + \phi$, where ϕ is the phase angle of T and is positive when measured counterclockwise from zero, and γ , the phase margin, is positive when measured counterclockwise from the 180° line (Fig. 11.1.7). The stability criterion under these conditions reads: Systems having a positive phase margin when their return ratio equal to $20 \log |T|$ goes through 0 dB (i.e., where $|T|$ crosses the unit circle in the Nyquist plot) are stable; if a negative γ exists at 0 dB, the system is unstable.

Bode's theorems show that the phase angle of a system is related to the attenuation or gain characteristic as a function of frequency. Bode's technique relies heavily on straight-line approximation.

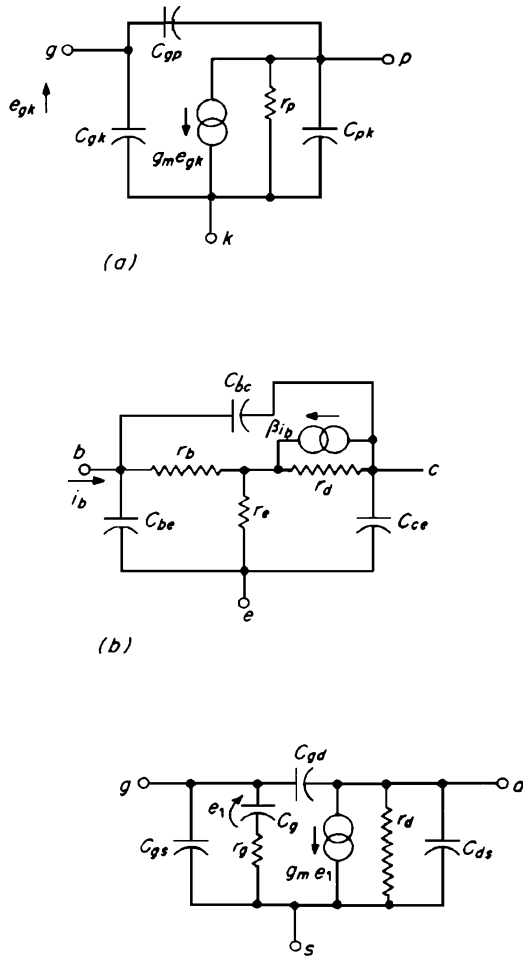

FIGURE 11.1.8 Equivalent circuits of active devices: (a) vacuum tube; (b) bipolar transistor; (c) field-effect transistor (FET).

Routh's Criterion for Stability. Routh's method has also been used to test the characteristic equations or return difference $F = 1 + T = 0$, to determine whether it has any roots that are real and positive or complex with positive real parts that will give rise to growing exponential responses and hence instability.

Root-Locus Method. The root-locus method of analysis is a means of finding the variations of the poles of a closed-loop response as some network parameter is varied. The most convenient and commonly used parameter is that of the gain K . The basic equation then used is

$$F = 1 + KT(s) = 1 - K \frac{(S - S_2)(S - S_4) \cdots}{(S - S_1)(S - S_3) \cdots} = 0$$

This is a useful technique in feedback and control systems, but it has not found wide application in amplifier design. A detailed exposition of the technique is found in Truxal.

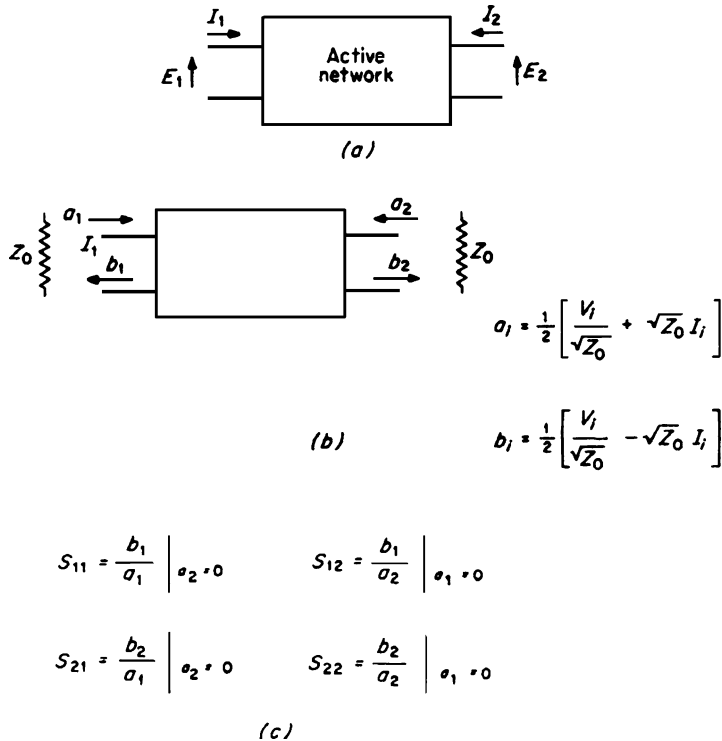

FIGURE 11.1.9 Definitions of active-network parameters: (a) general network; (b) ratios a_i and b_i of incident and reflected waves (square root of power); (c) s parameters.

Active Devices Used in Amplifiers

There are numerous ways of representing active devices and their properties. Several common equivalent circuits are shown in Fig. 11.1.8. Active devices are best analyzed in terms of the *immittance* or *hybrid matrices*. Figures 11.1.9 and 11.1.10 show the definition of the commonly used matrices, and their interconnections are shown in Fig. 11.1.11. The requirements at the bottom of Fig. 11.1.11 must be met before the interconnection of two matrices is allowed.

The matrix that is becoming increasingly important at higher frequencies is the S matrix. Here the network is embedded in a transmission-line structure, and the incident and reflected powers are measured and reflected coefficients and transmission coefficients are defined.

Cascaded and Distributed Amplifiers

Most amplifiers are cascaded (i.e., connected to a second amplifier). The two techniques commonly used are shown in Fig. 11.1.12. In the cascade structure the overall response is the product of the individual responses: in the distributed structure the response is one-half the sum of the individual responses, since each stage's output is propagated in both directions. In cascaded amplifiers the frequency response and gain are determined by the active device as well as the interstage networks. In simple audio amplifiers these interstage networks may become simple RC combinations, while in rf amplifiers they may become critically coupled double-tuned circuits. Interstage coupling networks are discussed in subsequent sections.

$\begin{bmatrix} E_1 \\ E_2 \end{bmatrix} = \begin{bmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{bmatrix} \times \begin{bmatrix} I_1 \\ I_2 \end{bmatrix}$	$z_{11} = \left(\frac{E_1}{I_1} \right)_{I_2=0}$	$z_{12} = \left(\frac{E_1}{I_2} \right)_{I_1=0}$
$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{bmatrix} \times \begin{bmatrix} E_1 \\ E_2 \end{bmatrix}$	$y_{11} = \left(\frac{I_1}{E_1} \right)_{E_2=0}$	$y_{12} = \left(\frac{I_1}{E_2} \right)_{E_1=0}$
$\begin{bmatrix} E_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} h_{11} & h_{12} \\ h_{21} & h_{22} \end{bmatrix} \times \begin{bmatrix} I_1 \\ E_2 \end{bmatrix}$	$h_{11} = \frac{1}{y_{11}}$	$h_{12} = \left(\frac{E_1}{E_2} \right)_{I_1=0}$
$\begin{bmatrix} I_1 \\ E_2 \end{bmatrix} = \begin{bmatrix} l_{11} & l_{12} \\ l_{21} & l_{22} \end{bmatrix} \times \begin{bmatrix} E_1 \\ I_2 \end{bmatrix}$	$l_{11} = \frac{1}{z_{11}}$	$l_{12} = \left(\frac{I_1}{I_2} \right)_{E_1=0}$
$\begin{bmatrix} E_1 \\ I_1 \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix} \times \begin{bmatrix} E_2 \\ -I_2 \end{bmatrix}$	$a_{11} = \frac{1}{l_{21}}$	$a_{12} = -\frac{1}{y_{21}}$
$\begin{bmatrix} E_2 \\ I_2 \end{bmatrix} = \begin{bmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{bmatrix} \times \begin{bmatrix} E_1 \\ -I_1 \end{bmatrix}$	$a_{21} = \frac{1}{z_{21}}$	$a_{22} = -\frac{1}{h_{21}}$
$\begin{bmatrix} b_1 \\ b_2 \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \times \begin{bmatrix} a_1 \\ a_2 \end{bmatrix}$	$b_{11} = \frac{1}{h_{12}}$	$b_{12} = -\frac{1}{y_{12}}$
	$b_{21} = \frac{1}{z_{12}}$	$b_{22} = -\frac{1}{l_{12}}$
	$S_{11} = \left(\frac{b_1}{a_1} \right)_{a_2=0}$	$S_{12} = \left(\frac{b_1}{a_2} \right)_{a_1=0}$
	$S_{21} = \left(\frac{b_2}{a_1} \right)_{a_2=0}$	$S_{22} = \left(\frac{b_2}{a_2} \right)_{a_1=0}$

FIGURE 11.1.10 Network matrix terms.

In distributed structures (Fig. 11.1.12b), actual transmission lines are used for the input to the amplifier, while the output is taken at one end of the upper transmission line. The propagation time along the input line must be the same as that along the output line, or distortion will result. This type of amplifier, noted for its wide frequency response, is discussed later.

OSCILLATORS: PRINCIPLES OF OPERATION

Introduction

An oscillator can be considered as a circuit that converts a dc input to a time-varying output. This discussion deals with oscillators whose output is sinusoidal, as opposed to the relaxation oscillator whose output exhibits abrupt transitions (see Section 14). Oscillators often have a circuit element that can be varied to produce different frequencies.

An oscillator's frequency is sensitive to the stability of the frequency-determining elements as well as the variation in the active-device parameters (e.g., effects of temperature, bias point, and aging). In many instances

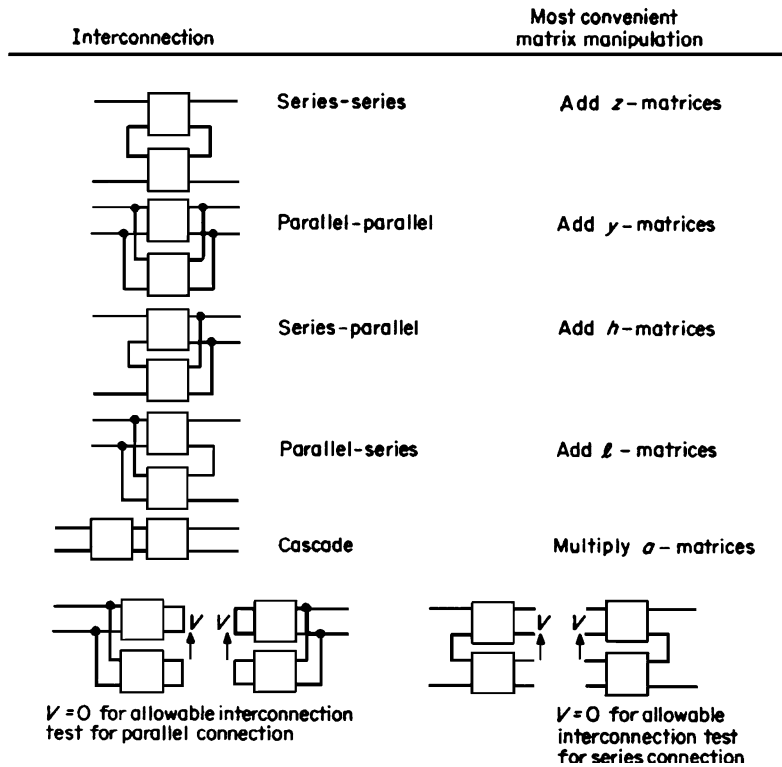

FIGURE 11.1.11 Matrix equivalents of network interconnections.

the oscillator is followed by a second stage serving as a buffer, so that there is isolation between the oscillator and its load. The amplitude of the oscillation can be controlled by automatic gain control (AGC) circuits, but the nonlinearity of the active element usually determines the amplitude. Variations in bias, temperature, and component aging have a direct effect on amplitude stability.

Requirements for Oscillation

Oscillators can be considered from two viewpoints: as using positive feedback around an amplifier or as a one-port network in which the real component of the input immittance is negative. An oscillator must have frequency-determining elements (generally passive components), an amplitude-limiting mechanism, and sufficient closed-loop gain to make up for the losses in the circuit. It is possible to predict the operating frequency and conditions needed to produce oscillation from a Nyquist or Bode analysis. The prediction of output amplitude requires the use of nonlinear analysis.

Oscillator Circuits

Typical oscillator circuits applicable up to ultra high frequencies (UHF) are shown in Fig. 11.1.13. These are discussed in detail in the following subsections. Also of interest are crystal oscillators. In this case the crystal is used as the passive frequency-determining element. The frequency range of crystal oscillators extends from a few hundred hertz to over 200 MHz by use of overtone crystals. The analysis of crystal oscillators is best done using the equivalent circuit of the crystal.

FIGURE 11.1.12 Multi-amplifier structures: (a) cascade; (b) distributed.

FIGURE 11.1.13 Types of oscillators: (a) tuned-output; (b) Hartley; (c) phase-shift; (d) tuned-input; (e) Colpitts; (f) Wien bridge.

FIGURE 11.1.14 Phase-locked-loop oscillator.

FIGURE 11.1.15 Injection-locked oscillator.

Synchronization

Synchronization of oscillators is accomplished by using phase-locked loops or by direct low-level injection of a reference frequency into the main oscillator. The diagram of a phase-locked loop is shown in Fig. 11.1.14 and that of an injection-locked oscillator in Fig. 11.1.15.

Harmonic Content

The harmonic content of the oscillator output is related to the amount of oscillator output power at frequencies other than the fundamental. From the viewpoint of a negative-conductance (resistance) oscillator, better results are obtained if the curve of the negative conductance (or resistance) versus amplitude of oscillation is smooth and without an inflection point over the operating range. Harmonic content is also reduced if the oscillator's operating point Q is chosen so that the range of negative conductance is symmetrical about Q on the negative conductance-versus-amplitude curve. This can be done by adjusting the oscillator's bias point within the requirement of $|G_C| = |G_D|$ for sustained oscillation (see Fig. 11.1.16).

Stability

The stability of the oscillator's output amplitude and frequency from a negative-conductance viewpoint depends on the variation of its negative conductance with operating point and the amount of fixed positive conductance in the oscillator's associated circuit. In particular, if the change of bias results in vertical translation of the conductance-(resistance)-versus-amplitude curve, the oscillator's stability is related to the change of slope at the point where the circuit's fixed conductance intersects this curve (point Q in Fig. 11.1.16). If the $|G_D|$ curve is of the shape of $|G_D|_2$, the oscillation can stop when a large enough change in bias point occurs for $|G_D|$ to be less than $|G_C|$ for all amplitudes of oscillation. Stabilization of the amplitude of oscillation may occur in the form of modifying G_C , G_D , or both to compensate for bias changes.

Particular types of oscillators and their parameters are discussed later in this section.

FIGURE 11.1.16 Device conductance vs. amplitude of oscillation.

CHAPTER 11.2

AUDIO-FREQUENCY AMPLIFIERS AND OSCILLATORS

Samuel M. Korzekwa, Robert J. McFadyen

AUDIO-FREQUENCY AMPLIFIERS

Samuel M. Korzekwa

Preamplifiers

General Considerations. The function of a preamplifier is to amplify a low-level signal to a higher level before further processing or transmission to another location. The required amplification is achieved by increased signal voltage and/or impedance reduction. The amount of power amplification required varies with the particular application. A general guideline is to provide sufficient preamplification to ensure that further signal handling adds minimal (or acceptable) signal-to-noise degradation.

Signal-to-Noise Considerations. The design of a preamplifier must consider all potential signal degradation from sources of noise, whether generated externally or within the preamplifier itself.

Examples of externally generated noise are hum and pickup, which may be introduced by the input-signal lines or the power-supply lines. Shielding of the input-signal lines often proves to be an acceptable solution. The preamplifier should be located close to the transmitting source, and the preamplifier power gain must be sufficient to override interference that remains after these steps are taken.

A second major source of noise is that internally generated in the amplifier itself. The noise figure specified in decibels for a preamplifier, which serves as a figure of merit, is defined as the ratio of the available input-to-output signal-to-noise power ratios:

$$F = \frac{S_i/N_i}{S_o/N_o}$$

where F = noise figure of preamplifier

S_i = available signal input power

N_i = available noise input power

S_o = available signal output power

N_o = available noise output power

Design precautions to realize the lowest possible noise figure include the proper selection of the active device, optimum input and output impedance, correct voltage and current biasing conditions, and pertinent design parameters of devices.

Low-Level Amplifiers

The low-level designation applies to amplifiers operated below maximum permissible power-dissipation, current, and voltage limits. Thus many low-level amplifiers are purposely designed to realize specific attributes other than delivering the maximum attainable power to the load, such as gain stability, bandwidth, optimum noise figure, and low cost.

In an amplifier designed to be operated with a 24-V power supply and a specified load termination, for example, the operating conditions may be such that the active devices are just within their allowable limits. If operated at these maximum limits, this is not a low-level amplifier; however, if this amplifier also fulfills its performance requirements at a reduced power-supply voltage of 6 V, with resulting much lower internal dissipation levels, it becomes a low-level amplifier.

Medium-Level and Power Amplifiers

The medium-power designation for an amplifier implies that some active devices are operated near their maximum dissipation limits, and precautions must be taken to protect these devices. If power-handling capability is taken as the criterion, the 5- to 100-W power range is a current demarcation line. As higher-power-handling devices come into use, this range will tend to shift to higher power levels.

The amount of power that can safely be handled by an amplifier is usually dictated by the dissipation limits of the active devices in the output stages, the efficiency of the circuit, and the means used to extract heat to maintain devices within their maximum permissible temperature limits. The classes of operation (A, B, AB, C) are discussed relative to Fig. 11.1.5. When single active devices do not suffice, multiple series or parallel configurations can be used to achieve higher voltage or power operation.

Multistage Amplifiers

An amplifier may take the form of a single stage or a complex single stage, or it may employ an interconnection of several steps. Various biasing, coupling, feedback, and other design alternatives influence the topology of the amplifier. For a multistage amplifier, the individual stages may be essentially identical or radically different. Feedback techniques may be used at the individual stage level, at the amplifier functional level, or both, to realize bias stabilization, gain stabilization, output-impedance reduction, and so forth.

Typical Electron-Tube Amplifier

Figure 11.2.1 shows a typical electron-tube amplifier stage. For clarity the signal-source and load sections are shown partitioned. For a multistage amplifier the source represents the equivalent signal generator of the preceding stage. Similarly, the load indicated includes the loading effect of the subsequent stage, if any.

The voltage gain from the grid of the tube to the output can be calculated to be

$$A_{v1} = -\frac{\mu R_l}{r_p + R_l}$$

Similarly, the voltage gain from the source to the tube grid is

$$A_{v2} = \frac{R_1}{(R_1 + R_g) + 1/j\omega C}$$

Combining the above equations gives the composite amplifier voltage gain

$$A_v = \frac{\mu R_1 R_l}{(r_p + R_l)[(R_1 + R_g) + 1/j\omega C]}$$

FIGURE 11.2.1 Typical triode electron-tube amplifier stage (biasing not shown).

This example illustrates the fundamentals of an electron-tube amplifier stage. Many excellent references treat this subject in detail.

Typical Transistor Amplifier

The analysis techniques used for electron-tube amplifier stages generally apply to transistorized amplifier stages. The principal difference is that different active-device models are used.

The typical transistor stage shown in Fig. 11.2.2 illustrates a possible form of biasing and coupling. The source section is partitioned and includes the preceding-stage equivalent generator, and the load includes subsequent stage-loading effects. Figure 11.2.3 shows the generalized h -equivalent circuit representation for transistors. Table 11.2.1 lists the h -parameter transformations for the common-base, common-emitter, and common-collector configurations.

FIGURE 11.2.2 Typical bipolar transistor-amplifier stage.

FIGURE 11.2.3 Equivalent circuit of transistor, based on h parameters.

TABLE 11.2.1 *h* Parameters of the Three Transistor Circuit Configurations

	Common-base	Common-emitter	Common-collector
h_{11}	h_{ib}	$h_{ib}(h_{fe} + 1)$	$h_{ib}(h_{fe} + 1)$
h_{12}	h_{rb}	$h_{ib}h_{ob}(h_{fe} + 1) - h_{rb}$	1
h_{21}	h_{fb}	h_{fe}	$-(h_{fe} + 1)$
h_{22}	h_{ob}	$h_{ob}(h_{fe} + 1)$	$h_{ob}(h_{fe} + 1)$

FIGURE 11.2.4 Simplified equivalent circuit of transistor amplifier stage.

While these parameters are complex and frequency-dependent, it is often feasible to use simplifications. Most transistors have their parameters specified by their manufacturers, but it may be necessary to determine additional parameters by test.

Figure 11.2.4 illustrates a simplified model of the transistor amplifier stage of Fig. 11.2.2. The common-emitter *h* parameters are used to represent the equivalent transistor. The voltage gain for this stage is

$$A_v = \frac{V_o}{V_i} = -\frac{h_{fe} R_L}{R_g + h_{ie}}$$

The complexity of analysis depends on the accuracy needed. Currently, most of the more complex analysis is performed with the aid of computers. Several transistor-amplifier-analysis references treat this subject in detail.

Typical Multistage Transistor Amplifier

Figure 11.2.5 is an example of a capacitively coupled three-stage transistor amplifier. It has a broad frequency response, illustrating the fact that an audio amplifier can be useful in other applications. The component values are

$$R_1 = 16,000 \ \Omega \quad R_2 = 6200 \ \Omega \quad R_3 = 1600 \ \Omega \quad R_4 = 1000 \ \Omega$$

$$R_L = 560 \ \Omega \quad Q_1, Q_2, Q_3 = 2N1565 \quad C_1 = 10 \ \mu F \quad C_2 = 100 \ \mu F$$

FIGURE 11.2.5 Typical three-stage transistor amplifier.

11.22 AMPLIFIERS AND OSCILLATORS

This amplifier is designed to operate over a range of -55 to $+125^{\circ}\text{C}$, with an output voltage swing of 2 V peak to peak and frequency response down 3 dB at approximately 200 Hz and 2 MHz. The overall gain at 1000 Hz is nominally 88 dB at 25°C .

Biasing Methods

The biasing scheme used in an amplifier determines the ultimate performance that can be realized. Conversely, an amplifier with poorly implemented biasing may suffer in performance, and be susceptible to catastrophic circuit failure owing to high stresses within the active devices. In view of the variation of parameters within the active devices, it is important that the amplifier function properly even when the initial and/or end-of-life parameters of the devices vary.

Electron-Tube Biasing

Biasing is intended to maintain the quiescent currents and voltages of the electron tube at the prescribed levels. The tube-plate characteristics represent the biasing relations between the tube parameters.

The principal bias parameters (steady-state plate and grid voltages) can be readily identified by the construction of a load line on the plate characteristic. The operating point Q is located at the intersection of the selected plate characteristic with the load line.

Transistor Biasing

Although the methods of biasing a transistor-amplifier stage are in many respects similar to those of an electron-tube amplifier, there are many different types of transistors, each characterized by different curves. Bipolar transistors are generally characterized by their collector and emitter families, while field-effect transistors have different characterizations. The *npn* transistor requires a positive base bias voltage and current (with respect to its emitter) for proper operation; the converse is true for a *pnp* transistor.

Figure 11.2.6 illustrates a common biasing technique. A single power supply is used, and the transistor is self-biased with the unbypassed emitter resistor R_e . Although a graphical solution of the value of R_e could be found by referring to the collector-emitter curves, an iterative solution, described below, is also commonly used.

Because the performance of the transistors depends on the collector current and collector-to-emitter voltage, they are often selected as starting conditions for biasing design. The unbypassed emitter resistor R_e and collector resistor R_c , the primary voltage-gain-determining components, are determined next, taking into account other considerations such as the anticipated maximum signal level and available power supply V_{cc} . The last step is to determine the R_1 and R_2 values.

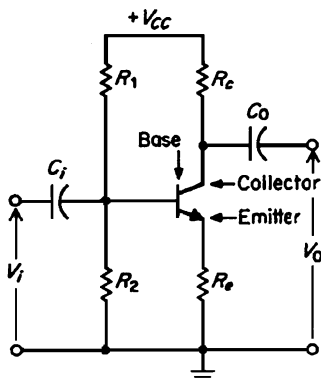

FIGURE 11.2.6 Capacitively coupled *npn* transistor-amplifier stage.

Coupling Methods

Transformer coupling and capacitance coupling are commonly used in transistor and electron-tube audio amplifiers. Direct coupling is also used in transistor stages and particularly in integrated transistor amplifiers. Capacitance coupling, referred to as *RC* coupling, is the most common method of coupling stages of an audio amplifier. The discrete-component transistorized amplifier stage shown in Fig. 11.2.6 serves as an example of *RC* coupling, where C_i and C_o are the input and output coupling capacitors, respectively.

FIGURE 11.2.7 Transformer-coupled *pnp* transistor-amplifier stage.

FIGURE 11.2.8 Classes of amplifier operation, based on transistor characteristics.

Transformer coupling is commonly used to match the input and output impedances of electron-tube amplifier stages. Since the input impedance of an electron tube is very high at audio frequencies, the design of an electron-tube stage depends primarily on the transformer parameters. The much lower input impedances of transistors demand that many other factors be taken into account, and the design becomes more complex. The output-stage transformer coupling to a specific load is often the optimum method of realizing the best power match. Figure 11.2.7 illustrates a typical transformer-coupled transistor audio-amplifier stage.

The direct-coupling approach is now also used for discrete-component transistorized amplifiers, and particularly in integrated amplifier versions. The level-shifting requirement is realized by selection from the host of available components, such as *npn* and *pnp* transistors and zener diodes. Since it is difficult to realize large-value capacitors via integrated-circuit techniques, special methods have been developed to direct-couple integrated amplifiers.

Classes A, B, AB, and C Operation

The output or power stage of an amplifier is usually classified as operating class A, B, AB, or C, depending on the conduction characteristics of the active devices (see Fig. 11.1.5). These definitions can also apply to any intermediate amplifier stage. Figure 11.2.8 illustrates relations between the class of operation and conduction using transistor parameters. This figure would be essentially the same for an electron-tube amplifier with the tube plate current and grid voltage as the equivalent device parameters.

Subscripts may be used to denote additional conduction characteristics of the device. For example, the electron-tube grid conduction can also be further classified as A_1 , to show that no grid current flows, or A_2 , to show that grid-current conduction exists during some portion of the cycle.

Push-Pull Amplifiers

In a single-ended amplifier the active devices conduct continuously. The single-ended configuration is generally used in low-power applications, operated in class A. For example, preamplifiers and low-level amplifiers are generally operated single-ended, unless the output power levels necessitate the more efficient power handling of the push-pull circuit.

In a push-pull configuration there are at least two active devices that alternately amplify the negative and positive cycles of the input waveform. The output connection to the load is most often transformer-coupled. An example of a transformer input and output in a push-pull amplifier is illustrated in Fig. 11.2.9. Direct-coupled push-pull amplifiers and capacitively coupled push-pull amplifiers are also feasible, as illustrated in Fig. 11.2.10.

FIGURE 11.2.9 Transformer-coupled push-pull transistor stage.

The active devices in push-pull are usually operated either in class B or AB because of the high power-conversion efficiency. Feedback techniques can be used to stabilize gain, stabilize biasing or operating points, minimize distortion, and the like.

Output Amplifiers

The function of an audio output amplifier is to interface with the preceding amplifier stages and to provide the necessary drive to the load. Thus the output-amplifier designation does not uniquely identify a particular amplifier class. When several different types of amplifiers are cascaded between the signal source and its load, e.g., a high-power speaker, the last-stage amplifier is designated as the output amplifier. Because of the high power requirements, this amplifier is usually a push-pull type operating either in class B or AB.

Stereo Amplifiers

A stereo amplifier provides two separate audio channels properly phased with respect to each other. The objective of this two-channel technique is to enhance the audio reproduction process, making it more realistic

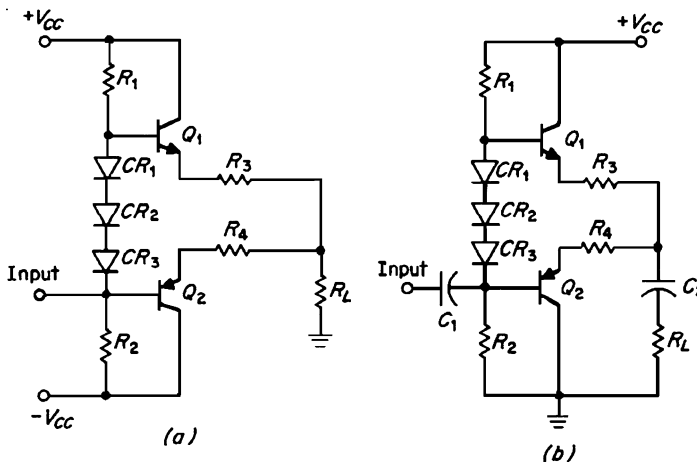

FIGURE 11.2.10 (a) Direct- and (b) capacitively coupled push-pull stages.

and lifelike. It is also feasible to extend the system to contain more than two channels of information. A stereo amplifier is a complete system that contains its power supply and other commonly required control functions.

Each channel has its own preamplifier, medium-level stages, and output power stage, with different gain and frequency responses for each mode of operation, e.g., for tape, phonograph, CD, and so forth. The input signal is selected from the phonograph input connection, tape input, or a turner output. Special-purpose trims and controls are also used to optimize performance on each mode. The bandwidth of the amplifier extends to 20 kHz or higher.

AUDIO OSCILLATORS

Robert J. McFadyen

General Considerations

In the strict sense, an audio oscillator is limited to frequencies from about 15 to 20,000 Hz, but a much wider frequency range is included in most oscillators used in audio measurements since knowledge of amplifier characteristics in the region above audibility is often required.

For the production of sinusoidal waves, audio oscillators consist of an amplifier having a nonlinear power gain characteristic, with a path for regenerative feedback. Single- and multistage transistor amplifiers with LC or RC feedback networks are most often used. The term *harmonic oscillator* is used for these types. *Relaxation oscillators*, which may be designed to oscillate in the audio range, exhibit sharp transitions in the output voltages and currents. Relaxation oscillators are treated in Section 14.

The instantaneous excursions of the operating point in a harmonic oscillator is restricted to the range where the circuit exhibits an impedance with a negative real part. The amplifier supplies the power, which is dissipated in the feedback path and the load. The regenerative feedback would cause the amplitude of oscillation to grow without bound were it not for the fact that the dynamic range of the amplifier is limited by circuit nonlinearities. Thus, in most sine-wave audio oscillators; the operating frequency is determined by passive-feedback elements, whereas the amplitude is controlled by the active-circuit design.

Analytical expressions predicting the frequency and required starting conditions for oscillation can be derived using Bode's amplifier feedback theory, and the stability theorem of Nyquist. Since this analytical approach is based on a linear-circuit model, the results are approximate but usually suitable for design of sinusoidal oscillators. No prediction on waveform amplitude results, since this is determined by nonlinear-circuit characteristics. Estimates of the waveform amplitude can be made from the bias and limiting levels of the active circuits. Separate limiters and AGC techniques are also useful for controlling the amplitude to a prescribed level. Graphical and nonlinear analysis methods can also be used for obtaining a prediction of the amplitude of oscillation.

A general formulation suitable for a linear analysis of almost all audio oscillators can be derived from the feedback diagram in Fig. 11.2.11. Note that the amplifier internal feedback generator has been neglected: that is, y_{12A} is assumed to be zero. This assumption of unilateral amplification is almost always valid in the audio range even for single-stage transistor amplifiers.

The stability requirements for the circuit are derived from the closed-loop-gain expression

$$A_c = A/(1 - A\beta) \quad (1)$$

where the gain A is treated as a negative quantity for an inverting amplifier. Infinite closed-loop gain occurs when $A\beta$ is equal to unity, and this defines the oscillatory condition. In terms of the equivalent circuit parameters used in Fig. 11.2.1,

$$1 - A\beta = 1 - y_{21A} \frac{y_{12\beta}}{(y_{11A} + y_{11\beta})(y_{22A} + y_{22\beta}) - y_{12\beta}y_{21\beta}} \quad (2)$$

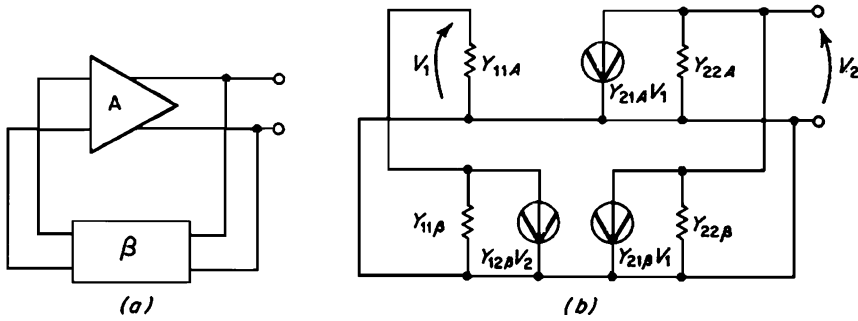

FIGURE 11.2.11 Oscillator representations: (a) generalized feedback circuit; (b) equivalent y-parameter circuit.

In the audio range, y_{21A} remains real, but the fractional portion of the function is complex because β is frequency-sensitive. Therefore, the open-loop gain $A\beta$ can be expressed in the general form

$$A\beta = y_{21A} \frac{A_r + jA_i}{B_r + jB_i} \tag{3}$$

It follows from Nyquist’s stability theorem that this feedback system will be unstable if, first, the phase shift of $A\beta$ is zero and, second, the magnitude is equal to or greater than unity. Applying this criterion to Eq. (3) yields the following two conditions for oscillation:

$$A_i B_r - A_r B_i = 0 \tag{4}$$

$$y_{21}^2 \geq \frac{B_r^2 + B_i^2}{A_r^2 + A_i^2} \tag{5}$$

Equation (4) results from the phase condition and determines the frequency of oscillation. The inequality in Eq. (5) is the consequence of the magnitude constraint and defines the necessary condition for sustained oscillation. Equation (5) is evaluated at the oscillation frequency determined from Eq. (4).

A large number of single-stage oscillators have been developed in both vacuum-tube and transistor versions. The transistor circuits followed by direct analogy from the earlier vacuum-tube circuits. In the following examples, transistor versions are illustrated, but the y-parameter equations apply to other devices as well.

LC Oscillators

The *Hartley oscillator* circuit is one of the oldest forms: the transistor version is shown in Fig. 11.2.12. With the collector and base at opposite ends of the tuned circuit, the 180° phase relation is secured, and feedback occurs through mutual inductance between the two parts of the coil. The frequency and condition for oscillation are expressed in terms of the transistor y parameters and feedback inductance L , inductor coupling coefficient k , inductance ratio n , and tuning capacitance C . The frequency of oscillation is

$$\omega^2 = \frac{1}{LC(1 + 2k\sqrt{n} + n) + nL^2(1 - k^2)(y_{11A}y_{22A})}$$

FIGURE 11.2.12 Hartley oscillator circuit.

FIGURE 11.2.13 Colpitts oscillator circuit.

The condition for oscillation is

$$y_{21A} \geq \frac{y_{11A} + ny_{22A} + n\omega^2 LC(1 - k^2)(y_{11A}y_{22A})}{k\sqrt{n} + n\omega^2 LC(1 - k^2)}$$

The admittance parameters of the bias network R_1 , R_2 , and R_3 , as well as the reactance of bypass capacitor C and coupling capacitor C_2 , have been neglected. These admittances could be included in the amplifier y parameters in cases where their effect is not negligible.

If

$$\frac{C}{L} \gg \frac{n(1 - k^2)(y_{11A}y_{22A})}{1 + 2k\sqrt{n} + n} \tag{6}$$

the frequency of oscillation will be essentially independent of transistor parameters.

The transistor version of the *Colpitts oscillator* is shown in Fig. 11.2.13. Capacitors C and nC in combination with inductance L determine the resonant frequency of the circuit. A fraction of the current flowing in the tank circuit is regeneratively fed back to the base through the coupling capacitor C_2 . Bias resistors R_1 , R_2 , R_3 , and R_L , as well as capacitors C_1 and C_2 , are chosen so as not to affect the frequency or conditions for oscillation. The frequency of oscillation is

$$\omega^2 = \frac{1}{LC} \left(1 + \frac{1}{n} \right) + \frac{1}{nC^2} (y_{11A}y_{22A})$$

The condition for oscillation is

$$y_{21A} \geq \omega^2 LC(nY_{11A} + Y_{22A}) - (y_{11A} + y_{22A})$$

Alternatively, the bias element admittances may be included in the amplifier y parameters.

In the Colpitts circuit, if the ratio of C/L is chosen so that

$$\frac{C}{L} \gg \frac{y_{11A}y_{22A}}{1 + n} \tag{7}$$

the frequency of oscillation is essentially determined by the tuned-circuit parameters.

FIGURE 11.2.14 Tuned-collector oscillator.

FIGURE 11.2.15 RC oscillator with high-pass feedback network.

Another oscillator configuration useful in the audio-frequency range is the tuned-collector circuit shown in Fig. 11.2.14. Here regenerative feedback is furnished via the transformer turns ratio N from the collector to base. The frequency of oscillation is

$$\omega^2 = \frac{1}{LC + N^2 L^2 y_{11A} y_{22A} (1 - k^2)}$$

The condition for oscillation is

$$y_{22A} \geq \frac{1}{Nk} (N^2 Y_{11A} + Y_{22A}) - \frac{\omega^2 NLC Y_{11A}}{k} (1 - k^2)$$

If the ratio of C/L is such that

$$\frac{C}{L} \gg N^2 y_{11A} y_{22A} (1 - k^2) \tag{8}$$

the frequency of oscillation is specified by $\omega^2 = 1/LC$. This circuit can be tuned over a wide range by varying the capacitor C and is compatible with simple biasing techniques.

RC Oscillators

Audio sinusoidal oscillators can be designed using an RC ladder network (of three or more sections) as a feedback path in an amplifier. This scheme originally appeared in vacuum-tube circuits, but the principles have been directly extended to transistor design. RC phase-shift oscillators can be distinguished from tuned oscillators in that the feedback network has a relatively broad frequency-response characteristic.

Typically, the phase-shift network has three RC sections of either a high- or a low-pass nature. Oscillation occurs at the frequency where the total phase shift is 180° when used with an inverting amplifier. Figures 11.2.15 and 11.2.16 show examples of high-pass and low-pass feedback-connection schemes. The amplifier is a differential pair with a transistor current source, a configuration which is common in integrated-circuit amplifiers. The output is obtained at the opposite collector from the feedback connection, since this minimizes external loading on the phase-shift network. The conditions for, and the frequency of, oscillation are derived, assuming that the input resistance of the amplifier, which loads the phase-shift network, has been adjusted to equal the

resistance R . The load resistor R_L is considered to be part of the amplifier output resistance, and it is included in y_{22A} . The frequency of oscillation for the high-pass case is

$$\omega^2 = \frac{y_{22A}}{2C^2R(2 + 3Ry_{22A})}$$

The condition for oscillation for the high-pass case is

$$y_{21A} \geq \frac{1}{R} \left(\frac{1 + 5R/R_L}{\omega^2 R^2 C^2} - \frac{R}{R_L} - 3 \right)$$

The frequency of oscillation for the low-pass case is

$$\omega = \frac{1}{RC} \sqrt{6 + 4 \frac{R}{R_L}}$$

The condition for oscillation for the low-pass case is

$$y_{21A} \geq \frac{1}{R} \left(23 \frac{R}{R_L} + 29 + 4 \frac{R^2}{R_L^2} \right)$$

Null-Network Oscillators

In almost all respects null-network oscillators are superior to the RC phase-shift circuits described in the previous paragraph. While many null-network configurations are useful (including the bridged-T and twin-T), the Wien bridge design predominates.

The general form for the Wien bridge oscillator is shown in Fig. 11.2.17. In the figure, an ideal differential voltage amplifier is assumed, i.e., one with infinite input impedance and zero output impedance.

FIGURE 11.2.16 RC oscillator with low-pass feedback network.

Frequency of oscillation ($M = N = 1$):

$$\omega_0 = \frac{1}{RC}$$

Condition for oscillation:

$$A \geq 8 = \frac{3(R_1 + R_2)}{R_1 - 2R_2}$$

FIGURE 11.2.17 Wien bridge oscillator circuit.

An integrated-circuit operational amplifier that has a differential input stage is a practical approximation to this type of amplifier and is often used in bridge-oscillator designs.

The Wien bridge is used as the feedback network, with positive feedback provided through the RC branches for regeneration and negative feedback through the resistor divider. Usually the resistor-divider network includes an amplitude-sensitive device in one or both arms which provides automatic correction for variation of the amplifier gain. Circuit elements such as a tungsten lamp, thermistor, and field-effect transistor used as the voltage-sensitive resistance element maintain a constant output level with a high degree of stability. Amplitude variations of less than ± 1 percent over the band from 10 to 100,000 Hz are realizable. In addition, since the amplifier is never driven into the nonlinear region, harmonic distortion in the output waveform is minimized. For the connection shown in Fig. 11.2.17, an increase in V will cause a decrease in R_2 , restoring V to the original level.

The lamp or thermistor have thermal time constants that set at a lower frequency limit on this method of amplitude control. When the period is comparable with the thermal time constant, the change in resistance over an individual cycle distorts the output waveform. There is an additional degree of freedom with the field-effect transistor, since the control voltage must be derived by a separate detector from the amplifier output. The time constant of the detector, and hence the resistor, are set by a capacitor, which can be chosen commensurate with the lowest oscillation frequency desired.

At ω_0 the positive feedback predominates, but at harmonics of ω_0 the net negative feedback reduces the distortion components. Typically, the output waveform exhibits less than 1 percent total harmonic distortion. Distortion components well below 0.1 percent in the mid-audio-frequency range are also achieved.

Unlike LC oscillators, in which the frequency is inversely proportional to the square root of L and C , in the Wien bridge ω_0 varies as $1/RC$. Thus, a tuning range in excess of 10:1 is easily achieved. Continuous tuning within one decade is usually accomplished by varying both capacitors in the reactive feedback branch. Decade changes are normally accomplished by switching both resistors in the resistive arm. Component tracking problems are eased when the resistors and capacitors are chosen to be equal.

Almost any three-terminal null network can be used for the reactive branch in the bridge; the resistor divider network adjusts the degree of imbalance in the manner described. Many of these networks lack the simplicity of the Wien bridge since they may require the tracking of three components for frequency tuning. For this reason networks such as the bridged-T and twin-T are usually restricted to fixed-tuned applications.

Low-Frequency Crystal Oscillators

Quartz-crystal resonators are used where frequency stability is a primary concern. The frequency variations with both time and temperature are several orders of magnitude lower than obtainable in LC or RC oscillator circuits. The very high stiffness and elasticity of piezoelectric quartz make it possible to produce resonators extending from approximately 1 kHz to 200 MHz. The performance characteristics of crystal depend on both the particular cut and the mode of vibration (see Section 5). For convenience, each "cut-mode" combination is considered as a separate piezoelectric element, and the more commonly used elements have been designated with letter symbols. The audio-frequency range (above 1 kHz) is covered by elements J, H, N, and XY, as shown in Table 11.2.2.

The temperature coefficients vary with frequency, i.e., with the crystal dimensions, and except for the H element, a parabolic frequency variation with temperature is observed. The H element is characterized by a

TABLE 11.2.2 Low-Frequency Crystal Elements

Symbol	Cut	Mode of vibration	Frequency range, kHz
J	Duplex 5°X	Length-thickness flexure	0.9–10
H	5°X	Length-width flexure	10–50
N	NT	Length-width flexure	4–200
XY	XY	XY flexure	8–40

negative temperature coefficient on the order of $-10 \text{ ppm}/^\circ\text{C}$. The other elements have lower temperature coefficients, which at some temperatures are zero because of the parabolic nature of the frequency-deviation curve. The point where the zero temperature coefficient occurs is adjustable and varies with frequency. At temperatures below this point the coefficient is positive, and at higher temperatures it is negative. On the slope of the curves the temperature coefficients for the N and XY elements are on the order of $2 \text{ ppm}/^\circ\text{C}$, whereas the J element is about double at $4 \text{ ppm}/^\circ\text{C}$.

Although the various elements differ in both cut and mode of vibration, the electric equivalent circuit remains invariant. The schematic representation and the lumped constant equivalent circuit are shown in

FIGURE 11.2.18 Symbol and equivalent circuit of a quartz crystal.

Fig. 11.2.18. As is characteristic of most mechanical resonators, the motional inductance L resulting from the mechanical mass in motion is large relative to that obtainable from coils. The extreme stiffness of quartz makes for very small values of the motional capacitance C , and the very high order of elasticity allows the motional resistance R to be relatively low. The shunt capacitance C_0 is the electrostatic capacitance existing between crystal electrodes with the quartz plate as the dielectric and is present whether or not the crystal is in mechanical motion. Some typical values for these equivalent-circuit parameters are shown in Table 11.2.3.

The H element can have a high Q value when mounted in a vacuum enclosure; however, it then has the poorest temperature coefficient. The N element exhibits an excellent temperature characteristic, but the piezoelectric activity is rather low, so that special care is required when it is used in oscillator circuits. The J and XY elements operate well in low-frequency oscillator designs, the latter having lower temperature drift. For the same frequency the XY crystal is about 40 percent longer than the J element. Where extreme frequency stability is required, the crystals are usually controlled to a constant temperature.

The reactance curve of a quartz resonator is shown in Fig. 11.2.19. The zero occurs at the frequency f_s , which corresponds to series resonance of the mechanical L and C equivalences. The antiresonant frequency f_p is dependent on the interelectrode capacitance C_0 . Between f_s and f_p the crystal is inductive and this frequency range is normally referred to as the *crystal bandwidth*

$$BW = f_s / (2C_0/C) \tag{9}$$

In oscillator circuits the crystal can be used as either a series or a parallel resonator. At series resonance the crystal impedance is purely resistive, but in the parallel mode the crystal is operated between f_s and f_p and is therefore inductive. For oscillator applications the circuit capacitance shunting the crystal must also be included when specifying the crystal, since it is part of the resonant circuit. If a capacitor C_L , that is, a negative reactance, is placed in series with a crystal, the combination will series-resonate at the frequency f_R of zero reactance for the combination.

$$f_R = f_s \left[1 + \frac{1}{(2C_0/C)(1 + C_L/C_0)} \right] \tag{10}$$

TABLE 11.2.3 Typical Crystal Parameter Values

Element	Frequency, kHz	L , H	C , pF	R , $k\Omega$	C_0 , pF	Q , approx
J	10	8,000	0.03	50	6	20,000
H	10	2,500	0.1	10	75	20,000
N	10	8,000	0.03	75	30	10,000
XY	10	12,000	0.02	30	20	30,000

$$f_s \approx \frac{1}{2\pi(LC)^{1/2}}$$

$$f_p \approx \frac{1}{2\pi\left(\frac{LC}{1+C/C_0}\right)}$$

FIGURE 11.2.19 Quartz-crystal reactance curve.

Condition for oscillation:

$$\left(\frac{R_1}{R_1 + R_4 + R}\right) \left(1 + \frac{R_3}{R_2}\right) \geq 1$$

FIGURE 11.2.20 Crystal oscillator using an integrated-circuit operational amplifier.

The operating frequency can vary in value due to changes in the load capacitance, and this variation is prescribed by

$$\Delta f_R = \frac{f_s}{2C_0/C} \frac{\Delta C_L/C_0}{(1 + C_L/C_0)^2} \tag{11}$$

This effect can be used to “pull” the crystal for initial alignment, or if the external capacitor is a voltage-controllable device, a VCO with a range of about ±0.01 percent can be constructed. Phase changes in the amplifier will also give rise to frequency shifts since the total phase around the loop must remain at 0° to maintain oscillation.

Although single-stage transistor designs are possible, more flexibility is available in the circuit of Fig. 11.2.20, which uses an integrated-circuit operational amplifier for the gain element. The crystal is operated in the series mode, and the amplifier gain is precisely controlled by the negative-feedback divider R₂ and R₃. The output will be sinusoidal if

$$\frac{V_D R_1}{R_1 + R} \left(1 + \frac{R_3}{R_2}\right) < V_{lim} \tag{12}$$

where V_D is the limiting diode forward voltage drop and V_{lim} is the limiting level of amplifier output.

Low-cost electronic wristwatches use quartz crystals for establishing a high degree of timekeeping accuracy. A high-quality mechanical watch may have a yearly accuracy on the order of 20 min, whereas many quartz watches are guaranteed to vary less than 1 min/year.

Generally the XY crystal is used, but other types are continually being developed to improve accuracy, reduce size, and lower manufacturing cost. The active gain elements for the oscillator are part of the integrated circuit that contains the electronics for the watch functions. The flexure or tuning-fork frequency is set generally to 32,768 Hz, which is 2¹⁵ Hz. This frequency reference is divided down on the integrated circuit to provide seconds, minutes, hours, day of the week, date, month, and so forth.

A logic gate or inverter is often used as the gain element in the oscillator circuit. A typical configuration is shown in Fig. 11.2.21. The resistor R₁ is used to bias the logic inverter for class A amplifier operation. The resistor R₂ helps reduce both voltage sensitivity of the network and crystal power dissipation. The combination of R₂ and C₂ provides added phase shift for good oscillator startup. The series combination of capacitors

C_1 and C_2 provides the parallel load for the crystal. C_1 can be made tunable for precise setting of the crystal oscillation frequency. The inverter provides the necessary gain and 180° phase shift. The π network consisting of the capacitors and the crystal provides the additional 180° phase shift needed to satisfy the conditions for oscillation.

Frequency Stability

Many factors contribute to the ability of an oscillator to hold a constant output frequency over a period of time and range from short-term effects, caused by random noise, to longer-term variations, caused by circuit parameter dependence on temperature, bias voltage, and the like. In addition to the temperature and aging effects of the frequency-determining elements, nonlinearities, impedance loading, and amplifier phase variations also contribute to instability.

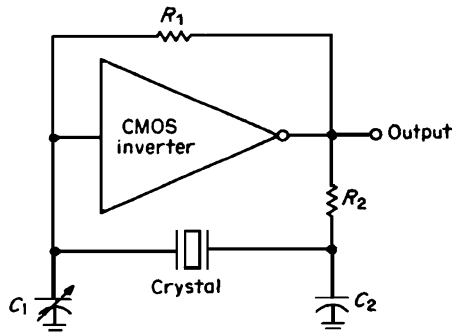

FIGURE 11.2.21 Crystal oscillator using a logic gate for the gain element.

Harmonics generated by circuit nonlinearities are passed through the feedback network, with various phase shifts, to the input of the amplifier. Intermodulation of the harmonic frequencies produces a fundamental frequency component that differs in phase from the amplifier output. Since the condition $A\beta = 1$ must be satisfied, the frequency of oscillation will shift so that the network phase shift cancels the phase perturbation caused by the nonlinearity. Therefore, the frequency of oscillation is influenced by an unpredictable amplifier characteristic, namely, the saturation nonlinearity. This effect is negligible in the Wien bridge oscillator, where automatic level control keeps harmonic distortion to a minimum.

The relationships shown in Fig. 11.2.17 were derived assuming that the amplifier does not load the bridge circuit on either the input or output sides. In the practical sense this is never true, and changes in the input and output impedances will load the bridge and cause frequency variations to occur.

Another source of frequency instability is small phase changes in the amplifier. The effect is minimized by using a network with a large stability factor, defined by

$$S = \left. \frac{d\phi}{d\omega/\omega_0} \right|_{\omega=\omega_0} \quad (13)$$

For the Wien bridge oscillator, which has amplitude-sensitive resistive feedback, the RC impedances can be optimized to provide a maximum stability factor value. As shown in Fig. 11.2.17, this amounts to choosing proper values for M and N . The maximum stability-factor value is $A/4$, and it occurs for $N = 1/2$ and $M = 2$. Most often the bridge is used with equal resistor and capacitor values; that is, $M = N = 1$, in which case the stability factor is $2A/9$. This represents only a slight degradation from the optimum.

Synchronization

It is often desirable to lock the oscillator frequency to an input reference. Usually this is done by injecting sufficient energy at the reference frequency into the oscillator circuit. When the oscillator is tuned sufficiently close to the reference, natural oscillations cease and the synchronization signal is amplified to the output. Thus the circuit appears to oscillate at the injected signal frequency. The injected reference is amplitude-stabilized by the AGC or limiting circuit in the same manner as the natural oscillation. The frequency range over which locking can occur is a linear function of the amplitude of the injected signal. Thus, as the synchronization frequency is moved away from the natural oscillator frequency, the amplitude threshold to maintain lock increases. The phase

error between the input reference and the oscillator output will also deviate as the input frequency varies from the natural frequency.

Methods for injecting the lock signal vary and depend on the type of oscillator under consideration. For example, LC oscillators may have signals coupled directly to the tank circuit, whereas the lock signal for the Wien network is usually coupled into the center of the resistive side of the bridge, i.e., the junction of R_1 and R_2 in Fig. 11.2.17.

If the natural frequency of oscillation can be voltage controlled, synchronization can be accomplished with a phase-locked loop. Replacing both R 's with field-effect transistors, or alternatively shunting both C 's with varicaps, provides an effective means for voltage controlling the frequency of the Wien bridge oscillator. Although more complicated in structure, the phase-locked loop is more versatile and has many diverse applications.

Piezoelectric Annunciators

Another important class of audio oscillators uses piezoelectric elements for both frequency control and audible-sound generation. Because of their low cost and high efficiency these devices are finding increasing use in smoke detectors, burglar alarms, and other warning devices. Annunciators using these elements typically produce a sound level in excess of 85 dB measured at a distance of 10 ft.

Usually the element consists of a thin brass disk to which a piezoelectric material has been attached. When an electric signal is applied across its surfaces, the piezoceramic disk attempts to change diameter. The brass disk to which it is bonded acts as a spring restraining force on one surface of the ceramic. The brass plate serves as one electrode for applying the electric signal to the ceramic. On the other surface a fired-on silver paste is used as an electrode. The restraining action of the brass disk causes the assembly to change from a flat to a convex shape. When the polarity of the electric signal reverses, the assembly flexes in the other direction to a concave shape. When the device is properly mounted in a suitable horn structure, this motion is used to produce high-level sound waves. One useful method is to clamp the disk at nodal points, i.e., at a distance from the center of the disk where mechanical motion is at a vibrational null.

The piezoelectric assembly will produce sound levels more efficiently when excited near the series-resonant frequency. The simple equivalent circuit used for the quartz crystal (Fig. 11.2.18) also applies to the piezoceramic assembly for frequencies near resonance. Generally the piezoelectric element is used as the frequency-determining element in an audio oscillator. The advantage of this method is that the excitation frequency is inherently near the optimum value, since it is self-excited. A typical piezoceramic 1-in diameter mounted on a $1\frac{3}{4}$ -in brass disk would have the following equivalent values: $C_0 = 0.02 \mu\text{F}$, $C = 0.0015 \mu\text{F}$, $L = 2 \text{ H}$, $R = 500 \Omega$, $Q = 75$, $f_s = 2.9 \text{ kHz}$, and $f_p = 3.0 \text{ kHz}$.

A basic oscillator, capable of producing high-level sound, is shown in Fig. 11.2.22. The inductor L_1 provides a dc path to the transistor and broadly tunes the parallel input capacitance of the piezoelectric element. C_1 is an optional capacitor which adds to the input shunt capacitance for optimizing the drive impedance to the element. Resistor R_1 provides base-current bias to the transistor so that oscillation can start.

The element has a third small electrode etched in the silver pattern. It is used to derive a feedback signal which, when resistively loaded by R_1 , provides an in-phase signal to the base for sustaining circuit oscillation. The circuit operates like a blocking oscillator in that the transistor is switched on and off and the collector voltage can fly above B-plus because of the inductor L_1 .

The collector load consisting of L_1 and C_1 can be replaced with a resistor, in which case the audio output will be less.

RADIO-FREQUENCY AMPLIFIERS

G. Burton Harrold

Small-Signal RF Amplifiers

The prime considerations in the design of first-stage rf amplifiers are gain and noise figure. As a rule, the gain of the first rf stage should be greater than 10 dB, so that subsequent stages contribute little to the overall amplifier noise figure. The trade-off between amplifier cost and noise figure is an important design consideration. For example, if the environment in which the rf amplifier operates is noisy, it is uneconomic to demand the ultimate in noise performance. Conversely, where a direct trade-off exists in transmitter power versus amplifier noise performance, as it does in many space applications, money spent to obtain the best possible noise figure is fully justified.

Another consideration in many systems is the input-output impedance match of the rf amplifier. For example, TV cable distribution systems require an amplifier whose input and output match produce little or no line reflections. The performance of many rf amplifiers is also specified in handling large signals, to minimize cross- and intermodulation products in the output. The wide acceptance of transistors has placed an additional constraint on first-stage rf amplifiers, since many rf transistors having low noise, high gain, and high frequency response are susceptible to burnout and must be protected to prevent destruction in the presence of high-level input signals.

Another common requirement is that first rf stages be gain-controlled by automatic gain control (AGC) voltage. The amount of gain control and the linearity of control are system parameters. Many rf amplifiers have the additional requirement that they be tuned over a range of frequencies. In most receivers, regardless of configuration, local-oscillator leakage back to the input is strictly controlled by government regulation. Finally, the rf amplifier must be stable under all conditions of operation.

Device Evaluation for RF Amplifiers

An important consideration in an rf amplifier is the choice of active device. This information on device parameters can often be found in published data sheets. If parameter data are not available or not a suitable operating point, the following characterization techniques can be used.

Network Analyzers. The development of the modern network analyzer has eliminated much of the work in device and circuit evaluation. These systems automate sweep frequency measurements of the complex device or

Parameter	Formula	Units	Rx meter measurement
h_{11b}	$j \frac{RX}{R+jX}$	ohms	h_{11b}
h_{22b}	$\frac{1}{R} + \frac{1}{jX}$	mhos	h_{22b}
$h_{21b}(-\alpha)$	$\frac{h_{11b}}{h_{11e}} - 1$	Magnitude angle	h_{11b}, h_{11e}
h_{12b}	$(Y_{22b} - h_{22b}) \frac{h_{11b}}{-h_{21b}}$	Magnitude angle	$h_{11b}, h_{11e}, Y_{22b}, h_{22b}$

Assumes: Determinate of $|h| \ll h_{21}$ and $h_{12} \ll 1$

R and X are Rx meter's reading of parallel resistance and reactance

FIGURE 11.3.1 Use of the Rx meter in device characterization.

circuit parameters and avoid the tedious calculations that were previously required. The range of measurement frequencies extends from a few hertz to 60 GHz.

Network analyzers perform the modeling function by measuring the transfer and impedance function of the device by means of sine-wave excitation. These transfer voltages/currents and the reflected voltages/currents are then separated, and the proper ratios are formed to define the device parameters. These results are then displayed graphically and/or in a digital form for designer use. Newer systems allow these data to be transferred directly to computerized design programs, thus automating the total design process. The principle of actual operation is similar to that described below under *Vector Voltmeter*.

Rx Meter.* This measurement technique is usually employed at frequencies below 200 MHz for active devices that have high input and output impedance. The technique is summarized in Fig. 11.3.1 with assumptions tacit in these measurements. The biasing techniques are shown. In particular, the measurement of h_{22b} requires a very large resistor R_e to be inserted in the emitter, and this may cause difficulty in achieving the proper biasing. Care should be taken to prevent burnout of the bridge when a large dc bias is applied. The bridge's drive to the active device may be reduced for more accurate measurement by varying the B-plus voltage applied to the internal oscillator.

Vector Voltmeter.* This characterization technique measures the S parameters; see Fig. 11.1.9. The measurement consists in inserting the device in a transmission line, usually 50 Ω characteristic impedance, and measuring the incident and reflected voltages at the two ports of the device.

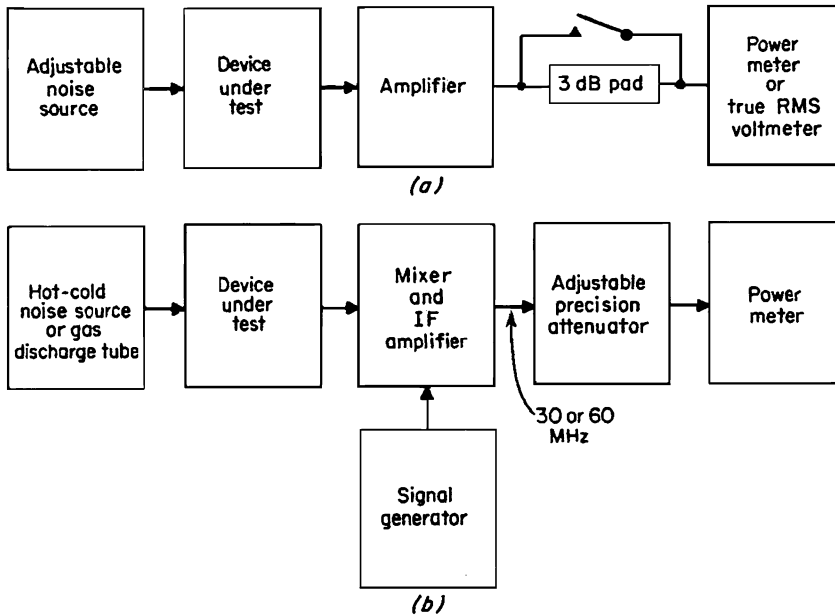

FIGURE 11.3.2 Noise-measurement techniques: (a) at low frequencies; (b) at high frequencies.

Several other techniques include the use of the H-P 8743 reflectometer, the general radio bridge GR 1607, the Rhode-Schwartz diagraph, and the H-P type 8510 microwave network analyzer to measure device parameters automatically from 45 MHz to 100 GHz with display and printout features.

Noise in RF Amplifiers

A common technique employing a noise source to measure the noise performance of an rf amplifier is shown in Fig. 11.3.2. Initially the external noise source (a temperature-limited diode) is turned off, the 3-dB pad short-circuited, and the reading on the output power meter recorded. The 3-dB pad is then inserted, the noise source is turned on, and its output increased until a reading equal to the previous one is obtained. The noise figure can then be read directly from the noise source, or calculated from 1 plus the added noise per unit bandwidth divided by the standard noise power available KT_0 , where $T_0 = 290$ K and $K =$ Boltzmann's constant $= 1.38 \times 10^{-23}$ J/K.

At higher frequencies, the use of a temperature-limited diode is not practical, and a gas-discharge tube or a hot-cold noise source is employed. The Y -factor technique of measurement is used. The output from the device to be measured is put into a mixer, and the noise output converted to a 30- or 60-MHz center-frequency (i.f.) output. A precision attenuator is then inserted between this i.f. output and the power-measuring device. The attenuator is adjusted to give the same power reading for two different conditions of noise power output represented by effective temperatures T_1 and T_2 . The Y factor is the difference in decibels between the two precision attenuator values needed to maintain the same power-meter reading. The noise factor is

$$F = \frac{(T_2/290) - T_1 Y / 290}{Y - 1} + 1$$

where T_1 = effective temperature at reference condition 1

T_2 = effective temperature of reference condition 2

Y = decibel reading defined in the text, converted to a numerical ratio

11.38 AMPLIFIERS AND OSCILLATORS

In applying this technique it is often necessary to correct for the second-stage noise. This is done by use of the cascade formula

$$F_1 = F_T - (F_2 - 1)/G_1$$

where F_1 = noise factor of first stage

F_T = overall noise factor measured

F_2 = noise factor of second-stage mixer and i.f. amplifier

G_1 = available gain of first stage

Large-Signal Performance of RF Amplifiers

The large-signal performance of an rf amplifier can be specified in many ways. A common technique is to specify the input where the departure from a straight-line input-output characteristic is 1 dB. This point is commonly called the *1-dB compression point*. The greater the input before this compression point is reached, the better the large-signal performance.

Another method of rating an rf amplifier is in terms of its third-order intermodulation performance. Here two different frequencies, f_1 and f_2 , of equal powers, p_1 and p_2 , are inserted into the rf amplifier, and the third frequency, internally generated, $2f_1 - f_2$ or $2f_2 - f_1$, has its power p_{12} measured. All three frequencies must be in the amplifier passband. With the intermodulation power p_{12} referred to the output, the following equation can be written:

$$P_{12} = 2P_1 + P_2 + K_{12}$$

where P_{12} = intermodulation output power at $2f_1 - f_2$ or $2f_2 - f_1$

P_1 = output power at input frequency f_1

P_2 = output power at input frequency f_2 , all in decibels referred to (0 dBm)

K_{12} = constant associated with the particular device

The value of K_{12} in the above formula can be used to rate the performance of various device choices. Higher orders of intermodulation products can also be used.

A third measure of large-signal performance commonly used is that of cross-modulation. In this instance, a carrier at f_D with no modulation is inserted into the amplifier. A receiver is then placed at the output and tuned to this unmodulated carrier. A second carrier at f_1 with amplitude-modulation index M_I is then added. The power of P_I of f_1 is increased, and its modulation is partially transferred to f_D . The equation becomes

$$10 \log (M_K/M_I) = P_I + K$$

where M_K = cross-modulation index of originally unmodulated signal at f_D

M_I = modulation index of signal f_1

P_I = output power of signal at f_1 , all in decibels referred to 1 mW (0 dBm)

K = cross-modulation constant

Maximum Input Power

In addition to the large-signal performance, the maximum power of voltage input into an rf amplifier is specified, with a requirement that device burnout must not occur at this input. There are two ways of specifying this input: by a stated pulse of energy or by a requirement to withstand a continuously applied large signal. It is also common to specify the time required to unblock the amplifier after removal of the large input. With the increased use of field effect transistors (FETs especially) having good noise performance, these overload characteristics have become a severe problem. In many cases, conventional or zener diodes, in a back-to-back configuration shunting the input, are used to reduce the amount of power the input of the active devices must dissipate.

RF Amplifiers in Receivers

RF amplifiers intended for the first stages of receivers have additional restrictions placed on them. In most cases, such amplifiers are tunable across a band of frequencies with one or more tuned circuits. The tuned

circuits must track across the frequency band, and in the case of the superheterodyne, tracking of the local oscillator is necessary so that a constant frequency difference (i.f.) is maintained. The receiver's rf section can be tracked with the local oscillator by the two- or the three-point method, i.e., with zero error in the tracking at either two or three points.

A second consideration peculiar to rf amplifiers used for receivers is the AGC. This requirement is often stated by specifying a low-level rf input to the receiver and noting the power out. The rf signal input is then increased with the AGC applied until the output power has increased a predetermined amount. This becomes a measure of the AGC effectiveness. The AGC performance can also be measured by plotting a curve of rf input versus AGC voltage needed to maintain constant output, compared with the desired performance.

A third consideration in superheterodynes is the leakage of the local oscillator in the receiver to the outside. This spurious radiation is specified by the Federal Communications Commission (FCC) in the United States.

Design Using Immittance and Hybrid Parameters

The general gain and input-output impedance of an amplifier can be formulated, in terms of the Z or Y parameters, to be

$$Y_{\text{in}} = y_{11} - \frac{y_{12}y_{21}}{y_{22} + y_L} \quad Y_{\text{out}} = y_{22} - \frac{y_{12}y_{21}}{y_{11} + y_s}$$

where y_L = load admittance
 y_s = source admittance
 Y_{in} = input admittance
 Y_{out} = output admittance
 G_T = transducer gain

and the transducer gain is

$$G_T = \frac{4 \operatorname{Re} y_s \operatorname{Re} y_L |y_{21}|^2}{|(y_{11} + y_s)(y_{22} + y_L) - y_{12}y_{21}|^2}$$

for the y parameters, and interchange of z or y is allowed.

The stability of the circuit can be determined by either Linvill's C or Stern's k factor as defined below. Using the y parameters, $y_{ij} = g_{ik} + jB_{ik}$, these are

Linvill:

$$C = \frac{|y_{12}y_{21}|}{2g_{11}g_{22} - \operatorname{Re} y_{12}y_{21}}$$

where $C < 1$ for stability does not include effects of load and source admittance.

Stern:

$$k = \frac{2(g_{11} + g_s)(g_{22} + g_L)}{|y_{12}y_{21}| + \operatorname{Re} y_{12}y_{21}}$$

where $k > 1$ for stability
 g_L = load conductance
 g_s = source conductance

The preceding C factor defines only unconditional stability; i.e., no combination of load and source impedance will give instability. There is an invariant quantity K defined as

$$K = \frac{2 \operatorname{Re} \gamma_{11} \operatorname{Re} \gamma_{22} - \operatorname{Re} \gamma_{12} \gamma_{21}}{|\gamma_{21} \gamma_{12}|} \quad \begin{array}{l} \operatorname{Re} \gamma_{11} > 0 \\ \operatorname{Re} \gamma_{22} > 0 \end{array}$$

11.40 AMPLIFIERS AND OSCILLATORS

where γ represents either the y , z , g , or h parameters, and $K > 1$ denotes stability.

This quantity K has then been used to define maximum available power gain G_{\max} (only if $K > 1$)

$$G_{\max} = |\gamma_{21}/\gamma_{12}|(K - \sqrt{K^2 - 1})$$

To obtain this gain, the source and load immittance are found to be ($K > 1$)

$$\gamma_s = \frac{\gamma_{12}\gamma_{21} + |\gamma_{12}\gamma_{21}|(K + \sqrt{K^2 - 1})}{2 \operatorname{Re} \gamma_{22}} - \gamma_{11} \quad \gamma_s = \text{source immittance}$$

$$\gamma_L = \frac{\gamma_{12}\gamma_{21} + |\gamma_{12}\gamma_{21}|(K + \sqrt{K^2 - 1})}{2 \operatorname{Re} \gamma_{11}} - \gamma_{22} \quad \gamma_L = \text{load immittance}$$

The procedure is to calculate the K factor, and if $K > 1$, calculate G_{\max} , γ_s , and γ_L . If $K < 1$, the circuit can be modified either by use of feedback or by adding immittances to the input-output.

Design Using S Parameters

The advent of automatic test equipment and the extension of vacuum tubes and transistors to be gigahertz frequency range have led to design procedures using the S parameters. Following the previous discussion, the input and output reflection coefficient can be defined as

$$p_{\text{in}} = S_{11} + p_L \frac{S_{12}S_{21}}{1 - p_L S_{22}} \quad p_L = \frac{Z_L - Z_0}{Z_L + Z_0}$$

$$p_{\text{out}} = S_{22} + p \frac{S_{12}S_{21}}{1 - p S_{11}} \quad p_s = \frac{Z_s - Z_0}{Z_s + Z_0}$$

where Z_0 = characteristic impedance

p_{in} = input reflection coefficient

p_{out} = output reflection coefficient

The transducer gain can be written

$$G_{\text{transducer}} = \frac{|S_{21}|^2 (1 - |p_s|^2)(1 - |p_L|^2)}{|(1 - S_{11}p_s)(1 - S_{22}p_L) - S_{21}S_{12}p_s p_L|^2}$$

The unconditional stability of the amplifier can be defined by requiring the input (output) impedance to have a positive real part for any load (source) impedance having a positive real part.

This requirement gives the following criterion:

$$|S_{11}|^2 + |S_{12}S_{21}| < 1 \quad |S_{22}|^2 + |S_{12}/S_{11}| < 1$$

and

$$\eta = \frac{1 - |\Delta|^2 - |S_{11}|^2 - |S_{22}|^2}{2|S_{12}S_{21}|} > 1 \quad \Delta_s = S_{11}S_{22} - S_{12}S_{21}$$

Similarly, the maximum transducer gain, for $\eta > 1$, becomes

$$G_{\max \text{ transducer}} = |S_{21}/S_{12}| (\eta \pm \sqrt{\eta^2 - 1})$$

(positive sign when $|S_{22}|^2 - |S_{11}|^2 - 1 + |\Delta_s|^2 > 0$) for conditions listed above.

The source and load to provide conjugate match to the amplifier when $\eta > 1$ are the solutions of the following equations, which give $|p_s|$, and $|p_L|$ less than 1

$$p_{ms} = C_1^* \frac{B_1 \pm \sqrt{B_1^2 - 4|C_1|^2}}{2|C_1|^2} \quad p_{mL} = C_2^* \frac{B_2 \pm \sqrt{B_2^2 - 4|C_2|^2}}{2|C_2|^2}$$

where

$$B_1 = 1 + |S_{11}|^2 - |S_{22}|^2 - |\Delta_s|^2 \quad B_2 = 1 + |S_{22}|^2 - |S_{11}|^2 - |\Delta_s|^2 \\ C_1 = S_{11} - \Delta_s S_{22}^* \quad C_2 = S_{22} - \Delta_s S_{11}^*$$

the star (*) denoting conjugate.

If $|\eta| > 1$ but η is negative or $|\eta| < 1$, it is not possible to match simultaneously the two-port with real source and load admittance. Both graphical techniques and computer programs are available to aid in the design of rf amplifiers.

Intermediate-Frequency Amplifiers

Intermediate-frequency amplifiers consist of a cascade of a number of stages whose frequency response is determined either by a filter or by tuned interstages. The design of the individual active stages follows the techniques discussed earlier, but the interstages become important for frequency shaping. There are various forms of interstage networks; several important cases are discussed below.

Synchronous-Tuned Interstages. The simplest forms of tuned interstages are synchronously tuned circuits. The two common types are the single- and double-tuned interstage.

The governing equations are:

1. Single-tuned interstage (Fig. 11.3.3a):

$$A(j\omega) = -A_r \frac{1}{1 + jQ_L(\omega/\omega_0 - \omega_0/\omega)}$$

where Q_L = loaded Q of the tuned circuit greater than 10

ω_0 = resonance frequency of the tuned circuit = $1/\sqrt{LC}$

ω = frequency variable

A_r = midband gain equal to g_m times the midband impedance level

For an n -stage amplifier with n interstages,

$$A_T = A^n(j\omega) = A_r^n \left[1 + \left(\frac{\omega^2 - \omega_0^2}{B\omega} \right)^2 \right]^{-n/2}$$

FIGURE 11.3.3 Interstage coupling circuits: (a) single-tuned; (b) double-tuned.

where $B = \omega_0/Q_L =$ single-stage bandwidth

$n =$ number of stages

$\omega_0 =$ center frequencies

$Q_L =$ loaded Q

$B_n = B\sqrt{2^{1/n} - 1}$ is the overall bandwidth reduction owing to n cascades

2. Double-tuned interstage (Fig. 11.3.3b):

$$A(j\omega) = \frac{g_m k}{C_1 C_2 (1 - k^2) \sqrt{L_1 L_2}} \frac{j\omega}{\omega^4 - ja_1 \omega^3 - a_2 \omega^2 + ja_3 \omega + a_4}$$

(for a single double-tuned stage), where

$$a_1 = \omega_r \left(\frac{1}{Q_1} + \frac{1}{Q_2} \right) \quad a_2 = \frac{\omega_r^2}{Q_1 Q_2} + \frac{1}{1 - k^2} (\omega_1^2 + \omega_2^2)$$

$$a_3 = \frac{\omega_r}{1 + k^2} \left(\frac{\omega_2^2}{Q_1} + \frac{\omega_1^2}{Q_2} \right) \quad a_4 = \frac{\omega_1^2 \omega_2^2}{1 - k^2}$$

The circuit parameters are

$R_1 =$ total resistance primary side

$C_1 =$ total capacitance primary side

$L_1 =$ total inductance primary side

$R_2 =$ total resistance secondary side

$C_2 =$ total capacitance secondary side

$L_2 =$ total inductance secondary side

$M =$ mutual inductance $= k\sqrt{L_1 L_2}$

$k =$ coefficient of coupling

$\omega_r =$ resonant frequency of amplifier

$\omega_1 = 1/\sqrt{L_1 C_1}$

$\omega_2 = 1/\sqrt{L_2 C_2}$

$Q_1 =$ primary Q at $\omega_r = \omega_r C_1 R_1$

$Q_2 =$ secondary Q at $\omega_r = \omega_r C_2 R_2$

$g_m =$ transconductance of active device at midband frequency

Simplification. If $\omega_1 = \omega_2 = \omega_0$, that is, primary and secondary tuned to the same frequency, then

$$\omega_r = \omega_0 \sqrt{1 - k^2}$$

is the resonant frequency of the amplifier and

$$A(j\omega_r) = \frac{+jkg_m \sqrt{R_1 R_2}}{\sqrt{Q_1 Q_2} (k^2 + 1/Q_1 Q_2)}$$

is the gain at this resonant frequency.

For maximum gain,

$$k_c = \frac{1}{\sqrt{Q_1 Q_2}} = \text{critical coupling}$$

and for maximum flatness,

FIGURE 11.3.4 Selective curves for two identical circuits in a double-tuned interstage circuit, at various values of k/k_C .

$$k_T = \sqrt{\frac{1}{2} \left(\frac{1}{Q_1^2} + \frac{1}{Q_2^2} \right)} = \text{transitional coupling}$$

If k is increased beyond k_T , a double-humped response is obtained.

Overall bandwidth of an n -stage amplifier having equal Q circuits with transitional coupled interstages whose bandwidth is B is

$$B_n = B(2^{1/n} - 1)^{1/4}$$

The governing equations for the double-tuned-interstage case are shown above. The response for various degrees of coupling related to $k_T = k_C$ in the equal-coil- Q case is shown in Fig. 11.3.4.

Maximally Flat Staggered Interstage Coupling

This type of coupling consists of n single-tuned interstages that are cascaded and adjusted so that the overall gain function is maximally flat. The overall cascade bandwidth is B_n , the center frequency of the cascade is ω_c , and each stage is a single-tuned circuit whose bandwidth B and center frequency are determined from Table 11.3.1. The gain of each stage at cascade center frequency is $A(j\omega_c) = -g_m/C_T[B + j(\omega_c^2 - \omega_0^2)/\omega_c]$, where C_T = sum of output capacitance and input capacitance to next stage and wiring capacitance of cascade, B = stage bandwidth, ω_0 = center frequency of stage, and ω_c = center frequency of cascade.

TABLE 11.3.1 Design Data for Maximally Flat Staggered n -tuples

n	Name of circuit	No. of stages	Center frequency of stage	Stage bandwidth
2	Staggered pair	2	$\omega_c \pm 0.35B_n$	$0.71B_n$

 For $Q_L > 20$

RADIO-FREQUENCY OSCILLATORS

G. Burton Harrold

General Considerations

Oscillators at rf frequencies are usually of the class A sine-wave-output type.

RF oscillators (in common with audio oscillators) may be considered either as one-port networks that exhibit a negative real component at the input or as two-port-type networks consisting of an amplifier and a frequency-sensitive passive network that couples back to the input port of the amplifier. It can be shown that the latter type of feedback oscillator also has a negative resistance at one port. This negative resistance is of a dynamic nature and is best defined as the ratio between the fundamental components of voltage and current.

The sensitivity of the oscillator's frequency is directly dependent on the effective Q of the frequency-determining element and the sensitivity of the amplifier to variations in temperature, voltage variation, and aging. For example, the effective Q of the frequency-determining element is important because the percentage change in frequency required to produce the compensating phase shift in a feedback oscillator is inversely proportional to the circuit Q , thus the larger the effective Q the greater the frequency stability. The load on an oscillator is also critical to the frequency stability since it affects the effective Q and in many cases the oscillator is followed by a buffer stage for isolation.

It is also desirable to provide some means of stabilizing the oscillator's operating point, either by a regulated supply, dc feedback for bias stabilization, or oscillator self-biasing schemes such as grid-leak bias. This stabilizes not only the frequency but also the output amplitude, by tending to compensate any drift in the active device's parameters. It is also necessary to eliminate the harmonics in the output since they give rise to cross-modulation products producing currents at the fundamental frequency that are not necessarily in phase with the dominant oscillating mode. The use of high- Q circuits and the control of the nonlinearity helps in controlling harmonic output.

Negative-Resistance Oscillators

The analysis of the negative-impedance oscillator is shown in Fig. 11.3.5. The frequency of oscillation at buildup is not completely determined by the LC circuit but has a component that is dependent upon the circuit resistance. At steady state, the frequency of oscillation is a function of $1 + R/R_{iv}$, or $1 + R_{ic}/R$, depending on the particular circuit where the ratios R/R_{ic} , R_{iv}/R are usually chosen to be small. While R is a fixed function of the

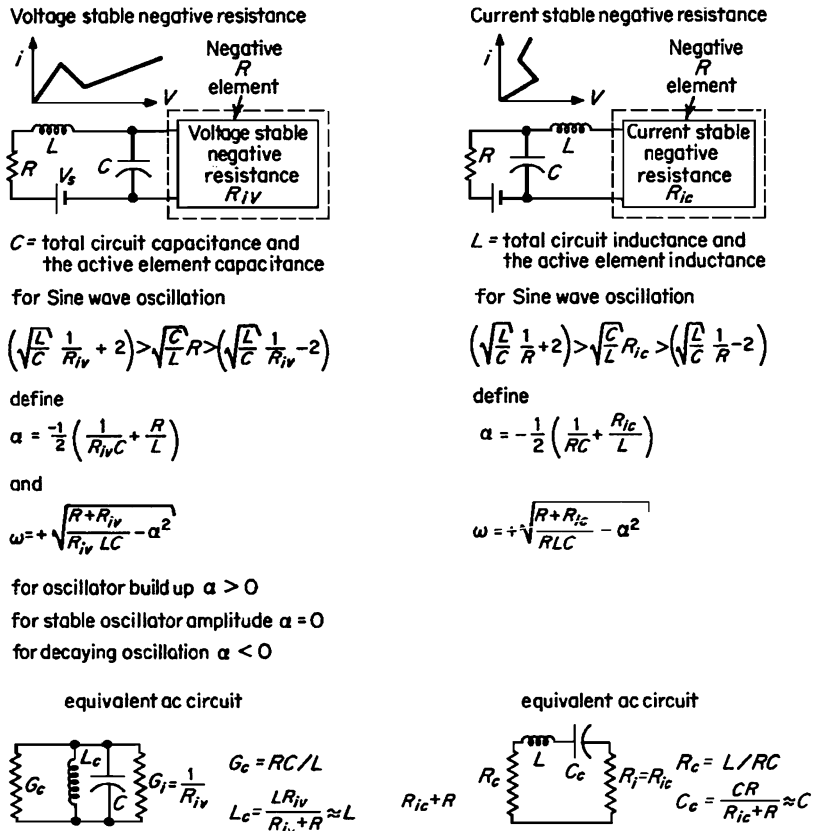

FIGURE 11.3.5 General analysis of negative-resistance oscillators.

loading, R_{ic} or R_{iv}/R must change with amplitude during oscillator buildup, so that the condition of $\alpha = 0$ can be reached. Thus R_{iv} , R_{ic} cannot be constant but are dynamic impedances defined as the ratio of the fundamental voltage across the elements to the fundamental current into the element.

The type of dc load for biasing and the resonant circuit required for the proper operation of a negative-resistance oscillator depend on the type of active element. R must be less than $|R_{iv}|$ or R must be greater than $|R_{ic}|$ in order for oscillation to build up and be sustained.

The detailed analysis of the steady-state oscillator amplitude and frequency can be undertaken by graphical techniques. The magnitude of G_i or R_i is expressed in terms of its voltage dependence. Care must be taken with this representation, since the shape of the G_i or R_i curve depends on the initial bias point.

The analysis of negative-resistance oscillators can now be performed by means of admittance diagrams. The assumption for oscillation to be sustaining is that the negative-resistance element, having admittance y_p , must equal $-y_c$, the external circuit admittance. This can be summarized by $G_i = -G_c$ and $B_i = -B_c$. A typical set of admittance curves is shown in Fig. 11.3.6. In this construction, it is assumed that $B_i = -B_c$, even during the oscillator buildup. Also shown is the fact that G_i at zero amplitude must be larger than G_c so that the oscillator can be started, that is, $\alpha > 0$, and that it may be possible to have two or more stable modes of oscillation.

Feedback Oscillators

Several techniques exist for the analysis of feedback oscillators. In the generalized treatment, the active element is represented by its y parameters whose element values are at the frequency of interest, having magnitudes

FIGURE 11.3.6 Admittance diagram of voltage-stable negative-resistance oscillators: (a) self-starting case, $\alpha > 0$; (b) circuit starts oscillating only if externally excited beyond point 1.

defined by the ratio of the fundamental current divided by fundamental voltage. The general block diagram and equations are shown in Fig. 11.3.7. Solution of the equations given yields information on the oscillator's performance. In particular, equating the real and imaginary parts of the characteristic equation gives information on amplitude and frequency of oscillation.

In many instances, many simplifications to these equations can be made. For example, if y_{11} and y_{12} are made small (as in vacuum-tube amplifiers), then

$$y_{21} = -(1/z_{21})(y_{22}z_{11} + 1) = -1/Z$$

This equation can be solved by equating the real and imaginary terms to zero to find the frequency and the criterion for oscillation of constant amplitude. This equation can also be used to draw an admittance diagram for oscillator analysis.

Characteristic equation:

$$y_{21} z_{21} + y_{11} z_{22} + y_{22} z_{11} + y_{12} z_{12} + \Delta_Y \Delta_Z + 1 = 0$$

$$\Delta_Y = y_{11} y_{22} - y_{12} y_{21} \quad \Delta_Z = z_{11} z_{22} - z_{12} z_{21}$$

If $y_{21} \gg y_{12}$ $y_{12} \approx 0$ and $[z]$ passive $z_{12} = z_{21}$

Then:

$$y_{21} z_{12} + y_{11} z_{22} + y_{22} z_{11} + \Delta_Y \Delta_Z + 1 = 0$$

FIGURE 11.3.7 General analysis of feedback oscillators.

FIGURE 11.3.8 Admittance diagram of feedback oscillator.

FIGURE 11.3.9 S-parameter and analysis of oscillators.

These admittance diagrams are similar to those discussed under negative-resistance oscillators. The technique is illustrated in Fig. 11.3.8.

At higher frequencies, the S parameters can also be used to design oscillators (Fig. 11.3.9). The basis for the oscillator is that the magnitude of the input reflection coefficient must be greater than unity, causing the circuit to be potentially unstable (in other words, it has a negative real part for the input impedance). The input reflection coefficient with a Γ_L output termination is

$$S'_{11} = S_{11} + \frac{S_{12}S_{21}\Gamma_L}{1 - S_{22}\Gamma_L}$$

Either by additional feedback or adjustment of Γ_L it is possible to make $|S'_{11}| > 1$. Next, establishing a load Γ_s such that it reflects all the energy incident on it will cause the circuit to oscillate. This criterion is stated as

$$\Gamma_L S'_{11} = 1$$

at the frequency of oscillation.

This technique can be applied graphically, using a Smith chart as before. Here the reciprocal of S'_{11} is plotted as a function of frequency since $S'_{11} > 1$. Now choose either a parallel or a series-tuned circuit and plot its Γ_s . If f_1 is the frequency common to $1/S'_{11}$ and Γ_s , and satisfies the above criterion, the circuit will oscillate at this point.

BROADBAND AMPLIFIERS

John W. Lunden, Jennifer E. Doyle

Introduction

In broadband amplifiers signals are amplified so as to preserve over a wide band of frequencies such characteristics as signal amplitude, gain response, phase shift, delay, distortion, and efficiency. The width of the band depends on the active device used, the frequency range, and power level in the current state of the art. As a general rule, above 100 MHz, a 20 percent or greater bandwidth is considered broadband, whereas an octave or more is typical below 100 MHz. As the state-of-the-art advances, it is becoming more common to achieve octave-bandwidth or wider amplifiers well into the microwave region using bipolar and FET active devices.

Hybrid-integrated-circuit techniques and new monolithic techniques eliminate many undesired package and bonding parasitics which can limit broadband amplifier performance. Additionally, distributed amplifiers, and other approaches which use multiple devices, have become more economical with increasing levels of integration.

It has become uncommon to use tube devices for new amplifier designs. Solid-state devices have replaced tubes in most amplifier applications because of superior long-term reliability and lower noise figures. In the following discussion both field-effect and bipolar transistor notations appear for generality.

FIGURE 11.3.10 RC-coupled stages: (a) field-effect transistor form; (b) bipolar junction transistor form.

Low-, Mid-, and High-Frequency Performance

Consider the basic common-source and common-emitter-broadband RC coupled configurations shown in Fig. 11.3.10. Simplified low-frequency small-signal equivalent circuits are shown in Fig. 11.3.11.

The voltage gain of the FET amplifier stage under the condition that all reactances are negligibly small is the midband value (at frequency f)

$$(A_{mid})_{FET} = \frac{-g_m}{1/r_{ds} + 1/R_L + 1/R_g} \approx -g_m R_L$$

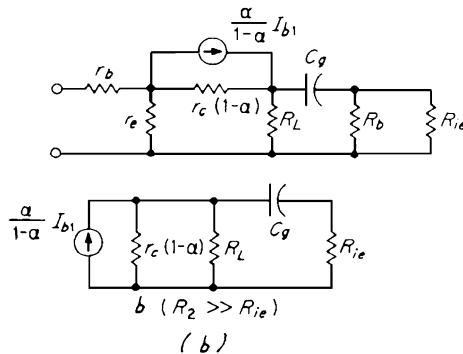

FIGURE 11.3.11 Equivalent circuits of the stages shown in Fig. 11.3.10: (a) FET form; (b) bipolar form.

If the low-frequency effects are included, this becomes

$$(A_{\text{low}})_{\text{FET}} = \frac{-g_m R_L}{1 + 1/j\omega R_g C_g} \frac{1 + 1/j\omega R_s C_s}{1 + (1 + g_m R_s)/j\omega C_s R_s} \left(= \frac{-g_m R_L}{1 + 1/j\omega R_g C_g} \text{ for } R_s = 0 \right)$$

The low-frequency cutoff is because principally of two basic time constants, $R_g C_g$ and $R_s C_s$. For C_s values large enough for the time constant to be much longer than that associated with C_g , a low-frequency cutoff or half-power point can be determined as

$$(f_1)_{\text{FET}} = \frac{1}{2\pi C_g [R_g + r_{ds} R_L / (r_{ds} + R_L)]}$$

If the coupling capacitor is very large, the low-frequency cutoff is a result of C_s . The slope of the actual rolloff is a function of the relative effect of these two time constants. Therefore, the design of coupling and bypass circuits to achieve very-low-frequency response requires very large values of capacitance.

Similarly, for a bipolar transistor stage, the midband current gain can be determined as

$$(A_{\text{mid}})_{\text{BJT}} = \frac{-\alpha r_c R_L}{[R_L + r_c(1-\alpha)] \left[R_{ie} + \frac{R_L r_c(1-\alpha)}{R_L + r_c(1-\alpha)} \right]} \approx \frac{-\alpha}{1-\alpha} \frac{R_L}{R_L + R_{ie}}$$

where

$$R_{ie} = r_b + \frac{r_e}{1-\alpha}$$

When low-frequency effects are included, this becomes

$$(A_{\text{low}})_{\text{BJT}} \approx \frac{-\alpha}{1-\alpha} \frac{R_L}{R_L + R_{ie} - j/\omega C_g} \quad \text{for } R_L \ll r_c(1-\alpha)$$

and

$$(f_1)_{\text{BJT}} = \frac{1}{2\pi C_g} \frac{1}{R_{ie} + \frac{R_L r_c(1-\alpha)}{R_L + r_c(1-\alpha)}} \approx \frac{1}{2\pi C_g} \frac{1}{R_{ie} + R_L}$$

If the ratio of low- to midfrequency voltage or current gain is taken, its reactive term goes to unity at $f = f_1$, that is, the cutoff frequency.

$$\frac{A_{\text{low}}}{A_{\text{mid}}} = \frac{1}{1 - j(f_1/f)} \quad \phi_{\text{low}} = \tan^{-1} \frac{f_1}{f}$$

These quantities are plotted in Fig. 11.3.12 for a single time-constant rolloff.

Caution should be exercised in assuming that reactances between input and output terminals are negligible. Although this is generally the case, gain multiplicative effects can result in input or output reactance values greater than the values assumed above, e.g., by the Miller effect:

$$C_{\text{in}} = C_{gs} + C_{gd}(1 + g_m R'_L)$$

FIGURE 11.3.12 Gain and phase-shift curves at low frequencies.

FIGURE 11.3.13 Gain and phase-shift curves at high frequencies.

Typically, the midfrequency gain equation can be used for frequencies above that at which $X_c = R_g/10$ below that at which $X_{c_g} = 10R_gR_L/(R_g + R_L)$ (for the FET circuit).

If the frequency is increased further, a point is reached where the shunt reactances are no longer high with respect to the circuit resistances. At this point the coupling and bypass capacitors can be neglected. The high-frequency gain can be determined as

$$(A_{\text{high}})_{\text{FET}} = \frac{-g_m}{1/r_{ds} + 1/R_L + j\omega C_L}$$

where C_L is the effective total interstage shunt capacitance.

$$(A_{\text{high}})_{\text{BJT}} \approx \frac{-\alpha}{1-\alpha} \frac{1}{1 + R_{ie} \left(\frac{1}{R_L} + \frac{j\omega C_c}{1-\alpha} \right)} \quad \text{for } R_L \ll r_c(1-\alpha)$$

The ratio of high- to midfrequency gains can be taken and upper cutoff frequencies determined

$$\begin{aligned} \left(\frac{A_{\text{high}}}{A_{\text{mid}}} \right)_{\text{FET}} &= \frac{1}{1 + j\omega C_L \frac{1}{(1/r_{ds}) + (1/R_L) + (1/R_g)}} \\ (f_2)_{\text{FET}} &= \frac{1}{2\pi C_L} \left(\frac{1}{r_{ds}} + \frac{1}{R_L} + \frac{1}{R_g} \right) \\ \left(\frac{A_{\text{high}}}{A_{\text{mid}}} \right)_{\text{BJT}} &= \frac{1}{1 + \frac{j\omega C_c r_c R_L R_{ie}}{R_{ie} [R_L + r_c(1-\alpha)] + R_L r_c(1-\alpha)}} \\ (f_2)_{\text{BJT}} &\approx \frac{1-\alpha}{2\pi C_c} \left(\frac{1}{R_L} + \frac{1}{R_{ie}} \right) \quad \text{and} \quad \phi_{\text{high}} = -\tan^{-1}(f/f_2) \end{aligned}$$

Dimensionless curves for these gain ratios and phase responses are plotted in Fig. 11.3.13.

Compensation Techniques

To extend the cutoff frequencies f_1 and f_2 to lower or higher values, respectively, compensation techniques can be used.

Figure 11.3.14 illustrates two techniques for low-frequency compensation. If the condition $R_g C_g = C_x R_x R_L / (R_x + R_L)$ is fulfilled (in circuit *a* or *b*), the gain relative to the midband gain is

$$\frac{A_{\text{low}}}{A_{\text{mid}}} = \frac{1}{1 - j(1/\omega R_g C_g)[R_L/(R_L + R_x)]} \quad \text{and} \quad f_1 = \frac{1}{2\pi R_g C_g} \frac{R_L}{R_L + R_x}$$

FIGURE 11.3.14 Low-frequency compensation networks: (a) bipolar transistor version; (b), (c) FET versions.

Hence, improved low-frequency response is obtained with increased values of R_x . This value is related to R_L and restricted by active-device operating considerations. Also, R_L is dependent on the desired high-frequency response. It can be shown that equality of time constants $R_L C_x = R_g C_g$ will produce zero phase shift in the coupling circuit (for $R_x > 1/\omega C_x$). The circuit shown in Fig. 11.3.14c is more critical. It is used with element ratios set to $R_L/R_x = R_g/R_c$ and $C_x/C_g = R_c/R_x$.

Various compensation circuits are also available for high-frequency-response extension. Two of the most common, the series- and shunt-compensation cases, are shown in Fig. 11.3.15. The high-frequency-gain expressions of these configurations can be written

$$\left| \frac{A_{\text{high}}}{A_{\text{mid}}} \right| = \sqrt{\frac{1 + a_1(f/f_2)^2 + a_2(f/f_2)^4 + \dots}{1 + b_1(f/f_2)^2 + b_2(f/f_2)^4 + b_3(f/f_2)^6 + \dots}}$$

The coefficients of the terms decrease rapidly for the higher-order terms, so that if $a_1 = b_1$, $a_2 = b_2$, etc., to as high an order of the f/f_2 ratio as possible, a maximally flat response curve is obtained.

For the phase response, $d\phi/d\omega$ can also be expressed as a ratio of two polynomials in f/f_2 , and a similar procedure can be followed. A flat time-delay curve results. Unfortunately, the sets of conditions for flat gain and linear phase are different, and compromise values must be used.

Shunt Compensation. The high-frequency gain and time delay for the shunt-compensated stage are

$$\left| \frac{A_{\text{high}}}{A_{\text{mid}}} \right| = \frac{1 + \alpha^2(f/f_2)^2}{\sqrt{1 + (1 - 2\alpha)(f/f_2)^2 + \alpha^2(f/f_2)^4}} \quad \phi = -\tan^{-1} \frac{f}{f_2} \left[1 - \alpha + \left(\frac{f}{f_2} \right)^2 \alpha^2 \right]$$

where $a = L/C_g R_L^2$ and $R_g \gg R_L$.

A case when R_g cannot be assumed to be high, such as the input of a following bipolar transistor stage, is considerably more complex, depending on the transistor equivalent circuit used. This is particularly true when operating near the transistor f_T and/or above the VHF band.

Series Compensation. In the series-compensated circuit, the ratio of C_x to C_g is an additional parameter. If this can be optimized, the circuit performance is better than in the shunt-compensated case. Typically, however, control of this parameter is not available due to physical and active-device constraints.

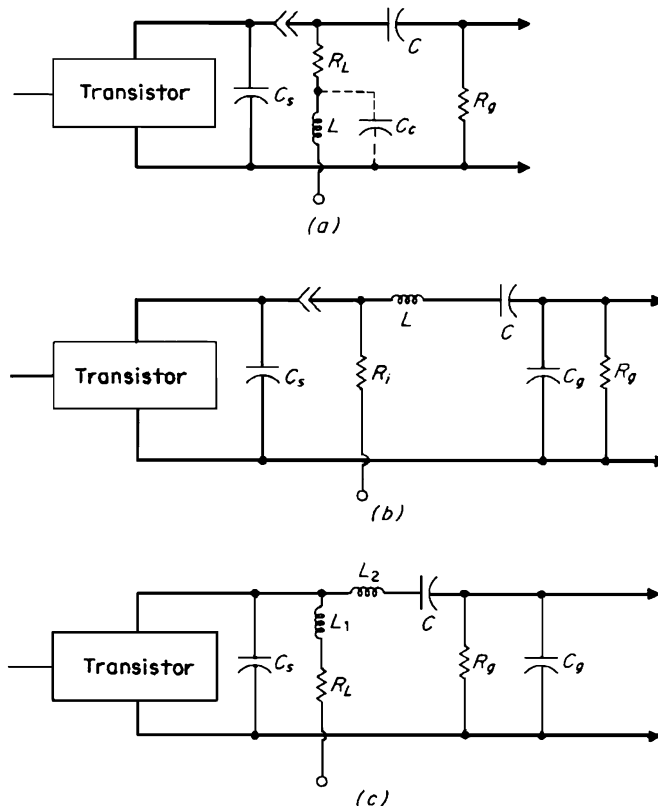

FIGURE 11.3.15 High-frequency compensation schemes: (a) shunt; (b) series; (c) shunt-series.

These two basic techniques can be combined to improve the response at the expense of complexity. The shunt-series-compensation case and the so-called “modified” case are examples. The latter involves a capacitance added in shunt with the inductance L or placing L between C_s and R_L .

For the modified-shunt case, the added capacitance C_c permits an additional degree of freedom, and associated parameter, $k_1 = C_c/C_s$.

Other circuit variations exist for specific broadband compensation requirements. Phase compensation, for example, may be necessary as a result of cascading a number of minimum-phase circuits designed for flat frequency response. Circuits such as the lattice and bridged-T can be used to alter the system response by reducing the overshoot without severely increasing the overall rise time.

Cascaded Broadband Stages

When an amplifier is made up of n cascaded RC stages, not necessarily identical, the overall gain A_n can be written

$$\left| \frac{A_n}{A_{\text{mid}}} \right| = \left[\frac{1}{1 + (f/f_a)^2} \right]^{1/2} \left[\frac{1}{1 + (f/f_b)^2} \right]^{1/2} \cdots \left[\frac{1}{1 + (f/f_n)^2} \right]^{1/2}$$

where f_a, f_b, \dots, f_n are the f_1 or f_2 values for the respective stages, depending on whether the overall low- or high-frequency gain ratio is being determined. The phase angle is the sum of the individual phase angles. If the stages are identical, $f_a = f_b = f_x$ for all, and

$$\left| \frac{A_n}{A_{mid}} \right| = \left| \frac{1}{1 + (f/f_x)^2} \right|^{n/2}$$

Stagger Peaking. In stagger tuning a number of individual bandpass amplifier stages are cascaded with frequencies skewed according to some predetermined criteria. The most straightforward is with the center frequencies adjusted so that the f_2 of one stage concludes with the f_1 of the succeeding stage, and so forth. The overall gain bandwidth then becomes

$$(GBW)_n = \sum_{n=1}^N (GBW)_n$$

A significant simplifying criterion of this technique is stage isolation. Isolation, in transistor stages particularly, is not generally high, except at low frequencies. Hence the overall design equations and subsequent overall alignment can be significantly complicated because of the interactions. Complex device models and computer-aided design greatly facilitate the implementation of this type of compensation. The simple shunt-compensated stage has found extensive use in stagger-tuned pulse-amplifier applications.

Transient Response

Time-domain analysis is particularly useful for broadband applications. Extensive theoretical studies have been made of the separate effects of nonlinearities of amplitude and phase response. These effects can be investigated starting with a normalized low-pass response function.

$$A(j\omega)/A(0) = \exp (a^m w^m - j b^n w^n)$$

where a and m are constants describing amplitude-frequency response and b and n are constants describing phase-frequency response. Figure 11.3.16 illustrates the time response to an impulse and a unit-step forcing function for various values of m , with $n = 0$. Rapid change of amplitude with frequency (large m) results in

FIGURE 11.3.16 Transient responses to unit impulse (left) and unit step (right) for various values of m .

overshoot. Nonzero, but linear, phase-frequency characteristics ($n = 1$) result in a delay of these responses, without introducing distortion. Further increase in n results in increased ringing and asymmetry of the time function.

An empirical relationship between rise time (10 to 90 percent) and bandwidth (3 dB) can be expressed as

$$t_r \cdot BW = K$$

where K varies from about 0.35 for circuits with little or no overshoot to 0.45 for circuits with about 5 percent overshoot. K is 0.51 for the ideal rectangular low-pass response with 9 percent overshoot; for the Gaussian amplitude response with no overshoot, $K = 0.41$.

The effect on rise time of cascading a number of networks n depends on the individual network pole-zero configurations. Some general rules follow.

FIGURE 11.3.17 Response to a unit step of n capacitively coupled stages of the same time constant.

1. For individual circuits having little or no overshoot, the overall rise time is

$$t_n = (t_{r1}^2 + t_{r2}^2 + t_{r3}^2 + \dots)^{1/2}$$

2. If $t_{r1} = t_{r2} = t_{rn}$,

$$t_n = 1.1\sqrt{nt_{r1}}$$

3. For individual stage overshoots of 5 to 10 percent, total overshoot increases as \sqrt{n} .
4. For circuits with low overshoot (~ 1 percent), the total overshoot is essentially that of one stage.

The effect of insufficient low-frequency response of an amplifier is sag of the time response. A small amount of sag (< 10 percent) can be described by the formula

$$E_{\text{sag}}/E_{\text{tot}} = T/2.75RC$$

where T is one-half period of a square-wave voltage.

Figure 11.3.17 illustrates the response to a step function of n capacitor-coupled stages with the same time constant. The effect of arithmetic addition of individual stage initial slopes determining the net total initial transition slope can be seen.

Distributed Amplifiers

This technique is useful for operation of devices at or near the high-frequency limitation of gain bandwidth. While the individual stage gain is low, the stages are cascaded so that the gain response is additive instead of multiplicative. The basic principle is to allow the input and output capacitances to form the shunt elements of two delay lines. This is shown in Fig. 11.3.18.

If the delay times per section in the two lines are the same, the output signals traveling forward add together without relative delay. Care must be taken to ensure proper terminating conditions. The gain produced by n devices, each of transconductance g_m , has a value of $G = ng_m Z_{02}/2$. Performance to very low frequencies can be achieved. The high-frequency limit is determined by the cutoff frequencies of the input and output lines or effects within the active devices themselves other than parasitic shunt capacities (e.g., transit time or alpha-fall-off effects).

For input and output lines of different characteristic impedances, the overall gain is given by

$$G = \frac{2Z_{01}}{Z_{01} + Z_{02}} \frac{ng_m Z_{02}}{2}$$

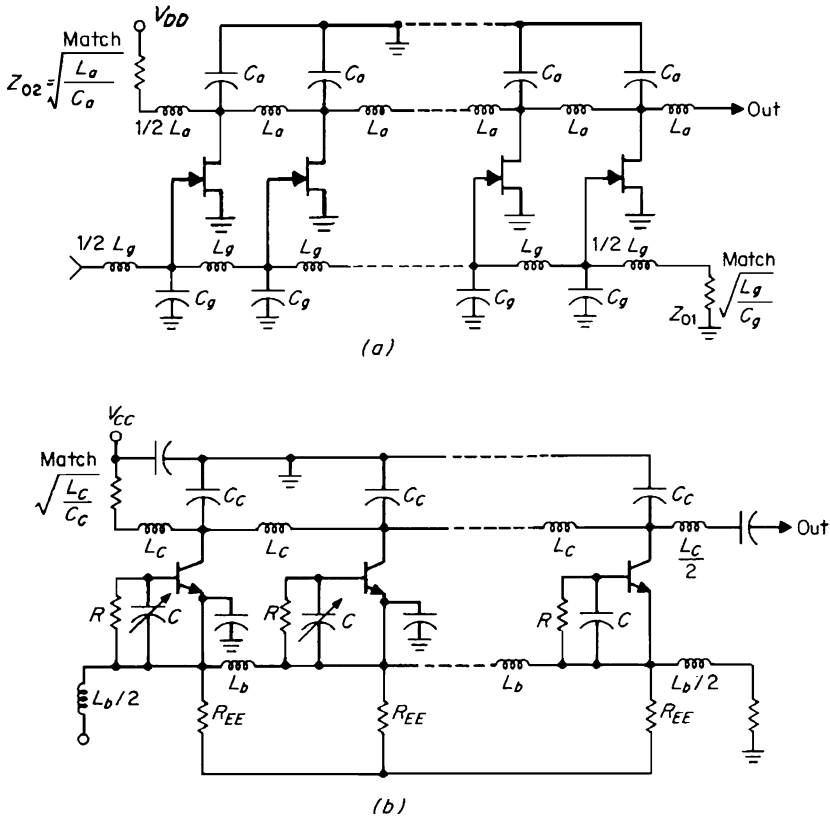

FIGURE 11.3.18 Distributed amplifier circuits: (a) FET version; (b) bipolar transistor version.

The characteristic impedances and cutoff frequencies are given as

$$Z_{01} = \sqrt{L_g/C_g} \quad Z_{02} = \sqrt{L_a/C_a}$$

$$f_{c1} = \pi/\sqrt{L_g C_g} \quad f_{c2} = \pi/\sqrt{L_a C_a}$$

There does not seem to be an optimum choice for Z_{02} ; a device with a high figure of merit is simply chosen, and the rest follows. There is, however, an optimum way in which N devices can be grouped, namely, in m identical cascaded stages, each with n devices, so that N is a minimum for a given overall gain A . N is a minimum when $m = \ln A$. Consequently, the optimum gain per stage $G = e = 2.72$.

Various techniques are utilized to determine the characteristics of the lumped transmission lines. Constant- K and m -derived filter sections are most common, augmented by several compensation circuit variations. The latter include paired gate-drain (base-collector), bridged-T, and resistive loading connections. The constant- K lumped line has several limitations, including the fact that the termination is not a constant resistance and that impedance increases with frequency and time delay also changes with frequency.

m -derived terminating half sections and time-delay equalizing sections result in a frequency-amplitude response that is quite flat at very high frequencies.

The effects of input loading and/or line loss modify the gain expression to

$$G = \frac{2(GB)}{f_c} \frac{e^{-a}(1 - e^{-n\infty})}{1 - e^{-\infty}}$$

where $\infty =$ the real part of propagation constant γ and

$$GB = \frac{g_m}{2\pi C_{\text{eff}}} \Big|_{\text{FET}}$$

The design of distributed amplifiers using bipolar transistors is more difficult because of the low input impedance. In addition, the intrinsic gain of the transistor (β or α) is a decreasing function of frequency.

The simplest approach in overcoming this problem is to connect a parallel RC in series with the base, as shown in Fig. 11.3.18*b*. By setting $RC = \beta_0/2\pi f_T$, the gain is made essentially independent of frequency up to about $f_T/2$, with an overall voltage gain of

$$A_v = (n\beta_0 Z_0/2R)^m$$

where m is the number of stages and n is the number of transistors per stage.

The increasing impedance of the constant- K line helps keep the frequency response flat, compensating for the increased loading of the bipolar transistor.

Another bipolar transistor approach involves the division of the frequency range into three regions to account for the losses. Each region is associated with a linear- Q variation with frequency of the transistor input-output circuits, approximated by shunt RC elements.

$$Q_{\text{in}} = w(C_{\text{in}} + C)/(G_{\text{in}} + G_k)$$

The lossless voltage gain is

$$A_L = f_T Z_0 / \{2f [1 - (f/f_c)^2]^{1/2}\}$$

In region I, the input impedance is high and the transistor supplies high voltage gain. In regions II and III, the voltage gains are given by

$$A_{\text{II}} = A_L n \frac{1 - nK_{\text{II}} Z_0 (f/f_c)^2}{4r_b' [1 - (f/f_c)^2]^{1/2}} \quad A_{\text{III}} = A_L n \frac{1 - nK_{\text{III}} Z_0}{4r_b' [1 - (f/f_c)^2]^{1/2}}$$

where $K_{\text{II}} = (f_c/f_Q)^2$

$$K_{\text{III}} = 1$$

$f_Q =$ frequency of min Q

Broadband Matching Circuits

Broadband impedance transformation interstage-coupling matching can be achieved with balun transformers, quarter-wave transmission-line sections, lumped reactances in configurations other than discussed above, and short lengths of transmission lines.

Balun Transformers. In conventional coupling transformers, the interwinding capacitance resonates with the leakage inductance, producing a loss peak. This limits the high-frequency response. A solution is to use transmission-line transformers in which the turns are arranged physically to include the interwinding capacitance as a component of the characteristic impedance of a transmission line. With this technique, bandwidths of hundreds of megahertz can be achieved. Good coupling can be realized without resonances, leading to the use of these transformers in power dividers, couplers, hybrids, and so forth.

Typically, the lines take the form of twisted wire pairs, although coaxial lines can also be used. In some configurations, the length of the line determines the upper cutoff frequency. The low-frequency limit is determined by the primary inductance. The larger the core permeability the fewer the turns required for a given low-frequency response. Ferrite toroids have been found to be satisfactory with widely varying core-material

characteristics. The decreasing permeability with increasing frequency is offset by the increasing reactance of the wire itself, causing a wide-band, flat-frequency response.

Quarter-Wave Transformers. The quarter-wavelength line transformer is another well-known element. It is simply a transmission line one-quarter wavelength long, with a characteristic impedance

$$Z_{\text{line}} = \sqrt{Z_{\text{in}}Z_{\text{out}}}$$

where Z_{in} and Z_{out} are the terminating impedances. The insertion loss of this line section is

$$10 \log \left[1 + \frac{(r-1)^2}{4r} \cos^2 \theta \right] \quad (\text{dB})$$

FIGURE 11.3.19 Bandwidth of a quarter-wave matching transformer.

where $r = Z_{\text{in}}/Z_{\text{out}}$ and $\theta = 2\pi L/\lambda = 90^\circ$ at f_0 .

Figure 11.3.19 shows the bandwidth performance of the quarter-wave line for several matching ratios. Such lines may be cascaded to achieve broader-band matching by reducing the matching ratio required of each individual section.

Lumped and Pseudo-Lumped Transformations. The familiar lumped-element ladder network, depending on the element values and realization, approximates a short-step transmission-line transformer or a tapered transmission line.

Feedback and Gain Compensation

Feedback. The bandwidth of amplifiers can be increased by the application of inverse feedback. A multiplicity of feedback combinations and analysis techniques are available and extensively treated in the literature. In addition, the related concept of feedforward has been investigated and successfully implemented. Figure 11.3.20 shows four feedback arrangements and formulas describing their performance. A major consideration, particularly for rf applications, is the control of impedance and loop-delay characteristics to ensure stability.

Gain Compensation. The power gain of a bipolar transistor amplifier typically falls 6 dB/octave with increasing frequency above the f_β value. The gain can be leveled (bandwidth-widened) by exact matching of the source impedance to the device at the upper frequency only, causing increasing mismatch with decreasing frequency and the associated gain loss. The overall flat gain is the value at the high best-match frequency. Sufficient resistive loss is usually required in this interstage to prevent instabilities in either driver or driven stage because of the mismatch unloading.

Power-Combining Amplifiers

Many circuit techniques have been developed to obtain relatively high output powers with given modest-power devices. Two approaches are the direct-paralleling and hybrid splitting-combining techniques. The direct-paralleling approach is limited by device-to-device variations and the difficulties in providing balanced conditions because of the physical wavelength restrictions. A technique commonly used at UHF and microwave frequencies to obtain multioctave response incorporates matched stages driven from hybrid couplers in a balanced configuration. The coupler offers a constant-source impedance (equal to the driving-port

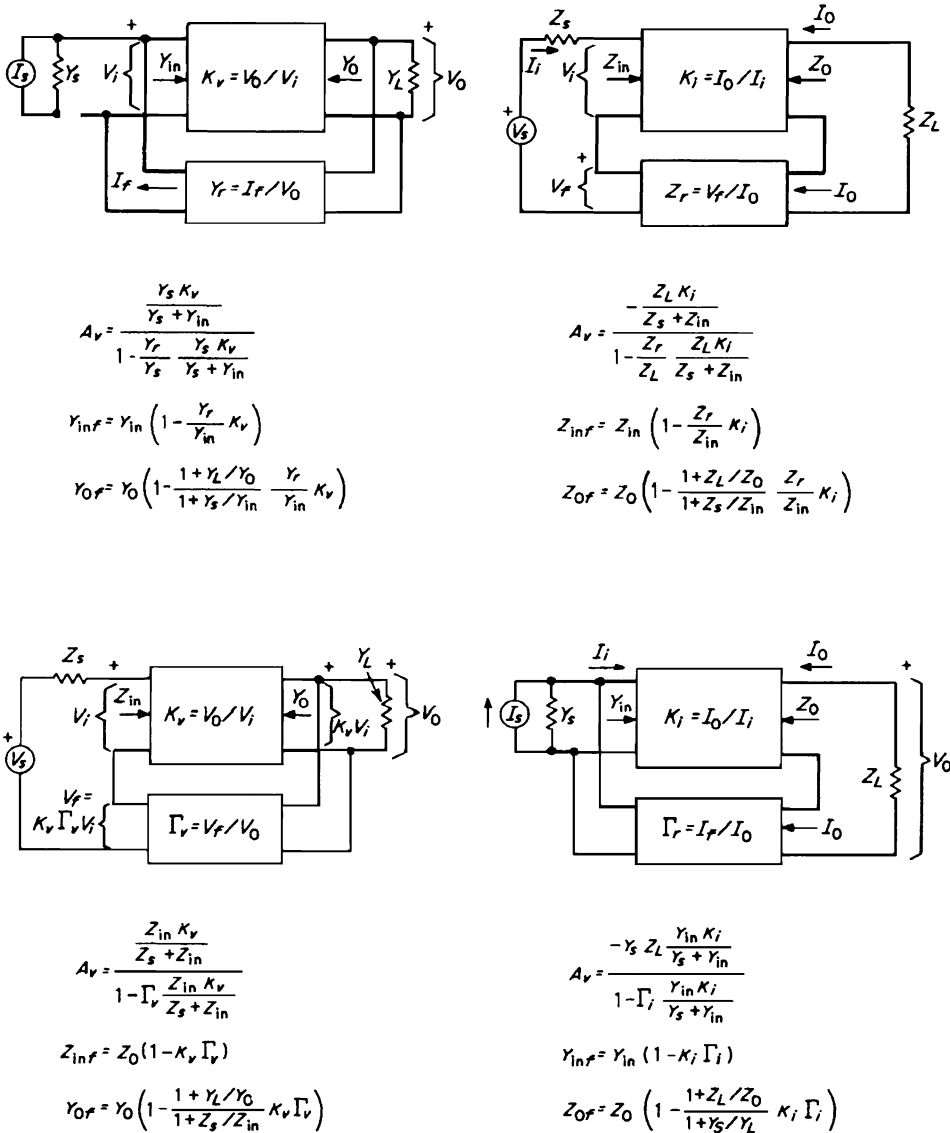

FIGURE 11.3.20 Four methods of applying feedback, showing influence on gain and input and output immittances (From Hakim "Junction Transistor Circuit Analysis," by permission of John Wiley & Sons, New York).

impedance) to the two stages connected to its output ports. Power reflected because of the identical mismatches is coupled to the difference port of the hybrid and dissipated in the idler load. The hybrid splitting-combining approach has proved quite effective in implementing high-output-level requirements (e.g., kilowatts at 1.4 GHz with bipolar transistors).

The hybrid splitting-combining approach enhances circuit operation. In particular, quadrature hybrids affect a voltage standing wave ratio (VSWR)-canceling phenomenon that results in extremely well-matched

FIGURE 11.3.21 Wide-band combining techniques: (a) wide-band quarter-wave coupler; (b) balanced combining amplifier configuration.

power-amplifier inputs and outputs that can be broadbanded on proper selection of particular hybrid trees. Also, the excellent isolation between devices makes reliable power-amplifier service possible.

Several hybrid-directional-coupler configurations are possible, including the split-T, branch-line, magic-T, backward-wave, and lumped. Important factors in the choice of hybrid for this application are coupling bandwidth, isolation, fabrication ease, and form. The equiamplitude, quadrature-phase, reverse-coupled transverse electromagnetic wave (TEM) $\lambda/4$ coupler is a particularly attractive implementation owing to its bandwidth and amenability to strip-transmission-line circuits. Figure 11.3.21 illustrates this coupler type. Other commonly used broadband microstrip hybrids include the Wilkinson and the Lange couplers.

Integrated Amplifiers

As broadband amplifier designs are extended into microwave frequencies, package parasitics begin to limit high-frequency performance. A hybrid integrated circuit (HIC) has transmission paths and passive components formed together on a low-loss substrate by etching and deposition techniques. Active devices, and some discrete passive components, are then connected to the substrate transmission paths by beam-leading, soldering, or wire bonding. The active devices may be chips, packaged devices, or chips mounted on carriers. HICs show improved high-frequency performance because of minimal lead lengths, and transmission lines which provide impedance matching.

The monolithic microwave integrated circuit (MMIC) includes all active devices, as well as passive components and interconnections, in the deposition process, which may require several steps. The elimination of wire bonds and package parasitics can result in multioctave bandwidths at microwave and even millimeter wave frequencies.

Monolithic circuits have been implemented using silicon bipolar technology at frequencies below 4 GHz. Because gallium arsenide metal-semiconductor field-effect transistor (MESFET) performance is superior at high frequencies, MMICs are usually designed on GaAs.

Generally, only 5 percent of a monolithic chip is used for active devices. As device yields are low and processing costs are high, the monolithic approach is expensive. Currently it is economical only when very high quantities are needed or when multioctave bandwidth or millimeter wave frequency operation is required, beyond what can be achieved with an HIC.

TUNNEL-DIODE AMPLIFIERS

Chang S. Kim

Introduction

Tunnel-diode (TD) amplifiers are one-port negative-conductive devices. Hence the problems associated with them are quite different from those encountered in conventional amplifier design. Circuit stabilization and isolation between input and output terminals are primary concerns in using this very wide-frequency-range device.

Although there are several possible amplifier configurations, the following discussion is limited to the most practical design, which uses a circulator for signal isolation. The advantage of the circulator-coupled form of tunnel-diode amplifier resides in the fact that it is thereby possible to convert a bilateral one-port amplifier into an ideal unilateral two-port amplifier. Tunnel diodes can provide amplification at microwave frequencies with a relatively simple structure and at a low noise figure.

Tunnel Diodes

Three kinds of tunnel diodes are available, namely, those using Ge, GaAs, and GaSb. V - I characteristics and corresponding small-signal conductance-voltage relationships are shown in Figs. 11.3.22 and 11.3.23, respectively. A typical small-signal tunnel-diode equivalent circuit is shown in Fig. 11.3.24. Here g_j , C_j , r_s , L , and C_p are the small-signal conductance, junction capacitance, series resistance, series inductance, and shunt capacitance, respectively. Noise generators e_s and i_j are included for subsequent discussion.

FIGURE 11.3.22 Characteristics of tunnel diodes.

FIGURE 11.3.23 Voltage-vs.- g_j characteristics of tunnel diodes of Fig. 11.3.22.

FIGURE 11.3.24 Small-signal equivalent circuit of tunnel-diode amplifier.

Stability

The stability criteria are derived from the immittance expression across the diode terminals and are quite complicated.

Using the short-circuit stable condition, the stability criteria can be simplified considerably. With reference to Fig. 11.3.24, with the external circuit connected, the total admittance Y_T across g_j can be expressed as

$$Y_T(s) = Y_i(s) - g_j = p(s)/q(s)$$

where $Y_i(s)$, the admittance facing g_j , is a positive real function. Since Y_i is connected in parallel with a short-circuit stable device with negative conductance g_j , Y_T is short-circuit-stable. This implies that, since $q(s)$ is always a Hurwitz polynomial, the stability condition is that $p(s)$ must also be Hurwitz polynomial.

A simple graphical interpretation of this stability condition is as follows. The plot* of $Y_T(\omega)$ can be obtained from the plot of $Y_i(\omega)$ by shifting the imaginary axis by $|g_j|$ along the real axis, as shown in Fig. 11.3.25. Since $q(s)$ has no roots in the right half plane, any encirclement of the origin of $Y_T(\omega)$ must come from the right-half-plane roots of $p(s)$ only. Therefore, the circuit will be stable if and only if $Y_T(\omega)$ does not encircle the origin (Fig. 11.3.25a). If g_j becomes large so that the origin is encircled by $Y_T(\omega)$ (Fig. 11.3.25b), the circuit is unstable.

Tunnel-Diode-Amplifier Design

A simplified block diagram of a circulator-coupled TD amplifier is shown in Fig. 11.3.26. The three basic circuit parts are the tunnel diode, the stabilizing circuit, and the tuning circuit, which includes a four-port circulator. The following conditions are imposed on the amplifier design:

1. In the band
 - a. $G_i = \text{Re } Y_i$ is slightly larger than $|g_j|$.
 - b. G_i is contributed by the tuning circuit only.
 - c. $B_i = \text{Im } Y_i = 0$ at the center frequency f_0 and small in the band.
2. Outside the band
 - a. $G_i = \text{Re } Y_i$ is larger than $|g_j|$
 - b. If $G_i \leq |g_j|$, B_j should not be zero.

To satisfy these conditions, a stabilizing circuit, shown in Fig. 11.3.26, is required. This circuit is designed so that the following relationships are satisfied:

$$Y_1(f_0) = Y_1(3f_0) = Y_2(f_0) = 0 \quad Y_1(2f_0) = Y_1(4f_0) = Y_2(3f_0) = 1/R \quad Y_s = Y_1 + Y_2$$

where f_0 is the center frequency.

*Here, the plot of $Y_T(\omega)$ represents the case of $Z_e(\omega)$ short-circuited; however, similar plots can be obtained for more general cases.

FIGURE 11.3.25 Representative plots of real and imaginary parts of Y_T : (a) stable condition; (b) unstable condition.

The equivalent circuit of Fig. 11.3.24 can be transformed into the parallel equivalent circuit of Fig. 11.3.27. The following identities relate the parameters of Figs. 11.3.24 and 11.3.27:

$$g_{jp} = 1/|Z_s|^2 g_j X \quad g_{sp} = r_s/|Z_s|^2$$

$$B = \omega C_p - \frac{\omega L - (1-1/X)1/\omega C_j}{|Z_s|^2} \quad \text{where } X = 1 + \omega^2 c_j^2 / g_j^2$$

$$|Z_s|^2 = \gamma_s - 1/|g_j| X + [\omega L - (1-1/X)1/\omega C_j]^2$$

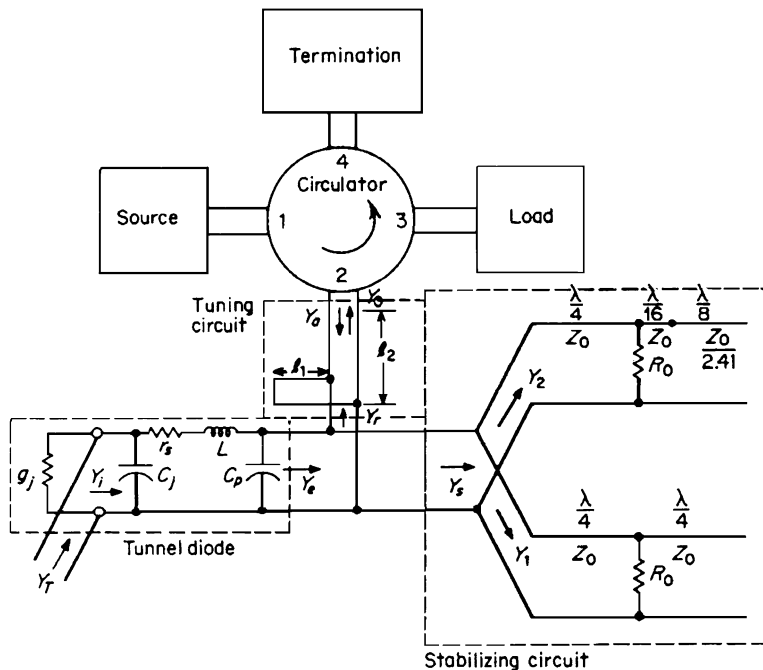

FIGURE 11.3.26 Tunnel-diode amplifier using circulator.

FIGURE 11.3.27 Parallel version of equivalent circuit of Fig. 11.3.24.

The gain can be expressed by

$$|\Gamma|^2 = \left| \frac{Y_e - Y_d}{Y_e + Y_d} \right|^2 \quad |\Gamma|_{f=f_0}^2 = \left| \frac{G_e - g_{sp} + |g_{jp}|}{G_e + g_{sp} - |g_{jp}|} \right|^2$$

where $B_e - B = 0$ at $f = f_0$, in which B_e is the reactive part of Y_e .

In this case, the tuning circuit is a more general matching circuit using combinations of parallel and series transmission lines. It should be noted that $|\Gamma|$ becomes 1, or $g_{sp} = |g_{jp}|$, as the operating frequency increases to f_r , the resistive cutoff frequency, which is defined by

$$f_r = \frac{|g_j|}{2\pi C} \sqrt{1 - \frac{1}{r_s |g_j|}}$$

It is desirable to have a device with f_r several times (at least three) larger than f_0 . Furthermore, it is desirable to make the self-resonance frequency f_x ,

$$f_x = \frac{1}{2\pi} \sqrt{\frac{1}{LC_j} - \left(\frac{g_j}{C_j}\right)^2}$$

as high as possible (higher than f_c) to improve the stability margin.

The gain expression can be modified to include the input amplifier admittance Y_a of Fig. 11.3.26 as follows:

$$|\Gamma|^2 = \left| \frac{Y_0 - Y_a}{Y_0 + Y_a} \right|^2$$

Similarly, the bandwidth can be determined from the expression for Γ^2 and f_x , above.

Typical germanium tunnel-diode parameters pertinent to S-, C-, and X-band amplifiers with approximate gains to 10 dB are shown in Table 11.3.2.

Noise Figure in TD Amplifiers

A noise equivalent circuit can be completed by inserting a current generator, $\overline{i_j^2}$ and a voltage generator $\overline{e_s^2}$, as shown in Fig. 11.3.24 (dotted lines). The mean-square values are determined from

$$\overline{i_j^2} = 2eI_{eq}\Delta f \quad \overline{e_s^2} = 2KTr_s\Delta f$$

where I_{eq} = equivalent shot-noise current = I_{dc} = dc current in negative-conductance region.

TABLE 11.3.2 Typical Germanium Tunnel-Diode Parameters

	S band	C band	X band
$ r_j = 1/g_j, \Omega$	70	70	70
C_j, pF	<1	<0.5	<0.2
L, H	<0.1	<0.1	<0.2
r_s, Ω	<0.1 r_j	<0.1 r_j	<0.1 r_j

The noise equivalent circuit of Fig. 11.3.24 can be transformed into a parallel-equivalent circuit of Fig. 11.3.27 having current generators $\overline{i_{jp}^2}$ and $\overline{i_{sp}^2}$ (dotted lines); $\overline{i_{jp}^2}$ and $\overline{i_{sp}^2}$ can be derived from the two equivalent circuits to be

$$\overline{i_{jp}^2} = 4KT(G_{eq} / |g_j|) |g_{jp}| \Delta f \quad \overline{i_{sp}^2} = 4KTg_{sp} \Delta f$$

where $G_{eq} = eI_{eq} / 2KT = 20I_{eq}$ at room temperature.

Tunnel diodes provide good noise performance with a relatively simple amplifier structure requiring only a dc source for bias. It is therefore a useful low-noise, small-signal amplifier for microwave applications.

PARAMETRIC AMPLIFIERS

Conrad E. Nelson

Introduction

The term *parametric amplifier* (paramp) refers to an amplifier (with or without frequency conversion) using a nonlinear or time-varying reactance. Development of low-loss variable-capacitance (varactor) diodes resulted in the development of varactor-diode parametric amplifiers with low noise figure in the microwave frequency region. Types of paramps include one-port, two-port (traveling-wave), degenerate (pump frequency twice the signal frequency), nondegenerate, multiple pumps, and multiple idlers. The most widely used amplifier is the nondegenerate one-port paramp with a circulator, because it achieves very good noise figures without undue circuit complexity.

One-Port Paramp with Circulator

The one-port paramp with circulator is illustrated in Fig. 11.3.28, and the simplified circuit diagram is shown in Fig. 11.3.29. The input signal and the amplified output signal (at the same frequency) are separated by the circulator. The cw pump source is coupled to a back-biased varactor to drive the nonlinear junction capacitance at the pump frequency. The signal and pump currents mix in the nonlinear varactor to produce voltages at many frequencies. The additional (idler) filter allows only the difference or idler current to flow at the idler frequency; i.e.,

$$f_i = f_p - f_s$$

FIGURE 11.3.28 One-port parametric amplifier and circulator.

The idler current remixes with the pump current to produce the signal frequency again. The phasing of this signal due to nonlinear reactance mixing is such that the original incident signal is reinforced (i.e., amplified) and reflected back to the circulator. The one-port paramp at band center is essentially a negative-resistance device at the signal frequency.

FIGURE 11.3.29 Circuit of one-port paramp using single-tuned resonators.

Power Gain and Impedance Effects

The one-port paramp power gain at the signal frequency is

$$G = \left| \frac{Z_{in} - R_g}{Z_{in} + R_g} \right|^2$$

where R_g is the signal-circuit equivalent generator resistance and Z_{in} is the input impedance at the signal frequency.

For a single-tuned signal circuit and a single-tuned idler circuit the input impedance at the signal frequency is

$$Z_{in} = \beta_s R_d + jX_s - \frac{\sigma \beta_s \beta_i R_d^2}{\beta_i R_d - jX_i} \quad \text{where } \sigma = \frac{m_1^2 f_c^2}{\beta_s \beta_i f_s f_i}$$

The diode loss resistance R_d has been modified at the signal and idler frequencies to include circuit losses (that is, $\beta \geq 1$). The signal and idler reactances are X_s and X_i , respectively, and must include the varactor junction capacitance. (In the simplified circuit the diode package capacitance has been neglected.) For a fully pumped varactor the cutoff frequency is

$$f_c = 1/2\pi R_d C_R$$

where C_R is the junction capacitance at reverse breakdown. The modulation ratio m_1 for an abrupt-junction diode is 0.25.

Bandwidth and Noise

Factors that determine the overall paramp bandwidth include the varactor characteristics (cutoff frequency, junction and package capacitance, and lead inductance), choice of idler (pump) frequency, the nature of the signal and idler resonant circuits and the choice of band-center gain. Multiple-tuned signal and idler circuits are often used to increase the overall paramp bandwidth.

At band center the effective noise temperature of the one-port paramp (due to the diode and circuit loss resistances at the signal and idler frequencies) is

$$T_e = T_d \frac{G-1}{G} \left(\frac{f_p}{f_i} \frac{\sigma}{\sigma-1} - 1 \right)$$

where T_d is the temperature of varactor junction and loss resistances. The effective noise temperature can be reduced by cooling the paramp below room temperature and/or by proper choice of pump frequency. Circulator losses must be included when determining the overall paramp noise figure.

Pump Power

The pump power required at the diode to fully drive a single varactor is

$$P_p = k_1 \beta_p R_d [\omega_p C_R (\phi - V_R)]^2 \quad (\text{watts})$$

where the pump circuit loss resistance and diode resistance = $\beta_p R_d$, and $k_1 = 0.5$ for an abrupt-junction varactor.

Gain and Phase Stability

The stability of the cw pump source (amplitude and frequency) is a significant factor in the overall paramp gain and phase stability. For small pump-power changes an approximate expression for the paramp power-gain variation is

$$\frac{\Delta G}{G} \approx \frac{G-1}{\sqrt{G}} \frac{\Delta P_p}{P_p}$$

Environmental temperature changes often require a temperature-regulated enclosure for the paramp and pump source.

At low levels of nonlinear distortion, the amplifier third-order relative power intermodulation product at band center is a function of the one-port amplifier gain and the incident signal power level; i.e.,

$$\Delta(\text{IMP}) \propto \frac{(G-1)^4 P_s^2}{G} \approx G^3 P_s^2 \approx G P_{\text{out}}^2$$

Thus low-band-center amplifier gains reduce this nonlinear distortion.

MASER AMPLIFIERS

Gunter K. Wessel

Introduction

A *maser* is a microwave active device whose name is an acronym derived from microwave amplification by stimulated emission of radiation. A *laser* is an amplifier or oscillator also based on stimulated emission but operating in the optical part of the spectrum. The expressions microwave, millimeter, submillimeter, infrared, optical, and ultraviolet maser are also in common use. Here the word maser is used for the whole frequency range of devices, the *m* standing for molecular.

A description of the laser principle, some of its properties and means of achieving laser operations, is given in Sec. 9.

In these devices, no tubes or transistors are employed in the radiation process, but the properties of atoms or molecules—as gases, liquids, or solids—serve for the amplification of the signals. Oscillators require the addition of a feedback mechanism. The interaction of the electromagnetic radiation with the maser material occurs in a suitable cavity or resonance structure. This structure often serves the additional purpose of generating a desired phase relationship between different spatial parts of the signal. The application of external energy, required for the amplification or oscillation process, is referred to as *pumping*. The pumping power consists, in many cases, of external electromagnetic radiation of a different frequency (usually higher) from that for the signal.

Microwave masers are used as low-noise preamplifiers and as time and frequency standards. The stimulated emission properties of atoms and molecules at optical frequencies, with their relatively high noise content, make the laser more useful for high-power light amplification and oscillation.

Maser Principles

In the processes of emission and absorption, atoms or molecules interact with electromagnetic radiation. It is assumed that the atoms possess either sharp internal-energy states or broader energy bands. A change of internal energy from one state to another is accompanied by absorption or emission of electromagnetic radiation, depending on the direction of the process. The difference in energy from the original to the final state is proportional to the frequency of the radiation, the proportionality constant being Planck's constant h .

The processes of the spontaneous emission and absorption were defined by Einstein.

Spontaneous emission:

$$-\frac{dN_2}{dt} = A_{21}N_2 \quad (1)$$

Absorption:

$$-\frac{dN_1}{dt} = B_{12}\mu(\nu_{12}, T)N_1 \quad (2)$$

where N_1 and N_2 are population densities of atoms or molecules of material having energy states E_1 and E_2 and an energy separation $E_2 - E_1 = h\nu_{12}$ between them, and A_{21} and B_{12} are the Einstein coefficients.

At high temperature, an inconsistency in the equilibrium system arises unless a second emission process, stimulated emission, takes place. The rate of stimulated emission is defined very similarly to that of absorption (the stimulated emission is sometimes called *negative absorption*):

$$-\frac{dN_2}{dt} = B_{21}\mu(\nu_{12}, T)N_2 \quad (3)$$

In temperature equilibrium, the rates of emission must be equal to the rate of absorption

$$A_{21}N_2 + B_{21}\mu N_2 = B_{12}\mu N_1 \quad (4)$$

Assuming that the ratio of the population densities is equal to the Boltzmann factor,*

$$N_1/N_2 = \exp(h\nu_{12}/kT) \quad (5)$$

Equation (4) yields, for the radiation density,

$$\mu(\nu_{12}, T) = \frac{A_{21}/B_{21}}{B_{12}/B_{21}\exp(h\nu_{12}/kT) - 1} \quad (6)$$

Equation (6) is identical with Planck's radiation law if we set

$$B_{12} = B_{21} \quad (7a)$$

and

$$A_{21}/B_{21} = 8\pi h\nu_{12}^3/c^3 \quad (7b)$$

where c is the velocity of light.

Equation (7a) shows the close relationship between stimulated emission and absorption. The rates of population decrease, for these two processes [Eqs. (2) and (3)] depend only on their respective population densities.

*It is assumed that the statistical weights are equal to 1.

Neglecting the spontaneous emission, the net absorption or the net stimulated emission of an incoming radiation depends, therefore, only on the difference in population density: for absorption, if $(N_1 - N_2) > 0$; for amplification, if $(N_1 - N_2) < 0$. In particular, if a system is in quasiequilibrium such that the upper energy state E_2 is more populated than the lower one, E_1 , it is capable of amplifying electromagnetic radiation.

To create and maintain the quasiequilibrium requires application of external energy since the natural equilibrium has the opposite population excess ($N_1 > N_2$). Different masers differ widely in the methods of how to accomplish the reverse in population density.

Properties of Masers

The properties of masers can be understood by analyzing Eqs. (1) to (7b), as follows.

Signal-to-Noise Ratio. From Eqs. (1) and (3) it follows that the Einstein coefficients A and B have different dimensions but the ratio $B_{21}\mu/A_{21}$ is dimensionless. Here μ is proportional to the strength of the incoming signal and $B_{21}\mu$ is proportional to the amplified signal strength. A_{21} is proportional to the noise contribution because of spontaneous emission. After rewriting Eq. (7b),

$$B_{21}\mu/A_{21} = c^3\mu/8\pi h\nu_{12}^3 \quad (8)$$

the ratio is found to be proportional to the signal-to-noise ratio of the amplifier. It thus becomes clear that the noise contribution (thermal or Johnson noise) is very small at microwave frequencies, whereas it becomes very large at optical frequencies (an increase of 15 orders of magnitude for an increase of 5 orders for the frequency). Microwave masers are therefore very useful as low-noise microwave preamplifiers.

Infrared, optical, and ultraviolet masers (lasers), on the other hand, are commonly used for power amplification and as powerful light sources (oscillators). The high content of spontaneous-emission noise does not make them easily applicable for low-noise amplification or sensitive detection of light, except in a few special cases.

Linearity and Line Width

The proportionality between the incoming signal strength, the radiation density μ , and the amplified signal strength means that a maser is a linear amplifier as long as it is not driven into saturation. The latter occurs when the excess population becomes $N_2 - N_1 \approx N_2$.

Line Width. In the absence of a strong interaction of the individual atoms of the material, either with the environment or with each other, the line width is determined by the average length of time of interaction of an atom with the radiation field. However, if regeneration because of feedback is taking place, the line width may be much narrower because of the following effect. It is assumed that the incoming radiation has a frequency distribution, as shown in Fig. 11.3.30. The amplified signal is proportional to the rate of stimulated emission dN_2/dt . According

FIGURE 11.3.30 Frequency distribution of radiation incoming to maser.

to Eq. (3), the latter is proportional to $\mu(\nu_{12})$. Thus the center portions of the line will be more amplified than the wings, leading to increasingly narrower line widths. In an oscillator the final width is ultimately limited by statistical fluctuations because of the quantum nature of the radiation.

The narrow line width coupled with the low-noise property of a microwave maser makes the latter useful as a time and frequency standard device. To reduce interaction, gases are used as microwave maser materials.

In low-noise microwave amplifiers one is usually interested in a relatively large bandwidth (typically 50 MHz or more). For such amplifier solid-state materials are used, with strong spin-spin interactions of atoms (for example, Cr^{3+} in ruby).

Tuning

Solid-state microwave masers can be tuned over a wide range of frequencies by adjustment of an external magnetic field, while the relative tuning range by a magnetic field is smaller by a factor of 10^{-4} to 10^{-5} in optical masers. Generally, in lasers, one has to depend on fixed frequencies wherever a suitable spectral line occurs in the material; however, modern liquid-dye lasers can be tuned over a relatively wide range in the visible spectrum.

Power Output

The power output owing to stimulated emission depends on the number of excess atoms ($N_2 - N_1$) available for the transition. Assuming p to be the probability of a transition per second, the power output is given by

$$P = (N_2 - N_1)h\nu_{12}p \quad (9)$$

Equation (9) shows that the power output of a microwave gas maser must be very low (for example, 100 to 1 pW) because the population density and the frequency are small. On the other hand, solid-state lasers and some gas lasers with very high efficiencies may have cw power outputs of 1000 W and more.

Coherence

The similarity between absorption and stimulated emission [as expressed in Eqs. (2), (3), and (7a)] means that the stimulated emission is a coherent process. In practice, this means that a beam of radiation will be amplified only in the direction of propagation of the incoming beam and when all atoms participate coherently in the amplification. This is very different from the noise-producing spontaneous emission, where the radiation is emitted isotropically and no phase relationship exists between the radiation coming from different atoms.

The coherence of the stimulated emission enables one to produce coherent light and radiation patterns similar to those which are well known and applied in the radio and microwave parts of the spectrum. In particular, it is possible by a suitable geometry of the device to produce a plane-parallel light beam whose divergence angle is limited only by diffraction. The divergence angle is given by

$$\alpha \approx \lambda/d \quad (10)$$

Time and Frequency Standards

The ammonia and hydrogen atomic-beam masers are used as time and frequency standards with operating frequencies of about 24 GHz and about 1.4 GHz, respectively. The reverse of population difference is achieved by focusing atoms in the excited state into a suitable microwave cavity, whereas the atoms in the lower state are defocused by a special focuser and do not reach the interior of the cavity. The microwave field in the cavity causes stimulated emission and amplification. If the cavity losses can be overcome, oscillations will set in. Time and frequency accuracy of 1 part in 10^{12} or higher can be obtained with modern maser standard devices.

Three- and Four-Level Devices

In many of the masers of all frequency regions, population reverse is obtained by a *three-level-maser* method first described by Bloembergen. Radiation from an external power source at the pumping frequency ν_p (Fig. 11.3.31) is applied to the material. E_3 may be a band to make the pumping more economical. The material is contained in a suitable cavity, a slow-wave structure, or other resonance structure which is resonant at the signal frequency ν_s . Under favorable conditions of the pumping power, the frequency ratio ν_s/ν_p , and the involved relaxation times, an excess population in the excited state E_2 over the ground state E_1 can be obtained. The interaction with the electromagnetic field of frequency ν_s causes stimulated emission. Thus amplification (and if required, oscillation) is produced.

FIGURE 11.3.31 Three-level maser.

FIGURE 11.3.32 Four-level maser.

The four-level maser (Fig. 11.3.32) has the additional advantage that the population of the ground state does not have to be reduced to less than 50 percent of its original equilibrium value and the level E_4 can remain a relatively wide band. The transfer of energy from E_4 to E_1 , and E_2 to E_1 , is by spontaneous decay or some other means like spin-lattice relaxation. Most solid-state microwave and optical masers are of the three- or four-level variety.

Semiconductor Lasers

Stimulated light emission can be obtained by carrier injection in certain semiconductor materials. Upon application of an external dc potential, recombination light emission can take place at the interface of an n - and p -type semiconductor (for example, Zn and Te in GaAs). The semiconductor laser requires only a very simple power source (a few volts of direct current). However, the laser material has to be cooled to liquid-nitrogen temperature and the power output is relatively low.

Applications

The particular properties of devices based on stimulated emission have resulted in numerous applications which often surpass the capabilities of standard devices. In some instances, e.g., holography, new fields have opened up through the emergence of lasers and masers.

Solid-state microwave preamplifiers for communication, radar, and radio astronomy have by far the best signal-to-noise ratio of all microwave amplifiers. The hydrogen-beam maser is the most accurate of all frequency and time standards.

Lasers have revolutionized the field of optical instrumentation and spectroscopy. They have made possible the new field of nonlinear optics. The laser is or may be used in many applications where large energy densities are required, as in microwelding, medical surgery, or even in cracking rocks in tunnel building. Lasers can be used as communication media where extremely large bandwidths are required. Optical radar, with its high precision owing to the short wavelength, uses lasers as powerful, well-collimated light sources. Their range extends as far as the moon.

ACOUSTIC AMPLIFIERS

Stephen W. Tehon, Y. J. Lin, Wen-Chung. Wang

Acoustoelectric Interaction

The acoustic amplifier stems from the announcement by Hutson, McFee, and White, in 1961, that they had observed a sizable influence on acoustic waves in single crystals of CdS caused by a bias current of charge carriers. CdS is both a semiconductor and piezoelectric crystal, and the interaction was found to involve an

FIGURE 11.3.33 Traveling wave of electric field intensity induced by traveling stress wave.

FIGURE 11.3.34 Normalized gain as a function of bias field.

energy transfer via traveling electric fields generated by acoustic waves, producing, in turn, bunching of the drift carriers. Quantitative analyses showing that either loss or gain in wave propagation could be selected by controlling the drift field were published by White.

Figure 11.3.33 illustrates the nature of the interaction. As an acoustic wave propagates in the crystal its stresses induce a similar pattern of electric field through piezoelectric coupling. Since the coupling is linear, compressive stresses in half the wave induce a forward-directed field, and tensile stresses in the remainder of the wave induce a backward-directed field. Drifting charge carriers tend to bunch at points of zero field to which they are forced by surrounding fields. When a charge carrier loses velocity in bunching, it gives its excess kinetic energy to the acoustic wave; when it gains velocity, it extracts energy from the wave. Therefore the drift field is effective for determining attenuation or amplification in the range near which carriers move at the speed of sound. Figure 11.3.34 illustrates the gain characteristic as a function of drift velocity. At the zero-crossover point, the carrier velocity is just equal to the velocity of propagation for the acoustic wave; the gain ranges from maximum attenuation up to maximum amplification over a relatively small change in bias. Beyond this range of drift velocity, bunching becomes decreasingly effective, and the interaction has less effect on the acoustic wave.

Piezoelectric Materials

Piezoelectricity is the linear, reversible coupling between mechanical and electric energy because of displacement of charges bound in molecular structure. Pressure applied to a piezoelectric material produces a change in observed surface density of charge, and conversely, charge applied over the surfaces produces internal stress and strain. If S is the strain, T the stress, E the electric field intensity, and D the dielectric displacement, the piezoelectric effect at a point in a medium is described by the pair of linear equations

$$S = sT + dE \quad D = dT + \epsilon E$$

where constant s = elastic compliance
 ϵ = permittivity
 d = piezoelectric constant
