Other noise-generating mechanisms often produce $1/f$ noise, examples being base-current noise in transistors and cathode current noise in vacuum tubes. Curiously enough, $1/f$ noise is present in nature in unexpected places, e.g., the speed of ocean currents, the flow of sand in an hourglass, the flow of traffic on Japanese expressways, and the yearly flow of the Nile measured over the last 2,000 years.[9] If you plot the loudness of a piece of classical music versus time, you get a $1/f$ spectrum! No unifying principle has been found for all the $1/f$ noise that seems to be swirling around us, although particular sources can often be identified in each instance.

8.1.4 Burst noise

Not all noise sources are characterized by a Gaussian (or even *smooth*) distribution of amplitudes. Most notorious among the exceptions is *burst noise* (also variously called *popcorn* noise, *bistable* noise, or *random telegraph signal* noise), seen occasionally in semiconductor devices (particularly in parts dating back to the 1970s and earlier). It consists of random jumps between two (usually) voltage levels, taking place on time scales of tens of milliseconds; when played out on a loudspeaker it sounds like the birth throes of popcorn. Figure 8.5 shows a typical waveform, the output of a vintage[10] 741 op-amp wired as a noninverting amplifier with G=100.

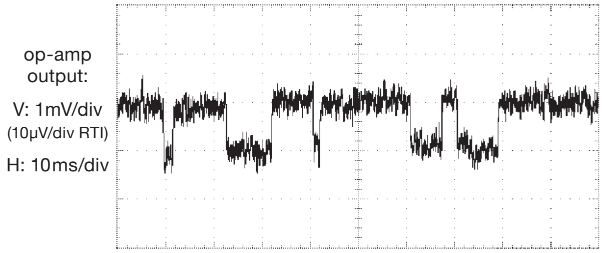

Figure 8.5. Burst noise from a 1973-vintage 741 op-amp, configured as an ×100 noninverting amplifier with grounded input. The output was bandpass filtered to 0.1 Hz–3 kHz, with 6 dB/octave rolloffs.

Viewed in the frequency domain, the effect of burst noise is a raised low frequency portion, without any obvious spectral peaks. You can see this in Figure 8.6, where the voltage noise spectrum of the noisy and quiet op-amp specimens are plotted.[11]

8.1.5 Band-limited noise

All circuits operate within some limited frequency band. So, although it's nice to talk about (and calculate with) noise-*density* quantities, what you usually care about is the rms noise voltage contained within some signal band of interest (called B in eq'n 8.1). In many cases you are dealing with a white noise source (e.g., Johnson noise or shot noise). If that is passed through a perfectly sharp bandpass filter (a "brick-wall" filter), the band-limited rms amplitude is simply $v_{\text{n(rms)}}=e_{\text{n}}\sqrt{B}$. But analog brick-wall filters aren't practical – so what you want to know is the equivalent bandwidth of a real filter, say a simple RC lowpass. It turns out that the equivalent brick-wall bandwidth is given by

$$B = \frac{\pi}{2} f_{3\text{dB}} = 1.57 f_{3\text{dB}} = \frac{1}{4RC} \quad \text{Hz}, \tag{8.9}$$

[9] A delightful reference is W. H. Press, "Flicker noises in astronomy and elsewhere," *Comm. on Astrophys.* **7**, 103–119 (1978). Available at `http://www.nr.com/whp/Flicker_Noise_1978.pdf`.

[10] Semiconductor manufacturers have worked hard to alleviate this problem (believed to be caused by intermittent trapping of charge carriers at defects and interfaces), and popcorn noise is largely a thing of the past. We tested ten samples of 741s, from six different manufacturers, before we found this one. A second sample from the same manufacturer and with the same date code showed no evidence of popcorn noise, as seen in the pair of spectra of Figure 8.6.

[11] It is possible that a related mechanism is responsible for similarly shaped noise plateaus seen in some JFETs; see for example the LSK389 in Figure 8.47.

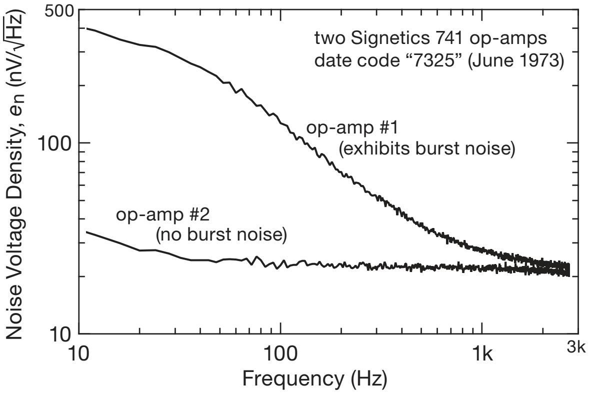

Figure 8.6. Spectrum of the burst noise produced by the same op-amp as used for Figure 8.5, along with that of a second op-amp from the same batch that exhibited no burst noise. The vertical scale shows RTI (referred to the input) rms noise densities.

where $f_{3\text{dB}}=1/2\pi RC$. You can use higher-order filters, of course, for example a 2-pole Butterworth lowpass filter; its equivalent brick-wall bandwidth is $B=1.11f_{3\text{dB}}$. For still higher-order filters (including bandpass) see the expressions in Table 8.4 on page 564. For slowly varying (or dc) signals you can instead do a simple averaging (as, for example, with an integrating ADC, see §13.8.3); in that case the equivalent noise bandwidth is $B=1/2T$, where T is the duration of the (uniform) averaging of the input signal. We’ll have a bit more to say about this in §8.13.1.

Of course, the noise spectrum may be other than white (e.g., it may be $1/f$ noise or a combination of white noise with a $1/f$ rising tail at low frequencies). In such a case you cannot simply multiply the noise density by the square root of the bandwidth. Instead you have to integrate the (changing) noise density over the bandpass. For an ideal brick-wall bandpass that is just $v_\text{n}^2=\int e_\text{n}^2(f)df$ from the lower to upper frequency cutoff of the filter. For a realizable filter you have to integrate the noise density, multiplied by the filter’s spectral response $H(f)$, over the bandpass: $v_\text{n}^2=\int |e_\text{n}(f)H(f)|^2df$. For an arbitrary noise spectrum this is what you would need to do. But life is simpler if you’re dealing with classic noise spectra like $1/f$ flicker noise, in which case the noise integrals can be expressed analytically. We’ve gathered these together in Table 8.4 on page 564, which includes results for white-, pink-, and red-noise spectra, when band limited by brick-wall, single-pole, 2-pole Butterworth, and m-pole Butterworth bandpass filters (response from f_1 to f_2). Those tabulated formulas let you get the results for lowpass ($f_1=0$) or highpass filters ($f_2=\infty$), which are just special cases of the more general bandpass filter.

We discuss this in plenty of detail later in the chapter, at §8.13.

8.1.6 Interference

As we mentioned earlier, an interfering signal or stray pickup constitutes a form of noise. Here the spectrum and amplitude characteristics depend on the interfering signal. For example, 60 Hz powerline pickup has a sharp spectrum and relatively constant amplitude, whereas car ignition noise, lightning, and other impulsive interferences are broad in spectrum and spiky in amplitude. Other sources of interference are radio and television stations (a particularly serious problem near large cities), nearby electrical equipment, motors and elevators, subways, switching regulators, and television sets. Cellphones often dwarf all other sources of RF interference. Even when not in use, the cellphone transmits periodically to tell the cell tower its location, generating interference with a distinctive galloping rhythm.[12] The same goes for mobile computers that use the cellular network for Internet access.

In a slightly different guise you have the same sort of problem generated by anything that puts a signal into the parameter you are measuring. For example, an optical interferometer is susceptible to vibration, and a sensitive RF measurement (e.g., nuclear magnetic resonance, NMR or MRI) can be affected by ambient RF. Many circuits, as well as detectors and even cables, are sensitive to vibration and sound; they are *microphonic*, in the terminology of the trade.

Many of these noise sources can be controlled by careful shielding and filtering, as we discuss later in the chapter. At other times we are forced to take Draconian measures, involving massive stone tables (for vibration isolation), constant-temperature rooms, anechoic chambers, and electrically shielded (“Faraday cage”) rooms.

8.2 Signal-to-noise ratio and noise figure

Before getting into the details of amplifier noise and low-noise design, we need to define a few terms that are often used to describe amplifier performance. These involve ratios of noise voltages, measured at the same place in the circuit. It is conventional to refer noise voltages to the input of an amplifier (although the measurements are usually made at the output), i.e., to describe source noise and amplifier noise in terms of microvolts *at the input* that would

[12] Which you can hear at `www.covingtoninnovations.com/michael/blog/0506/050622-cellnoise.mp3`.

generate the observed output noise. This makes sense when you want to think of the relative noise added by the amplifier to a given signal, independent of amplifier gain; it's also realistic, because most of the amplifier noise is usually contributed by the input stage. Unless we state otherwise, noise voltages are referred to the input (RTI).

8.2.1 Noise power density and bandwidth

In the preceding examples of Johnson noise and shot noise, the noise voltage you measure depends both on the measurement bandwidth B (i.e., how much noise you see depends on how fast you look) and on the variables (R and I) of the noise source itself. So it's convenient to talk about an rms noise-voltage "density" e_n:

$$\upsilon_\text{n(rms)} = e_\text{n}B^{\frac{1}{2}} = (4kTR)^{\frac{1}{2}}B^{\frac{1}{2}} \quad \text{Vrms}, \tag{8.10}$$

where υ_n is the rms noise voltage you would measure in a bandwidth B. White-noise sources have an e_n that doesn't depend on frequency, whereas pink noise, for instance, has a e_n that drops off at 3 dB/octave. You'll often see e_n^2, too, the mean squared noise density. Since e_n always refers to rms and e_n^2 always refers to mean square, you can just square e_n to get e_n^2! Sounds simple (and it is), but we want to make sure you don't get confused.

Note that B and the square root of B keep popping up. Thus, for example, for Johnson noise from a resistor R,

$$\begin{aligned}
e_\text{nR}(\text{rms}) &= (4kTR)^{\frac{1}{2}} && && \text{V/Hz}^{\frac{1}{2}},\\
e_\text{nR}^2 &= 4kTR && && \text{V}^2/\text{Hz},\\
\upsilon_\text{n(rms)} &= \upsilon_\text{nR}B^{\frac{1}{2}} && = (4kTRB)^{\frac{1}{2}} && \text{V},\\
\upsilon_\text{n}^2 &= \upsilon_\text{nR}^2 B && = 4kTRB && \text{V}^2.
\end{aligned}$$

On datasheets you may see graphs of e_n or e_n^2, with units like "nanovolts per root Hz" or "volts squared per Hz." The quantities e_n and i_n that will soon appear work just the same way.

When you add two signals that are uncorrelated (two noise signals, or noise plus a real signal), you add their noise *power*; that is, their *squared* amplitudes add:

$$\upsilon = (\upsilon_\text{s}^2 + \upsilon_\text{n}^2)^{\frac{1}{2}},$$

where υ is the rms signal obtained by adding together a signal of rms amplitude υ_s and a noise signal of rms amplitude υ_n. The rms amplitudes[13] *do not* add.

8.2.2 Signal-to-noise ratio

Signal-to-noise ratio (SNR) is simply defined as

$$\text{SNR} = 10\log_{10}(\upsilon_\text{s}^2/\upsilon_\text{n}^2) = 20\log_{10}(\upsilon_\text{s}/\upsilon_\text{n}) \quad \text{dB} \tag{8.11}$$

where the voltages are rms values, and some bandwidth and center frequency are specified; i.e., it is the ratio, in decibels, of the rms voltage of the desired signal to the rms voltage of the noise that is also present.[14] The "signal" itself may be sinusoidal, or a modulated information-carrying waveform, or even a noiselike signal itself. It is particularly important to specify the bandwidth if the signal has some sort of narrowband spectrum, because the SNR will decrease as the bandwidth is increased beyond that of the signal: the amplifier keeps adding noise power, while the signal power remains constant.

8.2.3 Noise figure

Any real signal source or measuring device generates noise because of Johnson noise in its source resistance (the real part of its complex source impedance). There may be additional noise, of course, from other causes. The *noise figure* (NF) of an amplifier is simply the ratio, in decibels, of the output of the real amplifier to the output of a "perfect" (noiseless) amplifier of the same gain, with a resistor of value R_s connected across the amplifier's input terminals in each case. That is, the Johnson noise of R_s is the "input signal":

$$\text{NF} = 10\log_{10}\left(\frac{4kTR_\text{s} + \upsilon_\text{n}^2}{4kTR_\text{s}}\right) \tag{8.12}$$

$$= 10\log_{10}\left(1 + \frac{\upsilon_\text{n}^2}{4kTR_\text{s}}\right) \quad \text{dB}, \tag{8.13}$$

where υ_n^2 is the mean squared noise voltage per hertz contributed by the amplifier, with a noiseless (cold) resistor of value R_s connected across its input. This latter restriction is important, as you will see shortly, because the noise voltage contributed by an amplifier depends very much on the source impedance (Figure 8.7).

Noise figure is handy as a figure of merit for an amplifier when you have a signal source of a given source impedance and want to compare amplifiers (or transistors, for which the NF is often specified). The NF varies with frequency

[13] Which, we emphasize, are the convenient and familiar quantites found on datasheets, etc. For example, we're used to thinking of a 3 nV/$\sqrt{\text{Hz}}$ amplifier as quiet; it's hard to recognize a 0.9×10^{-17} V^2/Hz amplifier as the same thing.

[14] The expression in terms of squared amplitudes suggests a ratio in terms of *power*, which is the origin of the decibel ratio definition. But the "20log$_{10}$" form is widely used, even when there is no actual power, for example with an open-circuit load (or, more confusingly, when the result is at odds with the actual power ratio, for example when expressing the ratio of amplitudes created by a signal transformer).

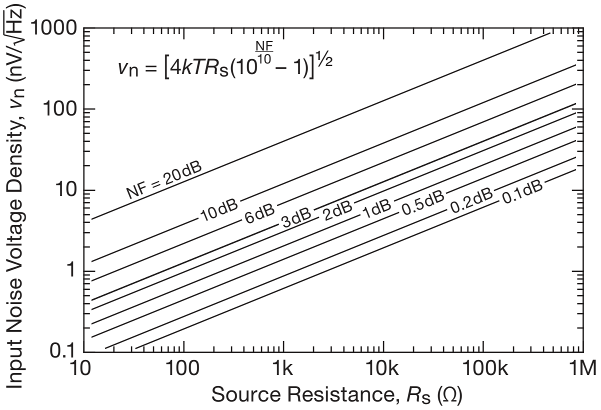

Figure 8.7. Effective input-noise-voltage density versus noise figure and source resistance.

and source impedance, and it is often given as a set of contours of constant NF versus frequency and R_s(we'll see examples later, in Figures 8.22 and 8.27). It may also be given as a set of graphs of NF versus frequency, one curve for each collector current, or a similar set of graphs of NF versus R_s, one for each collector current. *Note*: the foregoing expressions for NF assume that the amplifier's input impedance is much larger than the source impedance, i.e., $Z_{in} \gg R_s$. However, in the special case of RF amplifiers, you usually have $R_s = Z_{in} = 50\,\Omega$, with the NF defined accordingly. For this special case of matched impedances, simply remove the factor "4" from eq'ns 8.12 and 8.13.

Big fallacy: don't try to improve things by adding a resistor in series with a signal source to reach a region of minimum NF. All you're doing is making the source noisier to make the amplifier look better! Noise figure can be very deceptive for this reason. To add to the deception, the NF specification (e.g., NF = 2 dB) for a transistor or FET will always be for the optimum combination of R_s and I_C. It doesn't tell you much about actual performance, except that the manufacturer thinks the noise figure is worth bragging about.

In general, when evaluating the performance of some amplifier, you're probably least likely to get confused if you stick with a SNR calculated for that source voltage and impedance. Here's how to convert from NF to SNR:

$$\mathrm{SNR} = 10\log_{10}\left(\frac{v_s^2}{4kTR_s}\right) - \mathrm{NF(dB)(at}\ R_s) \quad \mathrm{dB}, \qquad (8.14)$$

where v_s is the rms signal amplitude, R_s is the source impedance, and NF is the noise figure of the amplifier for source impedance R_s. See §§8.3.1 and 8.5.6 for some noise figure calculation examples.

8.2.4 Noise temperature

Rather than noise *figure*, you sometimes see noise *temperature* used to express the noise performance of an amplifier. Both methods give the same information, namely the excess noise contribution of the amplifier when driven by a signal source of impedance R_s; they are equivalent ways of expressing the same thing.

Look at Figure 8.8 to see how noise temperature works: we first imagine the actual (noisy) amplifier connected to a *noiseless* source of impedance R_s (Figure 8.8A). If you have trouble imagining a noiseless source, think of a resistor of value R_s cooled to absolute zero. There will be some noise at the output, even though the source is noiseless, because the amplifier has noise. Now imagine constructing Figure 8.8B, where we magically make the amplifier noiseless and bring the source R_s up to some temperature T_n such that *the output noise voltage is the same as in Figure 8.8A*. T_n is called the noise temperature of the amplifier, for source impedance R_s.

As we remarked earlier, noise figure and noise temperature are simply different ways of conveying the same information. In fact, you can show that they are related by the following expressions:

$$T_n = T\left(10^{\mathrm{NF(dB)}/10} - 1\right) \quad \mathrm{Kelvin}, \qquad (8.15)$$

$$\mathrm{NF(dB)} = 10\log_{10}\left(\frac{T_n}{T} + 1\right), \qquad (8.16)$$

where T is the ambient temperature, usually taken as 293°K.

Generally speaking, good low-noise amplifiers have noise temperatures far below room temperature (or,

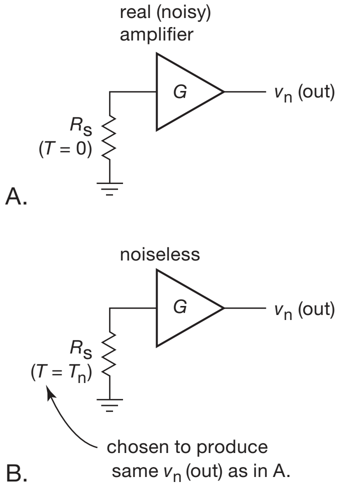

Figure 8.8. Noise temperature.

equivalently, they have noise figures far less than 3 dB). Later in the chapter we explain how you go about measuring the noise figure (or temperature) of an amplifier. First, however, we need to understand noise in transistors and the techniques of low-noise design. We hope the discussion that follows will clarify what is often a murky subject.

8.3 Bipolar transistor amplifier noise

The noise generated by an amplifier is easily described by a simple noise model that is accurate enough for most purposes. In Figure 8.9, e_n and i_n represent the transistor's internal noise, modeled as a noise voltage e_n in series with the input, combined with a noise current i_n injected at the input. The transistor symbol itself (or amplifier, in general) is assumed noiseless, and it simply amplifies the input-noise voltage it sees (caused by its own e_n, combined with its i_n flowing through the input signal's source impedance R_s). That is, the amplifier contributes a total noise voltage e_a, referred to the input, of

$$e_a(\text{rms}) = [e_n^2 + (R_s i_n)^2]^{\frac{1}{2}} \qquad \text{V/Hz}^{\frac{1}{2}}. \tag{8.17}$$

The two terms are simply the squared values of the amplifier input-noise voltage, and the noise voltage generated by the amplifier's input noise current passing through the source resistance.[15] Because the two noise terms are usually uncorrelated, their squared amplitudes add to produce the effective noise voltage seen by the amplifier. For low source resistances the noise voltage e_n dominates, whereas for high source impedances the noise current i_n generally dominates.

Just to get an idea of what these look like, look at Figure 8.10, which shows a graph of e_n and i_n versus I_C and f for the excellent (but, sadly, discontinued[16]) low-noise *npn* 2SD786. We go into some detail now, describing these and showing how to design for minimum noise. It is worth noting that voltage noise and current noise for a bipolar transistor are in the range of nanovolts and picoamps per root hertz (i.e., $\text{nV}/\sqrt{\text{Hz}}$ and $\text{pA}/\sqrt{\text{Hz}}$); for FETs the current noise is lower, down in the $\text{fA}/\sqrt{\text{Hz}}$ range.

8.3.1 Voltage noise, e_n

The equivalent voltage noise looking in series with the base of a bipolar transistor arises from collector-current shot noise generating a noise voltage across the intrinsic emitter resistance[17] r_e, Johnson noise generated in the base resistance $r_{bb'}$, and (as we'll see later) base current shot noise through that resistance. Deferring for the moment the base current term (which most often does not contribute significantly to a BJT's voltage noise), the input noise voltage density looks like this:

$$e_n^2 = 2qI_C r_e^2 + 4kTr_{bb'} \tag{8.18}$$

$$= 4kT\left(\frac{V_T}{2I_C} + r_{bb'}\right) \tag{8.19}$$

$$= 4kT\left(\frac{r_e}{2} + r_{bb'}\right) \quad \text{V}^2/\text{Hz}, \tag{8.20}$$

where we've eliminated r_e in the second form (eq'n 8.19) and I_C in the third form (eq'n 8.20) by remembering that $r_e = V_T/I_C = kT/qI_C$.

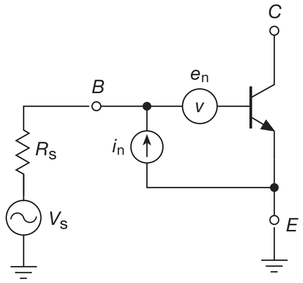

Figure 8.9. Noise model of a transistor.

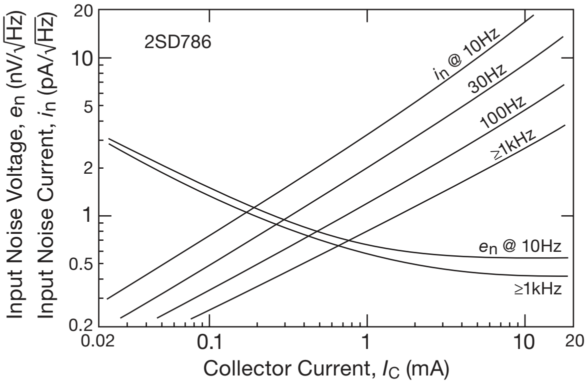

Figure 8.10. Equivalent rms input noise voltage (e_n) and noise current (i_n) versus collector current for a 2SD786 *npn* transistor, adapted from the datasheet.

[15] An additional term, important at higher frequencies or when i_n is small, is the noise current i_n generated by e_n in combination with the input capacitance: $i_n = e_n \omega C_{in}$. See §§8.11.3 and *4x.3.4*.

[16] The 2SD786 was for many years the standard to which low-noise transistors aspired. We feature it here because it is well characterized, with a wealth of information and excellent noise performance. Our nomination for its successor is the ZTX851 (with ZTX951 *pnp* complement), characterized and used in numerous examples later in the chapter.

[17] Properly speaking, there is no "resistance" r_e; rather, it represents the inverse transconductance of the transistor: $r_e = \upsilon_b/i_c = 1/g_m$ (or the voltage change at the base corresponding to changes in collector current). It's really just a convenient way of speaking. Be careful, though, when thinking of it loosely as a resistor: it is a "noiseless" resistance; that is, it has no Johnson noise.

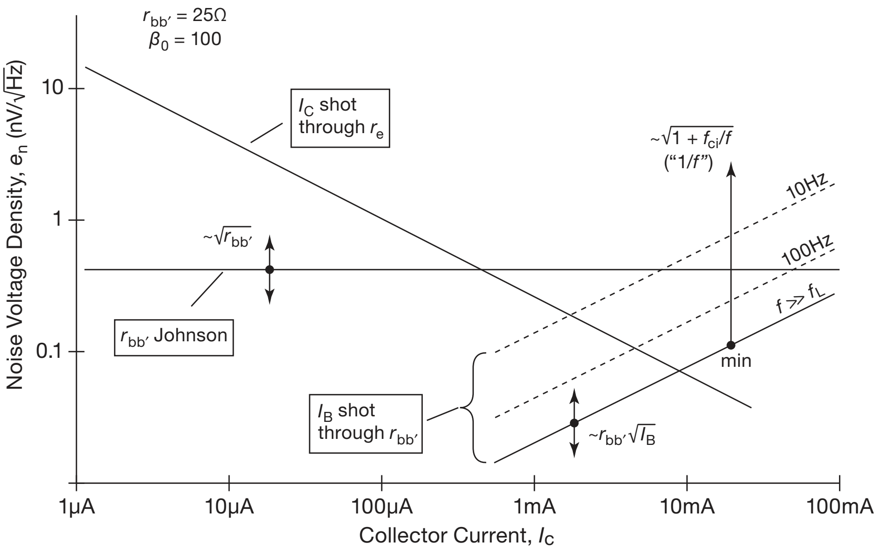

Figure 8.11. Input noise voltage e_n in a BJT. At low currents the shot noise in I_C through r_e dominates; otherwise the Johnson noise in $r_{bb'}$ is the dominant term. However, at low frequencies and high currents, the base-current shot noise through $r_{bb'}$ causes e_n to rise again. These curves assume typical values of flicker-noise breakpoint (f_{ci} ~1 kHz) and base resistance ($r_{bb'}$~25 Ω), with double-sided arrows indicating variation with $r_{bb'}$, and the arrow upward from "min" indicating $1/f$ rise with decreasing frequency.

The third form is handy because it lets you think about the noise voltage as if arising from combining the separate Johnson noise from two resistors. To get a sense of the scale of BJT noise voltage, it's helpful to know that the base resistance $r_{bb'}$ for typical BJTs (see Table 8.1a on page 501) goes from a few ohms to a few hundred ohms; thus the second term's noise voltage contribution is typically in the range of 0.2 nV/$\sqrt{\text{Hz}}$ to 2 nV/$\sqrt{\text{Hz}}$ (we like to remember that a 100 Ω resistor has e_n=1.28 nV/$\sqrt{\text{Hz}}$, and that e_n scales as the square root of R).

As for the first term in eq'n 8.20, it's telling us that the *collector shot-noise current through* r_e *produces the same noise voltage as the Johnson noise of a fictional resistor of value* $R = r_e/2$. For example, in a BJT running at 100 µA (thus r_e=250 Ω) this amounts to $e_n = \sqrt{4kT \cdot 125\,\Omega}$, or 1.4 nV/$\sqrt{\text{Hz}}$. This is a useful thing to know, for example when choosing resistor values so as not to compromise the noise performance of a low-noise amplifier. Lest we leave the wrong impression, we hasten to emphasize again that the intrinsic emitter resistance r_e is *not* a "real" resistor – it does not have Johnson noise; the noise-voltage term we're describing arises solely from the noise voltage generated by collector shot-noise current flowing through a noiseless r_e.[18]

Both voltage-noise terms in eq'ns 8.18 and 8.20 have a flat (white) spectrum, with a Gaussian distribution of instantaneous amplitude. Because r_e falls inversely with collector current, a BJT's e_n falls as $1/\sqrt{I_C}$ with rising collector current, ultimately reaching a minimum that depends on $r_{bb'}$ (Figure 8.11). For this reason it's usually best to run at relatively high collector currents if the objective is to minimize noise voltage; the price you pay is increased base current and increased heating. Taking again the excellent 2SD786 as an example, at frequencies above 1 kHz it has an e_n of 1.5 nV/$\sqrt{\text{Hz}}$ at I_C=100 µA and 0.6 nV/$\sqrt{\text{Hz}}$ at I_C=1 mA (Figure 8.10). This transistor uses special geometry to achieve an unusually low $r_{bb'}$ of 4 Ω, which is needed to realize the lowest values of e_n.

Of course, if you need to operate at a low collector current (where the effect of r_e dominates), it's of no particular benefit to have a low value of $r_{bb'}$. To make this point graphically, we plotted in Figure 8.12 the predicted and measured e_n versus collector current for six low-noise *npn* transistors, using a simple one-parameter model based upon $r_{bb'}$ alone. Selecting a transistor with low $r_{bb'}$ really matters at higher currents, though, which is where you have to operate if you want to achieve e_n values southward of 1 nV/$\sqrt{\text{Hz}}$.[19] We illustrate that point dramatically in §8.5.9, in an input stage with e_n<0.1 nV/$\sqrt{\text{Hz}}$.

The voltage-noise density e_n at 1 kHz, as plotted in

[18] See §8.3.5 for some further discussion of this subtle point.

[19] The effective $r_{bb'}$ is said to increase slightly at low currents. For example, if the 2N5089 excess noise at 10 µA (5.9 nV/$\sqrt{\text{Hz}}$ instead of 4.5 nV/$\sqrt{\text{Hz}}$) is due to $r_{bb'}$, we can calculate that $r_{bb'}$ increased from

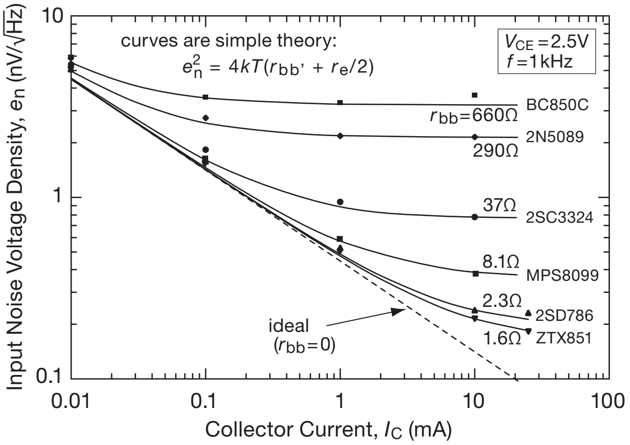

Figure 8.12. A simple model of BJT noise voltage (shot noise current through r_e, combined with Johnson noise of base resistance, solid curves) provides a good first approximation to measured noise values (datapoints at four currents), shown here for six selected low-noise BJTs. The dashed line shows the theoretical minimum noise voltage at current I_C, as given in eq'n 8.18. The measured noise is 10%–20% high at collector currents below 100μA. See Figure 8.17 for the noise spectra of these six BJTs at I_C=10 mA.

Figure 8.12, does not tell the whole story, of course. If you care about the noise at lower frequencies, you have to worry about a component of the transistor's noise that is frequency dependent, usually in the form of a rising $1/f$ flicker-noise tail (characterized by a $1/f$ corner frequency f_c). For BJTs, the $1/f$ noise in their e_n comes from one additional noise term that we've ignored thus far – the noise voltage produced by the base's noise current i_n flowing through the transistor's own $r_{bb'}$, i.e., $e_n{=}i_n r_{bb'}$. This latter term becomes a significant contributor to e_n only at low frequencies and at relatively high collector currents. But it is quite important for another reason: it flows through the input signal's source resistance, generating an additional noise voltage $v_n{=}i_n R_{sig}$. Let's look at the business of input noise current, after which we briefly revisit transistor e_n with this effect included.

8.3.2 Current noise i_n

The transistor's input noise current generates an additional noise voltage across the input signal source impedance. The main source of base-current noise is shot-noise fluctuation in the steady base current,

$$i_n = \sqrt{2qI_B} = \sqrt{2qI_C/\beta_0} \quad \text{A/Hz}^{\frac{1}{2}}, \qquad (8.21)$$

which is Gaussian noise exhibiting a flat frequency spectrum (i.e., white noise); we've used the symbol β_0 here to emphasize that it's the beta *at dc*.

There is in addition a flicker-noise component that rears its ugly head at low frequencies. The latter exhibits the typical $1/f$ frequency dependence, with a corner frequency that we'll call f_{ci}; i.e., it contributes a term $2qI_B f_{ci}/f$ to the overall i_n^2. It rises somewhat more rapidly with I_C, owing to a rising $1/f$ breakpoint, typically with f_{ci} going as $I_B^{1/3}$ to $I_B^{1/4}$. See Figures 8.13 and 8.14. Typical current-noise corner frequencies are $f_{ci}{\sim}$50–300 Hz at 1–10 μA, and 200 Hz–2 kHz at 1 mA.

Note that this simple base-current shot noise is *not* collector-current shot noise divided by beta. If it were, it would be $\sqrt{2qI_C}/\beta_0$ rather than the correct (and larger) $i_n{=}\sqrt{2qI_C}/\sqrt{\beta_0}$ (as given by eq'n 8.21). In fact, to first order the base-current shot noise is uncorrelated with the collector-current shot noise.

However, at high frequencies this is no longer true, leading to one final current-noise term: at frequencies approaching the transistor's f_T (i.e., as the current gain approaches unity) the decreasing beta makes the collector-current's shot noise visible at the base.

Putting these terms together, we have, finally

$$i_n^2 = 2q\frac{I_C}{\beta_0}\left(1+\frac{f_{ci}}{f}\right)+2qI_C\left(\frac{f}{f_T}\right) \quad \text{A}^2/\text{Hz}, \qquad (8.22)$$

where the last term effectively represents a frequency-dependent beta.

Taking the example of the 2SD786 again (Figure 8.10), above 1 kHz i_n is about 0.25 pA/$\sqrt{\text{Hz}}$ at I_C=100 μA and 0.8 pA/$\sqrt{\text{Hz}}$ at I_C=1 mA. The noise current increases and the noise voltage decreases as I_C is increased. In the next subsection (§8.3.3) we see how this dictates operating current in low-noise design. Figure 8.15 shows graphs of i_n versus frequency and current for a pair of low-noise transistors.

Current-noise times input impedance The input-noise current flowing through the input signal's source impedance generates a noise-voltage density of magnitude $v_n{=}i_n Z_s$, which combines (as sum of squares) with the transistor's input noise-voltage density.[20] Usually the source impedance is resistive, in which case you need to

290 Ω at 10 mA to about 900 Ω at 10 μA (threefold over 3 decades), or approximately as $(I_c)^{-1/6}$. (SPICE transistor noise models include a parameter for this effect.)

[20] The primary complicating issues are increases of i_n with temperature, and with decreasing frequency ($1/f$ behavior).

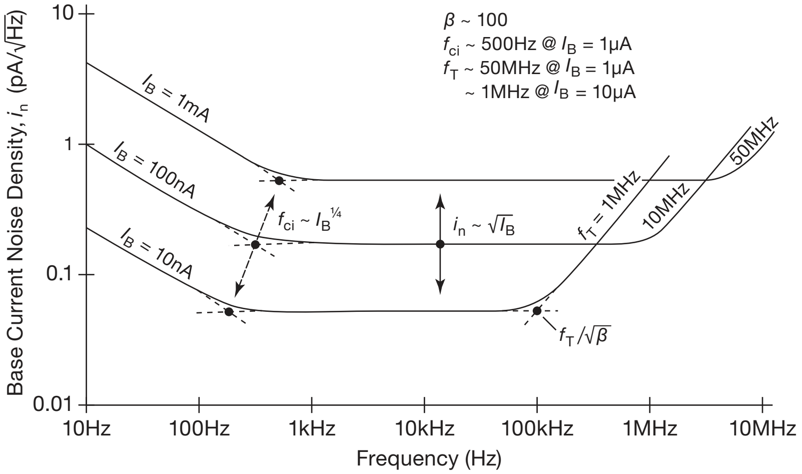

Figure 8.13. Input noise-current density i_n versus frequency in a BJT. At mid-frequencies it is entirely base-current shot noise, proportional to $\sqrt{I_B}$. At low frequencies i_n rises as $1/\sqrt{f}$ (it is the noise *power* that goes as $1/f$); however, the $1/f$ breakpoint (f_{ci}) rises with increasing current, so that at a given low frequency below f_{ci} the noise current rises faster than the square root of base current, as shown. At high frequencies the falling beta ($\beta \rightarrow 1$ at f_T) causes the noise density to rise $\propto f$. These curves assume a typical value of flicker noise breakpoint (f_{ci} ~500 Hz at I_B=1 μA), with the solid arrow indicating variation of i_n with base current, and the dashed arrow indicating variation of $1/f$ breakpoint with base current.

add its Johnson noise as well; in other words, the total input-referred squared noise voltage is

$$v_n^2 = e_n^2 + 4kTR_s + (i_n R_s)^2 \quad \mathrm{V^2/Hz}. \tag{8.23}$$

If the source impedance is *reactive*, however, the current noise contribution (the last term in the equation) will be frequency dependent. A common situation in which this matters is an ac-coupled input signal. If you aren't thinking about noise, you'd normally choose the blocking capacitor value based on the downstream load impedance (transistor input impedance and bias resistor), to set the low-frequency rolloff somewhat below the lowest frequency of interest. That could be a rather small capacitance (if the amplifier has a high input impedance, or if the low-frequency cutoff isn't terribly low), through which the noise current would generate substantial noise voltage (and, of course, increasing proportional to the capacitor's reactance $X_C = 1/2\pi fC$, i.e., proportional to $1/f$).[21]

So, you need to turn the process around: first, choose the capacitor value to keep its noise-voltage contribution $v_n = i_n X_C$ small enough at the lowest frequency of operation (and remember that base-current noise often exhibits a $1/f$ tail); then choose the transistor's input bias resistor value to get the desired low-frequency rolloff. We've been bitten by this issue, surprised by a $1/f$ noise voltage ($1/f$ in *amplitude*, not power) caused by the blocking capacitor's reactance versus frequency. To fix the problem we had to increase the blocking capacitor's value by a factor of 50!

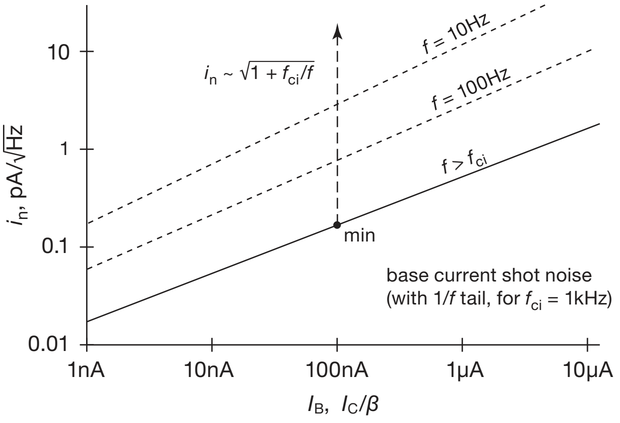

Figure 8.14. Input noise current in a BJT is shot noise, scaling as the square root of base current for frequencies above the $1/f$ corner frequency f_{ci}. At lower frequencies the curve is steeper, because f_{ci} itself rises with increasing current (see Figure 8.15).

8.3.3 BJT voltage noise, revisited

As suggested in §8.3.1, the transistor's input *current* noise i_n can become a significant contributor to the voltage noise e_n seen at its input terminals, owing to the noise voltage

[21] Note that an ideal capacitor (or inductor, for that matter) generates no Johnson noise.

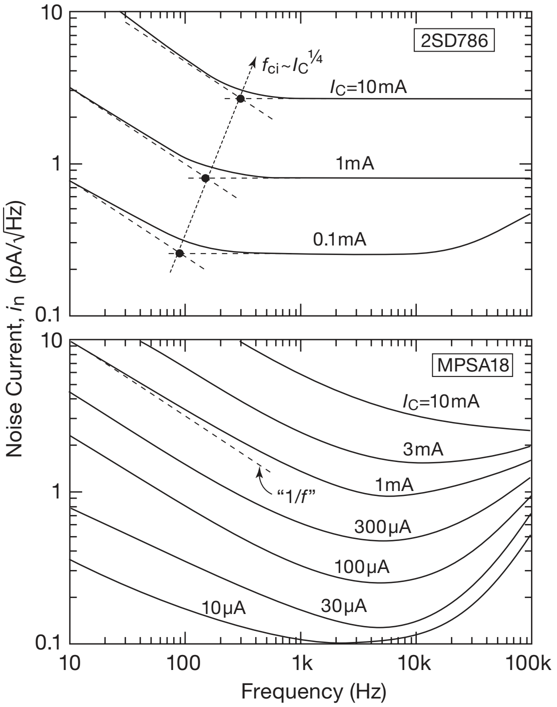

Figure 8.15. Noise current (i_n) versus frequency for two low-noise *npn* transistors. The low-frequency noise current exhibits a somewhat greater rise with collector current, owing to a rising $1/f$ corner frequency.

generated across its internal $r_{bb'}$ by its own input-noise current i_n. Because i_n is shot noise in the dc base current, it increases as the square root of collector current (for constant beta); and, because i_n of a BJT is seriously afflicted by a $1/f$ low-frequency tail, its contribution to the overall e_n is seen primarily (and often *only*) at low frequencies. A more detailed noise model of the bipolar transistor lets us incorporate this effect.

Adding this noise term to our original (incomplete) BJT noise voltage formula, eq'n 8.18, we have

$$e_n^2 = 2qI_C r_e^2 + 4kTr_{bb'} + 2q\frac{I_C}{\beta_0} r_{bb'} \left(1 + \frac{f_{ci}}{f}\right), \ \mathrm{V^2/Hz}, (8.24)$$

where, as before, the first term can be replaced by $2kTr_e$, and, as in eq'n 8.22, the current-noise corner frequency f_{ci} rises approximately as the fourth root of I_C.

To see how this works out, look at Figure 8.16, where we've plotted separately (for three choices of collector current) the e_n from the first two terms (as dashed lines) and the e_n from the third term (as thin solid lines). The thick solid lines represent the total voltage noise, i.e., including all three terms of eq'n 8.24. For these calculated curves we used typical BJT noise parameters (β=200, $r_{bb'}$=50 Ω, f_{ci}=1 kHz at I_C=1 mA).

This shows how the $i_n r_{bb'}$ noise-voltage term competes with the other two e_n noise terms, dominating at high collector current and low frequency. Although the noise-current $1/f$ breakpoint f_{ci} increases only mildly with I_C, its contribution acts to create a rapidly rising noise-*voltage* breakpoint f_c. Compare this with Figure 8.11, where the same effect can be seen: there, however, e_n is plotted versus collector current, with a family of several spot frequencies.

To maintain some perspective here, note that additional noise voltage is evident only at very low frequencies (Figure 8.16 goes down to 0.01 Hz!) and at relatively high current densities. It's not something over which to lose sleep.[22] This can be seen in the measured noise-voltage curves plotted in Figure 8.17, where the effect (at the substantial collector current of 10 mA) is serious above 10 Hz only for BC850 with its unusually high $r_{bb'} \approx 750\,\Omega$. In fact, for transistors with attractively low $r_{bb'}$ the e_n improvement gained from running at high collector current more than compensates for the rise at low frequencies that comes from the base-current shot-noise contribution, as seen in Figure 8.18.

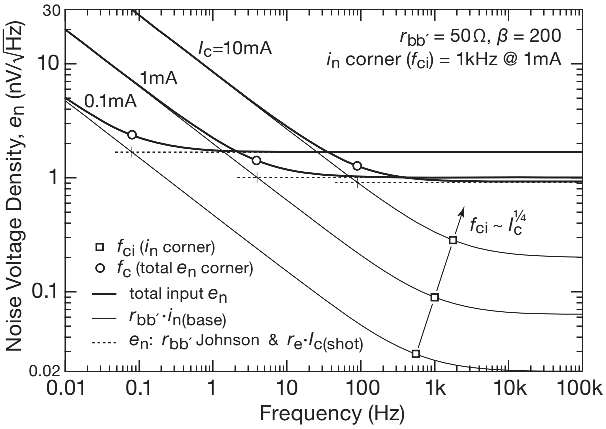

Figure 8.16. BJT noise-voltage density versus frequency (from eq'n 8.24) for a hypothetical transistor with the listed parameters, showing the effect of current noise i_n at low frequencies and high collector currents.

[22] But if you *are* losing sleep over $1/f$ problems in a high-I_C low-noise amplifier, there's a cute trick, namely to stack a pair of transistors so that their $1/f$ noise fluctuations cancel. See Broderson, Chenette, and Jaeger, "A superior low-noise amplifier," 1970 IEEE ISSCC, p 164. Suppression of low-frequency noise by a factor of five is possible. The penalty for using their two-transistor trick is a 3 dB increase in the higher-frequency (white noise) component of e_n.

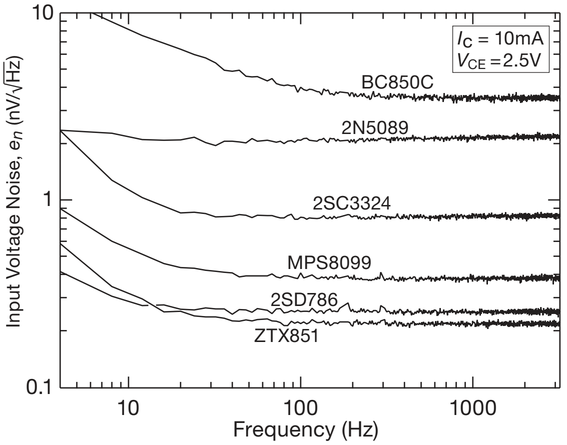

Figure 8.17. Measured input noise-voltage spectra (e_n versus frequency at I_C=10 mA) for the six BJTs of Figure 8.12.

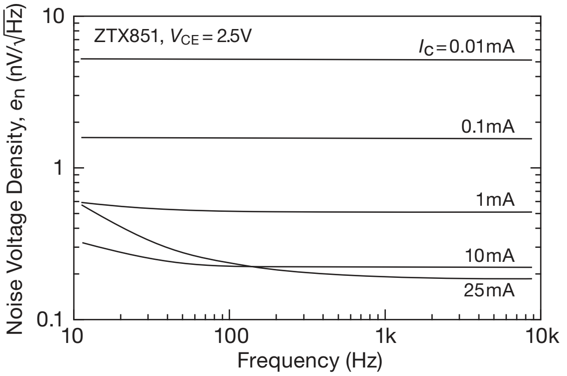

Figure 8.18. Measured input noise-voltage spectra for a ZTX851 at five choices of collector current. Base noise current adds noise voltage at low frequencies and high current, but you're still ahead at collector currents up to 10 mA.

8.3.4 A simple design example: loudspeaker as microphone

Let's put this noise theory into practice by designing a simple and inexpensive ac-coupled audio amplifier that runs on low current from a single +9 V supply (which could be a battery, or a "wall-wart" ac adapter), with input noise of just a few nV/$\sqrt{\text{Hz}}$. If you want to have an application in mind, think about a front-door intercom, where the small loudspeaker also serves reciprocally as a microphone.[23]

To get a handle on the noise specifications, we put a few small "8 Ω" loudspeaker samples on our lab bench, spoke to them in a normal voice, and measured output audio voltages in the range of 30–100 μVrms. Let's aim for a signal-to-noise ratio of 40 dB or better; that translates to an input noise voltage of 0.5 μVrms or less. And let's keep the component cost *really* low – we'll aim for 25¢.

The basic circuit Figure 8.19 shows the circuit, an ac-coupled common-emitter stage (with bypassed emitter resistor) driving an emitter follower. We're not worried about distortion (with output swings in the tens of millivolts, from ∼50 μV input levels), but we want plenty of voltage gain, and bypassing the emitter resistor eliminates it as a noise source. We provisionally chose operating currents of 100 μA, to be revisited (as with any circuit design) after an initial evaluation of the circuit's performance.

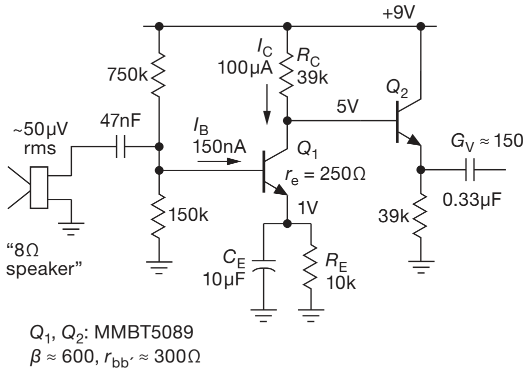

Figure 8.19. Low noise, and even lower cost: a simple audio preamp for running a loudspeaker "backward."

Noise calculation We chose the '5089 for this example because it's widely available (half a million in stock at Mouser and DigiKey, four different manufacturers), it's inexpensive ($0.026 in qty 100), and it promotes itself for low-noise amplifier applications.[24] It has lots of current gain (400 minimum, 600 typical at 100 μA), but it suffers from relatively high base resistance $r_{bb'} \approx 300\,\Omega$.

From eq'n 8.24 it's easy to calculate the various noise voltage density (e_n) contributions (and the reader is encouraged to do so), referred to the input (RTI):

Shot noise of I_C through r_e	$r_e\sqrt{2qI_C}$	1.4 nV/$\sqrt{\text{Hz}}$
Johnson noise in $r_{bb'}$	$\sqrt{4kTr_{bb'}}$	2.2 nV/$\sqrt{\text{Hz}}$
Johnson noise in R_C	$\sqrt{4kTR_C}/G_V$	0.17 nV/$\sqrt{\text{Hz}}$
Shot noise of I_B through $r_{bb'}$	$r_{bb'}\sqrt{2qI_B}$	0.066 nV/$\sqrt{\text{Hz}}$

[23] To those who suspect that "the walls have ears," this may suggest interesting possibilities for surveillance.

[24] For example, ON Semiconductor explicitly calls it a "Low Noise Transistor"; Fairchild and NXP call it a "General Purpose Transistor," but promote it for "low noise, high gain, general purpose amplifier applications" and "low-noise input stages in audio equipment," respectively.

The dominant noise source is Johnson noise in Q_1's internal base resistance, followed by collector shot noise flowing through Q_1's intrinsic emitter resistance r_e of 250Ω at its collector current of 0.1 mA. The last two terms are negligible by comparison: there's plenty of Johnson noise in Q_1's collector resistor, but owing to that stage's voltage gain of ~150 it is an insignificant contribution when referred to the input (RTI). Even smaller is the voltage noise produced by base-current shot noise flowing through $r_{bb'}$. There are other noise possibilities, but they are vanishingly small by comparison: as an example, the Johnson-noise current in the bias divider flowing through the speaker's 8 Ω source impedance generates a noise voltage density of just 0.003 nV/$\sqrt{\text{Hz}}$.

Performance From these noise-voltage *densities* we arrive at the total rms noise voltage over the signal bandwidth: $v_n = e_n\sqrt{\Delta f} = 142$ nVrms, where e_n is the combined noise-voltage density of 2.6 nV/$\sqrt{\text{Hz}}$, and Δf is the audio bandwidth (for which we've used the "telephone bandwidth" of 3 kHz). Compared with the nominal 50 μVrms audio input, that amounts to a signal-to-noise ratio of 51 dB – not bad for the price!

Speaking of which, component cost is a "performance" parameter, of sorts. A quick search of the usual distributors (DigiKey, Mouser, Newark, Future) turned up the following prices (SMT components – chip resistors and capacitors, SOT-23 transistors):

	qty 100	qty 1k
Q_1,Q_2	\$0.026	\$0.023
C_{in}	\$0.032	\$0.012
C_E	\$0.068	\$0.039
C_{out}	\$0.034	\$0.017
resistors	\$0.012	\$0.004
total parts	\$0.246	\$0.134

Variations We exceeded our targets of SNR and cost, so we could leave it at that. But it's always good to review an initial design, looking to improve things. Here the noise budget is dominated by the relatively high base resistance of these "low-noise" transistors. We could improve the noise performance by choosing an input-stage transistor with lower $r_{bb'}$ – look ahead to Table 8.1a on page 501, and at Figure 8.12, to see some candidates. However, once you've driven down the $r_{bb'}$ Johnson noise, the collector shot noise through r_e becomes the dominant term, and you're forced to increase the collector current to reap further improvements in v_n.[25] In fact, as Figure 8.12 shows, down at I_C=100 μA the '5089 is hardly worse (not even a factor of 2) than transistors with the lowest $r_{bb'}$.

Looked at another way, we could instead stick with the inexpensive and widely available MMBT5089, and reduce somewhat the collector current (say, to 50 μA), with very little increase in overall noise: the noise density would increase from 2.6 nV/$\sqrt{\text{Hz}}$ to 3.0 nV/$\sqrt{\text{Hz}}$, which would reduce the audio–band SNR by just 1 dB (from 50.9 dB to 49.8 dB). Certainly worth it, if you're running from a battery.

8.3.5 Shot noise in current sources and emitter followers

We remarked earlier (in §8.1.2) that shot noise is suppressed in the classic BJT current source (redrawn in Figure 8.20A). You might at first think this is obvious, because the collector current is just the emitter current (apart from a small base current contribution), in which shot noise is absent (as it always is in metallic conductors). But at the collector you've got just the sort of barrier in which shot noise is unavoidable.

OK, you might say, perhaps the current source *does* exhibit shot noise, but surely at the emitter terminal you've got a quiet current (and thus an absence of noise voltage) – just look at that resistor!

Paradoxically, that intuition is wrong. It turns out that the current source is "quiet," but the emitter follower's output *does* indeed include a noise voltage just equal to a shot-noise current (calculated from I_C) flowing through r_e, i.e., just the $r_e\sqrt{2qI_C}$ we saw in eq'n 8.24.[26]

It's actually rather easy to test this. Look at Figure 8.20C, where a ~10 μA current source is loaded with a 1 MΩ collector resistor. Absent collector shot noise, we should see only a Johnson-noise voltage density of 181 nV/$\sqrt{\text{Hz}}$ at the collector,[27] to be compared with a noise voltage 10× higher if the collector current has the statutory shot noise $i_n = \sqrt{2qI_C}$. Meanwhile, at the emitter, that shot-noise current, flowing through r_e, would produce a noise-voltage density of 4.8 nV/$\sqrt{\text{Hz}}$; in the absence of emitter shot noise the follower would be quiet (apart from the other sources of BJT noise in eq'n 8.24).

We built circuit C, and... (drumroll)... we measured 190 nV/$\sqrt{\text{Hz}}$ at the collector (consistent with Johnson

[25] To see how far you can take this, visit the "extreme challenge" in §8.5.9.

[26] To which you must of course add the additional terms, Johnson noise and base current shot noise in $r_{bb'}$.

[27] This is $\sqrt{2}$ times the 128 nV/$\sqrt{\text{Hz}}$ Johnson noise of a 1 MΩ resistor. The $\sqrt{2}$ arises because this is a unity-gain inverter, so R_E's Johnson noise contributes an equal uncorrelated noise voltage.

$r_e\, i_n$(shot) = 4.8 nV/√Hz)
to test "quiet follower"

Figure 8.20. Shot noise is suppressed in the transistor current source, A, but not in the emitter follower, B. This is easily confirmed by measuring the noise-voltage density in the test circuit C.

noise alone, i.e., a quiet current source); and we measured $4.93\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ at the emitter (consistent with collector-current shot noise through r_e). Evidently shot noise is suppressed in the current source, but not in the follower. Interesting! And, to test the possibility that collector current *never* exhibits shot noise, we put a bypass capacitor between the base and emitter terminals. The noise voltage at the collector jumped up, to $1679\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$, which agrees well with the shot-noise formula's predicted[28] $1664\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$. How can we understand this?

To get an understanding of this puzzle, it's best to start with what *must* be true and see where it leads. Look at Figure 8.21, as we take it in steps.

1. We know for sure that the emitter current is quiet, because it's the current through a metallic conductor. And any worry we might have that this current could become noisy because of the fluctuations in the transistor's base-to-emitter *voltage* (i.e., input-voltage noise) is easily addressed: we can reduce any such effect (already negligible, because noise variations $v_{n(BE)}$ are down in the microvolts) by as much as we like by simply increasing both R_E and the negative supply voltage proportionally.

2. Somewhere within the transistor there must be a diffusive collector current that is subject to classic uncorrelated charge-flow shot noise, $i_n = \sqrt{2qI_{C(dc)}}$, and over which the transistor has no control.

3. But this is a three-terminal device with negligible base current, so we know that the current flowing into the collector terminal equals the current flowing out of the emitter terminal (in the limit of large beta); and the latter is "quiet."

4. So it must be the case that the controllable portion of the BJT's collector current is fluctuating in just such a way as to cancel the shot noise fluctuations.

For that to be so, the input voltage V_1 to the BJT transconductance model must be such that $g_m V_1 = I_E - i_n$, and so the input noise-voltage portion of V_1 is just

$$e_n = -i_n/g_m \qquad (8.25)$$

which (recall $r_e = 1/g_m$) is the familiar $i_n r_e$ form from eq'n 8.24.

This may seem like a circular argument; but in a real sense this is how this component of the base-to-emitter noise voltage is (and must be) created. This line of reasoning also explains nicely the presence of noise voltage e_n at the emitter of our test circuit (and, of course at the output of an emitter follower, or at the input of a common-emitter amplifier, etc.). And it explains also why bypassing the emitter liberates the full shot noise at the collector of our current source: such a connection invalidates the starting assumption (#1, above) because the capacitor diverts

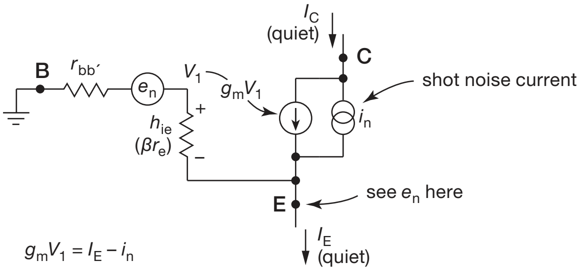

Figure 8.21. Three-terminal simplified "hybrid-π" model of the current-source–follower of Figure 8.20C. The noise voltage e_n reflects the unavoidable internal shot-noise current i_n. If the emitter current is quiet, so will be the resulting collector current I_C.

[28] For this test the collector current was 8.65 μA, constrained by operation from batteries, thus the slightly smaller shot-noise prediction.

entirely the emitter current at signal frequencies. In fact, it creates a grounded-emitter amplifier (rather than a current source or follower), in which the full input-noise voltage as given above (eq'n 8.25) is amplified by the transconductance g_m to produce an output-noise current equal to $g_m e_n$. And that is exactly the full (unsuppressed) shot noise corresponding to the dc collector current I_C (rewind to step #2, above), which is what we measured in our test setup.

A final (and important) point: the shot-noise suppression in the current source requires a quiet emitter current sink, satisfied in this case by a large (compared with r_e) pull-down resistor R_E (here 1M versus 2.5k). But that's not the case for, say, an undegenerated current mirror. This raises the quantitative question, how large must R_E be, to be "large" in this sense?

This is easy enough to figure out: at the emitter we have a noise voltage e_n equivalent to the Johnson noise of a resistor of value $r_e/2$ and with source impedance equal to r_e; i.e., a noise current equivalent to the Johnson-noise current of a resistor of value $2r_e$. This is diluted by the quiet (i.e., shot-noise-free) pull-down resistor R_E, so that the reduction of current noise at the collector is in the ratio $\sqrt{2r_e/R_E}$. For example, at 1 mA collector current we have an impedance seen at the emitter of r_e=25 Ω, with a noise voltage equivalent to that of a 12.5 Ω resistor, or a noise current equivalent to that of a 50 Ω resistor. So a 50 Ω pull-down resistor reduces the noise by 3 dB, and a 4.95 kΩ pulldown reduces it by 20 dB, etc. Stated more generally, the reduction in collector noise current i_n is in the ratio $\sqrt{50\text{mV}/V_{R_E}}$, where V_{R_E} is the dc voltage across the emitter pull-down resistor R_E.

8.4 Finding e*n* *from noise-figure specifications*

Transistor datasheets traditionally provided some tabulated values for e_n, and (often) graphs at selected collector currents of e_n and i_n versus frequency (or e_n and i_n versus collector current at selected frequencies), as we've seen for the 2SD786 and the MPSA18.

That was *then*! Now you see instead tabulations and graphs of noise figure (NF) – see for example the contours of constant NF plotted against I_C and R_s for the low-noise 2SC3324 *npn* bipolar transistor[29] from Toshiba (Figure 8.22).

There's a lot of information in these plots, even though they tell the story only at two frequencies (10 Hz and 1 kHz; it would sure be nice to see a plot of noise parameters versus frequency). Let's see how much we can squeeze out of these two plots.

8.4.1 Step 1: NF versus I_C

We can make a plot of NF versus collector current, for each of a set of source resistances, by simply reading off values along a horizontal line in Figure 8.22. It's helpful to use a spreadsheet program with plotting capabilities such as Microsoft Excel, or (if you want to show off) a more sophisticated mathematical package such as MATLAB® or Mathematica®. Figure 8.23 shows what you get by reading across the 1 kHz plot of Figure 8.22 for six values of source resistance. Here we estimated NF values for half-decade steps of I_C (thus 10 μA, 30 μA, 100 μA, and so on), plotted them in Excel, then smoothed them with Bézier curves in Adobe Illustrator®. Noise-figure values below 1 dB should not be considered reliable, because Figure 8.22 (from which the data were derived) shows no contours below NF=1 dB.[30] The dashed line indicates NF=3 dB, where the noise contributed by the transistor is equal to the Johnson noise in the source resistor.

Before moving on, let's get some intuition about these curves. For low values of R_s the source has low Johnson-noise voltage (e.g., R_s=100 Ω has e_n=1.3 nV/$\sqrt{\text{Hz}}$), quite a bit less than the transistor's input e_n at small collector currents.[31] That's why the noise figure improves with increasing collector current. On the other hand, for large values of R_s the transistor's voltage noise is unimportant compared with the resistor's much larger Johnson noise. But now when we operate at large collector currents the transistor's input *current* noise (base current shot noise: $i_n \approx \sqrt{2qI_B}$) generates a substantial noise voltage across that larger R_s, such that the noise voltage at the input terminal is much larger than Johnson noise alone, hence a large (poor) noise figure.

8.4.2 Step 2: NF versus R_s

Figure 8.24 is an analogous plot, this time however showing NF versus *source resistance* (instead of I_C) for each of

[29] The *pnp* complement is the 2SA1312.

[30] The datasheet lists a value of 0.2 dB (typical) in the tabulated data, at 1 kHz, 100 μA collector current, and 10 kΩ source resistance, a set of conditions that puts you nicely in the "eye" of the contour plot. But the datasheet also lists a worst-case (maximum) value of 3 dB! You'll have to do some cherry picking if you need NF=0.2 dB.

[31] Recall that the latter is approximately collector-current shot noise through r_e: $e_n \approx \sqrt{2qI_C} \cdot (kT/qI_C)$. That's equal to the Johnson noise of a fictitious resistor of value R=$r_e/2$, which is 100 Ω at I_C=125 μA. So the transistor's e_n rises with falling collector current, as $e_n \propto 1/\sqrt{I_C}$.

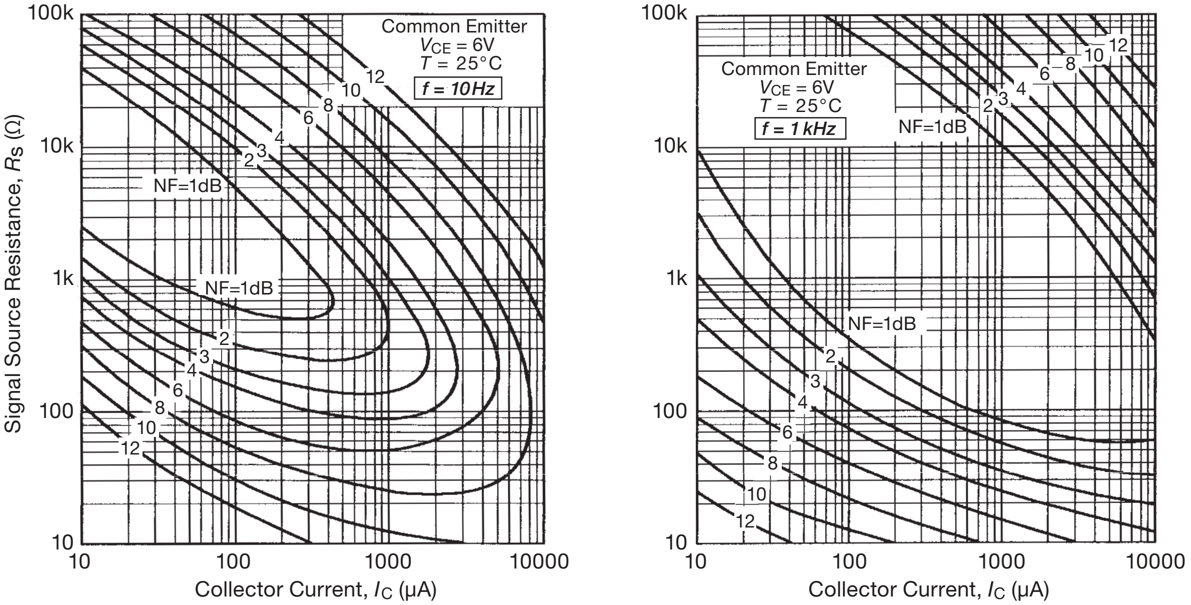

Figure 8.22. Toshiba's datasheet for its low-noise 2SC3324 *npn* transistor does not provide values or graphs for input voltage noise e_n. Instead you get these graphs of noise figure (NF) versus collector current and source resistance.

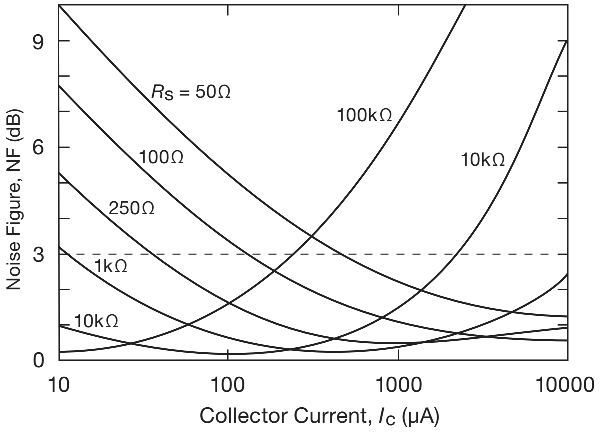

Figure 8.23. 2SC3324 noise figure versus collector current, from the datasheet contour plots shown in Figure 8.22.

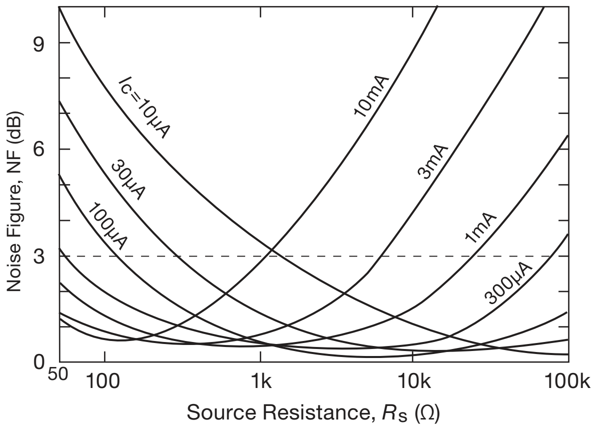

Figure 8.24. 2SC3324 noise figure versus source resistance, from the data of Figure 8.22.

a set of collector currents; it is taken from the same 1 kHz contour curves of Figure 8.22, this time reading off values along vertical lines of constant I_C. It's a useful graph for determining, approximately, the optimum operating current for a signal of a given source impedance.

8.4.3 Step 3: getting to e_n

The previous two graphs (NF versus I_C, NF versus R_s) are simply reorganizations of the manufacturer's 1 kHz noise figure contour plot (Figure 8.22). We didn't need to calculate anything.

That's not the situation with noise voltage, e_n. Here we need to invert the defining equation (eq'n 8.13) for noise figure in order to find e_n:

$$e_n = \sqrt{4kTR_s}\,\sqrt{10^{\mathrm{NF}/10} - 1}. \qquad (8.26)$$

The first term is the signal source resistor's Johnson-noise voltage density, and the second term is the multiplying factor attributable to the transistor's noise contribution, as given by its noise figure. The latter includes contributions from both e_n and i_n; so we must use the NF values for small source resistance so that the contribution from the transistor's i_n is negligible.[32]

Figure 8.25 shows what you get for e_n versus collector current, beginning with the noise-figure values corresponding to R_s=50 Ω (from Figure 8.23 or 8.22). In common with most devices, this transistor exhibits the familiar "flicker-noise" excess below its "$1/f$ noise corner-frequency" (see §8.1.3, and also §5.10.6).

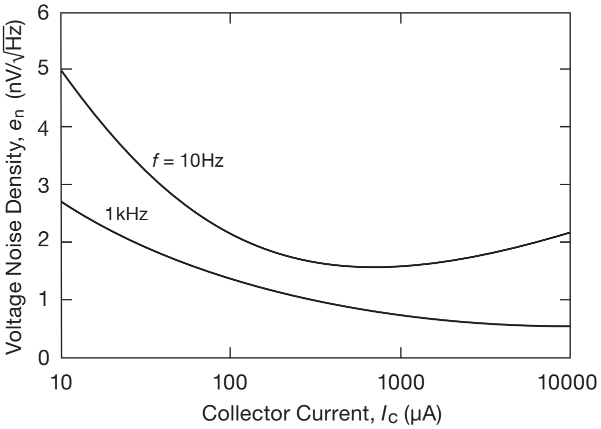

Figure 8.25. 2SC3324 noise voltage versus collector current, derived from the data of Figure 8.22.

8.4.4 Step 4: the spectrum of e_n

We complained earlier about the lack of noise data versus frequency – it's given only for 10 Hz and 1 kHz. But we can fill in the details, on the reasonable assumption that the noise power at low frequencies goes approximately as $1/f$ (that is, $e_n \propto 1/\sqrt{f}$), and that the two datapoints straddle the $1/f$ noise corner-frequency.

To do this, we first find the $1/f$ corner frequency f_c from the e_n values that straddle it. To a good approximation,

$$f_c = f_L \left(\frac{e_{nL}^2}{e_{nH}^2} - 1 \right), \tag{8.27}$$

where e_{nL} is the noise density at a frequency f_L below the corner frequency, and e_{nH} is the noise density well above f_c (see the discussion on page 566). Once we've got f_c, we can find e_n versus frequency:

$$e_n(f) = e_{nH}\sqrt{1+f_c/f}. \tag{8.28}$$

Because the corner frequency depends on collector current, we read off e_{nL} and e_{nH} from Figure 8.25 for each of four decade values of I_C, and then plot the corresponding e_n versus f. Figure 8.26 shows the resulting noise-voltage spectra.

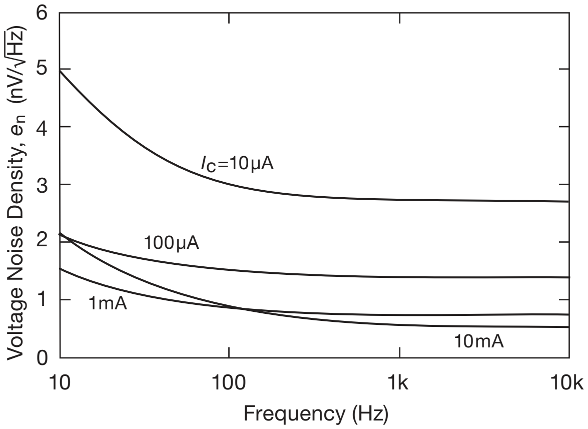

Figure 8.26. 2SC3324 noise voltage versus frequency, deduced from the curves of Figure 8.25.

8.4.5 The spectrum of i_n

By a similar procedure we could extract curves of current noise i_n versus frequency. Above the $1/f$ corner we would see base-current shot noise ($i_n = \sqrt{2qI_b}$), with the characteristic $1/f$ rise at low frequencies.

Once you've gotten plots of e_n and i_n versus frequency, you have all the basic information contained within a noise-figure contour plot. Look ahead to §8.9.1E, and especially Figure 8.58, to see how you can use e_n and i_n to predict the total effective input noise density versus source resistance. The graphic shown in the upper left of that figure shows how to find the breakpoints that separate the e_n-dominated (low-R_s) region, the source Johnson-noise-dominated (mid-R_s) region, and the i_n-dominated (high-R_s) region. We prefer that simpler approach, and we'll be using e_n and i_n extensively in the rest of the chapter.

8.4.6 When operating current is not your choice

Knowing how e_n and i_n vary with collector (or drain) current helps in setting the operating point for optimum noise performance, as we'll see in the next section.

[32] Similarly, we could extract i_n from the NF values for large source resistance, where the transistor's e_n contribution is negligible.

Sometimes, though, the choice has already been made, by person or persons unknown. In such a case you live with what you're given. Figure 8.27 shows an example, with published noise-figure contours for the Stanford Research Systems model SR560 preamplifier (§8.6.4). It's clear from the high input noise resistance (∼200 kΩ) that this is a JFET-input amplifier, and that its noise performance is far from optimum with a source of low impedance: NF=15 dB for R_s=50 Ω(!); compare that with the ∼2 dB noise figure of the 2SC3324 running at I_C=5 mA.

What *not* to do OK, you say, I'll put a 200k resistor in series with the input signal, and, voilà, I'll get a 0.05 dB noise figure.

Don't do that! What you've done is to add lots of noise to the input signal, so that it dominates over the amplifier's noise. An amplifier like this is optimized for high-*Z* signal sources and is far from optimum for 50 Ω systems. What you *can* do, if you insist on using it with a 50 Ω source, is to transform the source impedance upward by a modest factor with a signal transformer, for example a North Hills HB0904 (50 Ω:1200 Ω, with 1 kHz–6 MHz bandpass) or a Mini-Circuits T16-6T-X65 ((50 Ω:800 Ω, with 30 kHz–75 MHz bandpass). This puts you in the ∼3 dB territory of noise figure, quite an improvement over the NF=15 dB you get with a bare 50 Ω source. For more discussion of signal transformers, see §8.10.

8.5 Low-noise design with bipolar transistors

The fact that e_n falls and i_n rises with increasing I_C provides a simple way to optimize transistor operating current to give lowest noise with a given source. Look at the model again (Figure 8.28). The noiseless signal source v_s has added to it an irreducible noise voltage from the Johnson noise of its source resistance:

$$e_R^2(\text{source}) = 4kTR_s \quad (\text{V}^2/\text{Hz}). \tag{8.29}$$

The amplifier adds noise of its own, namely,

$$e_a^2(\text{amplifier}) = e_n^2 + (i_nR_s)^2 \quad (\text{V}^2/\text{Hz}). \tag{8.30}$$

Thus the amplifier's noise voltage is added to the input signal, and, in addition, its noise current generates a noise voltage across the source impedance. These two are uncorrelated (except at very high frequencies), so you add their squares. The idea is to reduce the amplifier's total noise contribution as much as possible. That's easy, once you know R_s, because you just look at a graph of e_n and i_n versus I_C in the region of the signal frequency, picking I_C to minimize $e_n^2 + (i_nR_s)^2$. Alternatively, if you are lucky and have a plot of noise-figure contours versus I_C and R_s, you can quickly locate the optimum value of I_C.

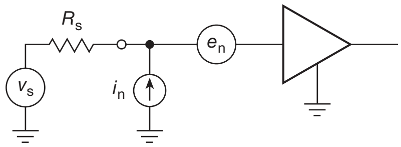

Figure 8.28. Amplifier noise model.

8.5.1 Noise-figure example

As an example, suppose we have a small signal in the region of 1 kHz with source resistance of 10k, and we wish to make a low-noise common-emitter amplifier with a 2N5087. From the datasheet graphs of e_n and i_n versus collector current (Figure 8.29), we see that the sum of voltage and current terms (with 10k source) is minimized for a collector current of about 20–40μA. Because the current noise is falling faster than the voltage noise is rising as I_C is reduced, it might be a good idea to use slightly less collector current, especially if operation at a lower frequency is anticipated (i_n rises rapidly with decreasing frequency). We can estimate the noise figure using i_n and e_n at 1 kHz:

$$\text{NF} = 10\log_{10}\left(1 + \frac{e_n^2 + (i_nR_s)^2}{4kTR_s}\right) \text{ dB}. \tag{8.31}$$

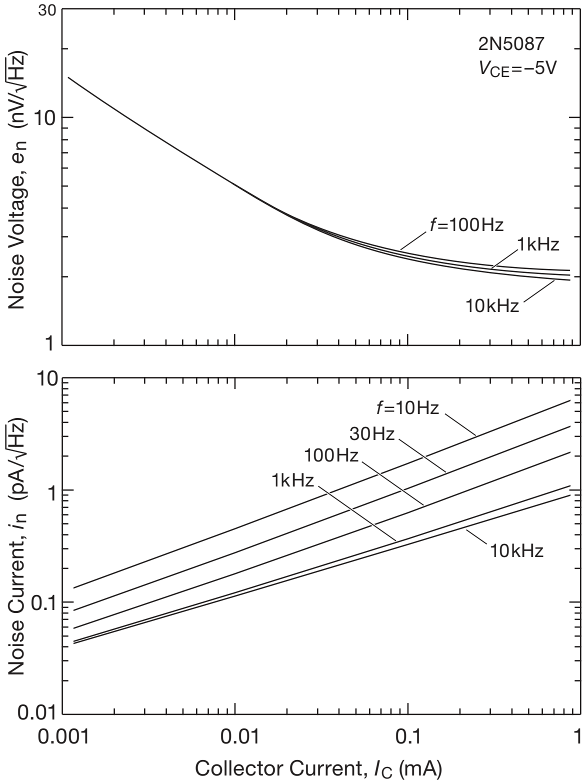

Figure 8.29. Voltage and current noise versus frequency for the 2N5087 *pnp* transistor.

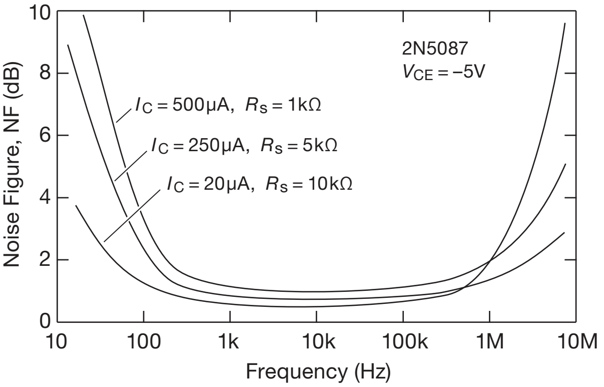

Figure 8.30. Noise figure (NF) versus frequency, for three choices of I_C and R_s, for the 2N5087.

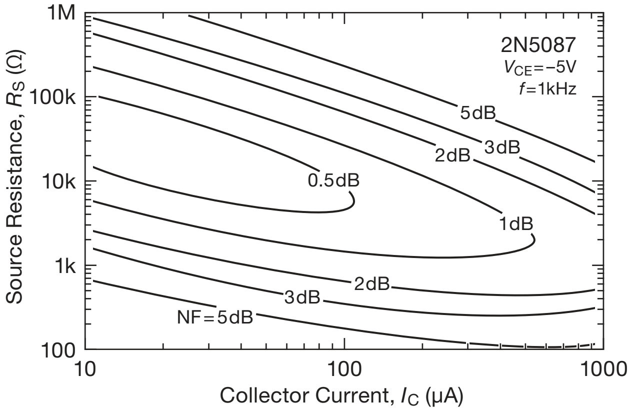

Figure 8.31. Contours of constant narrowband noise figure for the 2N5087 transistor. (From the ON Semiconductor datasheet.)

Reading from Figure 8.29, at I_C=20 μA, e_n=3.7 nV/$\sqrt{\text{Hz}}$ and i_n=0.17 pA/$\sqrt{\text{Hz}}$; and $4kTR_s$=1.65 × 10^{-16} V^2/Hz for the 10k source resistance. The calculated noise figure is therefore 0.42 dB. This is consistent with the datasheet's graph (Figure 8.30) showing NF versus frequency, in which they have chosen this operating current for R_s=10k. This choice of collector current is also roughly what you would get from the graph in Figure 8.31 of noise-figure contours at 1 kHz, although the actual noise figure can be estimated only approximately from that plot as being slightly less than 0.5 dB.

Exercise 8.2. Find the optimum I_C and corresponding noise figure for R_s=100k and f=1 kHz, using the graph in Figure 8.29 of e_n and i_n. Check your answer from the noise-figure contours (Figure 8.31).

For the other amplifier configurations (follower, grounded base) the noise figure is essentially the same, for given R_s and I_C, since e_n and i_n are unchanged. Of course, a stage with unity voltage gain (a follower) may just pass the problem along to the next stage,[33] since the signal level hasn't been increased to the point that low-noise design can be ignored in subsequent stages.

8.5.2 Charting amplifier noise with e_n and i_n

The noise calculations just presented, although straightforward, make the whole subject of amplifier design appear somewhat formidable. If you misplace a factor of Boltzmann's constant, you suddenly get an amplifier with a 10,000 dB noise figure! In this section we present a simplified noise-estimation technique of great utility.

The method consists of first choosing some frequency of interest in order to get values for e_n and i_n versus I_C from the transistor datasheets. Then, for a given collector current, you can plot the total noise contributions from e_n and

[33] "Kicking the can down the road," in the political parlance of our time.

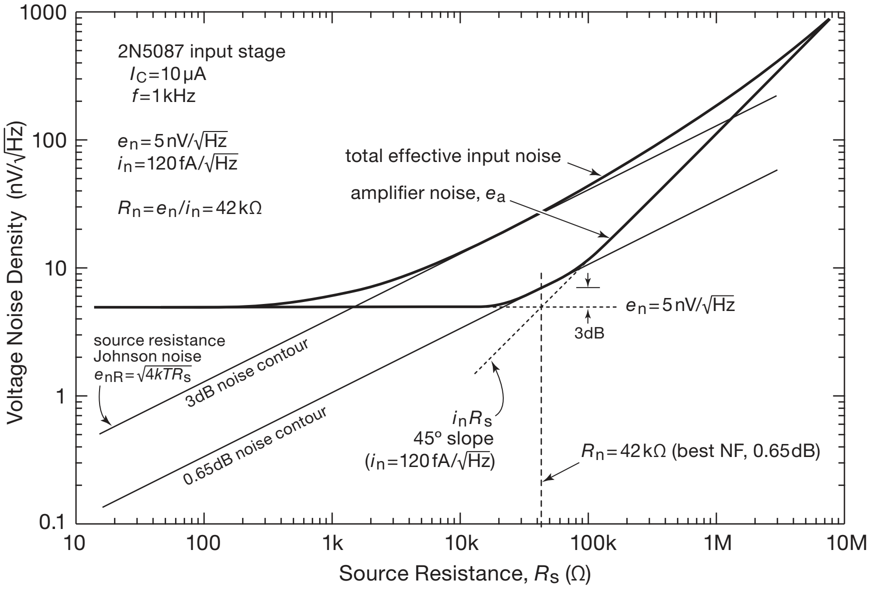

Figure 8.32. Total amplifier input voltage noise (e_a) plotted from the e_n and i_n parameters. The "total effective input noise" curve includes the Johnson noise from a resistive input source, i.e., Z_s=R_s.

i_n as a graph of e_a versus source resistance R_s. Figure 8.32 shows what that looks like at 1 kHz for an input stage using a 2N5087 *pnp* transistor running at 10 μA of collector current. The e_n noise voltage is constant, and the i_nR_s voltage increases proportional to R_s, i.e., with a 45° slope. The amplifier noise curve is drawn as shown, with care being taken to ensure that it passes through a point 3 dB (voltage ratio of 1.4) above the crossing point of individual voltage- and current-noise contributions. Also plotted is the noise voltage of the source resistance, which is also the 3 dB NF contour. The other lines of constant noise figure are simply straight lines parallel to this line, as you will see in the examples that follow.

The best noise figure (0.65 dB) at this collector current and frequency occurs for a source resistance of 42kΩ, and the noise figure is easily seen to be less than 3 dB for all source resistances between 2kΩ and 1MΩ, the points at which the 3 dB NF contour intersects the amplifier noise curve.

The next step is to draw a few of these noise curves on the same graph, using different collector currents or frequencies, or maybe a selection of transistor types, in order to evaluate amplifier performance. Before we go on to do that, let's show how we can talk about this same amplifier using a different pair of noise parameters, the noise resistance R_n and the noise figure NF(R_n), both of which pop right out of the graph.

We'll have some fun with this technique later (§8.7), after we've learned about noise in JFETs, by refereeing over a world championship low-noise shootout between a best-in-class BJT (2SD786) and a comparably excellent JFET (2SK170).

8.5.3 Noise resistance

The lowest noise figure in this example occurs for a source resistance R_s=42k, which equals the ratio of e_n to i_n. That defines the noise resistance:

$$R_n = \frac{e_n}{i_n} \quad \text{ohms.} \tag{8.32}$$

You can find the noise figure for a source of that resistance from our earlier expression, eq'n 8.31, for noise figure:

$$\text{NF(at } R_n) = 10\log_{10}\left(1+1.23\times10^{20}\frac{e_n^2}{R_n}\right)\ \text{dB} \quad \approx \quad 0.31\,\text{dB}.$$

Noise resistance isn't actually a real resistance in the transistor, or anything like that. It is a tool to help you quickly find the value of source resistance for minimum noise figure, ideally so that you can vary the collector current to shift R_n close to the value of source resistance you're actually using. R_n corresponds to the point where the e_n and i_n lines cross.

The noise figure for a source resistance equal to R_n then follows simply from the preceding equation.

8.5.4 Charting comparative noise

It's easy to compare candidate transistors with this charting technique, plotting total amplifier noise for each of a selection of possible collector currents. We've done this in Figure 8.33, where we compare total amplifier noise (which includes source resistance Johnson noise) versus source resistance for the high-beta 2N5962 and the low-$r_{\mathrm{bb}'}$ ZTX851 *npn* transistors, using measured values of beta and $r_{\mathrm{bb}'}$ listed in Table 8.1a on page 501. You can see that the high-beta part operated at low collector current is the clear winner for high source resistances, where its relatively high $r_{\mathrm{bb}'}$ (480 Ω) is harmless, being swamped by the Johnson noise of the signal source. By contrast, for low source resistances (say 1k and below) the ZTX851's admirably low $r_{\mathrm{bb}'}$ ($\sim$1.7Ω) achieves the lowest noise, particularly when operated at a relatively high collector current to minimize the "r_e" noise term (recall that collector-current shot noise through $1/g_m$ produces a noise voltage density e_n equivalent to the Johnson noise of a resistor of value $r_\mathrm{e}/2$, eq'n 8.20).

8.5.5 Low-noise design with BJTs: two examples

Let's put these ideas and equations to work, first by looking at a simple single-ended low-noise audio preamp that achieved popularity beginning in the 1980s, then by comparing with a classic differential design that addresses many of the shortcomings of the single-ended circuit.

A. The Naim preamp

Figure 8.34 shows the input stage used for many years in low-level preamps from the British manufacturer Naim Audio. It's an ac-coupled single-ended two-stage series feedback design (Figure 2.92), tailored for low input-noise voltage. The overall voltage gain is $G_\mathrm{V} = 1 + R_\mathrm{f}/R_\mathrm{E}$ (here 30 dB), with R_E chosen rather small to keep its Johnson noise-voltage contribution down below a nanovolt per root hertz (15 Ω has e_n=0.5 nV/$\sqrt{\mathrm{Hz}}$). The other significant noise term is the transistor's contribution from $r_{\mathrm{bb}'}$, which is variously specified on datasheets either as an e_n value (at some specified collector current) or graph, or as a noise-figure value or graph, or (rarely) as a value for $r_{\mathrm{bb}'}$ itself; or

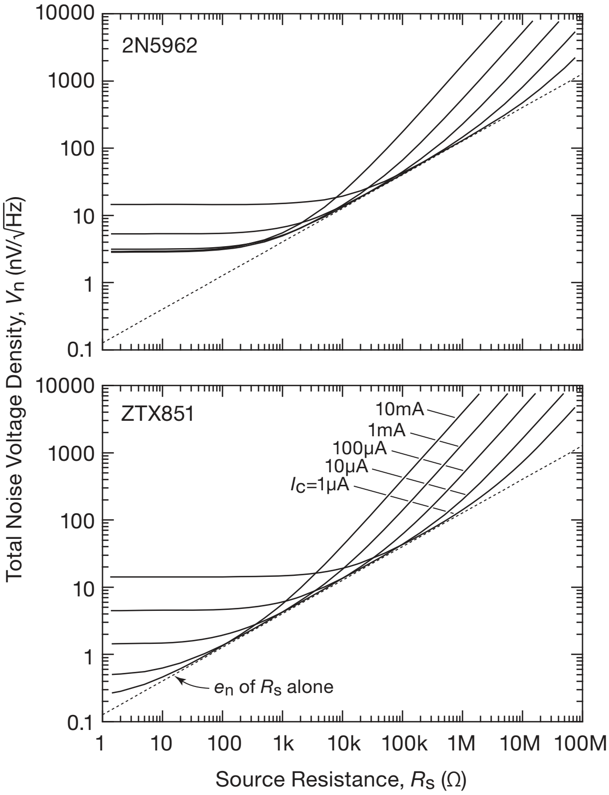

Figure 8.33. Comparing the total amplifier input-noise voltage versus source resistance of two candidate low-noise BJTs. The curves plot five decade values of collector current. For low source resistances the ZTX851's low $r_{\mathrm{bb}'}$ yields low noise at high collector currents; by contrast, the 2N5962's higher $r_{\mathrm{bb}'}$ limits the ultimate noise voltage, but its higher beta (thus lower base-current shot noise, $\sqrt{2qI_\mathrm{C}/\beta}$) results in improved performance with high source resistances. These curves include the Johnson noise of the source resistance.

(worst of all) perhaps none of these. For the "Low Noise" ZTX384C used in this preamp, the datasheet is rather, uh, *taciturn*, revealing only that NF=4 dB (max) from 30 Hz–15 kHz for R_s=2k and I_C=0.2 mA. This is not terribly helpful, because that corresponds to a seriously large Johnson-noise voltage of 6.9 nV/$\sqrt{\mathrm{Hz}}$.

The fact is that these amplifiers were pretty quiet. One reason is that worst-case specifications of difficult-to-measure parameters tend to be overly pessimistic. For example, the contemporary low-noise *npn* 2SC3324 specifies (for a particular test condition) NF=3 dB (max), but 0.2 dB (typ). Naim may have selected parts for low noise. The other reason is that Naim's circuit actually uses five transistors in parallel (each with a 15 Ω emitter ballasting resistor) for Q_1, which drives down its noise voltage by a factor

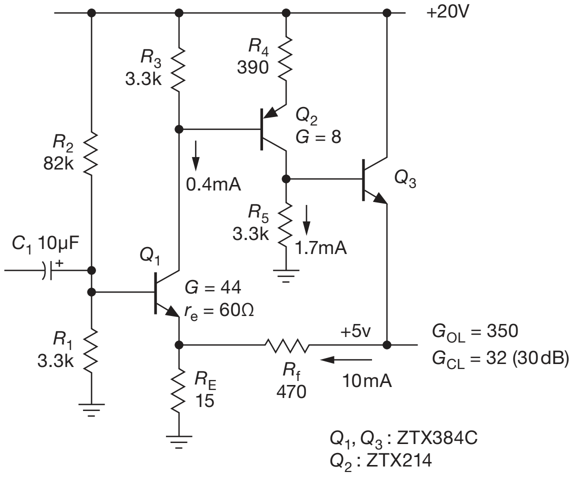

Figure 8.34. Low-level audio preamp, similar to that used in the NAIM NA323. Q_1 is made from a parallel connection of four or five selected transistors.

of $\sqrt{5}$. Bottom line: this preamp's noise was likely in the neighborhood of $1\,\text{nV}/\sqrt{\text{Hz}}$, as befits a preamp designed for the low signal levels characteristic of the moving-coil phono cartridges for which it was optimized.

This circuit is simple; but there are tradeoffs caused by the small R_E that was chosen for low noise. It makes the bias scheme somewhat problematical, with the bias divider R_1R_2 acting more as a current source (compared with the classic voltage biasing, for example as in Figure 2.35), thus making the quiescent operating point rather dependent on Q_1's beta. The low value of R_E also results in a low input impedance, owing to the required stiff bias divider's impedance of 3.2 kΩ.[34]

B. A better design: dc-coupled differential preamp

Many of the shortcomings of the Naim preamp are nicely addressed in the dc-coupled differential preamp shown in Figure 8.35, which retains the former's desirable low-noise performance. It's basically the classic 2-stage op-amp configuration (e.g., Figures 4.43 or 2.91), here simplified with a single-ended class-A output stage with current-sink active load (with the assumption that the next stage will not require substantial drive current).

This circuit eliminates electrolytic blocking capacitors, both at the input and in the gain-setting feedback divider R_1R_2; it minimizes Early effect nonlinearity in the input stage; and its use of active (current-source) loads both improves its overall linearity (through improved single-stage linearity, plus higher loop gain) and provides stable and predictable biasing. The price you pay in exchange is small: increased circuit complexity, and the 3 dB increase in noise (owing to Q_2's contribution). At these collector currents the noise is dominated by the Johnson noise of the base resistance $r_{bb'}$. So, as with the Naim amplifier, the input transistors could be implemented as a parallel array of matched-V_{BE} transistors (even if single transistors are used, the pair should be matched to ∼10 mV or so), or (better) implemented with larger die-size transistors with lower $r_{bb'}$.[35]

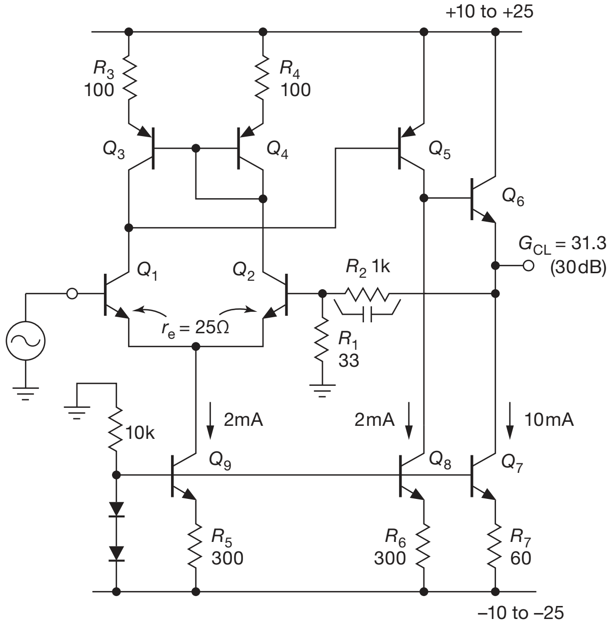

Figure 8.35. A low-noise dc-coupled audio preamplifier with predictable biasing.

8.5.6 Minimizing noise: BJTs, FETs, and transformers

Bipolar transistor amplifiers can provide very good noise performance over the range of source impedances from about 200 Ω to 1 MΩ, with corresponding optimum collector currents generally in the range of several milliamps down to a microamp. (With low source impedances you want to minimize e_n, whereas with high source impedances

[34] Which dominates the impedance seen looking into the base ($\beta R_E G_{loop}$), the latter about 50 kΩ.

[35] For example the inexpensive 2SD2653, specified to 2A continuous collector current, but with high beta even at low currents: $\beta \approx 500$ at I_C=1 mA. See §8.5.9B.

you want to minimize i_n; as we’ve seen, that dictates high and low collector current, respectively).

If the source impedance is high, say greater than 100k or so, transistor *current* noise dominates, and the best device for low-noise amplification is a FET. Although their voltage noise is usually greater than that of bipolar transistors, the gate current (and its noise) can be exceedingly small, making them ideally suited for low-noise high-impedance amplifiers. We’ll dive into FET noise shortly (§8.6), after an entertaining “challenge” interlude.

For very low source impedances (say 50 Ω), transistor voltage noise will always dominate, and noise figures will be poor. One approach in such cases is to use a signal transformer to raise the signal level (and impedance), treating the signal on the secondary as before. Transformers have their drawbacks, of course: they’re ac coupled; they operate over only a few decades of bandwidth (and never to dc); those intended for low-frequency operation are bulky and expensive and exhibit nonlinearities; and they are susceptible to magnetic pickup. Nevertheless, they can be the magic sauce when you’re dealing with a low impedance signal (say less than 100 Ω); see §8.10.

8.5.7 A design example: 40¢ “lightning detector” preamp

Here’s an interesting design challenge, and a chance to exercise some of our noise theory. Imagine we want to manufacture an inexpensive photodiode amplifier that runs on low current from a 9V battery, with input noise of just a few $\mathrm{nV}/\sqrt{\mathrm{Hz}}$, and with response time of a few microseconds. You can think of this as a simple “lightning detector,” because lightning is almost unique in delivering microsecond-scale pulses of light in the outdoor environment.[36] In a fully refined implementation this could serve as a useful early warning device to install in locations where you’d want to be indoors when the sky is becoming electric – golf courses, harbors, soccer fields, etc. Here we explore the basics, a launching point to inspire the electronic hobbyist. It will turn out that we can do the job with standard parts, for a total component cost (in 1000-piece quantities) of just $0.40. It will be a “throwaway” device, manufactured in the millions, with commensurate profits and fame (dream on!). Let’s take it in easy stages, as shown in Figures 8.36A–E (similarly labeled in the following paragraphs).

A. Block diagram We back-bias the PIN photodiode to lower its capacitance (thus lower noise and faster response), and we use a blocking capacitor into the summing junction of a transimpedance stage to eliminate the dc level from ambient light and leakage current. The feedback resistor R_f sets the gain ($G=-R_f$ volts/amp).

B. Discrete design, first iteration We need inverting feedback, so we begin with a grounded-emitter stage (Q_1), with an emitter follower (Q_3) to create a low-impedance output and feedback source.

C. Add cascode This circuit will be running at low currents (0.1 mA or so), thus relatively high impedances at which Miller effect causes a significant bandwidth reduction. So we add a cascode (Q_2) atop the gain stage’s collector.

D. Inverted cascode A 9 V battery is down to 6 V at end-of-life, so now we’re running out of headroom! We want to keep plenty of dynamic range, so we fix this problem by turning the cascode around, creating an “inverted cascode,” in which collector current variations in Q_1 pass through *pnp* cascode transistor Q_2, while the latter continues to clamp Q_1’s collector voltage. The output follower plays a dual role here, with its V_{BE} setting Q_2’s collector current: $I_{C2}=V_{BE3}/R_3$.

E. Front-end follower and input current noise At the $\sim 50\,\mu$A collector current in Q_1 that we’ll need to get sufficient bandwidth, there would be too much current noise at the input. (Remember that the input signal is a *current*.) So we add a high-beta follower (Q_4) and choose a collector current of 1 μA as an initial trial value. We also choose a large feedback resistor R_2 to minimize its noise current as seen at the input, with shunt capacitance C_c to limit the bandwidth to 100 kHz. The idea is to calculate the input noise to see where the dominant contribution comes from, then iterate the design toward an optimum. We’ve filled in component values for an initial design.

[36] Roughly 90% of lightning activity is cloud-to-cloud, stretching over large distances and exhibiting relatively long rise- and fall-times; their signals look not unlike typical background “cultural” noise. The remaining 10% are lightning strikes to ground (which matter to us!), with unique short rise-time signatures, typically less than 5 μs in duration (even for distant ground strikes). This allows us to create filters to distinguish weak distant cloud-to-ground lightning strikes from nearby transient interference of other origins. The circuit described here is a simple low-noise preamp suitable for use with such filters and discriminators.

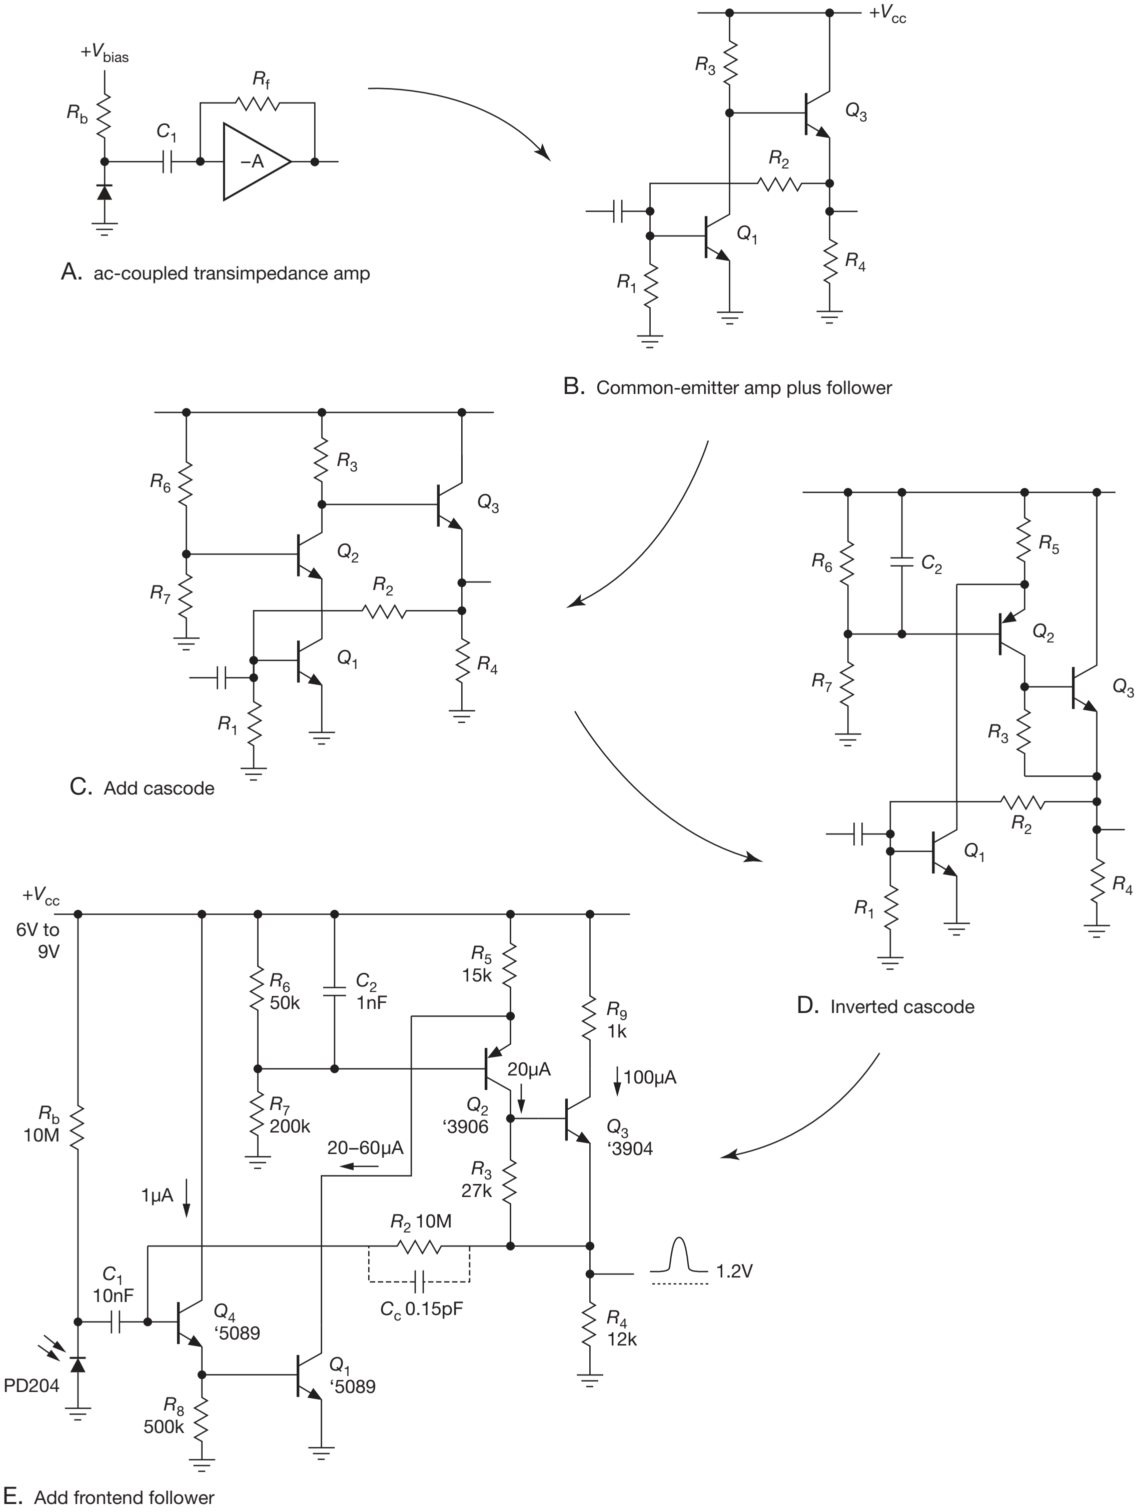

Figure 8.36. Tutorial evolution of a low-noise and low-power photodiode amplifier built with low-cost discrete components. Apart from Q_1 and the photodiode, all parts are available in surface-mount packages (prepend "MMBT" to transistor part numbers, e.g., MMBT5089).

Calculating the noise performance Let's estimate the noise current at the input; that's what competes with the (current) signal from the photodiode. There's shot noise in Q_4's base current, and there's Johnson-noise current from the feedback resistor R_2 and the photodiode bias resistor R_b. In addition, we have to worry about noise *voltage* at the input: in combination with the input capacitance C_{in} it creates an input noise current $i_n{=}e_n\omega C_{in}$ (as we'll see in detail in §8.11). Input noise voltage is the combined e_n contributions of Q_1 and Q_4, each having Johnson noise in their $r_{bb'}$ and collector shot noise through their r_e. Let's take these in turn.

Noise current Estimating Q_4's $\beta{\approx}350$ at its $1\,\mu$A collector current, we find that its base current of 3 nA creates a shot-noise density $i_{n(shot)}{=}\sqrt{2qI_B}{=}30\,\text{fA}/\sqrt{\text{Hz}}$. Feedback resistor R_2 and bias resistor R_b create a Johnson-noise current $i_{n(R)}{=}\sqrt{4kT/R}{=}57\,\text{fA}/\sqrt{\text{Hz}}$. These combine (square root of sum-of-squares) to create $i_n(\text{total}){=}65\,\text{fA}/\sqrt{\text{Hz}}$.

Noise voltage Emitter follower Q_4, running at $1\,\mu$A, generates a shot noise voltage across its r_e of $e_{n(shot4)}{=}r_e\sqrt{2qI_C}{=}14.3\,\text{nV}/\sqrt{\text{Hz}}$. Its internal base resistance of $\sim 300\,\Omega$ adds a relatively insignificant Johnson-noise voltage $e_{n(J4)}{=}\sqrt{4kTr_{bb'}}{=}2.2\,\text{nV}/\sqrt{\text{Hz}}$, for a combined $e_{n4}{=}14.5\,\text{nV}/\sqrt{\text{Hz}}$.

Grounded-emitter amplifier Q_1, running at nominal $40\,\mu$A and with an $r_{bb'}$ of $\sim 300\,\Omega$, generates corresponding noise voltages $e_{n(shot1)}{=}r_e\sqrt{2qI_C}{=}2.3\,\text{nV}/\sqrt{\text{Hz}}$ and $e_{n(J1)}{=}\sqrt{4kTr_{bb'}}{=}2.2\,\text{nV}/\sqrt{\text{Hz}}$, for a combined $e_{n1}{=}3.2\,\text{nV}/\sqrt{\text{Hz}}$.

Combining the noise voltages of Q_1 and Q_4, we find[37] $e_n(\text{total}){=}14.8\,\text{nV}/\sqrt{\text{Hz}}$. Evidently Q_4 is the big noise gorilla in the room here; but let's continue with the analysis.

In combination with the input capacitance of ~ 10 pF (5 pF for the photodiode, 2.5 pF for Q_4's C_{cb}, and 2.5 pF for wiring capacitance) that noise voltage creates an effective input-current noise (§8.11.3)of $i_n{=}e_n\omega C_{in}{=}90\,\text{fA}/\sqrt{\text{Hz}}$, if we take for ω a characteristic frequency of 100 kHz.

Verifying feedback stability This is a feedback circuit, with the ever-present potential for oscillation. And, in a transresistance configuration like this, the shunt capacitance at the input combines with the large-value feedback resistor to introduce an additional lagging phase shift. We deal with this in detail in §§*4x.3* and 8.11; the criterion for stability is that the open-loop amplifier's unity-gain bandwidth must satisfy

$$f_T(\text{open-loop}) > f^2_{R_2C_c}/f_{R_2C_{in}}. \qquad (8.33)$$

(Stated differently, the feedback network's -3 dB rolloff frequency must be less than the geometric mean of (a) the amplifier's open-loop unity-gain frequency and (b) the -3 dB rolloff frequency of the feedback resistor in combination with the input capacitance.)

So, for the circuit of Figure 8.36E we require $f_T(\text{open-loop}) > 106\text{kHz}^2/1.6\text{kHz}$, or 7 MHz. We estimate the amplifier's open-loop unity gain as follows.

(a) The low-frequency voltage gain is $G{=}g_{m1}R_{load}$, where R_{load} is the impedance seen at cascode transistor Q_2's collector.

(b) The latter is $R_{load}{=}R_4{\cdot}g_{m3}R_3{\approx}1.3\,\text{M}\Omega$, so the low-frequency open-loop gain G_{OL} ranges from 1000 to 3000 for Q_1 collector currents from $20\,\mu$A to $60\,\mu$A, (battery voltage from 6 V to 9 V), respectively.

(c) This gain rolls off at 6 dB/octave, starting at a frequency set by R_{load} in combination with the capacitance seen at Q_2's collector; taking $C_{cb}{\sim}2.5$ pF for each of Q_2 and Q_3, that's $f_{3dB}{=}25$ kHz.

(d) That brings the amplifier's open-loop gain down to unity at about 25 MHz (for Q_1's minimum collector current), a good margin of stability given our 7 MHz requirement.

The cascode was essential for getting this bandwidth at these low currents. Without it the gain stage (Q_1) would see its load capacitance multiplied by the voltage gain of 1000, owing to Miller effect.[38]

Optimization The contributions from amplifier noise currents ($65\,\text{fA}/\sqrt{\text{Hz}}$) and from noise voltage generating noise current through the input capacitance ($90\,\text{fA}/\sqrt{\text{Hz}}$) are in the same ballpark. The latter rises proportional to frequency, and dominates, slightly, at the high-frequency end of the bandpass; but when integrated over the amplifier's passband, the two noise terms contribute comparable integrated noise, totaling approximately $I_n{=}30$ pArms (therefore 0.3 mVrms at the amplifier's output).

The lion's share of the noise current, then, comes from the 10M gain-setting and biasing resistors. These could be raised in value, though R_b must not be so large that the photodiode saturates in nighttime ambient light. The latter problem could be circumvented by sensing the voltage at the photodiode and using it to control a quiet biasing current source. If the resistor noise were brought down

[37] At these low collector currents we found actual measured noise voltages to be about 25% higher than those predicted by simple theory.

[38] See also the section "Analysis by Equivalent Circuits" in Chapter *2x* for a discussion of classical feedback analysis in circuits like this.

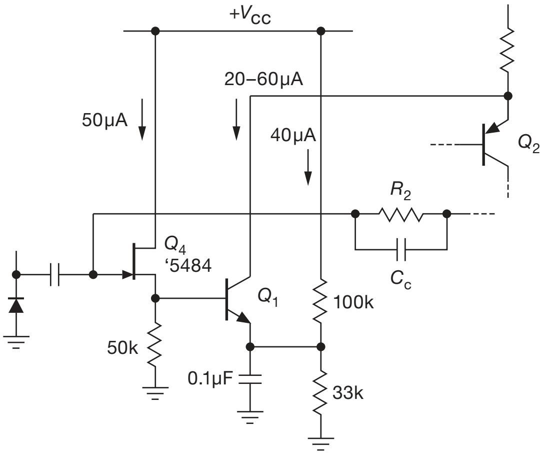

Figure 8.37. Replacing Figure 8.36's BJT input transistor with a low-capacitance JFET reduces input noise voltage and noise current by a factor of 3.

enough, the dominant remaining noise source would be Q_4, whose voltage noise (multiplied by ωC_{in}) and current noise are comparable. Raising its operating current reduces its voltage noise, but increases its current noise. We seem to be stuck.

But no, we're *not*! If we replace the BJT input follower with a low-capacitance JFET (Figure 8.37), we can score a significant improvement. The voltage noise of a 2N5484 ($C_{\text{in}}{\approx}2.2\,\text{pF}$) running at $50\,\mu\text{A}$ is about $e_{\text{n}}{=}5\,\text{nV}/\sqrt{\text{Hz}}$ (based on measurements at $100\,\mu\text{A}$), and its current noise is negligible; so we reduce the transistor noise contribution by a factor of 3 (for an additional cost of 5–10 cents). Of course, this makes sense only if the R_{b} and R_2 Johnson-noise contributions can be reduced by at least a factor of 4. With those improvements the amplifier's total integrated input noise becomes $I_{\text{n}}{\approx}10\,\text{pArms}$. That's comparable to shot noise in the photodiode's leakage current (3 nA, typ, at $-10\,\text{V}$ and 25°C) – no point in grooming the amplifier further.

We take up the subject of low-noise design with JFETs shortly, in §8.6.

8.5.8 Selecting a low-noise bipolar transistor

It's important to select the right transistors, and appropriate operating currents, in order to optimize a circuit's low-noise performance. This task has been made more difficult as some of the finest low-noise favorites have been recently discontinued by one manufacturer after another (most of these came in through-hole packages, not favored for machine assembly). Often this means you can't simply choose a part used in someone else's good design. The task is made difficult also by the lack of relevant information in datasheets – noise-voltage curves, or even a mention of noise voltage is the exception in most contemporary BJT datasheets. We come to your rescue with Tables 8.1a,b, where we've listed a range of good candidate transistors,[39] along with measured noise parameters such as e_{n}, $r_{\text{bb}'}$, V_{A} (Early voltage), and plots of beta versus collector current. Herewith a guide to the table, and to the task of selecting and using a low-noise transistor.[40]

The **beta** or h_{FE} column shows the manufacturer's stated minimum values. While the *typical* beta is often much higher, you have to accept the reality that a minimum-beta part may end up in your circuit (unless you are willing to screen incoming parts). The manufacturer's beta specs are often at higher currents than you'll be using, and the beta may be severely degraded at lower currents, see the discussion of recombination and Gummel plots in §*2x.13*. To see which transistors are susceptible to this, we measured beta versus collector current, going from $1\,\mu\text{A}$ to 100 mA, with the results shown in Figure 8.39 (with corresponding labels in the **Beta plot** column of Tables 8.1a,b) . The falloff of beta at low current is summarized in the **Linearity** column in the table, rating the transistors on a scale of 1 (large beta falloff at microamp currents) to 5 (beta does not change with current). Note how some parts run out of steam at currents above 1mA; these are small-die parts running at high current density. Keep in mind our measurements were taken at $V_{\text{CE}}{=}5\,\text{V}$, and that the high-current beta of some BJTs falls rapidly at lower collector voltages (a saturation effect).[41] Our measured plots go to 50 mA, but the datasheets of some larger-die parts (like the ZTX851) provide curves of beta going as high as 10 A.

Some BJT types are measured by the manufacturer and

[39] In many cases these transistors are not promoted by the manufacturer as "low noise." We made some guesses, then ordered and tested samples of some 100 different types.

[40] Some advice about finding parts. It's helpful to search using the inner (numeric) portion of the part name, because there may be versions with differing prefixes or suffixes. You'll have an easier time finding surface-mount parts than through-hole parts – see the notes in the SOT-23 column of Table 8.1a. Some parts are stocked only at specialty suppliers, such as B&D Enterprises, MCM, Donberg Electronics, Encompass, and Littlediode. Discontinued parts may also be available on eBay, in small quantities suitable for making specialized laboratory instruments. Some large Pacific rim distributors have good older-part inventory and sell from their websites, through Alibaba, or on eBay. The Sanyo four parts near the bottom of the table have been discontinued, but they make other parts that may offer similar performance.

[41] We've not provided measurements of beta at lower voltages, but we are confident that the low-noise winners (the *npn* ZTX851 and *pnp* ZTX951) do very well in this respect, having been designed as high-current transistors with low saturation voltage.

Table 8.1a Low-noise BJTs[a]

binned into beta categories. For example the BC850 has A, B, and C grades, with typical betas at 2 mA of 180, 290, and 520, respectively. It's tempting to go for the highest-grade part in your design, but often you'll find no availability at the distributors. The higher beta grades also suffer from degraded noise performance, lower V_{CEO} ratings and lower Early voltages (i.e., lower output impedances).[42]

Looking at the BC850 again, you see that it's a small-area transistor that you'd probably use at much lower currents than the 2 mA at which its beta is specified; so it's nice to see in Figure 8.39 that its beta drops by less than 10% at 1 μA, compared, say, with the 2N5962, whose beta drops by 50%. The popular *npn* 2N3904 holds steady, but the beta of its *pnp* sibling 2N3906 drops by a factor of 3 over four decades of current, a common situation with *pnp* parts. However, there's plenty of good news: the betas of the *pnp* BC860 and ZTX718 drop less than 20% at 1 μA and the beta of the lower-gain 2N5087 is flat clear down to 1 μA.

Before discussing the all-important noise measurements, let's look at the **Early voltage**, or V_A column. Look back to §§2.3.2 and *2x.8* for a discussion of the Early effect. The Early voltage V_A provides an estimate of the BJT's output conductance (and output impedance): $g_{oe}=1/r_o=I_C/(V_A+V_{CE})$. We can also estimate a maximum possible single-stage gain (that is, with $R_L=\infty$), $G_{max}=g_m/g_{oe}$. By substituting $g_m=I_C/V_T$, we get (ignoring V_{CE} compared with the usually much larger V_A) $G_{max}=V_A/V_T$.

While it's possible to overcome the drawbacks of a low Early voltage, for example by adding a cascode stage (see §§2.4.5B and *3x.4*) or by adding emitter degeneration, it's frequently convenient not to have to do so. For such applications it's best to restrict your choices to BJTs with relatively high V_A. As the entries in Table 8.1a demonstrate, though, the *pnp* member of an *npn–pnp* complementary pair (they're grouped together in the table) usually suffers from dramatically lower Early voltages; e.g., the *pnp* BC860C has V_A=30 V compared with the *npn* BC850C's value of 220 V. This is unfortunate, because *pnp* transistors are useful in current mirrors for *npn* differential amplifiers, where their low Early voltage greatly reduces the stage gain. The problem can be solved in several ways, for example by adding emitter degeneration in the *pnp* mirror, as in Figure 8.35, or by using a Wilson mirror.

Looking at the table's **maximum collector voltage** (V_{CEO}) values, we see many low-noise BJTs with ratings

[42] For example, the 2N5089 has a minimum beta of 450, compared with 300 for the '5088; its maximum voltage is reduced to 25 V from 30 V, and, most significantly, our samples showed somewhat (~10%) higher measured e_n noise. Similarly, the D version of the ZXTN19020 has a beta of 300 (versus 200 for the C version), with 10% higher e_n. As another example, measuring the Q grade of the 2SB1197K (min beta of 120) gave us an Early voltage of V_A=110 V, whereas for the R grade (min beta of 180) the Early voltage dropped to 70 V.

of 120 V or more, leading us to wonder why they have such a high voltage rating. Could it be to achieve a high Early voltage? Perhaps, but it's been observed that high-voltage "video-output" transistors often exhibit admirably low noise voltage. For example, Sanyo's 2SC3601 has a very low measured e_n of $0.22\,\text{nV}/\sqrt{\text{Hz}}$, with an $r_{bb'}$ of $1.7\,\Omega$.[43]

In general, high voltage transistors have lower betas; for example, the 300 V MPSA42 (#20 on our graph), has the lowest gain. A contender for the part with highest beta, the Linear Integrated Systems' IT124 (based on an old Intersil part), suffers from a V_{CEO} rating of just 2 V (!) in exchange for its superbeta gain. Happily, they've morphed the design into their LS301 with an 18 V rating, and it wins the beta contest (curve #44) with an astonishing β=3000 at 1 μA.[44]

A significant task is choosing the transistor's operating current. It's tempting to scan down the table's "Noise parameters" columns and pick a part near the bottom with an e_n under $0.5\,\text{nV}/\sqrt{\text{Hz}}$. But watch out for the high base-current noise that these transistors create, when operated at the relatively high collector currents needed for those low e_n values. For example, the winning ZTX851 has a very attractive e_n=$0.5\,\text{nV}/\sqrt{\text{Hz}}$ at I_C=10 mA. But, with its β of 220 (see Figure 8.39), its base current of 45 μA creates an input noise current i_n (=$\sqrt{2qI_C}$) of $3.8\,\text{pA}/\sqrt{\text{Hz}}$. That sounds small – but it creates an additional voltage noise of $0.19\,\text{nV}/\sqrt{\text{Hz}}$ across even a low 50 Ω source impedance, adding 3 dB to the transistor's input noise voltage. The problem only gets worse with higher source impedances, because the added i_nZ_s noise voltage grows linearly with source impedance, compared with Johnson noise from a resistive source (which grows as the square root of R_s).[45] For example, this base current noise creates $2.3\,\text{nV}/\sqrt{\text{Hz}}$ with a 600 Ω source impedance.

We took the table's noise measurements at high-enough currents to eliminate the I_C term in the BJT noise equation $e_n=[4kT(r_{bb'}+0.5V_T/I_C)]^{\frac{1}{2}}$ (see Figure 8.10), because we wanted to expose their $r_{bb'}$ values. But usually you'll want to operate at lower currents. For example, reducing the ZTX851's current to 1 mA raises the noise voltage by a factor of 2.3 (to $0.48\,\text{nV}/\sqrt{\text{Hz}}$), but the decrease in base current (to 5 μA) lowers the noise current by a factor of 3.2, to $1.2\,\text{pA}/\sqrt{\text{Hz}}$. At this lower current the i_nR_s noise-voltage contribution drops to $0.72\,\text{nV}/\sqrt{\text{Hz}}$ for a 600 Ω source impedance, for a total amplifier noise of $0.86\,\text{nV}/\sqrt{\text{Hz}}$, considerably lower than the $2.3\,\text{nV}/\sqrt{\text{Hz}}$ at 10 mA collector current, and nicely lower than the $3.1\,\text{nV}/\sqrt{\text{Hz}}$ of 600 Ω resistive Johnson noise. Sometimes you may want to operate at a really low current, where the r_e (=V_T/I_C) term dominates and the contribution of the $r_{bb'}$ term is insignificant.

The measured noise that is listed in Table 8.1a is based on a small sampling of contemporary parts. Because some of these parts are not specifically intended for low-noise applications, the manufacturer does not specify (or control) their noise properties. It is important to keep this in mind, because you may encounter batches of parts with degraded noise. Figure 8.40 shows an example: four parts from a single batch of power transistors of a type that have been favored by audio enthusiasts, but which exhibited disappointingly wide variation in low-frequency noise voltage.

These tradeoff considerations were discussed at length in §8.5, and they're illustrated in Figure 8.32, where the concept of a transistor's noise resistance R_n=e_n/i_n is shown. Look back at Figure 8.33, where we compared the voltage noise of the small-die high-beta 2N5962 with that of the large-die low-$r_{bb'}$ ZTX851, at collector currents ranging from 1 μA to 10 mA.[46] The '851 outperforms the '5962 for source impedances of less than 1 kΩ when operated at a collector current of 100 μA or more. Conversely, the '5962 beats the '851 for source impedances above 100k for almost any value collector current.

Figure 8.41 compares the noise voltage versus source resistance for six exemplary low-noise transistors at operating currents of 10 μA and 1 mA. The parts are ranked by increasing e_n at 1 mA collector current and with low source resistance, i.e., they are ranked by increasing $r_{bb'}$. While it's impressive to see $0.5\,\text{nV}/\sqrt{\text{Hz}}$ performance of the lowest-noise parts (like the ZTX851), it's sobering to realize that this holds only if the resistive component of the source impedance is below 10 Ω. Note the generally inverse relationship of the ranking at high R_s relative to that at low R_s. Note also how at a collector current of 10 μA all of the transistors have comparable noise voltages for source resistances less than 10k, although the high beta

[43] It also has a low C_{ob}=2 pF, much lower than the other low-e_n BJTs listed near the bottom of Table 8.1a, demonstrating that it's possible to combine low capacitance with low $r_{bb'}$.

[44] We ordered some IT124s, but they sent us LS301 parts, tested to pass the easier IT124 specs!

[45] And, of course, you can have a high-impedance signal source that is not resistive and therefore has little or no Johnson noise.

[46] These curves were prepared with a spreadsheet, using as input our measured beta and $r_{bb'}$ data of Table 8.1a.

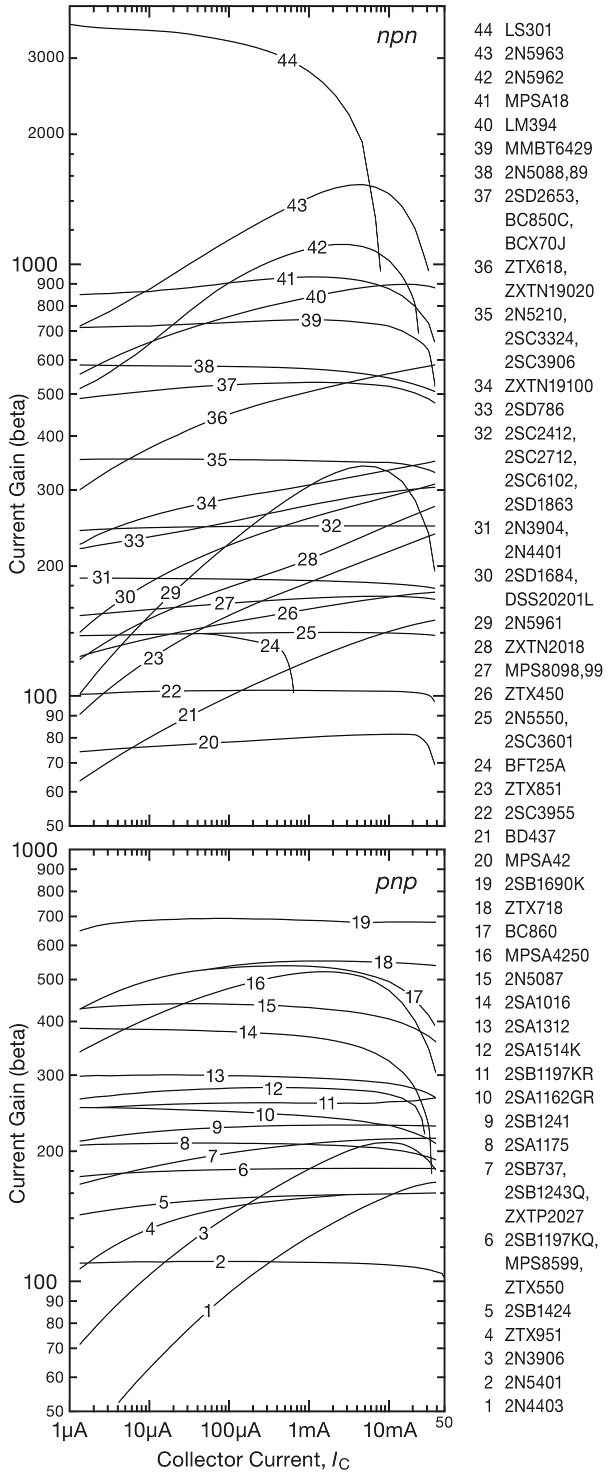

Figure 8.39. Measured beta versus collector current, at $V_{CE}=5$V, for the transistors in Table 8.1a. Use these data with $i_n=\sqrt{2qI_C/\beta}$ to find the base-current noise at the chosen collector current.

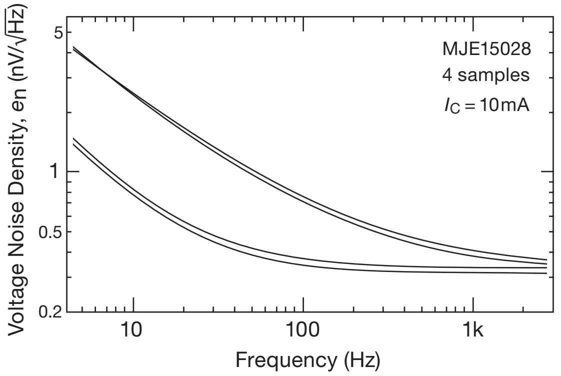

Figure 8.40. Because of their very low base resistance ($r_{bb'}$), the MJE15028-33 family of 8A bipolar power transistors have been used by audio experimenters to make low-noise audio amplifiers. That sounded good, to us... but we discovered >10 dB variations in their (unspecified) low-frequency noise, even within a single batch of parts.

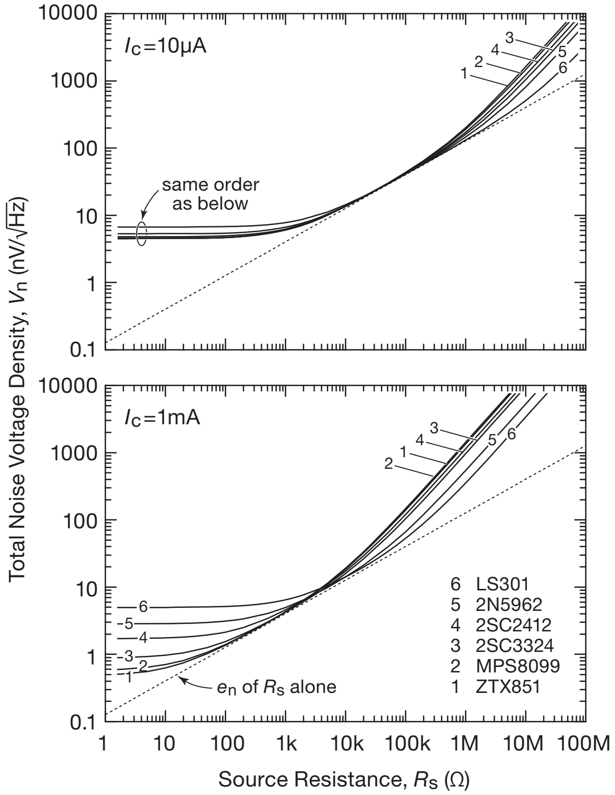

Figure 8.41. Comparing total input noise of six BJT candidates, plotted as in Figure 8.33. For low source resistance you want a transistor with low $r_{bb'}$, operated at high current; for high source resistance you want a high-beta transistor, operated at low current.

parts shine above 1 MΩ.[47] These data and analysis illustrate how low-noise performance can be optimized for a given source impedance by selecting the right transistor and running it at the right current for the job.

The curves in Figures 8.33 and 8.41 include the Johnson noise from a resistive source, R_s, and would not be valid for reactive high-impedance sources such as capacitive sensors. In that case the e_n and the i_nZ_s traces meet, similar to the 0.65 dB line in Figure 8.32, without being pushed up by an intervening R_s region.

The typical values of **capacitance** listed in Table 8.1a are from the datasheet specifications, or sometimes from plots, and generally at V_{CE}=10 V. Most of the listed values are C_{ob}, although some are C_{cb}. These are related by $C_{ob}=C_{cb}+C_{ce}$, but the C_{ce} contribution is usually small, often well under 25%.

The four columns of optimum **noise parameters** deserve some explanation. They experiment with the concept of reducing I_C until the noise-voltage contribution from r_e (i.e., collector-current shot noise times $1/g_m$) raises the overall voltage noise by 50% over its high-current (i.e., $r_{bb'}$ Johnson noise alone) value. Put another way, the idea is to throttle down the collector current in order to reduce the transistor's noise *current*, but only to the extent that it increases the transistor's noise *voltage* by a modest amount. That collector current is listed, along with the corresponding e_n and i_n (conservatively calculated from the specified minimum beta), and the transistor's noise resistance $R_n=e_n/i_n$ at that current. If you buy into the idea of not running the BJT at an "excessive current" and are willing to compromise e_n to reduce i_n, these values give an upper limit for I_C and a lower limit for e_n.[48]

Looking at the bottom quarter of the table, now with this "optimum" perspective, it's sobering to see the low R_n values, ranging from 30 Ω to 125 Ω. And much of the next quartile has trouble getting above 400 Ω. This means that for commonly encountered signal impedances above 100–400 Ω, the amplifier's noise contribution when operated at the "optimum" collector current would be dominated by the i_nZ_s contribution (i.e., input-noise current flowing through the signal's source impedance). We'd be strongly motivated to drive down i_n, by finding parts with higher beta, and by lowering I_C. In this sense the "optimum" current is really a maximum practical current. Looking out of the corner into which we've painted ourselves, the alternative of a quiet JFET (instead of a BJT) looks seriously worth considering.

And that is the subject we take up in the next major section (§8.6), after taking a brief (but challenging) interlude.

8.5.9 An extreme low-noise design challenge: transformerless ribbon microphone preamp

We looked around for a challenging application, one that requires unusually low input noise voltage. A traditional application is a "moving-coil" phonograph cartridge, with its very low signal voltage (∼1 mV at maximum groove modulation, thus a mere 0.1 μV for an 80 dB dynamic range). Problem is, it's *too* traditional![49]

A closely related technology is used in the *ribbon microphone*, in which an outrageously delicate strip of metal foil (typically 2 μm thick – that's a mere 4 wavelengths of light!) is suspended in a magnet's gap, there wafted about by the ambient sound field. You can think of it as a single-turn generator, propelled by the sound's subtle vibrations. Ribbon mics were the first truly high fidelity microphones: they're the clunky big studio mics you see in old movies. These things go back to the 1930s, with models from RCA (the classic 44B) and BBC–Marconi (named, with British understatement, the "Type A"). They're clunky because they have a large magnet inside; they weigh typically 5–10 pounds. They continue to be built and used today,[50] favored by some for their "smooth sound," variously described (in the inimitable language of the audiophile) as "intimate, warm and detailed, yet never harsh."

The output signal from a ribbon mic is tiny by comparison even with the low-level moving-coil phono cartridge: at the standard sound pressure level of 1 Pa you

[47] You may be tempted to use a high-gain low-$r_{bb'}$ part at 10 μA, because its current noise would be no worse than that of a part with higher $r_{bb'}$; but notice the dramatically higher capacitances associated with low $r_{bb'}$, which can really degrade performance with input signals of high impedance.

[48] BJTs with high beta at low currents tend to have poor (i.e., high) $r_{bb'}$ values. Recognizing that high R_n and low $r_{bb'}$ are both desirable, we can define a figure of merit FOM = $R_n/r_{bb'}$. Going from the top to the bottom of Table 8.1a, the transistors have FOM values ranging from 20 to 70. The discontinued low-e_n favorites (2SD786 and 2SB737) stand out with FOM = 51. Others with FOMs greater than 50 are the ZTX718, DSS2020, ZXTN19020, 2SB1690, 2SD2653, 2N5088 and '5089. The MMBT6429 takes first place with FOM = 69, and the 2N5089 and BC850C take the second and third places. This would support the notion that the parts at the top of the table are the winners, rather than those at the bottom. This does reinforce the concept that you need to pick the right part for the job.

[49] Although vinyl records have a faithful base of devotees, who favor the "silky smoothness" and "warmer" sound, said to be best captured with a moving-coil cartridge's "clarity and transparency of tone."

[50] See, for example, Wes Dooley's website ribbonmics.com.

get 50–100 μV directly from the ribbon. That sounds like plenty of signal – until you realize that this reference level of one pascal corresponds to +94 dB SPL. That's *loud* – a jackhammer at 5 feet! A sensitive microphone needs to get down another 80 dB or so to capture the quietest sounds in a concert.[51] At those levels the signal directly from the ribbon is a mere 5–10 nVrms. To set the scale, an op-amp with the lowest voltage noise density (LT1028, e_n=0.85 nV/$\sqrt{\text{Hz}}$) has an input-noise voltage of about 100 nVrms, integrated over the audio band of 20 Hz–20 kHz; that's 20–25 dB larger than the quiet-level audio output directly from the ribbon.

So ribbon mics invariably include an audio step-up transformer, with a turns ratio typically of 1:30. That increases the signal amplitude by the same ratio, so that a well-designed low-noise audio amplifier does not compromise the low-level performance. But transformers can be problematical, both in terms of linearity and in maintaining a flat response over the 1000:1 frequency-range of high-quality audio. We could eliminate the transformer entirely by designing an amplifier whose input-noise voltage is at least 20 dB better than that of an LT1028, i.e., with $e_n \leq 0.1\,\text{nV}/\sqrt{\text{Hz}}$.

A. A simple 70 *pico*volt per-root-hertz preamp test design

To get to this kind of noise level you've got to use a BJT (or, as we'll see, a bunch of them in parallel). You pay a price in terms of input current (i.e., relatively low input impedance); but we're aided here by the very low native source impedance of the ribbon, which is less than 1 Ω over the whole audio band. We seek a transistor with low base resistance ($r_{bb'}$), which we'll operate at relatively high collector current in order to drive down the r_e noise contribution (collector shot noise flowing through r_e); recall that the latter is numerically the same as the Johnson noise created by a "real" resistor of value $R = r_e/2$.

To set the scale, note that our target noise voltage of $e_n = 0.1\,\text{nV}/\sqrt{\text{Hz}}$ corresponds to the Johnson-noise voltage created by a 0.6 Ω resistor! In other words, we need a transistor whose $r_{bb'}$ is significantly less than that, and we need to run it at a collector current of at least ~50 mA (where the "r_e" noise contribution is equivalent to that of a 0.25 Ω resistor). And we need a circuit configuration that delivers on that low-noise promise.

There are several possible circuit configuration choices. We could try something like the Naim circuit of Figure 8.34 – but we'd have to reduce R_E to a fraction of an ohm, forcing Q_3 to drive a very stiff load. The same problem afflicts the "better" design of Figure 8.35. They have in common the need to keep the impedance of the feedback signal very low.

Two approaches we settled on are shown, in simplified form, in Figure 8.42. Both circuits dispense with feedback, arguing that a class-A preamp (of moderate gain, say $G \approx 100$) for microvolt-level signals is inherently linear. The single-ended common-emitter amplifier is simplest, and has a 3 dB noise advantage compared with a differential configuration. But it requires a *huge* input blocking capacitor ($\lesssim$150,000 μF to preserve the signal's very low source impedance down to a few hertz), which causes a long startup settling time; it's esthetically ugly, too. We

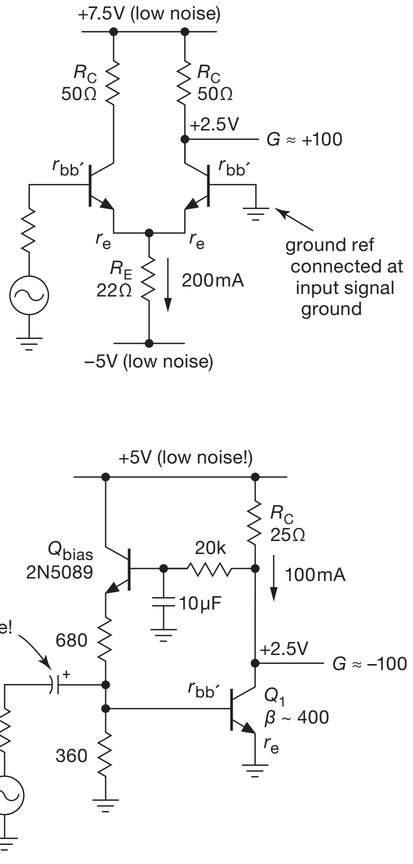

Figure 8.42. Ribbon microphone preamp configurations. Compared with the dc-coupled differential circuit, the single-ended circuit is quieter, but requires a very large blocking capacitor at the input. In either case it's necessary to use multiple paralleled transistors so that the effective base resistance $r_{bb'}$ is in the range of 0.1 Ω or less. See Figure 8.45.

[51] A *classical* music concert, that is. No problem of low levels in a rock concert.

did use this circuit to characterize a slew of candidate low-noise BJTs (look ahead to Figure 8.92 and associated discussion), but for our entry to the ribbon-mic preamp challenge we went with the dc-coupled differential open-loop configuration shown. No giant input capacitors here; but to deal with the doubled noise power we had to reduce $r_{bb'}$ and r_e by a factor of 2 (i.e., we doubled the number of paralleled transistors used for each side of the input pair).

B. Choosing a low-noise BJT

For a circuit like this it's essential to use a transistor (or several in parallel) that exhibits very low input-noise voltage. That requires a base resistance $r_{bb'}$ down in the range of just a few ohms. Sadly, $r_{bb'}$ is rarely specified; and the excellent low-$r_{bb'}$ transistors of yesteryear have largely gone extinct. A case in point is the fine Toyo–Rohm 2SD786, with a specified typical $r_{bb'}$ of 4 Ω (it's *npn*; the 2SB737 *pnp* complement is better still, with a specified typical $r_{bb'}$ of 2 Ω). Actual samples of each performed even better, with measured $r_{bb'}$ values around 2.3 Ω and 1.2 Ω, respectively.

You can't get these anymore (and we won't part with any of our precious and dwindling "lifetime" stock! Even if you beg us.). What about the "low-noise" small-signal BJTs you *can* get, such as the 2SC3324? The good news is that they *do* specify their noise performance, as we saw in §8.4. The bad news is that they don't promise a whole lot ("NF=0.2 dB typ, 3 dB max"); and these small-geometry transistors are generally optimized for operation at low current, where the r_e noise contribution is so large that there's no need to keep $r_{bb'}$ small. For example, the 2SC3324 achieves its minimum noise figure around $I_C = 30\,\mu$A; at that current r_e is 830 Ω, and thus its $r_{bb'}$ noise contribution is insignificant as long as $r_{bb'}$ is kept below, say, 200 Ω. Our samples measured $r_{bb'} \approx 40\,\Omega$ – plenty good enough for these transistors' intended low-current application, but not helpful here.

We embarked on a search for low-$r_{bb'}$ transistors and found that the situation is not bleak. It's just unspecified. In the circuit design community you'll find mention of good noise properties with large-geometry transistors (i.e., power transistors).[52] We measured the noise voltage (details later) of a few dozen promising candidates (most of which are listed in Table 8.1a on page 501), and found that, indeed, some of the large geometry ("power") transistors have $r_{bb'}$ values down below 10 Ω, and deliver quite respectable input-referred e_n when operated at currents of 10 mA or so (where the r_e contribution is equivalent to Johnson noise from a 1.25 Ω resistor). Figure 8.17 (back on page 486) shows that the ZTX851 (a 5 A, 60 V transistor, lacking any official low-noise endorsement) performs on a par with the legendary 2SD786; you can see, also, that the larger $r_{bb'}$ of the smaller geometry "low noise" parts like the 2N5089 and 2SC3324 makes them non-competitive in this high-I_C/low-e_n arena.

As we remarked earlier (§8.3.1), where we showed a plot (Figure 8.12) of e_n versus collector current for six candidate low-noise transistors, there's not much benefit in having a low $r_{bb'}$ if you are operating at low current (where the effect of r_e dominates); but it really matters at higher currents, which is where you have to operate if you want to achieve e_n values southward of 1 nV/$\sqrt{\text{Hz}}$.

To emphasize this latter point, we show in Figure 8.43 a plot of the voltage noise spectra of the ZTX851 over a large range of collector currents (seen earlier in Figure 8.18, and here extended down to 4 Hz). The lesson here is that you have to run plenty of current to get really low e_n. Don't overdo it, though: as seen in the earlier Figure 8.18, at still higher currents the low-frequency noise rises, owing to a rapidly increasing base-current flicker-noise contribution. For this transistor the "sweet spot" is at a collector current of ∼5 mA.

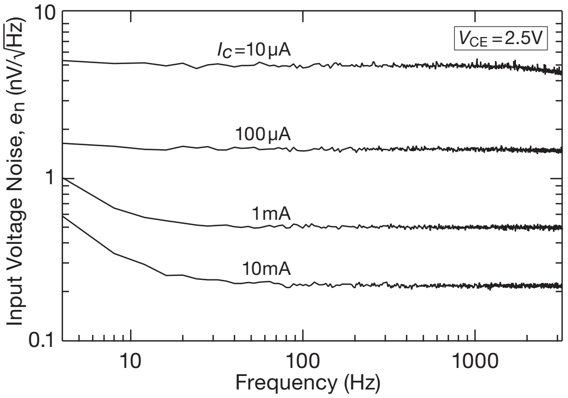

Figure 8.43. To reap the benefits of a transistor with desirable low base spreading resistance $r_{bb'}$ (thus low Johnson noise), you must operate at a high enough collector current to make the r_e noise contribution comparably small, as shown in these measured noise spectra of a ZTX851 *npn* transistor.

C. Beating the 0.1 nV/$\sqrt{\text{Hz}}$ goal

Among our candidates, we found that the quietest *pnp* transistors were somewhat better than their *npn* cousins. For example, at $I_C = 10$ mA a typical (average of six samples) *pnp* ZTX951 measured $e_n = 0.20$ nV/$\sqrt{\text{Hz}}$, compared with 0.21 nV/$\sqrt{\text{Hz}}$ for the ZTX851 *npn* complement

[52] Check out the website of the remarkable Uwe Beis (www.beis.de), who has used the MJE13007 (8 A 400 V); or Ovidiu's low-noise designs at www.synaesthesia.ca, with reported $r_{bb'}$ values below 2 Ω for the 2SC3601 and 2SC2547.

(corresponding to $r_{bb'}$ values of 1.2 Ω and 1.5 Ω, respectively). We're not sure why this is so, although as we remarked earlier the noise specifications of the legendary *npn* 2SD786 (with *pnp* 2SB737 complement) indicate the same trend.[53]

We used the differential circuit variant of Figure 8.42, with a parallel array of transistors for each of the input pair, followed with a G=30 quiet op-amp stage (made with the tried-and-tested LT1128, whose input noise voltage is $\lesssim$1 nV/$\sqrt{\text{Hz}}$ all the way down to 10 Hz). Ordinarily you'd include a small "emitter-ballasting" resistor in series with each emitter of the parallel array, chosen to drop ∼50 mV or so in order to equalize the currents and prevent current hogging; at 10 mA per transistor that would amount to 5 Ω, adding an unacceptable amount of noise voltage. It's often said that transistors from a single production batch are inherently matched in their base-emitter voltage drops; out of curiosity we measured V_{BE} for a batch of 100 each of ZTX851 and ZTX951, with the results shown in the histogram of Figure 8.44. The matching is quite good, enough so that no emitter ballasting resistors are needed.[54] The same is *not* true for JFETs, by the way; see Figure 3.17's histogram of three hundred representative *n*-channel parts, painstakingly made[55] from three batches of 100 JFETs, in the popular 2N5457–59 series of *n*-channel parts (graded by I_{DSS}).

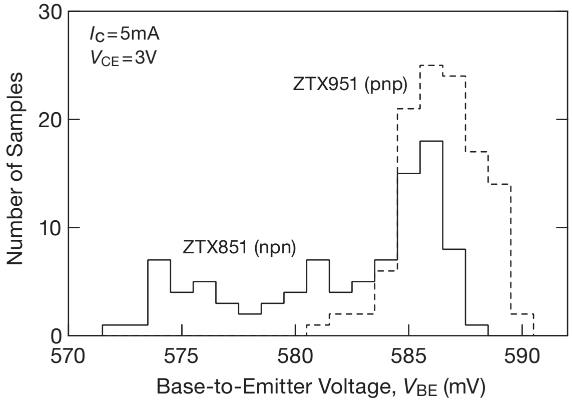

Figure 8.44. Distribution of measured V_{BE} in a batch of 100 each of *npn* and *pnp* parts.

For a circuit like this, with resistive collector loads and emitter pulldowns, the dc supply rails must be quiet, because noise on the rails appears unattenuated at the output. Here we used a so-called *capacitance multiplier* to eliminate supply noise; it's a useful subcircuit – see the description in §8.15.

The final results?…(drumroll)…here are measured noise voltages for several transistor configurations (with some graphs in Figure 8.45):

		I_C	e_n (nV/$\sqrt{\text{Hz}}$)	
transistor	qty	(mA)	@1 kHz	@100 Hz
ZTX951	2×16	2×100	0.085	0.10
	2×32	2×200	0.070	0.09
BD437	2×24	2×100	0.095	0.17
	2×24	2×200	0.080	0.13
2SC3601E	2×12	2×200	0.093	0.18

This is impressively low input noise voltage – you rarely see figures below 0.5 nV/$\sqrt{\text{Hz}}$ – but it's only fair to point out the unusual nature of this challenge, with its ultralow source impedance of less than an ohm, thus tolerant of the low input impedance (and relatively high input current) of a grounded-emitter amplifier stage running at a collector current of 100 mA. Getting to much lower input currents, though, is best accomplished with JFETs, as we'll see presently.

D. Measuring BJT noise

How did we make these transistor noise measurements? There are fancy commercial instruments you can buy to measure noise parameters (e_n, i_n, NF) of discrete transistors (BJT or FET); these are generally aimed at RF and microwave characterization (although the discontinued

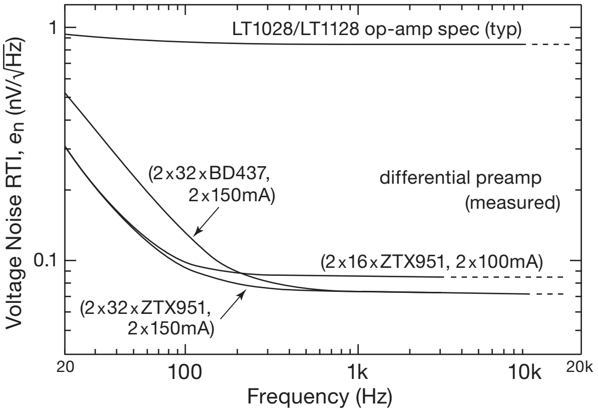

Figure 8.45. Measured noise voltage spectra for the amplifier of Figure 8.42, with three choices of input transistor and operating current. The preamp with 64 ZTX951 transistors is the winner.

[53] This may be related to the larger die size needed for a similarly-performing *pnp* transistor.

[54] We found similarly good matching for a batch of BD437s (an inexpensive and widely available BJT for "medium-power linear and switching applications").

[55] *Literally*! One's fingertips were rendered quite tender, after lead-forming and inserting three hundred transistors.

HP/Agilent 4470A measured e_n, i_n, and NF at eleven spot frequencies, two per decade from 10 Hz to 1 MHz). We took a more modest route, building our own simple circuit. It's basically the device under test (DUT) configured as a grounded emitter amplifier stage, with settable collector current and collector-to-emitter voltage, and provision for determining its voltage gain. Knowing the latter, you measure the output noise voltage spectrum, first with the input bypassed (to get e_n), then with a series resistor at the input (to get i_n). It's described in detail in §8.12.2.

8.6 Low-noise design with JFETS

Picking up where we left off (at §8.5.6), for high source impedances it's transistor *current* noise that dominates, thus favoring FETs, usually in the form of a JFET. Compared with BJTs, JFETs generally have greater voltage noise, but very much lower gate current (and current noise), and so they're the universal choice for low-noise high-impedance amplifiers. In this context it is sometimes useful to think of Johnson-noise voltage, in combination with the signal's source resistance, as a *current* noise $i_n = v_n/R_s$ (as plotted earlier in Figure 8.1). This lets you compare source-noise contributions with amplifier current noise.

We can use the same amplifier noise model for FETs, namely a series noise-voltage source and a parallel noise-current source. You can analyze the noise performance with exactly the same methods used for bipolar transistors. For example, see the graphs in Figure 8.53 in §8.7 where we referee the "bipolar/FET shootout."

8.6.1 Voltage noise of JFETs

For JFETs the voltage noise e_n is essentially the Johnson noise of the channel resistance, given approximately by

$$e_n^2 = 4kT\left(\frac{2}{3}\frac{1}{g_m}\right) \quad \mathrm{V^2/Hz}, \qquad (8.34)$$

where the inverse transconductance term takes the place of resistance in the Johnson-noise formula; in other words, the noise voltage is the same as the Johnson noise produced by a resistor of value $R=\frac{2}{3}\frac{1}{g_m}$ (analogous to the input noise voltage of a BJT, whose e_n is equivalent to the Johnson noise of a resistor of value $R=\frac{1}{2}\frac{1}{g_m}$). You can see from Figure 8.46 (measured noise voltage versus transconductance[56]) that this sets a reliable lower bound to the actual noise voltage, which can be somewhat greater in practice.

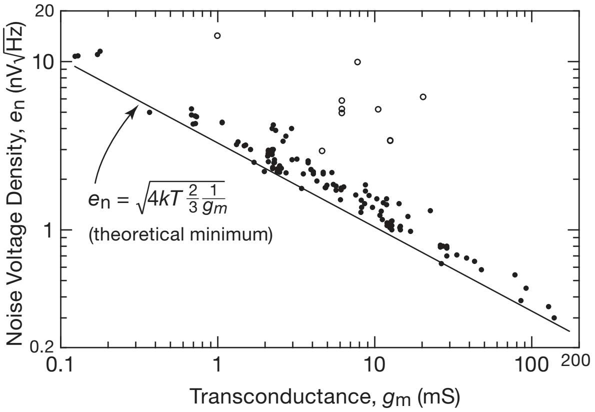

Figure 8.46. Testing the JFET noise formula: scatterplot of measured noise voltage density (well above the $1/f$ corner frequency) versus measured transconductance for a selection of 50 different JFET types, operated at various drain currents. Open circles indicate JFETs whose noise had not flattened to the white-noise floor at our maximum frequency.

Because the transconductance rises with increasing drain current (as $\sqrt{I_D}$, see §3.3.3, Figure 3.54, and Table 3.7), it is generally best to operate FETs at high drain current for lowest voltage noise. However, because the e_n is Johnson noise, which goes only as $1/\sqrt{g_m}$, and that in turn goes as $\sqrt{I_D}$, e_n is finally inversely proportional to the fourth root of I_D. With such a mild dependence of e_n on I_D it doesn't pay to run at a drain current so high that other properties of the amplifier are degraded. In particular, a FET running at high current gets hot, which (a) decreases g_m, (b) increases offset voltage drift and CMRR, and (c) raises gate leakage dramatically; the latter effect can actually *increase* voltage noise, because there is some contribution to e_n from flicker noise associated with the gate leakage current.

There is another way to increase g_m and therefore decrease JFET voltage noise: by paralleling a pair of JFETs, you get twice the g_m, but of course this is at twice the I_D. But now if you run the combination at the previous I_D,

[56] More than 100 measurements on some 65 transistors chosen from 50 different types, and at various currents ranging from 75 μA to 50 mA, creating many different g_m test values. We followed the declining e_n with rising frequency until we found the high-frequency white-noise floor. This yielded a wide range of conditions under which to test the formula. No parts were better, but many were 10% to 30% worse. Others were much worse, up to ×2. For some the noise continued to fall with increasing frequency, so we couldn't find the noise floor; these are indicated with open circles on the graph. The takeaway lesson: get g_m as high as possible for low e_n. Remember, paralleling or using larger-die JFETs is a good way to increase g_m. But watch out for high capacitance and leakage. And keep in mind that $1/f$ noise and low-frequency noise plateaus can dominate your design. Examine our plots and the data for JFETs in Table 8.2 on page 516. For critical projects, take your own measurements.

you still improve g_m by a factor of $\sqrt{2}$ over the single-JFET value, without increasing total drain current; so you decrease e_n by a factor of the 4th root of 2, to 84% of the single-JFET value.[57] In practice you can simply parallel a number of matched JFETs, or look for a large-geometry JFET like the IFN146 ($0.7\,\text{nV}/\sqrt{\text{Hz}}$) or IF3601 ($0.3\,\text{nV}/\sqrt{\text{Hz}}$) mentioned earlier.[58]

There is a price to pay, however. All the capacitances scale with the number of paralleled JFETs. As a result, high-frequency performance (including noise figure) is degraded. In practice you should stop paralleling additional transistors when the circuit's input capacitance roughly matches the source's capacitance. If you care about performance at high frequencies, choose JFETs with high g_m and low C_{rss}; you might consider the ratios g_m/C_{rss} and g_m/C_{iss} to be high-frequency figures of merit (recall that $f_{\text{T}}{=}g_m/2\pi C$, where C is the input capacitance or Miller capacitance, depending on the circuit configuration). Note that circuit configurations can also play an important role; e.g., the cascode circuit can be used to eliminate the Miller effect (gain multiplication) on C_{rss}.

In Figure 8.52 we've plotted an extensive collection of measured noise voltage for many of the JFETs in Table 8.2. See also Table 3.7, with additional JFET characteristics (not related to noise), and the "Measured transconductance" graph in §*3x.2* for plots of JFET transconductance versus drain current.

A. JFET 1/*f* voltage noise

Like their BJT brothers, most JFETs suffer also from rising noise voltage density at low frequencies, as seen in the measured data of Figure 8.47. In some cases (such as the 2SK170B) the $1/f$ noise is quite subdued and can be characterized by a single noise-corner frequency f_{c}, similar to BJTs. In such cases the noise corner can be estimated with eq'n 8.27, and, once f_{c} is known, the noise density can be calculated with eq'n 8.28. The plot shows 1 kHz noise voltage density ranging from $1\,\text{nV}/\sqrt{\text{Hz}}$ for the 2SK170B, to $2.8\,\text{nV}/\sqrt{\text{Hz}}$ for the low-capacitance 2N5457, to $11\,\text{nV}/\sqrt{\text{Hz}}$ for the small-die PN4117 (for which the drain current is I_{DSS}, here $75\,\mu\text{A}$).

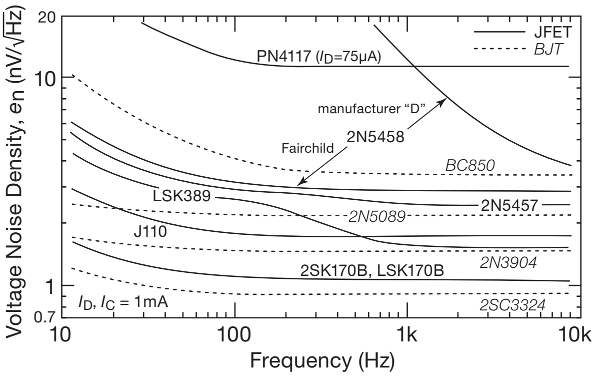

Figure 8.47. Measured voltage noise density versus frequency for several BJTs and JFETs, illustrating the $1/f$-like rise at low frequencies. See Figure 8.52 for an extensive set of JFET noise plots.

But some JFETs suffer from an elevated low-frequency noise plateau region,[59] like that of the LSK389. This part has an attractively low-noise density of $1.8\,\text{nV}/\sqrt{\text{Hz}}$ at 1 kHz and above, but it rises, in a snake-like curve, to twice that value in the 100 Hz region. This is not a terribly serious drawback for this otherwise excellent part, and it still enjoys low wideband noise levels of about 70 nVrms and 180 nVrms for 1 kHz and 10 kHz total bandwidths, respectively.

Sometimes this effect can get out of hand. For example, compare Fairchild's quiet version of the 2N5486, with $e_{\text{n}}{=}3\,\text{nV}/\sqrt{\text{Hz}}$, with the noisy sample we measured from "manufacturer D": the latter's $4.5\,\text{nV}/\sqrt{\text{Hz}}$ at 10 kHz climbs steeply at lower frequencies, going off-scale at 700 Hz. It climbs to $50\,\text{nV}/\sqrt{\text{Hz}}$ at 100 Hz, some 15× that of the quiet Fairchild JFET with the same part number. As a result the noisy part has about $1\,\mu\text{V}$ of wideband noise (to 1 kHz). For a stunning comparison of noise variation

[57] The 4th root noise-to-current relationship holds for JFETs operated in their high current density region, say above $I_{\text{DSS}}/100$ (see the "Measured transconductance" plots of g_m versus I_{D} in §*3x.2*), but at low current densities (where $g_m{\propto}I_{\text{D}}$) the decrease in noise will approach a square-root relationship, just as with BJTs. For example, the measured noise in an IF3601 increased by a factor of 2.8 (nearly $\sqrt{10}$) when the drain current was reduced from 1 mA to 0.1 mA.

[58] Paralleling JFETs lowers the current density, pushing the g_m versus I_{D} plot up toward its maximum, where it would match that of a BJT, see Figure *3x.10*, which shows a given JFET's potential for improvement. Some parts (such as the IF3601) are already close to this limit, so that little further improvement can be expected.

[59] Called "roller-coaster" noise by Motchenbacher and Connelly. The mechanism for the excess $1/f$ noise was identified in the early 1960s as a bulk rather than surface effect, involving random capture or emission of electrons trapped in the depletion region. See, for example, P. O. Lauritzen, "Low-frequency generation noise in junction field effect transistors," *Solid-State Electron.*, **8**, 1, 41–58 (1965), or C. T. Sah, "Theory of low-frequency generation noise in junction-gate field-effect transistors," *Proc. IEEE*, **52**, 7, 795–814 (1994). In the time domain this noise can take the form either of discrete steps between two or more voltage levels ("popcorn" or "telegraph" noise) or random sudden voltage excursions (burst noise); see Figures 8.5 and 8.6 for examples of popcorn noise in a vintage 741 BJT op-amp.

in 2N5486s made by multiple manufacturers, see the measured spectra in Figure 8.51. The noisiest part in that group has a 210 nV/$\sqrt{\text{Hz}}$ plateau, resulting in about 2.5 μVrms low frequency integrated voltage noise. In its defense, the 2N5486 "RF Amplifier" datasheet lists noise-figure specifications only at 100 MHz and 400 MHz. Note also that this low-frequency-noise excess does not affect operation at much higher frequencies (where "$e_n \cdot C_{in}$" noise, discussed in §8.11, rears its ugly head).

Although it's common to talk about $1/f$ noise and a corresponding corner frequency f_c, the reality is that many JFETs do not conform to such a neat model. In their datasheets, manufacturers deal with the issue of excess low-frequency noise in several ways. First, they may avoid a noise specification altogether. Second, they may give the e_n noise-density spec at relatively high frequencies – 10 kHz, 100 kHz, or even higher. Third, they may provide instead an rms noise voltage specification at some specified bandwidth. Fourth, they may give an intentionally high (conservative) specification, such as 115 nV/$\sqrt{\text{Hz}}$ max, or perhaps a 3 dB noise figure for R_s=1 MΩ (whose source noise-voltage density is a high 126 nV/$\sqrt{\text{Hz}}$). Fifth, they may give an e_n spec at say 100 Hz (where it's useful), but give a *typical* value only. Finally, for parts intended for high-frequency amplification, they may give their noise spec at *radio* frequencies – 100 MHz or higher.

8.6.2 Current noise of JFETs

At low frequencies the current noise i_n is extremely small, arising from the shot noise in the gate leakage current (Figure 8.48):[60]

$$i_n = \sqrt{2qI_G} = (3.2 \times 10^{-19} I_G)^{\frac{1}{2}} \quad \text{A/Hz}^{\frac{1}{2}}. \tag{8.35}$$

The noise current rises with increasing temperature, as the gate leakage current rises. Watch out for the rapidly increasing gate leakage in *n*-channel JFETs that occurs for operation at high V_{DG} and/or high I_D (see §3.2.8). A dose of reality: it's hard to estimate with any accuracy the level of current noise in JFETs, because the gate leakage is poorly specified. Too often you see unrealistically high worst-case specifications, for example I_G=1 nA (max), whereas at normal ambient temperatures it's more typically down in the 1–10 pA range. With such low bias currents the input noise-current density is very small, e.g., 1.8 fA/$\sqrt{\text{Hz}}$ for a gate leakage current of 10 pA. That noise current would generate an e_n just 1.8 nV/$\sqrt{\text{Hz}}$ through a signal source impedance of 1 MΩ (which, by the way, would itself have a Johnson-noise voltage of 128 nV/$\sqrt{\text{Hz}}$; the source resistance would have to reach 5 GΩ before the noise voltage generated by the JFET's noise current would match the Johnson noise of the source).

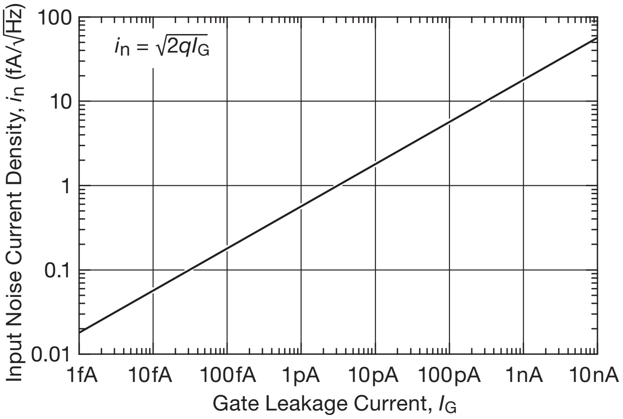

Figure 8.48. Input shot-noise current density versus FET gate leakage current.

At moderate to high frequencies there are additional noise and resistive terms.

(a) If there's a summing junction (for example in a transimpedance amplifier) then the input noise voltage e_n driving the input capacitance C_{in} generates a noise current of i_n=$e_n \omega C_{in}$, see §8.11 for details.

(b) In a common-source amplifier without cascode, there is an effective resistive part of the (normally capacitive) input impedance seen looking into the gate. This comes from the effect of feedback capacitance (Miller effect) when there is a phase shift at the output caused by load capacitance; i.e., the part of the output signal that is shifted 90° couples through the feedback capacitance C_{rss} to produce an effective resistance at the input, given by

$$R = \frac{1+\omega C_L R_L}{\omega^2 g_m C_{rss} C_L R_L^2} \text{ ohms} \tag{8.36}$$

Both effects rise linearly with frequency above a breakpoint, and both have similar breakpoint frequencies, typically in the range of 2–100 kHz for low-leakage JFETs.

As an example, the 2N5486 *n*-channel JFET has a noise current of ∼5 fA/$\sqrt{\text{Hz}}$ and a noise voltage e_n of 2.5 nV/$\sqrt{\text{Hz}}$, both at I_{DSS} and 10 kHz. These figures are roughly 200 times better in i_n and 2 times worse in e_n than the corresponding figures for the 2N5087 BJT used in connection with the noise figure plots in §8.5.1 (Figure 8.29). If we assume a 470 Ω load with 5 pF of shunt capacitance

[60] In addition, there is a flicker $(1/f)$ current-noise component in some FETs.

(68 MHz drain rolloff), the noise current begins climbing at about 30 kHz, and reaches levels of concern to the RF designer in the 10–100 MHz region.[61] It's not uncommon to see a cascode transistor added to suppress the effect and to improve the high-frequency gain.

With FETs you can achieve good noise performance for input impedances in the range of 10k to 100M. As we've seen (Figure 8.27), and whose secrets will be revealed presently (§8.6.4), the SRS model SR560 preamp has a noise figure of 1 dB or better for source impedances from 5kΩ to 20MΩ in the frequency range from 100 Hz to 10 kHz. Its performance at moderate frequencies corresponds to a noise voltage of $4\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ and a noise current of $0.013\,\mathrm{pA}/\sqrt{\mathrm{Hz}}$.

8.6.3 Design example: low-noise wideband JFET "hybrid" amplifiers

You can improve on the noise performance of commercial JFET preamps (and op-amps) by combining the best discrete JFETs with an op-amp in a "hybrid" design. Several nice circuit examples are shown in progressive examples in other chapters: (a) an ac-coupled low-noise wideband amplifier (to ∼20 MHz) with $e_\mathrm{n}{\approx}1\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ in Figure 3.34; (b) an analogous dc-coupled amplifier with $e_\mathrm{n}{\approx}2\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ in Figure 3.37; and (c) a dc-coupled low-noise wideband differential amplifier with $e_\mathrm{n}{\approx}2\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ in §*3x.4*.

The reader is encouraged to spend a few minutes (or even a half hour!) reviewing those examples, which illustrate important techniques in low-noise amplifier design with discrete JFETs (and also when combined with an op-amp second stage). Here we complete the progression of such hybrid designs with a dc-coupled *instrumentation amplifier* (INA; see §5.15) of comparably low-noise and wide bandwidth.

The circuit in Figure 8.49 is an evolution of the single-ended dc-coupled hybrid amplifier of Figure 3.37, two of which here form the differential amplifier input of the classic three-amplifier INA. The voltage gain (difference input to single-ended output) is $G{=}100$, set by the ratio $1{+}2R_\mathrm{f}/R_\mathrm{g}$. The ±2% trim of R_f2 is used to maximize the common-mode rejection ratio, a desirable feature that is responsible for much of the INA's fame. JFETs need help to achieve low offset voltage (Q_1 specifies 20 mV, worst case), so we've added an offset balance in $Q_{1a,b}$'s drain.

As for noise, the LSK389B[62] specifies a typical e_n of $0.9\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ at 1 kHz and $I_\mathrm{D}{=}2$ mA. At our 5 mA drain current we can expect slightly better; but the noise of each differential pair (e.g., $Q_{1a,b}$) is larger by a factor of $\sqrt{2}$, with another factor of $\sqrt{2}$ to account for the combined noise of the upper and lower differential pairs. As with the single-ended amplifier of Figure 3.37, the op-amp's noise ($e_\mathrm{n}{\sim}12\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$) is reduced by a factor of the JFET pair's gain (∼20) when referred to the input. The overall noise voltage of this instrumentation amplifier is thus $\sim 2\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$. Combined with its bandwidth (∼20 MHz, for signal source impedance ≤1k Ω), this is better performance than can be had in available instrumentation amplifiers.

Can we do better? The easiest way to beat down the JFET voltage noise is to add a second pair of JFETs at each input, paralleling the existing gate and drain terminals, but with each pair pulled down with its own 10 mA current sink (and with the drain resistors now 500 Ω). That reduces the input voltage noise by $\sqrt{2}$, and there is no need to worry about V_GS matching between the separate JFET matched pairs (figure out why). Finally, if you want to minimize input current, add a pair of cascode transistors to keep the V_DS of Q_1 below 5 V; see §3.2.8 and Figures 5.61 and 8.67.

8.6.4 Designs by the masters: SR560 low-noise preamplifier

It's always instructive to look at the innards of a good commercial product. Stanford Research Systems (SRS) has a nice line of scientific instruments, among which you'll find their SR560 low-noise preamplifier, in continuous production since 1989. It uses a differential JFET front-end for high input impedance (100 MΩ‖25 pF), and it has a nice set of panel controls that let you select things like the voltage gain (calibrated ×1 to ×50,000, in a 1–2–5 sequence or uncalibrated over the same range), frequency response (via switchable lowpass and highpass sections), ac or dc coupling, phase inversion, and so on. It's a good performer – noise-voltage density better than $4\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$, response flat to ±0.5 dB to 1 MHz, 0.01% typical distortion, and output swing to 10 Vpp.

We showed this puppy's specified noise-figure contours in Figure 8.27. Let's look under the hood to see how they did it. Figure 8.50 shows the front-end amplifier circuit, in full detail (Figure 8.50A) and in simplified forms (circuit B, block diagram C).

[61] We made bench measurements that confirmed (within a factor of 2) the resistive input component predicted by eq'n 8.36. In a JFET common-source amplifier without cascode this effect could greatly lower the Q of an RF-tuned circuit.

[62] An available substitute for the excellent but discontinued 2SK389 from Toshiba.

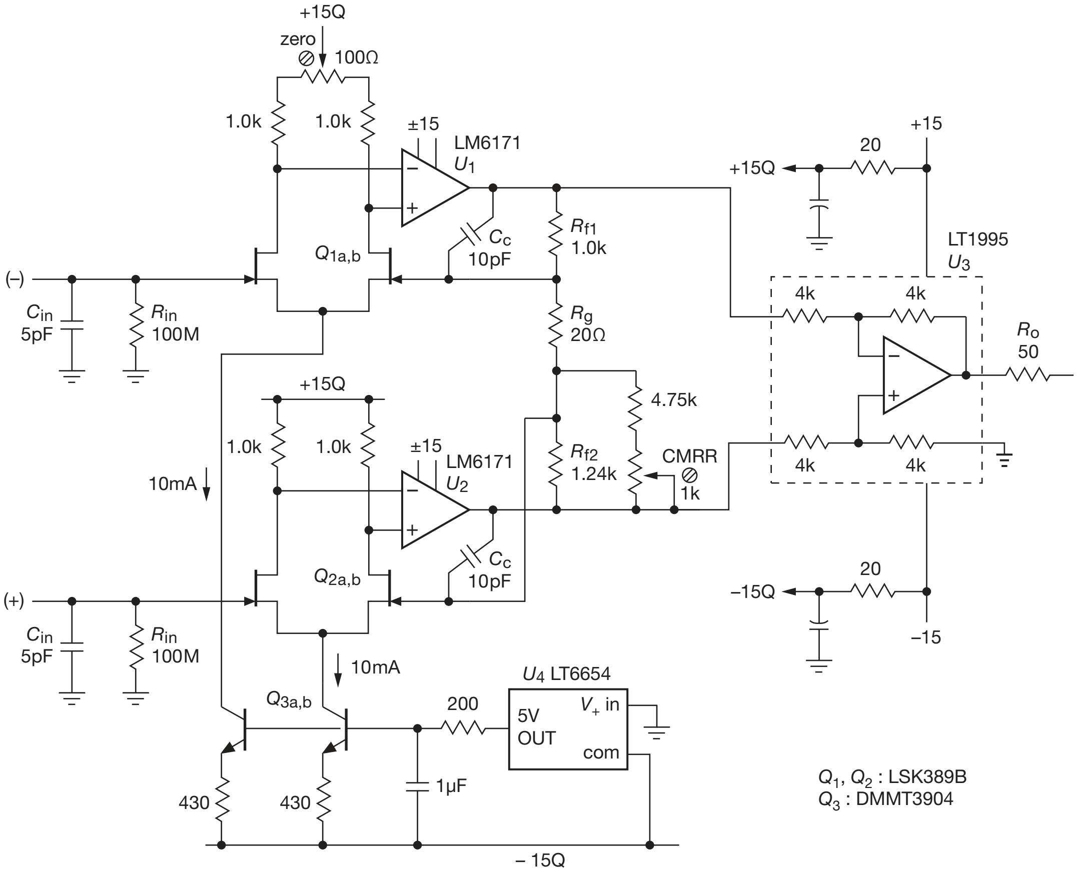

Figure 8.49. Hybrid JFET-input low-noise wideband instrumentation amplifier: G=100, $e_n \approx 2\,\text{nV}/\sqrt{\text{Hz}}$, BW≈ 20 MHz.

Overall topology Matched low-noise JFET pair Q_{1ab}, running at 4.6 mA (close to its guaranteed minimum I_{DSS}, see below), forms the fully differential first stage, in a hybrid configuration in which the JFET differential output drives an op-amp (analogous to Figure 3.37), but here configured with feedback to Q_{1a}'s source terminal so that both JFET gates are available as external inputs. The overall configuration is therefore a differential "current-feedback amplifier" (CFB, see §*4x.6*), analogous to the single-ended hybrid circuit of Figure 3.34, and instrumentation amplifier configuration "C" in Figure 5.88. The first-stage native voltage gain is selectable as ×10 or ×2; for the latter a 499 Ω series resistor is switched in, and thus unity net gain is seen at the second stage's input. The second stage is an LT1028 low-noise op-amp ($e_n \sim 1\,\text{nV}/\sqrt{\text{Hz}}$ at 10 Hz), G=10, with $\lesssim$100 Ω source impedance at both inputs to preserve low noise voltage. With the input divider the overall second-stage gain is ×2, ×5, or ×10.

JFET bias The designer nicely finessed the business of uncertain I_{DSS} by sensing the average drain voltage, comparing it with a +6.2 V reference, and closing the loop via integrator U_2. This is a reliable way to deal with loose I_{DSS} specs, for example those of the original NPD5564 dual JFET (I_{DSS}=5 mA min, 30 mA max). That JFET is no longer available from the original manufacturer,[63] but fortunately there's a superior replacement (LSK389B), with pleasantly tighter I_{DSS} specs (6 mA min, 12 mA max), and, as a bonus, lower noise voltage (at I_D=2 mA the NPD5564's typical noise-voltage densities at 10 Hz and at 1 kHz are $12\,\text{nV}/\sqrt{\text{Hz}}$ and $3.8\,\text{nV}/\sqrt{\text{Hz}}$, respectively; the LSK389B's corresponding figures are $2.5\,\text{nV}/\sqrt{\text{Hz}}$ and $0.9\,\text{nV}/\sqrt{\text{Hz}}$).

[63] Currently InterFET (direct sales only) is offering their similarly-spec'd IFN5564

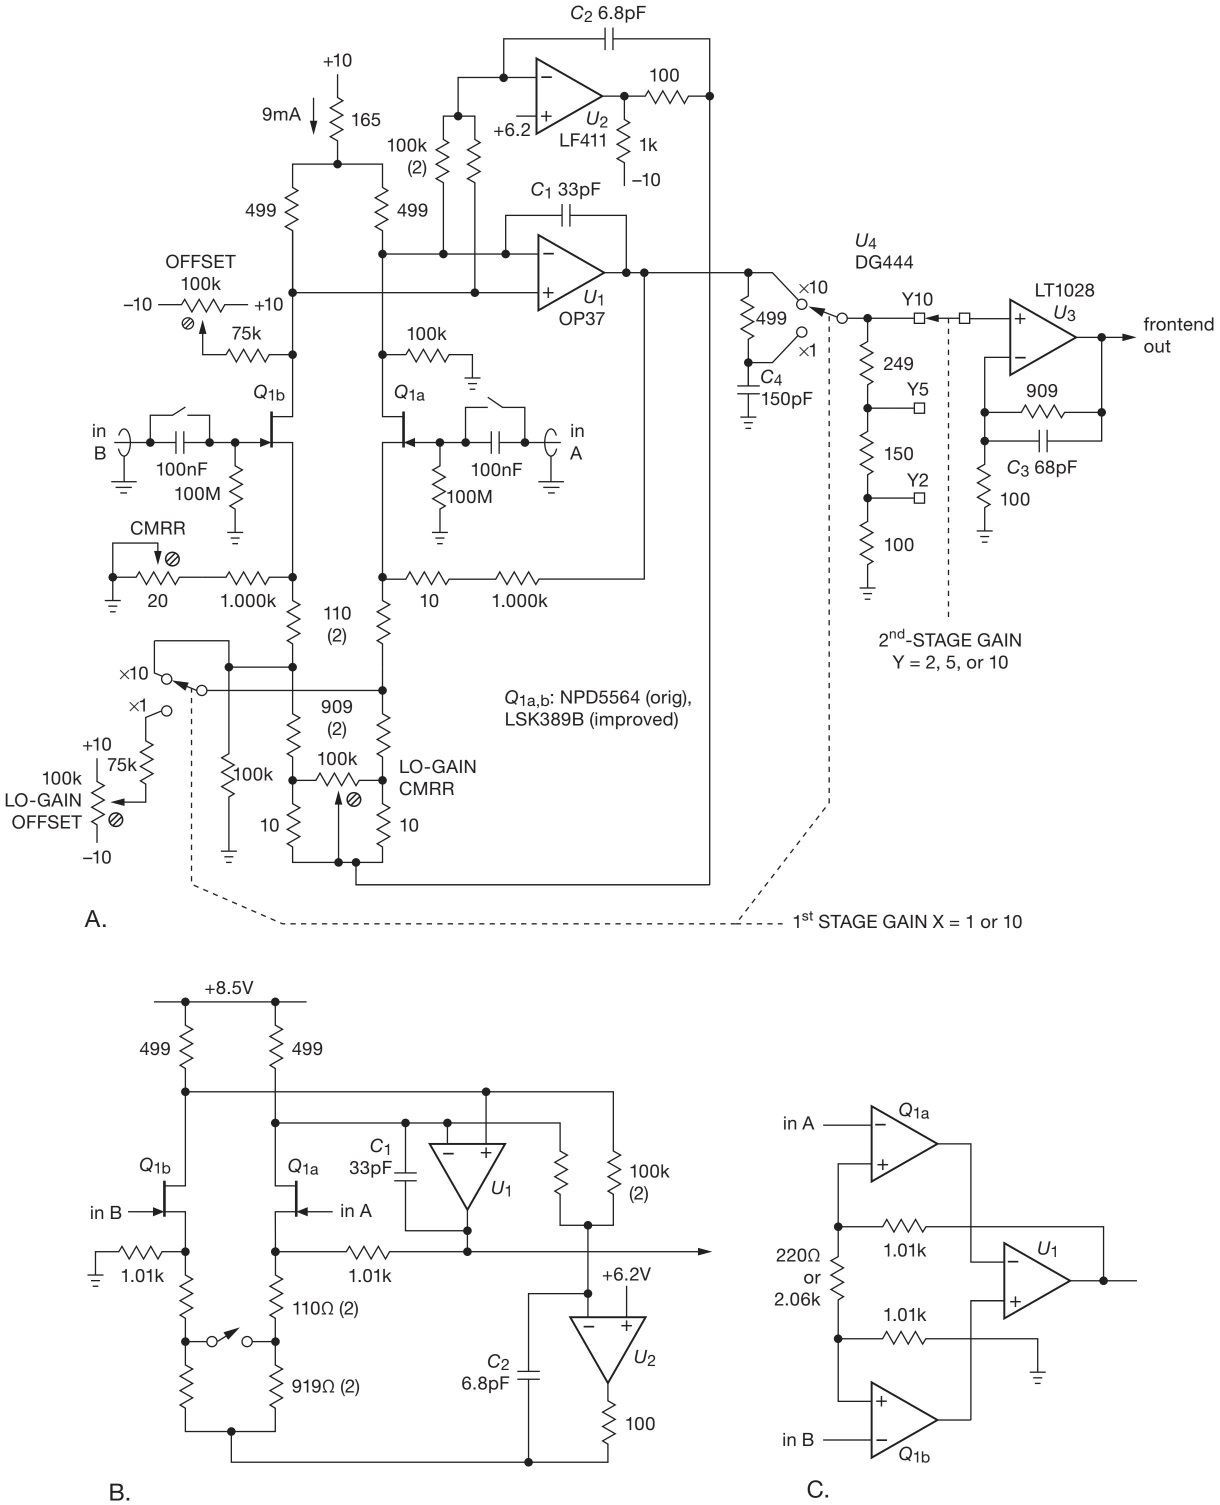

Figure 8.50. Front-end amplifier stages of the Stanford Research Systems SR560 Low-Noise Preamplifier (A: detailed; B and C: simplified). Some details of input signal switching have been omitted.

Bandwidth In the *signal path*, amplifier U_1 is a decompensated low-noise (e_n~3.5 nV/$\sqrt{\text{Hz}}$ typ at 10 Hz) wideband (f_T~63 MHz) op-amp, here configured as an integrator with f_T=5 MHz (33 pF and 1.0 kΩ). Its slew rate of 17 V/μs translates to a first-stage output of 5 Vpp at the instrument's rated 1 MHz bandwidth. In the second stage, capacitor C_3 limits the bandwidth to ~2 MHz. In the first-stage *bias path* (which matters for common-mode rejection), integrator U_2 has an output slew rate of 10 V/μs (min), so it can follow a 3 Vpp common-mode input (the instrument's rated maximum) at the full 1 MHz rated bandwidth. The integrator's unity-gain bandwidth is 230 kHz (6.8 pF and 50 kΩ), thus a bias-setting loop gain of 230 at 1 kHz. That puts an increasing CMRR burden on U_1 at higher frequencies, evident in the instrument's CMRR specification: > 90 dB to 1 kHz, decreasing by 6 dB/octave (i.e., as $1/f$) above 1 kHz.[64]

Offset voltage These dual JFETs are not in the same league as precision-matched BJTs, and they don't claim to be. The NPD5564 (the best grade in its family) has a specified maximum offset voltage (i.e., gate-source mismatch, $|V_{GS1}-V_{GS2}|$) of 5 mV at I_D=2 mA; the LSK389B, though excelling in noise performance, is considerably poorer, with a maximum mismatch of 20 mV (specified at I_D=1 mA). The SR560 deals with this problem by throwing pots at it: there's a 10-turn OFFSET trimmer in Q_{1b}'s drain, with enough range (±0.13 mA) to balance a worst-case offset, and a second 10-turn trimmer down in the source resistor string to independently balance the offset when switched to low gain. There is a pair of analogous CMRR trimmers, 20-turns each. We've done the calibration routine (complete with some iteration of the not-very-orthogonal adjustments), and can attest to the fussiness of getting (and sustaining) deep offset and CMRR nulls.

Noise voltage To minimize noise voltage, the JFETs are operated at relatively high current, and the resistor values (in the source, drain, and signal path generally) are intentionally small. With the original noise budget of ~4 nV/$\sqrt{\text{Hz}}$ it was acceptable, for example, to use 110 Ω resistors in the JFET sources. But a series pair of that resistance produces a Johnson noise-voltage density of 2 nV/$\sqrt{\text{Hz}}$, a bit more than we'd like when paired with these quieter JFETs. An optimized design would reduce those values by perhaps a factor of 2.

Miscellany Low-level signal switching (e.g., ac/dc/gnd input coupling, ×1/×10 gain selection, and A/B input interchange) is done with electromechanical relays. Not just any old relay, though – these guys use relays with gold-cladded twin contacts (intended for stable low resistance, even with low-level signals where there is no contact cleaning; see §*1x.6.1*). And these relays are the *latching* type, where a momentary pulse switches the state, thus eliminating noise-inducing coil currents in the steady state; this further eliminates local heating as a source of drift. In this instrument a microcontroller runs all relays and indicator lights, sensing a front-panel command (or external digital control), and appropriately pulses relays as needed to change their state.

8.6.5 Selecting low-noise JFETS

As we mentioned earlier, bipolar transistors offer the best noise performance with low source impedances, owing to their lower input-voltage noise. Voltage noise, e_n, is reduced by choosing a transistor with low base resistance, $r_{bb'}$, and operating at high collector current (as long as h_{FE} remains high). For higher source impedances the current noise can be minimized instead by operating at lower collector current.

At high values of source impedance, FETs are the best choices. Their voltage noise can be reduced by operating at higher drain currents, where the transconductance is highest. FETs intended for low-noise applications have high κ values (see §3.1.4), which generally means high input capacitance. For example, the low-noise 2SK170 has a typical C_{iss} of 30 pF, whereas the PN4117–9 series of low-current FETs has a *maximum* C_{iss} of just 3 pF.

Table 8.2 on the following page presents a selection of JFET candidates for low-noise circuits. It's meant to be used in conjunction with Table 3.7, which has more extensive tabular data, including single-sample measurements. Also refer to Figure *3x.10*'s transconductance plots, and Figure 8.52's noise plots. The entries near the bottom of Table 8.2 are dual JFETs, suitable for differential stages; but note that their V_{os} is not impressive – generally far inferior to even the poorest op-amps (the interdigitated LS840, whose layout is shown in Figure 3.18, is the best of the lot, with 2 mV typical, 5 mV worst-case offset voltage).

We favor JFETs with high transconductance and low gate-cutoff voltages, but sadly many of the old favorites with superior performance have been discontinued. NXP's BF862 has become a "go-to" low-noise part, both quiet and with attractively low capacitance. Toshiba's 2SK170 has been single-handedly kept in stock by large factory purchases by Mouser, and the second-source LSK170 is

[64] The high-frequency CMRR could likely be improved by configuring U_1's output to control a pair of current-sink transistors biasing Q_{1ab}.

PREFIXES: IF = interFET, LS = Linear Integrated Systems, PMB = NXP.

NOTES: ◊ = √Hz. * = same as row above. (a) sorted by decreasing voltage noise, and also by part number within a family. (b) preferred part. (c) complement 2SJ74. (d) discontinued, shown for comparison. (e) mV, max. (f) Fairchild part, others are much noisier. (g) LS840 has an interdigitated die. (k) dual unmatched J310. (m) maximum, or g_m@I_{DSS}. (n) RF JFET, high 1/f noise from several manufacturers. (o) also MPF4393 from ON Semi. (p) also PMBF- from NXP, very noisy. (t) typical.

A selection of currently available low-noise discrete JFETs. See also Table 3.7, which includes single-sample measurements of I_{DSS}, $V_{GS(off)}$, g_m, and g_{os}. The "Noise curve" column refers to corresponding measured noise spectra plotted in Figure 8.52. Some JFET types (e.g., the 2N5484–6 series) are intended for RF applications, and may exhibit high noise voltage density at low frequencies, as seen in the measured spectra of Figure 8.51. See also §3x.2 for plots of measured transconductance versus drain current.

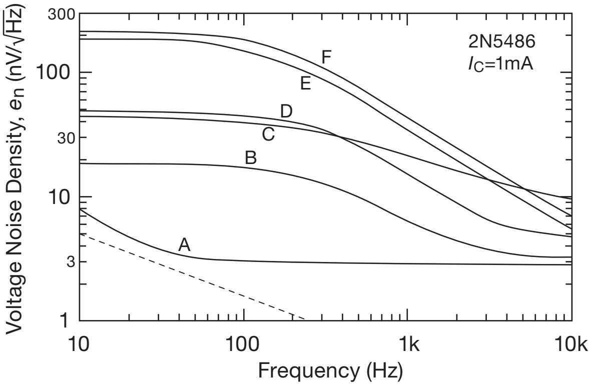

Figure 8.51. Beware unspecified noise parameters: measured voltage noise spectra of six 2N5486 JFET samples from five manufacturers (Fairchild's produced the winning "A" curve). Befitting its intended application as a "High-Frequency Amplifier," some datasheets specify noise performance only at high frequencies (e.g., ≥100 MHz). The slope of $1/f$ noise is indicated by the dashed line. JFETs "E" and "F" have 2.5 μVrms low-frequency noise (to 1 kHz).

available directly from Linear Integrated Systems, who also offer a matched dual version of the venerable '170, the LSK389. The excellent IFN146 and IFN147 are available directly from InterFET. Also consider the Fairchild J107, a low-cost switch that can moonlight as a low-noise JFET; with luck it will remain available.

Unspecified "low-noise" transistors *An important caution:* It is risky to rely on unspecified noise parameters, for instance the assumption (absent a manufacturer's e_n specification) that all transistors of a given part number will exhibit similar noise voltage to that measured in a sample batch. To see what can happen in practice, look at Figure 8.51, where we've plotted the measured noise-voltage spectra of six samples of a 2N5486 *n*-channel JFET. In fact, transistors even from the same manufacturer and production run may show large variations, as seen in Figure 8.40's measured noise spectra of four power transistors taken from a single batch. Figure 8.52 shows comparisons of the noise characteristics of a number of popular and useful JFETs.

Be aware of JFET weaknesses When we discussed the many considerations in choosing a low-noise *bipolar* transistor (§8.5.8), one factor of importance was the transistor's output resistance r_o (or, if you prefer, its output conductance, g_{oe}). For a BJT this is described by its Early voltage[65] V_A, whose measured values are listed in Table 8.1a on page 501. Most *npn* BJTs have fairly high V_A values, which is to say they have a high output resistance, thus ordinarily not a serious concern.

But that's not the case for JFETs. If you tried measuring an analogous "Early voltage" for JFETs, you would be disappointed in their low values. The parameter commonly used to describe the variation of drain current with drain voltage is output conductance, g_{os}, which varies with both drain voltage and drain current. For many JFETs the output conductance (ideally zero) is high enough to have a serious affect on amplifier gain. Because the value of a JFET's g_{os} is roughly proportional to its transconductance (g_m), we've defined a parameter $G_{max}=g_m/g_{os}$, which represents the maximum voltage gain of a common-source amplifier with high-impedance drain load.[66] This parameter is not listed in Table 8.2, but you can find it in the JFET listing of Table 3.7. You need to take it into account when designing a JFET amplifier stage, perhaps circumventing its gain-killing effect by adding a cascode; see §*3x.4*.

Some JFETs suffer also from a severe drop in transconductance at drain voltages of less than 2 V, especially at high drain currents; see the plots of transconductance versus drain voltage in §*3x.2*. If you're thinking of doing anything unusual in a low-noise JFET design, you'd do well to study first the JFET-specific material in Chapters 3 and *3x*.

8.7 Charting the bipolar–FET shootout

Let's have some fun with the graphical noise-charting technique we introduced in §8.5.2. A perennial bone of contention among engineers is whether FETs or bipolar transistors are "better." We dispose of this issue with characteristic humility by matching two of the best contenders and letting them deliver their best punches.

In the bipolar corner we have the magnificent 2SD786, whose vital statistics are displayed in Figure 8.10 and listed in Table 8.1a on page 501. Its noise voltage is $\sim$0.5 nV/$\sqrt{\text{Hz}}$ at 1 mA, with an admirably low $1/f$ noise corner well below 10 Hz; and its very low $r_{bb'}$ (we measured 2.3 Ω) allows us to get down to the 0.25 nV/$\sqrt{\text{Hz}}$ territory at higher collector currents. It has plenty of beta, too: above 200 at currents all the way down to 1 μA, which is helpful in achieving a low noise-*current*. It has been a perennial favorite among audio enthusiasts.

The FET entry is the 2SK170 *n*-channel JFET, known far and wide for its stunning low-noise performance, reputed to exceed that of bipolar transistors. Its very low

[65] Introduced in §2.3.2, and discussed in detail in §*2x.8*.

[66] We like G_{max} because it is largely independent of drain current, and varies in a predictable way (linearly) with drain voltage.

measured noise voltage can be seen in Figure 8.54, and its vital statistics are listed in Table 8.2 on page 516. According to its datasheet, it was trained only for drain currents ranging from 200 μA to 10 mA; but we've conservatively extrapolated its noise parameters down to 100 μA, so that we can evaluate it with drain currents ranging from 100 μA to 10 mA. We have high hopes for this fighter, given its very low input-current noise (~1 fA/$\sqrt{\text{Hz}}$, the shot noise corresponding to its gate leakage current of ~3 pA). In Figure 8.53 we've charted their total amplifier noise voltage versus source resistance at 1 kHz, just as we did for the 2N5087.[67]

[67] In our previous edition the contenders were the LM394 self-described "ultra well-matched monolithic NPN transistor pair" (e_n=1 nV/$\sqrt{\text{Hz}}$ at I_C=1 mA, versus 0.6 nV/$\sqrt{\text{Hz}}$ for this edition's 2SD786 championship contestant) and the 2N6483 matched monolithic *n*-channel JFET pair (e_n=4 nV/$\sqrt{\text{Hz}}$ at I_C=100 μA, versus 1.7 nV/$\sqrt{\text{Hz}}$ for this edition's 2SK170 entry). This edition's fighters are single transistors, rather than matched monolithic duals. Both contenders from the previous edition are long retired, having fought the good fight for several decades.

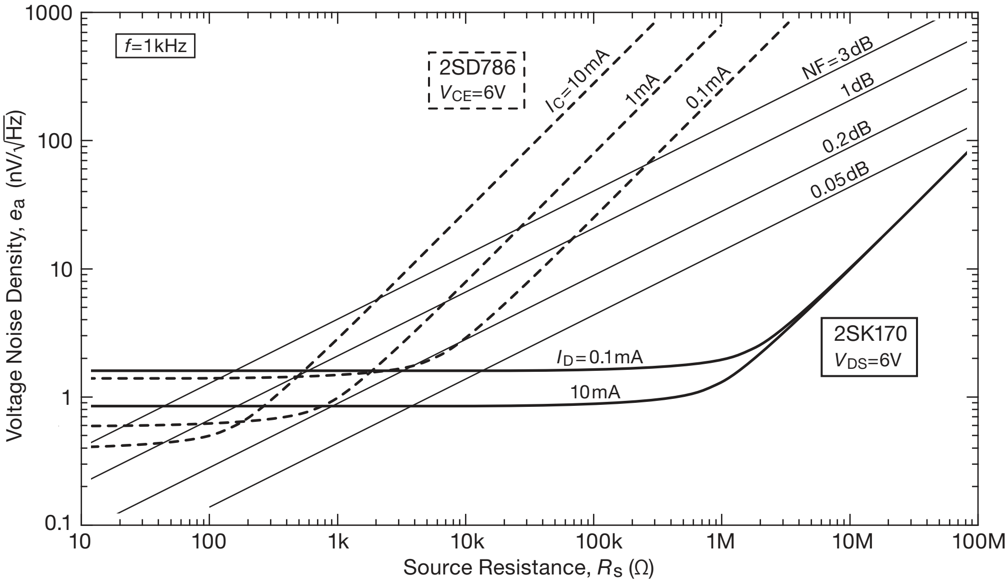

Figure 8.53. Comparison of total amplifier input voltage noise density (e_a) at 1 kHz, for the 2SD786 *npn* bipolar transistor (dashed lines) and the 2SK170 *n*-channel JFET (solid lines).

And the winner? Well, it's a split decision. The FET won points on lowest minimum noise figure, NF(R_n), reaching a phenomenal 0.0005 dB noise figure (that's a noise temperature of just 33 *milli*kelvin!), and dipping below 0.2 dB from 1k to 100M source impedance. For high source impedances, FETs remain unbeaten. The bipolar transistor is best at low source impedances, particularly below 5 kΩ, and it can reach a 0.2 dB noise figure for source resistances R_s from 1–10 kΩ, with a suitable choice of collector current. Although its victory in terms of noise alone is slim, it has other important virtues, notably its superior predictability of V_{BE} compared with a JFET's loosely characterized V_{GS}.

Just as in boxing, where the best fighters of yesteryear have retired from the rigors of competing, we must remind our readers, with some sadness, that the 2SD786 has been discontinued by Toyo–Rohm; and Toshiba's 2SK170 is sometimes available, sometimes not. However, also as in boxing, there are some younger contenders for the best low-noise transistor who haven't yet had a chance to compete in a world championship. The replacement LSK170 JFET from Linear Integrated Systems performs almost as well as its mentor; and the ZTX851 BJT from Zetex, though unspecified in noise performance, appears to outperform even the champion 2SD786 (as seen in the measured noise spectra of Figures 8.12 and 8.17).

And, if it's *really* low-noise voltage you want, consider the IF3601 from InterFET, with its 0.35 nV/$\sqrt{\text{Hz}}$ typical noise voltage *even down at 30 Hz*! And this is a *JFET*, with low input current (100 pA typ, hence low i_n, about 6 fA/$\sqrt{\text{Hz}}$), and thus the noise resistance is about 60k. When used as an amplifier with a source impedance equal to its noise resistance (i.e., R_s=60k), its performance is unbeatable – the noise figure is 0.001 dB. InterFET and Linear Integrated Systems JFETs must be purchased directly from the manufacturer, but in our experience they're happy to accept small orders.

Before you go out and buy a bushel of these remarkable JFETs, consider the remarks of the critics, who claim it is muscle-bound – it has high input and feedback capacitance (650 pF and 80 pF, respectively), which limits its usefulness at high frequencies. Its relative, the IFN146, is better in this regard, at the expense of higher e_n (75 pF and 15 pF, respectively, with e_n=0.7 nV/$\sqrt{\text{Hz}}$). These same critics argue that a bipolar complementary pair like the ZTX851 and ZTX951, with e_n as low as 0.3 nV/$\sqrt{\text{Hz}}$, can offer even better performance at moderate source impedances and frequencies.

8.7.1 What about MOSFETs?

The dominant FET species on the planet, by a demographic ratio of at least 10^{12}:1, is the *MOS*FET, of which the JFET is the poor (and neglected) sister. *We* haven't neglected

JFETs, though, because they're the best choice for discrete low-noise design, particularly when low noise at low frequencies is important (e.g., audio). As will be evident in §8.9, JFETs also dominate as input stages within op-amps where both low input current and low noise voltage are important.

So, what about MOSFETs for low-noise design? One problem is that you cannot get small MOSFETs as discrete parts. And MOSFETs tend to have much higher voltage noise than JFETs, particularly at low frequencies where the $1/f$ noise dominates – the $1/f$ knee can be as high as 10 kHz to 100 kHz. Figure 8.54 makes this point dramatically, plotting measured noise-voltage density versus frequency for a selection of representative MOSFETs, JFETs, and BJTs. The quietest BJTs are the winners (with low-noise JFETs not far behind), whereas at these audio frequencies the MOSFETs aren't even in the ballpark (and perhaps not even in the same city). For this reason you wouldn't normally choose a MOSFET for best-in-class low-noise amplifiers below 1 MHz.

MOSFETs *are* used as low-noise linear amplifiers, however, in the form of integrated circuits intended for radiofrequency applications. At those frequencies their noise performance is good enough, and the CMOS process allows convenient integration and low cost.

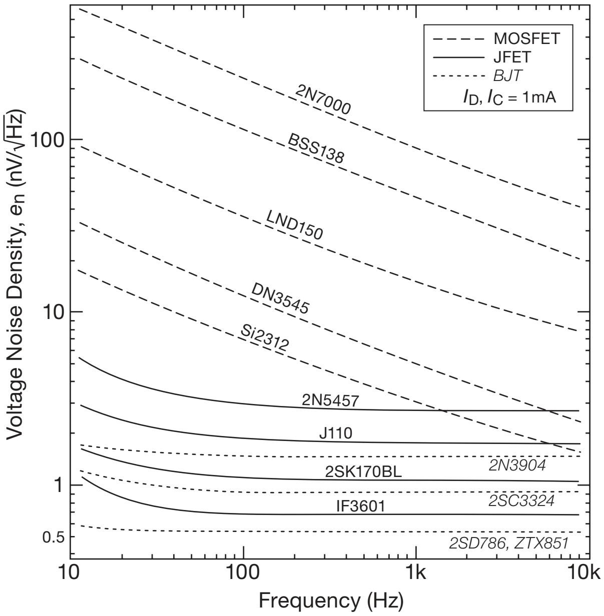

Figure 8.54. Comparison of measured noise-voltage spectra for some popular transistors: MOSFETs, JFETs, and BJTs. We included within each species both a "quietest" part and an inexpensive (<\$0.05 in quantity) and popular "jellybean."

MOSFETs are used also in "zero-drift" op-amps: their noise voltage density e_n is not impressive – typically in the range of 25–100 nV/$\sqrt{\text{Hz}}$ – but they exhibit no $1/f$ rise at low frequencies, so they compete as the quietest amplifiers for very low-frequency applications. This is seen clearly in Figure 5.54.[68]

8.8 Noise in differential and feedback amplifiers

Low-noise amplifiers are often differential, to obtain the usual benefits of low drift and good common-mode rejection. When you calculate the noise performance of a differential amplifier, there are three points to keep in mind: (a) be sure to use the individual collector currents, not the sum, to get e_n and i_n from data sheets; (b) the i_n seen at each input terminal is the same as for a single-ended amplifier configuration; and (c) the e_n seen at one input, with the other input grounded, say, is 3 dB larger than the single-transistor case, i.e., it is multiplied by $\sqrt{2}$.

In amplifiers with feedback, you want to take the equivalent noise sources e_n and i_n out of the feedback loop, so you can use them as previously described when calculating noise performance with a given signal source. Let's call the noise terms brought out of the feedback loop e_A and i_A, for *amplifier* noise terms. Thus the amplifier's noise contribution to a signal with source resistance R_s is

$$e^2 = e_A^2 + (R_s i_A)^2 \quad \text{V}^2/\text{Hz}. \qquad (8.37)$$

Let's take the two feedback configurations separately.

Noninverting For the noninverting amplifier (Figure 8.55) the input noise sources become[69]

$$i_A^2 = i_n^2 \quad \text{A}^2(\text{rms}), \qquad (8.38)$$

$$e_A^2 = e_n^2 + 4kTR_\parallel + (i_n R_\parallel)^2 \quad \text{V}^2(\text{rms}), \qquad (8.39)$$

where e_n is the "adjusted" noise voltage for the differential configuration, i.e., 3 dB larger than for a single-transistor stage. The additional noise-voltage terms arise from Johnson noise and input-stage noise current in the feedback resistors. Note that the effective noise voltage and current are now not completely uncorrelated, so calculations in which their squares are added can be in error by a maximum factor of 1.4.

[68] The OPA188 and OPA2188 high-voltage CMOS autozero op-amps are among the best you may find, with an e_n of 9 nV/$\sqrt{\text{Hz}}$ and a noise corner at 0.4 Hz. We won't vouch for their input *current* noise.

[69] See C. D. Motchenbacher and J. A. Connelly, *Low-noise Electronic System Design*, Wiley (1993), who show the complete expression for a full differential amplifier.

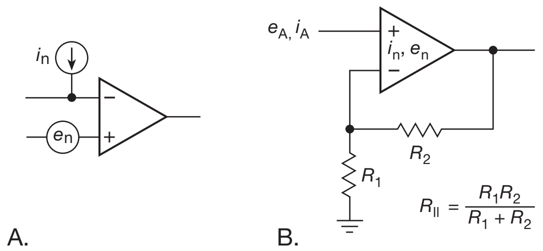

Figure 8.55. A. Noise model of the op-amp. B. Noise sources in the noninverting amplifier.

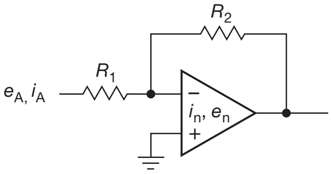

Figure 8.56. Noise sources in the inverting amplifier.

For a follower, R_2 is zero, and the effective noise sources are just those of the differential amplifier alone. Note that these drawings and formulas assume that the signal source resistance is zero (or at least small compared with $R_{\|}$, so as not to add Johnson noise).[70]

Inverting For the inverting amplifier (Figure 8.56) the input noise sources become

$$i_A^2 = i_n^2 + 4kT\frac{1}{R_1} \quad \mathrm{A}^2(\mathrm{rms}), \tag{8.40}$$

$$e_A^2 = e_n^2\left(1+\frac{R_1}{R_2}\right)^2 + 4kTR_1\left(1+\frac{R_1}{R_2}\right) + (i_nR_1)^2 \quad \mathrm{V}^2(\mathrm{rms}). \tag{8.41}$$

For differential amplifiers and ordinary op-amps the two input terminals have comparable input noise voltages, and noise currents. This is not true, however, for current-feedback (CFB) op-amps (§*4x.6*), where the noise current at the inverting input is generally much larger than at the non-inverting input.

Operational amplifiers These have differential inputs, so they play by the same rules. Op-amps dominate most analog designs, and for good reason: they are highly evolved and deliver excellent performance. There are thousands of op-amp choices, optimized for various combinations of parameters that include accuracy, speed, noise, power consumption, and supply voltage. If you can solve a design problem with op-amps, you probably should[71]. Following the theme of this chapter, low-noise design with op-amps is the subject of the next section.

8.9 Noise in operational amplifier circuits

Op-amp datasheets specify input noise in terms of e_n and i_n, just as with transistors and FETs. You'll see tabulated values, and usually plots of e_n and (sometimes) i_n versus frequency. Unlike design with discrete transistors, however, you don't get to adjust internal operating currents and component values – you only get to use them.

There are thousands of op-amps out there, with a good selection of parts aimed at low-noise applications. We've collected some 150 favorites in Tables 8.3a–8.3c, many of whose noise voltage and current density are plotted in Figures 8.60 and 8.61. How to choose among these? There's e_n and i_n, of course (and the corresponding $1/f$ low-frequency corner frequency f_c). But there are also all the usual performance tradeoffs: accuracy, speed, input current, power dissipation, and price. As an example, at $0.85\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ (and f_c=3.5 Hz) the LT1028 is among the lowest e_n op-amps available (curve A in the upper plot of Figure 8.60). But it draws 8.5 mA of supply current, with ∼1.8 mA devoted to the input stage alone. For all the reasons discussed in §8.3–§8.6, you can't match that kind of low-noise voltage in an op-amp whose total supply current is, say, 0.1 mA. And you may not want to: the LT1028's BJT inputs have plenty of bias current, with correspondingly high noise-current density ($\sim 1\,\mathrm{pA}/\sqrt{\mathrm{Hz}}$ – curve A again, this time in the lower plot of Figure 8.60). Put another way, the high-noise *current* of this low-e_n champ wipes out its noise advantage for an input signal of source impedance greater than 1 kΩ (its noise resistance, $R_n \equiv e_n/i_n$).[72]

Let's look more closely at low-noise design with op-amps. We begin with a guide to the extensive listing in Table 8.3.

[70] If an additional series resistor is added at the noninverting input (to balance input-current offsets, see Figure 4.55), consider shunting it with a capacitor to quiet its Johnson noise (e.g., C_1 in Figure 8.78).

[71] Look at it this way: an entire op-amp in a SOT-23 package is the same size as a single transistor in a SOT-23 package, and it may not cost much more. Table 8.3 lists over 60 op-amps that are available in SOT-23 packages, with prices as low as $0.72 (qty 25).

[72] While we're complaining about the LT1028, we might add that it's a bit pricey, about $6 apiece in modest quantity.

Notes: (a) see also op-amp tables in Chapters 4, 4x, and 5. (b) 0.01Hz or 0.1Hz to 10Hz. (c) calculated. (d) ***italics*** are lower-voltage JFET types. (d1) OP-37 decomp. (d2) OP228 decomp. (d3) OPA637 decomp. (d4) LT1037 decomp. (d5) OPA657 decomp. (d6) ADA4637 decomp. (d7) MAX4237 decomp. (d8) LMP7717 decomp. (g) LTC suggests LT1677, RRIO. (h) LTC suggests LT6200, 6230. (J) at 1kHz or 10kHz, except 10Hz for chopper types. (k) beyond the rail. (p) per amplifier. (q) ***italics*** are jellybeans. (s) SC70. (t) typical. (u) datasheet specs are 10x higher. (v) V_{OS} vs V_{CM} stable. (w) to 5V above the rail. (x) SOIC is non-std pinout. (y) DIP discontinued, NRND. **A:** specs at 5V. **B:** over-the-top, low I_B for $V_{CM}<V_{CC}-0.7$. **C:** OVP to +32V. **D:** LT1012 replacement, w/RRO. **E:** decomp, $G>5$. **F:** original classic. **G:** noisy classic. **H:** noisy, cheap; LM321 single. **I:** zero-drift, CMOS(!). **J:** improved OP177. **K:** 0.7ppm dist. **L:** classic audio. **M:** “RRIO LT1007.”

Notes: (a) listed within each category by decreasing e_n. (c) calculated. (d) see plots in Chapter 5. (g) for G=10 or G=20. (J) at 1kHz or 10kHz (above the 1/f corner), except 10Hz for auto-zero op-amps. (n) within 0.1V of V−. (p) per amplifier. (r) without C_{comp}. **(s)** SC70 available. (t) typical. (u) a pin sets G_{min}. (v) the LT1028 has a nasty ~10dB noise peak from 200kHz--600kHz. (w) at 100kHz. (x) G=1 with ext comp.

Comments: **A:** 0.1ppm distortion. **B:** lowest e_n; LTC suggests LT6200, LT6230. **C:** Hill favorite. **D:** use DDA pkg; Larkin favorite. **E:** OPA637 for DIP. **F:** improved SOIC pinout. **G:** LT6230-10 decomp. **H:** 1% dist at 50MHz. **K:** 0.03% dist at 10MHz. **L:** auto-zero. **M:** zero crossover.

8.9.1 Guide to Table 8.3: choosing low-noise op-amps

Table 8.3 lists a rich selection of op-amps suitable for low-noise applications. Here we provide a guide to the table entries, and advice for selecting op-amps. Because readers interested primarily in low-noise design with op-amps (rather than with discrete transistors) may have skipped over the earlier quantitative discussions of noise in connection with BJTs and JFETs, we restate below many of the basic ideas, with references to the relevant sections and figures. Readers whose route here (to what might be called “the promised land of op-amps”) has taken them through the details of discrete design (“the valley of complexity”) will find much of this discussion to be a welcome review.

A. Table sorting

In Table 8.3a we’ve listed BJT-input op-amps by increasing supply current I_Q, which correlates roughly with decreasing input noise voltage e_n. Once the latter falls below $5\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$, the entries are roughly ordered by decreasing e_n. For JFET-input op-amps (Table 8.3b) the entries are listed by increasing input bias current (up to 1 pA), then by decreasing e_n. CMOS op-amps are sorted by increasing I_Q, which correlates approximately with decreasing e_n. Table 8.3c is devoted to high-speed op-amps of all types, listed within each category by decreasing e_n.

B. Supply voltage, high voltage, low voltage

The table presents a good collection of low-noise op-amps, with a number of representative popular op-amps (some of which might well be called “noisy”) for comparison. The latter have other attractive features, such as low cost, high slew rate, low input bias current, low capacitance, low power, multiple manufacturers, and so on. The table separates “high-voltage” op-amps, capable of working with ±15 V supplies (or up to 36–44 V total supply), from op-amps that are limited to low voltages like 5–20 V maximum.

Note that many of the high-voltage op-amps (especially the bipolar types) can work also at very low supply voltages, as low as 2.2 V to 3 V total. So, for example, a precision “high-voltage” op-amp like the LT1677, which works fine with 3 V total supply, and which allows inputs and outputs to swing to either rail,[73] is also clearly an excellent low-voltage part. Op-amps whose inputs and outputs can swing to the negative rail qualify to be called “single-supply” op-amps, regardless of whether you run them from a single positive supply or from dual supplies.

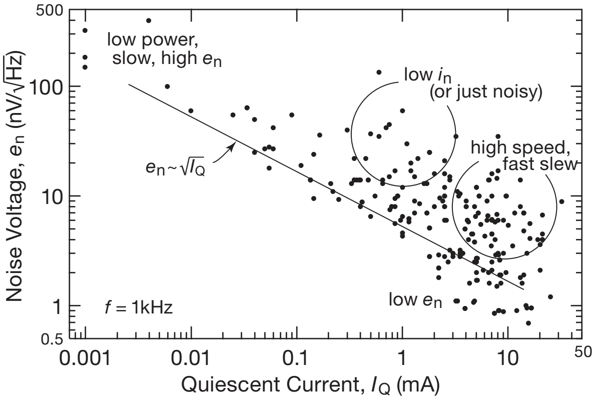

Figure 8.57. To minimize input noise voltage you have to run both BJTs and JFETs at relatively high quiescent currents. That trend extends to integrated op-amps, as seen here in a scatterplot of e_n versus I_Q for most of the op-amps in Table 8.3 and in Figures 8.60 and 8.61.

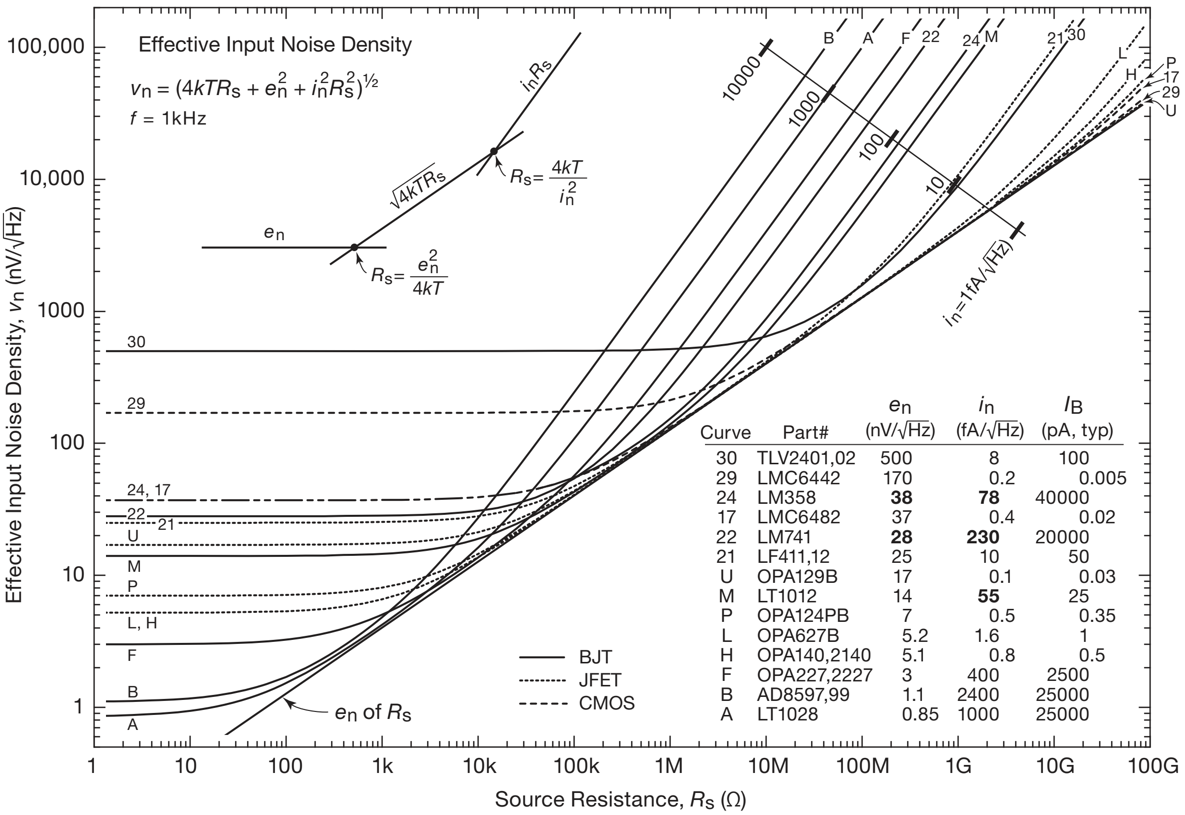
C. Supply current I_Q, and voltage noise

High supply current is also a major consideration for low noise voltage, e_n. Table 8.3 includes op-amps with very low I_Q, even though these op-amps have much higher noise. For example, the ISL28194 uses only 330 nA but has a high $265\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ noise density. By comparison, the quiet LT1028 has $0.85\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ of noise density, but requires 7.4 mA, or ∼20,000 times as much operating current.[74]

Figure 8.57 is a scatterplot of e_n versus I_Q for several hundred op-amps, showing the voltage-noise and supply-current tradeoff. You can see how the noise falls by approximately the square root of the operating current. Any part that’s within a factor of two of the best-available part at a given supply current might be considered a low-noise op-amp. The correlation with supply current is far from perfect. That’s because op-amp designers are balancing tradeoffs among many performance parameters, for example high slew rate, low input current, small die size (for small package size and low cost), and so on, at the expense of low noise voltage.

[73] The table has columns labeled “swing to supply” for inputs and outputs to both supply rails.

[74] Recall that collector [or drain] shot noise through r_e [or $1/g_m$] in BJTs [or JFETs] can be described equivalently as resistive Johnson noise created by a resistor of value $\frac{1}{2}r_\mathrm{e}$ [or $\frac{2}{3}\frac{1}{g_m}$], according to eq’ns 8.20 or 8.34. Because higher collector [or drain] currents produce lower r_e [or higher g_m], high operating currents are needed to lower an op-amp’s input-transistor noise voltage.



Curve	Part#	e_n (nV/√Hz)	i_n (fA/√Hz)	I_B (pA, typ)

Figure 8.58. Total noise (source resistor plus amplifier, at 1 kHz) versus source resistance for a selection of low-noise op-amps (letter labels); we've included a few "ordinary" op-amps (number labels) for comparison. The curve labels correspond to those in Table 8.3 and in Figures 8.60 and 8.61. The curves are generated from datasheet values of e_n and i_n, except for measured values (shown in bold font) for the noise parameters of the classic LM741 and LM358 (unspecified) and the LT1012 (datasheet value in error); the current noise of the LMC6482 is an estimate, as the datasheet value cannot be correct.

D. Voltage-noise density, current-noise density: e_n, i_n

Just as with discrete transistors, op-amp noise performance is specified by *voltage* noise, e_n, and *current* noise, i_n, and their variation with frequency; see §§8.3.1 and 8.3.2. Figure 8.58 and its embedded formula show how to combine e_n and i_n with the Johnson noise of your circuit's effective source resistance, R_s, to find an effective total input noise density for your circuit. Stated simply, there are three sources of noise: the op-amp's input voltage noise, the op-amp's current noise flowing through the signal's source impedance, and Johnson noise in the source impedance. These are uncorrelated, so to find the total noise-voltage density you add their squares (units of V^2/Hz) and take the square root. Fourteen representative op-amps are shown as examples in Figure 8.58, with the BJT types best at low source resistances and the JFET and CMOS types best at high resistances. Table 8.3 has datasheet specs for e_n and i_n at 1 kHz, from which you can determine what kind of trace a candidate part will make in such a plot.

E. Noise plots, e_n and i_n

It's one thing to look at reams of e_n and i_n values in datasheets, or to scan those values as organized in the three pages of Table 8.3; but it's another thing to compare noise-density plots, which include $1/f$ breakpoints and other unique information. Figures 8.60 and 8.61 show plots of datasheet e_n and i_n versus frequency for 60 of the op-amps in Table 8.3, where numbers and letters identify the corresponding traces in the plots.[75] Note how the voltage-noise plots range over a factor of 1000:1 (though most op-amps

[75] Figures 8.110 and 8.111 show *measured* noise spectra for a selection of these op-amps.

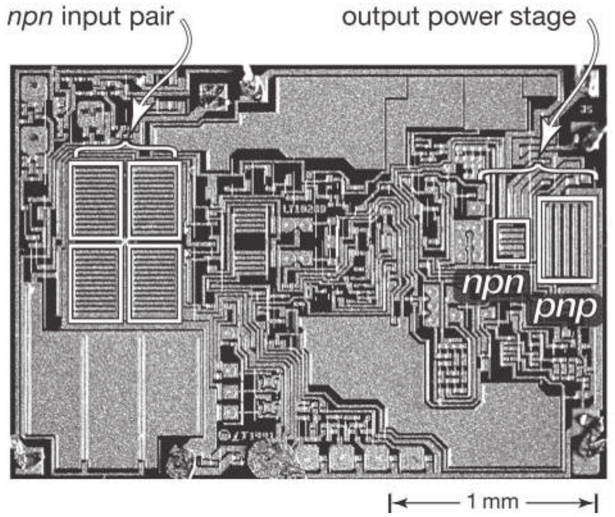

Figure 8.59. The LT1028 op-amp, introduced in 1981, remains the low-noise winner, despite repeated attempts on its title. The input stage runs at high current (1.8 mA total) for low e_n; and the large-input transistors keep the current density low, to achieve an impressively low $1/f$ corner frequency of 3.5 Hz.

are in the range of 1–100 nV/$\sqrt{\text{Hz}}$), whereas the current-noise plots range over a factor of nearly 10^6:1. The latter reflects the very large range of dc input bias currents, from femtoamps (for some CMOS parts) to tens of microamps (for high-speed BJT parts), a ratio of 10^{10}:1. The *noise* current goes only as the square root of the *dc* current, but hey, the square root of 10^{10} is still pretty large.

An op-amp with very low voltage noise e_n, such as trace A or 3 for the exemplary LT1028 (whose portrait we present in Figure 8.59) in the top panels, generally correlates with a high current noise i_n, as seen in the lower panels. This is a common e_n versus i_n tradeoff, which you have to take into account when selecting parts from Table 8.3 and the corresponding noise plots. As an inducement to learn about low-noise design with discrete transistors, look at traces 1 and 2 of Figure 8.61, the noise voltage of a best-in-class BJT and JFET. With parts like these you can achieve lower noise voltage than with any op-amp, creating a "hybrid low-noise op-amp" in which a discrete front-end (for lowest e_n) combines with an op-amp second stage (to provide gain, and the output stage). We illustrate this in Figures 8.66 and 8.67 in §8.9.5. For a full understanding of discrete low-noise design, see §§8.5 and 8.6.

In general, BJT op-amps have low $1/f$ noise-voltage corner frequencies, typically in the range of 1–30 Hz; but beware their generally much higher noise-*current* corner frequencies, 30 Hz–1 kHz or more. This can seriously affect designs with high-value feedback resistors or high signal source impedances.

If you are considering only op-amps with the lowest noise voltage (less than, say, 1.1 nV/$\sqrt{\text{Hz}}$), no others have a $1/f$ noise corner as low as the LT1028 and LT1128, at 3.5 Hz. These impressive parts also have a lower noise current than the other contenders. However, be warned that these op-amps have a nasty broad 15 dB noise peak (shown with admirable candor on the datasheet) starting at 150 kHz, and peaking at 400 kHz before fading away above 600 kHz. Other op-amps don't have this problem, but they have much higher corner frequencies (f_c), as high as 5 kHz for some of the high-speed op-amps.

F. I_B and i_n for BJT op-amps; I_B bias cancellation

Table 8.3 has typical and maximum input bias-current, or I_B, values.[76] In general, the listed current noise i_n comes from shot noise in the base current of a BJT op-amp or from gate leakage in a JFET or CMOS op-amp; so we'd expect the noise spec to be closely related to the bias current by the shot-noise equation $i_n = \sqrt{2qI_B}$. But many BJT op-amps use an input bias cancellation scheme (see §*4x.10*), to reduce greatly the dc bias current, I_B. However, the dc current cancellation in this scheme does not reduce the op-amp's i_n noise (in fact, it typically increases it, by $\sqrt{2}$). These op-amps are identified in the "bias cancel" column of Table 8.3a, and they typically have 10× to 40× more i_n noise than you'd expect from shot noise based on the specified bias current I_B.[77] This increased i_n noise is reflected in a lower R_n value, but ideally you'll not find the higher current noise and lowered feedback-resistor values to be a problem.

Bias cancellation near the rails Be careful when relying on listed bias currents with bias-cancelled rail-to-rail input op-amps, because their input bias current rises dramatically as the inputs approach the supply rails (see §5.7.2). Datasheets show this in graphical form, but they generally do not reveal this undesirable behavior in the listed performance data.

G. Current-feedback op-amps

Unlike voltage-feedback (VFB) op-amps, current-feedback (CFB) op-amps (used in wideband applications) generally have much higher dc bias currents and current noise at their "– input" than at their corresponding

[76] For BJT op-amps (Table 8.3a) the I_B values are in nanoamps, whereas for the JFET-input op-amps (Table 8.3b) the units are *pico*amps.

[77] In a few cases the manufacturers have misstated the i_n noise; for those the table provides a measured value, indicated with italics.

	Bipolar (BJT)	$I_Q^{p,t}$ (mA)	GBW^t (MHz)

(a) all have bias cancellation, except for types G and Q.
(p) per channel.
(t) typical.
(x) zero crossover.
(z) zero drift.

Figure 8.60. Voltage and current noise versus frequency for a selection of "low-noise" op-amps featured in Tables 8.3a–c on pages 522–524. All are adapted from datasheet plots, with the exception of measured i_n for op-amps G and J. The labels are in order of ascending e_n at 10 Hz. See Figures 8.110 and 8.111 for measured noise spectra of selected op-amps.

"+input". For CFB op-amps, Table 8.3c gives the current-noise value for the input with the lowest current and noise. The difference can be as large as a factor of ten. As always, study the datasheet, *carefully!*

H. Noise resistance R_n

The noise-resistance parameter $R_n \equiv e_n/i_n$ has its own column. This is the value of source resistance that corresponds to the minimum possible amplifier noise figure; see for example §8.5.1 and Figure 8.31. But its real usefulness is to let you see at a glance the maximum feedback resistor values you can use: the impedance R_s seen by the op-amp at its inputs should be 5× to 30× smaller than the op-amp's R_n value if you wish to ensure that e_n is the dominant noise source in your circuit; see Figure 8.58. The idea here is that you can't do anything about the e_n value you're stuck with, but you can lower your feedback resistor values to reduce the effect of the op-amp's i_n. But don't forget that you've got to keep the *signal's* source impedance small compared with R_n also. (Also, quite apart from the *noise* current, you may have to worry about the effects of the *dc* bias current flowing through the signal's source, which may be a sensor of relatively high dc resistance.) So in the end you may have to give up on your favorite low-e_n op-amp, and select one with lower i_n even if it has higher e_n.

There are no R_n values listed for the JFET and CMOS

Figure 8.61. Voltage and current noise versus frequency, for a selection of "popular" op-amps featured in Table 8.3 on pages 522–524; a low-noise JFET and BJT are included for comparison. All are adapted from datasheet plots, with the exception of measured e_n for op-amps #22 and #24 and BJT #1, and measured i_n for op-amp #23. The labels are in order of ascending e_n at 10 Hz.

op-amps in Table 8.3. That's because i_n is essentially the shot noise of the input bias current, a parameter that is poorly specified: you see typical values of a picoamp or less, but hedged with maximum values a thousand times larger. And, of course, these are leakage currents, which rise exponentially with temperature. But not to worry – the typical room-temperature input currents are sufficiently low that the corresponding R_n values are generally a gigaohm or greater, as seen clearly in Figure 8.58.

I. I_B and i_n for JFET and CMOS op-amps

The input bias-current, I_B, has typical and maximum values. Usually the i_n shot noise of I_B is calculated in the most optimistic fashion, from the *typical* value of I_B. For BJT op-amps the maximum I_B is generally no more than 2× to 3× its typical value. But the situation is quite different for JFET and CMOS op-amps, where the maximum-to-typical I_B ratios are much greater, e.g., 60× for the TLC4501A or 800× for the LMC6442A.[78] This is especially true for low-cost parts with impressively low I_B specs. *A caution*: beware, the input current may be strongly affected by common-mode voltage, and the listed spec is usually with V_in at mid-supply.

Another issue: Table 8.3's listed I_B values are for an optimistic 25°C. See §5.10.7 and Figure 5.38 for the dramatic effect of elevated temperatures on JFET and CMOS op-amps (caused both by ambient and in-box heating, as well as by the op-amp's self-heating, see below). Because of these uncertainties in estimating bias current, you can't say with any precision what the input noise current i_n will be for JFET or CMOS op-amps. You can say, though, that (except at high temperatures) it will be quite a bit less than that of BJT-input op-amps, as revealed in the lower plots of Figures 8.60 and 8.61.

J. I_B and junction temperature

As we point out in §5.7.2 (and in further detail in §*4x.10*), BJT op-amps with bias-current cancellation are very effective at high temperatures (see Figure 5.6) and under some conditions they may offer the lowest i_n performance. This is especially true for low-supply-current op-amps, whose input-stage collector currents are a fraction of their already low I_Q. For example, the LT6010A still enjoys under 50 pA typical bias current at 100°C (see the datasheet's plot), much lower than the 1200 pA suffered by the OPA134 CMOS op-amp, which looked superior at 25°C. However, even in this case the *noise* current i_n of the hot JFET op-amp still wins over the hot BJT op-amp, by about a factor of 5. That is because the BJT's low bias current is the result of excellent bias cancellation, which is fine when you care about dc input current, but which does not reduce the *noise* current of the much larger uncancelled bias current.

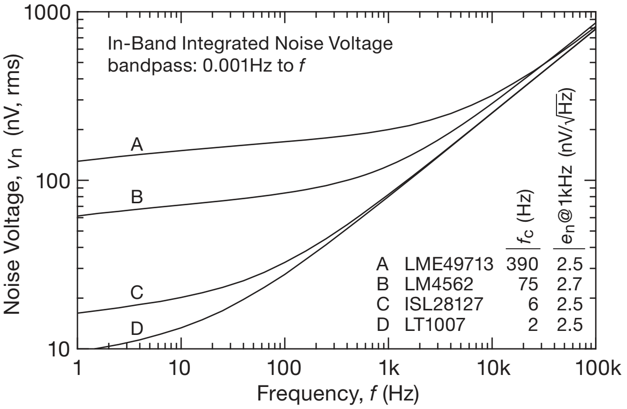

Figure 8.62. A desirably low value of e_n at the usual 1 kHz frequency listed in datasheets doesn't tell the whole story. An op-amp with a high $1/f$ corner frequency f_c will have greater integrated in-band noise voltage, as seen in these four op-amps of comparable 1 kHz e_n values. Note that the effect extends far above the $1/f$ corner frequency.

When thinking about elevated temperatures, keep in mind that in-box and on-board temperatures are often significantly higher than the ambient exterior, especially if power circuitry is involved. Some op-amps also experience significant additional self-heating. For example, our favorite OPA627 JFET op-amp dissipates 210 mW when powered with ±15 V supplies; in the SOIC-8 package this causes the junction temperature to rise 34°C above ambient. Unlike some other parts, the OPA627 and '637 are tested realistically, after a warm-up delay. This is partly responsible for their higher cost.

K. $1/f$ noise and the $1/f$ corner frequency f_c

Figures 8.60 and 8.61 show increasing noise at low frequencies. This is called $1/f$ noise, discussed in various circuit contexts, e.g., in §§5.10.6, 8.1.3, 8.3, and 8.13. Table 8.3 includes $1/f$ voltage-noise corner frequencies f_c, calculated from datasheet noise parameters via eq'n 8.60. Watch out for op-amps that may have attractively low e_n (as specified at the usual 1 kHz), but that suffer from high $1/f$ corner frequencies. If your circuit's bandwidth is less than $\sim 10 f_\text{c}$ you should consider its effects.

[78] For very low input-current op-amps you'll often see an overly conservative (high) maximum I_B spec, dictated by the manufacturer's desire for fast and inexpensive automatic testing. Only high-priced parts get treated to slow and expensive low-current tests.

Figure 8.63. Integrated in-band noise voltage for a selection of low-noise and popular op-amps, based on datasheet plots and tabulated values of noise-voltage density. The op-amp labels correspond to those in Figures 8.60 and 8.61 and the listings in Table 8.3. See also Figure 5.54, which includes auto-zero op-amps and extends down to 0.001 Hz.

L. Noise, "integrated noise"

Figure 8.62 shows the *integrated noise* for four low-noise op-amps, the result of adding up (i.e., integrating) the noise density (sometimes called "spot noise") over the operating bandwidth. It has units of voltage (e.g., μVrms), in contrast to noise density, which has units of voltage divided by square root of bandwidth (e.g., nV/$\sqrt{\text{Hz}}$). Sometimes integrated noise is loosely called the "noise voltage," or just the "noise." Integrated noise may be written as v_n, or V_n, but never e_n. In Figure 8.62 the four op-amps have comparable specified e_n *at 1 kHz*, but widely varying $1/f$ corner frequencies f_c, ranging from 2–400 Hz, producing dramatically different integrated noise when used entirely below 1 kHz. In fact, the ghost of the low-frequency noise is seen lurking up to ~10 kHz.

Figure 8.63 plots integrated noise for three dozen op-amps. In general JFET op-amps are worse than BJT op-amps at low frequencies, and CMOS op-amps are worse still. The plots were calculated from the table's e_n and f_c values, according to eq'n 8.59. At high frequencies, where white noise predominates, the plots simplify to $v_n = e_n\sqrt{f_2}$.

Chopper and auto-zero op-amps (not shown in the figure) do not suffer from $1/f$ noise, but they suffer from higher voltage noise, and generally excessive current noise.

See Table 5.6 and Figure 5.54; the latter illustrates how chopper op-amps are generally noisier than low-noise BJT op-amps above 1–10 Hz.

M. 0.1–10 Hz peak–peak voltage noise

The 0.1–10 Hz peak–peak voltage-noise specification $V_{n(pp)}$ in Table 8.3 is of importance when you are choosing op-amps for low-frequency applications that are sensitive to $1/f$ noise. The manufacturer usually determines this spec from 10-second oscilloscope measurements of a filtered output (see §8.13 and Figure 8.64), but it can also be estimated from eq'n 8.59 (which idealizes to a brick-wall bandpass characteristic). We have seen manufacturers using single-pole, two-pole *RC* pairs, and two- or three-pole Butterworth filters. Comparing datasheet values for a few hundred op-amps shows that multiplying by a factor of six matches the brick-wall equation's $V_n(\mathrm{rms})$ value to the datasheet's filtered peak–peak value. We used this approach to check the datasheet values, or to obtain calculated values where the manufacturer had none.

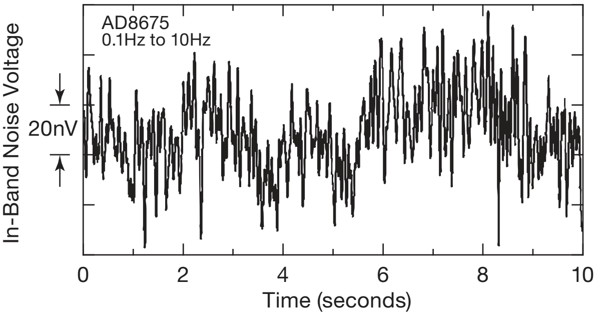

Figure 8.64. Datasheets sometimes provide low-frequency noise voltage snapshots, like this one for the AD8675. The corresponding noise spectrum is similar to curve 8 in Figure 8.61. (Adapted with permission of Analog Devices, Inc.)

N. Input capacitance C_{in}

Op-amp input capacitance is a serious issue when you are considering $e_n{\cdot}C_{in}$ noise in transimpedance amplifiers (TIAs); see §8.11. For some high-impedance sensors, input capacitance acts both as an additional high-frequency load, and it provides a way for high-frequency noise on the power-supply rails to be coupled to the input as noise current. Some op-amps provide both common-mode and differential capacitance values; for these we have taken the larger value for the table (as always, we suggest careful study of the datasheet before embarking on a design).

Quite often, op-amps with low e_n use large area input transistors, with correspondingly greater capacitance, as can be seen in the e_n–vs.–C_{in} scatterplot of Figure 8.65. Ignoring BJT op-amps and noisy op-amps, the trend shows an increasing noise penalty for low input capacitance. But some parts are exceptions, and we consider them to be quite valuable. An excellent JFET op-amp is the LT1793 with a specified C_{in} of 1.5 pF; even with its relatively high e_n of 5.8 nV/$\sqrt{\mathrm{Hz}}$ it still enjoys the lowest $e_n{\cdot}C_{in}$ figure of merit, FOM=9 nV-pF.[79]

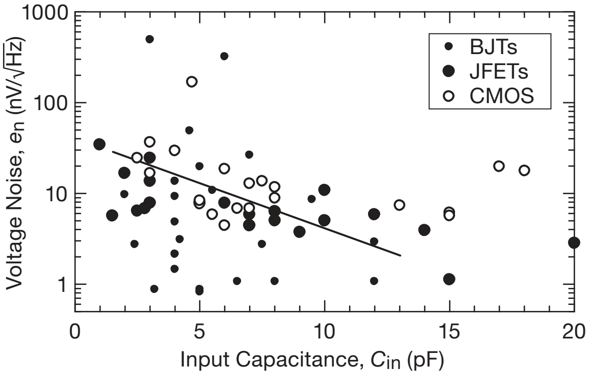

Figure 8.65. Op-amps with low voltage noise tend to have higher capacitance; this is especially true of low-noise JFET-input op-amps, with their large-area input transistors.

Often we have a high-capacitance sensor, or some input coax cable, etc., so in addition to an $e_n{\cdot}C_{in}$ op-amp FOM (with C_{ext}=0), we create additional effective $e_n{\cdot}C_{in}$ current noise from the external shunt capacitance of, say, 25 pF. Now a low value of e_n becomes more important, and the OPA827, OPA627, and LT1792 are the new winners, with the LT1793 and OPA365 remaining as contenders. The AD743 with its e_n of 2.9 nV/$\sqrt{\mathrm{Hz}}$ *could be* the overall winner for C_{ext}>25 pF, but sadly it's entered the land of NRND ("Not Recommended for New Designs"). We recommend that you grab 'em if you can find 'em! Finally, for high-C_{ext} applications, consider discrete designs (see §8.3 and Figure 8.66) that can outperform the best IC op-amps.

Op-amps with small-geometry low-capacitance input transistors nonetheless suffer from the necessary added capacitance of their input protection devices. Truly low-capacitance op-amps may be more susceptible to static damage during handling. Bipolar transistors are less susceptible to static damage and tend to have much lower capacitance than low-noise JFET and CMOS op-amps, but their high I_B and i_n values will often preclude their use in

[79] Other parts to consider are the OPA124, OPA121, AD8067, and OPA656, the latter with an f_T of 230 MHz. For CMOS op-amps consider the OPA365, with a 0.2 pA I_B (typ) spec.

high-impedance circuits. An exception would be for transimpedance amplifiers above, say, 1–10 MHz, but for these applications you'll need to look at the table of high-speed op-amps, Table 8.3c; those parts aren't evaluated here.[80] If a bipolar op-amp's $C_{\rm in}$ is unstated, you can often assume that it's in the range of 2–5 pF.

8.9.2 Power-supply rejection ratio

Quite apart from noise sources *within* the op-amp, any noise (or interfering signals) on the power-supply rails will couple to the output, attenuated by the power-supply rejection ratio (PSRR). Typical op-amps have pretty good PSRR at low frequencies (roughly $1/G_{\rm OL}$, so 80–140 dB), but the PSRR drops as $1/f$ at higher frequencies, allowing substantial supply-noise coupling. Often the high-frequency PSRR is particularly poor with respect to one or the other supply rail because of coupling by the internal compensation capacitor; see §*4x.7*. For example, at frequencies above 10 Hz, the LT1012 positive-rail PSRR is 25 dB worse than the negative-rail PSRR; and the micropower LT6003's negative-rail PSRR plummets to less than 10 dB at 1 kHz! Simple *RC* filtering for the sensitive stages (or a capacitance multiplier, see §8.15.1) can largely solve this problem. Be sure to read the datasheet, though, or you may not even know you *have* a problem.

8.9.3 Wrapup: choosing a low-noise op-amp

In summary, when choosing an op-amp for a low-noise application, begin by restricting your attention to op-amps that meet your other needs, such as accuracy, speed, power dissipation, supply voltage, input and output swing, and the like. Then choose among this subset, based upon their noise parameters. Generally speaking, *you want op-amps with low $i_{\rm n}$ for high signal impedances, and op-amps with low $e_{\rm n}$ for low signal impedances.* As we've seen, the total input-referred squared noise-voltage density is just

$$v_{\rm n}^2 = 4kTR_{\rm sig} + e_{\rm n}^2 + \left(i_{\rm n}R_{\rm sig}\right)^2 \quad {\rm V}^2/{\rm Hz}, \tag{8.42}$$

where the first term is due to Johnson noise and the last two terms are due to op-amp noise voltage and current.[81] Clearly the Johnson noise sets a lower bound to the input-referred noise. Refer back to Figure 8.58 for an easy graphical look at $v_{\rm n}$ (at 1 kHz) as a function of $R_{\rm sig}$ for a selection of low-noise op-amps from Table 8.3;[82] these span a representative range of $e_{\rm n}$ and $i_{\rm n}$, from which you can interpolate for op-amps not shown explicitly.

This plot illustrates graphically the tradeoff between low noise *voltage* (where the BJT parts – solid lines – are king), and low noise *current* (where the CMOS parts – dashed lines – are the winners). A good low-noise JFET op-amp like the OPA140 combines the best (nearly) of both worlds. But note that the voltage noise of even a simple (and noisy) CMOS part like the LMC6482 is irrelevant when driven by a source resistance anywhere between 1 MΩ and 10 GΩ, where the op-amp's contribution to the total noise density is negligible.

See Figures 8.60 and 8.61 for op-amp spectral noise plots. For low-frequency amplifier applications see Figure 8.63, with its plots of total (integrated) rms noise $v_{\rm n}$ versus bandwidth.

Two cautions: (a) The total noise density plots ($v_{\rm n}$ versus $R_{\rm s}$) of Figure 8.58 characterize the performance only at 1 kHz. So an op-amp with a high $1/f$ noise corner will look considerably worse at, say, 10 Hz. Taking the example of the LMC6482 (curve #17), its $e_{\rm n}$ at 10 Hz is $\sim$170 nV/$\sqrt{\rm Hz}$, aligning it with curve #29. (b) Likewise, at *high* frequencies you care about input capacitance (especially in combination with GΩ-scale input impedances), and you care about the noise current generated by the op-amp's noise voltage in combination with the input capacitance ($i_{\rm nC}{=}e_{\rm n}\omega C_{\rm in}$). A quiet JFET op-amp like the OPA627 has nearly triple the input capacitance (because of its large-area input JFET) of its somewhat noisier (and less expensive) OPA656 cousin.

8.9.4 Low-noise instrumentation amplifiers and video amplifiers

In addition to the low-noise op-amps, there are some nice low-noise IC *instrumentation amplifiers* and low-noise *preamplifiers*. Unlike general-purpose op-amps, these generally have fixed voltage gain, or provision for attaching an external gain-setting resistor. Instrumentation amplifiers, intended for precision differential applications, are discussed extensively in Chapter 5 (§5.13). Those categorized as"video amplifiers" often have bandwidths into the tens of megahertz, though they can be used for low-frequency applications as well. Examples are the TI/Burr–Brown INA103 instrumentation amplifier, and the TI/National

[80] Table 8.3c features a new $e_{\rm n}C_{\rm in}$ figure-of-merit, useful for TIA designs.

[81] In addition, as described in §8.11.3, in the inverting configuration an amplifier's input noise *voltage* creates a noise *current* through the input capacitance, to the tune of $i_{\rm n}{=}e_{\rm n}\omega C_{\rm in}$.

[82] For comparison we included our jellybean JFET LF411, the legacy LM741 and LM358, and a few other popular op-amps that do not qualify as "low noise"; those have numeric labels.

LMH6517 or Linear Technology LTC6400-series video amplifiers. These amplifiers typically have e_n down in the $1\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ territory, achieved (at the expense of high input noise *current*, i_n) by running the input transistor at relatively high collector current.

8.9.5 Low-noise hybrid op-amps

Back in §8.9.1E we hinted at the possibility of a hybrid low-noise design, in which a low-noise BJT or JFET differential front-end could combine with a conventional op-amp to provide superior noise performance. The simplified circuits in Figures 8.66 and 8.67 show how this can be done, with BJTs and JFETs, respectively. These amplifiers are also a form of composite amplifier, a subject discussed in §*4x.5*.

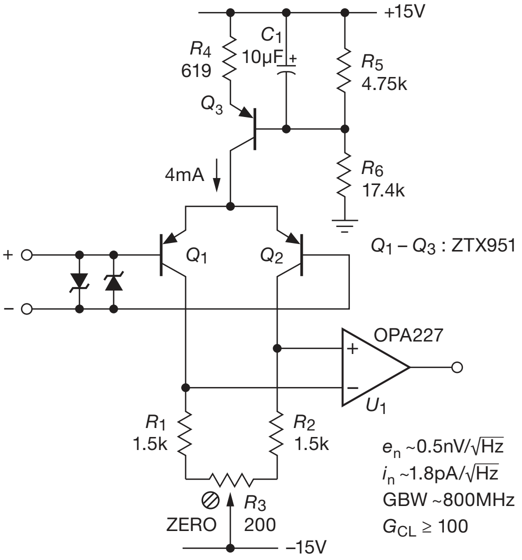

Figure 8.66. Combining the best of both worlds: a BJT hybrid wideband low-noise op-amp.

A. General design issues

Common-mode range In both cases we designed the circuit to provide a substantial common-mode input signal range (at least ±10 V), intending this to serve as a general-purpose low-noise op-amp substitute. For that reason the current sources in the emitter (or source terminal) are biased for compliance to within 2.5 V of their respective rails, and the collector load resistors (R_1 and R_2) in the BJT design are sized to drop only 3 V (thus accommodating negative input swing to at least -12 V). The JFET design is similarly biased; however, a volt or two is lost in the cascode transistors (Q_3 and Q_4) and in the negative V_{GS} of the input stage, reducing the positive common-mode input range to approximately +10 V.[83]

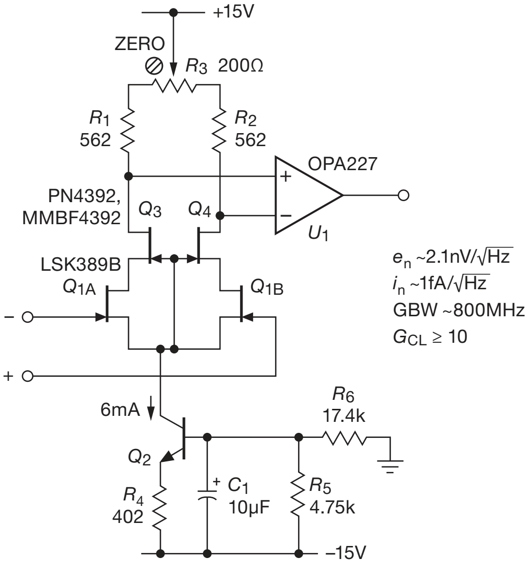

Figure 8.67. Another hybrid op-amp, this time with differential JFET cascode front-end.

Offset trim In the BJT circuit we used one of the quietest available transistors we found in our tests (the Zetex ZTX951); it is not available as a matched pair, so we provided an offset trim R_3, with a relatively large adjustment range (±6%). For the JFET circuit we used the LSK389 "matched" dual, but its worst-case offset of 20 mV mandates an even larger trim range, here ±17%. Ironically, the discrete BJT pair's V_{BE} mismatch is likely to be less than that of the matched JFET dual; at least that's been our experience; see, for example, the histogram of measured V_{BE}'s in Figure 8.44.

It's important to realize that a simple offset-trim circuit that unbalances the load resistances, as shown here, greatly compromises the common-mode rejection ratio of the differential input. Additionally, the unbalanced load greatly compromises attenuation of noise in the current source (which would be at least ×50 with 1% load resistors). A better method involves balancing the currents seen at the collector (or drain) load resistors; see for example Figure 8.80 later in the chapter.

Minimum closed-loop gain Because there's voltage

[83] If the cascode runs out of compliance it simply disappears, becoming a low-R_{on} switch.

gain in the transistor front-ends of these hybrid amplifiers (about ×120 for the BJT, ×12 for the JFET), the overall loop gain is substantially greater than that of the second-stage op-amp alone (which by itself is quite high, roughly 160 dB at low frequencies). To ensure stability (given that the OPA277 is unity-gain stable), these hybrid amplifiers should be configured with a closed-loop gain of at least ×100 and ×10, respectively.[84]

B. Some detailed design issues

Choice of transistors Although its noise voltage is unspecified, we found excellent noise performance (and good consistency) with some Zetex bipolar transistors, notably their ZTX851 (*npn*) and ZTX951 (*pnp*). The latter were slightly better, with a measured input noise voltage corresponding to an admirably low base resistance of $r_{bb'}{\sim}1.2\,\Omega$ (thus, e.g., an e_n of $0.17\,\text{nV}/\sqrt{\text{Hz}}$ at 10 mA collector current), compared with $r_{bb'}{\sim}1.4\,\Omega$ for the *npn* ZTX851.[85] For the JFET circuit we chose the low-noise LSK389B from Linear Integrated Systems; it specifies $e_n{=}0.9\,\text{nV}/\sqrt{\text{Hz}}$ (typ) and $1.9\,\text{nV}/\sqrt{\text{Hz}}$ (max) at a drain current of 2 mA.[86] It's a large-geometry JFET (for low noise), with a correspondingly large capacitance of $C_{iss}{=}25$ pF. It has pleasantly high transconductance, specified as 20 mS (min) at 3 mA drain current.

Input current The BJT has the expected high input current, of course, given the relatively high collector current needed to keep e_n low; with the specified $\beta{=}200$ (typ) the input current is 10 μA. That's the price you pay for the lowest e_n. By comparison, the JFET circuit's input current is down in the 1 pA territory, judging from the graph of "excess gate current" shown for its predecessor 2SK389 (the LSK389 provides no analogous graphs or specification), and given the very low V_{DS} enforced by the cascode.

Overall noise voltage These are differential input stages, so you need to multiply the single-transistor e_n's by $\sqrt{2}$, which results in the values shown in the figures. For the JFET version, with its lower front-end gain, there is a small contribution also from the op-amp's input noise ($3\,\text{nV}/\sqrt{\text{Hz}}$), but when referred to the input that amounts to just $0.3\,\text{nV}/\sqrt{\text{Hz}}$, negligible in the total when combined with the larger front-end squared noise-voltage density.

Note that these are quiet amplifiers – so you need to present their inputs with low signal-source impedances to retain their low e_n. For the BJT version, for example, that implies a resistor value down around 10 Ω in the lower leg of the feedback divider.

Differential input voltage If your application can expose the differential BJT hybrid op-amp to more than ±5 V, add a pair of protective back-to-back diodes to prevent base-emitter breakdown and consequent transistor degradation. The differential JFET hybrid op-amp can be safely exposed to full-rail differential-input voltage. These op-amp input stages are running at rather high currents, so a substantial input voltage difference, maintained for more than a few milliseconds, will cause unbalanced heating and consequent input offset voltage. It's a good idea to thermally couple the input pair, and perhaps thermally isolate them from air currents as well.

8.10 Signal transformers

As mentioned earlier in §8.5.6, you're up against the wall when trying to minimize amplifier noise with a signal of very low source impedance Z_s, say less than 100 Ω. The noise voltage of a 50 Ω resistor, for example, is just $0.9\,\text{nV}/\sqrt{\text{Hz}}$, which puts you down at the limit of the quietest op-amps. And there are signal transducers with considerably lower resistance, for example magnetic coil pickups. If you are interested only in ac signals (as you would be, for a magnetic coil), you can use a transformer to raise the signal level (by the turns ratio, n:1), simultaneously raising the source impedance seen at the amplifier's input by that ratio squared; i.e., the amplifier sees a signal of source impedance n^2Z_s.

High-quality signal transformers are available from companies such as Jensen Transformers and Signal Recovery. For example, a signal in the audio band (say from 100 Hz to 10 kHz) with source impedance of 100 Ω would be a poor match for an amplifier like the SR560, whose lowest noise figure occurs for signals of source impedance around 500 kΩ (see Figure 8.27). The problem is that the amplifier's voltage noise is much larger than the signal source's Johnson noise; the resultant noise figure for that signal connected directly to the amplifier would be 12 dB. By using an external step-up transformer like the

[84] The OPA277 has an excellent phase margin, about 60°, to well past its 1 MHz GBW. If you need a lower closed-loop gain, you can add a series $R{+}C$ across the op-amp's inputs, effectively reducing the load resistance and open-loop gain at high frequencies.

[85] The *pnp* has lower noise than its *npn* sibling, but much poorer Early voltage, as Table 8.1a shows: $V_A{=}120$ V versus 410 V. If the (relatively low) Early voltages of the *pnp* pair are not matched, the CMRR will be degraded. If this is an issue, the circuit could be recast with an *npn* pair, or with an added cascode.

[86] Our measurements landed right in the middle, at $1.34\,\text{nV}/\sqrt{\text{Hz}}$ ($1.9\,\text{nV}/\sqrt{\text{Hz}}$ total for the differential pair).

Jensen JT-115K-E with its 1:10 turns ratio (150Ω:15kΩ impedances), the signal level is raised (along with its source impedance), thus overriding amplifier noise voltage. At this signal impedance the amplifier's noise figure is about 0.4 dB; however, the resistance of the transformer's windings[87] contributes to produce an overall noise figure of about 1.5 dB.

There's a tendency to associate transformers with mediocre performance; but well-engineered signal transformers like this one are pretty good: response ± 0.15 dB over the audio band (20 Hz–20 kHz), down 3 dB at 2.5 Hz and 90 kHz, distortion less than 0.1% even at 20 Hz,[88] and, as a bonus, common-mode rejection of 110 dB at 60 Hz. The Model 1900 signal transformer from Signal Recovery (originally from Princeton Applied Research) offers turns ratios of 1:100 and 1:1000. It has less bandwidth than the JT-115K-E, but it achieves a minimum noise figure of $\sim$0.5 dB for source resistances in the 0.8–10 Ω range owing to its low winding resistance of 0.04 Ω. This is somewhat better noise performance than the paralleled-BJT amplifier of §8.5.9; because of transformer limitations, however, it does not work over the full audio band.

At *radio* frequencies (e.g., beginning around 100 kHz) it is extremely easy to make good transformers, both for tuned (narrowband) and broadband signals. At these frequencies it is possible to make broadband "transmission-line transformers" of very good performance. It is at the very low frequencies (audio and below) that transformers become problematic.

Three comments:

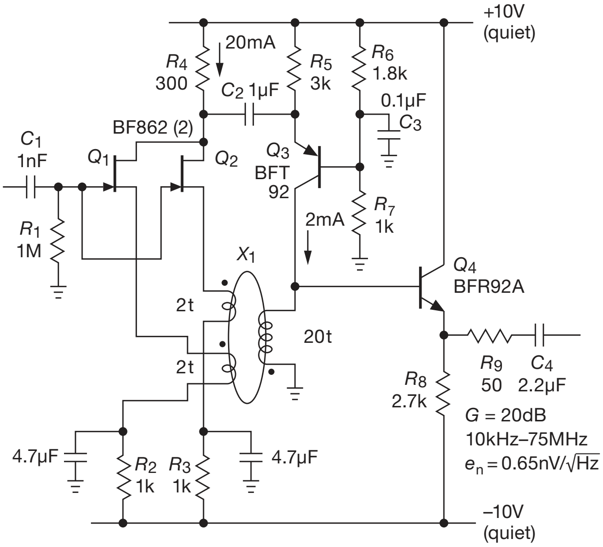
(a) The voltage rises proportional to the turns ratio of the transformer, whereas the impedance rises proportional to the square of the ratio. Thus a 2:1 voltage step-up transformer has an output impedance four times the input impedance (this is mandated by conservation of energy).

(b) Transformers aren't perfect. They are susceptible to magnetic pickup, and they have trouble at low frequencies (magnetic saturation) and at high frequencies (winding inductance and capacitance), as well as losses from the magnetic properties of the core and from winding resistance. The latter is a source of Johnson noise, as well. Nevertheless, when dealing with a signal of very low source impedance, you may have no choice, and transformer coupling can be very beneficial, as the preceding example demonstrates. Exotic techniques such as cooled transformers, superconducting transformers, and SQUIDs (superconducting quantum interference devices) can provide good noise performance at low impedance and voltage levels. With SQUIDs you can measure voltages of 10^{-15} V!

(c) Again, a warning: don't attempt to improve performance by adding a resistor in series with a low source impedance. If you do that, you're just another victim of the noise-figure fallacy.

8.10.1 A low-noise wideband amplifier with transformer feedback

Lest we leave the reader discouraged as to the merits of transformers in signal applications, we hasten to point out that some very impressive performance can be gotten with careful engineering. Figure 8.68 shows a nice example: a wideband low-noise amplifier with high input impedance,[89] with a transformer providing lossless (therefore noiseless) feedback to set the voltage gain via the turns ratio (here ×10). The transformer nicely solves also the problem of distributing identical feedback to multiple paralleled input JFETs, each of which is biased to the same 10 mA drain current.



X_1: Vitrovac T60009 - E4006 - W650, $A_L = 13\mu\text{H/t}^2$

Figure 8.68. Transformer feedback to paralleled JFETs achieves 650 pV/$\sqrt{\text{Hz}}$ input noise voltage in this wideband amplifier.

[87] At low frequencies this is simply the dc resistance of the copper wire; but at higher frequencies the effective noise-generating resistance rises owing to the skin effect; see Appendix H (§H.1.4) and §*1x.1*.

[88] Low frequencies are a transformer's Achilles' heel; at 1 kHz this particular transformer's distortion is just 0.001%.

[89] From J. Belleman at CERN; see http://jeroen.home.cern.ch/jeroen/tfpu.

The transformer shown is a small (6.5 mm O.D.) high-mu tape-wound toroid, with just a few turns in the windings to set the high end of the operating band to 75 MHz. That choice limits the low frequency end to frequencies above ∼10 kHz, but the nearly 10,000:1 frequency range is mighty impressive. The source pull-down resistors R_2 and R_3 set the drain current of the BF862 input JFETs to 10 mA (their specified minimum $I_{\rm DSS}$), where their voltage noise is 0.9 nV/$\sqrt{\rm Hz}$; the parallel pair improves that by $\sqrt{2}$, thus 0.65 nV/$\sqrt{\rm Hz}$. Bipolar *pnp* Q_3 forms an inverted cascode, with its $r_{\rm e}$ of 12 Ω diverting essentially all of the input transistors' drain signal. Both Q_3 and Q_4 are wide-band transistors (5 GHz); Q_3's collector current is chosen to cancel the dc magnetization induced in the transformer by the input transistors to prevent core saturation. The supply rails need to be quiet, best achieved with a capacitance multiplier (§8.15.1). A caution: this feedback circuit has two low-frequency breakpoints (from C_2 and from the transformer's rather low magnetizing inductance), leading to potential instability and a low-frequency *motorboating*-type oscillation. This is prevented here by the large capacitance of C_2, which puts its breakpoint far below that of the transformer.

8.11 Noise in transimpedance amplifiers

Transresistance amplifiers (or *transimpedance* amplifiers, "TIA," or sometimes just "current amplifiers") produce a voltage output in response to a *current* input. Their gain is therefore $V_{\rm out}/I_{\rm in}$, with units of ohms, hence their name.[90] We introduced transresistance amplifiers in Chapter 4 (§4.3.1), we evolved a TIA design for an inexpensive lightning detector (§8.5.7, Figure 8.36); and we look at issues of their feedback *stability* in §*4x.3*. As a reminder, the basic circuit, which we've seen before, is shown in Figure 8.69. Assuming ideal components, a current $I_{\rm sig}$ produces an output $V_{\rm out}=-I_{\rm sig}R_{\rm f}$, so the gain is simply $-R_{\rm f}$. They are used extensively in circuits where the input is a current, for example from a photodiode or photomultiplier, charged particle detector, tunneling microscope, or patch-clamp amplifier.

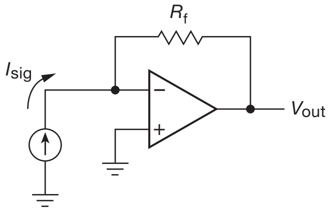


Figure 8.69. Transresistance amplifier: current in, voltage out.

The emphasis in this chapter is *noise*, which can arise in several ways in the TIA. The amplifier itself will have its input $e_{\rm n}$ and $i_{\rm n}$; and the feedback resistor creates a Johnson noise voltage that equates to an input noise current $i_{\rm nR}=\sqrt{4kT/R_{\rm f}}$ (thus favoring high values of $R_{\rm f}$). Capacitance also plays an important role, not only in stability and bandwidth, but also in converting the amplifier's noise *voltage* into a noise current. There's also likely to be what we might call *signal noise*: shot noise in the signal current, Johnson noise in the signal source's resistance, and other forms of signal fluctuation.[91] Let's see how this all plays out.

8.11.1 Summary of the stability problem

As we saw back in §4.3.1C (and which we discuss in greater detail in §*4x.3* in Chapter *4x*), capacitance to ground at the input (e.g., from a current-output sensor and its connecting cable), in combination with the (usually large) feedback resistance, produces a lagging phase shift in the feedback path. This is unstable when combined with the op-amp's 90° (or more) lagging phase shift. You cure this by putting a small capacitor $C_{\rm f}$ across the feedback

[90] This is the inverse of a device like a JFET, where an input *voltage* produces an output *current*. There the gain is $I_{\rm out}/V_{\rm in}$, with units of Ω^{-1} (siemens, previously called mhos), hence the name trans*conductance* amplifiers.

[91] Noise in the signal source itself may, in some situations, dominate over the noise contribution of a well-designed amplifier. Optical detectors, for example, are characterized by a "noise-equivalent power" (NEP), which is their electronic noise output stated in terms of optical input power (expressed as optical noise power density, generally in the range of fW/$\sqrt{\rm Hz}$). The NEP arises from the detector's dark current (a perfect detector would have zero NEP), a "drift current" that can be thought of as a form of leakage. You get such current when photodiodes are operated with a deliberate reverse-bias voltage (the so-called *photoconductive mode*), in which the capacitance is reduced, and the speed, linearity, and long-wavelength conversion efficiency are improved. If you want to detect very low light levels, and are willing to sacrifice speed, you should operate the photodiode with zero bias (the so-called *photovoltaic mode*), where the greatly reduced NEP arises mostly from a "diffusion current" related dark resistance, powered by the op-amp's offset voltage. For this purpose the photodiode's datasheet usually assumes a 10 mV offset (i.e., detector bias), but you can almost always do better than that. We've measured dark-adapted NEP levels four orders of magnitude better than specified, when driving an op-amp with 100 μV offset in a cool laboratory setting. Taking account of detector noise is an essential part of any system design whose ultimate job is to "convert photons into volts."

resistor (see §*4x.3* for details), which, however, seriously reduces the usable bandwidth. As we saw, you therefore need to use an op-amp of surprisingly high bandwidth in order to get even a modest circuit bandwidth. To put numbers on it, the circuit's usable bandwidth f_c is roughly the geometric mean of the op-amp's GBW (or f_T) and the rolloff frequency, $f_{RC} = 1/2\pi R_f C_{in}$, of the input capacitance; that is

$$\mathrm{GBW} = f_c^2/f_{\mathrm{RCin}}\,. \tag{8.43}$$

8.11.2 Amplifier input noise

A transimpedance amplifier input stage, whether discrete or op-amp, will have some noise voltage and current, characterized by densities e_n and i_n; these will exhibit the, by-now, usual $1/f$ rise at low frequencies. And, in addition to the low-frequency noise tail, the current noise will depend on the dc input current (bias current, for BJTs; leakage current for JFETs or MOSFETs), because at mid-frequencies the input noise current is simply shot noise of the dc current.

How do e_n and i_n affect the TIA's overall input noise? We'll see presently (§8.11.3) that e_n generates a noise current through the capacitance seen at the input, and in fact this can easily become the dominant noise term, particularly at higher frequencies. Before worrying about that effect, note simply that the input e_n flows through the feedback resistor, generating a noise-current density $i_n = e_n/R_f$ (and if the signal source has a finite source resistance, replace R_f with $R_f \| R_s$). These terms are usually small compared with the corresponding Johnson-noise currents, but they can grow to significant levels at low frequencies where the $1/f$ behavior may raise e_n by factors of 10× to 50× over its mid-frequency ("white") value.[92]

The current noise i_n of the input stage needs no conversion – it contributes directly to the TIA's equivalent input noise current (as square root of sum of squares). Low-bias op-amps with FET inputs (as well as discrete JFETs) will generally have quite low input-noise currents, down in the $\mathrm{fA}/\sqrt{\mathrm{Hz}}$ territory. But watch out for rising $1/f$ noise: the datasheet for the low-e_n JFET AD743, for example, shows i_n rising from its mid-frequency $7\,\mathrm{fA}\sqrt{\mathrm{Hz}}$ value to $100\,\mathrm{fA}\sqrt{\mathrm{Hz}}$ at 1 Hz; that would correspond to the shot noise from a dc bias of 30 nA! (Its typical room temperature input current is specified as 0.15 nA.) Watch out, also, for rising i_n (from rising leakage current in FETs) at elevated temperatures: the AD743 specifies i_n only at 25°C (where it's $7\,\mathrm{fA}\sqrt{\mathrm{Hz}}$ value is consistent with shot noise in 0.15 nA dc input current); but you can use their plot of dc input current versus temperature to find that $i_n = 40\,\mathrm{fA}\sqrt{\mathrm{Hz}}$ at 80°C (where the plot shows a dc input current of 5 nA) and rising further to $400\,\mathrm{fA}\sqrt{\mathrm{Hz}}$ at 125°C.

Temperature isn't the only contributor to JFET input current; there's the impact-ionization effect (§3.2.8), which can cause a devastating rise in input current (and noise) when a JFET is operated with drain-to-source voltages greater than a few volts. With a discrete JFET design you can prevent this by operating at low drain voltage (e.g., with a cascode); low-noise op-amps usually are designed with this effect in mind, but you will see increased input current (and current noise) as the input voltage approaches one of the rails (e.g., the positive rail for the LT1792 or ADA4627; the negative rail for the AD8610).

8.11.3 The $e_n C$ noise problem

In addition to the input stage's contributions of i_n (directly) and e_n (flowing through the feedback and input resistances), input *capacitance* (already an annoyance in terms of stability and bandwidth) creates interesting noise problems as well. For example, you might at first think that amplifier *voltage* noise is of little concern in an amplifier whose input is a current; because its feedback looks like a voltage follower, it would seem to produce at most an additive output voltage-noise contribution just equal to the input-voltage noise e_n (equivalent to an input-current-noise contribution of $i_n = e_n/R_f$). But you would be wrong! To see what happens, look at Figure 8.70, where the

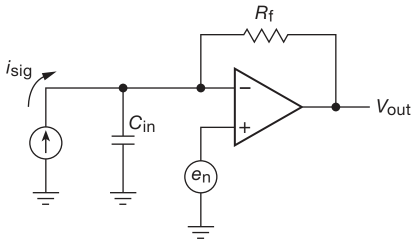

Figure 8.70. The capacitance at the input causes the amplifier's voltage noise e_n to create an input *current* noise $i_n = e_n \omega C_{in}$. Neither this "$e_n C$" current noise nor the amplifier's own input current noise is shown.

[92] For example, the voltage noise of the AD743 (quietest JFET op-amp, with $e_n = 2.9\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ at 10 kHz) grows to $23\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ at 1 Hz. The LT1792 grows to $30\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$, the OPA627 to $33\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$, and the ADA4627 to $42\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$. And the speedy OPA656 grows to $75\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ at 10 Hz! Not to be outdone, the otherwise-admirable AD8610 and 8620 JFET op-amps grow from $6\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ to about $200\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$. And when it comes to CMOS op-amps, whoa!

op-amp's internal differential-noise voltage e_n is modeled as a voltage in series with the noninverting terminal. Feedback forces the inverting terminal (with its capacitance C_{in} to ground) to follow, creating an actual input current $i_n(t){=}C_{in}\,dv_n(t)/dt$ (where $v_n(t)$ is the op-amp's input noise voltage); expressed as a noise *density*, we get

$$i_n{=}e_n\omega C_{in}{=}2\pi e_n C_{in} f. \qquad (8.44)$$

That is, the amplifier's voltage noise creates a noise current proportional to the capacitance at the input, and rising proportional to frequency. We refer to this input-noise current, produced by the amplifier's internal noise voltage, as "e_nC noise."[93]

8.11.4 Noise in the transresistance amplifier

Let's apply this kind of thinking to figure out the noise performance of the transresistance amplifier we looked at in §*4x.3*. We've redrawn it in Figure 8.71, with the op-amp's input-noise voltage e_n, noise current i_n, and shunt feedback capacitor C_f shown explicitly. In a typical high-speed (small-area) photodiode application you might have C_{in}~10–20 pF (but more if connected through a shielded cable), R_f ~1–10 MΩ, and, for a FET-input op-amp, e_n ~3–10 nV/$\sqrt{\text{Hz}}$ and i_n ~1–10 fA/$\sqrt{\text{Hz}}$.

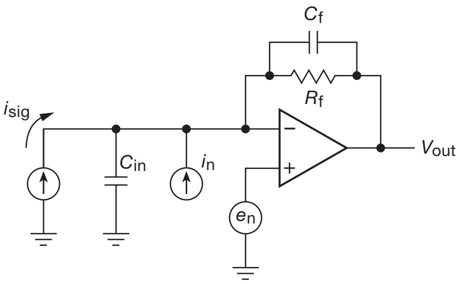

Figure 8.71. Noise in a photodiode amplifier. For the calculations we've used R_f=1 MΩ. Here C_{in} is the total capacitance seen at the input (amplifier, wiring, and input device capacitances).

We'll calculate the noise contributions (from e_n, i_n, and from Johnson noise in the feedback resistor) as effective current noise (versus frequency) *at the input*; after all, that's where the input current signal that we care about enters. For the time being we ignore the capacitor C_f, and use typical circuit values of R_f=1 M and C_{in}(circuit)=10 pF.

As we saw earlier, Johnson noise is flat with frequency, with a noise voltage $e_n = \sqrt{4kTR}$ volts per square root hertz; this translates to a short-circuit noise current of e_n/R; that is, $i_n = \sqrt{4kT/R}$ amps per square root hertz. So for a 1 MΩ feedback resistor at 25°C,

$$i_n = \left(\frac{4kT}{R_f}\right)^{\frac{1}{2}} = 1.28\times10^{-10}R_f^{-\frac{1}{2}} = 0.128\,\text{pA}/\sqrt{\text{Hz}}.$$

This is one to two orders of magnitude larger than the amplifier's input current noise, which we can therefore ignore. The last contribution is from the amplifier's e_n, which, as we remarked earlier, looks like an input current noise $i_n{=}2\pi e_n C_{in} f$. It rises proportional to frequency, becoming dominant over resistor Johnson noise at some crossover frequency that we'll call f_X. By equating the Johnson-noise current with the e_nC current, you can find[94]

$$f_X = \frac{\sqrt{4kT/R_f}}{2\pi e_n C_{in}}. \qquad (8.45)$$

It would continue to rise forever, except for the effect of the parallel capacitance C_f, which causes the noise current to flatten off at a frequency $f_c = 1/2\pi R_f C_f$ (caused by the R_fC_f pole cancelling the +6 dB/octave rising e_nC noise). If we further choose C_f so that f_c equals the geometric-mean frequency[95]

$$f_{GM} = \sqrt{f_{RCin} f_T}, \qquad (8.46)$$

we produce a slight peaking at f_c, with the pair of poles causing the e_nC noise to fall at −6 dB/octave (i.e., $\propto 1/f$) at higher frequencies, as seen in Figure 8.72.

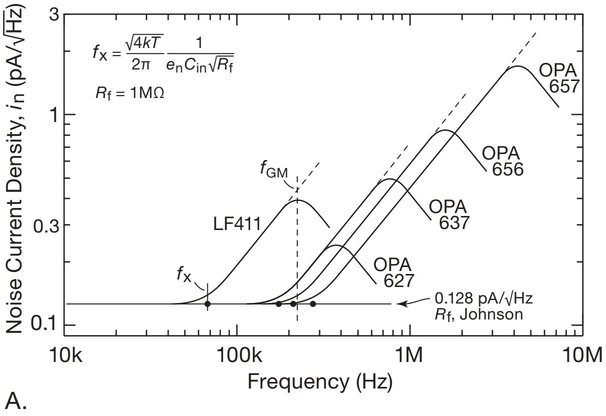
In Figure 8.72 we've plotted i_n(input) for the transresistance amplifier of Figure 8.71, with R_f=1M, for the op-amp choices and corresponding data shown in the figure's table. The plot shows clearly the reduction in input-referred total noise current that you get by choosing an amplifier with low input capacitance and low noise voltage, assuming of course that you are planning to limit the output bandwidth with a later stage of lowpass filtering.

It's interesting to note that, if all other things were equal, an op-amp with greater amplifier bandwidth would not reduce the input-referred noise current; it would simply extend the bandwidth of the transresistance amplifier. However, because faster op-amps tend to have less input capacitance, there is some noise advantage, particularly when the external input capacitance is as low as we've assumed here.

[93] In the literature you'll see descriptions like "noise gain peaking at higher frequency" and "a complex response to the op-amp's input noise voltage." But we like "e-sub-n-C": it's easy to say, and easy to remember.

[94] For R_f=1M this becomes $f_X(\text{Hz}){=}2\times10^7/e_nC_{in}$, where e_n and C_{in} are in units of nV/$\sqrt{\text{Hz}}$ and pF respectively.

[95] See the stability criterion in §*4x.3*.



Calculated f_C and f_X, with $C_{external}$ = 10pF and R_f=1M

Op-amp	e_n (nV/√Hz)	C_{amp} (pF)	$C_{in(total)}$ (pF)	f_T (MHz)	f_C (kHz)	f_X (kHz)
LF411	25	2	12	4	230	67
OPA627	4.5	15	25	16	320	178
OPA637	4.5	15	25	80	715	178
OPA656	7	3.5	13.5	230	1650	212
OPA657	4.8	5.2	15.2	1600	4100	274

B.

Figure 8.72. A. Input-referred noise-current spectrum for the photodiode amplifier in Figure 8.71. The crossover frequency f_X at which "e_nC" noise becomes dominant is marked with a dot for each configuration. For the LF411 example both f_X and the turnover frequency f_c are marked. In each case it is assumed that the compensation capacitor C_f is chosen so that f_c is equal to $f_{GM}=\sqrt{f_{RCin}f_T}$, thereby obtaining maximum amplifier bandwidth consistent with only modest peaking (damping ratio ζ=0.7); otherwise there will be a region of flat noise density, as in Figure 8.73. B. Input-referred current-noise parameters for the photodiode amplifiers of Figure 8.71, assuming an external input capacitance of 10 pF.

8.11.5 An example: wideband JFET photodiode amplifier

Continuing along this path, in Figure 8.73 we've plotted the transimpedance gain, noise gain, and effective input-noise current for a transimpedance amplifier made from an OPA656 (f_T=230 MHz, e_n=7 nV/$\sqrt{\text{Hz}}$), with a 1M feedback resistor and a conservative value of shunt capacitor (2 pF: f_c=76 kHz) to ensure stability with input capacitances as high as 1000 pF.

Note that there are two "gains" here: the *transimpedance gain* (top plot) is the ratio of output signal voltage to input signal current, a plot that is nominally flat up to the rolloff at f_c, but with the additional constraint imposed by the finite (and falling) op-amp open-loop gain G_{OL}. The *noise gain* (middle plot) is the ratio of output signal voltage to input noise voltage, with its characteristic rising "e_nC" slope proportional to frequency. It flattens at f_c, but (for op-amps of modest open-loop gain[96]) is further limited by G_{OL}.

Finally, the effective input-referred noise current seen at the output (bottom plot) is the sum of the e_nC noise and the feedback resistor's Johnson noise, as shaped by the amplifier's rolloff. Those noise-current terms (as seen at the input) are $e_n\omega C$ and $\sqrt{4kT/R_f}$, respectively. Here the Johnson noise dominates at low frequencies: a 1 MΩ resistor generates a (short-circuit) white-noise current of 0.13 pA/$\sqrt{\text{Hz}}$.

We measured this amplifier's output noise spectrum with the four values of input capacitance; we measured also the op-amp's input voltage noise (e_n). Figure 8.74 is a screen capture (from an SRS785 spectrum analyzer), labeled with corresponding input-referred i_n and e_n scales. The measured data are in reasonable agreement with the predictions of Figure 8.73, with the exception of some excess noise at the low-frequency end of the 10 nF plot. But Figure 8.73 assumed a constant (white-noise) value of 6 nV/$\sqrt{\text{Hz}}$ for e_n, whereas the measured voltage noise exhibits the usual $1/f$ rise at low frequencies, roughly triple its high-frequency value at 100 Hz.

8.11.6 Noise versus gain in the transimpedance amplifier

In the preceding discussion we casually took a round-number value of 1 MΩ for the feedback resistor R_f, without much consideration of the consequences for noise and bandwidth. From Figures 8.72, 8.73, and 8.74 it is easy to see that the low-frequency current noise floor is set by R_f's Johnson noise; so larger values of R_f would appear to be "better."

Not so fast! For a given input capacitance, larger values of R_f correspond to a lower input rolloff frequency ($\omega = 1/R_fC_{in}$), requiring more aggressive compensation

[96] Open-loop gain limitations may be encountered with very wideband op-amps (e.g., parts like the OPA655/6/7, with GBW values in the GHz region), but such limitations are rare for lower-frequency op-amps such as the OPA637.

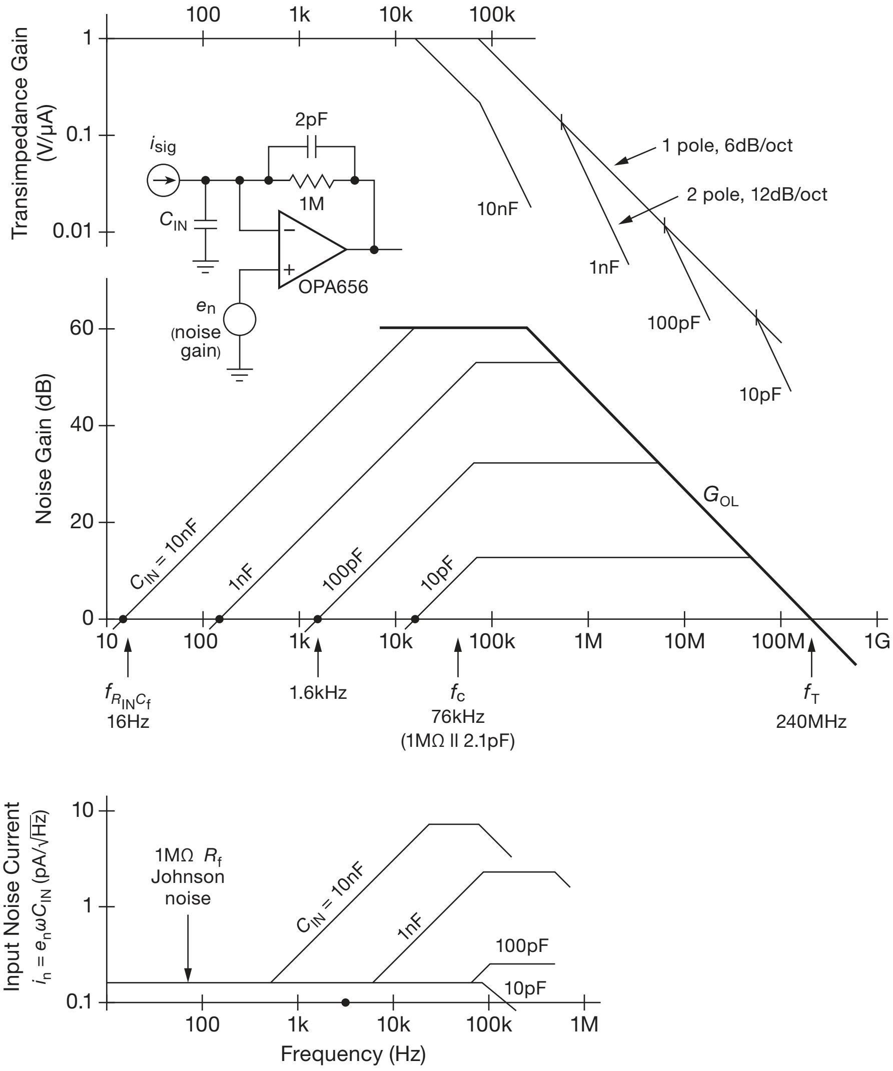


Figure 8.73. Charting the noise in a transimpedance amplifier. A 230 MHz op-amp is used to obtain ~75 kHz bandwidth for input capacitances from 10 pF to 1 nF. The transimpedance bandwidth is not much affected by input capacitance up to 1 nF, but a 10 nF capacitance reduces the bandwidth substantially. It does this without creating instability in this case, because of the OPA656's limited open-loop gain (65 dB).

(i.e., lower bandwidth f_c). If your noise is dominated by Johnson noise in R_f, and you don't care about bandwidth but want to minimize the low-frequency noise, then a larger R_f is good. But in a wideband photodiode amplifier in which the e_nC noise is dominant and in which you want to improve the bandwidth, it's better to reduce R_f.

But, *not too much!* Here's the reason: a goal in any transimpedance amplifier design should be to ensure that the amplifier adds insignificant noise to the inherent shot noise of the input signal. As we reduce R_f, however, its Johnson-noise current $\sqrt{4kT/R_f}$ increases, ultimately dominating over the input signal's irreducible shot-noise current $\sqrt{2qI_{in}}$. By equating these noise currents we get the condition $I_{in}R_f{=}2kT/q{=}50\,\text{mV}$. That is, to avoid adding amplifier noise, the feedback resistor should not be chosen so small that the voltage drop produced by the input (which could be a dc component of the input signal) is less than, say, 100 mV.

This noise–bandwidth tradeoff in the choice of feedback resistance is illustrated in Figure 8.75, where reducing

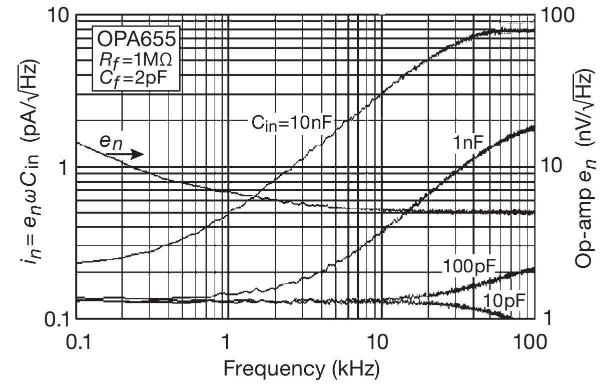

Figure 8.74. Measured input-referred current noise in the amplifier of Figure 8.73. The separate spectra have been here overlaid, with some helpful decorative legends.

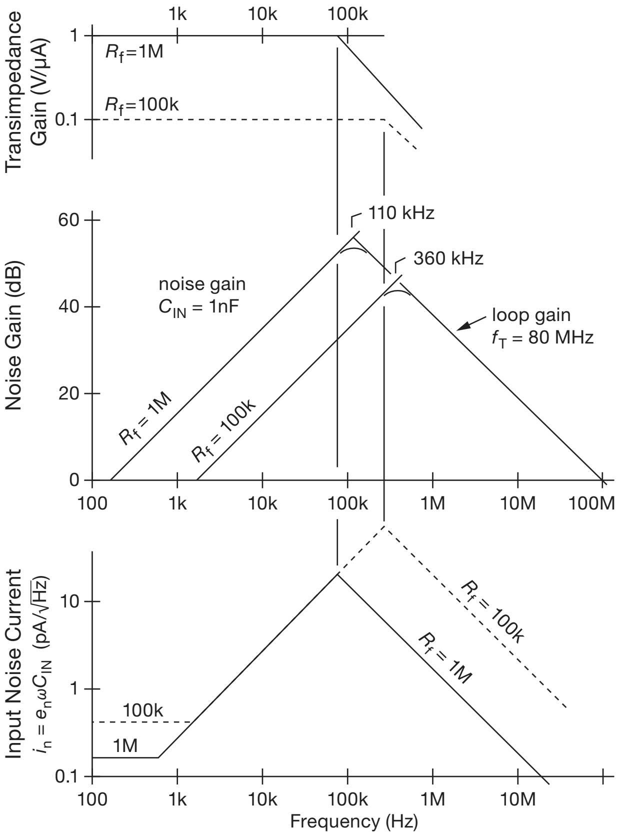

Figure 8.75. In a fast transimpedance amplifier, where e_nC noise dominates over R_f Johnson noise, you can increase the usable bandwidth by reducing R_f; recover the lost gain in a second-stage voltage amplifier.

R_f from 1M to 100k moves the input rolloff upward by a factor of 10, allowing an increase in amplifier bandwidth by a factor of roughly 3 (more precisely, $\sqrt{10}$). The price you pay is ×10 reduced gain (easily recovered with a downstream voltage amplifier stage), and increased low-frequency noise floor (still negligible compared with the e_nC high-frequency noise contribution). Of course, the increased bandwidth comes with a continuing increase in e_nC noise, as seen above 100 kHz in the bottom plot of Figure 8.75.

Happily, there some nice tricks you can use to mitigate these high-frequency e_nC noise effects. One method greatly reduces the effective capacitance at the input by "bootstrapping" the return side of the signal source, e.g., photodiode (and cable shield); another uses a common-base transistor stage (a cascode) to isolate the photodiode capacitance from the transimpedance stage. We'll describe these shortly, after a brief discussion of an important (and too often overlooked) issue: the need for a bandwidth-limiting lowpass filter at the output of the transimpedance stage.

8.11.7 Output bandwidth limiting in the transimpedance amplifier

If you're designing a real-world transimpedance amplifier with significant e_nC noise from capacitance at the input, it's important to add a lowpass filter section at the output. Look again at the noise gain plots in Figure 8.73. Because C_f was chosen for stability with the largest anticipated input capacitance, there is a broad band of noise at high frequencies, particularly for lesser values of input capacitance. This noise extends beyond the amplifier's bandwidth, and can contribute the lion's share of total output noise (remember that logarithmic frequency plots tend to conceal the fact that most of the bandwidth is at the high end).

To see this more clearly, look at Figure 8.76, an analogous set of plots for the current-input amplifier of Figure 8.77.[97] Here we've used a decompensated low-noise JFET op-amp, with C_f chosen such that the amplifier is stable with input capacitances up to 1000 pF. Noise gain and effective input noise current are plotted, for both 1000 pF and 100 pF at the input. The solid lines show U_1's output, and the dashed lines show the signal after a simple *RC* lowpass. Because the amplifier is overcompensated when C_{in}=100 pF, there's a substantial region (the dotted area) of

[97] A simplified version of the exemplary photodiode amplifier discussed in §*4x.3*.

out-of-band noise that is eliminated by the R_1C_1 filter. (The effect is minimal when the amplifier is critically compensated, with f_c nearly equal to f_{GM}, as seen in the 1000 pF plots, because the op-amp's open-loop gain rolloff accomplishes the same thing.)

In this circuit we added an output ×10 gain stage, so that the overall gain is 1 V/μA. That provides another opportunity for an additional section of lowpass filtering, via C_2. This might seem extreme, but remember that a single-section *RC* has a gentle rolloff, such that equivalent white-noise bandwidth extends well beyond its characteristic frequency ($1.57 f_{3dB}$, to be exact; see §8.13).

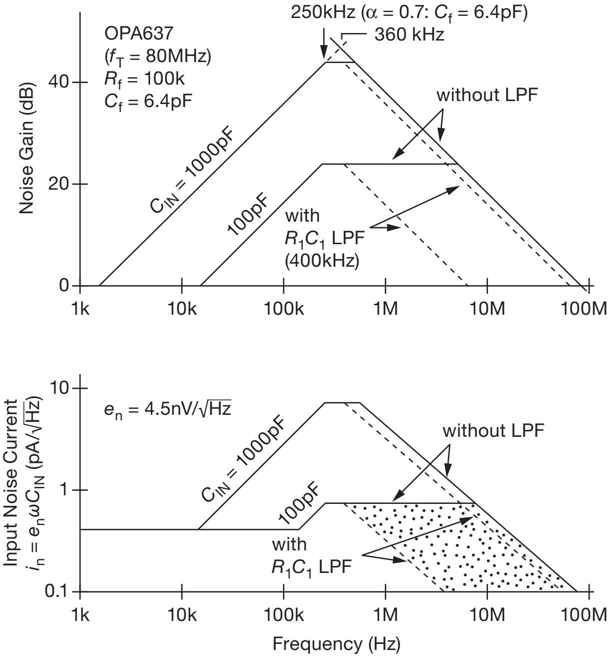

Figure 8.76. Noise plots for the current amplifier of Figure 8.77. Adding an output filter at or slightly above f_c greatly reduces the output noise.

8.11.8 Composite transimpedance amplifiers

When choosing an op-amp for use in a sensitive transimpedance amplifier, you want very low input noise current, thus a JFET or CMOS type. And if you want plenty of speed it's important to select an op-amp with low input noise voltage (to minimize the high-frequency e_nC_{in} noise current it produces), and especially so if the input capacitance is substantial. Finally, because the input noise current produced by the gain-setting feedback resistor R_f decreases as $1/\sqrt{R_f}$, a low-noise TIA requires a large-value feedback resistor.

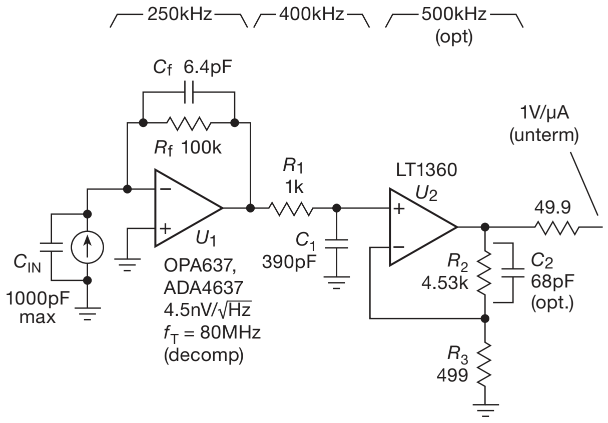

Figure 8.77. Current-input amplifier, BW=250 kHz, compensated for stability with input capacitances up to 1000 pF. The lowpass filters (R_1C_1 and R_2C_2) minimize out-of-band noise, particularly when C_{in} is less than the maximum.

But a large R_f produces a low input rolloff frequency ($f_{RCin}=1/2\pi R_fC_{in}$), just what you *don't* need when you're aiming for lots of bandwidth. We'll see presently (in §8.11.9) techniques, such as bootstrapping and cascoding, that can be used in some situations for greatly reducing the effective input capacitance in a transimpedance amplifier. But another approach is simply to select an op-amp with high-enough bandwidth f_T to produce the required TIA bandwidth ($\sim \sqrt{f_{RCin}f_T}$), as we illustrated in §*4x.3.3*.

This is a reasonable approach – but the performance you get with available op-amps often falls short. Table 8.3 shows that most fast op-amps (say $f_T \geq 350$ MHz) have relatively high noise voltage (e_n of 6 nV/$\sqrt{\text{Hz}}$ or greater), and quiet op-amps tend to be slow, like our low-noise winner, the AD743 (e_n=2.9 nV/$\sqrt{\text{Hz}}$ and f_T=4.5 MHz). From the table you can see also that some of the fastest op-amps are low-voltage parts, for example the OPA657 with f_T=1500 MHz, whose total supply voltage range is restricted to 9–13 V. That matters, because the larger values of feedback resistor needed for reduced noise produce more gain, therefore larger output swings (and static dc levels, when there's a nonzero dc component to the input current), favoring op-amps that can run on ±15 V.

So, what can be done? A nice approach is to separate the input-stage performance from that of the output stage, to optimize overall noise and speed capability. This can be done with a "composite amplifier," a powerful technique seen, for example, in Figures 5.47 and 13.48, and treated in some detail in §*4x.3*.

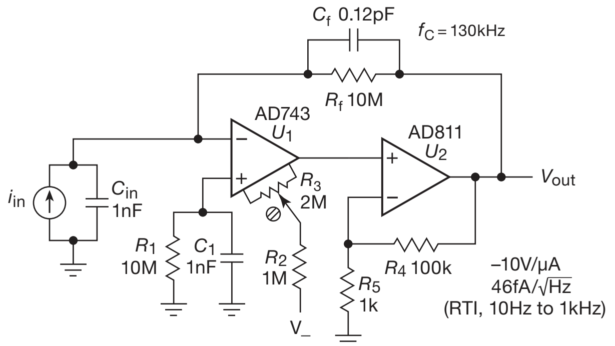

Figure 8.78. Low-noise wideband transimpedance amplifier, exploiting the combination of desirable properties of a pair of op-amps configured as a composite amplifier.

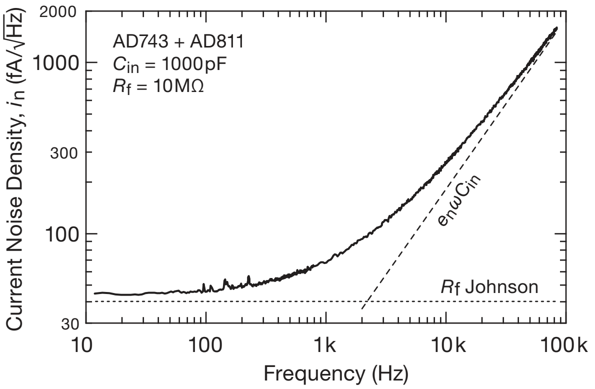

Figure 8.79. Measured current noise versus frequency for the amplifier of Figure 8.78, with a 1000 pF capacitor across the input. The dashed line shows the value of $e_n\omega C_{in}$ for e_n=2.9 nV/$\sqrt{\text{Hz}}$ (the AD743 datasheet's specified typical e_n), and the dotted line is $\sqrt{4kT/R_f}$, the Johnson-noise current of the 10M feedback resistor (after Kretinin & Chung, used with permission).

Figure 8.78 shows an example,[98] a TIA intended for low-level current signals burdened with a relatively high capacitance of 1000 pF. Here an AD743 low-noise input stage has been mated with a ×100 wideband AD811 output stage, thus maintaining the low e_n while boosting the composite amplifier's f_T by a factor of 100, to 450 MHz. Although the output stage has considerable bandwidth (it's a current-feedback amplifier intended for video applications), the AD743's meager 4.5 MHz bandwidth (with additional poles around that frequency and above, as evidenced by the datasheet's open-loop gain and phase plots) causes the composite amplifier to exhibit a −12 dB/octave rolloff above 5 MHz, reaching a 180° phase shift around 20 MHz. This sounds dangerous, but it's OK because that's well above our f_c frequency (see §*4x.3.2*), and it's above the intercept of the flattened noise gain with the open-loop gain (see Figure 8.73). So the configuration is stable, and in fact the second-stage bandwidth is more than needed.

The performance is quite good, with i_n≈50 fA/$\sqrt{\text{Hz}}$ from 10 Hz to 2 kHz when driven with an input capacitance of 1000 pF, and with bandwidth out to 100 kHz. But the input-noise voltage (2.9 nV/$\sqrt{\text{Hz}}$) in combination with the large input capacitance causes a rapidly rising e_nC_{in} noise current, reaching nearly 2000 fA/√Hz at 100 kHz (Figure 8.79). And the low-frequency noise floor is dominated by the Johnson-noise current of the feedback resistor R_f. Given that the AD743 is the quietest available JFET op-amp, we seem to have hit the limit of noise performance in a transimpedance amplifier driven with a highly capacitive source.

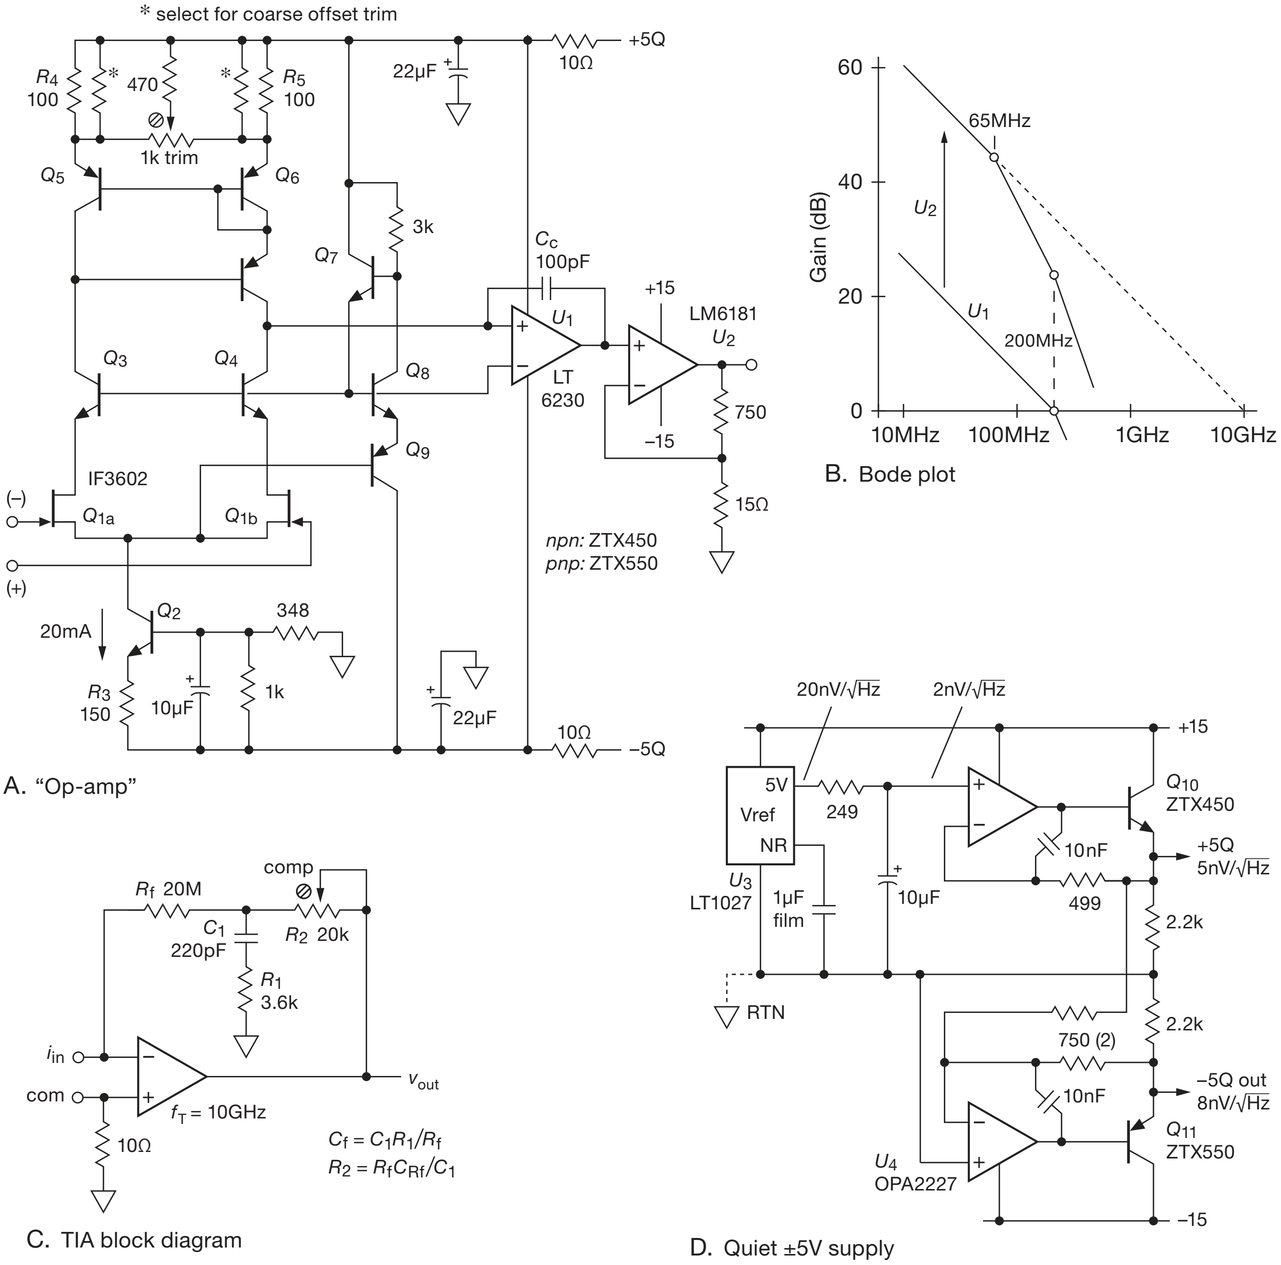
A. Hybrid composite transimpedance amplifier

We *could* do better, though, if we could find a way to reduce the already low e_n (which contributes the rising e_nC_{in} above around 10 kHz) while maintaining a large gain–bandwidth product. The technique that does the trick here is the use of a hybrid input stage to exploit the very low e_n of a large-area JFET pair like InterFET's IF3602 (e_n=0.3 nV/$\sqrt{\text{Hz}}$, typ, at 100 Hz). Of course, large-geometry JFETs have lots of capacitance (this JFET's C_{iss} is a whopping 300 pF), but that is not terribly serious when you've got a signal source that's burdened already with 1000 pF of capacitance. And we'll stick with the composite amplifier topology, to get the high open-loop amplifier bandwidth that we need in order to achieve reasonable TIA bandwidth with a highly capacitive input.

Figure 8.80 shows such a design. The "op-amp" is a 3-stage composite amplifier whose input stage Q_{1ab} is a common-source differential JFET with current mirror drain load Q_5Q_6, isolated with a cascode Q_3Q_4. The overall GBW is 10 GHz, as seen in the Bode plot of Figure 8.80B; this composite op-amp is not stable (!) when used as a voltage amplifier (at least for closed-loop gains <45 dB), but when configured as a transimpedance amplifier (Figure 8.80C) with an effective compensation capacitance of 0.032 pF (set by R_2 in the circuit shown[99]) across the 20M

[98] A. Kretinin and Y. Chung, "Wide-band current preamplifier for conductance measurements with large input capacitance," arXiv:1204.2239v1 (2012).

[99] Alternatively you can make R_f from a series string of four or five resistors (spaced out and away from ground) to reduce the total capacitance of their individual ∼0.15 pF parasitic shunt capacitances.



A. “Op-amp”

B. Bode plot

C. TIA block diagram

D. Quiet ±5V supply

Figure 8.80. Hybrid transimpedance amplifier, optimized for lowest noise with capacitive inputs of order ~ 1000 pF by the use of large-area input-stage JFETs with extraordinarily low noise voltage ($e_n = 0.35\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$). The composite amplifier (A) boosts the gain–bandwidth product f_T to 10 GHz, (B), to maintain an overall TIA bandwidth of ~ 250 kHz in spite of the large R_f and C_{in} (20 MΩ and 1000 pF). The transimpedance configuration (C) sets the gain at 20V/μA, with an effective C_f of 32 fF (created by the pole-zero network $C_1R_1R_2$, needed to cancel R_f's excessive self-capacitance (which we'll call C_{Rf}); see §*4x.3*, setting a dominant pole at 200 kHz to ensure stability. A low-noise voltage reference (D) is used to create quiet ± 5 V supply rails.

gain-setting feedback resistor, it is stable.[100] The input stage has a noise voltage density of $e_n{\approx}0.6\,\text{nV}/\sqrt{\text{Hz}}$. The second op-amp (LT6230) is a wideband (200 MHz) low-noise (1.1 nV/$\sqrt{\text{Hz}}$) op-amp, powered by a low-noise ±5 V power supply[101] (Figure 8.80D); with the JFET input stage, the combined GBW of these two stages is $f_T{=}g_m/2\pi C_c$, or about 200 MHz with a C_c of 100 pF. The last stage has a gain of 50 and an f_T of 65 MHz, boosting the composite amplifier's GBW to 10 GHz.

When configured as a transimpedance amplifier (i.e., Figures 8.80A and C), this circuit has 5× less noise voltage (thus 5× less e_nC_{in} noise) than the composite TIA of Figure 8.79. It also has greater bandwidth, thanks to its 20× higher f_T, even with the larger value of feedback resistor (20M, chosen to reduce its Johnson-noise current, given the quieter front-end). Look ahead to Figure 8.81 to see this comparison graphically.

Some details We measured $e_n{=}0.35\,\text{nV}/\sqrt{\text{Hz}}$ for an IF3602 JFET operating at 10 mA, and $0.3\,\text{nV}/\sqrt{\text{Hz}}$ at 25 mA; here we chose the lower drain current of 10 mA for lower dissipation and reduced $1/f$ noise. Because of the IF3602's very large capacitances (300 pF for C_{iss}, 200 pF for C_{rss}) we clamped the drains with a cascode, setting $V_{\text{DS}}{=}V_{\text{BE}}$ independently of V_{GS} and input common-mode level. This further reduces JFET power dissipation (to about 6 mW each), and prevents excessive "impact-ionization" gate current (§3.2.8).

The IF3602 pair is not well matched (specified $V_{\text{os}}{=}100$ mV max), which is especially troublesome in view of its very high transconductance (we measured $g_m{=}130$ mS at 10 mA, see the plot of measured JFET transconductances in §*3x.2*). If we try to trim the offset by unbalancing the drain resistors (with a circuit like that of Figure 8.67), we quickly find from $\Delta I_D/I_D{=}0.5\,g_mV_{\text{os}}/I_D$ that we need a 39% drain-current unbalance to null a worst-case input offset. Ouch! So we went with the scheme shown, in which a degenerated low-noise Wilson current mirror with selected fixed trim resistors sets the required unbalanced drain currents. The current mirror's noise-voltage contribution with 100 Ω emitter resistors R_4 and R_5, when referred to the JFET input terminals, is $e_n{=}\sqrt{4kT/R_4}\cdot 1/g_m$, or 0.1 nV/$\sqrt{\text{Hz}}$, an insignificant 4% contribution when the squared amplitudes are combined. Finally, a comment on the differential pair current sink Q_2: normally a differential pair's current sink noise is not terribly critical, because a reasonably well-balanced differential stage cancels the noise (e.g., 30× for a 3% balance). But here we face a possibly severe current imbalance to trim the offset voltage, so we've used a low-noise voltage regulator ($<$10 nV/$\sqrt{\text{Hz}}$), with further *RC* quieting of the current sink.

Exercise 8.3. Calculate the noise densities of the ±5Q supplies in Figure 8.80D. What is their rms noise?

B. Composite versus single-stage transimpedance amplifiers

The plots of transimpedance gain and input noise current in Figure 8.81 are a good way to see the performance enhancement you get with a composite TIA in the difficult situation of high input capacitance. The improved performance comes from the greater amplifier bandwidth f_T, and from the ability to create a quiet input stage.

Comparing first the single-stage (i.e., not composite) configurations A and B, you see the improved bandwidth gained from the faster OPA637, with the tradeoff of greater noise. Adding a (composite) second stage to the quieter configuration A gets you a lot of extra bandwidth with no increase of noise (configuration C, the circuit of Figure 8.78). The composite amplifier with an even lower-noise discrete input stage (configuration D, the circuit of

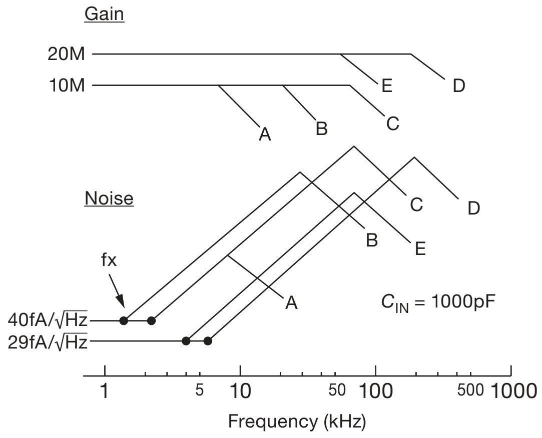


Figure 8.81. Comparing the performance of five transimpedance amplifiers when driven with a current signal of 1000 pF capacitance. A, AD743; B, OPA637; C, AD743 composite (Figure 8.78); D, IF3602 composite (Figure 8.80); E, OPA637 with BF862 bootstrap (similar to Figure 8.82); The feedback resistor R_f is 10 MΩ for circuits A–C, and 20 MΩ for D and E.

[100] With $C_{\text{in}}{=}1000$ pF, $f_{\text{RCin}}{\approx}8$ Hz and $f_T{=}10$ GHz, so $f_{\text{GM}}{\approx}280$ kHz; a 0.032 pF effective capacitance across R_f makes $f_c{=}200$ kHz.

[101] Where we've started with an LT1027 reference, which uses a buried zener for low $1/f$ noise, quieted further with a bypass capacitor at the noise-reduction pin. Adding a resistor to ground from the upper op-amp's inverting input lets you change the quiet split-supply voltages, e.g., to ±6 V, or whatever.

Figure 8.80) has yet more bandwidth, and can tolerate the larger R_f needed to fully exploit the amplifier's lower e_n. Finally, if you have the luxury of bootstrapping the input capacitance (see for example §8.11.9, Figure 8.82), the greatly lowered C_{in} lets you revert to the simple single-stage OPA637 configuration without a great sacrifice in performance.

This example illustrates once again a lesson we've learned over many decades of designing low-noise amplifiers, namely that circuit complexity increases rapidly as improvements are added to reach the limits of low-noise circuit performance.

8.11.9 Reducing input capacitance: bootstrapping the transimpedance amplifier

Input capacitance has not been our friend. As Figures 8.73, 8.74, and 8.76 make abundantly clear, input capacitance is the root of all evil, in terms of both noise and bandwidth. Large-area photodiodes are plagued with lots of capacitance (as much as 1000 pF or more); and, if the detector is at the end of a length of shielded cable, you can figure on an additional ~30 pF/ft of cable (this value is not arbitrary; see Appendix H).

As we hinted earlier, there are tricks by which you can greatly reduce the effective capacitance. Figure 8.82 shows an elegant solution,[102] namely an ac-coupled bootstrap of the return side of the capacitive input device (plus shielded cable, if any). In this circuit the JFET follower Q_1 drives the low side of the photodiode with a replica of any signal at the summing junction; Q_1's high transconductance (~25 mS) ensures a gain close to unity (output impedance ~40 Ω), thus a reduction of the photodiode's effective input capacitance (as seen at the summing junction) by at least a factor of 10.

But now we have to worry about noise introduced by Q_1 and associated circuitry. You might think first about Q_1's gate current, and also the capacitance C_{iss} that it adds to the input. For this particular JFET, things look pretty good: it has low gate input current (~1 pA, as long as you keep $V_{DS} < 5$ V), and low feedback capacitance (~2 pF). But the JFET's noise is another matter, because its e_n voltage noise generates an e_nC noise current in combination with the *unbootstrapped* photodiode (and cable) capacitance. This is in contrast to the op-amp's e_n, which now sees the much lower bootstrapped capacitance; both of these noise currents must come through R_f, generating output noise.

Figure 8.82. Follower Q_1 bootstraps the photodiode at signal frequencies, reducing its effective capacitance by a factor of 10 or more. The BF862 is especially well suited to this task, with its low capacitance and sub-nV/$\sqrt{\text{Hz}}$ noise. This lets us use a less-expensive op-amp (with less bandwidth and somewhat higher e_n) for U_1. We often add an emitter follower (not shown for simplicity). To find the break frequency of the e_nC_{in} noise, use eq'n 8.45 on page 539, with the "reduced" value of C_{in}; see text.

For this reason it's essential to choose a JFET with very low noise voltage, ideally much lower than the e_n of the op-amp. The BF862 is an excellent choice, with its impressively low[103] e_n~0.9 nV/$\sqrt{\text{Hz}}$. Even so, its noise contribution is larger than that of the op-amp (the latter benefitting, of course, from the JFET's successful reduction of effective photodiode capacitance), because the LTC1792 is a quiet (4.2 nV/$\sqrt{\text{Hz}}$) op-amp to begin with. For example, with a 1000 pF photodiode the op-amp's 4.2 nV/$\sqrt{\text{Hz}}$ acts on the (reduced) ~100 pF, while the JFET's 0.9 nV/$\sqrt{\text{Hz}}$ acts on the full 1000 pF of the photodiode. Making that quantitative, at 100 kHz the noise-current contributions are 0.26 pA/$\sqrt{\text{Hz}}$ and 0.57 pA/$\sqrt{\text{Hz}}$, respectively, for a combined noise current of 0.63 pA/$\sqrt{\text{Hz}}$. Although the JFET's noise dominates, we're still doing quite a bit better than the unbootstrapped configuration, with its noise current of 2.6 pA/$\sqrt{\text{Hz}}$.

We discuss transimpedance amplifiers in further detail (particularly issues of stability) in §*4x.3*. There we include a design for an input-capacitance-tolerant photodiode amplifier that exploits bootstrapping; the circuit is reproduced here in Figure 8.83. In this design we used the excellent (and not inexpensive) OPA637 (GBW=80 MHz,

[102] See Linear Technology's LTC6244 datasheet and their DN399 Design Note by Glen Brisebois.

[103] Inexpensive, too, about $0.50 in qty 25. And, according to Phil Hobbs, they can be paralleled without source ballasting (especially when taken from the same reel), because "they go from cutoff to I_{DSS} in about 400 mV. JFETs running near I_{DSS} have a low tempco as well. I use boatloads of them – they're Good Medicine."

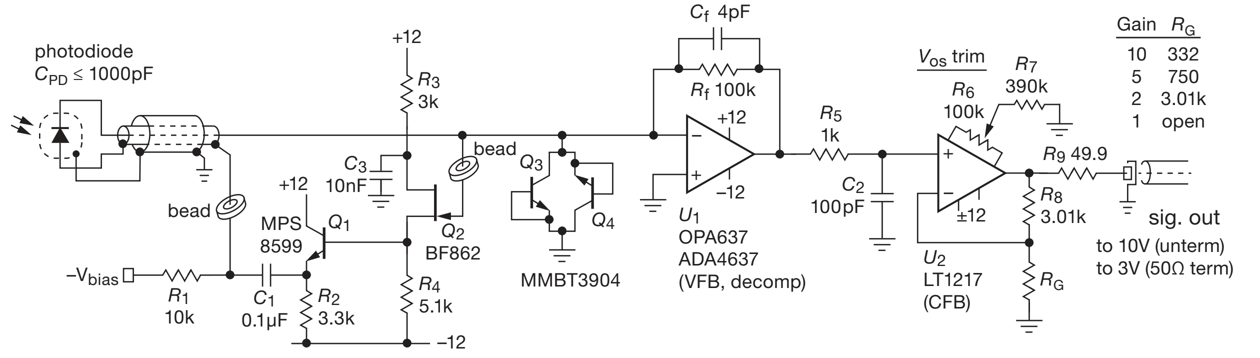

Figure 8.83. A complete photodiode amplifier, suitable for input capacitances up to 1000 pF. Input bootstrapping greatly reduces the effective photodiode and cable capacitance, for enhanced speed and reduced noise.

e_n=4.5 nV/$\sqrt{\text{Hz}}$). In Figure 8.84 we plot the noise and bandwidth, under the conservative estimate of a tenfold reduction of input capacitance. Bootstrapping improves the bandwidth, reduces the noise, and leaves the transimpedance gain unchanged.[104] Not bad!

Exercise 8.4. Design a TIA with an OPA637 op-amp and a BF862 JFET bootstrap follower, for input signals with C_{in}=1 nF. Use R_f=20 MΩ, and assume the BF862 has a noise voltage of 0.85 nV/$\sqrt{\text{Hz}}$ and a voltage gain (when driving the bootstrap terminal) of G_V=0.95. Evaluate your circuit's noise and gain performance, which should be not unlike that of curve E in Figure 8.81.

8.11.10 Isolating input capacitance: cascoding the transimpedance amplifier

Bootstrapping reduces the effective input capacitance (typically by an order of magnitude), allowing reduced noise and greater bandwidth from a capacitive current-output sensor such as a photodiode. But we can do even better: it's possible to isolate the input capacitance entirely, by interposing a common-base (cascode) stage between the input signal and the transimpedance amplifier.

There are some bumps along the way, so we'll take it in stages. We learned about this from Philip Hobbs, whose articles[105] make good reading for those interested in pursuing these techniques.

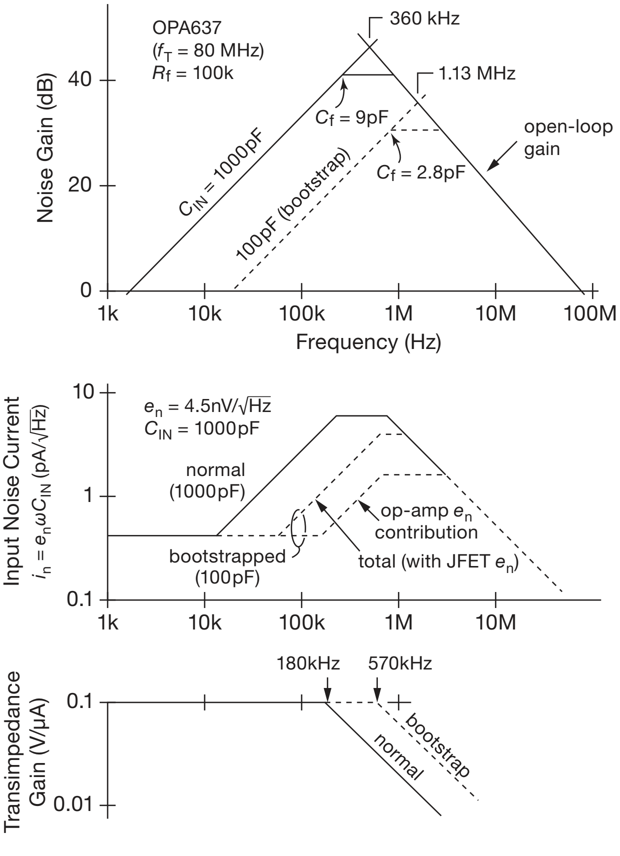

Figure 8.84. Noise, bandwidth, and gain for the bootstrapped photodiode amplifier. The reduced effective capacitance improves both the noise (via reduced e_nC) and bandwidth (via smaller stabilizing feedback capacitance C_f).

A. Creating a capacitance-isolating cascode

Step 1: unbiased cascode

Figure 8.86A shows the core idea, in which the current-sinking signal source drives the emitter of grounded-base

[104] Here the LT1792 costs $4.85 versus $18 for the OPA637 or $12 for the similar ADA4637, and the BF862 costs just $0.67. You often can do even better, with bootstrap-assisted op-amps of adequate performance down in the $2 territory.

[105] For a good first reading assignment, try his "Photodiode front ends – the REAL story," *Opt. Photon. News*, **12**, 42–45 (April 2001).

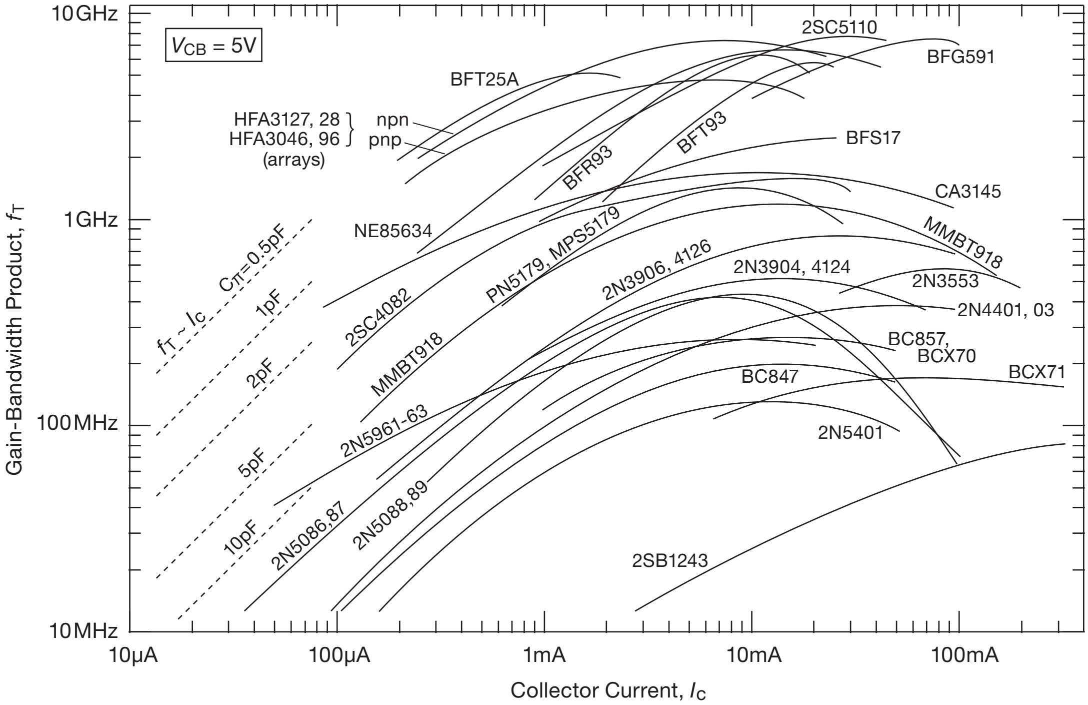

Figure 8.85. Gain-bandwidth product, f_T, versus collector current for selected bipolar transistors, as shown in the manufacturers' datasheets. Some wideband transistors are clear off the top.

npn transistor Q_1 (this is often called a "common-base amplifier"). Assuming reasonable transistor beta, most of that current appears at the collector – but with only the small collector output capacitance of Q_1, typically just a few picofarads.

A minor flaw here is that the input sits a diode drop below ground. But there are more serious snakes lurking in the Garden of Eden. We want good performance at very low signal currents, say fractions of a microamp. Down there we have to worry about falling transistor beta. Worse still, the input impedance r_e seen at the emitter is rising inversely with input current; at 1 μA it's 25 kΩ (recall r_e=25Ω/I_C[mA]). So the signal current is shunted to ground by the input capacitance at a frequency at which the reactance of C_{in}=25k or less; that is, the input rolls off at $f_{3dB} = 1/2\pi r_e C_{in}$, thus for example around 6.4 kHz for a 1μA signal with C_{in}=1000 pF.[106]

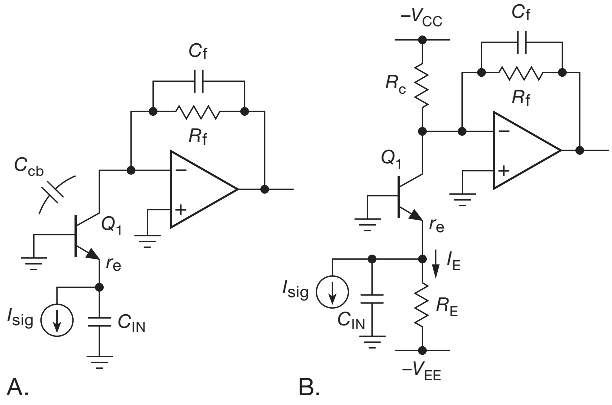

Figure 8.86. Isolating input capacitance with a common-base (cascode) input stage. A. Transistor Q_1 passes the signal current to the transimpedance amplifier, which sees only the small collector-to-base capacitance C_{cb}. B. Adding dc bias reduces r_e, greatly increasing the bandwidth.

[106] You also have to worry about the transistor's falling f_T at low currents; the reduced beta diverts emitter current into the base at high frequencies. For discussion and measurements see the section "BJT Bandwidth and f_T" in Chapter *2x*, and see Figure 8.85. In the latter you can see that the 2N5089 has an (extrapolated) f_T down around 2 MHz at 10μA, from which you can estimate that about 10% of the emitter current is diverted at 200 kHz.

Step 2: biased cascode

We can drive r_e down (and also preserve reasonable beta) by biasing Q_1, as shown in Figure 8.86B. With ±15 V supplies, we might choose R_C=R_E=60 kΩ to set I_C at 250 μA quiescent current; thus r_e=100 Ω. This raises the $r_e C_{in}$ rolloff to a quite respectable 1.6 MHz.

But now we've created three new problems. First, this substantial quiescent collector current means that R_C has to be critically chosen so that Q_1's collector operating point (when disconnected from the virtual ground) would be at ground; otherwise the transimpedance stage (if configured for high gain, say 1 V/μA; i.e., R_f=1 MΩ) will have a large output dc offset. Second, in this circuit the noise currents of R_C, R_E, and R_f are all combined at the summing junction; and the required lower R_C and R_E resistor values generate correspondingly larger Johnson-noise currents at the transimpedance input (recall that a resistor of value R generates a short-circuit Johnson-noise current of $i_n = \sqrt{4kT/R}$). Third, Q_1's higher operating current means higher base current and thus higher shot noise ($i_{n,\mathrm{base}} = \sqrt{2qI_B}$), which is another noise-current contribution at the transimpedance input.[107]

So here's the situation so far: with the circuit of Figure 8.86B we have achieved better bandwidth with a given input capacitance, compared with the previous transimpedance designs, but at the cost of (a) dc offset, (b) an input node that is a diode drop below ground, and (c) a noise–speed tradeoff in the choice of Q_1's quiescent current.

Can anything further be done? Read on...

Step 3: bootstrapped biased cascode

Yes! Combine the capacitance-reducing bootstrap trick with the biased cascode. Figure 8.87 shows how, this time as a fleshed-out design showing the specifics of component values and types.

To bring this into the real world, we chose a gallium phosphide UV photodiode that we use in the lab; its measured capacitance at 5 V of reverse bias is 460 pF (it is not specified on the datasheet). The photodiode's low side is bootstrapped by JFET follower Q_2 (as in the earlier Figure 8.82), reducing its effective capacitance tenfold, to ~50 pF.

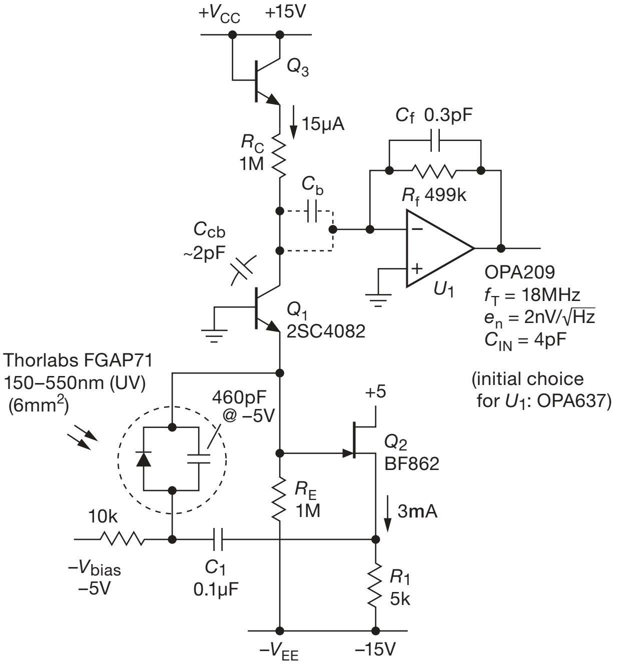

Figure 8.87. Bootstrapping the cascoded transimpedance amplifier to achieve wideband (1 MHz) low-noise performance with a photodiode of rather high capacitance. Optional blocking capacitor C_b can be used to eliminate dc offset in ac-coupled applications.

The next step is to choose the operating current for cascode transistor Q_1, such that its r_e is small enough so that the input $r_e C_{in}$ rolloff[108] does not compromise the bandwidth f_c set by the transimpedance stage U_1. We figure f_{GM} (eq'n 8.46) as usual (see §*4x.3*): the capacitance at U_1's input is the sum of Q_1's collector capacitance (2 pF) and U_1's own input capacitance (15 pF for our initial choice of an OPA637, whose low noise and wide bandwidth make it a favorite choice as an input stage for photodiode amplifiers); the 17 pF total puts U_1's input rolloff f_{RfCin} of 18.7 kHz, given our choice[109] of transimpedance gain (0.5 V/μA). The OPA637's decompensated f_T of 80 MHz gives us an f_{GM}=$\sqrt{f_{RfCin} f_T}$=1.22 MHz; we choose a value of feedback capacitor C_f to set the critical bandwidth f_c to be 0.7 MHz (a conservative ζ=1.2, to ensure stability), hoping for a transimpedance bandwidth f_b of 1 MHz. That's 0.46 pF, of which the resistor itself provides ~0.1 pF. You can use a pair of PCB traces, an adjustable pot with C_f=0.5pF (see Figure *4x.18*), or a "gimmick" (a few twists of a pair of insulated wires) to add the remaining 0.36 pF.

[107] There's a subtle point here: a current such as I_E that is generated by a voltage drop across a metallic conductor does not exhibit shot-noise current (the charge carriers do not act independently; see §8.1.2). But the base current *does* have the "full" shot noise given by the formula. That noise current manifests itself at the collector, because I_C=I_E(noiseless)−I_B(noisy).

[108] At high enough currents, transistor f_T is given by f_T=$1/2\pi r_e C_{in}$.

[109] Arrived at through an analogous process of speed–noise tradeoff, the details of which we will spare the reader.

B. Iteration: better op-amp choice

Something's amiss here: the OPA637 is a fine op-amp (with a price to match!), but it uses large-area JFETs to achieve its admirably low e_n, resulting in a high input capacitance of 15 pF. That's not a worry when you have, say, an input signal accompanied by lots of capacitance (e.g., a photodiode and some shielded cable). But here it's at a low capacitance node (Q_1's collector) where it dominates the rolloff, forcing the high f_T requirement.

Let's redo the calculation, assuming we use an op-amp with lower capacitance, say C_{in}=4 pF. Now f_{RfCin}=53 kHz, and for an f_b of 1 MHz with ζ=1 (so f_c=0.7 MHz) we need an op-amp with $f_T \geq 9$ MHz. Our effort is rewarded, for now there are many possibilities. We can choose the OPA209 from Table 8.3, with its f_T of 18 MHz and low cost of $2.27.[110] That gives us f_{GM}=0.98 MHz, so we can set f_b=f_{GM}=1 MHz, and with ζ=1 (critical damping) we have f_c=0.7 MHz and C_f=3 pF.

Knowing that the transimpedance stage has a usable bandwidth of 1 MHz, we next set the quiescent current of cascode transistor Q_1 high enough so that the rolloff of r_e, combined with the 50 pF (bootstrapped) effective photodiode capacitance, is at a somewhat higher frequency. Here an I_C of 15 μA gives us an r_e (the impedance the signal sees at the emitter) of 1.7 kΩ and thus an input rolloff frequency of 1.9 MHz. The reduced C_{in} produced by the bootstrap allows us to run Q_1 at this low current, with the benefit that the Johnson noise current contributed by Q_1's 1 MΩ collector and emitter resistors is no larger than that of R_f. The base current shot noise is similarly reduced; here it contributes an input-referred noise current of 0.1 pA/$\sqrt{\text{Hz}}$ (to be compared with the 0.26 pA/$\sqrt{\text{Hz}}$ combined contribution of R_C, R_E, and R_f).

Some details:[111]

(a) Bootstrap follower Q_2 must drive the low side of the photodiode with an output impedance that is much lower than Q_1's input impedance (i.e., r_e, here 1.7 kΩ); that's satisfied here, where Q_2's high transconductance ensures a low output impedance of $Z_o = 1/g_m \sim 40\,\Omega$.[112]

(b) We chose first a 2N5089 for the cascode transistor Q_1, because of its high beta at low currents (β=400 min at I_C=100 μA) and low output capacitance (2 pF), both of which promote low noise. But then we consulted Figure 8.85 and realized that it had too little GBW: f_T is just 2 MHz at 15μA. So we looked next at an MMBT918 (2N918), with a healthy f_T=13 MHz at 15μA. Its base would rob about f/f_T, about 8% at f_c and thus an insignificant contributor to the circuit's 3 dB rolloff at 1 MHz. But its beta is anemic, less than 40 at 15μA. So we settled finally on the 2SC4082 shown in the figure: it has f_T=20 MHz at 10μA, and a pleasantly flat beta curve with β=90 at 100μA (and likely not much lower at 15μA).

(c) There's an additional noise voltage contribution, in the form of the transistor's input noise voltage ($e_n = \sqrt{4kT[r_{bb'} + 0.5r_e]}$) generating an "$e_nC$" noise current through the photodiode's effective input capacitance. These parameters don't look unfavorable for the 2SC4082.[113]

C. A final trick: "Regulated Cascode" (RGC)

Figure 8.88 shows a circuit configuration that's achieved considerable popularity in the world of photonics, where you're dealing with data rates of *giga*bits per second. Transistors Q_1 and Q_2 form a tight local feedback loop, with cascode transistor Q_1's base "regulated" by Q_2. (Q_1 and Q_2 can be replaced by MOSFETs, as indicated.) The regulated cascode improves on the simple cascode of Figure 8.86 in two important ways. (a) The circuit's input impedance (at Q_1's emitter) is reduced by a factor of Q_2's voltage gain, greatly increasing the $R_{in}C_{in}$–limited bandwidth; and (b) the input noise voltage is set by Q_2, rather than by Q_1, so the latter can be run at desirable low currents without the usual noise penalty.

To expand on this a bit, remember that input capacitance in the simplest transimpedance amplifier (Figure 8.70) is both a bandwidth killer (via R_fC_{in}) and a noise enhancer

[110] The OPA209 may even be *too good* for the job, with its e_n of 2.2 nV/$\sqrt{\text{Hz}}$. We require only that the op-amp's e_n be significantly less than that of Q_1 multiplied by the ratio of the reduced (bootstrapped) input capacitance to the capacitance at the op-amp's input node (here that works out to 7.5 nV/$\sqrt{\text{Hz}}$), and also that it be significantly less than the e_n of Q_2 multiplied by the ratio of the full input capacitance to the capacitance at the op-amp's input node (which usually works out to an even larger value of maximum e_n). In other words, we could have chosen an op-amp not intended for low-noise applications from the tables in Chapter *4x*.

[111] For a great read, see Phil Hobbs' book *Building Electro-Optical Systems, Making It All Work*, 2nd ed., Wiley (2009); a fine collection of tricks for designing cascode photodiode amplifiers, including series-peaking inductors and T-coils to extend the bandwidth, noise cancellers, and more.

[112] We usually add an emitter follower running at a few milliamps to further stiffen the guard signal, especially if it may be driving the external shield of a coax line where it is susceptible to pickup of AM radio stations, etc.; see Figure *4x.19*.

[113] The 2SC4082 has $r_{bb'}C_c$=6 ps, which (with C_{ob}=0.9 pF) implies an $r_{bb'}$ less than 10 Ω.

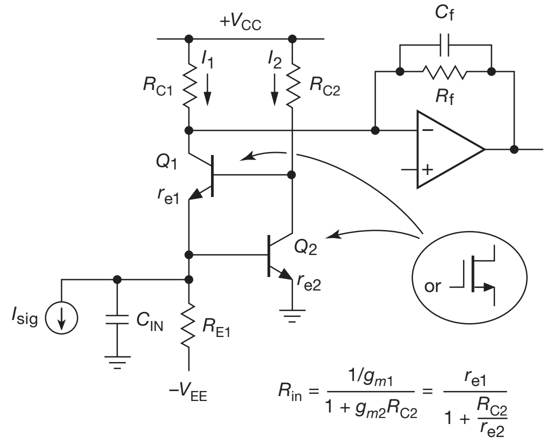

Figure 8.88. A "regulated cascode" input stage to transimpedance amplifier U_1 allows capacitance-isolating cascode Q_1 to operate at low current without a corresponding e_n penalty. It also reduces the impedance seen at the capacitive input (by a factor of G_{V2}), for enhanced bandwidth.

(via e_nC). We struggled with this, and the stability issues it presents, first by adding enough feedback compensation to ensure stability, then piling on op-amp speed to recover some bandwidth. Then we fiddled with circuit configurations to address directly the problem of input capacitance: first we bootstrapped the low side of the photodetector to *reduce* the effective input capacitance; then we added a cascode input stage to *isolate* the input capacitance, but that raised the circuit's input impedance (sacrificing bandwidth); so we biased the cascode to reduce R_{in}; and finally we bootstrapped the biased cascode.

All well enough. But the result was an input stage that had to run at significant collector current, generating a difficult-to-tame dc offset that seriously limits the amount of gain in the transimpedance stage. This is not a good situation, particularly if you want to sense small input currents.

The regulated cascode elegantly addresses these problems, by allowing the cascode stage (Q_1) to run at low current (so the circuit works well with small-signal currents), while circumventing the bandwidth and noise penalties (by driving down R_{in}, and by allowing Q_2 to replace Q_1's voltage noise). To minimize input *current* noise you should operate Q_1 at low collector current, but make sure you don't reduce the bandwidth excessively;[114] see the discussion in the "BJT bandwidth and f_T" section of Chapter *2x*. A variation of this configuration, in integrated form, is used in most contemporary fiber-optic receivers.[115]

8.11.11 Transimpedance amplifiers with capacitive feedback

There is a way to eliminate completely the Johnson-noise contribution of the gain-setting feedback resistor R_f, namely to eliminate the resistor itself. Feedback is then provided by the capacitor C_f alone, forming an integrator. The output signal must be differentiated to recover an output proportional to the input signal current; and of course both the integrator and differentiator must be reset (interrupting its operation) often enough to prevent saturation. To preserve the low noise of the input stage, the voltage noise of the differentiator op-amp must be significantly less than that of the input (integrating) op-amp.

Although capacitance feedback may seem an unusual approach, in fact, for ordinary TIAs operating at modestly high frequencies with high-value feedback resistors (say 100 MΩ and above), the self-capacitance of the resistor conceptually turns the amplifier into an integrator, with the resistor playing something akin to a reset role. Once one starts thinking along these lines, the idea of deliberately raising the feedback capacitance to ∼1 pF is no longer so scary. See §*4x.8* for an example circuit and discussion.

This technique is often used in "patch-clamp" amplifiers[116] and other low-level current detectors, for example, chilled germanium or silicon x-ray detectors (called IGX and Si(Li) respectively), in which the integrator is reset by an optical pulse from an LED (thus avoiding switch leakage effects).

A more common application of such an integrating transimpedance amplifier is for the readout of an imaging detector, where the quantity of interest is the total charge delivered during the brief readout, rather than its current-versus-time waveform. For this application you need to know only the *change* in integrator output voltage caused

[114] The worry, of course, is that Q_1 will have poor f_T at low collector current. But these designers know how to make impressively good microwave transistors in their ICs.

[115] See, for example, E. Säckinger and W. Guggenbühl, "A high-swing, high-impedance MOS cascode circuit," *IEEE J. Solid-State Circuits* **25**, 1 (1990); S. M. Park, "1.25-Gb/s regulated cascode CMOS transimpedance amplifier for gigabit ethernet applications," *IEEE J. Solid-State Circuits* **39**, 1 (2004); or Z. Lu et al., "Broad-band design techniques for transimpedance amplifiers," *IEEE Trans. Circuits Sys.* **54**, 3 (2007).

[116] For example, the Axon 200B patch-clamp amplifier is claimed to achieve an open-input noise current of just $0.2\,\mathrm{fA}/\sqrt{\mathrm{Hz}}$ at 150 Hz when operated in capacitance-feedback mode and thermoelectrically cooled; that's equivalent to the shot noise of 0.1 pA of leakage current.

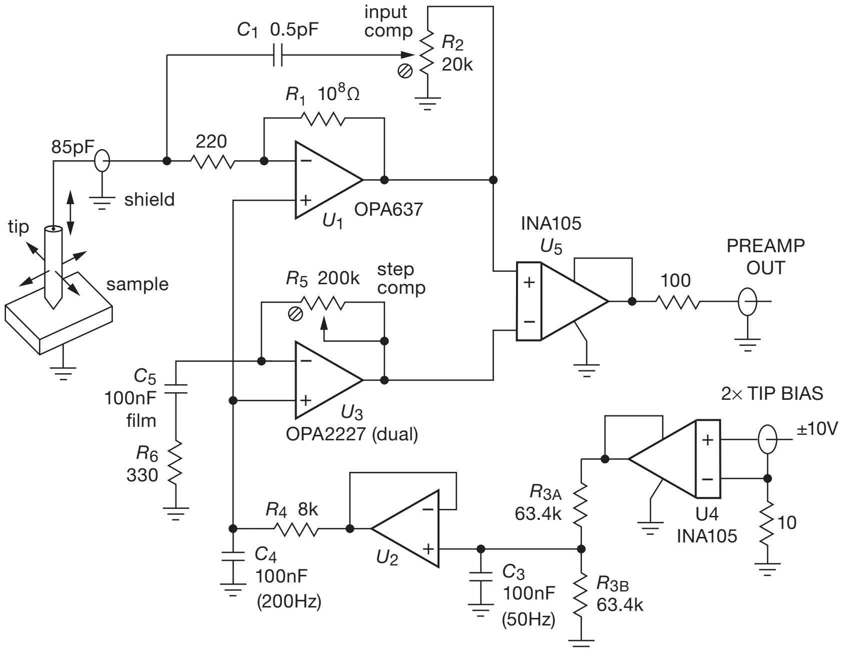

Figure 8.89. A low-noise transimpedance preamp for a scanning tunneling microscope (STM), where tip current signals are in the nanoamp range. The tip-to-sample voltage is set by the "tip-bias" input; the frequency response goes to ∼10 kHz, and the gain is 0.1 V/nA. Trimmer R_2 adjusts the effective feedback capacitance, to compensate the 100 pF (or more) of capacitance seen at the shielded input line emerging from the cryogenic vacuum chamber.

by the charge delivery. This technique is known as "correlated double-sampling," and dates back to the 1950s; see the footnote on page 571.

8.11.12 Scanning tunneling microscope preamplifier

Scanning tunneling microscopy (STM), dating to Binnig and Rohrer's work in the early 1980s,[117] allows one to image the surface topography (and other properties) of a sample at the atomic level. Figure 8.89 shows a sharp metallic tip hovering above a sample in a vacuum chamber, connected to a current-measuring preamp. When the tip is close to the surface (∼1 nm, about ten atom diameters) and biased to ∼1 V, a current of order 1 nA flows via quantum-mechanical "tunneling" through the potential barrier. The current is very sensitive to tip-to-sample spacing, varying exponentially such that the current typically increases by an order of magnitude when the spacing is reduced by 0.1 nm.[118]

To form a topographic image, the tip is held at a fixed voltage and scanned across the sample, with its spacing controlled by a piezo actuator such that the measured tip current is held constant. The piezo drive voltage is then a measure of variations in the surface height, with a vertical resolution better than an atomic diameter. If the tip's point is made sufficiently small (no more than a few atoms wide), the horizontal resolution is likewise of atomic scale. Figure 8.90 shows an example, an STM image of a silicon surface.

The STM preamp is a transimpedance amplifier, usually mounted at a flange on the vacuum chamber, where it receives the tip's tunnel current signal through a length of shielded line. That adds input capacitance, typically in the range of 50–200 pF. Because the preamp is within the tip spacing servo loop, it needs plenty of bandwidth, say 20 kHz, to permit rapid scanning, thus requiring careful loop compensation (see §*4x.3*). The preamp also needs to apply the tip-bias voltage.

In Figure 8.89 the transimpedance stage U_1 is an OPA637, an 80 MHz (decompensated) JFET op-amp with 16 pF of input capacitance and $4.5\,\text{nV}/\sqrt{\text{Hz}}$ input voltage noise (see Table 8.2 on page 516). That's rather a lot of

[117] See for example their article "Scanning tunneling microscopy," *Helvetica Physica Acta* **55**, 726–735 (1982).

[118] See for example J. A. Golovchenko, "The tunneling microscope: a new look at the atomic world," *Science* **232**, 48–53 (1986).

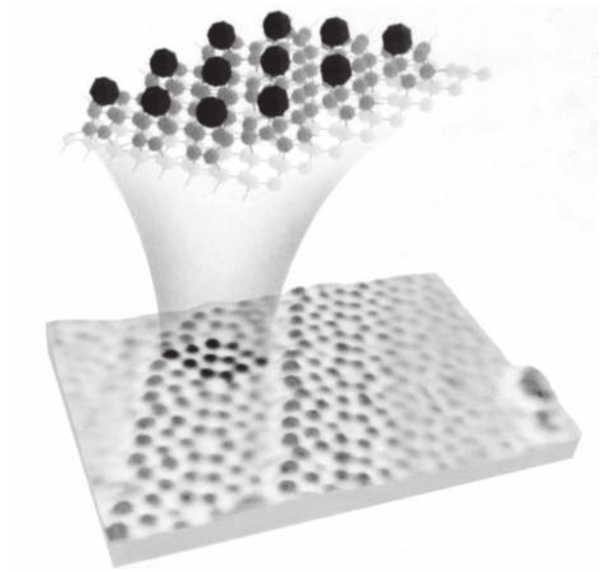

Figure 8.90. Structure of a 10×10 nm square region of a silicon crystal surface, imaged at the atomic level by an STM. The graphic model (expanded above) elucidates the observed surface structure (known as a *reconstruction*, because the surface atoms adopt a different arrangement compared with the bulk; here several atomic planes are seen, in a characteristic "7×7" reconstruction). This first image of an atomic step is adapted from the cover illustration accompanying the article referenced in Footnote 118 on page 553. (Courtesy J. Golovchenko)

input capacitance, but here it's insignificant compared with the cable capacitance, and in exchange we get a quiet wideband amplifier with low input current. Tip bias is set by the dc voltage at U_1's noninverting input; the op-amp's output is offset by the bias voltage, which we remove with difference amplifier U_5 (see §5.14 and Table 5.7).[119]

Exercise 8.5. Calculate the preamp's bandwidth for C_1=0.1 pF with C_{in}=100 pF, and also calculate the maximum allowed input capacitance. Show your stability criteria. Make a graph of the total effective input-noise-current spectral density, with curves for several values of C_{in}, including the maximum value (don't forget R_1's Johnson noise). Calculate the corresponding f_x breakpoint frequencies.

This exercise demonstrates that e_nC_{in} noise is a serious limitation in overall speed and performance. Note that it's not just the op-amp's e_n that matters here – it's combined with noise in the bias voltage applied to U_1's noninverting input. To keep the bias voltage quiet, we use a difference amplifier U_4 to isolate ground path noise in its computer-controlled DAC, and we add a pair of *RC* lowpass filters in the bias path through U_2; the filter at U_2's output is needed because otherwise the voltage noise from U_2 would make a significant contribution to that of U_1, as the next exercise demonstrates. Op-amp U_3 buffers the bias voltage into the 25k input impedance of U_5.

Exercise 8.6. Calculate and draw a graph of the allowed spectral noise for U_2 and for the computer's bias-voltage DAC signal (input to U_4), assuming that the noise voltage of the final bias applied to U_1's noninverting input is no more than 30% of that contributed by U_1 itself.

If the STM tip scanning is momentarily stopped, the bias voltage can be changed in a ramp or a series of steps, creating an *I–V* scan that can be used to determine additional information about the atom immediately under the tip. One approach is to repeatedly stop and make *I–V* scans. In this way the STM can provide not only an elevation map of the surface, but also a map of elemental composition. But changing the tip-bias voltage causes a pulse of current i=$C_{\text{in}}\,dV/dt$ that is seen and amplified by the TIA op-amp U_1. A nice way to deal with this effect is to add R_5 and C_5 such that R_5C_5=R_1C_{in}. This creates a cancelling pulse at the inverting input of U_5, allowing an accurate tunneling current to be measured before the voltage has completely settled. This greatly speeds up the full *I–V* scan.

This kind of circuitry is useful in other current-input applications, such as patch-clamp amplifiers in neurophysiology. It's basically a form of source-measure unit (SMU), a handy device we used to make the JFET transconductance measurements in §*3x.2* and the BJT beta plots in Figure 8.39.

8.11.13 Test fixture for compensation and calibration

To adjust the input compensation (R_2 in Figures 8.80, 8.89 and *4x.17*) you'd like a clean source of nanoamp-scale square waves supplying a calibrated current at the input connector; with the input cable in place you'd then adjust R_2 for best step response. You might imagine rigging up a 1 V square wave in series with a 1 GΩ resistor. The problem is that the resistor's parasitic shunt capacitance of ~0.1 pF causes input current spikes at each transition of

[119] A higher-gain difference-amplifier could be used for U_5 (e.g., an INA106 with G=10), as long as the tunneling currents are no more than a few nanoamps. STM preamps are often operated at very low current levels, with R_1=10^9 Ω. The summing-junction node connections (both sides of the 220 Ω resistor, along with the op-amp's inverting input) are often placed on Teflon standoffs to prevent PCB leakage currents.

the square wave; it takes only 0.01 V/μs of input slewing to produce 1 nA current pulses.

Figure 8.91 shows two solutions to this problem. In circuit A a tunable input series *RC* (lowpass, or "pole") compensates the current-scaling resistor R_2's parallel parasitic capacitance C_p (highpass, or "zero"). For this simple model of parasitic capacitance, cancellation requires $R_1C_1{=}R_2C_\mathrm{p}$. The optional isolated input connector suppresses ground path current spikes between the signal generator and the preamp and oscilloscope. Circuit B takes a different approach, using a small series capacitor (into the summing junction at the output) as a differentiator; $i{=}C_2dV_\mathrm{in}/dt$ predicts a ±1 nA output square wave for a 0.5 Vpp input triangle wave at 1 kHz. This circuit is the simpler, but its performance depends sensitively on the quality of the triangle wave at its turning points; we've gotten good results from Agilent 33120A (and later models) synthesized function generators. Your mileage may vary.

8.11.14 A final remark

We remind the reader that we've loosely referred to transimpedance amplifiers as "photodiode amplifiers"; that is, of course, just one application (though an important one) among many.

Our treatment in this chapter is concerned primarily with noise in transimpedance amplifiers, assuming familiarity with the basics. Be sure to visit §*4x.3* for an introduction to transimpedance amplifiers, a treatment of stability and bandwidth, and a healthy collection of important and useful tricks.

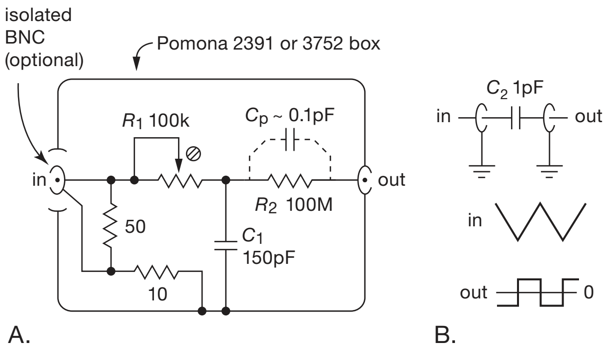

Figure 8.91. Test fixture for producing a nanoamp square-wave input for compensating and calibrating a transimpedance amplifier. A. Adjustable R_1C_1 (a "pole") cancels the peaking caused by R_2's shunt capacitance (a "zero"), so that a 0.1 V square wave creates a clean 1 nA output square wave of current into a summing junction. B. Capacitive differentiator converts a 500 mV (peak-to-peak) 1 kHz triangle voltage wave into a ±1 nA square current wave at the output summing junction.

8.12 Noise measurements and noise sources

It is a relatively straightforward process to determine the equivalent noise voltage and current of an amplifier, and from these the noise figure and signal-to-noise ratio for any given signal source. That's all you ever need to know about the noise performance of an amplifier. Basically the process consists of putting known noise signals across the input, then measuring the output-noise signal amplitudes within a certain bandwidth. In some cases (e.g., a matched input-impedance device such as a radiofrequency amplifier) an oscillator of accurately known and controllable amplitude is substituted as the input signal source.

Later we discuss the techniques you need to do the output voltage measurement and bandwidth limiting. For now, let's assume you can make rms measurements of the output signal with a measurement bandwidth of your choice.

8.12.1 Measurement without a noise source

For an amplifier stage made from an FET or transistor and intended for use at low to moderate frequencies, the input impedance is likely to be very high. You want to know e_n and i_n so that you can predict the SNR with a signal source of arbitrary source impedance and signal level, as we discussed earlier. The procedure is simple.

First, determine the amplifier's voltage gain G_V by actual measurement with a signal in the frequency range of interest. The amplitude should be large enough to override amplifier noise, but not so large as to cause amplifier saturation.

Second, short the input and measure the rms noise output voltage, e_s. From this you get the input noise voltage per root hertz from

$$e_\mathrm{n} = \frac{e_\mathrm{s}}{G_\mathrm{V}B^{\frac{1}{2}}} \quad \mathrm{V/Hz}^{\frac{1}{2}} \tag{8.47}$$

where B is the bandwidth of the measurement (see §8.13).

Third, put a resistor R across the input and measure the new rms noise output voltage, e_r. The resistor value should be large enough to add significant amounts of current noise, but not so large that the input impedance of the amplifier begins to dominate. (If this is impractical, you can leave the input open and use the amplifier's input impedance as R.) The output you measure is just

$$e_\mathrm{r}^2 = [e_\mathrm{n}^2 + 4kTR + (i_\mathrm{n}R)^2]BG_\mathrm{V}^2, \tag{8.48}$$

from which you can determine i_n to be

$$i_\mathrm{n} = \frac{1}{R}\left[\frac{e_\mathrm{r}^2}{BG_\mathrm{V}^2} - (e_\mathrm{n}^2 + 4kTR)\right]^{\frac{1}{2}}. \qquad (8.49)$$

With some luck, only the first term in the square root will matter (i.e., if current noise dominates both amplifier voltage noise and source resistor Johnson noise).

Now you can determine the SNR for a signal V_s of source impedance R_s, namely,

$$\begin{aligned}\mathrm{SNR(dB)} &= 10\log_{10}\left(\frac{V_\mathrm{s}^2}{v_\mathrm{n}^2}\right)\\ &= 10\log_{10}\left[\frac{V_\mathrm{s}^2}{[e_\mathrm{n}^2 + (i_\mathrm{n}R_\mathrm{s})^2 + 4kTR_\mathrm{s}]B}\right], \qquad (8.50)\end{aligned}$$

where the numerator is the signal voltage (presumed to lie within the bandwidth B) and the terms in the denominator are the amplifier noise voltage, amplifier noise current applied to R_s, and Johnson noise in R_s. Note that increasing the amplifier bandwidth beyond what is necessary to pass the signal V_s only decreases the final SNR. However, if V_s is broadband (e.g., a noise signal itself), the final SNR is independent of amplifier bandwidth. In many cases the noise will be dominated by one of the terms in the preceding equation.

8.12.2 An example: transistor-noise test circuit

For the measured noise data in Table 8.1a we used the circuit in Figure 8.92. It's basically an elaboration of the simple single-ended grounded-emitter amplifier of Figure 8.42, with provision for gain calibration, and sockets and test points for component substitution. The single-ended configuration requires a large input blocking capacitor. Follower Q_2 biases the device under test (DUT) to the nominal quiescent voltage point by way of R_8, with choice of R_C setting the quiescent current. Optional resistor R_B permits measurement of both β and i_n. The unusually long *RC* time constants throughout (capacitance multiplier, input and output blocking networks) are needed to suppress excess low frequency noise; the circuit takes many seconds to settle.

This circuit could be improved in several ways (but it was not, owing to operator exhaustion).[120]

8.12.3 Measurement with a noise source

The preceding technique of measuring the noise performance of an amplifier has the advantage that you don't need an accurate and adjustable noise source, but it requires an accurate voltmeter and filter, and it assumes that you know the gain versus frequency of the amplifier, with the actual source resistance applied. An alternative method of noise measurement involves applying broadband noise signals of known amplitude to the amplifier's input and observing the relative increase of output noise voltage. Although this technique requires an accurately calibrated noise source, it makes no assumptions about the properties of the amplifier, because it measures the noise properties right at the point of interest, at the input.

Again, it is relatively straightforward to make the requisite measurements. You connect the noise generator to the amplifier's input, making sure that its source impedance R_g equals the source impedance of the signal you ultimately plan to use with the amplifier. You first note the amplifier's output rms noise voltage, with the noise-source attenuated to zero output signal. Then you increase the noise source rms amplitude V_g until the amplifier's output rises 3 dB (a factor of 1.414 in rms output voltage). The amplifier's input noise voltage in the measurement bandwidth, for this source impedance, equals this value of added signal. The amplifier therefore has a noise figure

$$\mathrm{NF(dB)} = 10\log_{10}\left(\frac{V_\mathrm{g}^2}{4kTR_\mathrm{g}}\right). \qquad (8.51)$$

From this you can figure out the SNR for a signal of any amplitude with this same source impedance, using eq'n 8.14:

$$\mathrm{SNR\,(dB)} = 10\log_{10}\left(\frac{V_\mathrm{s}^2}{4kTR_\mathrm{s}}\right) - \mathrm{NF}(R_\mathrm{s}). \qquad (8.52)$$

There are nice calibrated noise sources available, most

[120] Some details, for the curious: the circuit sets both I_C and V_CE for the DUT by means of a collector-to-base feedback loop. Lowpass filter R_5C_3 attenuates negative feedback that would unduly lower the transistor's common-emitter gain. The job of the large-value capacitor C_2 is to ground the base at all signal frequencies (as low as 4 Hz for our measurements) so we can measure $r_{\mathrm{bb}'}$ (from its Johnson noise), and also the noise voltage created across $r_{\mathrm{bb}'}$ by the low-frequency $1/f$ tail of base-current noise. But capacitor C_2, in combination with bias-setting pot R_8, adds a second lagging phase shift (a second pole) within the feedback loop, creating a low-frequency bias instability; confusingly, this mimics $1/f$ noise in the DUT at the low end of the spectrum. We could address this by introducing a compensating zero (e.g., a small resistor in series with C_3), but we were reluctant to tamper further with the circuit. The dominant pole is R_8C_2, and for low-frequency noise measurements down in the sub-nV/$\sqrt{\mathrm{Hz}}$ territory we found ourselves increasing C_2, to 0.15 F and even 0.35 F (!), and waiting for the modest instabilities to settle. This defeated our original goal, which was to avoid the large emitter bypass capacitors normally used with other non-feedback bias configurations – but, whatever, we were able to get reliable noise data for the plots and tables. The reader is welcome to experiment further.

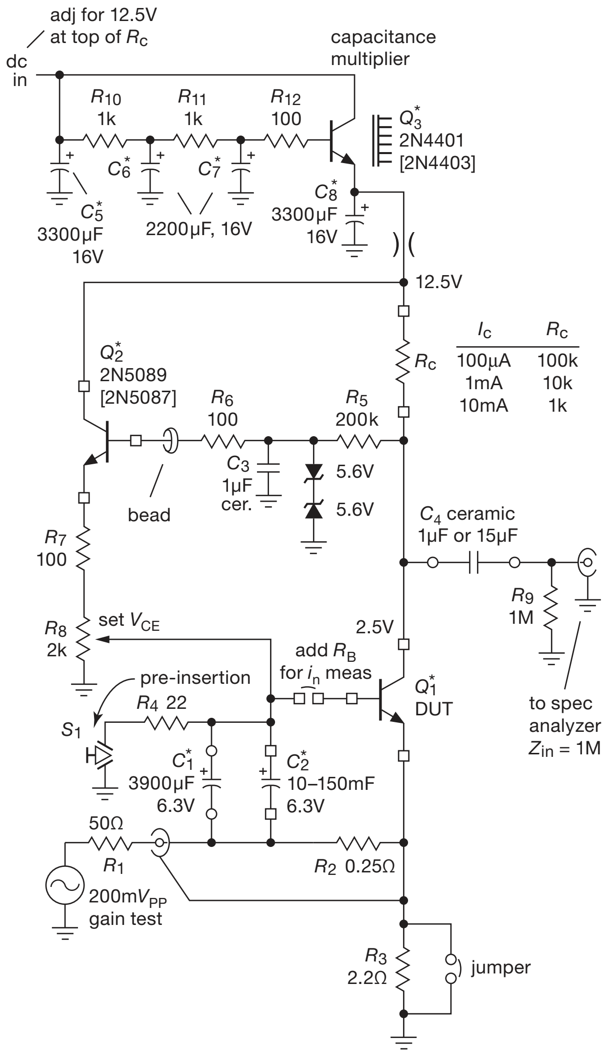

Figure 8.92. Transistor noise test circuit. Q_3 and associated components form a noise-eliminating capacitance multiplier. Polarities shown are for an *npn* device under test (DUT); for *pnp* reverse the polarity of components marked with asterisks. The gain-calibrating input signal is replaced by a 0 Ω shorting plug during noise measurement.

of which provide means for attenuation to precise levels in the microvolt range. Note: once again, the preceding formulas assume $R_{in} \gg R_s$. If, on the other hand, the noise-figure measurement is made with a *matched* signal source, i.e., if $R_s = Z_{in}$, then omit the factors "4" in the preceding expressions.

Note that this technique does not tell you e_n and i_n directly, just the appropriate combination for a source of impedance equal to the driving impedance you used in the measurement. Of course, by making several such measurements with different noise source impedances, you could infer the values of e_n and i_n.

A nice variation on this technique is to use resistor Johnson noise as the "noise source." This is a favorite technique used by designers of very low noise radiofrequency amplifiers (in which, incidentally, the signal source impedance is usually 50 Ω and matches the amplifier's input impedance). It is usually done the following way: a dewar of liquid nitrogen holds a 50 Ω "termination" (a fancy name for a well-designed resistor that has negligible inductance or capacitance) at the temperature of boiling nitrogen, 77°K; a second 50 Ω termination is kept at room temperature. The amplifier's input is connected alternately to the two resistors (usually with a high-quality coax relay), and the output noise power (at some center frequency, with some measurement bandwidth) is measured with an RF power meter. Call the results of the two measurements P_C and P_H, the output noise power corresponding to cold and hot source resistors, respectively. It is then easy to show that the amplifier's noise temperature, at the frequency of the measurement, is just

$$T_n = \frac{T_H - YT_C}{Y-1} \quad \text{Kelvin}, \qquad (8.53)$$

where $Y = P_H/P_C$, the ratio of noise powers. The noise figure is then given by eq'n 8.16, namely,

$$\text{NF(dB)} = 10\log_{10}\left(\frac{T_n}{290}+1\right). \qquad (8.54)$$

Exercise 8.7. Derive the foregoing expression for noise temperature. *Hint*: begin by noting that $P_H = \alpha(T_n + T_H)$ and $P_C = \alpha(T_n + T_C)$, where α is a constant that will shortly disappear. Then note that the noise contribution of the amplifier, stated as a noise temperature, *adds* to the noise temperature of the source resistor. Take it from there.

Exercise 8.8. Amplifier noise temperature (or noise figure) depends on the value of signal source impedance, R_s. Show that an amplifier characterized by e_n and i_n (as in Figure 8.28) has minimum noise temperature for a source impedance $R_s = e_n/i_n$. Then show that the noise temperature, for that value of R_s, is given by $T_n = e_n i_n/2k$.

If you don't want to bother with liquid nitrogen and are interested only in relatively low-frequency amplifiers, you can exploit the curious fact that a BJT's input noise voltage (at low currents, where $r_{bb'}$ effects are insignificant) is equal to the Johnson noise of a real resistor of value $r_e/2$. For example, if you ground the base, tie the collector to +5 V, and pull down the emitter through 10k to −5 V, you'll see at the emitter a noise signal with 50 Ω source impedance and 150K noise temperature. Add a blocking capacitor, and alternate this noise source with a real 50 Ω resistor (use a coax relay, not a CMOS switch!), and you've got a simple (and seriously inexpensive!) two-temperature noise calibrator.[121]

A. Amplifiers with matched input impedance

This last technique is ideal for noise measurements of amplifiers designed for a matched signal-source impedance. The most common examples are in radiofrequency amplifiers or receivers, usually meant to be driven with a signal source impedance of 50 Ω, and that themselves have an input impedance of 50 Ω. See Appendix H for an explanation of this departure from our usual criterion that a signal source should have a small source impedance compared with the load it drives. In this situation, e_n and i_n are irrelevant as separate quantities; what matters is the overall noise figure (with matched source) or some specification of SNR with a matched signal source of specified amplitude.

Sometimes the noise performance is explicitly stated in terms of the *narrowband* input signal amplitude required for obtaining a certain output SNR. A typical radiofrequency receiver might specify a 10 dB SNR with a 0.25 μV rms input signal and 2 kHz receiver bandwidth. In this case the procedure consists of measuring the rms receiver output with the input driven by a matched sinewave source initially attenuated to zero, then increasing the (sinewave) input signal until the rms output rises 10 dB, in both cases with the receiver bandwidth set to 2 kHz. It is important to use a meter that reads true rms voltages for a measurement where noise and signal are combined (more about this later). Note that radiofrequency noise measurements often involve output signals that are in the audiofrequency range.

8.12.4 Noise and signal sources

Broadband noise can be generated from the effects we discussed earlier, namely Johnson noise and shot noise. The shot noise in a vacuum diode is a classic source of broadband noise that is especially useful because the noise voltage can be predicted exactly; zener diode noise is also widely used in noise sources, as are gas discharge tubes. These extend from dc to very high frequencies, making them useful in audiofrequency and radiofrequency measurements. Look ahead to Figure 13.121 for an example of a "true random" noise generator.

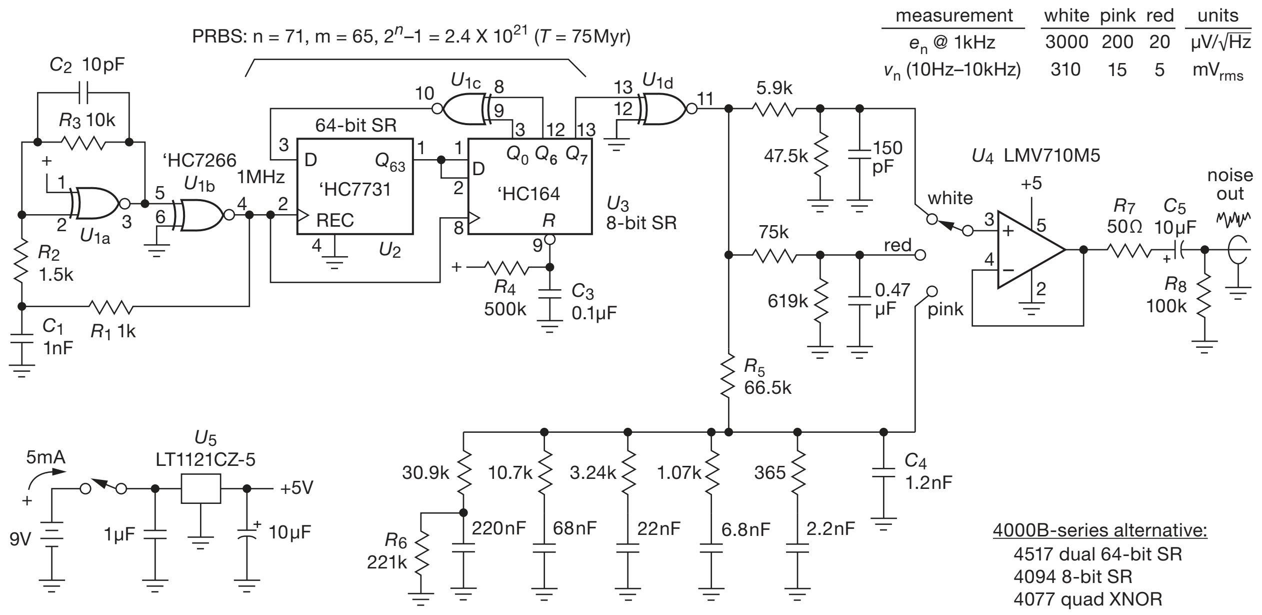
Versatile signal sources are available with precisely controlled output amplitude (down to the microvolt range and below) over frequencies from a fraction of a hertz to many gigahertz, programmable via GPIB, USB, or LAN. An example is the Agilent model E8257D synthesized signal generator, with output frequencies from 0.25 MHz to 20 GHz, calibrated amplitudes from 40 nV to 1 V rms, modulation and frequency sweeping modes, handsome digital display and bus interface, and nifty accessories that extend the frequency range to 500 GHz. This is a bit more than you usually need to do the job. And at +45 dB$ it likely costs a bit more than you're interested in paying. For a tenth the price (and a hundredth the bandwidth) you can get one of Tektronix's "Arbitrary Function Generators," for example the 2-channel AFG3102C (about $6k), which provide a Gaussian noise output in addition to standard waveforms (sine, square, pulse, triangle, etc.) and arbitrary (programmed) waveforms. And if it's only a *noise* waveform you want, you can get broadband noise sources like the Noisecom NC346 (10 MHz–18 GHz).

Some versatile noise sources can generate pink noise as well as white noise. Pink noise has equal noise power per *octave*, rather than equal power per hertz. Its power density (power per hertz) drops off at 3 dB/octave (though to the ear it sounds more like spectrally flat random noise than does white noise). It is widely used as a source signal for audio systems; in a typical application you would equalize a speaker system, driven with a pink noise source, by taking measurements with a handheld real-time spectrum analyzer (e.g., the Smaart® acoustic software tools). Because an *RC* filter's attenuation falls at 6 dB/octave, a more complicated filter is necessary to generate a pink spectrum from a white-noise input. Read the next subsection to see how this is done.

A. Pseudorandom noise source

We can make an interesting noise source by using digital techniques, in particular by connecting long shift registers with their input derived from a modulo-2 addition of several of the later bits (see §§11.3.1 and 13.14). The resultant output is a pseudorandom sequence of 1s and 0s that, after lowpass filtering, generates an analog signal of white spectrum up to the lowpass filter's breakpoint, which must be well below the frequency at which the register is shifted. These things can be run at very high frequencies, generating noise up to many megahertz or more. The "noise" has the interesting property that it repeats itself exactly after a time interval that depends on the register length (an n-bit maximal-length register goes through $2^n - 1$ states before repeating). Without much difficulty, that time can be made to be very long (years, or millennia), although most often a period of a second is long enough. For example, a 50-bit

[121] We learned this trick from Phil Hobbs, who suggests the use of a diode like an MBD301 (which doesn't suffer from high-level injection at 500 μA) instead of a BJT.



measurement	white	pink	red	units
e_n @ 1kHz	3000	200	20	μV/√Hz
v_n (10Hz–10kHz)	310	15	5	mV$_{rms}$

Figure 8.93. Pseudorandom noise source providing three colors of analog noise from 10 Hz to 100 kHz, with measured values of output noise density (at 1 kHz) and band-limited noise voltage (4-pole Butterworth, 10 Hz–10 kHz).

register shifted at 10 MHz will generate white noise up to 1 MHz or so, with a repeat time of 3.6 years.

The circuit shown in Figure 8.93 uses a 71-bit maximal-length shift register, clocked at 1 MHz, to generate a digital pseudorandom waveform that is spectrally flat (±0.07 dB) out to 100 kHz. The pseudorandom bit sequence is ridiculously long – with a 1 MHz clock it repeats in about 75 million years. Creating either white or red noise is easy: the "white" selection simply filters the raw 2-level waveform through an *RC* lowpass at 200 kHz, above the band of interest, to suppress the (wideband) clocking edges. The "red" selection inserts instead a lowpass filter at 5 Hz, below the band of interest, so the output rolls off at the usual 6 dB/octave.

Pink noise is trickier; you need a filter that reduces the white-noise amplitude by a factor of $1/\sqrt{2}$ (rather than 1/2) for every doubling of frequency. The usual analog method is to use a parallel set of series *RC* sections (as in Figure 8.93), with the characteristic frequency of each successive section increasing by a fixed ratio (here ×10, i.e., one decade) with an impedance that decreases by the square root of that same ratio (here $\sqrt{10}$). Even with such generous decade spacing you do remarkably well, as seen in the SPICE results of Figure 8.94, where the deviation from ideal −3 dB/octave behavior is just ±0.25 dB over the 5-decade frequency range of 10 Hz to 1 MHz.[122]

Simulations are fun, but the "rubber hits the road" when you actually build something and measure its performance. We did that, and Figure 8.95 shows the measured spectra of the circuit of Figure 8.93, which, to within the thickness of the (wiggly) lines, performs as advertised.

A few notes on the circuit

We cannot resist a few comments on the circuit design. As always, there are several choices at each step: a good design balances issues of performance, cost, complexity, availability of components, power, reliability, and (dare we say it?) *elegance*. For example, the ∼1 MHz clocking signal could be supplied from a $2 crystal-oscillator module; but for this application it needn't be accurate or stable, and so we chose to use two unused sections of the quad XNOR to make a simple *RC* relaxation oscillator. (We haven't seen this particular implementation used elsewhere, but it is completely straightforward: it is the topology of Figure 7.5, with U_{1a} configured as a noninverting Schmitt buffer, followed by the U_{1b} inverter. The hysteresis is set by R_2R_3, to 0.65 V, with small speed-up capacitor C_2. The frequency is set by R_1C_1.)

[122] A bit of candor here: to achieve this performance we did a bit of fine tuning to arrive at the circuit's choice of 1% resistor values.

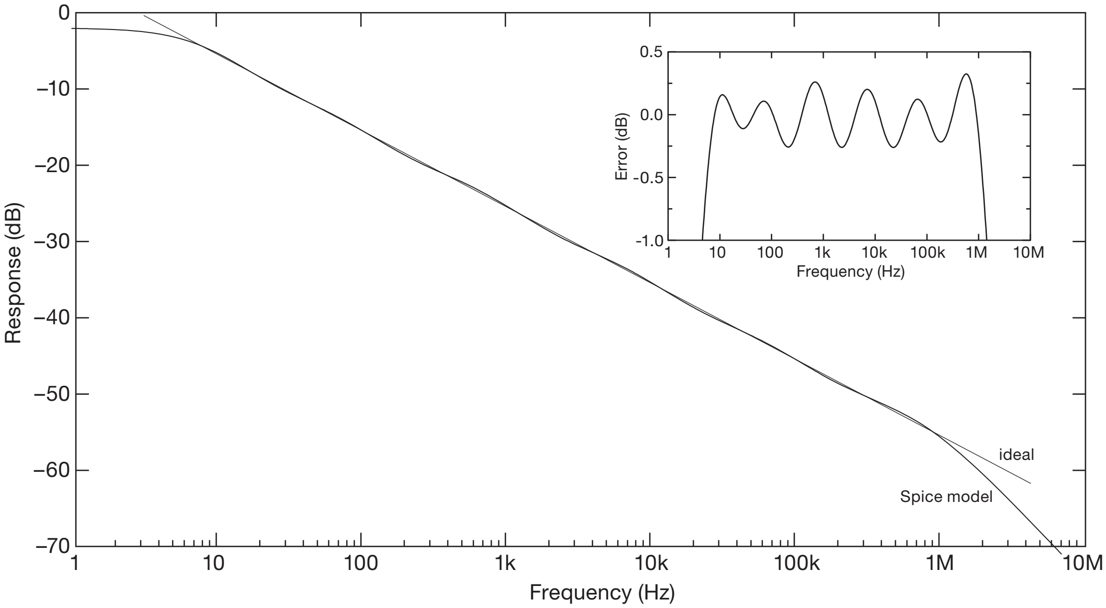


Figure 8.94. Simulation in SPICE of the pink-noise filter (R_5 and components below) in Figure 8.93.

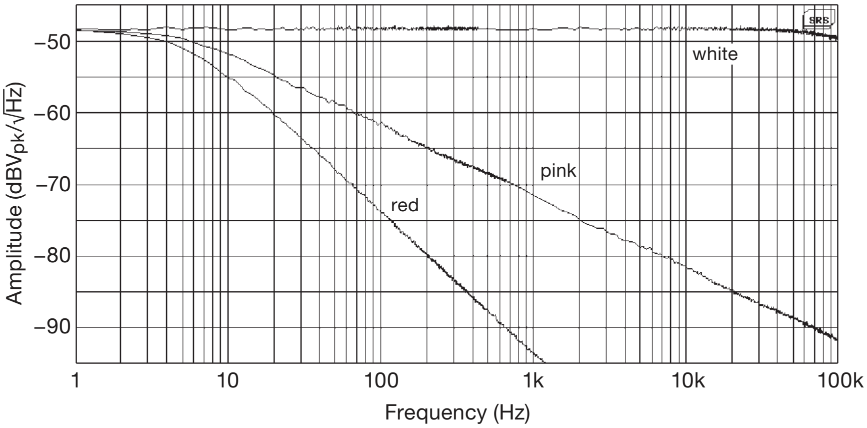

Figure 8.95. Measured spectra of the circuit of Figure 8.93. Each plotted spectrum is made from two 800-point FFT spectra to span the full 100,000:1 frequency range. The measured total noise voltage v_n and noise densities e_n are listed in Figure 8.93.

We chose the 74HC logic family because parts are readily available, easy to prototype (through-hole DIP), plenty fast, and of low power.[123] There are standard logic functions for what we needed, so we chose that path (rather than the alternatives: a cPLD, FPGA, or microcontroller). Available shift registers were either too small (8 stages), or outrageously large (the ’HC7731 we used is 256 stages, as four separate 64-stage shift-register banks). We went with the latter, using only one bank, and appending a ’HC164 8-stage parallel-out shift register so we could get at the needed taps (here m=65 and n=71; see Table 13.14). Note the use of exclusive-NOR (rather than exclusive-OR), to prevent the stuck state of all zeros and thus guarantee startup.

The output buffer is a nice BiCMOS rail-to-rail input/

[123] We could have used instead the “high-voltage” 4000B CMOS parts listed on the diagram, running directly from the 9 V battery. But there would be tradeoffs. (a) We would want to clamp the output to a stable amplitude, requiring some extra components; and (b) we would be clocking at a frequency uncomfortably close to the specified upper limit at low battery, foreclosing on any flexibility for going to a faster clock, say 10 MHz.

output op-amp, with 5 MHz GBW, low input current (4 pA, typ), plenty of output drive capability (±20 mA), and modest power consumption (1.2 mA); it's noisy ($20\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$, with a high $1/f$ corner frequency), but that hardly matters when you're amplifying noise anyway. The series resistor R_7 ensures stability into capacitive loads and (if you care) provides source termination into 50 Ω cable.

For the 5 V regulator (U_5) we initially reached for something from the legacy LP2950 or LM2931 series of low-dropout linear regulators. But the LP2950 is intolerant of reversed input polarity (a feat easy enough to accomplish when replacing a 9 V battery); and both regulators are somewhat fussy when it comes to the output capacitor. In particular, they require some minimum amount of equivalent series resistance (ESR),[124] which is worrisome – how is one expected to deal with the low-ESR ceramic bypass capacitors that litter the rest of the circuit? Happily, there are nice LDOs that do not burden the designer with such worries: the LT1121-5 we chose is stable with output capacitors of zero ESR, and it's tolerant of reverse input (to −30 V); it also has the usual overcurrent and overtemperature protection.

There's more extensive discussion of pseudorandom noise, along with another pseudorandom noise source design (Figure 13.119), in §13.14.

8.13 Bandwidth limiting and rms voltage measurement

8.13.1 Limiting the bandwidth

All the measurements we have been talking about assume that you are looking at the noise output only in a limited frequency band. In a few cases the amplifier may have provision for this, making your job easier. If not, you have to hang some sort of filter on the amplifier output before measuring the output noise voltage.

***RC* filter** The easiest thing to use is a simple *RC* lowpass (or bandpass) filter, with 3 dB point(s) set at roughly the bandwidth you want. For accurate noise measurements, you need to know the "equivalent noise bandwidth" (ENBW), i.e., the width of a perfect "brick-wall" filter that lets through the same noise voltage (Figure 8.96). This noise bandwidth is what should be used for *B* in all the preceding formulas. It is not terribly difficult to do the mathematics, and you find, for an *RC* lowpass filter,

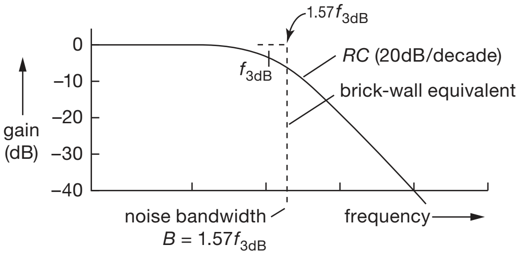

Figure 8.96. Equivalent brick-wall noise bandwidth for *RC* lowpass filter.

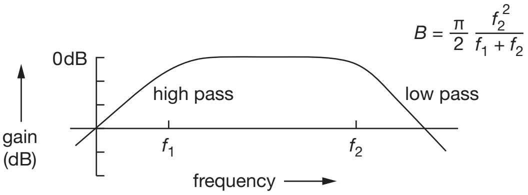

Figure 8.97. Equivalent brick-wall noise bandwidth for *RC* bandpass filter. For the case $f_1 = f_2$ the midband gain is −6 dB.

$$B = \frac{\pi}{2} f_{3\mathrm{dB}} = 1.57 f_{3\mathrm{dB}}. \tag{8.55}$$

For a pair of cascaded lowpass *RC* sections (buffered so they don't load each other), the magic formula becomes $B = 1.22f_{3\mathrm{dB}}$. For the Butterworth lowpass filters discussed in §§6.2.6 and 6.3.2, the noise bandwidth is

$$\begin{aligned} B &= 1.57f_{3\mathrm{dB}} = \tfrac{1}{4RC} && \text{(1 pole)},\\ B &= 1.11f_{3\mathrm{dB}} \approx \tfrac{1}{5.6RC} && \text{(2 poles)},\\ B &= 1.05f_{3\mathrm{dB}} \approx \tfrac{1}{6RC} && \text{(3 poles)},\\ B &= 1.025f_{3\mathrm{dB}} \approx \tfrac{1}{6.1RC} && \text{(4 poles)}. \end{aligned}$$

If you want to make band-limited measurements up at some center frequency, you can use a pair of *RC* filters (Figure 8.97), in which case the noise bandwidth is as indicated. You may wish to use higher-order Butterworth filters for more precise bandpass characteristics. In that case you'll need to know the corresponding equivalent noise bandwidths; don't panic – they're listed in Table 8.4 on page 564.

***RLC* filter** Another way to make a bandpass filter for noise measurements is to use an *RLC* circuit. This is

[124] From the LP2950 datasheet: "Ceramic capacitors whose value is greater than 1000 pF should not be connected directly from the LP2951 output to ground. Ceramic capacitors typically have ESR values in the range of 5 to 10 mΩ, a value below the lower limit for stable operation (see curve Output Capacitor ESR Range). The reason for the lower ESR limit is that the loop compensation of the part relies on the ESR of the output capacitor to provide the zero that gives added phase lead. The ESR of ceramic capacitors is so low that this phase lead does not occur, significantly reducing phase margin. A ceramic output capacitor can be used if a series resistance is added (recommended value of resistance about 0.1 Ω to 2 Ω)."

better than a pair of cascaded highpass and lowpass *RC* filters if you want your measurement over a bandpass that is narrow compared with the center frequency (i.e., high Q). Figure 8.98 shows both parallel and series *RLC* circuits and their exact noise bandwidths. In both cases the resonant frequency is given by $f_0 = 1/2\pi\sqrt{LC}$. You might arrange the bandpass filter circuit as a parallel *RLC* collector (or drain) load, in which case you use the expression as given. Alternatively (recall Figure 1.107), you might interpose the filter as shown in Figure 8.99; for noise-bandwidth purposes the circuit is exactly equivalent to the parallel *RLC*, with $R = R_1 \| R_2$.

Figure 8.98. Equivalent *brick-wall* noise bandwidth for *RLC* bandpass filter. For the parallel circuit (A) the source signal is a current, and the output is the voltage across the terminals; for the series configuration (B) the input is a voltage applied across the circuit, and the output is the resulting current.

Averaging As we mentioned in §8.1.5, another way to accomplish lowpass filtering of a slow signal (a dc voltage, say, in the presence of additive white noise) is simply to average it over some time interval T; this is the same averaging operation as is done by an integrating ADC (e.g., in a digital voltmeter, see §13.8.3). In that case the equivalent noise bandwidth[125] is $B{=}1/2T$. Thus, for example, an averaging duration of 1 second admits a noise bandwidth of 0.5 Hz. This is a simple lowpass "filter" – but one that is less sharp even than a single-section *RC* (the latter falls off at 6 dB/octave, compared with 3 dB/octave for the time average).

Figure 8.99. Interstage *RLC* bandpass filter.

Digital filter Digital signal processing (DSP) is an effective way to implement extremely well-defined filter functions, with their characteristics easily modified by changing the stored numerical coefficients. See §6.3.7 for more detail.

Frequency translation Imagine you want to make measurements of the "spot noise voltage" in some narrow bandwidth (say 10 Hz) centered at some relatively high frequency f_{in}, where the latter may be up at tens to hundreds of kilohertz, or perhaps even a megahertz or more. That is, the ratio $Q{=}f_{\text{in}}/\Delta f$ is very large, say greater than a thousand. Such a high-Q bandpass filter is pretty difficult to implement! But there's a good way to do the measurement without filter heroics.

The trick is to shift (translate) the frequency band of interest down to a much lower frequency, where it's easy to make a narrowband filter. The technique is called *heterodyning*, and it's a basic technique in most radiofrequency communications systems. It's easiest to understand if you think initially of a single input frequency. Figure 8.100 shows the basic scheme, in which an input signal voltage (at frequency f_{in}) is multiplied by a sinusoidal voltage (at frequency f_{LO}) from a *local oscillator* ("LO"), creating a pair of sinusoidal signals at frequencies $f_{\text{in}} \pm f_{\text{LO}}$.[126] The multiplier is called a *mixer*, and its output is filtered to eliminate one of the mixing products. Mixers can be in the form of an active circuit (a "4-quadrant multiplier"), or, for use at higher frequencies, a passive transformer-coupled diode arrangement called a *balanced mixer*.

In a communications application there may be several stages of frequency translation, passing through several intermediate-frequency ("IF") stages where amplification and filtering takes place.[127] For a simple noise-measuring

[125] It is important to distinguish the operation of an averaging time T when measuring a static signal, as just described, from the use of a time "window" (again of duration T) to bound the measurement interval of an ac signal. In the latter case the use of such a *rectangular window* imposes a resolution bandwidth $B{=}1/T$ (i.e., twice that of the dc measurement). In digital signal processing the business of windowing plays an important role; see for example Harris, F. J., "On the use of windows for harmonic analysis with the discrete Fourier transform," *Proc. IEEE* **66** 51–83 (1978). We'll see this same theme, in connection with *synchronous signal averaging*, in §8.14, where synchronous (or "lock-in") detection of signals over some time duration T produces the same bandwidth reduction: $B{=}1/T$.

[126] From the identity $\cos x \cos y{=}\frac{1}{2}\cos(x{+}y) + \frac{1}{2}\cos(x{-}y)$, with $x{=}2\pi f_{\text{in}}$ and $y{=}2\pi f_{\text{LO}}$.

[127] For example, in an FM radio the LO is set 10.7 MHz below the desired station, with the 10.7 MHz IF signal amplified and demodulated. Radiofrequency and communications techniques are discussed in greater detail in Chapter 13 of this book's second edition.

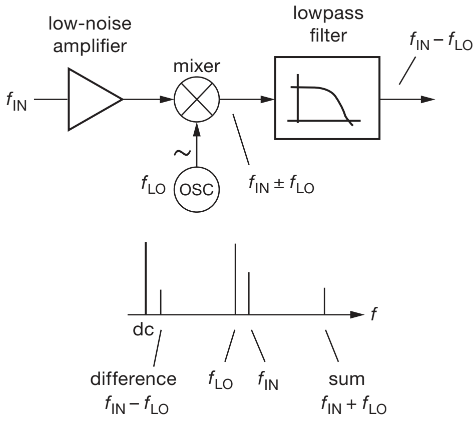

Figure 8.100. Heterodyne frequency shifting: the mixer produces sum and difference frequencies; only the latter survives the lowpass filter.

application it may be adequate to mix directly to "baseband," by tuning the LO to the frequency at which the spot noise voltage is to be measured. This is the same process used in *synchronous detection*, described later in §§8.14 and 13.13.6D. Commercial synchronous (lock-in) amplifiers let you make narrowband spot noise voltage measurements at any frequency in their range, extending to 100 kHz (for typical lock-in amplifiers) to as high as 200 MHz (e.g., for the SR844).

8.13.2 Calculating the integrated noise

Let's begin with the simple single-section *RC* lowpass band-limiting filter. From its equivalent brick-wall bandwidth (eq'n 8.55), the integrated noise-*voltage* output from filtering a white-noise input of noise *density* e_n is found by taking the square root of

$$v_\mathrm{n}^2 = e_\mathrm{n}^2 B = e_\mathrm{n}^2 \frac{\pi}{2} f_{3\mathrm{dB}} \quad \mathrm{V}^2(\mathrm{rms}) \tag{8.56}$$

and analogously for noise *current*.

Things get more complicated if the noise density e_n depends on frequency, as it does, for example, with $1/f$ ("pink") noise. In such a case you must integrate, over frequency, the squared noise density $e_\mathrm{n}^2(f)$ times the filter's spectral power bandpass characteristic. And it's common to use a *bandpass* filter, with both lower and upper frequency limits (call them f_1 and f_2). Then an ideal "brick-wall" (or should it be "squash court"?!) bandpass filter has unit response between f_1 and f_2, and a noise bandwidth of $B = f_2 - f_1$.

Brick walls are hard to implement in analog technology, and a simple expedient, as suggested earlier, is simply to use a cascaded pair of *RC*'s, with 3 dB frequencies of f_1 and f_2. With a bit of mathematical finesse you could demonstrate proficiency by performing the appropriate integrals, thus figuring the output noise voltage for the "standard noises" (white, or $1/f$, or even $1/f^2$). A shortcut is to exploit the brilliance of Wolfram's impressive *Mathematica* program. A colleague[128] did this for us, and Table 8.4 on the next page summarizes the results, for those three colors of noise, and for four styles of bandpass filters (brick-wall, simple *RC* (single-pole; that is, a pair of cascaded *RC* sections), 2-pole Butterworth, and *m*-pole Butterworth.

The expressions listed give you the integrated squared noise voltage v_n^2, for given lower and upper -3 dB frequency limits f_1 and f_2, and noise voltage density e_n (Figure 8.101); the rms noise voltage is then gotten by taking the square root: $V_{\mathrm{n(rms)}}=\sqrt{v_\mathrm{n}^2}$. For pink noise ($1/f$ in power) and red noise ($1/f^2$ in power) the noise density e_n is a function of frequency; for these expressions we have used for the overall multiplying factor the noise density at the high band end; that is, $e_\mathrm{n}^2(f_2)$ (abbreviated as e_{n2}^2 in the table), which is the squared noise density at $f=f_2$, in units of V^2/Hz.

Note that you can set f_1=0, in the expressions for white noise, to get the dc-to-f_2 (lowpass-limited) noise voltage. If you do so, you'll get the expressions shown on page 561. This does not work for pink or red noise, though, because the integral diverges at zero frequency, conveyed in these expressions by the embarrassment of a zero denominator in the log's argument (pink) or, worse, in the result itself (red). This is why $1/f$ noise is typically measured with a 0.1 Hz to 10 Hz limited bandwidth, etc.; see Figures 8.102 and 8.103.

Noise *current* is treated just the same: substitute everywhere the noise current density i_n in place of e_n, to find the integrated noise current $I_{\mathrm{n(rms)}}$.

A. The high end matters most

To calculate the integrated noise voltage over some bandpass, you need to integrate the noise power density (e_n^2) over frequency, taking account of the filter's passband response (call that $H(f) \equiv V_\mathrm{out}/V_\mathrm{in}$, and don't worry about phase); that is,

$$v_\mathrm{n}^2 = \int_{f_1}^{f_2} e_\mathrm{n}^2 H^2(f)\, df \quad \mathrm{V}^2(\mathrm{rms}); \tag{8.57}$$

and then you take the square root: $V_{\mathrm{n(rms)}} = \sqrt{v_\mathrm{n}^2}$.

So, looking at log–log plots of filter passbands like

[128] Jason Gallicchio, again!

Table 8.4 Noise Integrals[a]

	Noise Spectral Shape		
	white	pink	red
Filter Type	$(e_\mathrm{n} = \mathrm{const})$	$(e_\mathrm{n} \sim 1/\sqrt{f})$	$(e_\mathrm{n} \sim 1/f)$
brickwall	$e_\mathrm{n}^2\ (f_2 - f_1)$	$e_{n2}^2\ f_2 \log_e \dfrac{f_2}{f_1}$	$e_{n2}^2\ \dfrac{f_2}{f_1}(f_2 - f_1)$
1-pole (*RC*)	$e_\mathrm{n}^2\ \dfrac{\pi}{2}\ \dfrac{f_2^2}{f_1 + f_2}$	$e_{n2}^2\ \dfrac{f_2^3}{f_2^2 - f_1^2}\ \log_e \dfrac{f_2}{f_1}$	$e_{n2}^2\ \dfrac{\pi}{2}\ \dfrac{f_2^3}{f_1(f_1 + f_2)}$
2-pole Butterworth	$e_\mathrm{n}^2\ \dfrac{\pi}{2\sqrt{2}}\ \dfrac{f_2^4}{(f_1 + f_2)(f_1^2 + f_2^2)}$	$e_{n2}^2\ \dfrac{f_2^5}{f_2^4 - f_1^4}\ \log_e \dfrac{f_2}{f_1}$	$e_{n2}^2\ \dfrac{\pi}{2\sqrt{2}}\ \dfrac{f_2^5}{f_1(f_1 + f_2)(f_1^2 + f_2^2)}$
***m*-pole Butterworth**	$e_\mathrm{n}^2\ \dfrac{\pi/2m}{\sin(\pi/2m)}\ \dfrac{f_2 - f_1}{1 - (f_1/f_2)^{2m}}$	$e_{n2}^2\ \dfrac{f_2}{1 - (f_1/f_2)^{2m}}\ \log_e \dfrac{f_2}{f_1}$	$e_{n2}^2\ \dfrac{\pi/2m}{\sin(\pi/2m)}\ \dfrac{f_2 - f_1}{1 - (f_1/f_2)^{2m}}$

Notes: (a) Values of the mean-squared noise voltage, v_n^2, in a frequency band from f_1 to f_2, as bandpass limited by the indicated filter type. The noise voltage density e_n2 is the value of e_n at $f = f_2$.

those in Figure 8.101, you might at first think that a bandpass filter with symmetrical and sharp rolloffs at both low and high ends is needed. But – surprise – the v_n^2 integral weights the high end disproportionately, as you can see from Figure 8.102, where we've plotted the value $e_\mathrm{n}^2 H^2(f)$ for white noise (e_n=1) over a 100:1 bandpass, on *linear* frequency and amplitude scales (because that's what integrals do for a living). The integral is the area under the curve, lazily accumulating lots of unwanted spectrum for a single-section *RC* at the high end, but acquiring some discipline with higher orders; by contrast, the filter order at the low end matters hardly at all. And this general behavior persists, even with a narrower 10:1 passband (Figure 8.103).

We've taken the simple case of white noise, with its uniform spectral density. But the situation is not much changed even when the noise density is rising at low frequencies (e.g., pink noise, with $e_\mathrm{n}^2 \propto 1/f$): the combination of a response $H^2 \propto f^2$, integrated over a small frequency span at low frequency, kills off the modestly increasing noise density.

8.13.3 Op-amp "low-frequency noise" with asymmetric filter

Because "the high end matters most," the *low-frequency noise-voltage* specifications (0.1–10 Hz) reported on many op-amp datasheets are measured with an asymmetrical filter, often a single-section highpass at 0.1 Hz cascaded with a 2-section (or sometimes higher-order) lowpass at 10 Hz. Here are the equivalent noise bandwidths for bandpass filters that are first-order (*RC*) highpass at f_1 and second-order Butterworth lowpass at f_2; as before, for pink or red noise the multiplying factor is the noise density at the upper frequency limit f_2, i.e., "e_n2"$\equiv e_\mathrm{n}(f_2)$:

$$v_\mathrm{n}^2 = e_\mathrm{n}^2\,\frac{\pi}{4}\,\frac{\sqrt{2}f_1^2 f_2^3 - 2f_1 f_2^4 + \sqrt{2}f_2^5}{f_1^4 + f_2^4} \quad \text{(white)},$$

$$v_\mathrm{n}^2 = e_\mathrm{n2}^2\,\frac{\pi f_1^2 f_2^3 + 4 f_2^5 \log_\mathrm{e}(f_2/f_1)}{4(f_1^4 + f_2^4)} \quad \text{(pink)}, \qquad (8.58)$$

$$v_\mathrm{n}^2 = e_\mathrm{n2}^2\,\frac{\pi}{4}\,\frac{\sqrt{2}f_1^3 f_2^3 - \sqrt{2}f_1 f_2^5 + 2f_2^6}{f_1^5 + f_1 f_2^4} \quad \text{(red)}.$$

Op-amp datasheets usually specify a 0.1 Hz to 10 Hz bandwidth for their listed low-frequency noise voltage; as often as not, it is defined with an asymmetric filter. But, curiously, they tend to list a peak-to-peak value (rather than rms), taken from a 10-second 'scope capture (similar to the bottom trace in Figure 8.4). It's common to estimate the rms noise voltage with this rule of thumb: $v_\mathrm{n(rms)} \approx v_\mathrm{n(pp)}/6$.

A. Op-amp low-frequency noise voltage

Operational amplifiers (with the exception of auto-zeroing op-amps) exhibit the, by now, familiar noise-density characteristic: flat at higher frequencies (call it e_nH), but rising approximately as $e_\mathrm{n} \propto 1/\sqrt{f}$ (pink noise) for frequencies below the $1/f$ noise corner (call that frequency f_c). If you know f_c and e_nH, you can use the expressions in Table 8.4 to estimate the integrated noise voltage over any span of bandpass f_1 to f_2.

There are three possibilities. (a) The bandpass is entirely

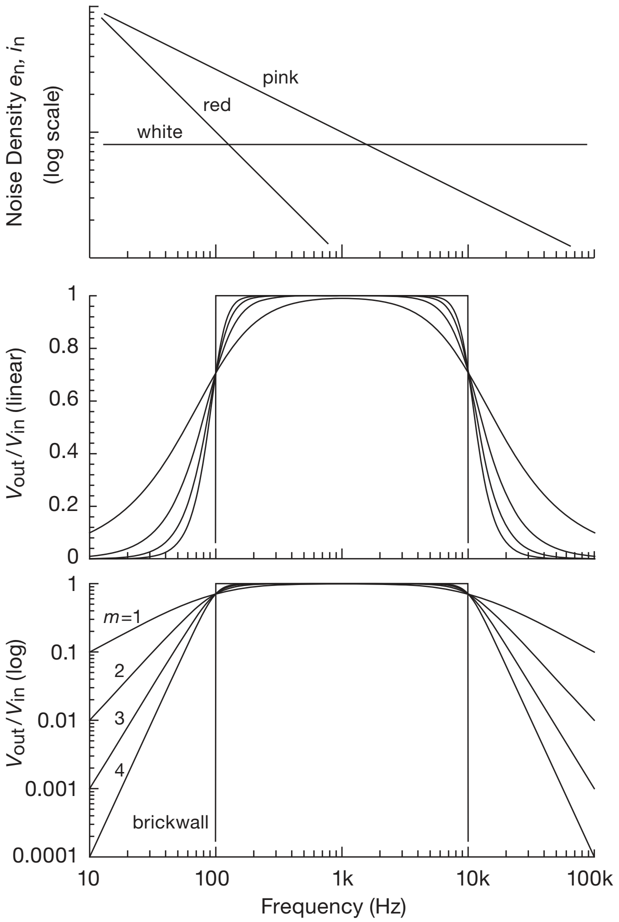

Figure 8.101. Spectral shapes of the three classic noises, and the bandpass filters used to evaluate their integrated noise voltage or current.

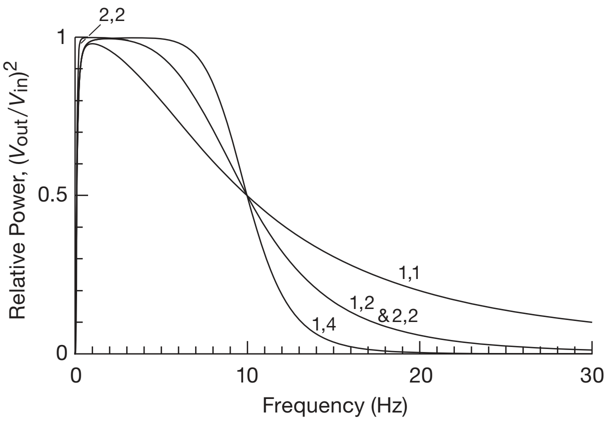

Figure 8.102. Power spectrum of filtered white noise, for 0.1–10 Hz Butterworth bandpass filters of the indicated orders (at their "low,high" ends; thus a "1,2" bandpass filter consists of a first-order highpass RC at f_1 cascaded with a second-order Butterworth lowpass at f_2).

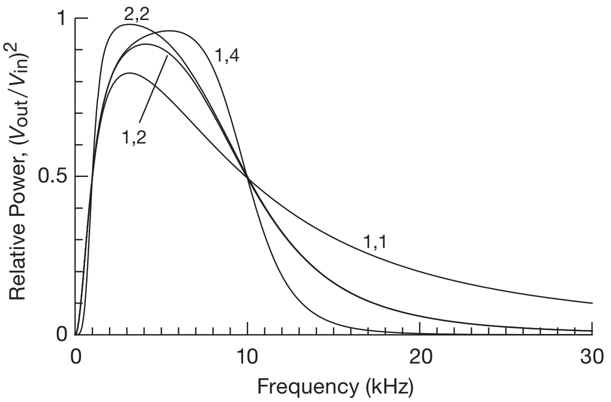

Figure 8.103. Power spectrum of filtered white noise, for 1 kHz–10 kHz Butterworth bandpass filters of the indicated orders ("low,high" ends).

in the white noise region, i.e., $f_1 > f_c$; (b) the bandpass is entirely in the pink noise region, i.e., $f_2 < f_c$; or (c) the bandpass straddles the $1/f$ corner frequency. For the first two cases, use the corresponding expression from Table 8.4 corresponding to the filter characteristic in use. For case (c), just calculate the separate white and pink v_n^2 contributions over the full passband (f_1 to f_2), and take their sum. In the idealized case of a brick-wall bandpass filter, this process gives an integrated noise voltage of

$$v_n^2 = e_{nH}^2\left(f_2 - f_1 + f_c \log_e \frac{f_2}{f_1}\right) \quad \mathrm{V}^2(\mathrm{rms}). \qquad (8.59)$$

This is what we've done to create the integrated noise curves in Figure 5.54 (in §5.11.1), based on the datasheet noise densities plotted in Figure 5.37 (in §5.10.6) and Figure 8.63 (from the data plotted in Figures 8.60 and 8.61).[129] Figure 8.104 shows an example, using the AD8671's datasheet e_n curve ($1/f$ corner at 5 Hz) to find the integrated-noise voltage v_n as a function of upper cutoff frequency (it's necessary to choose a nonzero low-frequency limit f_1 to prevent divergence).

[129] A spreadsheet program provides a handy way to make such calculations, and to plot the results.

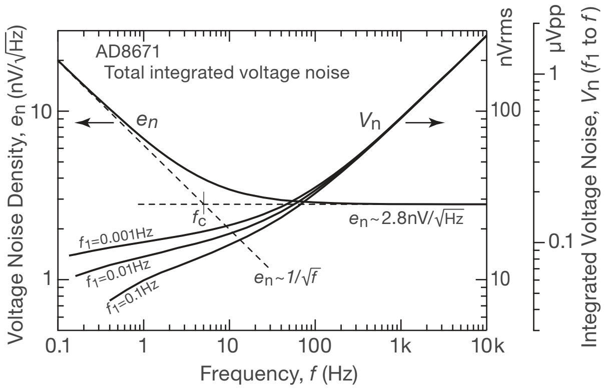

Figure 8.104. This op-amp's voltage noise density e_n has its $1/f$ corner frequency f_c at 5 Hz. Integrating the noise power ($\sim e_n^2$) from a low frequency f_1 up to a cutoff frequency $f_2{=}f$ gives the squared integrated noise voltage v_n^2, from which these curves of v_n result. If f_1 were set to zero, the v_n integral would diverge.

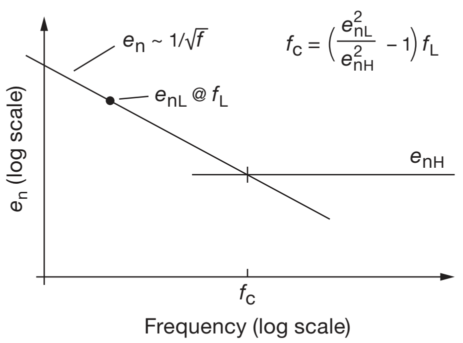

Figure 8.105. For the textbook noise density ($1/f$ at low frequencies, flat at high frequencies) you can get the corner frequency from the e_n values at two points.

8.13.4 Finding the 1/*f* corner frequency

If you're looking at a plot of noise density versus frequency, you can try to "eyeball" the $1/f$ corner frequency f_c. But it's nice to be able to find f_c from a pair of tabulated values when there's no graph available (often e_n is specified at 10 Hz and at 1 kHz in a datasheet's tabulated data); and anyway some folks are impressed by an equation or two in a not-inexpensive book like this one. You can figure it out, guided by Figure 8.105; the result is

$$f_c = \frac{e_{nL}^2 - e_{nH}^2}{e_{nH}^2} f_L = \left(\frac{e_{nL}^2}{e_{nH}^2} - 1\right) f_L \quad \text{Hz}, \qquad (8.60)$$

where e_{nL} is the noise density at some frequency f_L that is below the corner frequency, and e_{nH} is the noise density well above f_c.

A. Noise voltage over the decades

A white-noise source (i.e., e_n constant), filtered to a bandwidth B (for example with a brick-wall bandpass $f_2{-}f_1{=}B$), has integrated noise voltage $v_n{=}e_n\sqrt{B}$. So, looking at successive decades of bandpass (0.1–1 Hz, 1–10 Hz, 10–100 Hz, etc.), we expect to see the noise voltage increasing by factors of $\sqrt{10}$; and that's why, of course, "the high end matters most." The situation for pink noise is different: the $1/f$ dependence of e_n^2 compensates for the increasing bandwidths, yielding a constant noise voltage, as you can verify by looking at the expression for brick-wall-filtered pink noise on page 564. These dependencies are illustrated nicely in the integrated noise plots of Figure 5.54 and Figures 8.62 and 8.63, where the low-frequency $1/f$ characteristic of conventional op-amps causes their integrated noise voltage to flatten at the low-frequency end; by contrast, auto-zero op-amps exhibit constant e_n at low frequencies, so their integrated noise voltage continues to decrease by 10 dB/decade as the bandwidth is reduced.

Do bench measurements confirm this behavior? Look at the 'scope traces in Figure 8.106, which are single-shot waveforms of band-limited input noise current in an LT1012 BJT op-amp. The noise-current amplitude decreases about 10 dB from the top decade to the next decade down, but it appears to level off and then *increase* again at the lowest decade. That suggests a current noise density i_n that rises faster than the $1/\sqrt{f}$ of pink noise; and indeed the measured current noise spectrum of the LT1012, shown in Figure 8.111, is "steeper than pink." In contrast, an op-amp whose low-frequency noise conforms to an ideal pink-noise spectrum would exhibit approximately constant noise amplitude per decade of bandwidth, once well below the $1/f$ corner frequency.

B. Forever 1/*f* ?

You often hear talk about low-frequency noise power conforming to a "$1/f$ law," as if there's some statutory requirement involved. You might at first think that this cannot possibly be true, because (you say to yourself) a $1/f$ power spectrum cannot continue forever, since it would imply unlimited noise amplitude. If you waited long enough, the input offset voltage (or input current, in this case) would become unbounded. In fact, the popular mythology of a low-frequency noise catastrophe (to which your thinking would have fallen victim) is quite without merit: even if the noise power *density* continues as $1/f$ all the way down to zero frequency, its total noise power (i.e., the *integral* of noise power density) diverges only logarithmically, given that $\int f^{-1} df = \log_e f$. To put some numbers to it, the total noise power in a pure $1/f$ spectrum between 1 *micro*hertz and

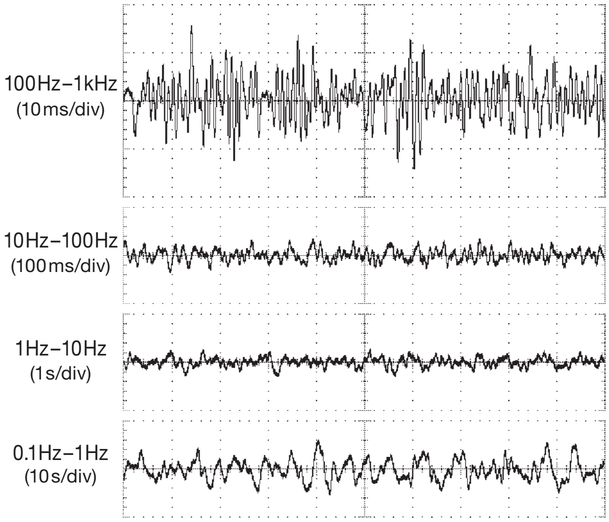

Figure 8.106. LT1012 noise current versus time, for successive decade bandpasses. Vertical: 5 pA/div. Horizontal: scaled to bandpass, as indicated.

10 Hz is only 3.5 times greater than that between 0.1 Hz and 10 Hz; going down another six decades (to 10^{-12} Hz), the corresponding ratio grows only to 6.5. Put another way, the $1/f$ total noise power, going all the way down to a frequency that is the reciprocal of 32,000 years (when Neanderthals still roamed the planet, and there were no op-amps), is just six times greater than that of the usual datasheet 0.1–10 Hz "low-frequency noise." So much for catastrophes.

To find out whether the low-frequency noise of real op-amps continues to conform to a $1/f$ spectrum, we measured the current noise spectrum of an LT1012 op-amp all the way down to 0.5 *milli*hertz,[130] with the result of Figure 8.107. As we remarked above, this op-amp is unusual in that its current noise density i_n rises faster than the usual $1/\sqrt{f}$ (pink noise) for a decade around 1 Hz; but even so it settles back to the canonical pink noise, and ultimately becomes something closer to "pale white" ($f^{-1/4}$ or slower).

You could conclude that this demonstrates the unphysical nature of $1/f$ behavior all the way down to zero. But there's another possible explanation, namely that this op-amp is afflicted with some mild burst noise. That would be consistent with the "faster-than-pink" slope around 1 Hz (recall the burst-noise spectrum in Figure 8.6), and it would also lead you to incorrectly attribute a "slower-than-pink" slope at the low frequency end of the spectrum in Figure 8.107.

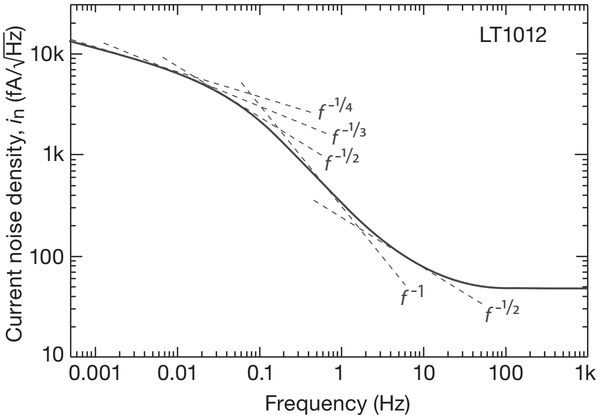

Figure 8.107. Measured LT1012 noise current spectrum, extending down to 500 microhertz. Several slopes are shown, for your amusement.

If this latter explanation is correct, measurements at even lower frequencies (to 0.00001 Hz, say) would confirm a continuing $1/f$ (pink) slope. But it takes a full day to reach 10 μHz, which is why reliable long timescale data are hard to find. An interesting datapoint is provided by Daire's measurement of the "Spectral Noise Distribution" of a Keithley 6430 high sensitivity (0.05 fA resolution) source-measure instrument,[131] which displays a $1/f$ character all the way down to a microhertz (corresponding to a time scale of several weeks). With this in mind, it is quite possible that the low-frequency flattening seen in Figure 8.107 is indeed an artifact of a burst-noise plateau. Or maybe not – there's no statutory requirement that extremely-low-frequency noise must obey a $1/f$ (pink-noise) spectrum.

8.13.5 Measuring the noise voltage

There is a class of test instruments, called *spectrum analyzers* or *dynamic signal analyzers*, that measure and display the frequency spectrum of an input signal. One style is optimized for low-frequency and audio use, generally up to ~100 kHz or so, with spectral calculations done with a discrete Fourier transform; examples are the Stanford Research Systems SR780/5 and the Agilent U8903A. At the other end you find RF and microwave spectrum analyzers whose upper frequency limits range from ~3 GHz

[130] We averaged 100 power spectra, accumulating a 2000-second time series for each one: not a quick experiment!

[131] Adam Daire, "Counting electrons: how to measure currents in the attoampere range," Keithley Instruments, Inc., September 2005. Available as a pdf from www.keithley.com.

to upward of 50 GHz; these use an internal swept oscillator and mixer scheme (often augmented with a digital Fourier transform backend) to map out the spectrum sequentially. A popular configuration accommodates the frequency range from 9 kHz to 3 GHz, often with an internal "tracking generator" that lets you sweep the responses of filters or amplifiers; examples are the Agilent E4403 and the Rohde & Schwarz FSL3.

These instruments are quite flexible, with a wide range of input gain settings, frequency spans, display scaling, and so on. The low-frequency instruments have 1 MΩ input impedance, convenient for circuit measurements (e.g., op-amp or voltage-reference noise spectra), whereas the RF analyzers present the standard 50 Ω (or 75 Ω, for video applications) input impedance. To measure an op-amp noise spectrum, for example, just use the circuit of Figure 8.108, with R_s=0; you'll get a spectrum like the lower curve in Figure 8.109. Voltage-noise spectra for some op-amps thus measured are shown in Figure 8.110.

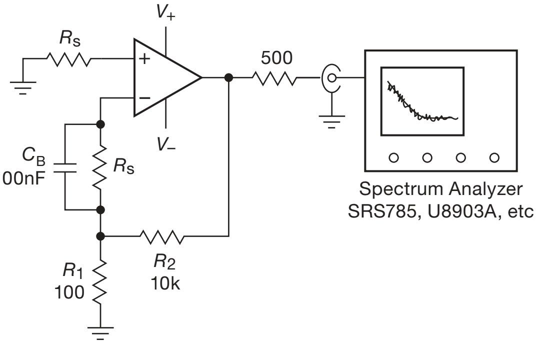

Figure 8.108. Measuring op-amp noise voltage and current spectra. For e_n, set R_s=0; for i_n, choose R_s substantially larger than the amplifier's noise resistance (R_n=e_n/i_n). Use a shielded box with filtered dc feedthroughs.

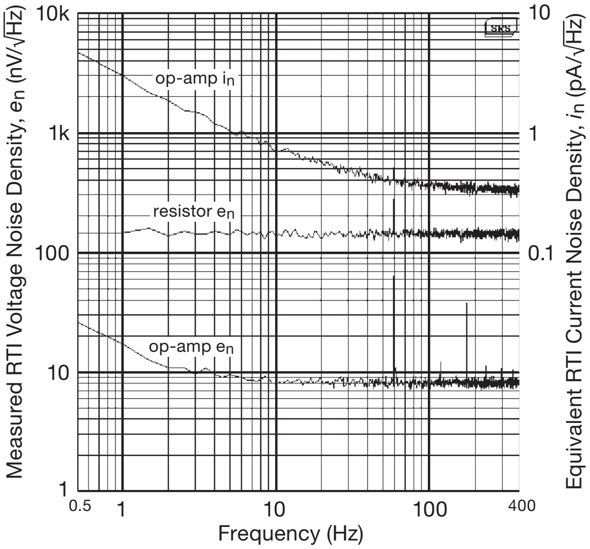

Figure 8.109. Voltage and current noise spectra of an OPA277 op-amp, measured with the circuit of Figure 8.108. The Johnson noise of the 1 MΩ resistor R_s used for the i_n measurements sets a "noise floor," here seen to be well below the op-amp's measured i_n.

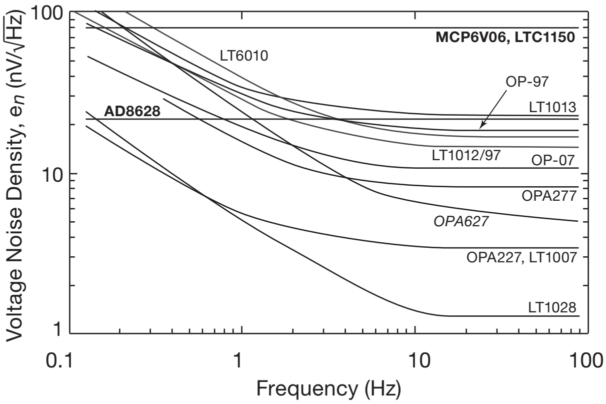

Figure 8.110. Measured voltage-noise-density spectra of a selection of op-amps. The **boldface** parts are auto-zero amplifiers, which circumvent the $1/f$ "flicker-noise" demon by repetitive offset correction; the *italic* OPA627 is a JFET-input op-amp. See also Figures 8.60 and 8.61.

The most accurate way to make integrated output noise voltage measurements is to use a true rms voltmeter. These operate either by measuring the heating produced by the signal waveform (suitably amplified) or by using an analog squaring circuit followed by averaging. If you use a true rms meter, make sure it has response at the frequencies you are measuring; some of them go up to only a few kilohertz. True rms meters also specify a "crest factor," the ratio of peak voltage to rms that they can handle without great loss of accuracy. For Gaussian noise, a crest factor of 3 to 5 is adequate.

You can use a simple averaging-type ac voltmeter instead, if a true rms meter is unavailable. In that case, the values read off the scale must be corrected. As it turns out, all averaging meters (VOMs, DMMs, etc.) already have their scales adjusted, so what you read isn't actually the *average*, but rather the rms voltage *assuming a sine-wave signal*. For example, if you measure the powerline voltage in the United States, your meter will read something close to 117 V. That's fine, but if the signal you're reading is Gaussian noise, you have to apply an additional correction. The rule is as follows: to get the rms voltage of Gaussian noise, multiply the "rms" value you read on an averaging ac voltmeter by 1.13 (or add 1 dB). Warning: this works fine if the signal you are measuring is pure noise (e.g., the output of an amplifier with a resistor or noise source as input), but it won't give accurate results if the signal consists of a sinewave added to noise.

A third method, not exactly world famous for its accuracy, consists of looking at the noise waveform on an oscilloscope: the rms voltage is 1/6 to 1/8 of the peak-to-peak value (depending on your subjective reading of the pp amplitude). It isn't very accurate, but at least there's no problem getting enough measurement bandwidth.

8.13.6 Measuring the noise current

An easy way to measure input noise current in an op-amp is to use the circuit of Figure 8.108, with a large input resistor R_s. Its value has to be large enough so that the noise voltage generated across it by the op-amp's input noise current is at least comparable to (and preferably much larger than) the op-amp's noise voltage: $i_n R_s \gtrsim e_n$. Another way to put it is to say that $R_s \gtrsim R_n$, the op-amp's noise resistance.

We're not done yet. It's also necessary that $i_n R_s$ dominates over the resistor's Johnson-noise voltage density: $i_n R_s \gtrsim \sqrt{4kTR_s}$. That is, R_s looks like a current noise source of $i_n = \sqrt{4kT/R_s}$, so you have to choose a large-enough value so that the op-amp's input current noise dominates. We find it easiest to remember Johnson noise voltage and current values for a round-number resistance, and then scale it according to the square root of R. So, take note: the Johnson noise of a 1 MΩ resistor is e_n=127 nV/$\sqrt{\text{Hz}}$ (open-circuit), scaling as $\sqrt{R}$; and i_n=127 fA/$\sqrt{\text{Hz}}$ (short-circuit), scaling as $1/\sqrt{R}$.

Figure 8.111 shows input current noise spectra for a selection of op-amps (most of which have BJT inputs with bias-current cancellation), measured with the circuit of Figure 8.108 with R_s=100 MΩ (for which the resistor's Johnson-noise voltage is equivalent to a current-noise density of 12.7 fA/$\sqrt{\text{Hz}}$), and was so measured with an OPA627 JFET-input op-amp (whose voltage- and current-noise contributions are negligible by comparison). The two auto-zero (chopper-stabilized) parts exhibit a flat low-frequency noise spectrum, in contrast to the usual "pink" $1/f$ rising noise power density of conventional op-amps. But auto-zeros usually have nasty spectral peaks at higher frequencies, caused by the clocked switching at the input (those for the AD8628A are around 15 kHz, off the right-hand end of the graph; but Figure 5.52 shows them handsomely, for the MCP6V06).

Table 8.5 Auto-zero Noise Measurements

	Noise Voltage			Spectral pk	Noise Current

Notes: (a) broad spectrum, slight rise at 2.2kHz and harmonics. (b) output noise dominated by V_n, unable to measure I_n separately. (c) auto-zero at power-up, no corrections thereafter. (d) precision conventional CMOS op-amp, for comparison. (e) at 10Hz/1kHz. (f) no spectral features; peak amplitudes for bandwidths to 1kHz/10kHz/100kHz. (g) at 1Hz. (s) spikey waveform, value listed is the peak amplitude. (t) typical.

A caution: datasheet values for input current noise are sometimes seriously in error, evidently because the manufacturer did not measure it, believing that it was accurately predicted by a shot noise calculation based on dc input current. We were curious, and measured the input noise of a dozen auto-zero op-amps, with the results in Table 8.5 on the current page. And how interesting! The datasheet values for *voltage* noise were correct; but for some of the parts, the specified *current* noise values were far too optimistic, sometimes by as much as a factor of fifty. Interestingly, some datasheets even admit what they've done; for example, the i_n entry for each of the three LTC parts is accompanied by a footnote saying "Current noise is calculated from the formula $i_n = \sqrt{2qI_B}$, where q=1.6·10^{-19} coulombs." This same error afflicts some BJT-input op-amps, in particular those with input bias cancellation, where the (incorrect) current noise in the datasheet evidently was calculated from the shot noise corresponding to the *net* (i.e., cancelled) input current, rather than from the much larger uncancelled input current. See §§*4x.10* and 5.10.8 for details.

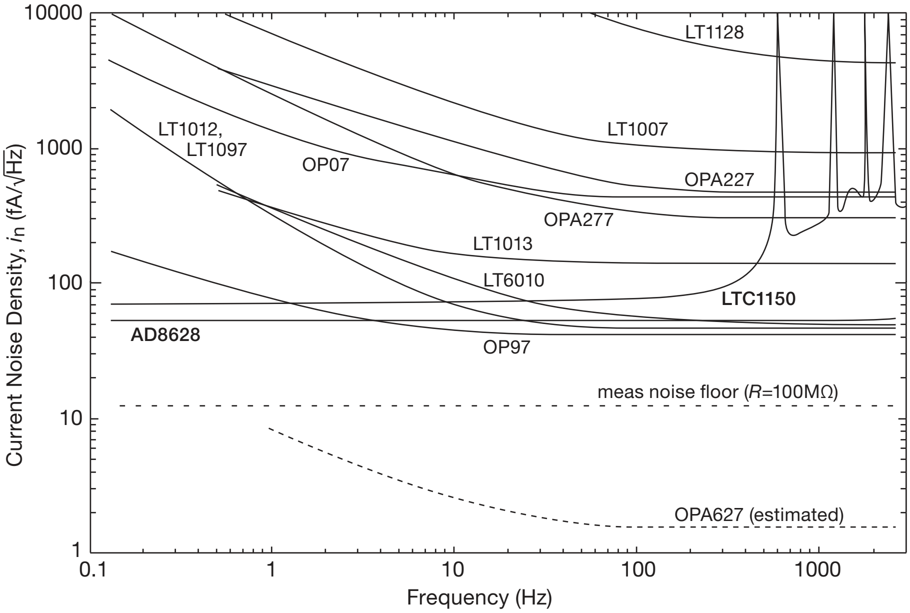

Figure 8.111. Measured current noise density spectra for most of the op-amps of Figure 8.110. The **boldface** parts are auto-zero amplifiers, which circumvent the $1/f$ "flicker-noise" demon by repetitive offset correction, but exhibit switching-induced clock noise at higher frequencies (see the expanded plot in Figure 5.52). See also Figures 8.60 and 8.61.

A. Some limitations: bandwidth, stability, dc offset

This simple i_n measurement scheme – letting the device under test amplify its own input current noise, as a voltage developed across a large input resistor – has some drawbacks, which seriously limit the ability to measure noise currents down in the low fA/$\sqrt{\text{Hz}}$ range. As just discussed, you've got to use sufficiently large values of R_s to overcome both the amplifier's e_n and the resistor's Johnson noise. For a noise current of 1 fA/$\sqrt{\text{Hz}}$, for example, that requires R_s at least 10 GΩ (equivalent i_n contribution is 1.3 fA/$\sqrt{\text{Hz}}$). But now you've got to worry about the dc voltage produced by the input bias current: a current of 10 pA, for example, causes 100 mV of dc input, thus saturation at the output after G=100. You've also got to worry about instability, because it doesn't take much feedback capacitance from the output pin to the noninverting input to make the amplifier into an oscillator. That can be tamed by a small shunt capacitor to ground, but the added capacitance reduces the (already small) bandwidth: with our R_s=10 GΩ, for example, a mere 1 pF of input capacitance limits the measurement bandwidth to 16 Hz! And in our measurements we needed additional shunt capacitance to prevent low-frequency oscillation in our (socketed) test jig.

B. Improved bandwidth with a current amplifier

The lesson here is that it's not easy to make measurements of low-level input current noise in good amplifiers. You can do better, though, by using a carefully designed *external* current amplifier (which presents a low impedance input, i.e., a virtual ground) connected directly to the noninverting input of the device under test, as in Figure 8.112. For example, the DL Instruments[132] Model 1211 "current preamplifier" has a specified input current noise of 1.5 fA/$\sqrt{\text{Hz}}$ (corresponding to a 10 GΩ feedback resistor to its input summing junction) and a bandwidth of 400 Hz; it is an "electrometer" configuration (dc negative feedback to an input summing junction), so it holds its input within 0.2 mV of ground at full-scale input current. Some other suppliers of low-noise-current amplifiers and current-measuring instruments are Laser Components (for example their Model DDPCA-300, with switchable gains from 10^4 V/A up to 10^{13} V/A, and with noise as low as 0.2 fA/$\sqrt{\text{Hz}}$ in the most sensitive ranges), and Keithley (for example their Model 428, with switchable gains from 10^3 V/A up to 10^{11} V/A).

Figure 8.112. Measuring op-amp current noise with a sensitive external current amplifier.

8.13.7 Another way: roll-your-own fA/√Hz instrument

Commercial high-performance current amplifiers can cost quite a bundle – you're talking numbers like 30–40 dB\$. It's nice to have such a general-purpose bench instrument on hand, of course. But if all you want is to measure low-level op-amp input-current noise, and you're willing to make a special-purpose test jig, you can wire up something like the circuit in Figure 8.113. With the values shown you can measure noise currents down to 0.1 fA/√Hz (or less, with a larger R_s), with a component cost of just a few dollars.

This circuit takes an unusual approach, and is worth a bit of discussion. Our first idea was to eliminate entirely the noise-producing feedback resistor: recall that a resistor of value R has a Johnson noise-voltage density $e_n=\sqrt{4kTR}$, thus an equivalent noise-current density $i_n=\sqrt{4kT/R}$; so, for example, to keep that i_n contribution less than 1 fA/√Hz requires an R_f greater than 16,000 MΩ (with consequent problems of bandwidth, offset, and stability). So here we use instead a feedback *capacitor!*[133] This makes an integrator, here implemented as a composite amplifier in which the device-under-test (DUT) (configured as a follower) drives an inverting op-amp stage whose unity-gain bandwidth is limited (by C_{comp}, in combination with R_1) to ∼16 kHz. We don't need any more bandwidth, and this overcompensation ensures stability.

Ignoring for the moment the DUT's dc input leakage current, this integrator converts input current noise to output voltage noise according to $v_n=i_n/\omega C_f$. So, for example, a flat (white) i_n spectrum produces a v_n whose spectral amplitude falls as $1/f$, or, equivalently, its noise power density falls as $1/f^2$ (red noise). Of course, there's also voltage noise e_n in both op-amps, which gets added to v_n (in the usual square root of sum of squares manner of uncorrelated noise); by choosing a smaller value for C_f we can reduce the effect of the e_n's, because smaller values of C_f produce larger current-to-voltage "gain." (Another way to put it is that the effective current noise produced by the input noise voltage e_n is $i_n=e_n\omega C_f$. Equivalently, the current-noise measurements extend only up to a frequency $\omega=i_n/e_nC_f$,

[133] This isn't as nutty as it sounds. In fact, it is the method of choice ("correlated double-sampling") used in certain low-noise applications, for example photodiode or CCD imager readout amplifiers, where the thermal noise produced by a conventional feedback resistor is unacceptable. (An engineer would say that a capacitor has no Johnson noise; a physicist would say that a capacitor may have kT worth of thermal energy on average, but, being uncoupled from the thermal bath, that energy does not fluctuate.) This technique may have been originated by Garwin, who used it in the 1950s for high-energy physics instrumentation, and then in 1969 for image detector readout (where Garwin instructed "read twice to cancel kT").

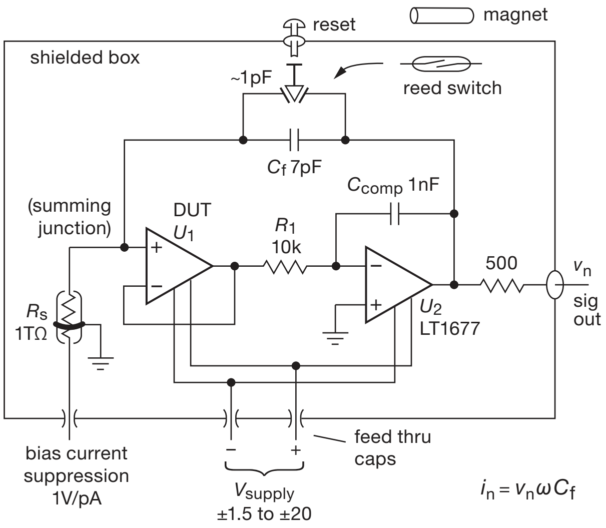

Figure 8.113. Measuring i_n down to 0.1 fA/$\sqrt{\text{Hz}}$, with bandwidths out to ~1 kHz, using a composite integrator. The suppression resistor R_s (made by Welwyn) has an integral metallic guard band, used to intercept leakage currents on the outside of its glass envelope (hey, this is a *really* high-value resistor: 1 TΩ is a million megohms!); the 7 pF value for C_f includes wiring and switch capacitances. The reset switch presented educational challenges (see text).

above which the amplifier's voltage noise dominates.) For this circuit we chose the LT1677 for U_2, because it combines pretty low voltage noise (3.2 nV/$\sqrt{\text{Hz}}$) with low bias current, wide operating voltage range (±1.5 V to ±20 V), and rail-to-rail output.

Figure 8.114 shows a screen capture of the voltage-noise spectrum of the circuit of Figure 8.113, when an LTC1049 auto-zero op-amp is plugged into the DUT socket. It conforms accurately to $1/f$, evaluating to i_n=100 fA/$\sqrt{\text{Hz}}$ over this frequency range, agreeing with the i_n measurement we made using the circuit of Figure 8.108 (and reported in Table 8.5 on page 569). There's no hint of a leveling off at the high frequency end, consistent with a predicted measurement bandwidth of ~10 kHz for the i_n and e_n of this op-amp.

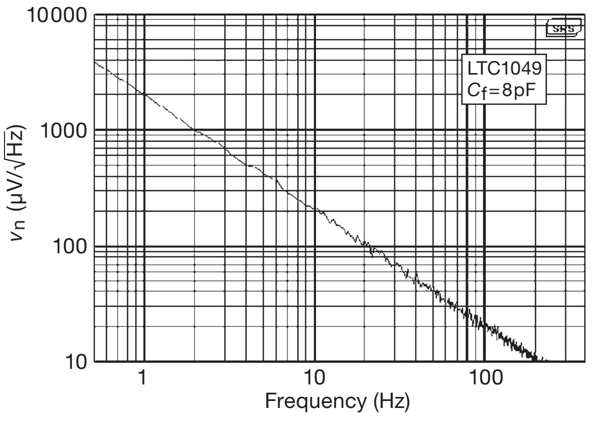

Figure 8.114. Measured voltage-noise density v_n from the circuit of Figure 8.113, for an LTC1049 auto-zero op-amp. The $1/f$ amplitude spectrum of the integrator's output (v_n) corresponds to a flat input current noise spectrum over this range of frequencies, with a value i_n=100 fA/$\sqrt{\text{Hz}}$.

Having calibrated the technique (and having confirmed the calibration by measuring also the AD8628 auto-zero op-amp), we used it to measure the tough cases – the conventional op-amps listed in Table 8.5, with current-noise values down in the ~1 fA/$\sqrt{\text{Hz}}$ territory – with the results listed. For those measurements the bandwidth extends only to ~1 kHz, above which the op-amp's voltage noise e_n, in combination with the input capacitances to ground (both within the op-amp, and externally as wiring, etc.), creates an "e_nC" equivalent input current noise (more precisely, $e_n\omega C_{in}$) that dominates the small current noise of the amplifier itself.

We also measured an LMC6081, which should have even lower current noise, given its specified typical input current I_b of 10 fA; for this op-amp the measured v_n corresponds to an i_n of 0.15 fA/$\sqrt{\text{Hz}}$. That sounds pretty good – but the expected current noise, calculated as I_B shot noise, should be quite a bit lower, about 0.06 fA/$\sqrt{\text{Hz}}$. So now we have to confess that the resistorless purity of this measurement technique has been compromised by the "current-suppression" resistor R_s, needed to cancel the dc input current. We used a very large value (1 TΩ, that's 10^6 megohms!) to reduce the added noise current, which here amounts to $i_n=\sqrt{4kT/R_s}$=0.13 fA/$\sqrt{\text{Hz}}$. So for this op-amp what we've actually measured is the noise introduced by the bias-suppression resistor! We could do better, say with a 100 TΩ resistor (you can get these things, for example the 3810-series from Welwyn), which would push the added noise down by a factor of ten. We could do better, that is, if you really believe that you can keep all other insulation resistances (moisture, fingerprints, etc.) that high; a tall order.[134]

A. An amusing complication: the reset switch

Here's a little story about reality, and some considerable confusion on the way to ultimate enlightenment. Right "out of the box" this circuit worked nearly perfectly. But there was one curious complication: when the integrator RESET switch was pressed, the output went obediently to zero; but when the switch was released, the output took a large jump – typically to a value in the range of +1.5 V to +2 V. What could cause *that?* Most likely, some sort of electrostatic charging caused by the movement of the plastic parts, in a pushbutton switch series of which we've grown quite fond (Panasonic EVQ2130x–EVQ2150x series, which are compact, inexpensive, pleasantly tactile, and nearly free of annoying contact "bounce").

We pondered this, and decided to substitute a magnetically operated *reed switch* – a small sealed tubular glass envelope containing a pair of contacts, with a wire sticking out each end, and which is actuated by bringing a small permanent magnet in proximity (these things are widely used, most familiarly for door and window switches in home alarm systems). The reed switch has good properties: when OFF its capacitance is ∼0.3 pF and its resistance is greater than 10^{12} Ω. And, with the switch inside the shielded aluminum box and the magnet outside, there would be no opportunity for accumulation of static charge. Better still, with no dc-actuated coil (as in a conventional relay, or a reed relay) there would be no magnetic or electric coupling to the sensitive circuit.

This worked considerably better. But still not as expected: imagine our surprise when the output took a −50 mV step when the switch was opened. What could be causing *that?* We guessed at first that it might be due to a flux rearrangement when the (magnetic) contacts opened, injecting a pulse of charge equal to the change in flux that was linked by the circuit wiring. Easy to check: just move the switch in close proximity to the op-amp, reducing greatly the circuit's enclosed area. We did that, and, encouragingly, the output jump changed sign (now a positive jump, of about the same magnitude). OK, we thought, move the switch halfway back to where it was and the effect should go to zero. It didn't: still +50 mV.

This was really weird! On an inspiration we guessed that we might have reversed the ends when we made the first change, so we flipped the switch over and – aha! – the jump reversed sign (back to −50 mV).

So the reed switch seemed to have an asymmetry, and a memory of its own, such that it injected some charge (not much: $Q=C_f\Delta V=0.35$ pC) when opened. What could be causing that? We spoke with some wise colleagues, who suggested we think about the difference of "work function" between the two contacts in the switch (which might plausibly be chosen of different metals, to prevent cold-weld sticking), and who mumbled terms like "Fermi levels," "contact potential difference," and the "Kelvin probe" technique for measuring the latter.

OK, so we tried a reed switch of different design, and also one from a different manufacturer (for the original Hamlin MDRR-4 we substituted first a Hamlin MDSR-10, then a Coto RI-01BAA), both of which exhibited the same curious effect, though with different amplitudes (15 mV and 100 mV, respectively).

Time to call for help! The Hamlin datasheet proclaims hospitably "For details on electrical specifications, contact Hamlin." So we did. We learned that the contact pairs are identical, in fact they just make a zillion of them, all the same, and take any two for each switch. There goes all that Fermi-level theory!

Finally we figured it out.[135] Glass is a darned good insulator, and it's easy to deposit charge onto the reed switch's glass envelope just by handling it (removing it from its plastic bag, etc.). There's a fancy name for this: it's called the *triboelectric effect*. A simpler name is static electricity. Glass is one of the classic materials, and in courses on

[134] Indeed! We tested this proposition by breathing heavily into the box, then remeasuring the bias suppression through R_s: it increased 20-fold, owing to the external leakage path evidently created by moisture condensation, returning to its dry value a minute later. That is why these "High-value Glass-sealed" resistors from Welwyn are outfitted with a conductive guard ring, which can be connected to ground (as shown) to shunt off such external leakage currents: the portion of the case between the guard ring and the summing junction then has no voltage drop across it (more precisely, a voltage equal to the op-amp's offset voltage, a millivolt or less); thus no leakage current flows. We confirmed this with an encore of the breathing test.

[135] Isn't it curious that it's always the *last* conjecture that proves to be correct?

electricity you see demonstrations of glass rods being rubbed with cat's fur.[136] With some charge stuck on the glass, the electric field that it produced caused the electrodes of the reed switch to acquire a small amount of opposing charge when separated.

Here's what we did to confirm this conjecture: we took an inch of woven metal cloth,[137] grounded one end with a clip lead, wrapped it around the reed switch, and slid it along the length several times, to provide an opportunity for any static charge on the glass surface to take a hike. And it did: after one treatment the output-voltage step was reduced to a negligible ∼2 mV.

The moral: sensitive measurements (here we're talking femtoamps and picofarads) can reveal effects that are so small that you've never thought about them. They can seriously disrupt your work. . . but there's a redeeming delight in discovering them for yourself. And then eliminating them.

8.13.8 Noise potpourri

Herewith a collection of interesting, and possibly useful, facts.

1. The averaging time required in an indicating device to reduce the fluctuations of a rectified noise signal to a desired level for a given noise bandwidth is

$$\tau \approx \frac{1600}{B\sigma^2} \text{ seconds,} \tag{8.61}$$

where τ is the required time constant of the indicating device to produce fluctuations of standard deviation σ percent at the output of a linear detector whose input is noise of bandwidth B.

2. For band-limited white noise, the expected number of maxima per second is

$$N = \sqrt{\frac{3(f_2^5 - f_1^5)}{5(f_2^3 - f_1^3)}}, \tag{8.62}$$

where f_1 and f_2 are the lower and upper band limits. For $f_1 = 0, N = 0.77f_2$; for narrowband noise ($f_1 \approx f_2$), $N \approx (f_1 + f_2)/2$.

3. rms-to-average (i.e., average magnitude) ratios:

Gaussian noise: rms/avg $= \sqrt{\pi/2} = 1.25 = 1.96$ dB,
sinewave: rms/avg $= \pi/2^{\frac{3}{2}} = 1.11 = 0.91$ dB,
square wave: rms/avg $= 1 = 0$ dB.

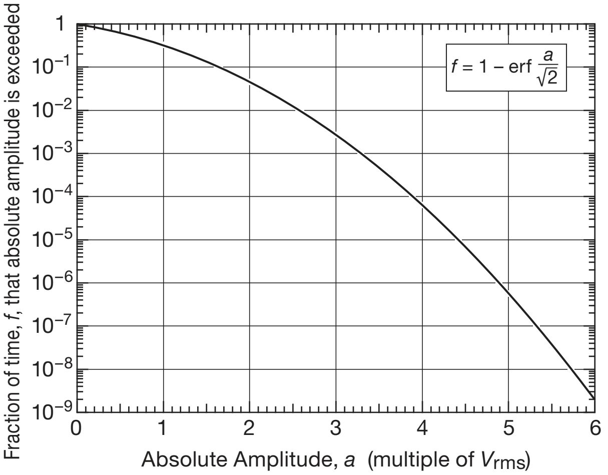

Figure 8.115. Relative occurrence of amplitudes in Gaussian noise. Potentially useful for estimating false trigger rates, required "crest factor" in rms measurements, and the like.

4. Relative occurrence of amplitudes in Gaussian noise. Figure 8.115 plots the fractional time that a given amplitude level is exceeded by a Gaussian noise waveform of unit rms amplitude.

5. Positive-threshold crossing rate of lowpass-filtered Gaussian white noise of unit rms amplitude is

$$\text{TCR} = \frac{\text{BW}}{\sqrt{3}} \exp\left(-V_{\text{th}}^2/2\right) \text{ crossings/second,} \tag{8.63}$$

where V_{th} is the positive threshold voltage and BW is the brick-wall lowpass bandwidth.[138]

6. Standard deviation of noise resulting from quantization error is

$$\sigma_n = \frac{\text{LSB}}{\sqrt{12}} \approx 0.3\,\text{LSB}. \tag{8.64}$$

8.14 Signal-to-noise improvement by bandwidth narrowing

As luck would have it, the signals you often want to measure are buried in noise (where the "noise" may include other signals nearby in frequency, i.e., interference), frequently to the extent that you can't even see them on an

[136] Or is it a cat being rubbed with glass wool?

[137] Wrapped around some foam, this handy stuff is used to make flexible conductive shielding gaskets. Check out the self-stick "fabric-over-foam" gasket materials from Laird Technologies, e.g., their rectangular 4046 or D-shaped 4283.

[138] The crossing rate through a pair of symmetrical thresholds (i.e., the rate of crossings of *magnitude* greater than V_{th}) is double that obtained from the formula. We thank Phil Hobbs for this fact, found along with many others in his fine book referenced on page 551.

oscilloscope. Even when external noise isn't a problem, the statistics of the signal itself may make detection difficult, as, for example, when counting nuclear disintegrations from a weak source, with only a few counts detected per minute. Finally, even when the signal is detectable, you may wish to improve the detected signal strength in order to make a more accurate measurement. In all these cases some tricks are needed to improve the signal-to-noise ratio. They all amount to a narrowing of the detection bandwidth in order to preserve the desired signal while reducing the total amount of (broadband) noise accepted.

The first thing you might be tempted to try when thinking of reducing the bandwidth of a measurement is to hang a simple lowpass filter on the output, in order to average out the noise. There are cases where that therapy will work, but most of the time it will do very little good, for a couple of reasons. First, the signal itself may have some high frequencies in it, or it may be centered at some high frequency. Second, even if the signal is in fact slowly varying or static, you invariably have to contend with the reality that the density of noise power usually has a $1/f$ character, so as you squeeze the bandwidth down toward dc you gain very little. Electronic and physical systems are twitchy, so to speak.

In practice, there are a few basic techniques of bandwidth narrowing that are in widespread use. They go under names like signal averaging, transient averaging, boxcar integration, multichannel scaling, pulse-height analysis, lock-in detection, and phase-sensitive detection. All of these methods assume that you have a repetitive[139] signal; that's no real problem, since there is almost always a way to force the signal to be periodic, assuming it isn't already. Here we discuss an important one of these techniques, known as "lock-in" or "synchronous" detection.

8.14.1 Lock-in detection

This is a method of considerable subtlety. It consists of two steps. (1) Some parameter of the source signal is *modulated*; for example, an LED might be driven with a square wave at a fixed frequency. (2) The detected (and noisy) signal is *demodulated*, for example by multiplying it by a fixed-amplitude reference signal at the same modulating frequency. The modulation moves the source signal spectrum up to the modulating frequency, above noisy $1/f$ low-frequency backgrounds, and away from other noise sources (such as ambient-light fluctuations in the case of the LED example). The demodulation step creates a dc output proportional to the signal, which can be lowpass filtered (a simple *RC* filter may be adequate) to narrow the detected bandwidth.

To understand the method, it is necessary to take a short detour into the phase detector, a subject we first take up in §13.13.2.

A. Phase detectors

In §13.13.2 we describe phase detectors that produce an output voltage proportional to the phase difference between two digital (logic-level) signals. For purposes of lock-in detection, you need to know about *linear* phase detectors, because you are nearly always dealing with analog voltage levels.

The simplest circuit[140] is shown in Figure 8.116. An analog signal passes through a linear amplifier whose gain is reversed by a square-wave "reference" signal controlling a FET switch (see Table 3.3 or 13.7 for candidates). The output signal passes through a lowpass filter, *RC*. That's all there is to it. Let's see what you can do with it.

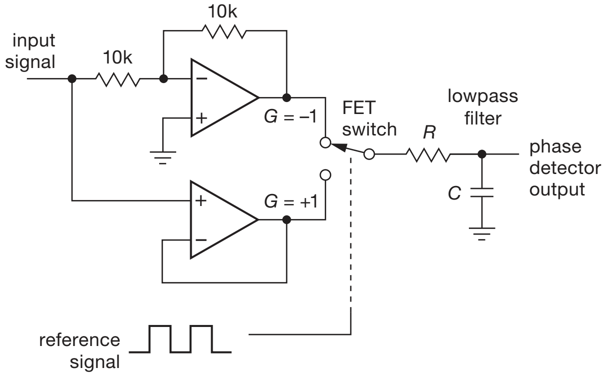

Figure 8.116. Phase detector for linear input signals. Most simply, you can implement this with a dual op-amp and a CMOS switch IC. This scheme is used in the monolithic AD630.

Phase-detector output

To analyze the phase-detector operation, let's assume we apply a signal

$$E_s \cos(\omega t + \phi)$$

to such a phase detector, whose reference signal is a square wave with transitions at the zeros of $\sin \omega t$, i.e., at

[139] Or, more generally, a *known* signal variation to which the measured signal can be correlated.

[140] But less than ideal: the square-wave modulation causes response at odd harmonics. The use of an analog multiplier like the AD633 or AD734, driven by a sinewave reference, eliminates this deficiency.

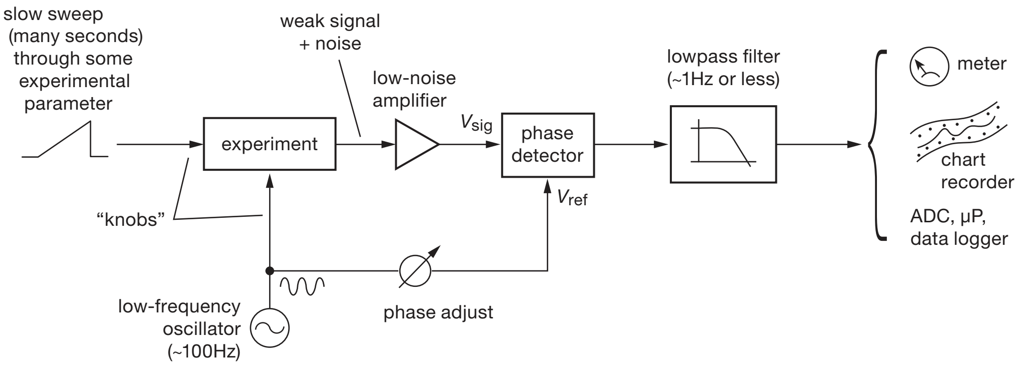

Figure 8.117. Lock-in amplifier detection.

$t = 0, \pi/\omega, 2\pi/\omega$, etc. Let us further assume that we average the output, V_{out}, by passing it through a lowpass filter whose time constant is much longer than one period:

$$\tau = RC \gg T = 2\pi/\omega.$$

Then the lowpass filter output is

$$\langle E_s \cos(\omega t+\phi)\rangle|_0^{\pi/\omega} - \langle E_s \cos(\omega t+\phi)\rangle|_{\pi/\omega}^{2\pi/\omega},$$

where the angle brackets represent averages and the minus sign comes from the gain reversal over alternate half-cycles of V_{ref}. As an exercise, you can show that

$$\langle V_{out}\rangle = -(2E_s/\pi)\sin\phi.$$

Exercise 8.9. Perform the indicated averages by explicit integration to obtain the preceding result for unity gain.

Our result shows that the averaged output, *for an input signal of the same frequency as the reference signal*, is proportional to the amplitude of E_s and sinusoidal in the relative phase.

We need one more result before going on: what is the output voltage for an input signal whose frequency is close to (but not equal to) the reference signal? This is easy, because in the preceding equations the quantity ϕ now varies slowly, at the difference frequency:

$$\cos(\omega+\Delta\omega)t = \cos(\omega t+\phi) \quad \text{with } \phi = t\Delta\omega,$$

giving an output signal that is a slow sinusoid:

$$V_{out} = (2E_s/\pi)\sin(t\Delta\omega),$$

which will pass through the lowpass filter relatively unscathed if $\Delta\omega < 1/\tau = 1/RC$ and will be heavily attenuated if $\Delta\omega > 1/\tau$.

B. The lock-in method

Now the so-called lock-in (or phase-sensitive) amplifier should make sense. First you make a weak signal periodic, as we've discussed, say at a frequency in the neighborhood of 100 Hz. The weak signal, contaminated by noise, is amplified and phase detected relative to the modulating signal. Look at Figure 8.117. In many cases you'll want to measure the weak signal as some experimental condition is varied – you'll have an experiment with two "knobs" on it, one for fast modulation to do phase detection, and one for a slow sweep through the interesting features of the signal (in NMR, for example, the fast modulation might be a small 100 Hz modulation of the magnetic field, and the slow modulation might be a frequency sweep 10 minutes in duration through the resonance). The phase shifter is adjusted to give maximum output signal, and the lowpass filter is set for a time constant long enough to give a good signal-to-noise ratio. The lowpass-filter rolloff sets the bandwidth, so a 1 Hz rolloff, for example, gives you sensitivity to spurious signals and noise only within 1 Hz of the desired signal. The bandwidth also determines how fast you can adjust the "slow modulation," because now you must not sweep through any features of the signal faster than the filter can respond; people use time constants of fractions of a second up to tens of seconds or more.[141]

Note that lock-in detection amounts to *bandwidth narrowing*, with the bandwidth set by the post-detection lowpass filter. Another way to reduce the detection bandwidth is with the technique of *signal averaging*, in which the results of repetitive measurements (e.g., frequency sweeps) are accumulated; this is a common option on instruments such as spectrum analyzers. In either case the effect of the modulation is to center the signal at the fast modulation

[141] In the old days the slow modulation was done with a geared-down clock motor turning an actual knob on something.

frequency, rather than at dc, in order to get away from $1/f$ noise (flicker noise, drifts, and the like).

C. Two methods of “fast modulation”

There are several ways to do the fast modulation: the modulation waveform can be either a very small sinewave or a very large square wave compared with the features of the sought-after signal (line shape versus magnetic field, for example, in NMR), as sketched in Figure 8.118. In the first case the output signal from the phase-sensitive detector is proportional to the *slope* of the line shape (i.e., its derivative), whereas in the second case it is proportional to the line shape itself (providing there aren’t any other lines out at the other endpoint of the modulation waveform). This is the reason all those simple NMR resonance lines come out looking like dispersion curves (Figure 8.119).

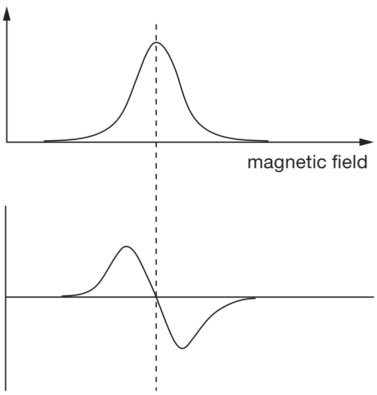

Figure 8.119. Line-shape differentiation resulting from lock-in detection.

For large-shift square-wave modulation there’s a clever method for suppressing modulation feedthrough, in cases where that is a problem. Figure 8.120 shows the modulation waveform. The offsets above and below the central value kill the signal, causing an on–off modulation of the signal at *twice* the fundamental of the modulating waveform. This is a method for use in special cases only; don’t get carried away by the beauty of it all!

Large-amplitude square-wave modulation is a favorite with those dealing in infrared astronomy, where the telescope’s secondary mirrors are rocked to switch the image back and forth on an infrared source. It is also popular in radio astronomy, where it’s called a Dicke switch.

Commercial lock-in amplifiers have a variable-frequency modulating source and tracking filter, a switchable-time-constant post-detection filter, a good low-noise wide-dynamic-range amplifier (you wouldn’t be using lock-in detection if you weren’t having noise problems), and a nice linear phase detector. They also let you use an external source of modulation. The phase shift is adjustable, so you can maximize the detected signal. The whole item comes packed in a handsome cabinet, with a meter or digital display showing the output signal. Typically these things cost a few thousand dollars. Stanford Research Systems has a nice selection of lock-in amplifiers, including several that use digital signal-processing methods for enhanced linearity and dynamic range. In these the amplified input signal is accurately digitized (to 20 bits), the “oscillator” is a computed lookup table of (quadrature) sines and cosines, and the “mixer” is a numeric multiplier. Ordinarily lock-in amplifiers are of rather limited signal bandwidth, typically 100 kHz. But by using the radiofrequency “heterodyne” technique (input frequency band translation via linear mixing with a “local oscillator”), the lock-in method can be extended into high radio-frequencies. For example, the SR844 goes to 200 MHz; it uses a hybrid of analog techniques (input filtering and downconversion) and digital signal processing (baseband digitizing and synchronous detection).

To illustrate the power of lock-in detection, we set up a small demonstration for our students. We use a lock-in to modulate a small LED of the kind used for panel

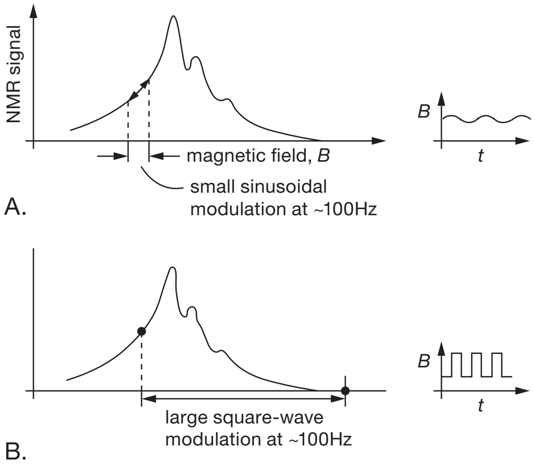

Figure 8.118. Lock-in modulation methods. A. Small sinusoid. B. Large square wave.

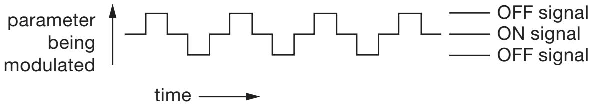

Figure 8.120. Modulation scheme for suppressing modulation feedthrough.

indicators, with a modulation rate of a kilohertz or so. The current is very low, and you can hardly see the LED glowing in normal room light. Six feet away a phototransistor looks in the general direction of the LED, with its output fed to the lock-in. With the room lights out, there's a tiny signal from the phototransistor at the modulating frequency (mixed with plenty of noise), and the lock-in easily detects it, using a time constant of a few seconds. Then we turn the room lights on, at which point the signal from the phototransistor becomes just a huge messy waveform, jumping in amplitude by 50 dB or more. The situation looks hopeless on the oscilloscope, but the lock-in just sits there, unperturbed, calmly detecting the same LED signal at the same level. You can check that it's really working by sticking your hand in between the LED and the detector. It's darned impressive.

At the other end of the cost spectrum, synchronous detection is used to accomplish the same rejection of ambient light in some inexpensive light-beam-detection components, for example the S6809/46 and S6986 from Hamamatsu. These ICs come in a clear plastic case (several available package styles) containing an integrated photodiode, preamp, and synchronous detector with logic-level output; included also is the internal oscillator and output driver for the external LED light source. They cost about $6 in small quantities.

8.15 Power-supply noise

Amplifier circuits that do not have a high degree of power-supply rejection are susceptible to noise (and signals) on the dc power supplies. If the dc rails are noisy, the output will be too, so you've got to keep them quiet. The problem is not as bad as it could be, though, because supply noise appears unamplified at the output, with the amplifier's signal gain of, say, ×100 signal gain. Still, dc power supplies are rarely quiet even to the level of $100\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ (100 times a reasonable input noise target of, say, $1\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$). That is why the dc rails in many of the circuits in this chapter are marked "quiet."

How noisy are typical dc bench power supplies? You'll see specs like "0.2 mVrms, 2 mVpp," which sounds respectable enough until you realize that signal levels in a sensitive circuit may be far smaller. For example, the output noise level over the 20 kHz audio band of the preamp of Figure 8.42 is just $1\,\mu$Vrms ($v_{\mathrm{n(out)}}=G_{\mathrm{V}}e_{\mathrm{n(in)}}\sqrt{\Delta \mathrm{f}}$). So such a supply's specified noise is 46 dB above the output noise floor.

Specs are one thing, actual performance is another. To get a measure of the power supply noise scene we measured two dozen dc supplies from our lab's collection, with the resulting spectra of Figure 8.123.[142]

The spread in noise performance is stunning – the outstanding performer (#4) turned out to be a "precision power source" half a century old (we bought it in 1967), with an ovenized compartment for the zener reference and (discrete) error amplifier. By comparison, a contemporary bench supply with elegant digital readout like #12 is nearly 100 times (40 dB) as noisy. Not to be outdone, the real screamers turn out to be a simple switchmode cellphone charger (#22), and an unregulated wall-wart (#23) whose powerline-tracking output wanderings dominate the low-frequency spectrum. At the other end, nothing beats a lead-acid battery (#3, right down at our measurement noise floor) for the utmost in inherently quiet dc sources.[143]

What accounts for these large differences? Switching supplies are inherently noisy, of course. But even among the linear supplies there is a 100× spread (40 dB) in noise voltage. A quiet dc regulated supply must have plenty of loop gain, implemented with low-noise amplifiers. And it's critically important to select a low-noise voltage reference (particularly down at low frequencies, where it can't be quieted with filters); see the discussion and plots in §9.10.

8.15.1 Capacitance multiplier

A nice trick for cleaning up a noisy supply is a "capacitance multiplier" circuit (Figure 8.121). We introduced this back in §8.5.9, where we explored the properties of a BJT input stage with $e_{\mathrm{n}}{\sim}0.07\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$. Here we choose R small enough so that there is at most a volt or so drop at maximum load current, then choose C for a long-enough time constant RC to attenuate adequately the portion of the noise spectrum you care about. For our ribbon-mic amplifier we elaborated on this a bit, with a 2-stage RC filter of ∼2 s time constant; it's shown in the top portion of the BJT noise-measuring circuit of Figure 8.92. There we increased RC until the output noise spectrum was down to the analyzer's noise floor.

Note that the capacitance multiplier compromises the dc output regulation – there's no feedback from its output pin. However, this technique is especially effective when

[142] These supplies were tested "as is," with no effort to confirm their operation within original specifications. The reader is cautioned not to rely on these data when making purchasing decisions.

[143] The battery was being trickle charged at the same current as its load for curve #3. If the battery is being discharged (without replenishment) by the load, the slight downward voltage "tilt" appears as a low-frequency excess, seen here in curve #2.

added upstream of the regulating pass element (i.e., after the rectifier and storage capacitor). We have applied this simple modification to commercial power supplies and scientific instruments with great success. It's a far easier way to achieve 100× lower output ripple than the alternative of raising the control-loop gain and bandwidth. If you do this, be sure there's enough drop across Q_1 to handle the full ripple amplitude – in this location the 120 Hz (or 100 Hz) ac ripple at full load current may be as much as a few volts. You can add a resistor from the base to ground to increase the dc drop across Q_1; or you can use a MOSFET, whose larger operating V_{GS} may provide adequate headroom.

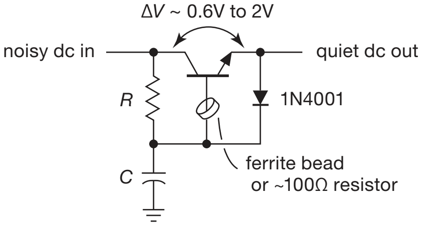

Figure 8.121. A "capacitance multiplier" for filtering incoming dc consists of an emitter follower biased with a smoothed (lowpass-filtered) replica of the noisy input. A bead or small resistor prevents oscillation.

Figure 8.122 shows the effect of Figure 8.92's capacitance multiplier, measured with two of the power supplies that appear in Figure 8.123's crowd. For each supply we measured (a) the spectrum directly from the output terminals (solid curves), (b) the spectrum downstream of the capacitance multiplier (dashed curves), and, for comparison, (c) the spectrum with 10,000 μF across the power supply's terminals (dotted curve). In all cases the measured output was loaded with 100 Ω. The capacitance multiplier is stunningly effective in eliminating power supply noise,[144] and it's a far better use of 10,000 μF than the brute-force approach of putting the same capacitance directly across the dc terminals.

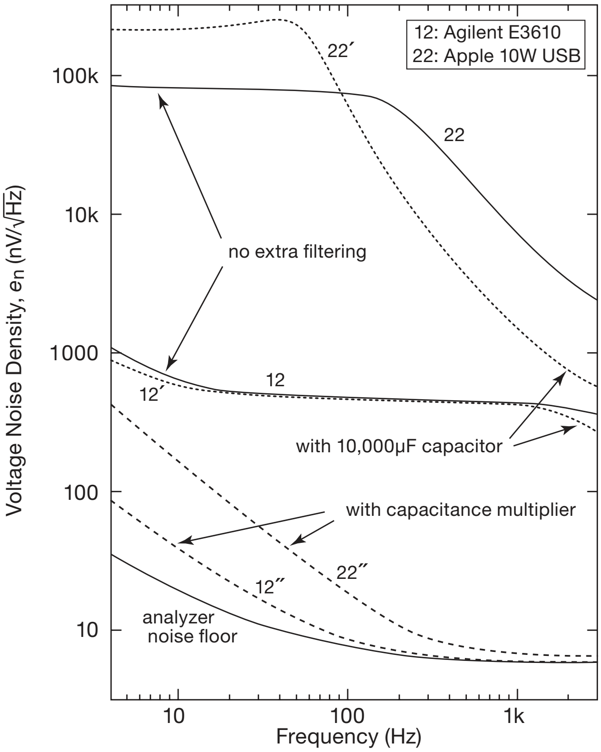

Figure 8.122. A capacitance multiplier is highly effective in eliminating power-supply noise, as shown in these measured noise spectra of two of the supplies whose spectra are included in Figure 8.123 (with same label numbers). Solid curves, power supply alone; dotted curves, (single-prime label), with added 10,000 μF capacitor across the dc output terminals; dashed curves (double-prime label), with capacitance multiplier shown in Figure 8.92.

8.16 Interference, shielding, and grounding

"Noise" in the form of interfering signals, 60 Hz pickup, and signal coupling via power supplies and ground paths can turn out to be of far greater practical importance than the intrinsic noise sources we've just discussed. These interfering signals can all be reduced to an insignificant level (unlike thermal noise) with proper circuit design, layout, and construction. In stubborn cases the cure may involve a combination of filtration of input and output lines, careful layout and grounding, and extensive electrostatic and magnetic shielding. In these subsections we offer some suggestions that may help illuminate this dark area of the electronic art.[145]

8.16.1 Interfering signals

Interfering signals can enter an electronic instrument through the powerline inputs or through signal input and output lines. In addition, signals can be capacitively

[144] Except at very low frequencies, where there's no substitute for a power supply with a stable voltage reference.

[145] For more extensive advice see the popular classics: R. Morrison, *Grounding and Shielding: Circuits and Interference*, Wiley–IEEE Press (2007), and H. Ott, *Noise Reduction Techniques in Electronic Systems*, Wiley–Interscience (1988).

Figure 8.123. All dc power supplies are not created equal! Measured noise voltage spectra of many varieties of supplies found in our lab. Dashed lines are switching supplies; the rest are linear. A 100 Ω load was used in most cases. Spectral peaks (“tonals”) at powerline frequency and harmonics have been edited out for clarity; they range from 5 dB to more than 50 dB above the smoothed baseline, as listed. A drifting output voltage produces a rising low-frequency tail.

coupled (electrostatic coupling) onto wires in the circuit (the effect is more serious for high-impedance points within the circuit), magnetically coupled to closed loops in the circuit (independent of impedance level), or electromagnetically coupled to wires acting as small antennas for electromagnetic radiation. Any of these can become a mechanism for coupling of signals from one part of a circuit to another. Finally, signal currents from one part of the circuit can couple to other parts through voltage drops on ground lines or power-supply lines.

A. Eliminating interference

Numerous effective tricks have been evolved to handle most of these commonly occurring interference problems. Keep in mind the fact that these techniques are all aimed at reducing the interfering signal or signals to an acceptable level; they rarely eliminate them altogether. Consequently, it often pays to raise signal levels, just to improve the signal-to-interference ratio. Also, it is important to realize that some environments are much worse than others; an instrument that works just dandy on the bench may perform miserably on location. Some environments worth avoiding are those (a) near a radio or television station (RF interference), (b) near a subway (impulsive interference and powerline garbage), (c) near high-voltage lines (radio interference, frying sounds), (d) near motors and elevators (powerline spikes), (e) in a building with triac lamp dimmers and heater controllers (powerline spikes), (f) near equipment with large transformers (magnetic pickup), and (g) near arc welders (unbelievable pickup of all sorts). Herewith a gathering of advice, techniques, and black magic.

B. Signals coupled through inputs, outputs, and powerline

The best bet for powerline noise is to use a combination of RF line filters and transient suppressors on the ac powerline. You can achieve 60 dB or better attenuation of interference above a few hundred kilohertz this way, as well as effective elimination of damaging spikes.

Inputs and outputs are more difficult, because of impedance levels and the need to couple desired signals that may lie in the frequency range of interference. In devices like audio amplifiers you can use lowpass filters on inputs *and outputs* (much interference from nearby radio stations enters via the speaker wires, acting as antennas). In other situations shielded lines are often necessary. Low-level signals, particularly at high impedance levels, should always be shielded. So should the instrument cabinet.

C. Capacitive coupling

Signals within an instrument can get around handsomely via electrostatic coupling: some point within the instrument has a 10 volt signal jumping around; a high-Z input nearby does some sympathetic jumping, too. The best things to do are to reduce the capacitance between the offending points (move them apart), add shielding (a complete metal enclosure, or even close-knit metal screening, eliminates this form of coupling altogether), move the wires close to a ground plane (which "swallows" the electrostatic fringing fields, reducing coupling enormously), and lower the impedance levels at susceptible points, if possible. Op-amp outputs don't pick up interference easily, whereas inputs do. More on this later.

D. Magnetic coupling

Unfortunately, low-frequency magnetic fields are not significantly reduced by metal enclosures. A dynamic microphone, audio recorder, low-level amplifier, or other sensitive circuit placed in close proximity to an instrument with a large power transformer will display astounding amounts of 60 Hz pickup. The best therapy here is to avoid large enclosed areas within circuit paths and try to keep the circuit from closing around in a loop. Twisted pairs of wires are quite effective in reducing magnetic pickup, because the enclosed area is small, and the signals induced in successive twists cancel.

When dealing with very low level signals, or devices particularly susceptible to magnetic pickup (tape heads, inductors, wire-wound resistors), it may be desirable to use magnetic shielding. "Mu-metal shielding" is available in preformed pieces and flexible sheets. If the ambient magnetic field is large, it is best to use shielding of high permeability (high mu) on the inside, surrounded by an outer shield of lower permeability (which can be ordinary iron, or low-mu shielding material), to prevent magnetic saturation in the inner shield. Of course, moving the offending source of the magnetic field is often a simpler solution. It may be necessary to exile large power transformers to the hinterlands, so to speak. Shielded inductors (e.g., pot cores) are configured so that the magnetic material (usually ferrite) provides a closed magnetic path. Toroidal transformers have smaller fringing fields than the standard frame types, and a single reverse turn (or arranging the winding pattern to return back to where it begins) cancels the one-turn effective area of the toroid's winding.

E. Circuit boards and cables

Both capacitive and magnetic coupling occurs, also, between traces on circuit boards or between line pairs in cables and ribbons. Magnetic coupling is sometimes called *inductive* coupling, to distinguish it from capacitive coupling. This business of "crosstalk" is a rich subject, dealt with in good detail in references such as Johnson and Graham's *Handbook of Black Magic*.[146] Perhaps unintiutively, it turns out that the magnitudes of inductive and capacitive crosstalk are generally comparable, but they behave differently as seen at the two ends of a pair of closely spaced lines: forward-going crosstalk is proportional to the signal's slew rate, but the capacitive and inductive components are of opposite sign and tend to cancel. For reverse-going crosstalk the coupled signal looks like a flat-topped pulse (of width equal to the round-trip travel time), with capacitive and inductive components reinforcing. If the driving impedance does not match the line's characteristic impedance (see Appendix H), that "near-end crosstalk" (aka *NEXT*) signal will reflect and become forward going, contributing to (and often dominating) the "far-end crosstalk" (or *FEXT*).

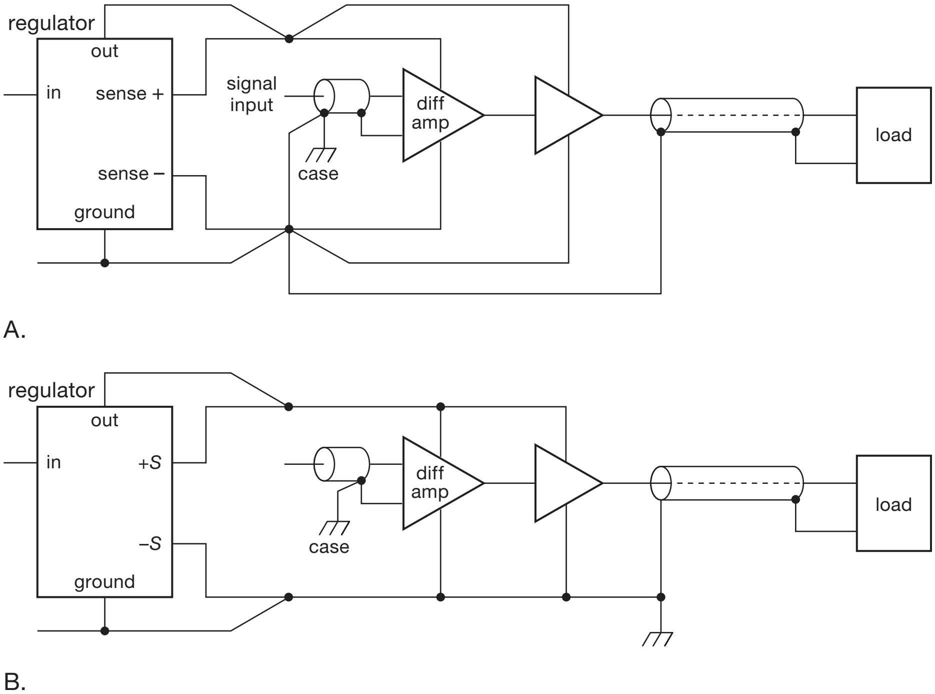

Figure 8.124. Ground paths for low-level signals. A. Right. B. Wrong.

See also additional discussion in Chapter 12 (§12.9, “Digital signals and long wires”).

F. Radiofrequency coupling

RF pickup can be particularly insidious, because innocent-looking parts of the circuit can act as resonant circuits, displaying enormous effective cross-section for pickup. Aside from overall shielding, it is best to keep leads short and avoid loops that can resonate. Ferrite beads may help, if the problem involves very high frequencies. Doing good deeds can sometimes create havoc. For example, you may want to use several ceramic capacitors to improve power-supply bypassing; but in combination with the inductance of the connecting supply rails they can form a lovely parasitic tuned circuit somewhere in the HF to VHF region (tens to hundreds of megahertz), nudged by active circuits into ringing and even oscillation.[147]

8.16.2 Signal grounds

Ground leads and shields can cause plenty of trouble, and there is a lot of misunderstanding on this subject. The problem, in a nutshell, is that currents you forgot about that are flowing through a ground line can generate a signal seen by another part of the circuit sharing the same ground. The technique of a ground “mecca” (a common point in the circuit to which all ground connections are tied) is often seen, but it’s a crutch; with a little understanding of the problem you can handle most situations intelligently.

A. Common grounding blunders

Figure 8.124 shows a common situation. Here a low-level amplifier and a high-current driver are in the same instrument. The first circuit is done correctly: both amplifiers tie to the supply voltages at the regulator (right at the sensing leads), so *IR* drops along the leads to the power stage don’t appear on the low-level amplifier’s supply voltages. In addition, the load current returning to ground does not appear at the low-level input; no current flows from the ground side of the low-level amplifier’s input to the circuit mecca (which might be the connection to the case near the BNC input connector).

In the second circuit there are two blunders. Supply-voltage fluctuations caused by load currents at the high-level stage are impressed on the low-level supply voltages. Unless the input stage has very good supply rejection, this can lead to oscillations. Even worse, the load current

[147] One cure is to include some aluminum electrolytic capacitors – their lossy series resistance damps the resonance.

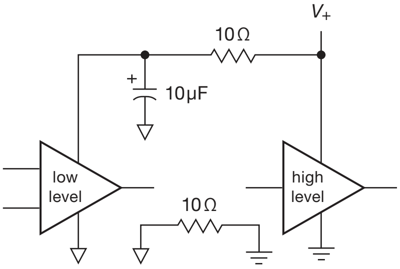

Figure 8.125. Decoupling the dc rail supplying low-level stages.

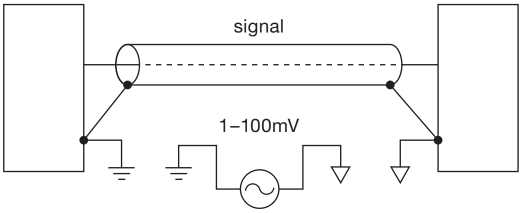

Figure 8.126. When connecting signals between instruments, you may see 100 mV (or more) differences (at powerline frequency) between their local grounds, even when they are bridged as shown.

returning to the supply makes the case "ground" fluctuate with respect to power-supply ground. The input stage ties to this fluctuating ground, a very bad idea. The general idea is to look at where the large signal currents are flowing and make sure their *IR* drops don't wind up at the input. In some cases it may be a good idea to decouple the supply voltages to the low-level stages with a small *RC* network (Figure 8.125). In stubborn cases of supply coupling it may pay to put a zener or 3-terminal regulator on the low-level-stage supply for additional decoupling.

8.16.3 Grounding between instruments

The idea of a controlled ground point within one instrument is fine, but what do you do when a signal has to go from one instrument to another, each with its own idea of "ground"? Some suggestions follow (and see also the extensive treatment of the transmission of *digital* signals in §12.9).

A. High-level signals

If the signals are several volts, or large logic swings, just tie things together and forget about it (Figure 8.126). The voltage source shown between the two grounds represents the variations in local grounds you'll find on different powerline outlets in the same room or (worse) in different rooms or buildings. It consists of some 60 Hz voltage, harmonics of the line frequency, some radiofrequency signals (the powerline makes a good antenna), and assorted spikes and other garbage. If your signals are large enough, you can live with this.

B. Small signals and long wires

For small signals this situation is intolerable, and you will have to go to some effort to remedy the situation. Figure 8.127 shows some ideas. In the first circuit, a coaxial shielded cable is tied to the case and circuit ground at the driving end, but it is kept isolated from the case at the receiving end (use a Bendix 4890-1 or Amphenol 31-010 insulated BNC connector). A differential amplifier is used to buffer the input signal, thus ignoring the small amount of "ground signal" appearing on the shield. A small resistor and bypass capacitor to ground is a good idea to limit ground swing and prevent damage to the input stage. The alternative receiver circuit in Figure 8.127A shows the use of a "pseudodifferential" input connection for a single-ended amplifier stage (which might, for example, be a standard noninverting op-amp connection, as indicated). The 10 Ω resistor between amplifier common and circuit ground is large enough to let the signal source's reference ground set the potential at that point, because it is much larger than the impedance of the source's ground. Any noise present at that node, of course, appears also at the output. However, this becomes unimportant if the stage has sufficiently high voltage gain, G_V, because the ratio of desired signal-to-ground noise is reduced by G_V. Thus, although this circuit isn't truly differential (with infinite CMRR), it works well enough (with effective CMRR $= G_V$). This pseudo-differential ground-sensing trick can be used also for low-level signals *within* an instrument, when ground noise is a problem.

In the second circuit (Figure 8.127B), a shielded twisted pair is used, with the shield connected to the case at both ends. Because no signal travels on the shield, this is harmless. A differential amplifier is used as before on the receiving end. If logic signals are being transmitted, it is a good idea to send a differential signal (the signal and its inverted form), as indicated. Ordinary differential amplifiers can be used as input stages, or, if the ground interference is severe, special "isolated amplifiers" are available from manufacturers like Analog Devices, Inc. and TI/Burr–Brown. The latter permit kilovolts of common-mode signals. So do optoisolator modules (§12.7), a handy solution for digital signals in some situations.

At radio frequencies, transformer coupling offers a convenient way of removing common-mode signal at the

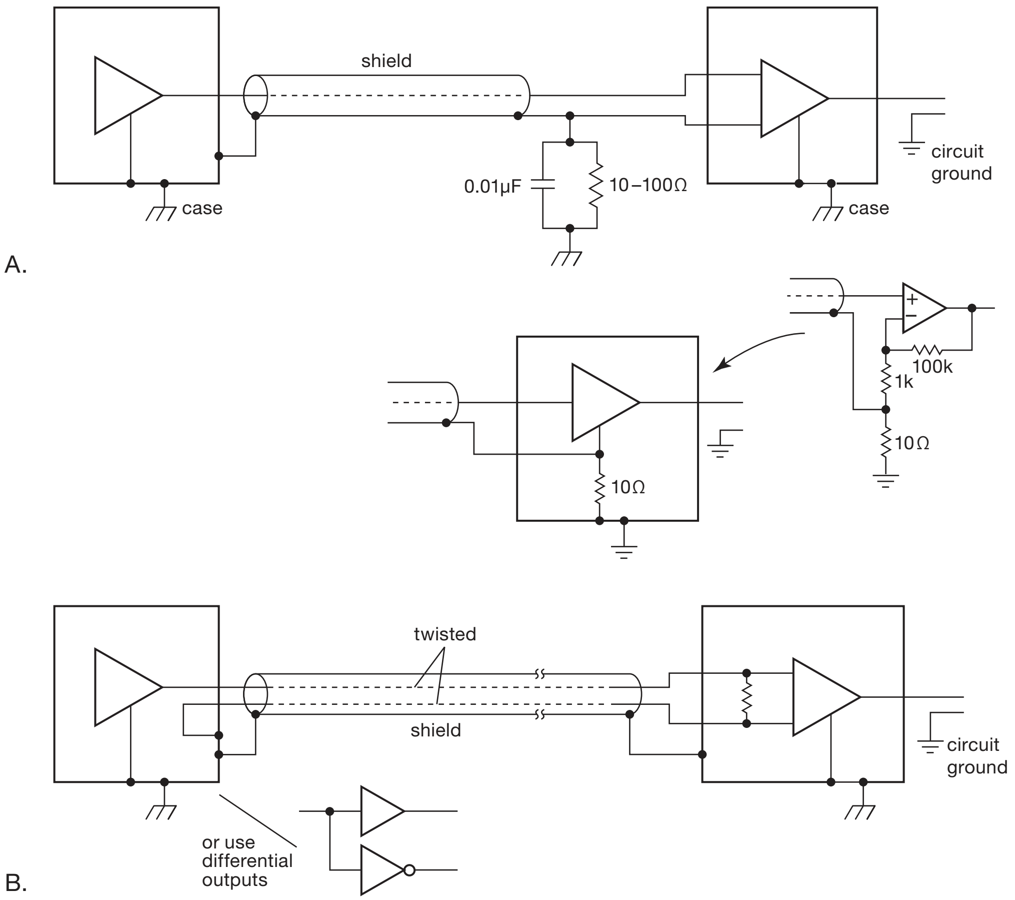

Figure 8.127. Ground connections for low-level signals through shielded cables.

receiving end; this also makes it easy to generate a differential bipolarity signal at the driving end. Transformers are popular in audio applications as well, although they tend to be bulky and lead to some signal degradation, as described in §8.10.

For very long cable runs (measured in miles) it is useful to prevent large ground currents flowing in the shield at radio frequencies. Figure 8.128 suggests a method. As before, a differential amplifier looks at the twisted pair, ignoring the voltage on the shield. By tying the shield to the case through a small inductor, the dc voltage is kept small while preventing large radiofrequency currents. This circuit also shows protection circuitry to prevent common-mode excursions beyond ±10 V.

Figure 8.129 shows a nice scheme to save wires in a multiwire cable in which the common-mode pickup has to be eliminated. Because the signals all suffer the same common-mode pickup, a single wire tied to ground at the sending end serves to cancel the common-mode signals on each of the *n* signal lines. Just buffer its signal (with respect to ground at the receiving end) and use it as the comparison input for each of *n* differential amplifiers looking at the other signal lines.

The preceding schemes work well to eliminate common-mode interference at low to moderate frequencies, but they can be ineffective against radiofrequency interference, owing to poor common-mode rejection in the receiving differential amplifier.

One possibility here is to wrap the whole cable around a ferrite toroid (Figure 8.130). That increases the series inductance of the whole cable, raising the impedance to common-mode signals of high frequency and making it easy to bypass them at the far end with a pair of small bypass capacitors to ground. The equivalent circuit shows why this works without attenuating the differential signal: you have a series inductance inserted into both signal lines

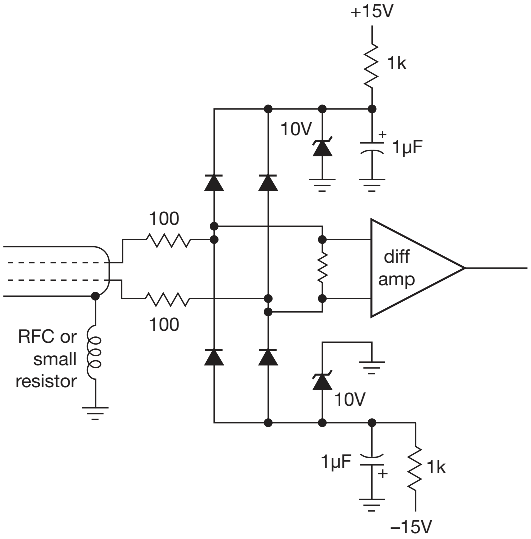

Figure 8.128. Input-protection circuits for use with very long lines.

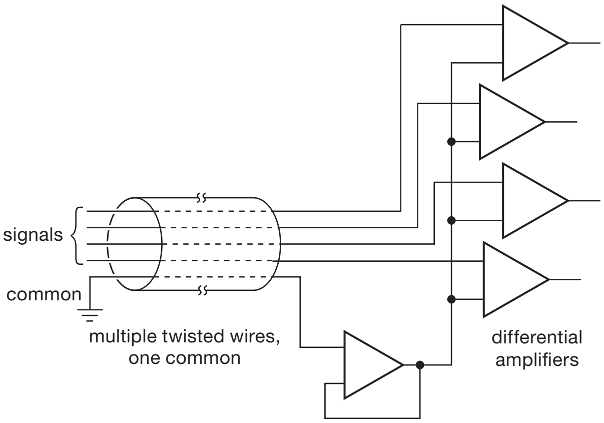

Figure 8.129. Common-mode interference rejection with long multiwire cables.

and the shield, but they form a tightly coupled transformer of unit turns ratio, so the differential signal is unaffected. This can be thought of as a "1:1 transmission-line transformer" (see §13.10 in the second edition of this book).

C. Floating signal sources

The same sort of disagreement about the voltage of "ground" at separated locations enters in an even more serious way at low-level inputs, just because the signals are so small. An example is a magnetic tape head or other signal transducer that requires a shielded signal line. If you ground the shield at both ends, differences in ground potential will appear as signal at the amplifier input. The best approach is to lift the shield off ground *at the transducer* (Figure 8.131).

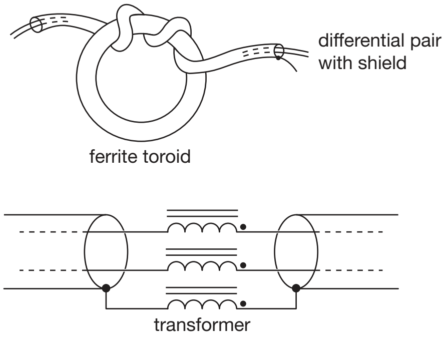

Figure 8.130. Wrapping a coaxial or multi-wire cable around a ferrite core for high-frequency common-mode suppression.

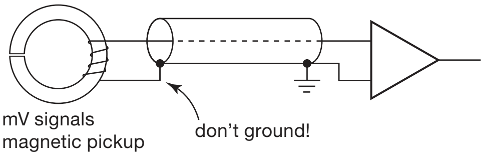

Figure 8.131. Preventing sneak ground currents: tie the shield to ground at the receiving end only.

D. Isolation amplifiers

Another solution to serious ground-contention problems is the use of an "isolation amplifier." Isolation amplifiers (isoamps) are commercial devices intended for coupling an analog signal (with bandwidth clear down to dc) from a circuit with one ground reference to another circuit with a completely different ground (Figure 8.132). In fact, in some bizarre situations the "grounds" can differ by many

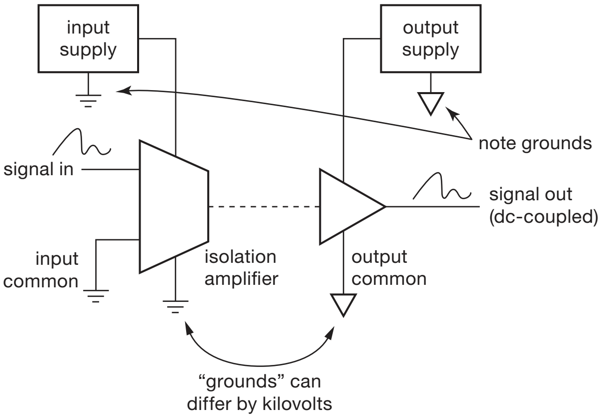

Figure 8.132. Isolation amplifier concept.

kilovolts! Isolation amplifiers are mandatory for medical electronics in which electrodes are applied to human subjects, in order to isolate completely those connections from any instrument circuits powered directly from the ac powerlines. Currently available isolation amplifiers use one of three methods.

1. Transformer isolation of a high-frequency carrier signal, which is either frequency modulated or pulse-width modulated with the relatively low bandwidth signal (dc to 10 kHz or so) to be isolated (Figure 8.133). This method is used in isolation amplifiers from Analog Devices, Inc. Transformer-isolated iso-amps have the convenient feature of requiring dc power only on one side; they all include a transformer-coupled dc-to-dc converter in the package. Transformer-coupled iso-amps can isolate up to 1.5 kV and have typical bandwidths of 5 kHz, though some units (e.g., the AD215) go to 120 kHz. The latter has 0.015% maximum nonlinearity, and costs about $80 in single-piece quantities.
2. Optically coupled signal transmission via an LED at the sending end and photodiode at the receiving end. This technique is typified by the ACPL-C79 series from Avago. These devices use a delta–sigma modulation and demodulation scheme, and achieve a bandwidth from dc to 200 kHz. This series is inexpensive (about $5 in modest quantity), with maximum nonlinearity of 0.06%. An interesting alternative, which involves no clocking signal or carrier frequency, is to couple an LED at the sending end to a photodiode at the receiving end. To achieve good linearity you use feedback from a second matched photodiode at the transmitting side that receives light from the same LED, thus cancelling nonlinearities in both LED and photodiode (Figure 8.134; see also Figure 12.90 in Chapter 12). Some additional analog optoisolation techniques are discussed in §12.7.4, and related digital isolated couplers in §12.7.2.

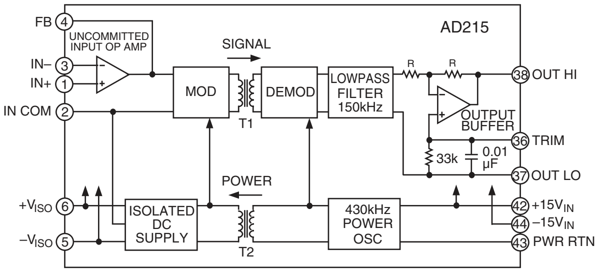

Figure 8.133. AD215 transformer-coupled isolation amplifier. (Adapted from the AD215 datasheet, courtesy Analog Devices, Inc.)

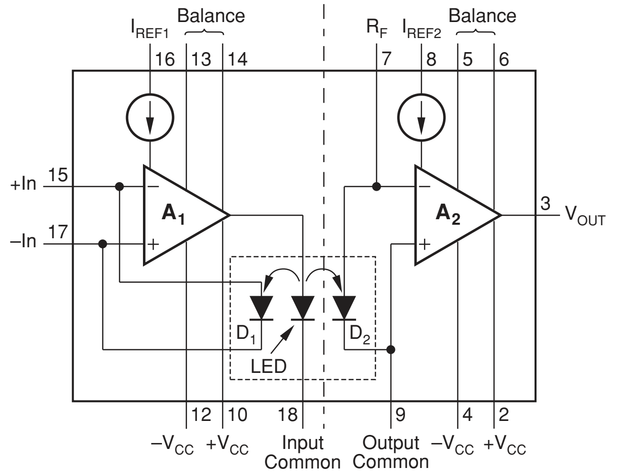

Figure 8.134. Unmodulated optical coupling eliminates clocking noise, with feedback from a matched detector to achieve reasonable linearity. (Adapted from the ISO100 datasheet, courtesy of Texas Instruments.)

3. Capacitively coupled isolation of a high-frequency carrier signal, which is modulated with the signal to be isolated (Figure 8.135). This technique is typified by the ISO122 and ISO124 from TI/Burr–Brown (Figure 8.136). There is no feedback, as with transformer isolation, but for most models you need power supplies at both ends. This usually isn't a problem, as you are likely to have electronics at both ends, generating and using the signal. If not, you can get an isolated dc–dc converter to use with the iso-amp. The ISO124 isolates to 1.5 kV, with 0.01% maximum nonlinearity and

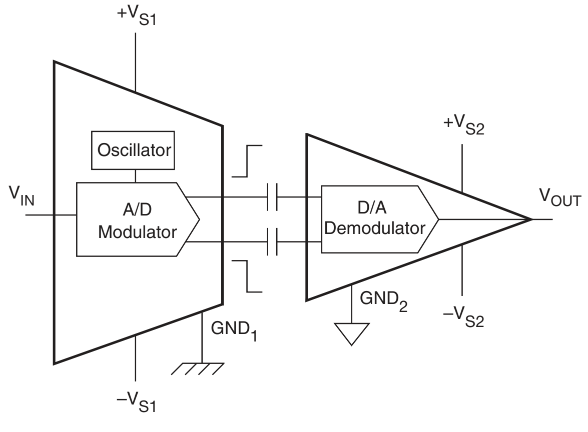

Figure 8.135. Capacitively-coupled isolation amplifier. (Adapted from the Burr–Brown Application Bulletin AB-047, courtesy of Texas Instruments.)

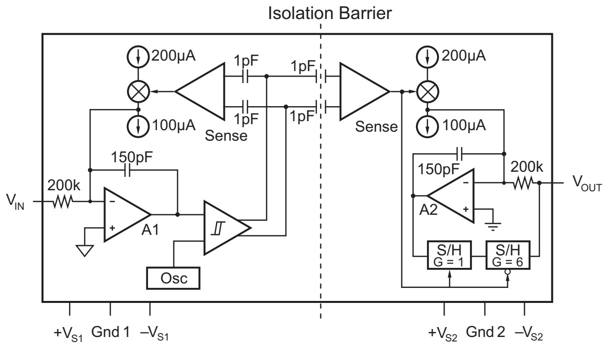

Figure 8.136. ISO124 capacitively-coupled isolation amplifier. (Adapted from the ISO124 datasheet, courtesy of Texas Instruments.)

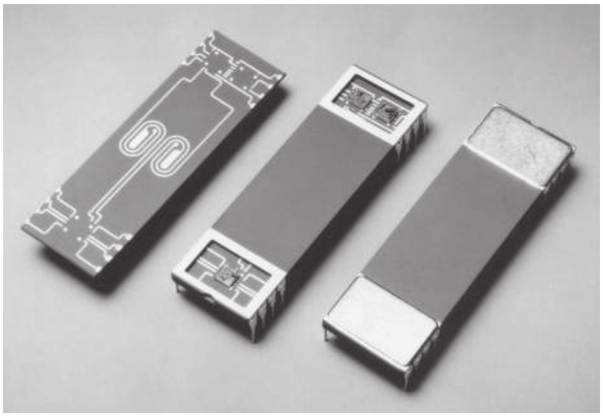

Figure 8.137. Burr–Brown (TI) ISO106 isolation amplifier, courtesy of Texas Instruments.

50 kHz bandwidth; it costs $18 in single-piece quantities. Figure 8.137 shows nicely the innards of one of these capacitively coupled devices.

These isolation amplifiers are all intended for *analog* signals. The same sorts of ground problems can arise in digital electronics, where the solution is simple and effective: optically coupled isolators ("optoisolators") are available, with plenty of bandwidth (10 MHz or more), isolation of several kilovolts, and low cost (a dollar or two). They are discussed extensively in Chapter 12.

A caution: isolation amplifiers can introduce noise of their own, particularly those that use some form of signal modulation (which is most of them!). For the latter you've got a residue of the modulating clock frequency; and all isolation amplifiers (whether clocked or not) introduce broadband noise of the usual sort. One remedy for clock noise is to add an analog lowpass filter at the output of the receiving side. For more detail see the helpful application document "Noise Sources in Applications Using Capacitive Coupled Isolated Amplifier" (Application Bulletin SBOA028, available at the Texas Instruments website, www.ti.com).

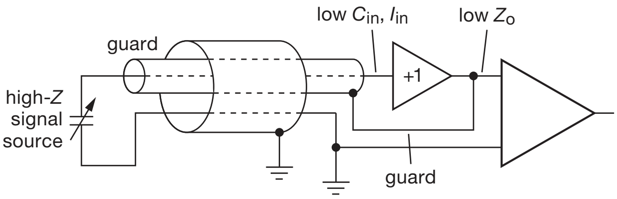

Figure 8.138. Using a guard to raise input impedance.

E. Signal guarding

A closely related issue is signal *guarding*, an elegant technique to reduce the effects of input capacitance and leakage for small signals at high impedance levels. You may be dealing with signals from a micro-electrode or a capacitive transducer, with source impedances of hundreds of megohms. Just a few picofarads input capacitance can form a lowpass filter, with rolloffs beginning at a few hertz! In addition, the effects of insulation resistance in the connecting cables can easily degrade the performance of an ultra-low input current amplifier (bias currents less than a picoamp) by orders of magnitude. The solution to both these problems is a *guard electrode* (Figure 8.138).[148]

A follower bootstraps the inner shield, effectively eliminating leakage current and capacitive attenuation by keeping zero voltage difference between the signal and its surroundings. An outer grounded shield is a good idea, to keep interference off the guard electrode; the follower has no trouble driving that capacitance and leakage, of course, given its low output impedance.

You shouldn't use these tricks more than you need to; it would be a good idea to put the follower as close to the signal source as possible, guarding only the short section of cable connecting them. Ordinary shielded cable can then carry the low-impedance output signal out to the remote amplifier.[149]

F. Coupling to outputs

Ordinarily the output impedance of an op-amp is low enough that you don't have to worry about capacitive signal coupling. In the case of high-frequency or fast-switching

[148] We saw this earlier, in §8.11.9.

[149] Discussed in more detail, in connection with high-impedance microelectrodes, in §15.08 of the second edition of this book.

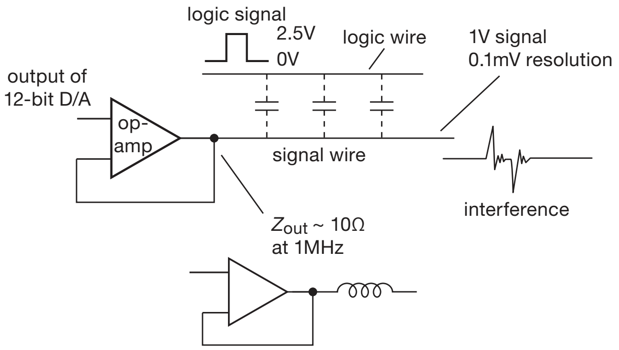

Figure 8.139. Digital cross-coupling interference with linear signals.

interference, however, you have just cause for alarm, particularly if the desired output signal involves some degree of precision. Consider the example in Figure 8.139. A precision signal is buffered by an op-amp and passes through a region containing digital logic signals jumping around with slew rates of 0.5 V/ns. The op-amp's closed-loop output impedance rises with frequency, typically reaching values of 10 to 100 Ω or more at 1 MHz (see §5.8.3). How large a coupling capacitance is permissible, to keep coupled interference less than the analog signal's resolution of 0.1 mV? The surprising answer is a maximum of 0.02 pF.

There are some solutions. The best thing is to keep your small analog waveforms out of the reach of fast-switching signals. A moderate bypass capacitor across the op-amp's output (with perhaps a small series resistor, to maintain op-amp stability) will help, although it degrades the slew rate. You can think of the action of this capacitor as lowering the frequency of the coupled charge bundles to the point where the op-amp's feedback can swallow them. A few hundred picofarads to ground will adequately stiffen the analog signal at high frequencies (think of it as a capacitive voltage divider). Another possibility is to use a low-impedance buffer such as the LT1010, or a power op-amp such as the LM675. Don't neglect the opportunity to use shielding, twisted pairs, and proximity to ground planes to reduce coupling.

Additional Exercises for Chapter 8

Exercise 8.10. Prove that SNR $= 10\log_{10}(v_s^2/4kTR_s) -$ NF(dB) (at R_s).

Exercise 8.11. A 10 μV (rms) sinewave at 100 Hz is in series with a 1M resistor at room temperature. What is the SNR of the resultant signal (a) in a 10 Hz band centered at 100 Hz, and (b) in a 1 MHz band going from dc to 1 MHz?

Exercise 8.12. A transistor amplifier using a 2N5087 is operated at 100μA collector current and is driven by a signal source of impedance 2000 Ω. (a) Find the noise figure at 100 Hz, 1 kHz, and 10 kHz. (b) Find the SNR (at each of listed frequencies) for an input signal of 50 nV (rms) and an amplifier bandwidth of 10 Hz.

Exercise 8.13. Measurements are made on a commercial amplifier (with Z_{in} =1M) in order to determine its equivalent input noise e_n and i_n at 1 kHz. The amplifier's output is passed through a sharp-skirted filter of bandwidth 100 Hz: a 10 μV input signal results in a 0.1 V output. At this level the amplifier's noise contribution is negligible. With the input shorted, the noise output is 0.4 mV rms. With the input open, the noise output rises to 50 mV rms. (a) Find e_n and i_n for this amplifier at 1 kHz. (b) Find the noise figure of this amplifier at 1 kHz for source resistances of 100 Ω, 10k, and 100k.

Exercise 8.14. Noise measurements are made on an amplifier using a calibrated noise source whose output impedance is 50 Ω. The generator output must be raised to 2 nV/$\sqrt{\text{Hz}}$ in order to double the output noise power of the amplifier. What is the amplifier's noise figure for a source impedance of 50 Ω?

Exercise 8.15. Your boss tells you she's working on a supersensitive pressure-change instrument that uses a diaphragm-type pressure sensor with a 350 Ω strain-gage bridge. She tells you there's a 10 Hz measurement bandwidth, either from a filter or an integrating ADC, and she asks you to select an op-amp for the input stage. First consider auto-zero amplifiers (see §5.11 Table 5.6, and Figure 5.54). (a) Is a bipolar op-amp better than a JFET op-amp? Hint, don't forget i_n. (b) The bridge has a standard 2 mV/V full-scale output, and your boss is planning a 2.5 V excitation voltage. What will be your system's noise floor as a fraction of full scale? (c) Should you suggest to your boss that she consider running the ADC faster and averaging the results? (d) A fellow engineer (who suffers the indignities of the same boss) suggests that a silicon strain-gauge pressure sensor might be better, because they have higher output, 2.5 mV/V. You find sensors with R_s=1.4 kΩ to 3 kΩ. Choose a good op-amp for this case, and calculate the system performance.

Exercise 8.16. Digital oscilloscope input stage (*this is a difficult problem!*). Your assignment is to design an input stage for a low-cost "oscilloscope app," to be powered by a single +3.3 V supply from the mobile device's lithium-ion battery. The 'scope's architecture calls for attenuating its probe signals to 1 mV per division via a range switch, then amplifying and digitizing this signal, with a goal of peak-to-peak noise no more than 5% of a division. The screen shows ten vertical divisions, and you need to be able to shift it vertically through ±5× over-range, plus there's a 40 mV budget for "software offset." (a) What is the total input range, and what is your rms input noise level goal? (b) If a 14-bit ADC is used, what is the LSB resolution?

An ADS7946 14-bit ADC has been selected; it draws 0.5 mA from +3.3V when converting at 100 kSPS and meets cost goals at

$6 in qty 1k. (c) What is a reasonable ADC input voltage range, and how much gain will you need to provide?

The ADC is capable of 2 Msps, for a 1 MHz bandwidth, but there are plans to use a faster ADC in a later revision; hence your design-spec bandwidth is 10 MHz. (d) What is your spectral noise-density goal?

Standard oscilloscopes are dc coupled, have a 1 MΩ‖15 pF input impedance, and do not exhibit visible dc shifts with source impedance. (e) Create a design that meets all your specs. Low power consumption is a big plus.

Review of Chapter 8

An A-to-Q summary of what we have learned in Chapter 8. This summary reviews basic principles and facts in Chapter 8, but it does not cover application circuit diagrams and practical engineering advice presented there.

¶A. Noise Basics.

See §8.1. The random noise you care about is characterized by its *density* (rms noise amplitude in a 1 Hz band of frequency), §8.2.1. Noise *voltage* density is called e_n, and has units like nV/$\sqrt{\text{Hz}}$. Likewise, the symbol for noise *current* density is i_n, with units like fA/$\sqrt{\text{Hz}}$. A noise current at an amplifier's input flows through the signal's source resistance, creating its own noise voltage density $e_n = i_n R_s$. Independent noise sources combine as the square root of the sum of their squares: $e_{n(\text{total})} = \sqrt{e_{n1}^2 + e_{n2}^2 + \cdots}$. If a noise source is uniform over frequency, it's called "white noise," and the rms noise voltage (as contrasted with noise voltage *density*) contained within a bandwidth B is just $v_n = e_n\sqrt{B}$. Knowing that, you can go to Table 8.3a–c on page 522, which lists e_n and i_n for a wide selection of op-amps, to figure out how much noise is added in an op-amp amplifier stage. Compare this with the input signal's noise level; or multiply by the amplifier's voltage gain and, voilà, you've got the output noise voltage density.

¶B. Noise Spectra.

Whatever its source, noise density can vary with frequency, see §8.1. White noise (e_n constant over frequency, up to some cutoff) is common, for example a resistor's Johnson noise (¶E, below) or the shot noise fluctuations of a steady current (¶F, below). Also prevalent is "$1/f$ noise," sometimes called flicker noise, or pink noise; it is characterized by a $1/f$ *power* spectrum (equal power per octave, or per decade), thus a voltage noise density $e_n(f)$ proportional to $1/\sqrt{f}$. Most electronic circuits (and many other physical phenomena) exhibit $1/f$ noise, often characterized by the "$1/f$ corner frequency" at which the $1/f$ noise component is equal to the white noise component. Finally, the term *red noise* refers to a noise density e_n proportional to $1/f$ (thus a $1/f^2$ power spectrum); see for example Figure 8.95. The rms noise voltage v_n in some bandwidth B (extending from f_1 to f_2) is gotten by integrating $e_n^2(f)$ over frequency, then taking the square root: $v_n = \sqrt{v_n^2}$, where $v_n^2 = \int_{f_1}^{f_2} e_n(f)^2\, df$. For a white spectrum this reduces to the simple $v_n = e_n\sqrt{B}$.

Actual circuit noise need not conform to these idealized spectra, which, however, are useful in characterizing the noise of real devices over chosen regions of frequency; see for example Figure 8.107. In real life, spectra may show a noise "shelf" (e.g., curve Z in Figure 8.52), or a noise peak (e.g., Figures 5.52 or 8.72).

¶C. Noise Amplitude Distribution.

Quite apart from its spectrum, one can characterize the amplitude distribution of noise; that is, the distribution of instantaneous amplitudes sampled in time. Most noise sources obey a Gaussian distribution (Figure 8.2), a fact that is of lesser concern than the important properties of noise spectrum and amplitude. A notable exception is *burst* noise (also called *popcorn* noise, *bistable* noise, or *telegraph* noise), which jumps randomly between several voltage levels (Figure 8.5). Burst noise was prominent in the early decades of semiconductor technology, but it has been largely banished in contemporary products. One suspects some low-level remnants remain, though, as evidenced for example in a comparison of the measured burst-noise spectrum of Figure 8.6 with the measured JFET noise spectra of Figure 8.51.

¶D. Sources of Noise.

The dominant sources of noise in electronic circuits (detailed in paragraphs ¶E–H below) are:

Johnson noise. Thermal fluctuations generate a noise voltage in a resistor.

Shot Noise. The discrete nature of electric charge creates fluctuations in a "steady" current.

Excess Noise. Various semiconductor phenomena contribute additional noise (often $\sim 1/f$ in power density) at low frequencies.

Amplifier Noise. Transistors (both BJTs and FETs) add noise, traceable to the above sources (e.g., Johnson noise of the base resistance $r_{bb'}$, shot noise of the collector current, and excess noise terms).

¶E. Johnson Noise.

Thermal fluctuations cause a self-generated noise voltage across the terminals of an unloaded resistor; this is *Johnson noise*, of (white-) noise voltage density $e_n = \sqrt{4k_B TR}$, where k_B is Boltzmann's constant. Don't bother remembering the latter; just remember the value of e_n for a round-number resistance (we like 1.28 nV/$\sqrt{\text{Hz}}$ for $R = 100\,\Omega$, or 4 nV/$\sqrt{\text{Hz}}$ for $R = 1\text{k}\Omega$), and scale by the square root of R. If short-circuited, a resistor generates a Johnson noise current $i_n = e_n/R$; that is, $i_n = \sqrt{4k_B T/R}$. See the graph in Figure 8.1 and the mini-table in §8.1.1.

Johnson noise is a fundamental physical phenomenon, and does not depend on the particular construction of the resistor (or resistance). However, when a steady current flows through a resistance, you may get some additional noise current (which you can think of as due to resistance fluctuations), generally with something approximating a $1/f$ power spectrum. This *excess noise* varies with resistor construction, being worst in a granular "carbon composition" type, but insignificant in a wirewound resistor.

¶F. Shot Noise.

The finiteness of the charge quantum (electron charge) causes statistical fluctuations even in a steady current. If the charges act independently, the (white-) noise current density is $i_\mathrm{n}=\sqrt{2qI_\mathrm{dc}}$, where q is the electron charge (1.6×10^{-19} coulombs). As with Johnson noise, it's handy to simply remember the value of i_n for a round-number dc current (e.g., $18\,\mathrm{pA}/\sqrt{\mathrm{Hz}}$ for $I_\mathrm{dc}=1\,\mathrm{mA}$), and scale by the square root of current.[150] See the mini-table in §8.1.2. *Important*: the shot-noise formula assumes that the charge carriers act independently; the current noise is greatly reduced if there are long-range correlations, as for example in a metallic conductor.

¶G. BJT Noise.

See §8.3. The primary noise terms of a BJT are an input noise voltage e_n in series with the base, combined with an input noise current i_n injected at the base (Figure 8.9). The amplifier's input-referred noise (i.e., ignoring the Johnson noise of the signal source's R_s) is then $e_{\mathrm{a(rms)}}=[e_\mathrm{n}^2+(R_\mathrm{s}i_\mathrm{n})^2]^{\frac{1}{2}}$. As you increase the collector current, e_n decreases and i_n increases, so there's an operating-current tradeoff. The ratio $e_\mathrm{n}/i_\mathrm{n}$ has units of resistance; it's called the *noise resistance*, and it's a useful quantity in circuit design; see ¶I below. Table 8.1a lists measured values of e_n for many low-noise BJT candidates.

Voltage noise, e_n. In the simplest model, the noise voltage term arises from two sources: collector shot-noise current flowing through the transistor's emitter resistance r_e, and Johnson noise in the transistor's internal base resistance $r_{\mathrm{bb}'}$. Combining these independent noise terms (eq'n 8.20), we get the total input-referred squared noise voltage, $e_\mathrm{n}^2=2qI_\mathrm{C}r_\mathrm{e}^2+4kTr_{\mathrm{bb}'}=4kT(r_\mathrm{e}/2+r_{\mathrm{bb}'})$. Put another way, the input noise voltage is equal to the combined Johnson noise of the transistor's base resistance ($r_{\mathrm{bb}'}$) and a fictional resistance equal to half its intrinsic emitter resistance ($r_\mathrm{e}/2$). The latter is inversely proportional to collector current, so a BJT's noise voltage decreases with increasing I_C, ultimately limited by its internal base resistance; see for example Figure 8.12. Thus to minimize BJT *voltage* noise, choose a part with a low $r_{\mathrm{bb}'}$, and operate at relatively high collector current. A more refined model includes the effects of base current shot noise, important at low frequencies and high collector currents; see Figure 8.11 and eq'n 8.24.

Current noise, i_n. The primary noise current term is shot noise in the dc base current, $i_\mathrm{n}=\sqrt{2qI_\mathrm{B}}$ (eq'n 8.21). Taking this term alone, you minimize BJT *current* noise by operating at low collector current. A more refined model includes a rising $\propto 1/\sqrt{f}$ noise current term at low frequencies, and a rising $\propto f$ noise current term at high frequencies caused by falling beta; see eq'n 8.22 and Figure 8.13.

¶H. JFET Noise.

See §8.6. The low-noise choice for signals of high source impedance are FETs, owing to their very low input current noise; JFETs are quieter than MOSFETs, and, unlike the latter, they are available as discrete small-signal parts (see Table 8.2).

Voltage noise, e_n. The dominant noise voltage term is Johnson noise in the channel resistance (eq'n 8.34), $e_\mathrm{n}^2\approx 4kT(\frac{2}{3}\frac{1}{g_m})$. Put another way, the noise voltage is equivalent to Johnson noise in a resistor of value $R=\frac{2}{3}\frac{1}{g_m}$; see Figure 8.46. To minimize JFET voltage noise, choose a JFET of high transconductance, and operate it at a relatively high drain current (note, however, that e_n falls slowly, only as the fourth root of I_D). As with BJTs, JFETs exhibit a rising $1/f$-like noise tail at low frequencies (Figure 8.52), with enormous variation among types, and manufacturers.

Current noise, i_n. At low frequencies the current noise is low, just shot noise of the gate (leakage) current: $i_\mathrm{n}=\sqrt{2qI_\mathrm{G}}$, see Figure 8.48. To frame this in numbers, a typical gate leakage current of 10 pA has a noise current density i_n of just $1.8\,\mathrm{fA}/\sqrt{\mathrm{Hz}}$, generating only $1.8\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ of noise voltage through a 1MΩ source resistance. That's down at the low end of transistor noise voltage, and it's completely dwarfed by the $128\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$ of Johnson noise produced by the source resistance itself. At rising frequencies there are some additional sources of input noise current. For example, in a transimpedance amplifier the gate input is a summing junction, at which the FET's *voltage* noise generates a noise current through

[150] Because both shot-noise current and Johnson-noise current go as $1/\sqrt{R}$, it's easy to derive this handy factoid: if the dc drop across a resistor is greater than 50 mV, shot noise dominates over the resistor's own Johnson noise.

the input capacitance, of magnitude $i_n = e_n \omega C_{in}$, see ¶N (below) and §8.11.

¶I. Noise Figure, Noise Temperature, and Noise Resistance.

See §8.2. Noise figure (NF) is a popular measure of added amplifier noise. It is the ratio (in dB) of the amplifier's output noise to the output of a noiseless amplifier of the same gain, each driven with a source resistance R_s: $\mathrm{NF}=10\log_{10}(1+v_n^2/4kTR_s)$, where v_n^2 is the mean squared noise voltage per hertz contributed by the amplifier when a noiseless (cold) resistor of value R_s connected across its input (see eq'n 8.13 and Figure 8.7). Another (and equivalent) way to quantify the excess noise contributed by an amplifier when driven by a signal of source resistance R_s is to state its noise *temperature* (T_n, see Figure 8.8 and eq'n 8.16).

An amplifier's noise figure (and its noise temperature) is minimum when driven by a signal of source resistance equal to its noise resistance, i.e., when $R_s = R_n = e_n / i_n$. Transistor datasheets sometimes provide contours of NF versus operating current and source resistance at a given frequency (e.g., Figure 8.22); for amplifiers where you have no control over operating current you'll find instead contours of NF versus frequency and source resistance (e.g., Figure 8.27). *Caution*: do not make the mistake of adding a series resistor to a signal of low source resistance to improve the noise figure (§8.4.6). Instead choose an amplifier that provides the noise figure you need with that input source resistance; in some situations (e.g., very low source resistance) you can use a signal transformer to make a lossless match to the amplifier's optimum source resistance.

¶J. Noise Sources and Measurements.

See §8.12. At low to moderate frequencies you can determine the noise properties of a transistor amplifier of known voltage gain by making two measurements of its rms output noise voltage in a known bandwidth, first with shorted input (to get e_n) and then with an appropriately chosen resistor across its input (to get i_n); see §8.12.1. Because you're measuring the integrated noise voltage, you need to know the equivalent noise bandwidth; see §8.13. A more general technique, applicable to amplifiers that require a matched source impedance (e.g., 50 Ω RF amplifiers) and insensitive to actual measurement bandwidth, is to drive the input with a calibrated noise source while observing the rms noise output; see §8.12.3. For frequencies up to a few tens of megahertz you can make your own "pseudorandom" noise source with a feedback shift register (§8.12.4A), or you can use an off-the-shelf noise source (a function generator, or noise diode; see §8.12.4) for frequencies well up into the gigahertz range. Resistor Johnson noise itself is the noise source for the "hot-load/cold-load" method, useful for low-noise microwave amplifiers; see eq'n 8.53 in §8.12.3.

¶K. Low-noise Design with Op-amps.

See §8.9. Just as with BJTs and FETs, op-amps exhibit input-referred voltage noise e_n and current noise i_n, whose magnitudes are characteristic of their input-stage transistor type. What's different, from a circuit designer's point of view, is that you don't have control over the stage's operating current. Instead you choose the op-amp type: FET-input for lowest i_n (for signals of high source impedance), BJT-input for lowest e_n (for signals of low source impedance). Among the FET-input types, the CMOS parts exhibit lower i_n but considerably higher e_n, compared with JFET types; the latter thus combine the best (nearly) of both worlds, see §8.9 the extensive Table 8.3 on page 522ff, and the noise plots in Figures 8.60, 8.61, and 8.63. A helpful graphical tool is the plot of *effective noise density* (v_n) versus source resistance, in which the op-amp's noise contributions (e_n, i_nR_s) are combined and plotted along with the source's Johnson noise, the latter setting a lower noise bound; i.e., $v_n^2 = 4kTR_s + e_n^2 + (i_nR_s)^2$, see Figure 8.58. Op-amp noise (with the exception of auto-zero op-amps) exhibits a typical rising $1/f$ low-frequency tail, characterized by a *corner frequency*, f_c. Auto-zero op-amps have no $1/f$ tail, but they have considerably higher broadband noise (both e_n and i_n), along with spectral noise peaks and chopping artifacts. Be sure to evaluate all noise sources in an op-amp design: a poor choice of component values may compromise the noise performance (e.g., Johnson noise from high-value resistors).

When choosing an op-amp for a low-noise application, begin by restricting your attention to op-amps that meet your other needs, such as accuracy, speed, power dissipation, supply voltage, input and output swing, and the like. Then choose among this subset, based upon their noise parameters.

¶L. Low-noise Design with BJTs.

See §8.5. Compared with op-amps, circuit design with discrete transistors gives you more control over noise parameters, but the price you pay is the additional labor associated with details of biasing and the like. A nice compromise is a *hybrid* approach, with a discrete front-end prepended to an op-amp, see §8.9.5. As with op-amps, a plot of total input noise versus source resistance is a useful graphical tool, see Figure 8.32 in §8.5.2, and Figure 8.41. The flexibility you get from control of operating current is illustrated nicely in Figure 8.33, where the curves shift downward with increasing collector current (lower e_n, higher i_n). Table 8.1a on page 501 lists datasheet and measured noise parameters for an extensive selection of low-noise BJTs; see also measured curves of current gain in Figure 8.39.

¶M. Low-noise Design with FETs.

See §8.6. You can't beat FETs for lowest input current noise, and for *discrete* amplifier circuits (or hybrid front-ends) you are limited to JFETs. In terms of device parameters, JFETs with large geometry have lowest e_n and highest g_m, but the large geometry means higher capacitance and leakage current (thus higher i_n), see Table 8.2 on page 516. If the JFET's input is a summing junction, the product of noise voltage and input capacitance creates a rising noise current $i_n = e_n \omega C_{in}$ (¶H, ¶N). As with BJTs, raising the operating current reduces a JFET's noise voltage, though not dramatically ($e_n \propto I_D^{-0.25}$). Watch out for some chronic problems with many JFETs: loose I_{DSS} and $V_{GS(th)}$ specs (a 5:1 range is typical), low transconductance, low output resistance, sharply rising gate current (thus i_n) at high temperatures and at elevated drain voltages (see §3.2.8), and poor low-frequency noise performance (see Figure 8.52).

¶N. Noise in Transimpedance Amplifiers.

See §8.11. Transimpedance amplifiers (TIA) convert an input current to an output voltage, with current feedback through a resistor R_f to the input summing junction, as introduced in §4.3.1, and elaborated in §*4x.3*. The noise sources are the amplifier's input i_n and e_n, and Johnson noise in R_f. Taking these in reverse order, the feedback resistor generates a Johnson noise *current* of $i_n = \sqrt{4kT/R_f}$; the amplifier's voltage noise e_n generates through the capacitance at the input a noise current of magnitude $e_n \omega C_{in}$, and through the feedback resistor a noise current of magnitude e_n/R_f; to these must be added the amplifier's own input noise current i_n. The choice of R_f is a compromise: the noise terms are minimized by choosing a high resistance, but, because of feedback stability requirements, the bandwidth suffers; see §§8.11.1, 8.11.4–8.11.6, and *4x.3*. These competing constraints can be mitigated with more complex configurations, used singly or in combination: a composite (2-stage) TIA (§8.11.8); or the use of a discrete first stage (i.e., a hybrid, §8.11.8A); or reduced capacitance by use of bootstrapping (§8.11.9) or a cascode connection (§8.11.10). The noise contribution of the feedback resistor can be eliminated entirely by replacing it with a *capacitor* (§8.11.11), forming an integrator; differentiating the output then recovers an output proportional to input current. Capacitor feedback is used in low-level detectors, and in the technique known as *correlated double-sampling*.

¶O. Lock-in Amplifiers.

See §8.14. For the detection of slowly-varying signals it is desirable to minimize added noise by narrowing the measurement bandwidth; and because of typical $1/f$ rising noise at low frequencies, amplification of signals should take place at frequencies above the $1/f$ corner frequency. In the elegant technique of *lock-in detection*, the slowly-varying signal is modulated (typically at a few hundred hertz), amplified, then demodulated with a phase detector, and finally lowpass filtered with a bandwidth appropriate to the original signal; see Figure 8.117.

¶P. Power-supply Noise.

See §8.15. All power supplies are not created equal, as stunningly illustrated by the measured spectra of Figure 8.123. When designing a dc supply, be sure to use a quiet voltage reference, and adhere to good low-noise design practice. Switchmode power supplies are inherently noisy, but attention to current paths and the use of filters can reduce conducted and radiated noise levels. With power supplies of any design, the addition of an outboard *capacitance multiplier* can reduce noise by 40 dB or more (Figure 8.122). See also the extensive treatment of dc power regulation in Chapter 9.

¶Q. Shielding and Grounding.

See §8.16. To paraphrase a cliché,[151] "One man's signal is another man's noise." In the real world, unintentionally coupled signals can easily overwhelm the subtle forms of noise that dominate this chapter. Mitigation techniques include wiring and trace layout (to minimize both capacitive and inductive coupling), raised signal levels, careful attention to grounding (both within and between instruments), shielding, filtering, balanced lines, common-mode chokes, guarding, signal transformers, and isolation amplifiers.

[151] "One man's trash is another man's treasure," perhaps deriving from Lucretius' 1st-century BCE epic poem *De Rerum Natura*, where he writes "Ut quod ali cibus est aliis fuat acre venenum" (What is food to one, is to others bitter poison).

VOLTAGE REGULATION AND POWER CONVERSION

CHAPTER 9

The control and conversion of power – power engineering – is a rich and exciting subfield of electrical engineering and electronic design. It encompasses applications ranging from high-voltage (kilovolts and upward) and high-current (kiloamperes and upward) dc transmission, transportation, and pulsing, all the way down to low-power fixed and portable (battery-operated) and micropower (energy-harvesting) applications. Perhaps of most interest to us in the context of circuit design; it includes the production of the voltages and currents needed in electronic circuit design.

Nearly all electronic circuits, from simple transistor and op-amp circuits up to elaborate digital and microprocessor systems, require one or more sources of stable dc voltage. The simple transformer–bridge–capacitor unregulated power supplies we discussed in Chapter 1 are not generally adequate because their output voltages change with load current and line voltage, and because they have significant amounts of powerline ripple (120 Hz or 100 Hz). Fortunately, it is easy to construct highly stable power supplies, by using negative feedback to compare the dc output voltage with a stable voltage reference. Such regulated supplies are in universal use and can be simply constructed with integrated circuit voltage-regulator chips, requiring only a source of unregulated dc input (from a transformer–rectifier–capacitor combination,[1] a battery, or some other source of dc input) and a few other components.

In this chapter we will see how to construct voltage regulators by using special-purpose integrated circuits. The same circuit techniques can be used to make regulators with discrete components (transistors, resistors, etc.), but because of the availability of inexpensive high-performance regulator chips, there is usually no advantage to using discrete components in new designs. Voltage regulators get us into the domain of high power dissipation, so we will be talking about heatsinking and techniques like "foldback limiting" to limit transistor operating temperatures and prevent circuit damage. These techniques can be used for all sorts of power circuits, including power amplifiers. With the knowledge of regulators we will have at that point, we will be able to go back and discuss the design of the unregulated supply in some detail. In this chapter we will also look at voltage references and voltage-reference ICs, devices with plenty of uses outside of power-supply design (for example in analog–digital conversion).

We begin with the *linear* regulator, in which feedback controls conduction in a series voltage-dropping "pass transistor" to hold constant the output voltage. Later we treat the important topic of *switching* regulators, in which one or more transistors are switched rapidly to transfer energy, via an inductor (or capacitor) to the load, again with voltage-regulating feedback. In a nutshell, linear regulators are simpler and generate "cleaner" (i.e., noise-free) dc output; switchers (the nickname for switching regulators and converters) are more compact and efficient (Figure 9.1), but noisier and usually more complex.

It would be wrong to leave the impression that voltage regulators are used exclusively in ac-powered dc supplies. In addition to their use in creating stable dc voltages from the ac powerline, voltage regulators are used widely also to produce additional dc voltages from an existing *regulated dc* voltage within a circuit: it's common to see, for example, a regulator that accepts an existing +5 V input and generates a +2.5 V or +3.3 V output; this is easily done with a linear regulator, in which feedback controls the voltage drop to maintain constant (and reduced) output voltage. Perhaps more surprising, you can use a switching regulator to convert a given dc input to a *larger* output voltage, to an output voltage of opposite polarity, or to a constant current (for example, to drive a string of LEDs). These applications are particularly relevant to battery-powered devices. The more general term *power converter* is often used in such applications, which include also creating an ac output from a dc input.

[1] Sometimes the transformer can be omitted; this is most commonly done in *switchmode* power supplies (SMPSs), see §9.6.

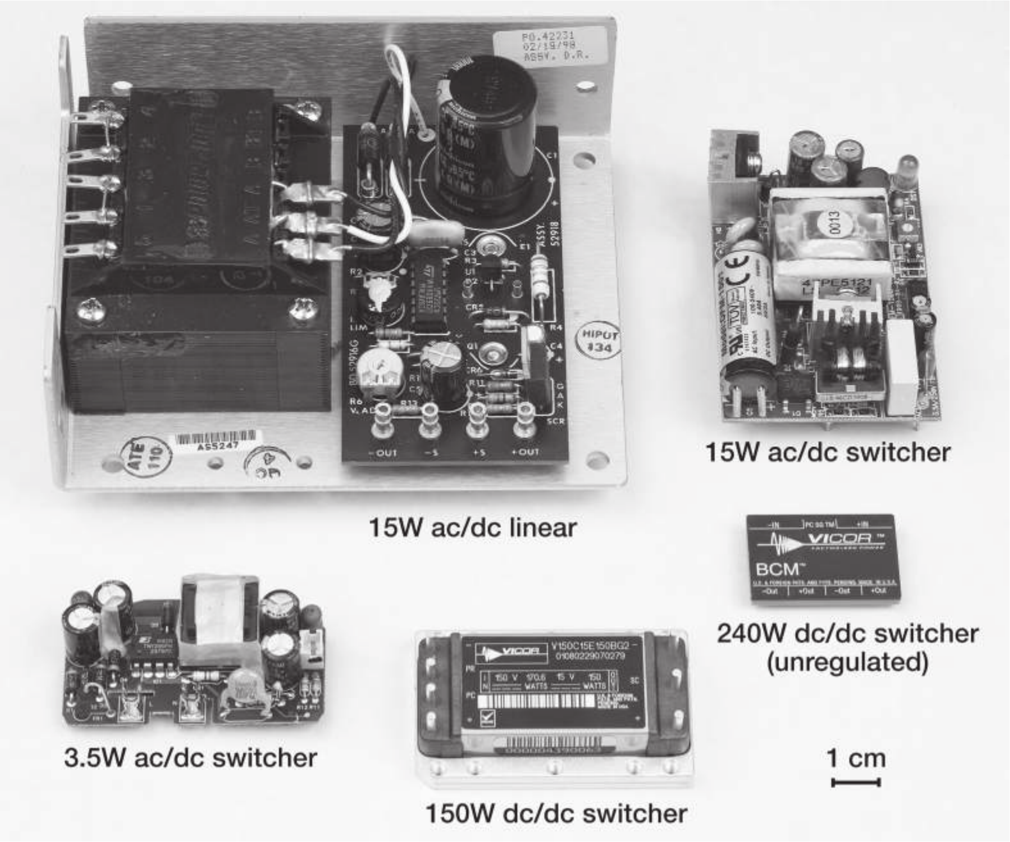

Figure 9.1. Switching power supplies ("switchers") are smaller and more efficient than traditional linear regulated power supplies, but the switching operation generates some unavoidable electrical noise.

9.1 Tutorial: from zener to series-pass linear regulator

To get started, let's look at the circuits in Figure 9.2. Recall that a zener diode is a voltage regulator, of sorts: it draws negligible current until the voltage across it is brought close to its zener voltage V_Z, at which point the current rises abruptly (look back at Figure 1.15 for a reminder). So a zener (or 2-terminal zener-like *reference* IC, see §9.10.2) biased through a resistor from a dc voltage greater than V_Z, as in Figure 9.2A, will have approximately V_Z across it, with the current set by the resistor:[2] $I_{\text{zener}} = (V_+ - V_Z)/R$. You can connect a load to this relatively stable output voltage; then, as long as the load draws less than I_{zener} (as just calculated), there will be some remaining zener current, and the output voltage will change little.

The simple resistor-plus-zener is occasionally useful as is, but it has numerous drawbacks: (a) you cannot easily change (or even choose precisely) the output voltage; (b) the zener voltage (which is also the output voltage) changes somewhat with zener current; so it will change with variations in V_+ and with variations in load current;[3] (c) you've got to set the zener current (by choice of R) large enough so that there's still some zener current at maximum load; this means that the V_+ dc supply is running at full current all the time, generating as much heat as the maximum anticipated load; (d) to accommodate large load currents[4] you would need a high-power zener; these are hard to find, and rarely used, precisely because there are much better ways to make a regulator, as we'll see.

Exercise 9.1. Try this out, to get a sense of the problems with

[2] With the exact I versus V curve of the zener in hand, you could determine the voltage and current exactly, using the method of *load lines*; see Appendix F, and §3.2.6B.

[3] These are called *line* and *load* variations, respectively.

[4] Or, more precisely, large *variations* in load current, and/or in V_+ dc input voltage.

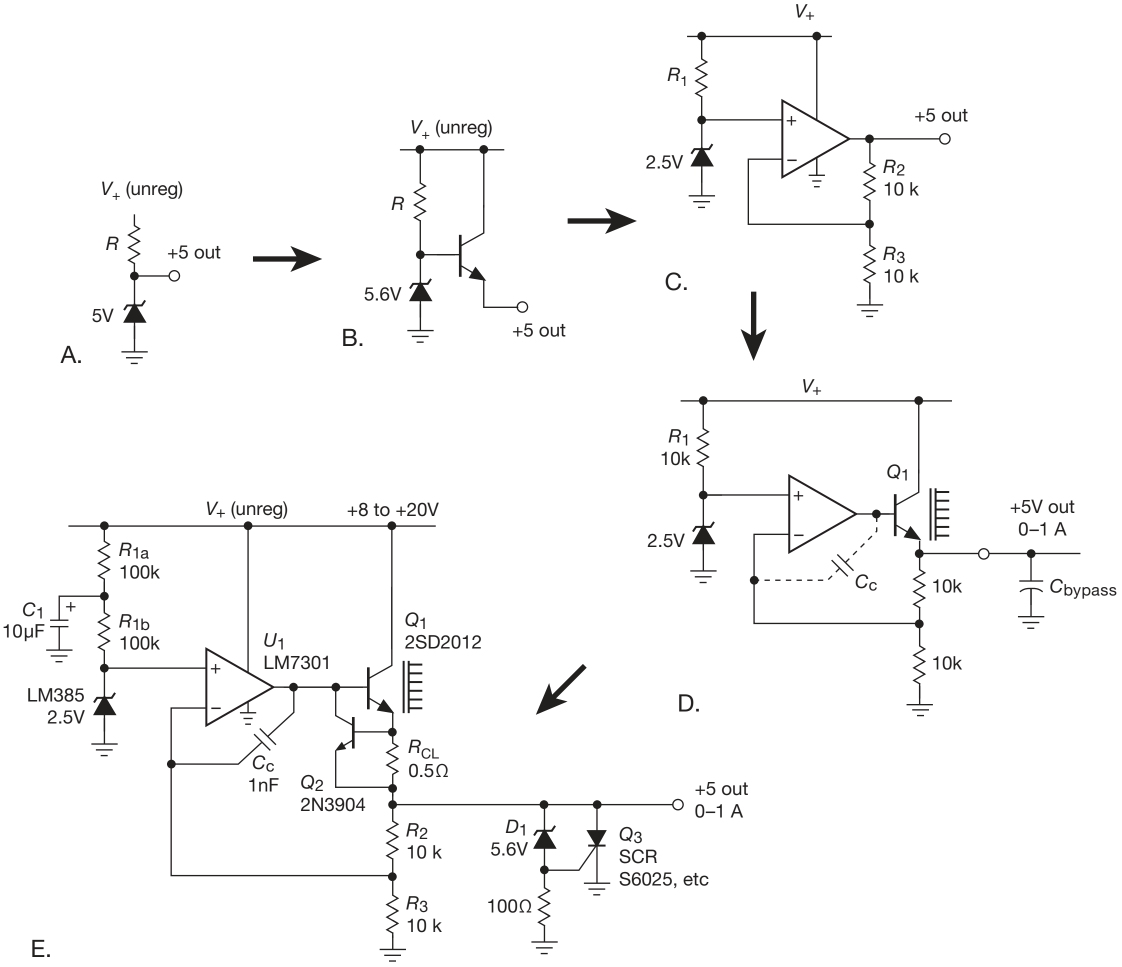

Figure 9.2. Evolving the (discrete-component) series-pass linear voltage regulator.

this simple regulator circuit: imagine we want a stable +5 V dc output, to power a load that can draw from zero to 1 A. We've built an unregulated dc supply (using a transformer, diode bridge, and capacitor) that puts out approximately +12 V when unloaded, dropping to +9 V at 1 A load. Those voltages are "nominal" and can vary ±10%.

(a) What is the correct resistor value, *R*, for the circuit of Figure 9.2A, such that the minimum zener current, under "worst-case" conditions, is 50 mA?

(b) What is worst-case (maximum) power dissipation in *R* and in the zener?

Contrasted with this approach – with its requirement for a 10 W zener at the desired output voltage, and nearly 10 W of power dissipation in each component, even at zero load – we'll see that it is a routine task to make a regulated power supply, with adjustable output voltage, without the need for a power zener and with 75% or better efficiency over most of the load-current range.

9.1.1 Adding feedback

We could improve the situation somewhat by tacking an emitter follower onto a zener (Figure 9.2B); that lets you run at lower zener current, and low quiescent dissipation when unloaded. But the output regulation is still poor (because $V_{\rm BE}$ varies with output current), and the circuit still does not allow adjustment of output voltage.

The solution is to use a zener (or other voltage reference device; see §9.10.2) as a low-current voltage reference, against which we compare the output. Let's take it in a few easy steps.

A. Zener plus "amplifier"

First we solve the problem of *adjustability* by following the zener reference with a simple dc amplifier (Figure 9.2C). Now the zener current can be small, just enough to ensure a stable reference. For typical zeners this might be a few milliamps, whereas for an IC voltage reference, 0.1–1 mA will usually suffice. This circuit lets you adjust the output voltage: $V_{\rm out} = V_{\rm Z}(1+R_2/R_3)$. But note that you are limited to having $V_{\rm out} \geq V_{\rm Z}$; note also that the output voltage comes from an op-amp, so it can at most reach V_+, with an output current limited by the op-amp's $I_{\rm out}$(max), typically 20 mA. We will overcome both these limits.

B. Adding outboard pass transistor

More output current is easy – just add an *npn* follower, to boost the output current by a factor of β. You might be tempted to just hang the follower on the op-amp's output, but that would be a mistake: the output voltage would be down by a $V_{\rm BE}$ drop, roughly 0.6 V. You could, of course, adjust the ratio R_2/R_3 to compensate. But the $V_{\rm BE}$ drop is imprecise, varying both with temperature and with load current, and so the output voltage would vary accordingly. The better way is to close the feedback loop around the pass transistor, as in Figure 9.2D; that way the error amplifier sees the actual output voltage, holding it stable via the circuit's loop gain. The inclusion of the output emitter follower boosts the op-amp's $I_{\rm out}$(max) by the beta of Q_1, giving us an available output current of an ampere or so. (We could use a Darlington, instead, for more current; another possibility is an *n*-channel MOSFET.) Q_1 will be dissipating 5–10 W at maximum output current, so you'll need a heatsink (more on this in §9.4.1). And, as we'll see next, you'll also need to add a compensation capacitor $C_{\rm C}$ to ensure stability.

C. Some important additions

Our voltage regulator circuit is nearly complete, but lacks a couple of essential features, related to loop stability and overcurrent protection.

Feedback loop stability

Regulated power supplies are used to power electronic circuits, typically festooned with many bypass capacitors between the dc rails and ground. (Those bypass capacitors, of course, are needed to maintain a pleasantly low impedance at all signal frequencies.) Thus the dc supply sees a large capacitive load, which, when combined with the finite output resistance of the pass transistor (and overcurrent sense resistor, if present), causes a lagging phase shift and possible oscillation. We've shown the load capacitance in Figure 9.2D as $C_{\rm bypass}$, a portion of which might be included explicitly (as a real capacitor) in the power supply itself.

The solution here, as with the op-amp circuits we worried about earlier (§4.9), is to include some form of *frequency compensation*. That is most simply done (as it is within op-amps) with a Miller feedback capacitor $C_{\rm C}$ around the inverting gain stage, as shown. Typical values are 100–1000 pF, usually found experimentally ("cut-and-try") by increasing $C_{\rm C}$ until the output shows a well-damped response to a step change in load (and then doubling that, to provide a good margin of stability). The IC regulators we'll see later will either include internal compensation, or they'll give you suggested values for compensation components.

Overcurrent protection

The circuit as drawn in Figure 9.2D does not deal well with a short-circuit load condition.[5] With the output shorted to ground, feedback will act to force the op-amp's maximum output current into the pass transistor's base; so that $I_{\rm B}$ of 20–40 mA will be multiplied by Q_1's beta (which might range from 50 to 250, say), to produce an output current of 1 A to 10 A. Assuming the unregulated V_+ input can supply it, such a current will cause excessive heating in the pass transistor, as well as interesting forms of damage to the misbehaving load.

The solution is to include some form of overcurrent protection, most simply the classic current-limiting circuit consisting of Q_2 and $R_{\rm CL}$ in Figure 9.2E. Here $R_{\rm CL}$ is a low-value *sense resistor*, chosen to drop approximately 0.6 V (a $V_{\rm BE}$ diode drop) at a current somewhat larger than the maximum rated current; for example, we might choose $R_{\rm CL} = 5\,\Omega$ in a 100 mA supply. The drop across $R_{\rm CL}$ is applied across Q_2's base–emitter, turning it on at the desired maximum output current; Q_2's conduction robs base current from Q_1, preventing further increase of output current. Note that the current-limit sense transistor Q_2 does not handle high voltage, high current, or high power; it sees at most two diode drops from collector to emitter, the op-amp's maximum output current, and the product of those two, respectively. During an overcurrent load condition, then, it typically would have to handle $V_{\rm CE} \leq 1.5$ V at $I_{\rm C} \leq 40$ mA, or 60 mW; that's peanuts for any general-purpose small-signal transistor.

Later we'll see variations on this simple overcurrent protection theme, including methods that limit to an

[5] Engineers like to refer to various bad situations such as this under the general rubric of *fault conditions*.

adjustable and stable current limit, and the technique known as *foldback current limiting* (§9.13.3).

Zener bias; overvoltage crowbar

We've shown two additional wrinkles in Figure 9.2E. First, we split the zener biasing resistor R_1 and bypassed the midpoint, to filter out ripple current. By choosing the time constant ($\tau = (R_{1a} \| R_{1b})C_1$) to be long compared with the ripple period of 8.3 ms, the zener sees ripple-free bias current. (You wouldn't bother with this if the dc supply V_+ were already free of ripple, for example a regulated dc supply of higher voltage.) Alternatively, you could use a current source to bias the zener.

Second, we've shown an "overvoltage crowbar" protection circuit consisting of D_1, Q_3, and the 100 Ω resistor. Its function is to short the output if some circuit fault causes the output voltage to exceed about 6.2 V (this can happen easily enough, for example if the pass transistor Q_1 fails by having a collector-to-emitter short, or if a humble component like resistor R_2 becomes open-circuited.). Q_3 is an SCR (silicon-controlled rectifier), a device that is normally nonconducting but that goes into saturation when the gate–cathode junction is forward-biased. Once turned on, it will not turn off again until anode current is removed externally. In this case, gate current flows when the output exceeds D_1's zener voltage plus a diode drop. When that happens, the regulator will go into a current-limiting condition, with the output held near ground by the SCR. If the failure that produces the abnormally high output also disables the current-limiting circuit (e.g., a collector-to-emitter short in Q_1), then the crowbar will sink a very large current. For this reason it is a good idea to include a fuse somewhere in the power supply, as shown for example in Figure 9.48. We will treat overvoltage crowbar circuits in more detail in §§9.13.1 and *9x.7*.

Exercise 9.2. Explain how an open circuit at R_2 causes the output to soar. What voltage, approximately, would then appear at the output?

9.2 Basic linear regulator circuits with the classic 723

In the preceding tutorial we evolved the basic form of the linear *series pass regulator*: voltage reference, pass transistor, error amplifier, and provisions for loop stability and overvoltage–overcurrent protection. In practice you seldom need to assemble these components from scratch – they are available as complete integrated circuits. One broad class of IC linear regulators might be thought of as flexible *kits* – they contain all the pieces, but you've got to hook up a few external components (including the pass transistor) to make them work; an example is the classic 723 regulator. The other class of regulator ICs are complete, with built-in pass transistor and overload protection, and requiring at most one or two external parts; an example is the classic 78L05 "3-terminal" regulator – its three terminals are labeled *input*, *output*, and *ground* (and that's how easy it is to use!).

9.2.1 The 723 regulator

The μA723 voltage regulator is a classic. Designed by Bob Widlar and first introduced in 1967, it is a flexible, easy-to-use regulator with excellent performance.[6] Although you might not choose it for a new design nowadays, it is worth looking at in some detail, because more recent regulators work on the same principles. Its block diagram is shown in Figure 9.3. As you can see, it is really a power-supply *kit*, containing a temperature-compensated voltage reference (7.15 V±5%), differential amplifier, series pass transistor, and current-limiting protective circuit. As it comes, the 723 doesn't regulate anything. You have to hook up an external circuit to make it do what you want.

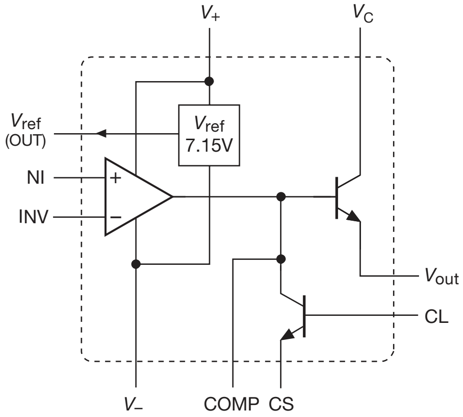

Figure 9.3. The classic μA723 voltage regulator.

The 723's internal *npn* pass transistor is limited to

[6] Building on the 723's success, other manufacturers introduced "improved" versions, such as the LAS1000, LAS1100, SG3532, and MC1469. However, while the 723 lives on, the improved versions are all gone! The 723 is "good enough," *very* inexpensive (about $0.15 in quantity), and is popular in many commercial linear power supplies, where the easily adjusted current limit is especially useful. It also has less noise than most modern replacements. And we like it for its pedagogic value.

150 mA, and it can dissipate about 0.5 W maximum. Unlike newer regulators, the 723 does not incorporate internal shutdown circuitry to protect against excessive load current or chip dissipation.

A. 723 regulator example: $V_{out} > V_{ref}$

Figure 9.4 shows how to make a positive voltage regulator with the 723 for output voltages greater than the reference voltage; it is the same circuit topology as the tutorial's Figure 9.2E. All the components except the three resistors and the two capacitors are contained in the 723. With this circuit, a regulated supply with output voltage ranging from V_{ref} up to the maximum allowable output voltage (37 V) can be made. Of course, the input voltage must stay a few volts more positive than the output at all times, including the effects of ripple on the unregulated supply. The "dropout voltage" (the amount by which the input voltage must exceed the regulated output voltage) is specified as 3 volts (minimum) for the 723. This is a bit large by contemporary standards, where the dropout voltage is typically 2 V, and much less for *low dropout* (LDO) regulators, as we'll see in §9.3.6. Note also that the 723's relatively high reference voltage means that you cannot use it in a power supply whose unregulated dc input is less than +9.5 V, its specified minimum V_+; this shortcoming is remedied in a large selection of regulators that use a lower-voltage *bandgap reference* (1.25 V or 2.5 V). And while we're complaining, we note that the reference is not exactly sterling in its initial accuracy – the production spread in V_{ref} is 6.8 to 7.5 volts – which means that you must provide for output-voltage trimming, by making R_1 or R_2 adjustable; we'll soon see regulators with excellent initial accuracy, for which no trim is needed.

It is usually a good idea to put a capacitor of a few microfarads across the output, as shown. This keeps the output impedance low even at high frequencies, where the feedback becomes less effective. It is best to use the output capacitor value recommended on the specification sheet, to ensure stability against oscillations. In general, it is a good idea to bypass power-supply leads to ground liberally throughout a circuit, using a combination of ceramic types (0.01–0.1 μF) and electrolytic or tantalum types (1–10 μF).[7]

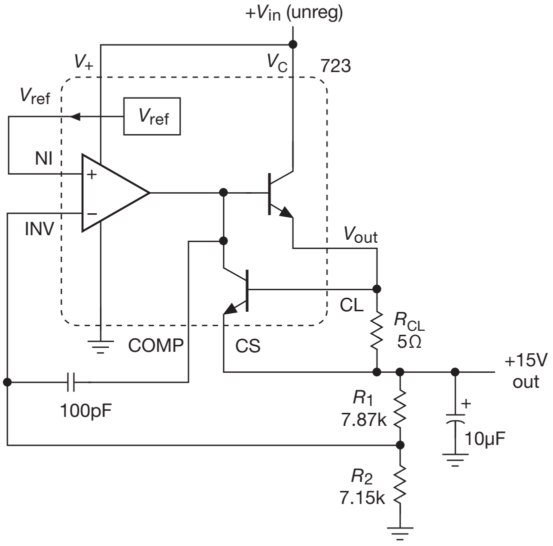

Figure 9.4. 723 regulator: configuration for $V_{out} > V_{ref}$, with 100 mA current limit.

B. 723 regulator example: $V_{out} < V_{ref}$

For output voltages less than V_{ref}, you just put the voltage divider on the reference (Figure 9.5). Now the full output voltage is compared with a fraction of the reference. The values shown are for a +5 V output. With this circuit configuration, output voltages from +2 V to V_{ref} can be produced. The output cannot be adjusted down to zero volts because the differential amplifier will not operate below 2 volts input, as specified on the datasheet. Note again that the unregulated input voltage must never drop below +9.5 V, the voltage necessary to power the reference.

For this example we've added an external pass transistor, in a Darlington configuration with the 723's small internal pass transistor, to get beyond the latter's 150 mA current limit. An external transistor is needed, also, because of power dissipation: the 723 is rated at 1 watt at 25°C (less at higher ambient temperatures; the 723 must be "derated" at 8.3 mW/°C above 25°C in order to keep the junction temperature within safe limits). Thus, for instance, a 5 volt regulator with +15 V input cannot deliver more than about 80 mA to the load. Here the external power transistor Q_1 will dissipate 14 W for V_{in}=12 V and maximum load current (2 A); that requires a *heatsink*, most often a finned metal plate designed to carry off heat (alternatively, the transistor can be mounted to one wall of the metal chassis housing the power supply). We will deal with thermal problems like these later in the chapter.[8] A trimmer

[7] The ceramic capacitors provide low impedance at high frequencies, whereas the larger electrolytics provide energy storage, and also damping of oscillations (via their internal equivalent series resistance, or ESR).

[8] And for a table of bipolar power transistors see Table 2.2 on page 106.

potentiometer has been used so that the output can be set accurately to +5 V; its range of adjustment should be sufficient to allow for resistor tolerances as well as the maximum specified spread in V_{ref} (this is an example of worst-case design), and in this case it allows about ±1 volt adjustment from the nominal output voltage. Note the low-resistance high-power current-limiting resistor necessary for a 2 amp supply.

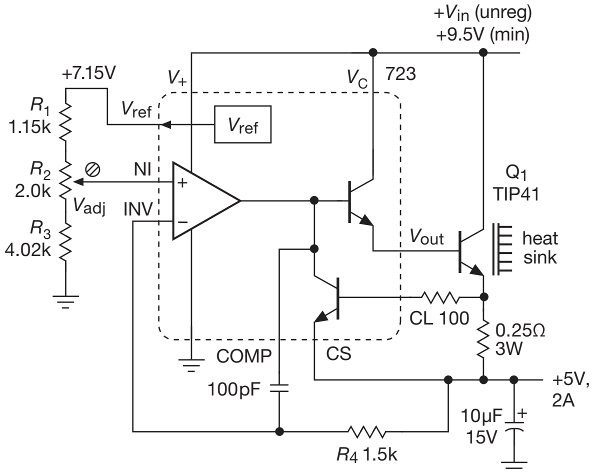

Figure 9.5. 723 regulator: configuration for $V_{\text{out}} < V_{\text{ref}}$, with 2 A current limit.

A third variation of this circuit is necessary if you want a regulator that is continuously adjustable through a range of output voltages around V_{ref}. In such cases, just compare a divided fraction of the output with a fraction of V_{ref} chosen to be less than the minimum output voltage desired.

Exercise 9.3. Design a regulator to deliver up to 50 mA load current over an output voltage range of +5 V to +10 V using a 723. *Hint*: compare a fraction of the output voltage with $0.5V_{\text{ref}}$.

C. Pass-transistor dropout voltage

One problem with this circuit is the high power dissipation in the pass transistor (at least 10 W at full load current). This is unavoidable if the regulator chip is powered by the unregulated input, since it needs a few volts of "headroom" to operate (specified by the dropout voltage). With the use of a separate low-current supply for the 723 (e.g., +12 V), the minimum unregulated input to the external pass transistor can be as little as 1.5 V or so above the regulated output voltage (i.e., two V_{BE}'s).[9]

9.2.2 In defense of the beleaguered 723

Lest we leave the wrong impression, we hasten to remark that rumors of the death of the vintage 723 regulator are greatly exaggerated.[10] We have been using dozens of linear regulated power supplies manufactured by Power One for more than three decades without a single failure. All of them use the humble 723 regulator chip, as do other OEMs ("original equipment manufacturers"). Here are some reasons not to overlook this remarkable design of the legendary Bob Widlar:

- very low cost, $0.17 (in qty 1000)
- many, many manufacturers
- fully settable current limit, including foldback
- good for pedagogy (that's why it's here!)
- the power dissipation is not in the control IC
- quiet voltage reference, plus can add filter
- works with *npn* or *pnp* pass transistors
- easily configured for negative outputs

9.3 Fully integrated linear regulators

The overall regulator circuit of Figure 9.5 has ten components, but only three terminals (IN, OUT, and GROUND), thus suggesting the possibility of an integrated solution, with on-chip voltage-setting resistors and with integrated components for current-limiting and loop compensation – a *3-terminal* regulator. The 723 is approaching half-century vintage (though still going strong!), during which the semiconductor industry has not been sleeping: contemporary linear regulator ICs generally integrate all regulator functions on-chip, including overcurrent and thermal protection, loop compensation, high-current pass transistor, and preset voltage divider for commonly used output voltages. Most of these regulators come also in adjustable versions, for which you provide only the voltage-setting resistor pair. And, with an additional terminal or two, you can get a "shutdown" control input and a "power-good" status output. Finally, a large and growing population of low-dropout regulators addresses low voltage applications, of increasing importance in low-power and portable electronic devices. Let's look at the choices favored for contemporary design.

[9] A trick you can use to reduce the minimum headroom to a single V_{BE} is to replace Q_1 with a *pnp* pass transistor (tie its emitter to V_{in} and drive its base from the V_{c} pin of the 723), forming a Sziklai pair rather than a Darlington (see §2.4.2A and Figure 2.77). If the input comes from an unregulated dc supply, however, you will always have to allow at least a few volts of headroom, because worst-case design dictates proper operation even at 105 Vac line input.

[10] Paraphrasing Mark Twain's famous remark, upon opening the newspaper and reading his obituary.

9.3.1 Taxonomy of linear regulator ICs

As a guide to the following sections, we've organized the universe of integrated linear voltage regulators into a few distinct categories, here simply listed in outline form. For each category we've listed typical example part numbers of devices that we are fond of, and use often. Read on for explanations of when and how to use them, a description of their distinguishing features, and some important cautions.

3-terminal fixed

9.3.2 Three-terminal fixed regulators

The original (and often good enough) 3-terminal regulator is the 78xx series (Figure 9.6), originated by Fairchild in the early 1970s.[11] It is factory trimmed to provide a fixed output, in which the voltage is specified by the last two digits of the part number, and can be any of the following: 05, 06, 08, 09, 10, 12, 15, 18, or 24. These regulators can supply up to 1 A of output current, and come in power packages (TO-220, DPAK, D^{2}PAK) that you attach to a heatsink or to an area of circuit-board copper. If you don't need much current, use the 78Lxx/LM340Lxx series, which come in small transistor packages, either surface-mount or TO-92 (through-hole). For negative output voltage use the 79xx/79Lxx (or LM320/320L) series. Figures 9.6 and 9.7 show, in simplified form, what's inside these inexpensive ($0.30) regulators.

Figure 9.8 shows how easy it is to make a +5 V regulator, for example, with one of these ICs. Here we've added also a 7905 negative regulator to create a −5 V regulated output from a more negative unregulated dc input. The bypass capacitors at the outputs ensure stability; they also improve transient response, and maintain a low output impedance at high frequencies (where the regulator's loop gain is low).[12] The input bypass capacitors are also needed

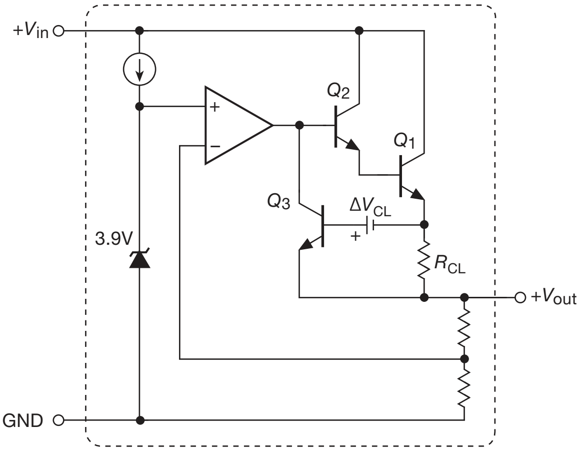

Figure 9.6. Simplified 78xx fixed 3-terminal positive voltage regulator. All components are internal, so only a pair of bypass capacitors is required (as in Figure 9.8). $R_{\rm CL}$, the current-sensing resistor, is 0.2 Ω, and develops somewhat less than a diode drop at full current; its drop is supplemented by an internal bias $\Delta V_{\rm CL}$, to turn on current-limiting transistor Q_3.

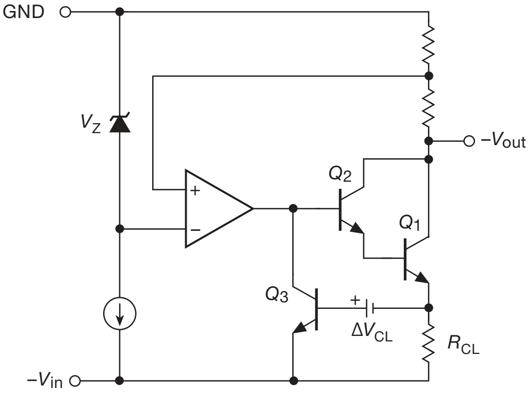

Figure 9.7. 79xx fixed 3-terminal negative voltage regulator.

[11] The LM340 series from National is essentially the same.

[12] A regulator's datasheet will always specify minimum required capacitance. It may go into considerably more detail, in cases where stability is an important issue, for example with low-dropout regulators (see later discussion). Note the larger capacitance values in the negative regulator circuit: they are needed to ensure stability, because the 7905 regulator's output comes from the collector of a common-emitter amplifier output stage (whose gain depends on load impedance), rather than from the emitter follower output stage of the 7805 positive regulator (whose gain is near unity); the larger bypass capacitor kills the loop gain at high frequency, preventing oscillation.

for stability; the values shown are the minimum suggested in the datasheets. However, if the input supply or output load is bypassed close to the regulator, the corresponding capacitors can be omitted.

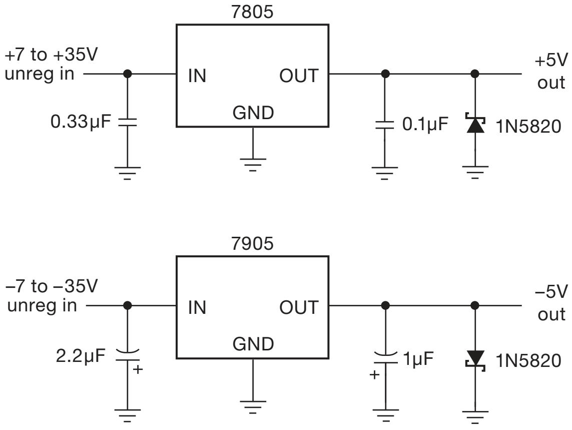

Figure 9.8. ±5 V regulated dc from a 7805/7905 regulator pair.

This regulator example includes a pair of reverse-protection Schottky (low-forward-drop) diodes, always a good idea when you have supplies of both polarities powering a circuit. Without the diodes, one of the supplies can bring the other into reverse output voltage, via the load; this reversed supply polarity can cause failure in the load (from transistors or ICs that are subjected to reverse supply voltage), or in the regulator (which may even go into a latchup condition). You often see the diodes omitted; don't get into this lazy habit!

These regulators have on-chip circuitry to prevent damage in the event of overheating or excessive load current; the chip simply shuts down, rather than blowing out. In addition, on-chip circuitry prevents operation outside the transistor safe operating area (see §9.4.2) by reducing available output current for large input–output voltage differentials. These regulators are inexpensive and easy to use, and they make it practical to design a system with many printed circuit boards (PCBs) in which the unregulated dc is brought to each board and regulation is done locally on each circuit card. Table 9.1 lists the characteristics of a representative selection of 3-terminal fixed regulators.

Three-terminal fixed regulators come in some highly useful variants. There are low-power and micropower versions (e.g., the LM2936 and LM2950, with quiescent current in the microampere range), and there are the very popular LDO regulators, which maintain regulation with only a few tenths of a volt input–output differential (e.g., the LT1764A, TPS755xx, and micropower LM2936, with typical dropout voltages ≈0.25 V). We'll discuss LDOs after taking a look at the very useful 3-terminal *adjustable* regulator.

Notes: (a) often called '7800 and '7900 series, e.g., "LM7800-series." L series available in TO-92, SO-8 and SOT-89 packages; regular series available in TO-220, DPAK, D2PAK, and TO-3. Some use buried-zener ref, some use bandgap. (b) A-suffix types are ±2% tol. (c) prefixes: uA, LM, MC, KA, NCP, L, NJM, etc. (d) L-series: 2.6 to 24V, regular: 5 to 24V. (e) some lower, 3.3mA to 4mA

9.3.3 Three-terminal adjustable regulators

Sometimes you want a nonstandard regulated voltage (say +9 V, to emulate a battery) and can't use a 78xx-type fixed regulator. Or perhaps you want a standard voltage, but set more accurately than the ±3% accuracy typical of fixed regulators. By now you're spoiled by the simplicity of 3-terminal fixed regulators, and therefore you can't imagine using a 723-type regulator circuit, with all its required external components. What to do? Get an "adjustable 3-terminal regulator"!

These convenient ICs are typified by the classic LM317 originally from National (Figure 9.9). This regulator has no ground terminal; instead, it adjusts V_{out} to maintain a constant 1.25 V (internal "bandgap" reference, §9.10.2) from the output terminal to the "adjustment" terminal. Figure 9.10 shows the easiest way to use it. The regulator puts 1.25 V across R_1, so 10 mA flows through it. The adjustment terminal draws very little current (50–100 μA), so the output voltage is just

$$V_{out} = 1.25\,(1 + R_2/R_1) \text{ volts.}$$

In this case the output voltage is +3.3 V, with an untrimmed accuracy of ≈3% (from the ±2% internal 1.25 V reference and the 1% resistors). If you want accurate settability,

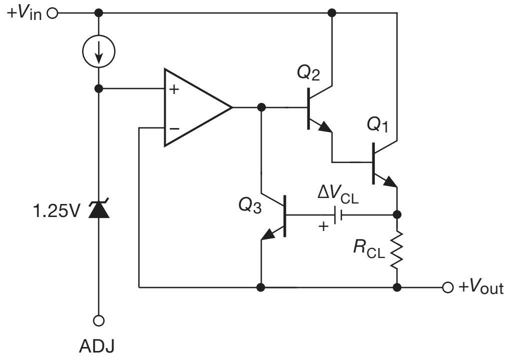

Figure 9.9. LM317 three-terminal adjustable positive voltage regulator.

replace the lower resistor with a 25 Ω trimmer in series with a 191 Ω fixed resistor, to narrow the trimmer's adjustment range to ±6%. If you want instead a wide adjustment range, you could replace the lower resistor with a 2.5k trimmer, for an output range of +1.25 V to +20 V. Whatever the output voltage, the input must be at least 2 V higher (the dropout voltage).

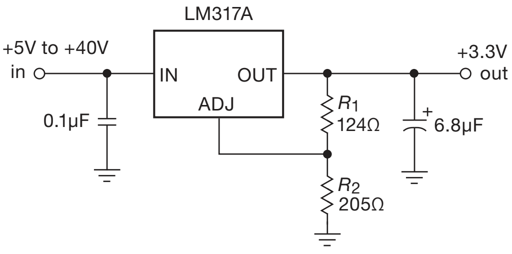

Figure 9.10. +3.3 V positive regulator circuit.

When using this type of regulator, choose your resistive divider values small enough to allow for a 5 μA change in adjustment pin current with temperature: many designers use 124 Ω for the upper resistor, as we've done, so that the divider alone sinks the chip's specified minimum load current of 10 mA. Note also that the current sourced out of the adjustment pin may be as large as 100 μA (the worst-case spec). The output capacitor, though not necessary for stability, greatly improves transient response. It's a good idea to use at least 1 μF, and ideally something more like 6.8 μF.

The LM317 is available in many package styles, including the plastic power package (TO-220), the surface-mount power package (DPAK and D^{2}PAK), and many small transistor packages (both through-hole TO-92, and a half dozen tiny surface-mount styles). In the power packages it can deliver up to 1.5 amps, with proper heatsinking; the low-power variant (317L) is rated to 100 mA, again limited by power dissipation. The popular LM1117 variant, also available from multiple manufacturers, improves on the dropout voltage of the classic 317 (1.2 V versus 2.5 V), but you pay a price (literally): in the TO-220 package it costs about $0.75 versus the 317's $0.20; it also has a more limited voltage range (see Table 9.2), and, in common with many low-dropout regulators, it requires a larger output capacitor (10 μF minimum).

Exercise 9.4. Design a +5 V regulator with the 317. Provide ±20% voltage adjustment range with a trimmer pot.

Three-terminal adjustable regulators are available with higher current ratings, e.g., the LM350 (3A), the LM338 (5A), and the LM396 (10A), and also with higher voltage ratings, e.g., the LM317H (60V) and the TL783 (125V). We've listed their properties in Table 9.2 on page 605. Read the datasheets carefully before using these parts, noting bypass capacitor requirements and safety diode suggestions. Note also that the rated maximum output currents generally apply at lower values of V_{in}–V_{out}, and can drop to as little as 20% of their maximum values as V_{in}–V_{out} approaches $V_{\text{in(max)}}$; the maximum output current drops also with increasing temperature.[13]

An alternative for high load currents is to add an outboard transistor (§9.13.4), though a high-current switching regulator (§9.6) is often a better choice. The LM317 family regulators are "conventional" (as opposed to low-dropout) linear regulators; typical dropout voltages are ≈2 V.

As with the fixed 3-terminal regulators, you can get lower-dropout versions (e.g., the popular LM1117, with 1.3 V maximum dropout at 0.8 A, or the heftier LT1083-85 series, with comparable dropout at currents to 7.5 A), and you can get micropower versions (e.g., the LP2951, the adjustable variant of the fixed 5V LP2950; both have I_Q=75 μA); see Figure 9.11. You can also get *negative* versions, though there's less variety: the LM337 (Figure 9.12) is the negative cousin of the LM317 (1.5 A), and the LM333 is a negative LM350 (3 A). There's more discussion ahead in §§9.3.6 and 9.3.9; see particularly Figure 9.24.

[13] As discussed later in §9.4.1, the junction temperature $T_J = P_{\text{diss}}(R_{\Theta JC}+R_{\Theta CS}+R_{\Theta SA})+T_A$, where the R_Θ are the thermal resistances from junction to case, case to heatsink, and heatsink to ambient. In situations with good heatsinking, you may choose to use a regulator of higher current rating and larger package style (e.g., the LM338K in its TO-3 metal can package) in order to take advantage of the much lower thermal resistance $R_{\Theta JC}$ (1°C/W versus 4°C/W for the LM317T in its TO-220 package). The larger parts also offer more relaxed safe-operating-area (SOA) constraints, e.g., at $V_{\text{in}}-V_{\text{out}}$=20 V the LM338 allows 3.5 A of output current, versus 1.4 A for the LM317.

Anatomy of a 317

The classic LM317, designed around 1970 by the legendary team of Widlar and Dobkin[14] has endured for more than four decades. Indeed, the generic 317 (along with the complementary LM337) has become the go-to part for linear regulators of modest current capability (to ∼1 A) in situations where you've got a few volts of headroom. And it has spawned a host of imitators and look-alikes, spanning a range of voltages, currents, and package styles, with some variants of lower dropout-voltage; see Table 9.2.

Its design exhibits a nice elegance, for example by combining the functions of error amplifier and zero-tempco bandgap reference. It was also one of the first regulators to include thermal overload and safe-area protection. Figure 9.13 is a simplified circuit of its essential innards, with part designations following the schematic diagram in the National Semiconductor (TI) datasheet.

The transistor pair Q_{17} and Q_{19} forms the bandgap voltage reference, operating at equal currents from the $Q_{16}Q_{18}$ mirror. Because Q_{19} has 10× larger emitter area (or 10 emitters), it operates at 1/10 the current density of Q_{17}, thus a V_{BE} that is smaller by $(kT/q)\log_e 10$, about 60 mV (§*2x.3.2*). That sets its current (via R_{15}) to be $I_{\text{Q19}}=\Delta V_{\text{BE}}/R_{15}=25\,\mu\text{A}$, and thus the pair's total current is 50 μA.[15] Note that the current has a linear dependence on absolute temperature (because the drop across R_{15} is $\propto T_{\text{abs}}$) – it is "PTAT" (proportional to absolute temperature).

Now for the classic "bandgap reference" temperature compensation: the positive tempco of current is exploited to cancel Q_{17}'s negative tempco of V_{BE}, which is nominally about 600 mV and goes as $1/T_{\text{abs}}$, or −2.1 mV/°C (§2.3.2). Cancellation occurs when R_{14} is chosen to drop a comparable 600 mV at the nominal 50 μA, thus a +2.1 mV/°C tempco – voilà: zero tempco at a reference voltage of ∼1.2 V (the extrapolated bandgap energy of silicon).

The bandgap reference is also the error amplifier: Q_{17}'s collector sees a high-impedance (current-source) load, buffered by three stages of emitter follower (in the full schematic there are five) to the output pin; so even with its relatively low transconductance ($g_m \sim 1/R_{14}$) there's plenty of loop gain in the error amplifier (whose input is the ADJ pin, offset by V_{ref}, relative to V_{out}).

Resistor R_{26} senses the output current, for current limiting via Q_{21}. A bias that depends on V_{in}–V_{out} is added (the battery symbol), for safe-operating-area protection. Additional components add hysteretic overtemperature shutdown (Q_{21} is paired with a *pnp* to make a latch). One final note: the Widlar–Dobkin duo also created the LM395 and LP395 protected-transistor ICs; these include the current and thermal limiting from the 317, but without the bandgap reference. They call it, modestly, the "Ultra-Reliable Power Transistor." The '395 transistor's base is the base of the *pnp* transistor Q_{15} in Figure 9.13. This yields a roughly 800 mV base-to-emitter voltage, with a 3 μA pullup base current. It's a great idea, but an LM395T costs about $2.50, whereas an LM317T costs about $0.50. So we use the '317 as our "pretty reliable power transistor," with its −1.2 V base-to-emitter voltage and 50 μA pullup base current, as for example in Figures 9.16 and 9.18.

9.3.4 317-style regulator: application hints

The LM317-style adjustable 3-terminal regulators are delightfully easy to use, and there are some nice tricks you can use to make them do more than simply create a fixed dc output voltage. There are also some basic cautions to keep in mind. In Figure 9.14 we've sketched some helpful circuit ideas.

Herewith a quick tour (keyed to the figure parts), taking them in order.

A: The regulator requires some minimum load current, because the operating current for the internal circuitry returns through the load. So if you want it to work clear down to zero external load, you should choose the upper feedback resistor R_1 small enough, i.e., so that $V_{\text{ref}}/R_1 \geq I_{\text{out(min)}}$ for the worst-case (maximum) value of $I_{\text{out(min)}}$. For $V_{\text{ref}}=1.25\,\text{V}$ and the classic LM317's $I_{\text{out(min)}}=10\,\text{mA}$, R_1 should be no larger than 125 Ω.[16] Of course, you could instead use a larger value of R_1 and add a load resistor to

[14] See Robert Widlar, "New developments in voltage regulators," JSSC, SC-6, pp 2–9, 1971, and US patent 3,617,859: "Electrical regulator apparatus including a zero temperature coefficient voltage reference circuit," filed 23 March 1970, issued 2 November 1971.

[15] The typical tolerance on resistor values in the planar silicon process (which is good for resistor *ratios*, but not absolute values) is ×0.5 to ×2, so the nominal 50 μA current sourced out of the ADJ pin can actually range from 25 μA to 100 μA.

[16] In contradiction to the LM117/317 datasheet's many circuit examples,

(z) the metal case or tab (for TO-220, TO-3, D-PAK) is connected to V_{out} for positive regulators, and to V_{in} for negative regulators.
Beware differing pinouts: positive versus negative, and variants like LR8 and LR12.

make up the difference; but then you incur some additional uncertainty of output voltage, owing to the adjustment pin current of ∼50 μA; see **E** below.

B: The standard 317-style regulator circuit (as in Figure 9.10) can adjust only down to V_{ref}. But you can trick a 317 into going down to zero by returning the lower leg of the output divider (R_2) to a negative reference. Be sure to sink enough current to bias that reference into conduction, as shown.

C: You can use a MOSFET switch (or a low R_{ON} analog switch) to shunt additional fixed resistors across the voltage-setting lower resistor, allowing selection of output voltage under logic-level control.

D: Alternatively, you can program the output voltage by applying a dc voltage via the ADJ pin; the output voltage will be V_{ref} greater. The programming voltage could be generated by a pot, as shown, or by a DAC. If programmed as in the circuit fragment shown, you would need to ensure that the external load satisfies the minimum load current specification (5 or 10 mA for most devices; see Table 9.2). You also need to take into consideration the effect of ADJ pin bias current through the larger than usual impedance, in this example rising to more than 1 kΩ at the pot's midposition; see **E**, next.

E: The ADJ pin sources ∼50 μA (see the box titled "Anatomy of a 317"), which causes the output voltage to become

$$V_{OUT} = V_{ADJ}\left(1+\frac{R_2}{R_1}\right)+I_{ADJ}R_2, \qquad (9.1)$$

where the last "error" term is caused by the ADJ pin current. For the worst-case I_{ADJ}=100 μA and nominal R_1=125 Ω

where the value of R_1 is 240 Ω. This design error most likely originated with illustrative circuit examples for the more tightly spec'd LM117 on the same datasheet, whose worst-case $I_{out(min)}$ is 5 mA (half that of the LM317). It's been 40 years, and no one at the factory seems to have noticed!

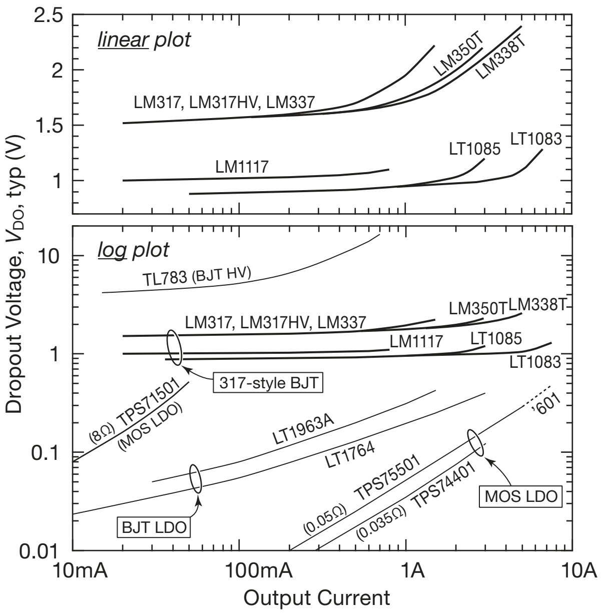

Figure 9.11. Typical dropout voltage (V_{IN}–V_{OUT}) versus load current for 317-style three-terminal regulators (bold curves). Representative low-dropout and high-voltage regulators are included for comparison. See also Figure 9.24.

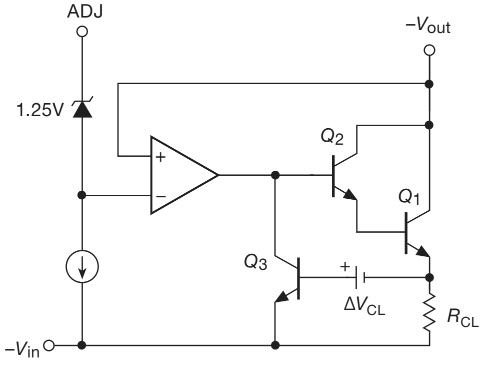

Figure 9.12. LM337 three-terminal adjustable negative voltage regulator. The common-emitter output stage requires at least 1 μF bypassing at input and output to ensure stability.

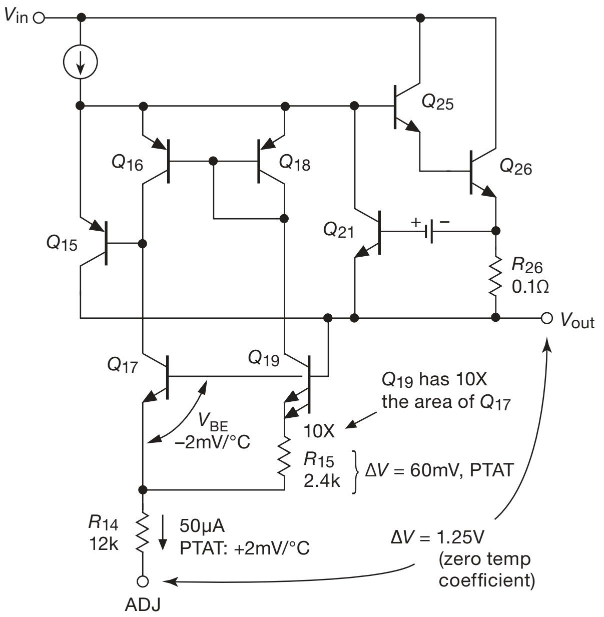

Figure 9.13. Simplified circuit of the 317-style linear regulator, illustrating its internal temperature-compensated bandgap reference; see the box "Anatomy of a 317."

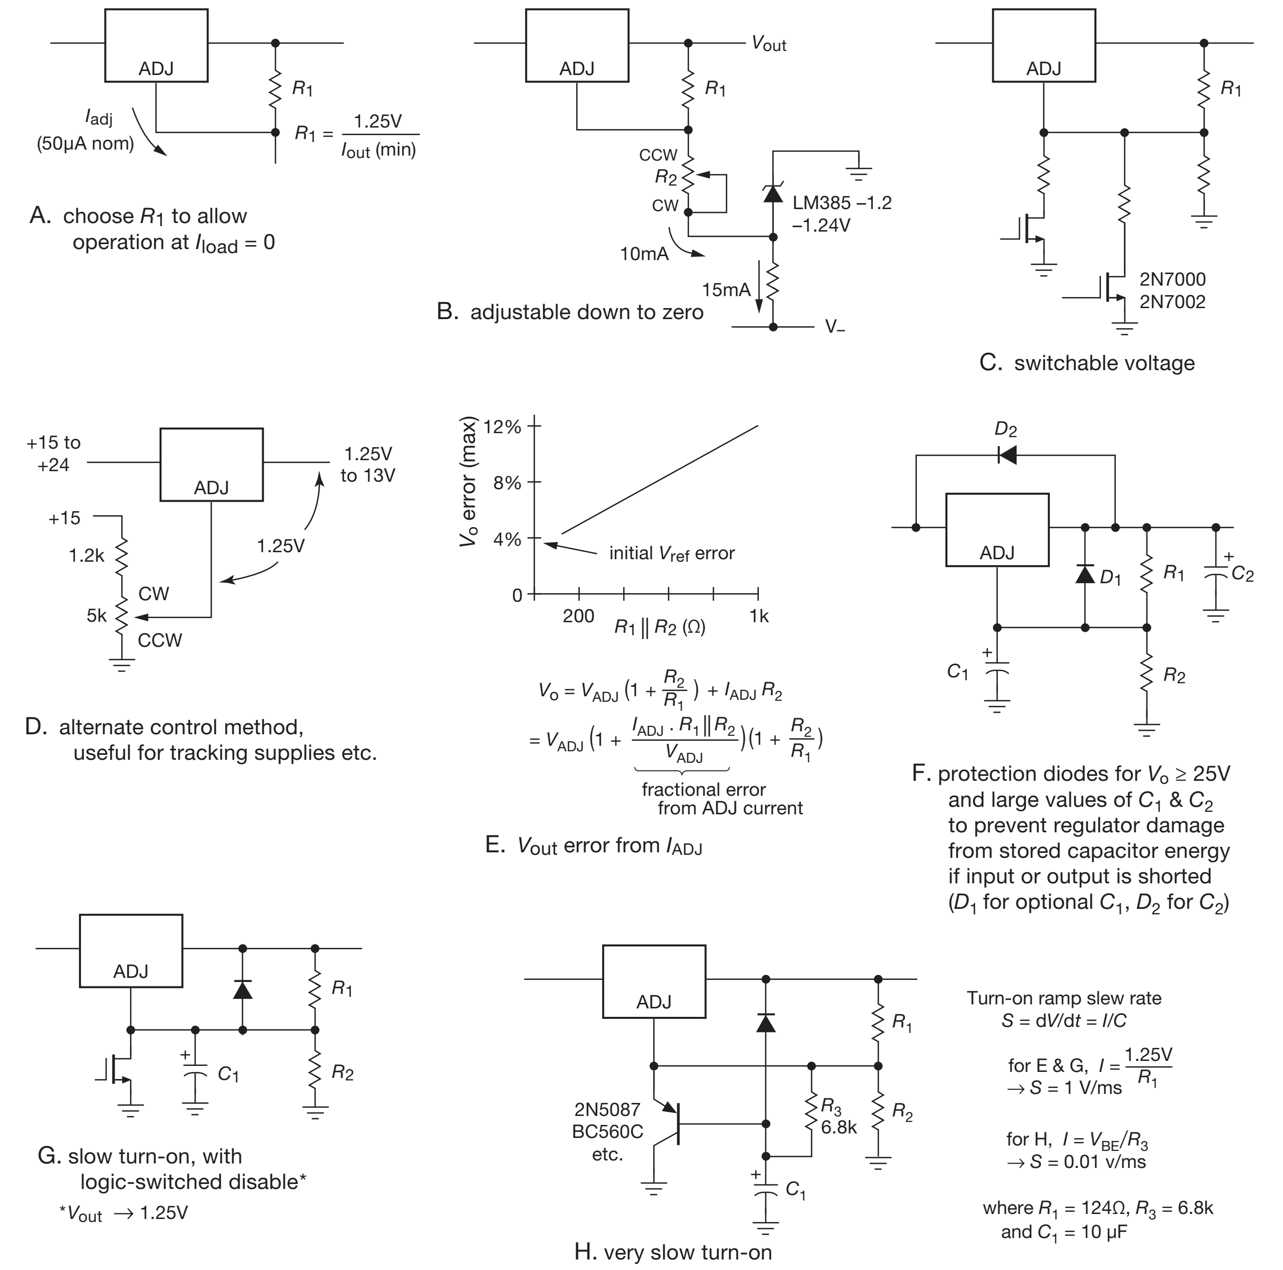
this amounts to a 1% increase in output voltage, above and beyond the initial V_{ref} uncertainty (usually 1% or 4%; see Table 9.2).[17] The current-induced error increases linearly with divider impedance, as indicated in the plot (which assumes a V_{ref} tolerance of 4%, a worst-case ADJ pin current of 100 μA, and no correction for the adjustment current, i.e., ignoring the last term of eq'n 9.1).

F: A linear regulator can be damaged by fault conditions in which bypass capacitors discharge suddenly through the regulator circuit, causing destructive peak currents. Diode D_2 prevents the output bypass capacitor from discharging through the regulator if the input is shorted; it never hurts to include such a diode, and it is definitely indicated for higher output voltages. Likewise, add diode D_1 if an optional noise reduction capacitor C_1 is used, to protect against input or output shorts.

G and H: You can extend the output-voltage ramp-up time[18] by bypassing the ADJ terminal with a large value

[17] If you care, you can calculate your resistor values from eq'n 9.1, using the datasheet's *typical* value for I_{ADJ}; that reduces the worst-case error by typically a factor of two (the ratio of maximum to typical I_{ADJ}).

[18] Why would you do that? Perhaps this short story, from our research lab, will provide some motivation: we built a ±15 kV supply, using a pair of Spellman MP15 dc–dc HV converters (+24 V input, +15 kV and −15 kV maximum outputs, 10 W), powered from a commercial ac-powered +24 Vdc switching supply. We mounted the HV output connectors (type SHV; see Figure 1.125) a safe 2″ apart. Imagine our surprise, then, when we powered it up, and a huge spark jumped between the connectors; must have been at least 50 kV! Scary. And *worrisome* – can this thing (and its load) survive repeated startups? Our first attempted cure was to ensure that the MP15's 0–10 V control voltage was set to zero volts at startup. No joy. Finally we added an LT1085 three-terminal regulator with controlled ramp to the +24 V input, and, voilà, no more lightning.



A. choose R_1 to allow operation at $I_{load} = 0$

B. adjustable down to zero

C. switchable voltage

D. alternate control method, useful for tracking supplies etc.

$$V_o = V_{ADJ}\left(1+\frac{R_2}{R_1}\right) + I_{ADJ}R_2$$
$$= V_{ADJ}\left(1+\underbrace{\frac{I_{ADJ}\cdot R_1\|R_2}{V_{ADJ}}}_{\text{fractional error from ADJ current}}\right)\left(1+\frac{R_2}{R_1}\right)$$

E. V_{out} error from I_{ADJ}

F. protection diodes for $V_o \geq 25V$ and large values of C_1 & C_2 to prevent regulator damage from stored capacitor energy if input or output is shorted (D_1 for optional C_1, D_2 for C_2)

G. slow turn-on, with logic-switched disable*

*$V_{out} \rightarrow 1.25V$

Turn-on ramp slew rate $S = dV/dt = I/C$

for E & G, $I = \frac{1.25V}{R_1}$ $\rightarrow S = 1$ V/ms

for H, $I = V_{BE}/R_3$ $\rightarrow S = 0.01$ v/ms

where $R_1 = 124\Omega$, $R_3 = 6.8k$ and $C_1 = 10$ μF

H. very slow turn-on

Figure 9.14. Application hints for the LM317-style three-terminal adjustable regulator, described in §9.3.4.

capacitor (be sure to add the protection diode; see **F** above). In both circuits the capacitor ramps up with a constant current, as indicated. Because R_1 is small, the capacitor value can become uncomfortably large (e.g., 100 μF for a 10 ms/V ramp with R_1=125 Ω), so you may want to add a follower, as in **H**. Note that these circuits do not ramp from zero output voltage – in **G** it jumps to V_{ref} (1.25 V) before ramping, and in **H** it jumps initially to $V_{ref}+V_{BE}$ (about 1.8 V). For the same reason the "disable" switch in **G** brings the output down only to V_{ref}.

Exercise 9.5. Draw a circuit (with component values), following the scheme of Figure 9.14C, to power a 12 V (nominal) dc cooling fan within an instrument: when little cooling is needed the circuit should provide +6 V (at which the fan runs, but quietly), but when more cooling is needed a logic-level signal (call it HOT) that is provided to your circuit will go HIGH (i.e., to +5 V) to switch on a MOSFET (as in the figure), at which point your circuit should increase the fan voltage to +12 V.

9.3.5 317-style regulator: circuit examples

Before moving on to the subject of low-dropout regulators, let's take a look at a few useful real-world examples that are easily handled with 317-style 3-terminal adjustable regulators: a 0 to ±25 V dual-tracking adjustable bench supply, a proportional fan speed control, and two ways to create an adjustable high-voltage dc supply.

A. Laboratory dual-tracking bench supply

It's nice to have an adjustable dual supply on the bench, for example with matched ("dual tracking") outputs that go from 0 to ±25 V at currents to 0.5 A. You can buy them for a few hundred dollars or so; but you can make one pretty easily with a pair of 3-terminal adjustable regulators. Figure 9.15 shows how, beginning with the unregulated dc inputs. The positive regulator is an LM317 in a TO-220 package (suffix T), with an appropriately sized heatsink ($R_{\Theta JC}$~2°C/W; see §9.4). To get adjustability down to zero volts we use the trick of Figure 9.14B (output sense divider return to -1.25 V). For the tracking negative output we negate accurately the voltage at U_1's ADJ pin to program the LM337 negative regulator.

A few details: we added a noise-suppression capacitor C_1 to U_1 (along with a protection diode), and we used a precision low-noise op-amp to generate the inverted control voltage (thus no capacitor is needed at U_2's ADJ pin). Resistors R_1 and R_6 provide the regulators' 10 mA minimum load current, but note that op-amp A_2 must be able to source 10 mA, and, likewise, R_5 must sink enough current to power the op-amp, sink the 10 mA through R_2, and bias the zener Z_1. Schottky diodes D_1 and D_2 protect against reverse polarity, for example from a load bridging both rails. Finally, if there is some way in which the dc inputs could be shorted abruptly to ground, diodes should be connected between input and output terminals of each regulator (as in Figure 9.14F), to protect them from the fault current flowing back from the output bypass capacitors (including whatever you've got in the powered external circuit); a couple of 1N4004 rectifiers would be fine here.

Exercise 9.6. Zener reference Z_1 (actually it's a low-current shunt regulator) has a specified current range of 50 μA to 20 mA. Show that this circuit respects those limits, by calculating the zener current at both maximum and minimum negative input voltage (i.e., at -38 V and at -28 V). Assume the dual op-amp's supply current is in the range of 3 mA to 5.7 mA.

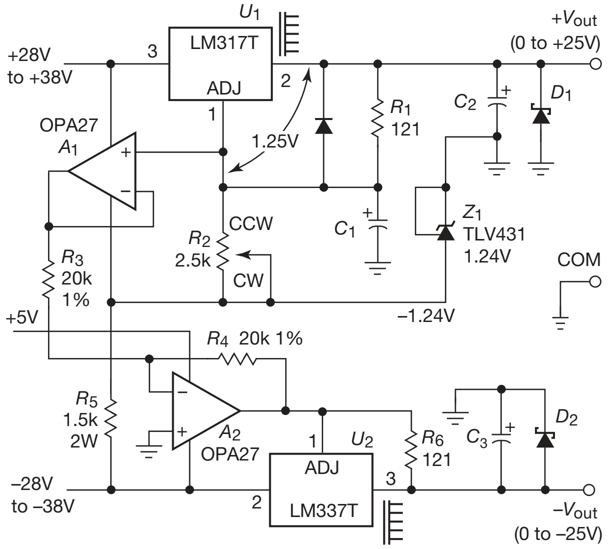


Figure 9.15. Laboratory dual-tracking bench supply, 0 to ±25 V, implemented with 317-style three-terminal linear regulators.

B. Proportional fan control

On–off (or high–low) fan control, as in Exercise 9.5, is simple; but you can do better than "bang–bang" control by tailoring the fan's drive voltage (thus fan speed) to hold the heatsink at a given elevated temperature setpoint. Figure 9.16 shows how to use an LM317T as a power driver, exploiting its internal protection (overtemperature, overcurrent) and its simple ADJ-pin control scheme. Here we've used the forever-popular LM358 op-amp as an integrator of the error signal from a bridge, one leg of which is a negative

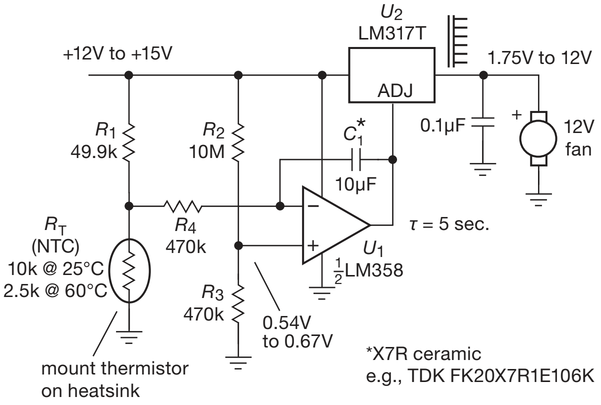

Figure 9.16. Controlling fan speed with analog feedback from a thermistor sensor, with 60°C setpoint. Fully analog control eliminates switching noise, and variable-speed operation minimizes acoustic noise.

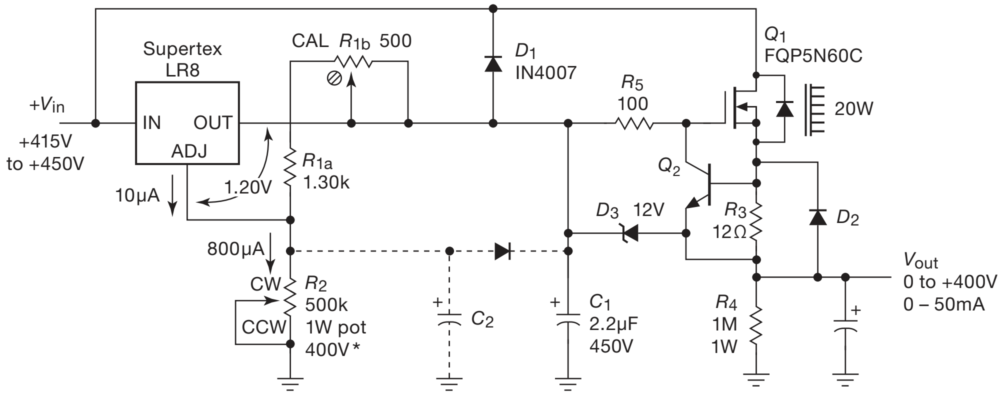

Figure 9.17. High-voltage adjustable supply I, 0 to 400 V, implemented with a low-current LR8 plus outboard MOSFET follower. * See text for R_2's voltage rating.

temperature coefficient (NTC) thermistor. The inputs are balanced at the 60°C setpoint, above which the integrator's output, and therefore the fan voltage, is driven positive. The integrator time constant R_4C_1 should be chosen somewhat longer than the thermal time constant from the heat source(s) to the thermistor sensor, to minimize feedback-loop "hunting."

We chose the LM358 for its low cost (as little as \$0.10 in unit quantity), single-supply operation (input and output to the negative rail), and robust tolerance to supply voltages well beyond +15 V. But its 50 nA worst-case input offset current forced us to use a rather large integrating capacitor. Ideally one would like an inexpensive single-supply op-amp with bias-compensated or FET inputs. Happily, there's the unusual single-supply OPA171, whose offset current is down in the tens of picoamps even at elevated temperature, and which operates over the full supply voltage range of 3 V to 36 V; it costs about a dollar (but you come out ahead, with the less expensive 0.47 μF capacitor that goes with a 10 MΩ resistor R_4).

C. High-voltage supply I: linear regulator

Figure 9.17 shows a simple circuit that extends the output current of the LR8 high-voltage 3-terminal regulator from Supertex. This part operates to 450 V, but it's limited to 10 mA of output current, and further limited by power dissipation (∼2 W in the D-PAK power package, depending on circuit-board foil pattern; see Figure 9.45) when operating at nearly its full rated voltage differential.

The regulator's minimum load current is specified as 0.5 mA, so we operate it at slightly less than 1 mA, with its output driving a high voltage power MOSFET follower. Feedback is local to the LR8, so the follower introduces an offset (slightly load dependent) that can be approximately trimmed to zero by R_{1b}. Q_2 provides current limiting, and diodes D_1–D_3 protect against the many injuries that are possible in a high voltage supply. Add capacitor C_2 (along with a protection diode) for noise reduction. The output-setting pot R_2 dissipates 320 mW at maximum output voltage, so it's wise to use a part rated at 1 W or more. Be sure to check the pot's specifications for a *voltage* rating, as well; for this application you could use a Bourns 95C1C-D24-A23 or a Honeywell 53C3500K.

D. High-voltage supply II: dc–dc switching converter

Another approach to generating regulated high-voltage dc is to use a switching dc–dc converter module. These come with a huge range of output voltages (to tens of kilovolts) and with selectable output polarity. You can get a wide variety of these with built-in regulator circuitry, intended to be powered by a low-voltage dc input (+5 V, or +15 V, etc.), and with the output voltage programmed via a variable resistor or by a low-voltage dc programming input. These are handy for generating the bias for a photomultiplier tube, avalanche photodiode detector, channel plate multiplier, or other devices that need a stable high-voltage low-current bias.

A less-expensive approach is to use a bare-bones dc–dc converter module that lacks internal regulation; for these the output voltage scales with input voltage – they are sometimes called "proportional" dc–dc converters. Typical units take a 0–12 V dc input, with output ranges going from as little as 100 V to as much as 25 kV, at power ratings from a fraction of a watt to 10 watts or so. Figure 9.18 shows how to do this, using one of EMCO's 3 W proportional converter modules. The output voltage is controlled by R_3, with the low end of the voltage range set by the LM317's 1.25 V minimum output. The optional current limit modification protects the converter when the output is overloaded.[19] The total cost of the external circuit components here adds up to less than \$0.75 in unit quantity – you can't beat that, for cheap!

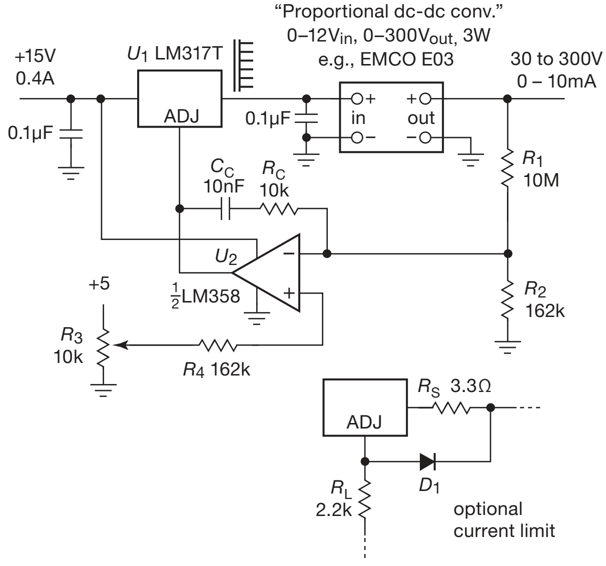

Figure 9.18. High-voltage adjustable supply II, implemented with a proportional dc–dc converter module powered by an LM317 with feedback control to the ADJ pin.

9.3.6 Lower-dropout regulators

There are applications where the ∼2 V dropout voltage (i.e., minimum input–output voltage differential) of these regulators is a serious limitation. For example, in a digital logic circuit you might need to create a +3.3 V supply from an existing +5 V; or (worse), a +2.5 V supply from an existing +3.3 V supply rail. Another application might be a portable device needing +5 V, and operating from a 9 V alkaline battery; the latter begins life at about 9.4 V, declining at end of life to 6 V or 5.4 V (depending on whether you subscribe to 1.0 V/cell or 0.9 V/cell as the definition of a fully exhausted battery). For these situations you need a regulator that can operate with a small input–output differential, ideally down to a few tenths of a volt.

One solution is to abandon linear regulators altogether and use instead a switching regulator (§9.6), which deals differently with voltage differential. Switchers (the nickname for switching, or switchmode, regulators) are popular in such applications; but they have problems of their own (particularly in terms of switching noise and transients), and you may prefer the placid calm, and simplicity, of a linear regulator.

Look again at the conventional linear regulators in Figures 9.6 and 9.9; the ∼2 V dropout is caused by the two cascaded V_{BE} drops of the Darlington output follower, plus another V_{BE} across the current-limiting sense resistor. The solution (inspired by Sziklai's complementary replacement for a conventional Darlington; see §2.4.2A) is to use a different output-stage topology, and a different current-limit scheme.

Figure 9.19 shows a partial solution. This design retains an *npn* output follower, but substitutes a *pnp* driver transistor; the latter can run close to saturation, eliminating one of the V_{BE} drops. Further, the current-limit sense resistor has been relocated in the collector ("high-side current sensing"), where it does not contribute to the dropout voltage (as long as its drop is less than a V_{BE} at current limit, which is easy to manage if a comparator is used to sense maximum current, as shown). With this circuit topology the LT1083-85 regulators (rated at 7.5 A, 5 A, and 3 A, respectively) achieve a typical dropout of 1 V at their maximum current.

We've used this series of regulators in many designs, with good success. Electrically they mimic the classic LM317 three-terminal adjustable regulator, with an internal 1.25 V referenced to the output pin. However, as with most low-dropout designs, these regulators are fussy about bypassing: the datasheet recommends 10 μF at the input, and at least 10 μF (tantalum) or 50 μF (aluminum electrolytic) at the output. If the ADJ pin is bypassed for noise reduction (see §9.3.13), the datasheet recommends tripling the output bypass capacitor value.

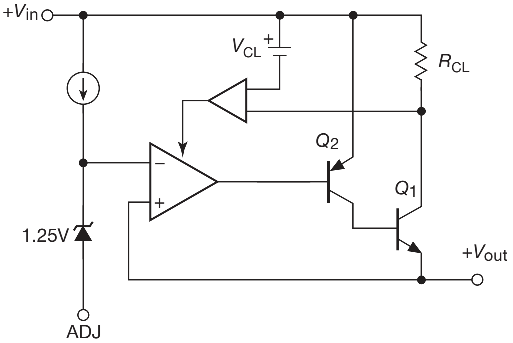

Figure 9.19. LT1083-85 series three-terminal positive regulators with reduced dropout voltage.

[19] We administered a torture test to an unprotected converter and measured an input current of 1.2 A.

9.3.7 True low-dropout regulators

The dropout voltage can be reduced further, by replacing the *npn* (follower) output stage with a *pnp* (common emitter) stage (Figure 9.20A). That eliminates the V_{BE} drop, the dropout voltage now being set by transistor saturation. To keep the dropout voltage as low as possible, the current-limit circuit eliminates the series sense resistor, using instead a fractional output-current sample, derived from a second collector on Q_1. This is less accurate, but "good enough," given that its job is merely to limit destructive currents: the datasheet for the 3 A LT1764A, for example, specifies a current limit of 3.1 A (minimum) and 4 A (typical).[20]

Many contemporary low-voltage regulators use MOSFETs, rather than bipolar transistors. The analogous LDO circuit is shown in Figure 9.20B. Like the bipolar LDO, these parts tend to be rather fussy about bypassing. For example, the TPS775xx regulators set requirements on both the capacitance and ESR of the output bypass: the capacitance must be at least 10 μF (with an ESR no less than 50 mΩ *and* no greater than 1.5 Ω), with the datasheet additionally showing regions of stability and instability in graphs plotting combinations of C_{bypass}, ESR, and I_{out}.

9.3.8 Current-reference 3-terminal regulator

All the regulators we've seen so far use an internal voltage reference (usually a 1.25 V "bandgap" reference), against which a voltage-divider fraction of the output is compared. The result is that you cannot have an output voltage less than that reference. In most cases this sets a lower bound of V_{out}=1.25 V (though a few can go down to 0.8 V, or even 0.6 V; see Table 9.3 on page 614).

Sometimes you want a lower voltage! Or you may want to have an adjustment range that goes clear down to zero volts. This has traditionally required an auxiliary negative supply, as for example in the book's previous edition's "laboratory bench supply" (its Figure 6.16).

A nice solution is the LT3080-style regulator, originated by Linear Technology (Figure 9.21). It is a 3-terminal adjustable positive regulator (with a fourth pin, in some package styles) in which the ADJ pin (called SET) sources an accurate *current* (I_{SET}=10 μA, ±2%); the error amplifier then forces the output to follow the SET pin. So, if you connect a resistor R from SET to ground, the output voltage will be simply $V_{\mathrm{out}} = I_{\mathrm{SET}}R$. The output-voltage range goes all the way to zero: when R=0, V_{out}=0.[21]

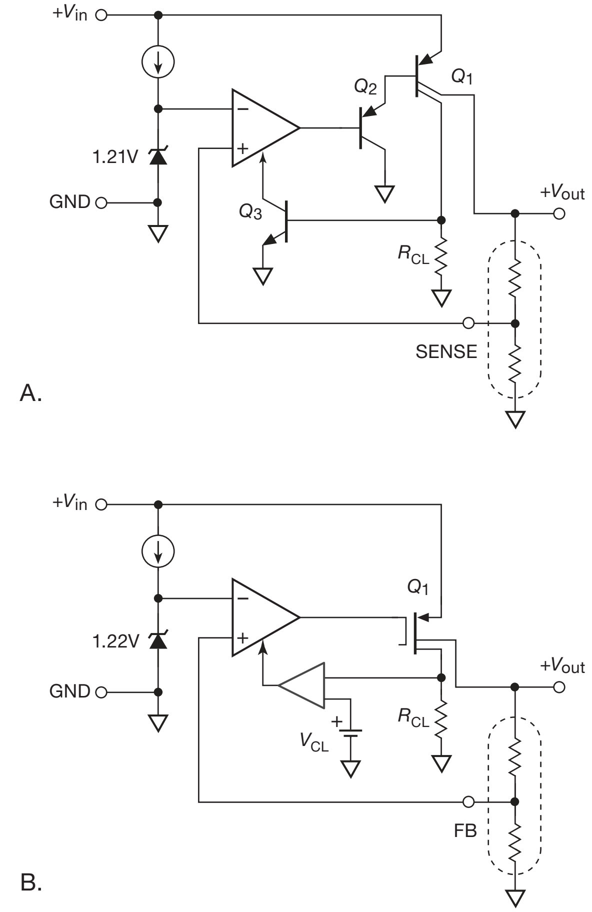

Figure 9.20. A. LT1764 (bipolar) and B. TPS75xxx (CMOS) positive LDO regulators.

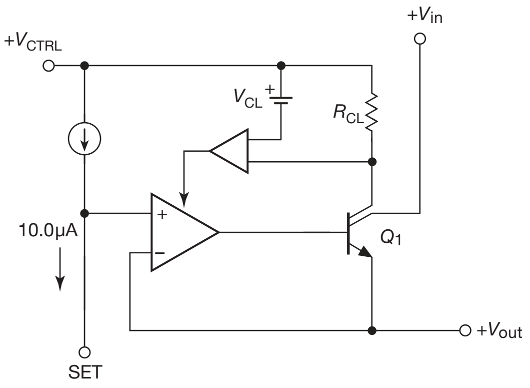

Figure 9.21. LT3080 "3-terminal" adjustable positive voltage regulator with precision current reference.

[20] The CMOS TPS755xx series of 5 A LDO regulators has a revealing current limit specification of 5.5 A (minimum), 10 A (typical), and 14 A (maximum).

[21] With one slight *gotcha*: the minimum load current is ~1 mA. So, for example, the output voltage into a 100 Ω load will not go below 0.1 V. To reach 0 V you need to sink a small current toward a negative supply.

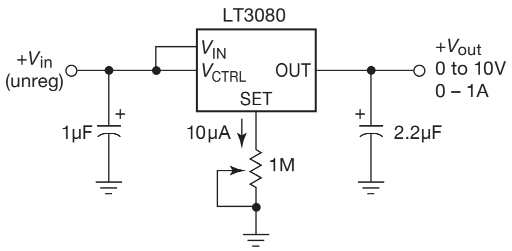

Figure 9.22. Positive regulator, adjustable down to 0 V.

Figure 9.22 shows the basic connection, here used to make a 0–10 V adjustable supply. The 3080-series architecture makes it easy to add an adjustable current limit, itself adjustable down to zero, as shown in Figure 9.23. The upstream regulator U_1 is by itself a 0–1 A current source; the cascaded regulators together act as a current-limited voltage source (or a voltage-limited current source, depending on the load).

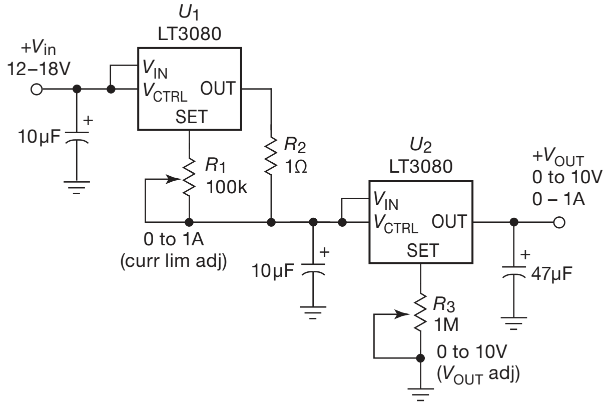

Figure 9.23. Adjustable “bench supply,” with independent voltage and current limit controls.

The 3080-style regulator includes a $V_{\rm CTRL}$ pin in the packages with more than three pins (e.g., TO-220-5), which lets you run the internal control circuitry from a higher input voltage. When operated that way, the LT3080 is a true low-dropout voltage regulator, with a typical dropout voltage of 0.1 V at 250 mA load current. Its low impedance (emitter follower) output requires only 2.2 μF output bypassing, with no minimum ESR requirement.

9.3.9 Dropout voltages compared

To summarize the business of dropout voltage in these various regulator designs, we plotted in Figure 9.24 the dropout voltages of a representative regulator of each type. The curves are taken from “typical” dropout specifications in the datasheets, all at 40°C, and are scaled to the rated maximum current of each device. Three categories are clearly seen: conventional regulators with Darlington *npn* pass transistor (top three curves); lower-dropout regulators with *pnp* driver and *npn* output follower (middle curve); and true low-dropout regulators with *pnp* or *p*MOS output stage (bottom four curves). Note particularly the resistive behavior of the CMOS regulators (bottom two curves), where the dropout voltage is linear in output current, and goes to zero at low current.

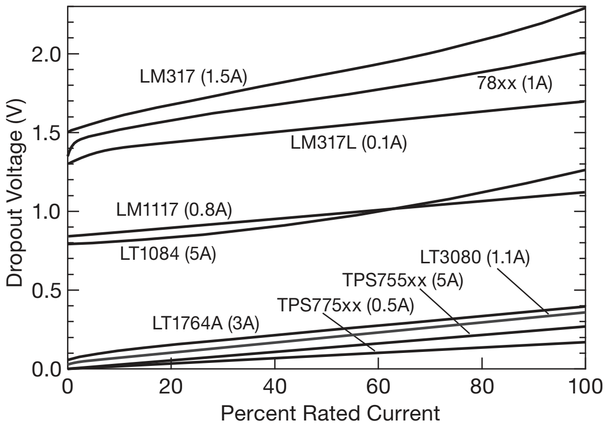

Figure 9.24. Linear regulator dropout voltage versus output current. The bottom pair of curves (TPS prefix) are CMOS; all others are bipolar. See also Figure 9.11.

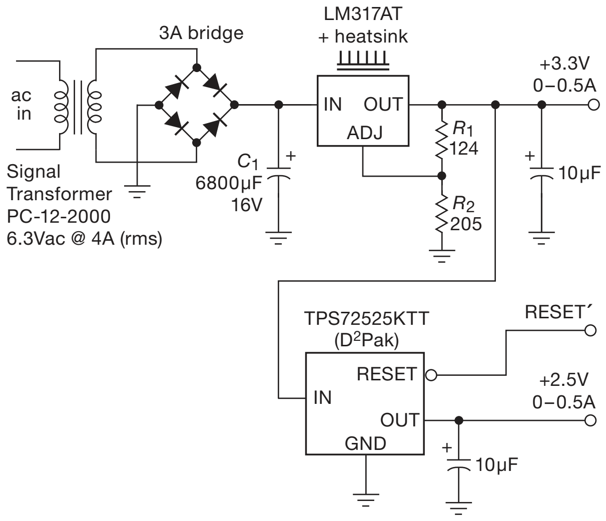

Figure 9.25. Dual low-voltage regulated supply.

9.3.10 Dual-voltage regulator circuit example

As an illustration, imagine we have a small digital circuit requiring +3.3 V and +2.5 V regulated supplies, each capable of supplying up to 500 mA. Figure 9.25 shows how to do this with a small PCB-mounted transformer driving an unregulated bridge rectifier, followed by a pair of linear regulators. The design is straightforward: (a) we began by choosing a transformer to deliver about +8 Vdc (unregulated) from Signal Transformer's nice selection; a unit with 6.3 Vrms is about right (its ac peak amplitude of $6.3\sqrt{2} \approx 9$ V is reduced by two diode drops); (b) we chose a conservative transformer current rating of 4 Arms, to allow for the extra heating caused by the relatively short current pulses in a bridge rectifier circuit ("small conduction angle," see §1.6.5); (c) the storage capacitor C_1 was then chosen (using $I = C\,dV/dt$) to allow ~1 Vpp ripple at maximum load current, with a voltage rating adequate to allow for the worst-case combination of high line voltage and zero output load; (d) for the +3.3 V output we used a 3-terminal adjustable regulator (LM317A, in a TO-220 power package), mounted on a small heatsink (10°C/W, adequate for the ~5 W maximum power dissipation; see §9.4; (e) finally, for the +2.5 V output we used a low-dropout CMOS fixed voltage regulator (the last two digits of the part number designate +2.5 V), taking its input from the regulated +3.3 V.

Several comments. (a) We have not shown details of the ac line input, including fuse, switch, and noise filter; (b) the bypass capacitor values shown are conservative (larger than the specified minimum), in order to improve transient response and provide robust stability; (c) the TPS72525 regulator includes an internal "supervisor" circuit providing a RESET′ output that goes LOW when the regulator falls out of regulation, often used to alert a microprocessor to save its state and shut down.

9.3.11 Linear regulator choices

Fixed or adjustable? 3-terminal or 4-terminal? Low dropout or conventional? How do you decide which type of integrated linear regulator to use? Here is some guidance.

- If you don't need low dropout, stick with a conventional regulator, either 3-terminal fixed (78xx/79xx style, Table 9.1) or 3-terminal adjustable (317/337 style, Table 9.2): they are less expensive, and they're stable with small-value bypass capacitors.
  - fixed: needs no external resistors; but limited voltage choices, and no trimmability.
  - adjustable: settable and trimmable, and fewer types to stock; but require a pair of external resistors.
- If you need adjustability down to zero volts, use a current-reference regulator (LT3080 style).
- If you need low dropout ($V_{\text{DO}} \le 1$ V) you have many LDO choices (Table 9.3):
  - For input voltages ≥ 10 V, use bipolar types:
    - ∗ LT1083-85, LM1117, LM350, LM338 style (fixed or adj) for ~ 1 V dropout;
    - ∗ LT1764A style (fixed or adj) for ~ 0.3 V (but see §9.3.12);
  - For input voltages ≤ 10 V there are many MOSFET LDOs (fixed or adj).
- If you need high efficiency, high power density, voltage stepup, or voltage inversion, use a switching regulator/converter (§9.6).

For high-current low-voltage applications, consider the use of a regulator that has separate control and pass-element input pins, like that shown in Figure 9.21. These are indicated in the "boost, bias pin" column of Table 9.3.

9.3.12 Linear regulator idiosyncrasies

These integrated regulators are genuinely easy to use, and, with their built-in overcurrent and thermal protection circuits, there's not much to worry about. Circuit designers should, however, be aware of the following idiosyncrasies.

A. Pinout variations

Our students succumb, with distressing frequency, to this gotcha: complementary polarity regulators, such as our favorite LM317 (positive) and LM337 (negative) 3-terminal adjustables, often have *different pinouts* (Figure 9.26). In the case of the 78xx/79xx fixed regulators, for example, this creates real mischief: the mounting tab is ground for the 78xx positive regulator (so you can screw it to the chassis, or solder it to the circuit board's ground plane), but for the 79xx negative regulator the tab is connected electrically to the input voltage – ground that and you're in real trouble![22]

	1	2	3	TAB
LM317	ADJ	OUT	IN	OUT
LM337	ADJ	IN	OUT	IN
78xx	IN	GND	OUT	GND
79xx	GND	IN	OUT	IN

Figure 9.26. Never assume that negative regulators have the same pinouts as their positive twins. In fact, don't assume *anything* without consulting the datasheet.

[22] This comes about because the IC's substrate (normally at the most negative voltage) is soldered to a metal mounting frame, which is the best pathway for heat removal.

Notes: (a) "Low Dropout" (LDO) regulators typically drop <100mV, except at the highest currents; sorted approximately by ascending I_Q and I_{out} capability, with some family grouping; the ADJ versions of some parts have less accuracy than the fixed versions (which can be laser trimmed). (b) 10Hz-100kHz, with no noise reduction cap, unless indicated otherwise. (c) input and other capacitors also required. (d) fixed voltage versions only. (e1) 100Hz-100kHz or 200Hz-100kHz. (e2) 10Hz-10kHz. (e3) 300Hz-50kHz. (e4) 10Hz-1MHz. (f) with NR cap. (f2) if the ADJ pin is bypassed, larger output capacitors are required, see datasheet. (g) output-input differential. (h) minimum load current. (k) qty 1k or more. (m) min or max. (n) ***bold italic*** indicates an inexpensive "jellybean." (nV) nV/√Hz, with 10nF filter cap. (o) "load-dump": withstands input voltage transients (or continuous inputs) to 60V (or 40V for some parts), and does not pass the spike through to the output; often associated with "automotive" parts. (p) power good. (q) some pkgs only. (r) delayed reset output for μC. (rec) recommended. (s) slew control. (t) typical. (ti) some of TI's parts have an internal EEPROM, allowing quick custom factory voltage programming. (tt) over operating temperature range. (u) unit qty. (v) adjustable version only. (v2) filter cap across feedback resistor. (w) ADJ and filter avail in 8-pin pkg. (x) reversed input voltage with excess current flow may damage part, a Schottky diode is recommended; although not marked "**Δ**," these parts may have a reverse-diode function. (y) check datasheet. (z) choose between two versions.
Δ = input-output back diode conducts, limit current; also, reverse supply not allowed, see note x. □ = protected against reverse polarity input.

Comments: **A:** current-programmed; $V_{control}$ dropout 1.6V max; 1mA min load. **B:** 100V for -HV version. **C:** -C suffix for looser tolerance and tempco, etc. **D:** ADP7104 suggested alternative. **E:** see also TI's TL1963A, $2.65. **F:** control and pass-transistor inputs. **G:** internal charge pump.

B. Polarity and bypassing

As we mentioned earlier, the negative versions of common positive regulators have a different output topology (an *npn* common emitter stage), and require larger bypass capacitors to prevent oscillation. Always "go by the book" (the datasheet, that is) – don't assume you know better. Also, be careful to connect the bypass capacitors with correct polarity (and see next).

C. Reverse polarity protection

An additional caution with dual supplies (whether regulated or not): almost any electronic circuit will be damaged extensively if the supply voltages are reversed. The only way that can happen with a single supply is if you connect the wires backward; sometimes you see a high-current rectifier connected across the circuit in the reverse direction to protect against this error. With circuits that use several supply voltages (a split supply, for instance), extensive damage can result if there is a component failure that shorts the two supplies together; a common situation is a collector-to-emitter short in one transistor of a push–pull pair operating between the supplies. In that case the two supplies find themselves tied together, and one of the regulators will win out. The opposite supply voltage is then reversed in polarity, and the circuit starts to smoke. Even in the absence of a fault condition like this, asymmetrical loads can cause a polarity reversal when power is turned off. For these reasons it is wise to connect a power rectifier (preferably Schottky) in the reverse direction from each regulated output to ground, as we drew in Figure 9.8.

Some regulator ICs are designed to block any current flow if the input voltage is lower than the output; these are marked with a bullet dot symbol (●) in the "reverse block" column in Table 9.3. Other regulator ICs go further and also block current flow for reversed *input* polarity; these are marked with a square symbol (□).

D. Ground-pin current

A particular idiosyncrasy of bipolar low-dropout regulators with *pnp* output stages (Figure 9.20) is the sharp rise in ground-pin current when the regulator is close to dropout. At that point the output stage is near saturation, with greatly reduced beta, and therefore requires substantial sinking base current. This is particularly noticeable when the regulator is lightly loaded, or unloaded, when it would otherwise have only a small ground-pin or quiescent current. As an example, the bipolar LT1764A-3.3 (fixed 3.3 V LDO), driving a 100 mA load, has a normal ground-pin current of about 5 mA, rising to ∼50 mA at dropout. The no-load quiescent current shows similar behavior, spiking to ∼30 mA from its normal ∼1 mA.[23] Manufacturers rarely advertise this "feature" on the front page of their datasheets, but you can find it inside, if you look. It is of particular importance in battery-operated devices. *A caution*: the quiescent ground-pin currents listed in the I_Q column of Table 9.3 are for a light load and with the input voltage above dropout.

E. Maximum input voltage

Table 9.3 lists the maximum specified input voltage for more than a hundred LDO linear regulators. CMOS regulators are good choices for low-voltage designs, and they come in a dazzling variety of fixed voltages (and, of course, adjustable versions): for example, the TPS7xxxx series from Texas Instruments includes a dozen types, each of which comes in a choice of 1.2, 1.5, 1.8, 2.5, 3.0, 3.3, or 5.0 volt outputs. But be careful, because many of these CMOS regulators have a specified maximum input voltage of just +5.5 V.[24] Some CMOS regulators, however, accept up to +10 V input; for higher input voltage you've got to use bipolar regulators, for example the LT1764A or LT3012, with input voltage ranges of +2.7–20 V and

[23] The load-induced additional ground current would normally be I_{load}/β driving the base of the *pnp* pass transistor, but during dropout the ever-zealous feedback loop provides a base drive appropriate for the LDO's maximum load-current rating. Some designs carefully limit this drive current, whereas others detect the saturation condition and limit the current accordingly. You've got to pay close attention to this behavior of candidate LDOs when designing battery operated devices, if you want to maximize remaining operating time after the battery voltage has dropped below the LDO's input criteria. Alternatively you may want to select an LDO that uses a *p*-channel MOSFET pass transistor and does not exhibit increased ground current at high loads or during dropout. For example, a 5 V regulator like the LT3008-5 runs at 3 μA, but this soars to 30 μA if the battery drops below 5 V. However, a TLV70450 (with internal *p*MOS pass transistor) suffers no increase at all, continuing to draw 3 μA under the same conditions.

[24] Contemporary regulator ICs, with their nanometer-scale features, are more susceptible to overvoltage transients and the like, as compared with robust legacy parts with their relatively large bipolar transistors. We've seen painful experiences, for example when a carefully designed and tested small PCB, filled to the brim with tiny parts, suffers unexplained failures in the field or at the customer's test sites. Sometimes this is due to uncontrolled (and arguably improper) user-supplied input transients. Adding a transient voltage suppressor (see Chapter *9x*) at the input is a wise precaution for regulator ICs powered from an off-card dc source. Low-voltage ICs (such as those with 6 V or 7 V absolute-maximum ratings) are best powered from an on-card regulated 5 V, etc., rather than from external sources of power. (An exception might be made for a 3.7 V Li-ion cell.) Be very careful!

4–80 V, respectively. See §9.13.2 for an interesting way to extend the input-voltage range, to as much as +1 kV!

F. LDO Stability

It's worth repeating that low-dropout regulators can be quite fussy about bypassing (see the comments in §9.3.7) and that there are large differences among different types. For example, the LDO Selection Guide from Texas Instruments includes a C_{out} column, whose entries range from "No Cap" to "100 μF tantalum." The symptoms of instability may manifest themselves as incorrect, or even zero, output voltage. The latter symptom flummoxed one of our students, who replaced an LP2950 (fixed 5 V LDO) several times before the real culprit was identified: he used a 0.1 μF ceramic bypass capacitor, which is less than the specified 1 μF minimum, and also whose equivalent series resistance (ESR; see §*1x.3*) is too low, a hazard discussed in the Application Hints section of the regulator's datasheet.[25] A more serious symptom of oscillation is output *overvoltage*: we had a circuit with an LM2940 LDO (+5 V, 1 A) that was bypassed in error with 0.22 μF (instead of 22 μF); its internal oscillation caused the measured dc output to go to 7.5 V!

Table 9.3 has two columns to assist in selecting a part, C_{out} (min) and ESR (min,max). But these numbers should be considered a rough guide, and they do not capture everything you need to know to ensure proper operation. You'll find more guidance (e.g., contours of stable operation versus capacitance, ESR, and load current; see for example Figure 9.27) in the plots and applications section of the datasheet – study it carefully!

G. Transient response

Because voltage regulators must be stable into any capacitive load (the sum of all downstream bypass capacitance, often many μF), their feedback bandwidth is limited (analogous to op-amp "compensation"), with typical loop bandwidths in the range of tens to hundreds of kilohertz. So you rely on the output capacitor(s) to maintain low impedance at higher frequencies. Or, to say it another way, the output capacitor(s) are responsible for holding the output voltage constant in the short term, in response to a step change in load current, until the regulator responds in the longer term. It's particularly important to include capacitors of low ESR (and equivalent series inductance, ESL) in the mix when you have low-voltage loads with abrupt current changes, as, for example, with microprocessors (which may generate steps of many amps).

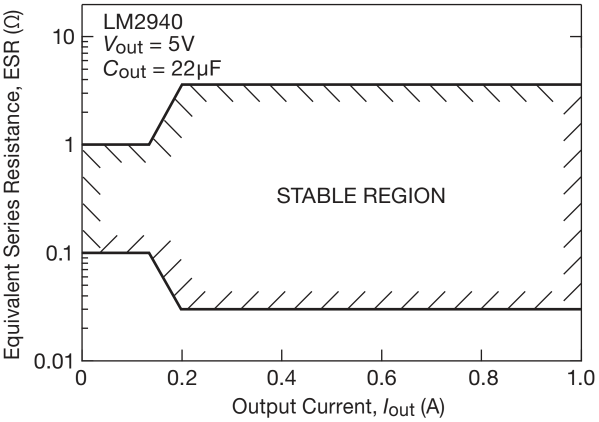

Figure 9.27. Low-dropout linear regulators can set rather fussy requirements for the ESR of the output capacitor, as seen for the LM2940; often you have to obey both minimum and maximum bounds – beware!

We rigged up a 1 V 6 A LDO regulator, using the Micrel MIC5191 control chip, and measured the output response when we made abrupt load steps between 2 A and 4 A, and between 1 A and 5 A. We compared the transient response with two prototype configurations: (a) on a solderable protoboard, using mostly through-hole components; and (b) on a carefully laid-out[26] printed circuit board, using mostly surface-mount components, and with plenty of additional capacitance at both input and output.[27] Figures 9.28–9.31 show the measured step responses. The use of plentiful low-inductance surface-mount technology (SMT) capacitors and low resistance (and low inductance)

[25] In these words: "Ceramic capacitors whose value is greater than 1000 pF should not be connected directly from the LP2951 output to ground. Ceramic capacitors typically have ESR values in the range of 5 to 10 mΩ, a value below the lower limit for stable operation (see curve Output Capacitor ESR Range). The reason for the lower ESR limit is that the loop compensation of the part relies on the ESR of the output capacitor to provide the zero that gives the added phase lead. The ESR of ceramic capacitors is so low that this phase lead does not occur, significantly reducing phase margin. A ceramic output capacitor can be used if a series resistance is added (recommended value of resistance about 0.1 Ω to 2 Ω)."

[26] Expertly done by our student Curtis Mead.

[27] Specifically, for the through-hole configuration we used a 10 μF radial tantalum and two 0.1 μF ceramic bypass capacitors at the input, and a 47 μF ceramic (X5R) SMT plus another 10 μF radial tantalum at the output. For the surface-mount configuration we used a 560 μF radial aluminum polymer capacitor, a 100 μF SMT tantalum polymer capacitor, and two 22 μF ceramic (X5R, 0805) SMT capacitors at both input and output, plus two more 10 μF ceramic (X5R, 0805) SMT capacitors at the output.

power and ground foils produce a stunning improvement: the peak output transient dip drops by a factor of 10 (from ∼40 mV to ∼4 mV for the larger step amplitude), and the output recovers to within a fraction of a millivolt (compared with a ∼6 mV drop for the larger step amplitude).

A different kind of transient-response issue concerns input-voltage transients, and the amount of spike feedthrough to the regulated output. This is different from the "Regulation, line" column in Table 9.3, which lists dc (or low-frequency) rejection of input variations. Input capacitors are somewhat helpful in reducing input-transient effects, but larger output capacitors, especially with low ESR, are a better defense. A special case is a so-called automotive "load dump," a rapid input spike caused, for example, by accidental disconnection of the car battery (from a loose connection, or corrosion, or human error) while being charged by the alternator. This can cause the normal 13.8 V power rail to spike to amplitudes of 50 V or more, causing a spike at a regulator's output. Worse, it can destroy the IC by exceeding its maximum specified input voltage (the "$V_{\rm in}$ max" column of Table 9.3). Parts specifically designed to deal with load dumps are marked with an "o" note in the corresponding $V_{\rm in}$ entry.

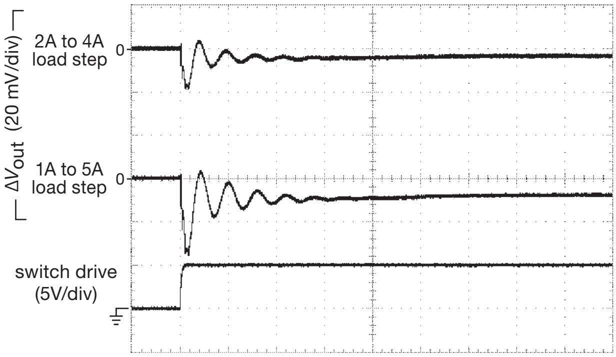

Figure 9.28. Output voltage response to a step increase in load current: 1 V 6 A LDO regulator, breadboarded primarily with through-hole components. Horizontal: 4 μs/div.

H. Noise

Linear regulators vary considerably in the level of output noise (that is, spectrum of output-voltage fluctuations). In many situations this may be unimportant, for example in a digital system, where the circuit itself is inherently noisy.[28] But for low-level or precision analog electronics where noise is important, there are regulators with superior noise specifications, for example the LT1764/1963 (40 μVrms,

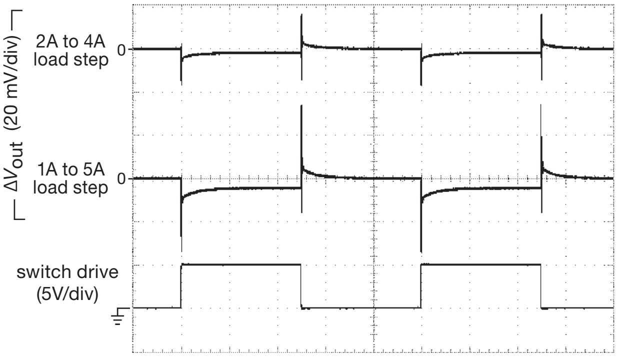

Figure 9.29. Same as Figure 9.28, with 'scope slowed to 400 μs/div to show full load cycle.

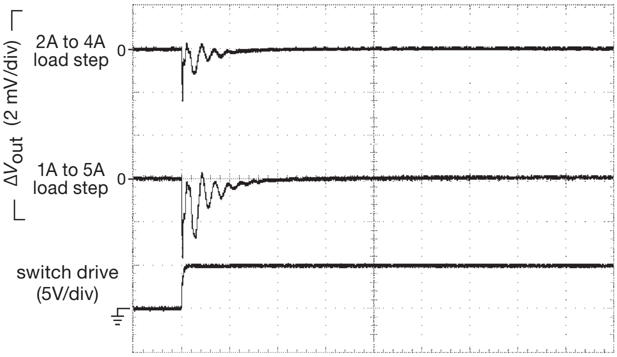

Figure 9.30. Same as Figure 9.28, but built on a printed circuit board using surface-mount capacitors. Note expanded vertical scale.

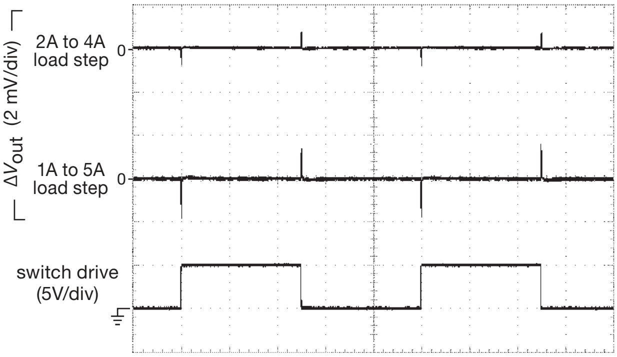

Figure 9.31. Same as Figure 9.30, with 'scope slowed to 400 μs/div to show full load cycle.

[28] In such systems the additional noise of a switching regulator (§9.6) is usually irrelevant, and so switching converters are almost universally used to power digital circuits. They are particularly well suited, owing to their small size and high efficiency, and especially so for the low dc supply voltages (∼1.0–3.3 V) used in digital logic.

10 Hz–100 kHz) or the ADP7102/04 (15 μVrms). Additionally, some regulators provide access to the internal voltage reference, so that an external filter capacitor can be added to suppress all but the low-frequency end of the noise spectrum, for example the LT1964 negative regulator (30 μVrms with 10 nF capacitor); see §9.3.13.

Because manufacturers specify noise characteristics differently (bandwidth, rms versus peak-to-peak, etc.), it can be difficult to compare candidate parts. We've made an attempt in the $V_n@V_{out}$ columns of Table 9.3, but be sure to consult the footnotes (and then the datasheets).

I. Shutdown protection

Some regulator types can be damaged if they see a large capacitance at their output, and the input voltage is brought abruptly to zero (e.g., by a crowbar, or an accidental short-circuit). In that situation the charged output capacitance can source a destructive current back into the regulator's output terminal. Figure 9.32 shows how to prevent such damage, in this case with the popular LM317. Although many engineers don't bother with this nicety, it is the mark of a careful circuit designer. A similar hazard exists when an external bypass capacitor is used to filter the voltage noise of the regulator's reference; see §9.3.13.[29]

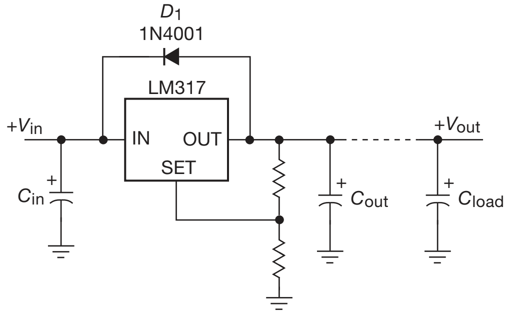

Figure 9.32. Diode D_1 protects the regulator if the input is suddenly grounded.

9.3.13 Noise and ripple filtering

The output noise from a linear regulator is caused by noise in the reference, multiplied by the ratio of V_{out}/V_{ref}, combined with noise in the error amplifier, and with noise and ripple at the input terminal that is not completely suppressed by feedback.[30] Some regulators let you add an external capacitor for lowpass filtering of the internal voltage reference and thus the dc output. Figure 9.33 shows several examples. In Figure 9.33A the ADJ pin of the LM317-style 3-terminal adjustable regulator is bypassed to ground; this provides significant noise improvement by preventing multiplication of the reference noise voltage by the factor $1 + R_2/R_1$ (the ratio of output voltage to 1.25 V reference voltage). It also improves the input ripple rejection ratio, from 65 dB to 80 dB (typical), according to the datasheet. Note the additional protection diode D_2, needed if the noise bypass capacitor C_1 is greater than 10 μF.

This scheme does not eliminate the reference noise, it just prevents it (an ac signal) from being "gained up" by the dc gain factor V_{out}/V_{ref}. The noise filtering in Figures 9.33B and C is more effective, because it filters the reference voltage directly. In Figure 9.33B the LT3080's SET pin, sourcing a stable 10 μA current, is converted to the output voltage by R_{SET}, filtered by C_1; the regulator's output is a unity-gain replica of this filtered voltage. With $C_1 = 0.1\,\mu$F, the reference noise is less than that of the error amplifier, producing an output noise of ~40 μVrms (10 Hz–100 kHz). Note that the noise-filtering capacitor slows the regulator's startup: a 0.1 μF capacitor in a 10 V regulator circuit (R_{SET}=1 MΩ) has a startup time constant $R_{SET}C_1$ of 100 ms.

Finally, Figure 9.33C shows a CMOS low-dropout regulator with a dedicated noise-reduction (NR) pin, for filtering directly the reference voltage presented to the error amplifier. With the recommended 0.1 μF capacitor the output noise voltage is ~40 μVrms (100 Hz–100 kHz). Regulators with this feature are marked in the "Filter pin" column of Table 9.3.

Prefiltering An effective way of reducing dramatically the output ripple at the powerline frequency (and its harmonics) is to prefilter the dc *input* to the regulator. This is also highly effective in attenuating broadband noise that may be present at the dc input; and it's easier than the alternative of increasing the regulator loop's gain and bandwidth. We discuss this in some detail in §8.15.1 ("Capacitance multiplier"), where we show the measured effects of prefiltering versus the brute-force approach of piling on lots of output capacitance (Figure 8.122).

See further discussion of noise in §9.10, in connection with voltage references.

[29] Many LDO regulator ICs include an internal diode sufficiently hardy to handle the reverse-discharge energy in modest (e.g., ≤10 μF) load capacitors. These are marked with a triangle symbol (△) in the "reverse block" column in Table 9.3. Other parts do not discharge the output capacitor if the input voltage is taken below the output; these ICs are marked with either a bullet dot (●) or a square (□).

[30] Table 9.3 includes a "Line regulation" column, but note that this is at dc and low frequencies where the loop gain is high; it is not necessarily indicative of high-frequency supply-noise rejection.

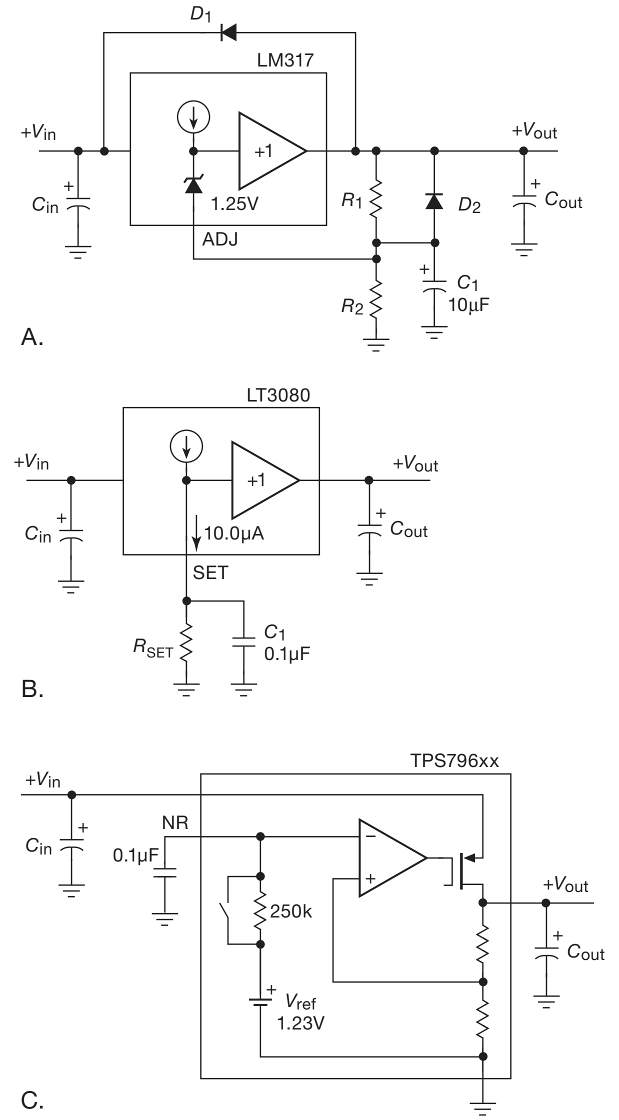

Figure 9.33. Reducing output-voltage noise (and improving transient line regulation) in linear regulators.

9.3.14 Current sources

A. Three-terminal regulators as current sources

A 3-terminal linear regulator can be used to make a simple current source by putting a resistor across the regulated output voltage (hence constant current $I_R = V_{reg}/R$), and floating the whole thing on top of a load returned to ground (Figure 9.34A). The current source is imperfect, however, because the regulator's operating current I_{reg} (which comes out the ground pin) is combined with the well-controlled resistor current to produce a total output current $I_{out} = V_{reg}/R + I_{reg}$. It's a reasonable current source, though, for output currents much larger than the regulator's operating current.

Originally this circuit had been implemented with a 7805, which has an operating current of ∼3 mA and additionally has the disadvantage of squandering a rather large 5 V (the lowest-voltage part in the 78xx series) to define the

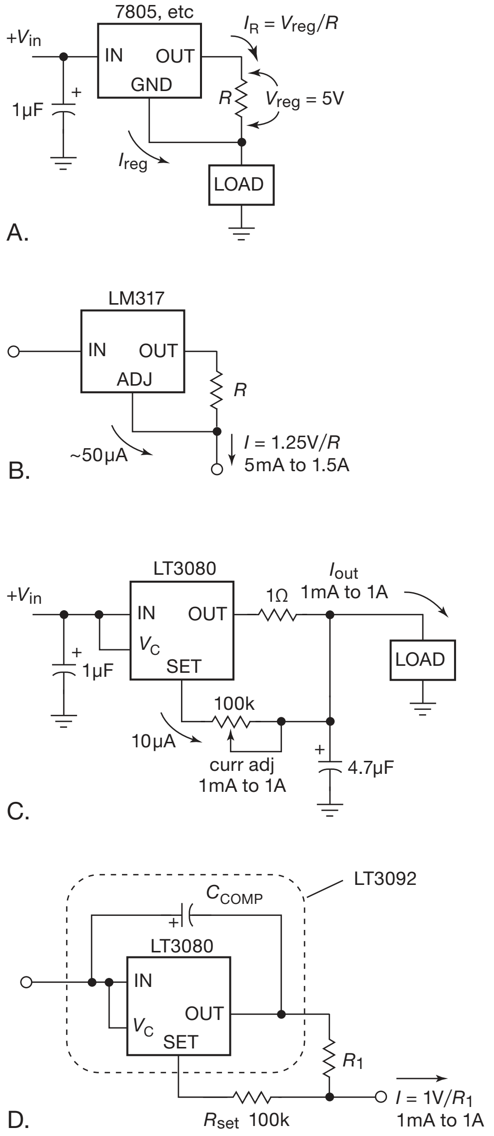

Figure 9.34. Three-terminal regulators used as current sources. The bypass and compensation capacitors can be eliminated in circuits C and D if the LT3080 is replaced by its internally compensated LT3092 variant (whose output current is limited to a maximum of 200 mA).

output current. Happily, with regulators like the LM317, this circuit (Figure 9.34B) becomes more attractive: only 1.25 V is used to set the current; and the regulator's operating current (∼5 mA) emerges from the *output* pin, and thus is accurately accounted for in setting $I_{\text{out}} = V_{\text{ref}}/R$. The only error term is the ADJ pin current of $\sim 50\,\mu$A, which gets added to the current through R: $I_{\text{out}} = V_{\text{ref}}/R + I_{\text{ADJ}}$. Because the minimum output current of 5 mA is 100 times larger, that is a small error even at the minimum output current, and smaller still at currents up to the regulator's maximum of 1.5 A. For this circuit, then, the output-current range is 5 mA–1.5 A. It requires a minimum voltage drop of 1.25 V plus the regulator's dropout voltage, or about 3 V; the maximum voltage *across the two terminals* is limited either to 40 V or (at higher currents) to the maximum junction temperature of 125°C (as determined by power dissipation and heatsinking), whichever is less.[31]

With the admirable LT3080-style regulator you can do better still, because its 10 μA SET-pin current reference lets you set the voltage across the current-setting resistor to be much less than the 1.25 V of a 317-style voltage-reference regulator. Its operating current is smaller as well (<1 mA), and the SET pin current (which gets added to the output current) is a stable and accurate 10.0 μA. Figure 9.34C shows how to make a (1-terminal) current source to ground with an LT3080, and Figure 9.34D shows how to make a 2-terminal "floating" current source, analogous to the LM317 current-source circuit. As with the latter, the voltage drop is limited to a maximum of 40 V (less at higher currents) at the high end; its lower dropout and low SET-derived reference voltage allows operation down to ∼1.5 V drop. The LT3092-series is a nice variant of the LT3080, designed specifically for use as a 2-terminal current source. It uses the same 10 μA reference current, and operates from 1.2 V to 40 V drop; its internal compensation is configured to require *no* external bypass or compensation capacitors. Based on the LT3092's datasheet plot of output impedance, the device's effective parallel capacitance is approximately 100 pF at 1 mA, 800 pF at 10 mA, and 6 nF at 100 mA.

Figure 9.35 shows, on a greatly expanded scale, the measured output currents of an LT3092 and an LM317, configured as 10 mA current sources. In our measurements the latter does a better job of maintaining constant current (versus voltage across it), but the LT3092 kicks in at a lower voltage.

Note that the current sources in Figures 9.34B and D are 2-terminal devices. Thus the load can be connected on either side. For example, you could use such a circuit to *sink* current from a load returned to ground, by connecting the load between ground and the input, and connecting the "output" to a negative voltage (of course, you could always use the negative-polarity 337, in a configuration analogous to Figure 9.34A.).

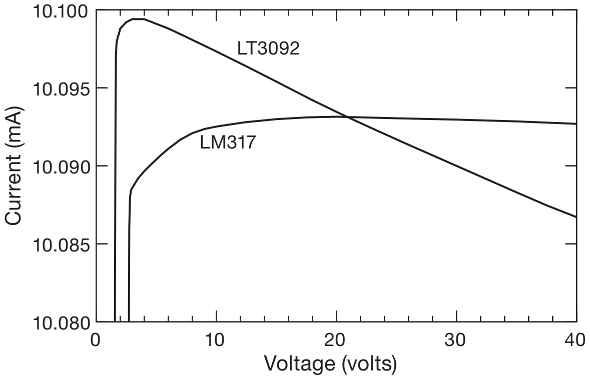

Figure 9.35. Measured current versus voltage drop for the current sources of Figures 9.34B and D, configured as 10 mA 2-terminal current sources. For the LM317, R_1=124 Ω; for the LT3092, R_1=20 Ω and R_{SET}=20k.

B. Lower currents

The above regulator-derived current sources are best suited for substantial output currents. For lower currents, or for higher voltages, there are some good alternatives.

LM334

It's worth knowing about the LM334 (originated by National Semiconductor), optimized for use as a low-power 2-terminal current source (Figure 9.36A). It comes in small-outline IC (SOIC) and TO-92 (transistor) packages and costs about $1 in small quantities. You can use it all the way down to 1 μA because the ADJ current is a small fraction of the total current; and it operates over a voltage range of 1–40 V. It has one peculiarity, however: the output current is temperature dependent – in fact, precisely proportional to absolute temperature (PTAT). So although it is not the world's most stable current source, you can use it as a temperature sensor! At room temperature (20°C, ∼293K) its tempco is about +0.34%/°C.[32]

[31] While we haven't experienced this ourselves, we've been told of possible issues with LM317-based current sources, such as long turn-on times, voltage retention, and poor voltage-compliance above a few kilohertz. It's always wise to test circuit performance fully (especially, uh, *creative* circuits).

[32] See also the discussion in §*2x.3*.

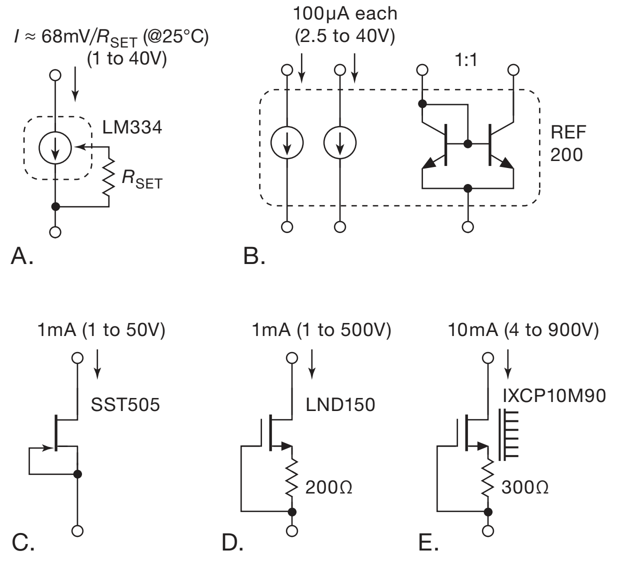

Figure 9.36. 2-terminal current source alternatives.

REF200

The REF200 is another current-source IC worth knowing about (Figure 9.36B). It has a pair of floating high-quality 100 μA (±0.5%) 2-terminal current sources (output impedance >200 MΩ over a voltage range of 3.5 V–30 V). It comes in dual in-line packages (DIP) and SOIC packages and costs about \$4 in small quantities. Unlike the LM334, the REF200's current sources are temperature stable (±25ppm/°C, typ). It also has an on-chip unit-ratio current mirror, so you can make a 2-terminal current source with fixed currents of 50 μA, 100 μA, 200 μA, 300 μA, or 400 μA. The datasheet asserts that "applications for the REF200 are limitless," though we are skeptical. Figure 9.37 shows measured current versus voltage for the parallel connection of the 100 μA pair.

Discrete-component current sources

When thinking about current sources, don't forget about 2-terminal devices like

(a) the humble JFET "current-regulator diode" (§3.2.2), which makes a simple 2-terminal current source (Figure 9.36C) that operates nicely up to 100 V (we plotted measured current versus voltage in Figure 9.38);
(b) a discrete JFET (see Tables 3.1, 3.7, and 8.2), configured similarly as a 2-terminal current source;
(c) the analogous use of a depletion-mode MOSFET (see Table 3.6 on page 210) like the Supertex LND150 (Figure 9.36D), discussed on this page (§9.3.14C);
(d) the series of 2-terminal "Constant Current Regulator and LED Driver" devices from ON Semiconductor. These are inexpensive (\$0.10–\$0.20 in qty 100), and are offered with selected currents (e.g., NSI50010YT1G: 10 mA, 50 V; NSIC2020BT3G: 20 mA, 120 V) and in adjustable versions (e.g., NSI45020JZ: 20–40 mA, 45 V). The datasheets don't say much about what's inside these things, but depletion-mode FETs are the likely culprits.

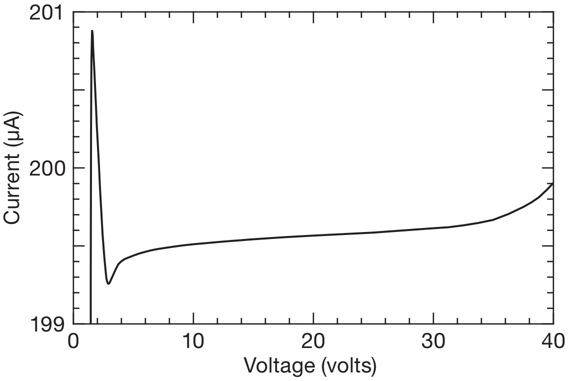

Figure 9.37. Measured current versus voltage for the REF200 two-terminal current source (parallel connection of the 100 μA pair).

Op-amp current-source configurations

If the application does not require a floating current source, then consider also

(d) the simple BJT current source (§2.2.6), drawn schematically in Figure 9.39A;
(e) the op-amp assisted BJT current source (§4.2.5), Figure 9.39B;
(f) the Howland current source (§4.2.5B), Figure 9.39C.

In these last three figures the bias voltage that programs the current is drawn as a floating battery; in a circuit implementation it would be a voltage relative to ground or to a supply rail, derived from a voltage reference.

C. High-voltage discrete current source

As mentioned above in the paragraph on discrete-component current sources, a simple source-biased depletion-mode MOSFET (Figures 9.36D and E) forms a pretty good 2-terminal current source. These parts come in convenient packages (TO-92, SMT, TO-220, D^{2}PAK), with voltage ratings to 1.7 kV; familiar examples are the LND150 and DN3545 from Supertex and the IXCP10M45S and IXCP10M90S from IXYS – see Table 3.6 on page 210. Because of the uncertainty in I_{D} versus V_{GS}, this sort of current source is not particularly precise or

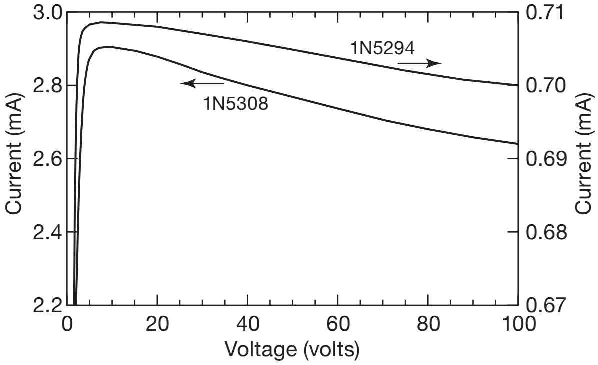

Figure 9.38. Measured current versus voltage for two members of the 1N5283 "current-regulator diode" (a JFET, actually) series.

predictable. But it's fine for noncritical applications, such as replacing a pullup resistor, and it has the advantage of operating to rather high voltages (500 V and 450 V for the Supertex parts; 450 V and 900 V for the IXYS). The IXYS datasheets call their product a "switchable current regulator." Figures 9.40 and 9.41 show some measured data for this simple circuit. The IXYS depletion-mode MOSFET line currently tops out at 1700 V (IXTH2N170). See §*3x.6* for a discussion of yet-higher-voltage versions (to 3 kV or more).

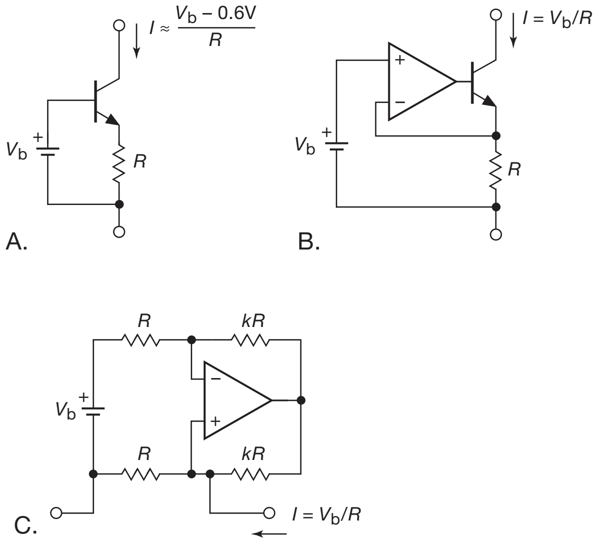

Figure 9.39. BJT and op-amp current sources, drawn in abbreviated form with a floating bias battery. For details see the relevant discussions in Chapters 2 (BJTs) and 4 (op-amps).

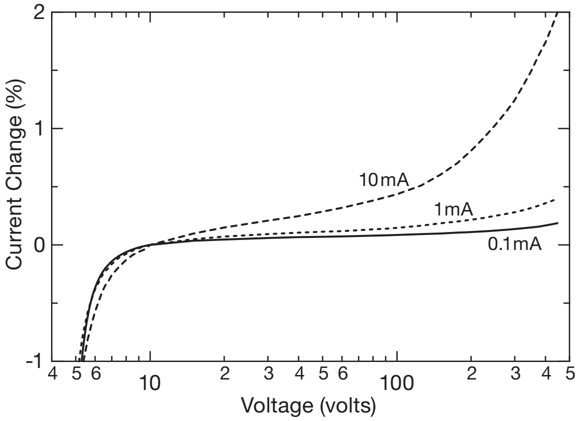

Figure 9.40. Measured current versus voltage for an IXCP10M45S depletion-mode power MOSFET, wired as a self-biased 2-terminal current source (as in Figure 9.36E).

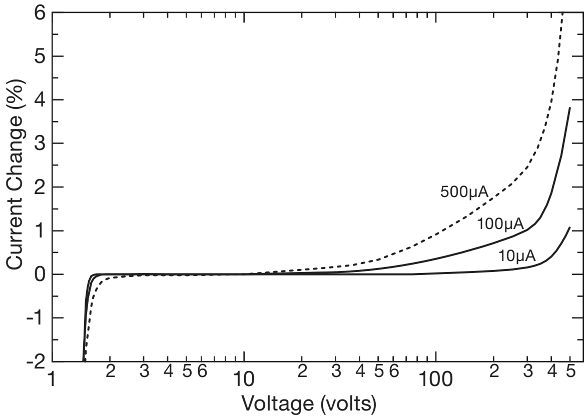

Figure 9.41. Measured current for the smaller LND150 depletion-mode MOSFET, a handy part for low-current applications (compare with Figure 9.40).

9.4 Heat and power design

Up to now we've been skirting the issue of *thermal management* – the business of dealing with the heat generated by transistors (and other power semiconductors) in which the power dissipation (the voltage drop times the current) is greater than a few tenths of a watt. The solution consists of some combination of passive cooling (conducting the heat to a heatsink or to the metal case of an instrument) and active (forced air or pumped liquid) cooling.

This problem is not unique to voltage regulators, of course – it affects linear power amplifiers, power-switching circuits, and other heat-generating components such as power resistors, rectifiers, and high-speed digital ICs. Contemporary computer processors, for example, dissipate many tens of watts and can be recognized by their attached finned heatsinks and blowers.

Linear voltage regulators get us into the topic "power electronics," because they are intrinsically inefficient: the full load current flows through the pass transistor, with a voltage drop at least adequate to prevent dropout. In the case of an unregulated dc input, as in Figure 9.25, that means a drop of at least a few volts; so with an amp of output current you've got at least a few watts... and you've got a problem. In the following sections we'll see how to solve it.

9.4.1 Power transistors and heatsinking

All power devices are packaged in cases that permit contact between a metal surface and an external heatsink. At the low-power end of the spectrum (up to a watt) the device may be cooled via conduction through its leads, soldered to a circuit board; the next step up is the surface-mount power packages with a larger tab (and with names like SOT-223, TO-252, TO-263, DPAK, and D^{2}PAK), or more advanced packages like the "DirectFET" (see Figure 9.46). For power dissipation greater than about 5 watts the packages (with names like TO-3, TO-220, and TO-247) will have mounting holes for attachment to a substantial heatsink; and really high power semiconductors come in modules (like the "miniBLOC" or "Powertap" – see Figure 9.47) meant for mounting off-PCB. With adequate heatsinking the latter types can dissipate up to 100 watts or more. With the exception of "isolated" power packages, the metal surface of the device is electrically connected to one terminal (e.g., for bipolar power transistors the case is connected to the collector, and for power MOSFETs to the drain).

The whole point of heatsinking is to keep the transistor junction (or the junction of some other device) below some maximum specified operating temperature. For silicon transistors in metal packages the maximum junction temperature is usually 200°C, whereas for transistors in plastic packages it is usually 150°C.[33] Heatsink design is then simple: knowing the maximum power the device will dissipate in a given circuit, you calculate the junction temperature, allowing for the effects of heat conductivity in the transistor, heatsink, etc., and the maximum ambient temperature in which the circuit is expected to operate. You then choose a heatsink large enough to keep the junction temperature well below the maximum specified by the manufacturer. It is wise to be conservative in heatsink design, because transistor life decreases rapidly at operating temperatures near or above maximum. Figure 9.42 shows a representative sample of heatsinks that we gathered from our lab's supply drawers.

Some people are cavalier about thermal design, and start worrying only if the component sizzles when they touch it with a wet finger. But it's far better to do it right initially! Read on...

A. Thermal resistance

To carry out heatsink calculations, you use *thermal resistance*, R_θ, defined as heat rise (in °C) divided by power transferred. For power transferred entirely by heat conduction, the thermal resistance is a constant, independent of temperature, that depends only on the mechanical properties of the joint. For a succession of thermal joints in "series," the total thermal resistance is the sum of the thermal resistances of the individual joints. Thus, for a transistor mounted on a heatsink, the total thermal resistance from transistor junction to the outside (ambient) world is the sum of the thermal resistance from junction to case $R_{\theta\mathrm{JC}}$, the thermal resistance from case to heatsink $R_{\theta\mathrm{CS}}$, and the thermal resistance from heatsink to ambient $R_{\theta\mathrm{SA}}$. The temperature of the junction is therefore

$$T_\mathrm{J} = T_\mathrm{A} + (R_{\theta\mathrm{JC}} + R_{\theta\mathrm{CS}} + R_{\theta\mathrm{SA}})P, \tag{9.2}$$

where P is the power being dissipated.

Let's take an example. The power-supply circuit of Figure 9.25, with 8 V unregulated dc input and full load (1 A) has a maximum LM317AT regulator dissipation of 4.7 W (4.7 V drop, 1 A). Let's assume that the power supply is to operate at ambient temperatures up to 50°C, not unreasonable for electronic equipment packaged together in close quarters. And let's try to keep the junction temperature below 100°C, well below its specified maximum of 125°C.

The allowable temperature difference from junction to ambient is thus 50°C, so the total thermal resistance from junction to ambient must be no more than $R_{\theta\mathrm{JA}} = (T_\mathrm{J} - T_\mathrm{A})/P = 10.6$°C/W. The specified thermal resistance from junction to case, $R_{\theta\mathrm{JC}}$, is 4°C/W, and the TO-220 power transistor package mounted with a heat-conducting pad has a thermal resistance from case to heatsink of about 0.5°C/W. So we've used up $R_{\theta\mathrm{JC}} + R_{\theta\mathrm{CS}} =$ 4.5°C/W of thermal resistance, leaving $R_{\theta\mathrm{SA}} = 6.1$°C/W for the heatsink. A quick scan of the ever-helpful DigiKey

[33] See Tables 2.2 and 3.4 for a selection of power transistors, including their maximum power dissipation assuming an (unrealistic) case temperature of 25°C. As we'll see, that's enough information to allow you to back out the thermal resistance $R_{\Theta\mathrm{JC}}$, from which you can figure out realistic values of maximum power dissipation, and thus appropriate heatsinking.

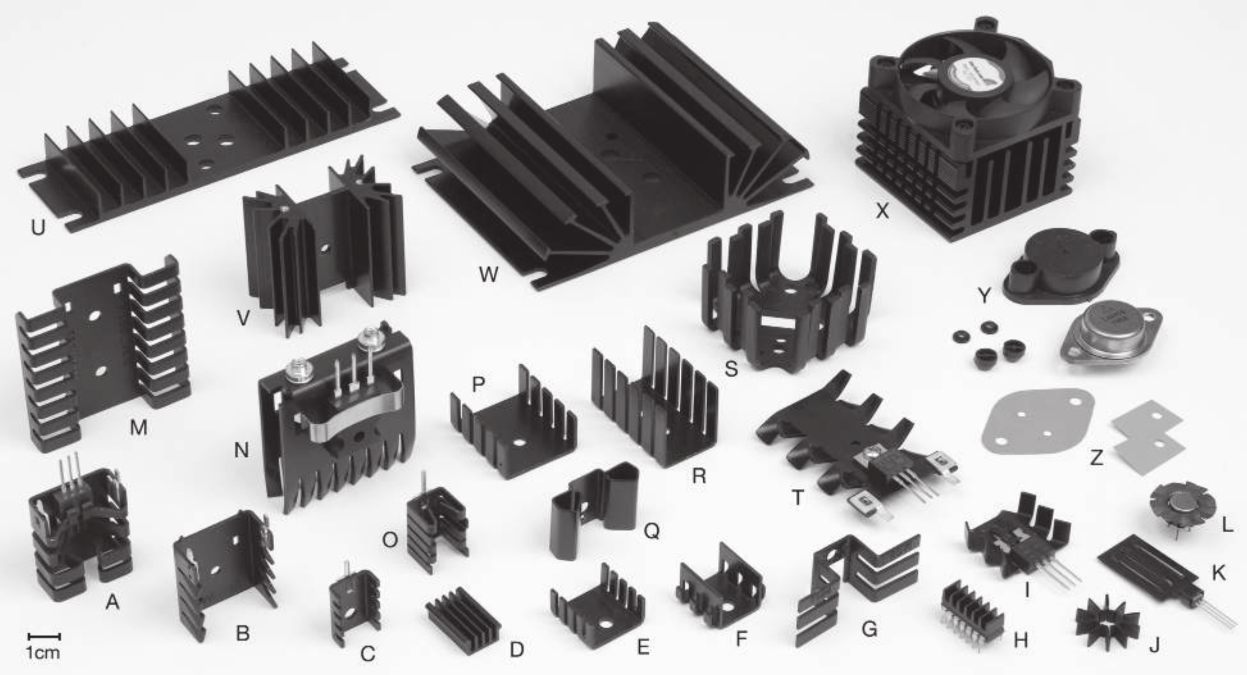

Figure 9.42. Heatsinks come in an impressive diversity, from little clip-on fins (I–L), to mid-sized PCB-mounting types (A–C, N, O, T), to large bolt-down units (U, W), to forced-air type used with microprocessors (X). The corresponding thermal resistance from sink to ambient, $R_{\Theta SA}$, ranges from about 50°C/W down to about 1.5°C/W. A TO-3 insulating cover is shown in (Y), along with shoulder washers and hole plugs; greaseless thermal insulating pads are shown in (Z). We've added alphabetic labels so readers can identify objects of interest when chatting on social media.

catalog finds many candidates, for example the Wakefield 647-15ABP "vertical board mounting" finned heatsink, with the requisite $R_{\theta SA} = 6.1°\text{C/W}$ in still air ("natural convection"). They're priced at about \$2, with 2000 pieces in stock. With a "forced convection" of 400 LFM (linear feet per minute) we could use instead the smaller (and cheaper, about \$0.35) model 270-AB; DigiKey's got 4000 in stock today.

Here's a "sizzle-test" for checking for adequate heatsinking: touch the power transistor with a dampened finger – if it sizzles, it's too hot! (Be careful when using this "rule-of-finger" test to explore around high voltages.) More generally approved methods for checking component temperatures are (a) a contacting thermocouple or thermistor probe (these often come as standard equipment with handheld or benchtop digital multimeters); (b) special calibrated waxes that melt at designated temperatures (e.g., the Tempilstik® wax pencil kits from Tempil, Inc.); and (c) infrared non-contacting temperature probes,[34] for example the Fluke 80T-IR, which generates 1 mV/°C or 1 mV/°F (switchable), operates from −18°C to +260°C, is accurate to 3% of reading (or ±3°C, if greater), and plugs into any handheld or benchtop DMM.

B. Comments on heatsinks

1. Where very high power dissipation (several hundred watts, say) is involved, forced air cooling is usually necessary. Large heatsinks designed to be used with a blower are available with thermal resistances (sink to ambient) as small as 0.05°C to 0.2°C per watt.
2. In cases of such high thermal conductivity (low thermal resistance, $R_{\theta SA}$), you may find that the ultimate limit to power dissipation is in fact the transistor's own internal thermal resistance, combined with its attachment to the heatsink (i.e., $R_{\theta JC} + R_{\theta CS}$). This problem has been exacerbated in recent years by the evolution of smaller ("shrink") semiconductor chip sizes. The only solution

[34] Infrared ear thermometers use this method to measure core body temperature via infrared emission from the eardrum, evidently accurately enough for clinical purposes; e.g., the Braun ThermoScan takes a measurement in one second, with an accuracy claimed to be significantly better than 1°C.

here is to spread the heat among several power transistors (in parallel or in series). When paralleling power transistors you have to be careful to make sure they share the current equally – see §2.4.4 and Figure 3.117.

Similarly, when connecting transistors in series, make sure that their off-state voltage drops are evenly distributed.

3. Figure 9.43, adapted from the Wakefield Engineering heatsink literature, gives a rough estimate of the physical volume of heatsink required to achieve a given thermal resistance. Note that curves are given for still air (natural convection) and for two values of forced air flow. Don't take these curves too literally – we just gathered data from a half dozen representative heatsinks, and then drew trend lines through them; they're probably good to a factor of two, but don't rely on it (or, at least, don't complain to us later!).

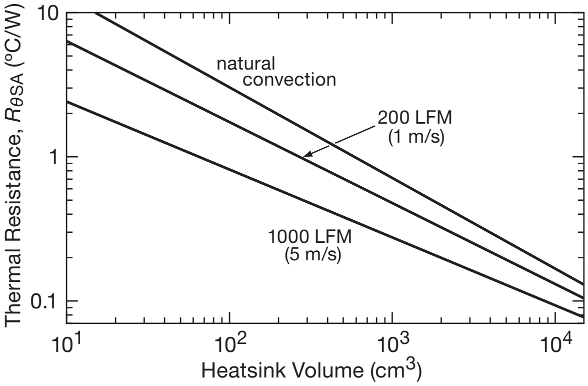

Figure 9.43. Rough guide to heatsink size needed for a given thermal resistance from sink to ambient ($R_{\theta SA}$).

4. When the transistor must be insulated from the heatsink, as is usually necessary (especially if several transistors are mounted on the same sink), a thin insulating washer is used between the transistor and sink, and insulating bushings are used around the mounting screws. Washers are available in standard transistor-shape cutouts made from mica, anodized (insulated) aluminum, beryllia (BeO), or polymer films such as Kapton®. Used with heat-conducting grease, these add from 0.14°C/W (beryllia) to about 0.5°C/W.

An attractive alternative to the classic mica-washer-plus-grease is provided by greaseless silicone-based insulators that are loaded with a dispersion of a thermally conductive compound, usually boron nitride or aluminum oxide ("Z" in Figure 9.42). They're clean and dry and easy to use; you don't get white slimy stuff all over your hands, your electronic device, and your clothes. You save lots of time. The electrically insulating types have thermal resistances of about 1–4°C/W for a TO-220 package footprint, comparable to values with the messy method; the non-insulating ("grease replacement") varieties do better – down in the 0.1–0.5°C/W for a TO-220 package. Bergquist calls its product line "Sil-Pad," Chomerics calls its "Cho-Therm," and Thermalloy calls its "Thermasil." We've been using these insulators, and we like them.

5. Small heatsinks are available that simply clip over the small transistor packages (like the standard TO-92 and TO-220, "I–L" in Figure 9.42). In situations of relatively low power dissipation (a watt or two) this often suffices, avoiding the nuisance of mounting the transistor remotely on a heatsink with its leads brought back to the circuit. In addition, there are various small heatsinks intended for use with the plastic power packages (many regulators, as well as power transistors, come in this package) that mount right on a PCB underneath the package. These are very handy in situations of a few watts dissipation; a typical unit is illustrated in Figure 2.3. If you've got vertical space over the PCB, it's often preferable to use a PCB-mounting stand-up heatsink (like A–C, N, O, or T in Figure 9.42), because these types take up less area on the PCB.

6. Surface-mount power transistors (such as the SOT-223, DPAK, and D^{2}PAK) carry their heat to the foil layer of a PCB via the soldered tab; here we're talking a few watts, not a hundred. You can see these packages in Figures 2.3 and 9.44. Figure 9.45 plots approximate values of thermal resistance versus foil area; these should be considered only a rough guide, because the actual heatsinking effectiveness depends on other factors such as the proximity of other heat-producing components, board stacking, and (for natural convection) board orientation.

7. Sometimes it may be convenient to mount power transistors directly to the chassis or case of the instrument. In such cases it is wise to use conservative design (keep it cool), especially because a hot case will subject the other circuit components to high temperatures and thus shorten their lives.

8. If a transistor is mounted to a heatsink without insulating hardware, the heatsink must be insulated from the chassis. The use of insulating washers (e.g., Wakefield model 103) is recommended (unless, of course, the transistor case happens to be at ground). When the transistor is insulated from the sink, the heatsink may be attached directly to the chassis. But if the transistor is accessible from outside the instrument (e.g., if the heatsink is

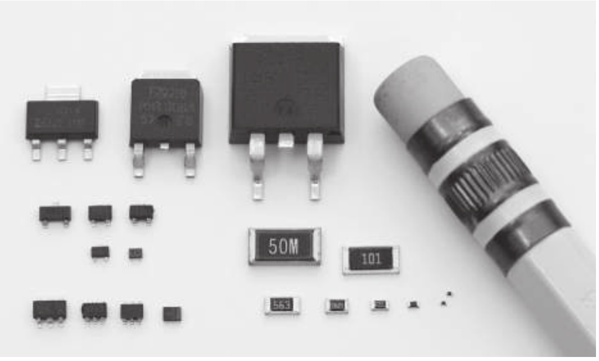

Figure 9.44. Power transistors come in convenient hand-solderable surface-mount packages that can dissipate up to several watts, through their mounting tab and leads, when soldered to a few square centimeters of foil area on a PCB (see Figure 9.45). The top three packages (SOT-223, DPAK, D^2PAK) are good for ~3 W when mounted on 6 cm^2 of PCB foil area; the smaller packages in the row below can dissipate ~0.5 W when similarly mounted. By way of comparison, the rectangular parts at lower right are chip resistors, tapering down from 2512 size to 0201 size (0603 metric).

mounted externally on the rear wall of the box), it is a good idea to use an insulating cover over the transistor (e.g., Thermalloy 8903N, "Y" in Figure 9.42) to prevent someone from accidentally coming in contact with it or shorting it to ground.

9. The thermal resistance from heatsink to ambient is usually specified for the sink mounted with the fins vertical and with unobstructed flow of air. If the sink is mounted differently, or if the air flow is obstructed, the efficiency will be reduced (higher thermal resistance[35]); usually it is best to mount it on the rear of the instrument with fins vertical.

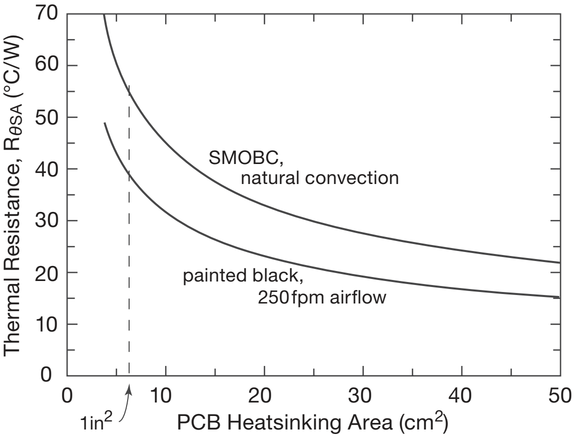

Figure 9.45. Approximate thermal resistance of isolated printed-circuit foil patterns. A soldermask layer (SMOBC means soldermask over bare copper) reduces the effectiveness, particularly when compared with forced air over exposed copper.

10. In the second edition of this book there is additional information: see Chapter 6 (Figure 6.6, page 315) on heatsinks, and Chapter 12 (Table 12.2 and Figure 12.17, page 858) on cooling fans.

Exercise 9.7. An LM317T (TO-220 case), with a thermal resistance from junction to case of $R_{\Theta JC}$=4°C/W, is fitted with an Aavid Thermalloy 507222 bolt-on heatsink, whose thermal resistance is specified as $R_{\Theta SA}$≈18°C/W in still air. The thermal pad (Bergquist SP400-0.007) specifies a thermal resistance of $R_{\Theta CS}$≈5°C/W. The maximum permissible junction temperature is 125°C. How much power can you dissipate with this combination at 25°C ambient temperature? How much must the dissipation be decreased per degree rise in ambient temperature?

9.4.2 Safe operating area

The point of heatsinking is to keep junction temperatures within specified limits, given some ambient temperature and some maximum power dissipation, as just described. Of course, you must stay also within the specified voltage and current ratings of the power transistor. This is displayed graphically as a dc safe-operating-area (SOA) plot, on axes of transistor voltage and current, at some specified case temperature (usually an unrealistic T_C=25°C). For MOSFETs this plot (on logarithmic voltage and current axes) is bounded simply by straight lines representing maximum voltage, maximum current, and maximum power dissipation (at the specified T_C, as set by $R_{\theta JC}$ and $T_{J(max)}$) – see, for example, Figure 3.95.

There are two amendments to this basic picture.

A. Second breakdown

The bad news: in the case of *bipolar transistors* the SOA is further constrained by a phenomenon known as *second breakdown*, an important failure mechanism that you must keep in mind when designing power electronics with bipolar transistors. This is discussed in §3.6.4C, where the effect can be seen in the SOA plots in Figure 3.95 as a further reduction of allowable collector current at high voltages. Because MOSFET power transistors are largely immune to second breakdown, they are often favored over BJTs for power-regulator pass transistors (the exceptions are some newer small-geometry types, see IR App Note IN-1155).

[35] As a rough guide, you can expect roughly 20% increase in $R_{\theta SA}$ for "fins horizontal," 45% for "fins up," and 70% for "fins down."

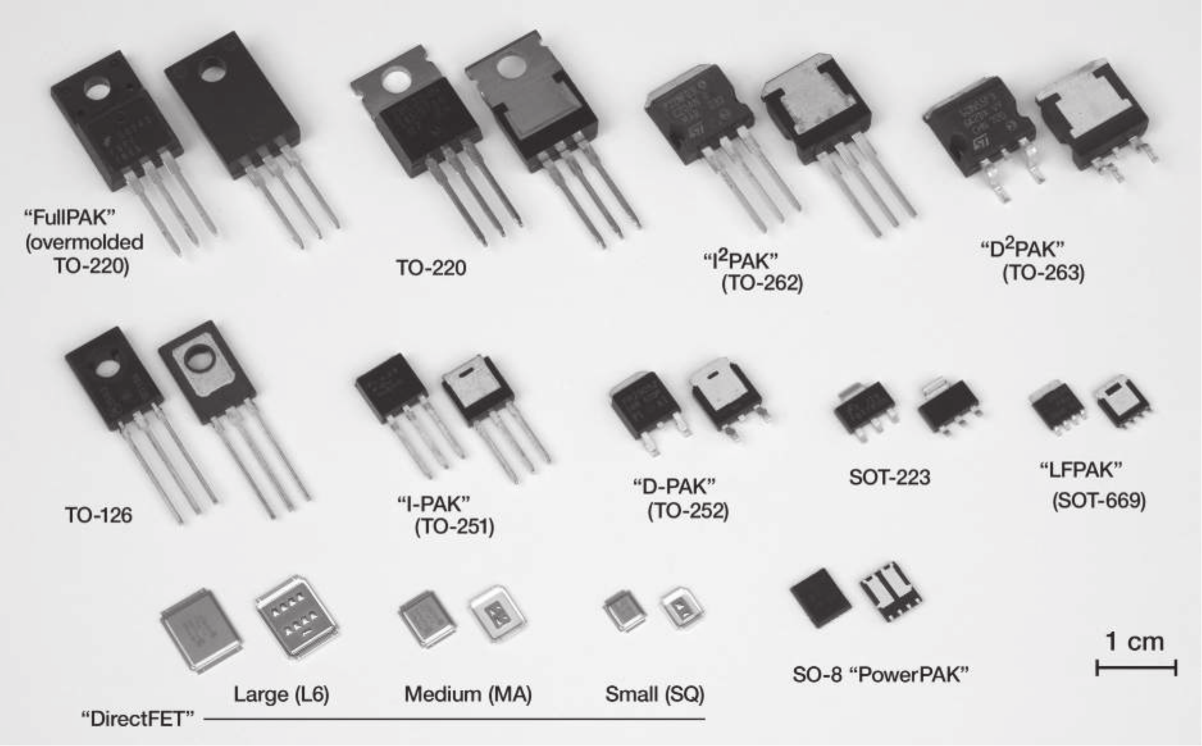

Figure 9.46. An extended selection of power packages, shown here and in Figure 9.47. The leadless packages in the bottom row require "reflow" solder techniques (trade in your soldering iron and wire solder for an oven and solder-paste dispenser!).

B. Transient thermal resistance

The good news: for pulses of short duration you can exceed the dc power-dissipation limit, sometimes by a large factor. That is because the mass of the semiconductor itself can absorb a short pulse of energy by heating locally ("heat capacity" or "specific heat"), limiting the temperature rise even if the instantaneous power dissipation is more than could be sustained continuously. This can be seen in the SOA plot (Figure 3.95), where the allowable power dissipation, for 100 μs pulses, is some 20 times greater than the dc value: an astonishing 3000 W versus 150 W. This is sometimes characterized on datasheets as a *transient thermal resistance* – a plot of R_θ versus pulse duration. The ability to dissipate very high peak power during short pulses extends to other electronic devices, for example, diodes, SCRs, and transient voltage suppressors. See §3.6.4C and the discussion in Chapter *9x*.

9.5 From ac line to unregulated supply

A regulated power supply that runs from ac line power begins[36] by generating "unregulated" dc, a subject we introduced in §1.6.2 in connection with rectifiers and ripple calculations. For the linear voltage regulators we've seen so far, the unregulated dc supply uses a transformer, both

[36] Well, it really begins back at the power plant! Perhaps worth knowing, though, is the situation at the wall plug: in the US the standard 3-prong outlet delivers its 120 Vrms ac across the "line" and "neutral" blades (the neutral is the slightly wider slot; it's on the upper left, if the outlet is oriented to look like a face), with the round safety ground returned to a good earth connection at the service entry. The power comes into the house as three wires from a center-tapped 240 V pole transformer, with the center tap (neutral) bonded to earth ground at the service entry. Any given 120 V outlet provides neutral (white wire) and one "live" phase (black); the outlets in a given room may be powered by one or the other phases. A 240 V appliance outlet brings both live phases, along with safety ground, to a different style socket (this is in contrast to European 220 or 240 V outlets, which provide line, neutral, and safety ground). The in-wall wiring consists of "Romex"-style plastic-insulated oval cable with solid copper conductors: AWG14 for a 15 A residential circuit, and AWG12 for a 20 A circuit.

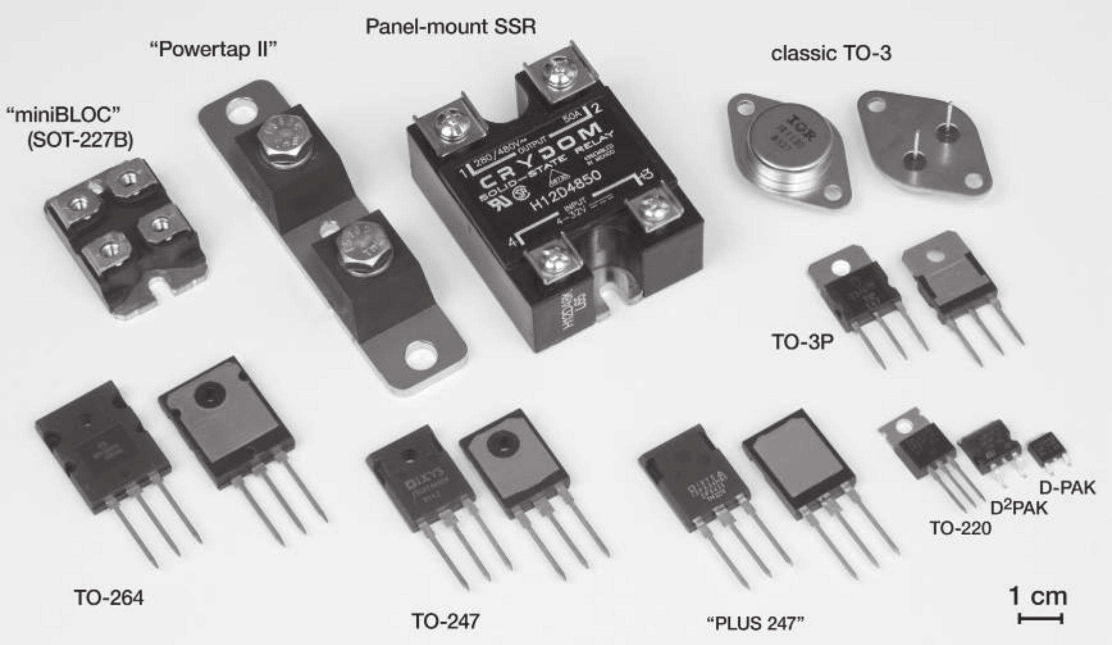

Figure 9.47. The larger cousins of the power packages in Figure 9.46, with three specimens from the latter shown for comparison. We're up in the tens to hundreds of watts with these when they are mounted on an appropriate heatsink.

to convert the incoming line voltage (120 Vrms in North America and a few other countries, 220 or 240 Vrms most everywhere else) to a (usually) lower voltage closer to the regulated output, and also to isolate the output from any direct connection to the hazardous line potentials ("galvanic isolation"); see Figure 9.48. Perhaps surprisingly, the switching power supplies we'll see shortly omit the transformer, generating line-derived dc at the powerline potential (∼160 Vdc or ∼320 Vdc), which powers the switching circuit directly. The essential galvanic isolation[37] is achieved instead with a transformer driven by the high-frequency switching signal.[38]

Transformer-isolated unregulated dc supplies are useful, also, for applications in which the stability and purity of regulated dc is unnecessary, for example high-power audio amplifiers. Let's look at this subject in more detail, beginning with the circuit shown in Figure 9.49. This is an unregulated ±50 volt (nominal) split supply, capable of 2 A output current, for a 100 watt linear audio amplifier. Let's go through it from left to right, pointing out some of the things to keep in mind when you do this sort of design.

9.5.1 ac-line components

A. Three-wire connection

Always use a 3-wire line cord with ground (green or green/yellow) connected to the instrument case. Instruments with ungrounded cases can become lethal devices in the event of transformer insulation failure or accidental connection of one side of the powerline to the case. With a grounded case, such a failure simply blows a fuse. You often see instruments with the line cord attached to the chassis (permanently) using a plastic "strain relief," made by Heyco or Richco. A better way is to use an IEC (International Electrotechnical Commission) three-prong male chassis-mounted connector, to mate with those popular line cords that have the three-prong IEC female molded onto the end. That way the line cord is conveniently removable. Better yet, you can get a combined "power-entry module," containing IEC connector, fuse holder, line filter, and switch, as we've used here. Note that ac wiring uses a nonintuitive color convention: black = "hot" (or "line"), white = neutral, and green = ground (or "protective earth").[39]

[37] There are occasions where isolation is not needed; see Chapter *9x* for a discussion of some low-power off-line power supplies (including a step-down technique that uses a capacitor instead of a transformer or inductor.)

[38] The advantage of this peculiar arrangement is that the transformer, running at a high frequency (20 kHz–1 MHz) is much smaller and lighter.

[39] IEC cords use brown = line, blue = neutral, and green/yellow = ground.

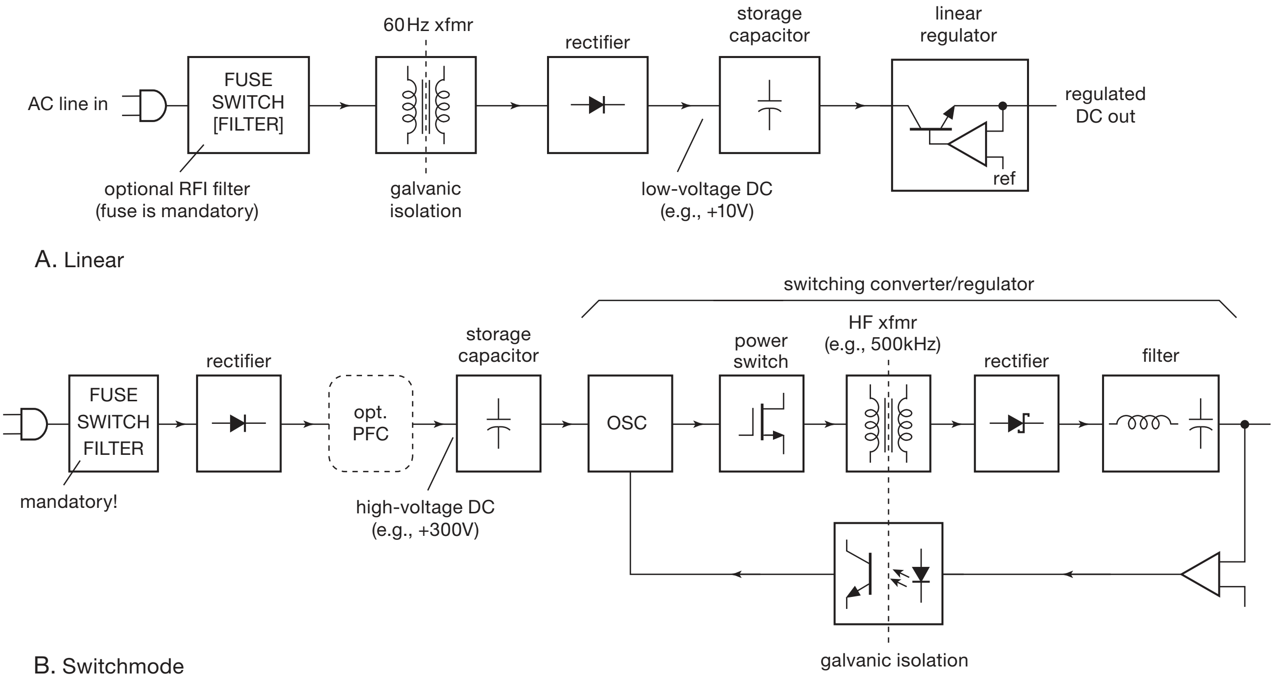

Figure 9.48. ac-line-powered ("offline") dc-output regulated supplies. A. In the linear supply the powerline transformer both isolates and transforms the input voltage. B. In the switching ("switchmode") converter the ac input is directly rectified to high-voltage dc, which powers the isolating switching converter. The PFC block performs power-factor correction, discussed later in §9.7.1C.

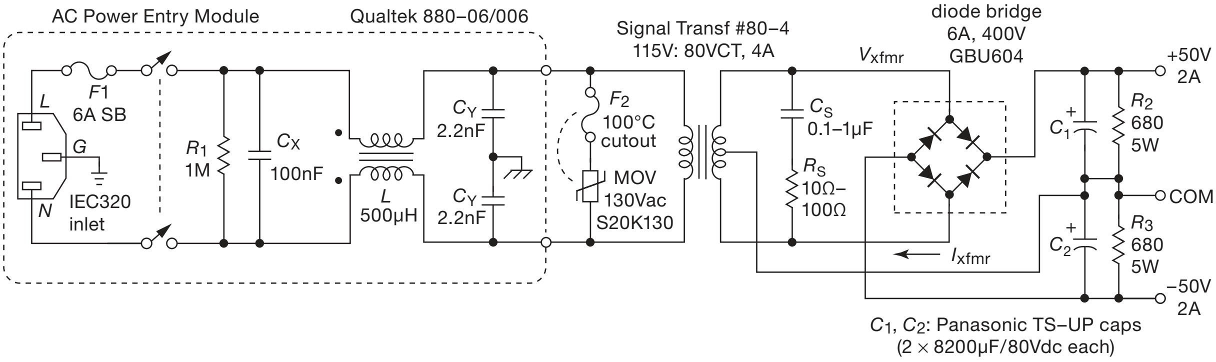

Figure 9.49. Unregulated ±50 V, 2 A power supply.

B. Fuse

A fuse, breaker, or equivalent function should be included in every piece of electronic equipment. A fuse holder, switch, and lowpass filter are often combined in the power entry module, but you can also wire them *à la carte*. The large wall fuses or circuit breakers (typically 15–20 A) in house or lab won't protect electronic equipment, because they are chosen to blow only when the current rating of the wiring in the wall is exceeded. For instance, a house circuit wired with 14-gauge wire will have a 15 A circuit breaker. Now, if a storage capacitor in our unregulated supply becomes short-circuited someday (a possible failure mode), the transformer might then draw 10 A primary current (instead of its usual 2–3 A). The house breaker won't open, but your instrument becomes an incendiary device, with its transformer dissipating over a kilowatt.

Some notes on fuses. (a) It is best to use a "slow-blow" type in the power-line circuit, because there is invariably a large current transient ("inrush current") at turn-on, caused mostly by rapid charging of the power-supply filter capacitors. (b) You may think you know how to calculate the fuse current rating, but you're probably wrong. A dc power supply of this design[40] has a high ratio of rms current to average current, because of the small conduction angle (fraction of the cycle over which the diodes are conducting). The problem is worse if overly large filter capacitors are used. The result is an rms current considerably higher than you would estimate. The best procedure is to use a "true rms" ac current meter to measure the actual rms line current, then choose a fuse of at least 50% higher current rating (to allow for high line voltage, the effects of fuse "fatigue," etc.). (c) When wiring cartridge-type fuse holders (used with the popular 3AG/AGC/MDL type fuse, which is almost universal in electronic equipment), be sure to connect the leads so that anyone changing the fuse cannot come in contact with the powerline. This means connecting the "hot" lead to the rear terminal of the fuse holder (the authors have learned this the hard way!). Commercial power-entry modules with integral fuse holders are cleverly arranged so that the fuse cannot be reached without removing the line cord.

C. Switch

In Figure 9.49 the switch is integral with the power entry, which is fine, but it forces the user to reach around the back to turn the thing on. When using a front-panel power switch, it's a good idea to put a line-rated capacitor (called X1 or X2) across its terminals, to prevent arcing. For similar reasons the transformer primary should have some bridging capacitance, which in this case is taken care of by the lowpass filter in the entry module.

D. Lowpass filter

Although they are often omitted, such filters are a good idea, because they serve the purpose of preventing possible radiation of radiofrequency interference (RFI) from the instrument via the powerline, as well as filtering out incoming interference that may be present on the powerline. These filters typically use an *LC* "π-section" filter (as in the figure), with the coupled inductor pair acting as a common-mode impedance. Power-line filters with excellent performance characteristics are available from several manufacturers, e.g., Corcom, Cornell–Dubilier, Curtis, Delta, Qualtek, and Schurter.[41] Studies have shown that spikes as large as 1 kV to 5 kV are occasionally present on the powerlines at most locations, and smaller spikes occur quite frequently. Line filters (in combination with transient suppressors, see below) are reasonably effective in reducing such interference (and thereby extending the life of a power supply and the equipment it powers).

E. Line-voltage capacitors

For reasons of fire and shock hazard, capacitors intended for line filtering and bypassing are given special ratings. Among other attributes, these capacitors are designed to be self-healing, i.e., to recover from internal breakdown.[42] There are two classes of line-rated capacitors: "X" capacitors (X1, X2, X3) are rated for use where failure would not create a shock hazard. They are used across the line (C_X in Figure 9.49; the common X2 type is rated for 250 Vac, with peak voltage of 1.2 kV). "Y" capacitors (Y1, Y2, Y3, Y4) are rated for use where failure would present a shock hazard. They are used for bypassing between the ac lines and ground (C_Y in Figure 9.49; the common Y2 type is rated for 250 Vac, with a peak voltage of 5 kV). Line-rated capacitors come in disc ceramic and in plastic-film flavors; the latter are usually a box geometry, with a flame retardant case. It's hard to miss these capacitors – they are usually festooned with markings proclaiming the various national certifications whose standards they meet[43] (Figure 9.50).

A *further* word about line-voltage capacitors: when the

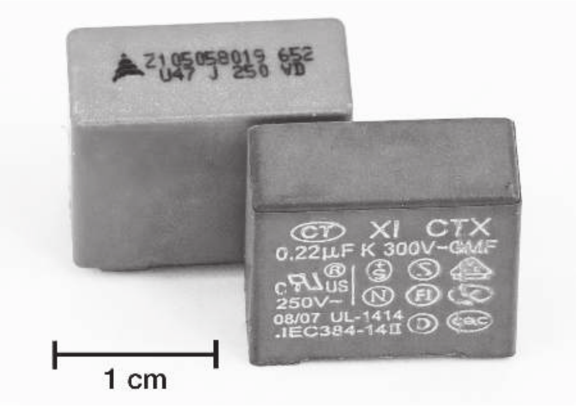

Figure 9.50. ac-line-rated capacitors flamboyantly display their safety ratings (right), compared with the minimalist decoration of a plain ol' film capacitor (left).

[40] Where the rectified input charges large storage capacitors at each voltage peak of the ac waveform. By contrast, switching power supplies with *power-factor correction* (PFC) nicely sidestep this problem; see §9.7.1C.

[41] Watch out, however, for misleading attenuation specifications: they are universally specified with 50 Ω source and load, because that's easy to measure with standard RF instrumentation, and not because it has any resemblance to the real world.

[42] For example, line-rated plastic film capacitors are constructed so that a perforating breakdown causes the metal plating near the hole to burn away, clearing the short-circuit.

[43] Here are some of them: UL, CSA, SEV, VDE, ENEC, DEMKO, FIMKO, NEMKO, SEMKO, CCEE, CB, EI, and CQC.

instrument is unplugged, the X capacitor may be left holding the peak ac line voltage, up to 325 V, which appears across the exposed power plugs! This can cause electrical shocks, and spark discharges. That's why there's a parallel discharge resistor, sized for a safe time constant of less than a second.[44] Here the Qualtek RFI filter module uses 1 MΩ, and the Astrodyne switching supply (§9.8) uses 540 kΩ. The latter continuously dissipates 100 mW when powered with 220 Vac line input, which could constitute one of the largest standby power losses in an "Energy Star" design. Power Integrations offers their CAPZero™ IC to solve this problem. This clever part works by looking for an ac-line-voltage reversal every 20 ms or less, and if it fails to see one it turns on, connecting two discharge resistors across the X capacitor.

Some designs have substantial high-voltage dc storage capacitors that need to be discharged when the power is off. Because of their large capacitance, the ac-sensing CAPZero would not work. Here you could use normally-on relay contacts, and energize the relay when external ac power is present. Or, if you don't like moving parts, a high-voltage depletion-mode MOSFET (see Table 3.6 on page 210) and a photovoltaic stack (see §12.7.5, Figure 12.91A) can do the job.

F. Transient suppressor

In many situations it is desirable to use a "transient suppressor" (or "metal-oxide varistor," MOV) as shown in Figure 9.49. The transient suppressor is a device that conducts when its terminal voltage exceeds certain limits (it's like a bidirectional high-power zener). These are inexpensive and small and can shunt hundreds of amperes of potentially harmful current in the form of spikes. Note the thermal cutout fuse: that protects in a situation in which the MOV starts to conduct partially (for example if the line voltage becomes highly elevated, or if an aged MOV exhibits lowered breakdown voltage from having absorbed large transients). Transient suppressors are made by a number of companies, e.g., Epcos, Littelfuse, and Panasonic. Effective transient suppression is an interesting challenge, and we discuss it further in Chapter *9x*.

G. Shock hazard

It is a good idea to insulate all exposed line-voltage connections inside any instrument, for example by using polymer heat-shrink tubing (the use of "friction tape" or electrical tape inside electronic instruments is strictly bush-league). Because most transistorized circuits operate on relatively low dc voltages (±15 V or less), from which it is not possible to receive a shock, the powerline wiring is the only place where any shock hazard exists in most electronic devices (there are exceptions, of course). The front-panel ON–OFF switch is particularly insidious in this respect, being close to other low-voltage wiring. Your test instruments (or, worse, your fingers) can easily come in contact with it when you go to pick up the instrument while testing it.

9.5.2 Transformer

Now for the transformer. Never build an instrument to run off the powerline without an isolating transformer! To do so is to flirt with disaster. Transformerless power supplies, which have been popular in some consumer electronics (radios and televisions, particularly) because they're inexpensive, put the circuit at high voltage with respect to external ground (water pipes, etc.).[45] This has no place in instruments intended to interconnect with any other equipment and should always be avoided. And use extreme caution when servicing any such equipment; just connecting your oscilloscope probe to the chassis can be a shocking experience.

The choice of transformer is more involved than you might at first expect. It may be hard to find a transformer with the voltage and current ratings you need. We have found the Signal Transformer Company unusual, with their nice selection of transformers and quick delivery. And don't overlook the possibility of having transformers custom-made if your application requires more than a few.

Even assuming that you can get the transformer you want, you still have to decide on the voltage and current rating. If the unregulated supply is powering a linear regulator, then you want to keep the unregulated dc voltage low, in order to minimize the power dissipation in the pass transistors. But you must be absolutely certain the input to the regulator will never drop below the minimum necessary for regulation (typically 2 V above the regulated output voltage, for conventional regulators like the LM317; or 0.5–1 V for low-dropout types) or you may encounter 120 Hz dips in the regulated output; in the design you need to allow for low line voltage (10% below nominal, say – 105 Vac in the US) or even brownout conditions (20% below nominal). The amount of ripple in the unregulated output is involved

[44] We have seen entirely too many designs that omit this discharge resistor; not good!

[45] Non-isolated off-line supplies are commonly found in some types of self-contained electronics, such as a screw-in LED light bulb, a wall clock, a smoke alarm, a Wi-Fi surveillance camera, a toaster or coffeemaker, and so on. We discuss some of these in Chapter *9x*.

here, because it is the *minimum* input to the regulator that must stay above some critical voltage (see Figure 1.61), but it is the *average* input to the regulator that determines the transistor dissipation.

As an example, for a +5 V regulator you might use an unregulated input of +10 V at the minimum of the ripple, which itself might be 1 to 2 volts peak-to-peak. From the secondary voltage rating you can make a pretty good guess of the dc output from the bridge, because the peak voltage (at the top of the ripple) is approximately 1.4 times the rms secondary voltage, less two diode drops. But it is essential to make actual measurements if you are designing a power supply with near-minimum drop across the regulator, because the actual output voltage of the unregulated supply depends on poorly specified parameters of the transformer, such as winding resistance and magnetic coupling (leakage inductance), both of which contribute to voltage drop under load. Be sure to make measurements under worst-case conditions: full load and low power-line voltage (105 V). Remember that large filter capacitors typically have loose tolerances: −30% to +100% about the nominal value is not unusual. It is a good idea to use transformers with multiple taps on the primary (the Triad F-90X series, for example), when available, for final adjustment of output voltage.

For the circuit shown in Figure 9.49, we wanted ±50 V output under full load. Allowing for two diode drops (from the bridge rectifier) we need a transformer with ∼52 V peak amplitude, or about 37 Vrms. Among the available transformer choices, the closest was the 40 Vrms unit shown, probably a good choice because of the effects of winding resistance and leakage inductance, which reduce slightly the loaded dc output voltage.

An important note: transformer current ratings are usually given as *rms* secondary current. However, because a rectifier circuit draws current only over a small part of the cycle (during the time the capacitor is actually charging), the secondary's rms current, and therefore the I^2R heating, will be significantly larger than the average rectified dc output current. So you have to choose a transformer whose rms current rating is somewhat larger (typically ∼ 2×) than the dc load current. Ironically, the situation gets worse as you increase capacitor size to reduce output ripple voltage. Full-wave rectification is better in this respect, because a greater portion of the transformer waveform is used. For the unregulated dc supply of Figure 9.49 we measured an rms current of 3.95 A at the transformer secondary when powering a 2 A dc load. The measured waveforms in Figure 9.51 show the pulsating nature of the current, as the rectified transformer output recharges the storage capacitors each half-cycle.

Naïvely you might expect that the conduction angle (fraction of the cycle during which the current flows) could be estimated simply by (a) calculating the capacitor's discharge between half-cycles, according to $I = C\,dV/dt$, then (b) calculating the time in the next half-cycle at which the rectified output exceeds the capacitor's voltage. However, this pretty scheme is complicated by the important effects of the transformer's winding resistance and leakage inductance, and the storage capacitor's ESR, all of which extend the conduction angle.[46] The best approach is to make measurements on the bench, perhaps informed by SPICE simulations using known or measured values of these parameters. In §9.5.4 we show results of such simulations.

9.5.3 dc components

A. Storage capacitor

The storage capacitors (sometimes called *filter* capacitors) are chosen large enough to provide acceptably low ripple voltage, with a voltage rating sufficient to handle the worst-case combination of no load and high line voltage (125–130Vrms).

At this point it may be helpful to look back at §1.7.16B, where we first discussed the subject of ripple. In general, you can calculate ripple voltage with sufficient accuracy by assuming a constant-current load equal to the average load current. (In the particular case that the unregulated supply drives a linear regulator, the load in fact is accurately a constant-current sink). This simplifies your arithmetic, since the capacitor discharges with a ramp, and you don't have to worry about time constants or exponentials (the measured waveforms in Figure 9.51, taken with a resistive load, illustrate the validity of this approximation).

For the circuit shown in Figure 9.49, we wanted approximately 1 Vpp output ripple at full 2 A load. From $I{=}C\,dV/dt$ we get (with $\Delta t{=}8.33\,\text{ms}$) $C{=}I\Delta t/\Delta V = 16,700\,\mu\text{F}$. The nearest capacitor voltage ratings are 63 V and 80 V; we chose the latter, in an abundance of caution. The available 16,000 μF/80 V capacitors are somewhat large physically (40 mm diameter × 80 mm long), so we decided to put a pair of 8200 μF capacitors (35 mm × 50 mm) in parallel (using smaller capacitors in parallel

[46] Although a transformer with a large leakage inductance might seem advantageous (because it increases the conduction angle losslessly), it has the undesirable effect of degrading voltage regulation under load; it also introduces a phase lag in the input current relative to the voltage, thus reducing the power factor. Furthermore, leakage inductance causes nasty voltage spikes to appear, owing to diode reverse recovery, as described in §*9x.6*.

also reduces the overall series inductance of the capacitor). Good design practice calls for the use of storage capacitors whose ripple current rating is conservatively larger than the value estimated from the dc output current and the conduction angle. In the above circuit, for example, we designed for a maximum dc load current of 2 A, from which we estimated an rms current of about 4 A in both the transformer secondary and the storage capacitor. The particular capacitors shown in the figure have a ripple current rating of 5.8 Arms at 85°C for each 8200 μF capacitor of the parallel pair, thus 11.6 Arms when combined to make either C_1 or C_2. This is definitely conservative! You can also calculate the heating, from the ESR specification of 0.038 Ω (maximum) per capacitor: each parallel pair has an ESR no greater than 19 mΩ, which produces a heating power of $P = I^2_{\text{rms}} R_{\text{ESR}} \approx 0.15$ W in each capacitor.

When choosing filter capacitors, don't get carried away: an oversize capacitor not only wastes space but also increases transformer heating (by reducing the conduction angle, hence increasing the ratio of rms current to average current). It also increases stress on the rectifiers. But watch out for loose capacitance tolerance: although the capacitors we used here have a rated tolerance of ±20%, electrolytic storage capacitors can be as loose as +100%/−30%.

The resistors R_2 and R_3 across the output in Figure 9.49 serve two purposes: they provide a minimum load (to keep the unloaded output from "soaring"); and they act as "bleeders" to discharge the capacitors when the unloaded supply is turned off. This is a good feature, because power supplies that stay charged after things have been shut off can easily lead you to damage some circuit components if you mistakenly think that no voltage is present.

B. Rectifier

The first point to be made is that the diodes used in power supplies (usually referred to as "rectifiers") are quite different from the small 1N914- or 1N4148-type signal diodes used in circuitry. Signal diodes are generally designed for high speed (a few nanoseconds), low leakage (a few nanoamps), and low capacitance (a few picofarads), and they can generally handle currents up to about 100 mA, with breakdown voltages rarely exceeding 100 volts. By contrast, rectifier diodes and bridges for use in power supplies are hefty objects with current ratings going from 1 A to 25 A or more, and breakdown voltage ratings going from 100 V to 1000 V or more. They have relatively high leakage currents (in the range of microamps to milliamps) and plenty of junction capacitance. General-purpose rectifiers of the sort used in Figure 9.49 are not intended for high speed, unnecessary for operation at the powerline frequency of 60 Hz. By contrast, in *switching* power supplies it's necessary to use high-speed rectifiers because of the characteristic switching frequencies of 20 kHz–1 MHz; there the use of "fast recovery" or Schottky-barrier rectifiers (or MOSFETs used as "synchronous rectifiers"[47]) is universal.

Typical of general-purpose rectifiers are the popular 1N4001–1N4007 series, rated at 1 A, and the 1N5400–1N5408 series, rated at 3 A, with reverse-breakdown voltages ranging from 50 to 1000 volts. The 1N5817–1N5822 series of Schottky rectifiers come in axial lead packages, with current ratings of 1–3 A, and voltage ratings of 20–40 V. Rectifiers with higher current ratings require heatsinking, and come in packages similar to power transistors (TO-220, D^{2}PAK, stud-mount, etc). Examples are the MBR1545 and 30CTQ045 dual Schottky rectifiers (available in TO-220 or D^{2}PAK power packages), rated at 15 A and 30 A, respectively, at 45 V, and the MUR805 to MUR1100 6 A rectifiers (in TO-220 packages), with voltage ratings to 1 kV. Plastic-encapsulated bridge rectifiers are quite popular also, with lead-mounted 1 A to 6 A types, and heatsink mountable packages in ratings up to 35 A or more.[48]

C. Damping network

The series *RC* across the transformer secondary in Figure 9.49 is often omitted, but it shouldn't be. This simple linear unregulated dc supply has the surprising ability to generate substantial microsecond-scale voltage spikes, which can create strong 120 Hz interference and other forms of mischief. It turns out that a pair of non-ideal characteristics (transformer leakage inductance, combined with rectifier reverse recovery time) work together to create a train of periodic sharp spikes, whose amplitude can be tens of volts. This nasty effect is easily tamed with a series *RC* "snubber" network, as shown. There's some interesting stuff going on here; you can read more about it (and see a dramatic example) in §*9x.6*.

9.5.4 Unregulated split supply – on the bench!

We built the power supply of Figure 9.49, mostly out of curiosity to see how closely the actual device compared

[47] Sometimes called *active rectifiers*.

[48] An interesting option for implementing an efficient bridge rectifier is the use of four MOSFETs as synchronous switches; their gate control signals can be generated conveniently with an elegant device like the LT4320 "Ideal Diode Bridge Controller," which senses zero crossings and does the right thing on its gate-control output pins. Check out its datasheet.

with our predictions. Figure 9.51 shows the ac voltage and current at one end of the transformer secondary, and the positive dc output voltage, with the power supply driving ±2 A resistive loads. The waveforms are pretty much as expected: (a) the ripple voltage is about 0.8 Vpp, somewhat less than our 1 Vpp estimate; our calculation was conservative, though, because we assumed the storage capacitors had to supply output current for a complete half-period ($1/2f_{ac} \approx 8$ ms), whereas in reality recharging begins after ∼6 ms; (b) the dc output voltage (54 V) is somewhat higher than expected, probably because the transformer voltage rating is for the full-rated load current of 4 A, and also because the powerline voltage in our lab was 3% above nominal; with no load the output rose to 60 V, typical of unregulated supplies; (c) the transformer current is confined to a fairly narrow conduction angle (about 60° of each 180° half-cycle), as expected; during conduction the ac waveform at the transformer secondary is flattened by the heavy load current because of the combined effects of leakage inductance and winding resistance.[49]

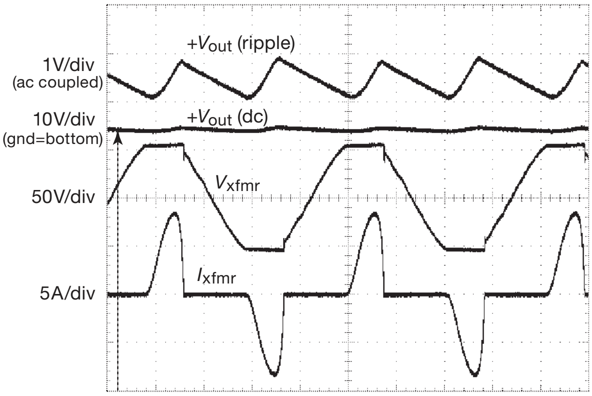

Figure 9.51. Measured waveforms for the unregulated dc power supply of Figure 9.49 driving ±2 A loads. Horizontal scale: 4 ms/div.

With a 2 A dc load on both outputs, the measured rms transformer current was 3.95 Arms. This doubling is caused by the shortened conduction angle: the *average* transformer current equals the dc output current, but the *rms* current is greater. This is sometimes described as a reduced *power factor* (the ratio of average input power to rms input power), an effect that is important in switching power supplies. With some cleverness it is possible to rectify incoming powerline ac to dc while maintaining nearly unity power factor, by means of a "power-factor correction" (PFC) input circuit; we'll explore this cleverness, briefly, in §9.7.1C.

And on the *computer*! (SPICE)

To explore the effects of component imperfections (winding resistance and leakage inductance in the transformer, series resistance in the capacitors) we ran a SPICE simulation (see Appendix J) of this circuit, beginning with measured parameters where possible (e.g., transformer resistance and inductances), values found in the SPICE libraries (e.g., rectifier forward voltage versus current) and plausible guesses for series resistance in the storage capacitors. With just a small amount of adjustment we obtained the simulation shown in Figure 9.52 (presented at the same scale factors as in Figure 9.51). The agreement is impressive (although the simulation somewhat underestimates the conduction angle, thus higher-than-measured transformer current).[50]

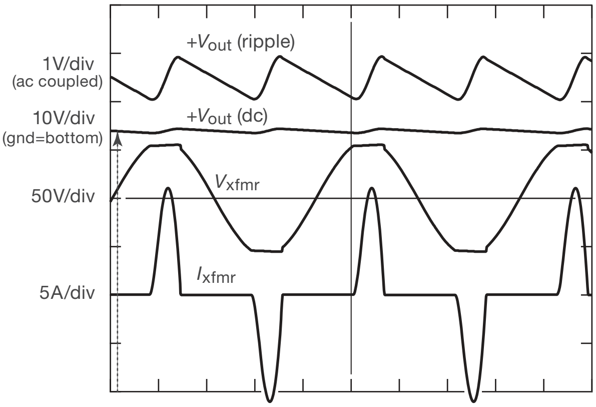

Figure 9.52. Waveforms from a SPICE simulation of the unregulated dc power supply of Figure 9.49, plotted on the same scales as those of Figure 9.51.

9.5.5 Linear versus switcher: ripple and noise

Coming next is the fascinating subject of *switching* regulators and power supplies. These have become dominant, owing to their combination of excellent efficiency, small

[49] For these waveform measurements we omitted Figure 9.49's R_SC_S damping network to reveal the spike (and jump) that is visible on the transformer ac voltage waveform, caused by the combination of transformer leakage inductance and diode recovery time; see §9.5.3C and §*9x.6*.

[50] The dominant circuit parameters used are: transformer primary R=0.467 Ω, L_L=1.63 μH, L_M=80 mH, turns ratio of 0.365, transformer secondary R=0.217 Ω, $L_{L(sec)}$=20 μH, damping network C_s=0.5 μF, R_s=30 Ω, rectifier "KBPC806" (Vishay 8A, 600V bridge), storage capacitor C=14,000 μF, ESR=0.01 Ω, load resistors 27 Ω (each side).

size and weight, and low cost. However, all is not roses: the rapid switching process generates transients at the switching frequency and its harmonics, and these can be extremely difficult to filter effectively. We'll discuss this soon enough... but it's worth taking a look now at Figure 9.53, where the bad stuff on the outputs of two 5 V power supplies are compared.

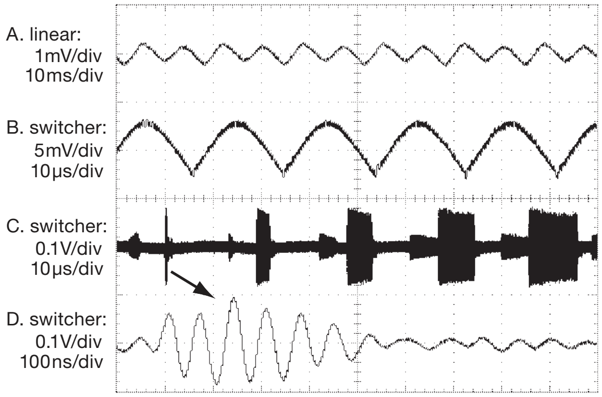

Figure 9.53. Comparing linear and switching power supply noise. All measurements are into a resistive load at 50% of rated current. A. Linear 5 V, 0.3 A supply, showing ~0.5 mVpp 120 Hz ripple. B. Switching 5 V, 2.5 A supply, measured directly across the output pins, showing ~6 mVpp ripple at the 50 kHz switching frequency (note scale change). C. Same switcher, but measured at a connected load 50 cm away (and with another factor of ×20 scale change), showing the large (~150 mV) switching spikes induced by high-frequency ground currents; note the frequency dithering seen in this persistent capture. D. Expanded trace of a single induced pulse, showing ringing at ~15 MHz.

9.6 Switching regulators and dc–dc converters

9.6.1 Linear versus switching

All the voltage-regulator circuits we have discussed so far work the same way: a linear control element (the "pass transistor") in series with the dc input is used, with feedback, to maintain constant output voltage (or perhaps constant current).[51] The output voltage is always lower in voltage than the input voltage, and significant power is dissipated in the control element, namely $P_{\text{diss}}=I_{\text{out}}(V_{\text{in}}-V_{\text{out}})$. As we've seen, the dc input to a linear regulator may be simply another (higher) regulated dc voltage within the system; or it may be unregulated dc that is derived from the powerline, via the by-now familiar transformer–rectifier–capacitor circuit.

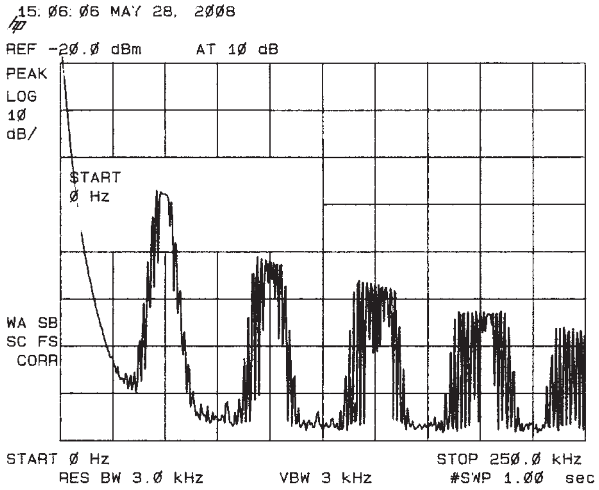

Figure 9.54. Averaged frequency spectrum of the switching power supply of Figure 9.53, showing the dithered ~50 kHz switching frequency and its harmonics.

Let's look a bit more at the issue of efficiency. Power supplies with *linear* regulators are necessarily inefficient, because the pass transistor carries the full load current, and it must have enough voltage drop to accommodate a worst-case combination of input ripple and low line voltage. The situation is exacerbated for low-output-voltage supplies: for example, a linear regulator to deliver +3.3 V at 10 A would use an unregulated dc voltage of perhaps +6 V to ensure adequate headroom; so you've got 27 W of pass-transistor dissipation while delivering 33 W to the load – that's 55% efficiency. You may not care that much about efficiency *per se*; but the wasted power has to be dissipated, which means a large heatsink area, blowers, etc. If you were to scale up this example to 100 A, say, you would have a serious problem removing the quarter of a kilowatt (!) of pass-transistor heat. You would have to use multiple pass transistors and forced-air cooling. The supply would be heavy, noisy, and hot.

There is another way to generate a regulated dc voltage (shown earlier in Figure 9.48B), which is fundamentally different from what we've seen so far – look at Figure 9.55. In this switching converter a transistor, operated as a saturated switch, periodically applies the full unregulated voltage across an inductor for short intervals. The inductor's current builds up during each pulse, storing $\frac{1}{2}LI^2$ of energy in its magnetic field. When the switch is turned off, some

[51] A minor variation on this theme is the *shunt regulator*, in which the control element is tied from the output to ground, rather than in series with the load; the simple resistor-plus-zener is an example.

or all[52] of this stored energy is transferred to a filter capacitor at the output, which also smooths the output (to carry the output load between charging pulses). As with a linear regulator, feedback compares the output with a voltage reference – but in a switching regulator it controls the output by changing the oscillator's pulse width or switching frequency, rather than by linearly controlling the base or gate drive.[53]

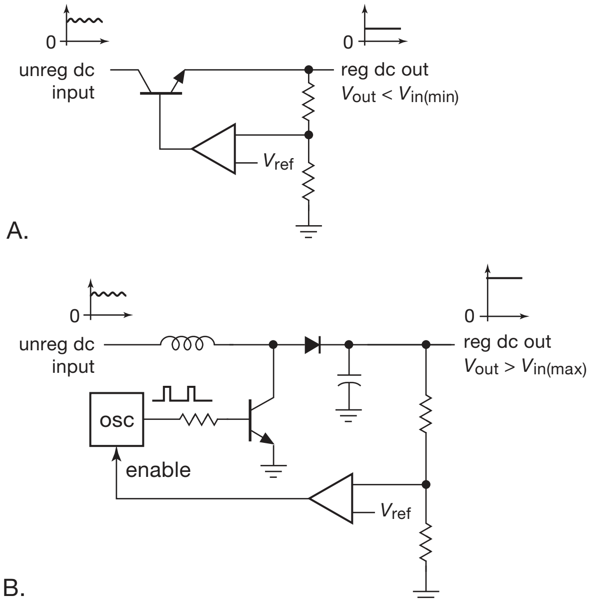

Figure 9.55. Two kinds of regulators: A. linear (series-pass); B. switcher (step-up, or "boost").

Advantages of switching converters

Switching regulators have unusual properties that have made them very popular:

(a) Because the control element is either off or saturated, there is very little power dissipation; switching supplies are thus very efficient, even when there is a large voltage difference between input and output. High efficiency translates to small size, because little heat needs to be dissipated.

(b) Switchers (slang for "switching power supplies") can generate output voltages *higher* than the unregulated input, as in Figure 9.55B; and they can just as easily generate outputs *opposite in polarity* to that of the input!

(c) The output storage capacitor can be small (in capacitance, and therefore in physical size), because the high operating frequency (typically 20 kHz–1 MHz) corresponds to a very short time interval (a few microseconds) between recharging.

(d) For a switching supply operated from the ac powerline input, the essential isolation is provided by a transformer operating at the switching frequency; it is *much* smaller than a low-frequency powerline transformer (see Figure 9.1).

The good news

The combination of small capacitor and transformer size, along with little power dissipation, permits compact, lightweight, and efficient ac-powered dc supplies, as well as dc-to-dc converters.[54] For these reasons, switching supplies (also known as *switchmode* power supplies, or SMPSs), are used almost universally in electronic devices such as computers, telecommunications, consumer electronics, battery-operated devices, and, well, just about everything electronic.

The bad news

Lest we leave too favorable an impression, we note that switching supplies do have their problems. The switching operation introduces "noise" into the dc output, and likewise onto the input powerline and as radiated electromagnetic interference (EMI); see Figures 9.53 and 9.54. Line-operated switchers (confusingly called "off-line") exhibit a rather large "inrush current" when initially powered on.[55]

[52] All of the stored energy goes forward if the inductor current is allowed to go to zero ("discontinuous-conduction mode," DCM); you get only a portion of the stored energy in "continuous-conduction mode" (CCM), in which the inductor's current does not go to zero before the next conduction cycle.

[53] One could object that we're unfairly comparing a *step-up* switching converter circuit with an inherently "step-down" linear pass regulator. Indeed, the switching topology that is analogous in function to the linear regulator is the *buck* regulator (shown presently, in Figure 9.61A). But we like the shock value of the boost switching converter, because it's unexpected that you can even do that if you've lived exclusively in the linear world.

[54] Examples of the former include the little power "bricks" that are used for laptop computers, cellphones, and the like, as well as the more substantial power supplies built into desktop computers. Examples of the latter are the "point of load" dc–dc converters that you find clustered around the processor on a computer motherboard: the processor might require 1.0 Vdc at 60 A (!); to generate that enormous current you use a set of 12 V to 1.0 V step-down converters, right at the point of load, supplied by a lower current 12 V "bus."

[55] For an example we opened to a random page in the power-supply section of the DigiKey catalog, and found a little ac-input 5 W switcher (5 Vdc, 1 A) with a specified powerline inrush current of. . . (drumroll). . . 40 A – that's a peak power of 4*kilo*watts!

And switchers have suffered from a bad reputation for reliability, with occasional spectacular pyrotechnic displays during episodes of catastrophic failure.

The bottom line

Fortunately, switching supplies have largely overcome the drawbacks of their earlier brethren (unreliability, electrical and audible noise, inrush current and component stress). Because they are small, lightweight, efficient, and inexpensive, switchers have largely replaced linear regulators over the full range of load power (from watts to kilowatts) in contemporary electronics, and particularly in large commercial production. Linear supplies and regulators are still alive and well, however, particularly for simple low-power regulation and for applications requiring clean dc power; and this last feature – the absence of pervasive switching noise – can be of major importance in applications that deal with small signals.

9.6.2 Switching converter topologies

In the following sections we tell you all about switching regulators and power supplies (collectively called "switching converters"), in several steps.

- First (§9.6.3) we look briefly at *inductorless* converters, in which the energy is carried from input to output by capacitors, whose connections are switched with MOSFETs. These are sometimes called "charge-pump converters," or "flying-capacitor converters." These simple devices can double or invert a dc input voltage, and they're useful for relatively low current loads (up to $\sim$100 mA).
- Next (§9.6.4) we describe converter topologies that use inductors, beginning with the basic dc–dc non-isolated switching converter, of the sort you would use within a circuit, or with battery power. There are three basic circuit topologies, used for (a) step-down (output voltage less than input), (b) step-up (output voltage greater than input), and (c) inverting (output polarity opposite to input). All of these use an inductor for energy storage during the switching cycle.
- Next (§9.6.10) we look at dc–dc converters in which a transformer couples the input and output circuits. In addition to providing galvanic isolation (which may or may not be needed), the transformer is desirable when there's a large ratio between input and output voltages. That is because the transformer's turns ratio provides a helpful voltage conversion factor that is absent in the non-isolated (transformerless) designs. Transformer designs also let you produce multiple outputs, and of either polarity.
- Finally (§9.7) we describe how the isolated converter permits power-supply designs that run straight from the rectified ac powerline. These "offline" supplies are, of course, the bread and butter of most line-powered electronics. And they have their special problems, related to safety, interference, inrush current, power factor, and the like.

And, characteristically, we give you plenty of advice on the subject: when to use switchers, when to avoid them; when to design your own, when to buy them. With characteristic humility, we won't leave you in any doubt!

9.6.3 Inductorless switching converters

The term "switching converter" usually means a power converter that uses inductors (and sometimes transformers), along with high-frequency transistor switches, to carry out voltage conversion. However, there is an interesting class of *inductorless* converters (also known as *charge-pump* converters, *switched capacitor* converters, or *flying-capacitor* converters) that can do some of the same tricks – generating an output voltage of opposite polarity, or an output voltage higher than the input. These converters are simpler and electrically quieter than converters with inductors, and they're handy when you need only a modest current (less than 100 mA or so). For example, you often have a source of +5 V (on a computer board, or a USB device), or perhaps +9 V from a battery, and you need a corresponding negative voltage because you want to run a dual-polarity op-amp. Just drop in a charge-pump inverter chip and two capacitors, and you're ready to go.[56]

Figure 9.56 shows how it goes: these devices have an internal oscillator and some CMOS switches, and they require a pair of external capacitors to do their job. When the input pair of switches is closed (conducting), C_1 charges to V_{in}; then, during the second half-cycle, C_1 is disconnected from the input and connected, upside-down, across the output. If $C_2 \ll C_1$, then the output voltage goes nearly to $-V_{\text{IN}}$ in one cycle of operation. In the more typical case of $C_2 \geq C_1$ it takes a number of cycles, from cold start, for the output voltage to equilibrate to $-V_{\text{IN}}$.

Similarly, you can create an output of $2V_{\text{in}}$, by arranging things so that C_1 charges as before, but then gets hooked in series with V_{in} during the second (transfer) half-cycle

[56] A good reference is M.D. Seeman & S.R. Sanders, "Analysis and optimization of switched-capacitor DC–DC converters," *IEEE Trans. Power Electron.* **23** (2) pp. 841–851 (2008).

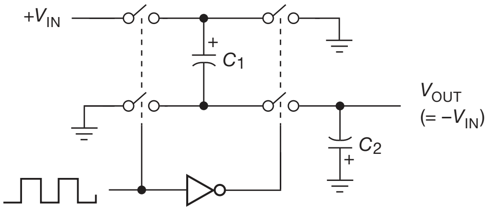

Figure 9.56. Charge-pump voltage inverter. An oscillator operates the switch pairs in alternation: the left-hand switches charge "flying capacitor" C_1 to a voltage of V_{IN}; the right-hand switches then apply that voltage, with reversed polarity, to the output storage capacitor C_2.

(Figure 9.57). The LT1026 and MAX680 conveniently integrate a positive doubler and an inverting doubler in one package: Figure 9.58 shows the simple circuitry required to generate an unregulated split supply from a single +5 V input.

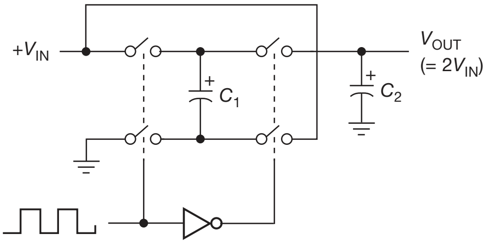

Figure 9.57. Charge-pump voltage doubler. Here the voltage on the flying capacitor, charged to V_{IN}, is added to the input voltage to generate an output voltage of twice V_{IN}.

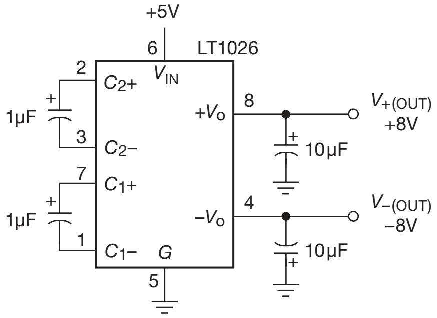

Figure 9.58. Generating a pair of unregulated ±8 V outputs from a single +5 V input.

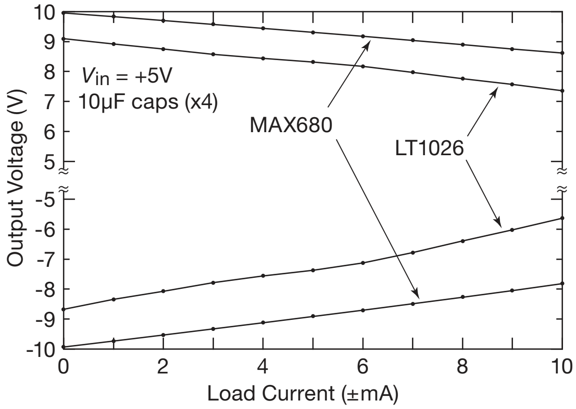

Figure 9.59. The output voltage of a charge-pump converter drops significantly under load, as seen here with measured data for the circuit of Figure 9.58, with either bipolar (LT1026) or CMOS (MAX680) devices. MOSFET switches have no voltage drop at zero current, where V_{out} is accurately equal to twice V_{in}.

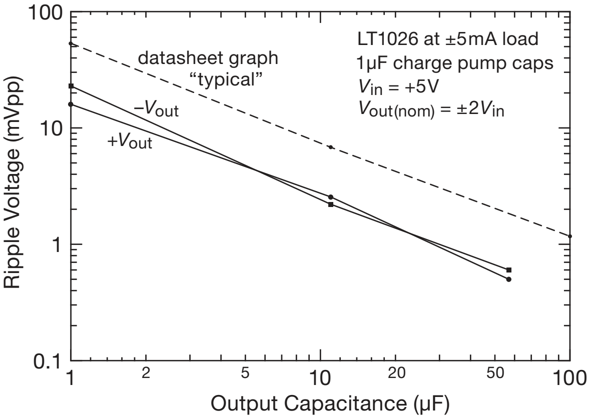

Figure 9.60. Reducing ripple with a larger output capacitor: measured peak-to-peak ripple voltage for the LT1026 doubler–inverter.

A. Limitations of inductorless converters

This charge-pump technique is simple and efficient, and requires few parts and no inductors. However, the output is not regulated, and it drops significantly under load (Figure 9.59). Also, in common with other switching power conversion techniques, the switching operation produces output ripple, which however can be reduced by using larger output capacitors (Figure 9.60), or by appending a low-dropout linear regulator (see below).[57] Furthermore, like most CMOS devices, charge pumps have a limited

[57] The ripple voltage is given approximately by $V_{\text{ripple}}(pp) = I_{\text{out}}/2f_{\text{osc}}C_{\text{out}} + 2I_{\text{out}} \cdot \text{ESR}$. The first term is just $I = CdV/dt$, and the second term adds the effect of the capacitor's finite equivalent series resistance.

Notes: (a) all are inductorless, and require several external caps; "regulated" types include either internal linear LDO post-regulator, or regulation via control of switching; sorted within categories by decreasing maximum V_{in}. (b) bipolar, see datasheet for typical V_{out}. (c) with other output unloaded. (d) both outputs loaded. (e) at max f_{osc}. (g) in x2 mode. (h) in x0.5 mode. (i) high f_{osc} allows small capacitors. (k) LV pin for low V_{in} range; many mfgs, prefixes LMC, NJU, TC, TL; see also MAX/LTC/TC1044, 1144, and TC962. (m) maximum. (n) at V_{in}=V_{out}/2 + 0.8V. (o) or Si7661. (p) freq pin selectable or adjustable. (q) last digit of p/n sets f_{osc}, except TPS60400, where f_{osc} varies cleverly with V_{in} and I_{out}. (r) unreg outputs also available on most; unless marked "LDO," all regulate via control of switching. (s) at V_{in}=1.2V. (u) last digit of p/n sets V_{out}. (v) V_n = 170μVrms in BW = 20Hz-10MHz. (vv) suffix selects V_{out}. (w) V_n = 60μVrms in BW = 10Hz-100KHz, 600μVpp for 10Hz-2.5MHz. (x) suffix sets f_{osc}. (y) or reg +3.3V; unreg x2 output also provided. (z) maximum usable.

supply-voltage range: the original charge-pump IC (the Intersil ICL7660) allows V_{in} to range from +1.5 V to +12 V; and although some successor devices (e.g., the LTC1144) extend this range to as much as +18 V, the trend is toward lower-voltage devices with greater output current and with other features.[58] Finally, unlike *inductive* switching converters (discussed next), which can generate any output voltage you want, the flying-capacitor voltage converter can generate only small discrete multiples of the input voltage. In spite of these drawbacks, flying-capacitor voltage converters can be very useful in some circumstances, for example to power a split-supply op-amp or a serial-port chip (see Chapters 14 and 15) on a circuit board that has only +5 volts available. Table 9.4 lists a selection of charge-pump voltage converters, illustrating a range of capabilities (voltage, regulation, output current, and so on).

[58] For example, more than half of Maxim's offerings are limited to +5.5 V input; and of the 67 offerings from Texas Instruments, only 7 can operate above +5.5 V input (and 28 of them are limited to +3.6 V or less). The story is similar for Linear Technology's 62 charge-pump converter offerings.

B. Variations

There are interesting and useful flying-capacitor variations, many of which are listed in Table 9.4, which is organized into unregulated and regulated varieties (each sorted by maximum input voltage). The unregulated types represent variations on the original ICL7660, including its similarly named successors (from TI, NJR, Maxim, Microchip, etc.) and pin-compatible upgrades ('7662, '1044, '1144); such multiply-sourced jellybean parts are widely available and inexpensive. More recent parts, for example the low-voltage TPS6040x, offer flexibility in switching frequency, and generally lower output resistance. Operation at higher frequency reduces output ripple (e.g., 35 mV at 20 kHz, but 15 mV at 250 kHz for the TPS6040x series), but it increases quiescent current (which goes from 65 μA to 425 μA in this example).[59]

The regulated types, like the LT1054 from LTC (with a maximum output current of 100 mA), include an internal voltage reference and error amplifier, so you can connect feedback to regulate the output voltage; the internal circuitry accommodates this by adjusting the switching control. Other converters regulate the output by including an internal low-dropout linear regulator, for greatly reduced output ripple (at the expense of some additional voltage drop); examples are the LTC1550 and 1682 series, with less than 1 mV peak-to-peak output ripple. Note that most of the "regulated" types let you use them as unregulated converters, if you wish.

There are also converters that *reduce* the input voltage by a rational fraction, e.g., by a factor of 1/2 or 2/3 (see if you can figure out how that is done!). At the other end, there are converters that are voltage quadruplers, for example the LTC1502, which generates a regulated +3.3 V at 10 mA from an input of 0.9–1.8 V (e.g., to power digital logic from a single alkaline cell).[60] And there are converters that can provide up to 500 mA of output current. Some charge-pump converters include internal capacitors, if you want to be especially lazy; but the selection is limited, and the price is high.

Finally, there is the LTC1043 uncommitted flying-capacitor building block, with which you can do all kinds of magic. For example, you can use a flying capacitor to transfer a voltage drop measured at an inconvenient potential (e.g., a current-sensing resistor at the positive supply voltage) down to ground, where you can easily use it. The LTC1043 datasheet has eight pages of similarly clever applications.

Then there are integrated circuits that include charge pumps to power their primary functions:

(a) Many RS-232/485 driver–receiver chips are available with integral ±10 V charge-pump supplies, to run from a single +5 V or +3.3 V supply. An example of the latter is the MAX3232E from Maxim (the originator of the MAX232, now widely second sourced), which can run from a single supply between +3 V and +5.5 V.

(b) Some op-amps use integral charge pumps to generate a voltage beyond the supply rail, so their inputs can operate rail-to-rail while maintaining a conventional high-performance architecture (see §4.6.3B); examples are the OPA369, LTC1152, and MAX1462-4.

(c) Charge pumps are used in many MOSFET "high-side drivers" (like the HIP4080 series from Intersil) and in fully integrated power MOSFETs (like the PROFET series of "smart highside high-current power switches" from Infineon); these generate the necessary above-the-rail gate bias for an *n*-channel MOSFET operating as a follower up at the positive rail.[61]

(d) Some complex digital logic devices (processors, memory) require elevated voltages, which they generate on-chip with charge pumps. The manufacturers are modest, and you don't even hear about these things.

9.6.4 Converters with inductors: the basic non-isolated topologies

The term *switching converter* (or *switchmode converter*[62]) is generally understood to mean a converter that uses some arrangement of inductors and/or transformers, in combination with transistor switches (usually MOSFETs, but also

[59] You can reduce ripple by using much larger output capacitors (with low ESR, to minimize the effect of current spikes), or, perhaps better, an output filter stage.

[60] Sadly, there are no charge-pump converters that take a single-cell input (0.9 V at end of life) up to +5 V (that would require at least a ×6 voltage conversion), although you could accomplish that task in two steps by cascading, say, a TPS60310 (0.9–3.3 V) with a TPS60241 (3.3–5 V). That would require two ICs and seven capacitors. But, happily, such a task is easily done with a boost-mode *inductive* switching converter (§9.6.6). For example, TI's TPS61222 comes in a tiny 6-pin SC-70 package, requires only a single external 4.7 μH inductor (plus input and output bypass caps), and delivers +5 V at 50 mA with 0.9 V input (an alkaline cell's end-of-life voltage). It costs less than $2 in single-piece quantities. Another approach to powering from a single alkaline cell is to use a charge-pump converter to generate +3.3 V, which then powers one or more inductive switching converters to generate the full set of voltages you need; the ENABLE input to the charge-pump converter can then be used to turn power on or off.

[61] For further detail see §3.5.3 and Figures 3.96 and 3.106.

[62] Switchmode power supplies are referred to as SMPSs, thus phrases like "SMPS technology."

IGBTs[63] for high voltages), to carry out efficient dc-to-dc conversion. A common characteristic of all such converters is this: in the first portion of each switching cycle the source of input power is used to increase the current (and therefore the energy) in an inductor; that energy then flows to the output during the second portion of the switching cycle. Switchmode power conversion is a major and vital area of electronics, and these converters are used in just about every electronic device.

There are literally hundreds of switchmode circuit variations, but they can be pared down to a few fundamental topologies. In this section we describe the three basic *nonisolated* designs – step-down, step-up, and invert – shown in Figure 9.61. After that we look at isolated converter designs; then we conclude with a look at the use of isolated converters fed from the ac powerline. Tables of selected switchmode converters (Tables 9.5a,b on pages 653 and 654) and controllers (Table 9.6 on page 658) appear later.

Along with the basic power-conversion *topologies* (which describe the circuitry that performs the voltage conversion itself), there is the important topic of *regulation*. Just as with linear voltage regulators, a sample of the output voltage is compared with a voltage reference in an *error amplifier*. Here, however, the error signal is used to adjust some parameter of the switching conversion, most often the pulse width; this is known as *pulse width modulation* (PWM).[64]

As we'll see, the pulse-width modulator circuits themselves fall into two categories (voltage mode and current mode), with important consequences in terms of response time, noise, stability, and other parameters. And, to introduce a bit of further complication, any of these switchmode circuit combinations may operate in a mode with the inductor's current dropping fully to zero by the end of each switching cycle, or in a mode in which the inductor's current never drops to zero. These modes of operation are known as *discontinuous-conduction mode* (DCM) and *continuous-conduction mode* (CCM), respectively, and they have major effects on feedback stability, ripple, efficiency, and other operating parameters of a switchmode regulator. We describe the basics of PWM with a few examples; but we will touch only lightly on the more advanced topics of voltage- versus current-mode PWM, and on loop compensation.

Figure 9.61. The basic nonisolated switching converters. The switch is usually a MOSFET. Schottky diodes are commonly used for the rectifiers, as shown; however, a MOSFET can be used as an efficient synchronously switched "active rectifier."

9.6.5 Step-down (buck) converter

Figure 9.61A shows the basic step-down (or "buck") switching circuit, with feedback omitted for simplicity. When the switch is closed, $V_{out} - V_{in}$ is applied across the inductor, causing a linearly increasing current (recall $dI/dt = V/L$) to flow through the inductor. (This current flows to the load and capacitor, of course.) When the switch opens, inductor current continues to flow in the same direction (remember that inductors don't like to change their current suddenly, according to the last equation), with the "catch diode" (or "freewheeling diode") now conducting to complete the circuit. The inductor now finds a fixed voltage $V_{out} - V_{diode}$ across it, causing its current to decrease linearly. The output capacitor acts as an energy "flywheel," smoothing the inevitable sawtooth ripple (the larger the capacitor, the smaller the ripple voltage). Figure 9.62 shows the corresponding voltage and current waveforms, assuming ideal components. To complete the circuit as a *regulator*, you would of course add feedback, controlling either the pulse width (at constant pulse repetition rate) or the

[63] Insulated-gate bipolar transistors, §3.5.7A.

[64] In some switchmode converters the regulation is done instead by varying the pulse *frequency*.

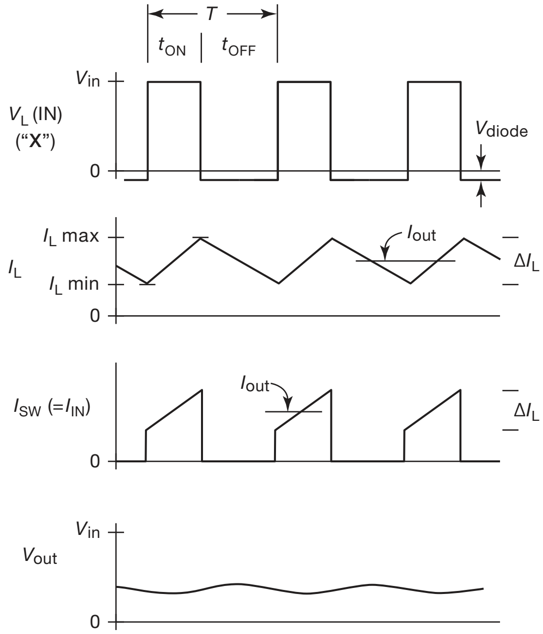

Figure 9.62. Buck converter operation. Inductor current ramps up during switch ON, and ramps down during switch OFF. The output voltage equals the input voltage times the duty cycle ($D \equiv t_{on}/T$). In the case of continuous inductor current (CCM; as shown here) the output current is equal to the average inductor current.

repetition rate (with constant pulse width) from an error amplifier that compares the output voltage with a reference.[65]

For all three circuits of Figure 9.61 the voltage drop across the catch diode wastes energy, reducing the conversion efficiency. Schottky diodes (as shown) are often used to mitigate this, but the best solution is to add a second switch across or in place of the diode. This is called *synchronous switching*; see the "synchronous" column in Tables 9.5a,b and 9.6.

Output voltage What is the output voltage? In the steady state the average voltage across an inductor must be zero, because otherwise its current is continually growing (according to $V = L dI/dt$).[66] So, ignoring voltage drops in the diode and switch, this requires that $(V_{in} - V_{out})\, t_{on} = V_{out} t_{off}$, or

$$V_{out} = DV_{in}, \tag{9.3}$$

where the "duty cycle" (or "duty ratio") D is the fraction of the time the switch is ON, $D = t_{on}/T$, and T is the switching period ($T = t_{on} + t_{off}$).

You can think about this in another way: the LC output network is a lowpass filter, to which is applied a chopped dc input whose average voltage is just DV_{in}. So, after smoothing, you get that average voltage as the filtered output. Note that, assuming ideal components, the output voltage from a buck converter running at fixed duty cycle D from a fixed input voltage is intrinsically regulated: a change in load current does not change the output voltage; it merely causes the inductor's triangular current waveform to shift up or down, such that the average inductor current equals the output current. (This assumes continuous inductor current, or CCM, as we discuss below.)

Input current What is the input current? If we assume ideal components, the converter is lossless (100% efficiency), so the input power must equal the output power. Equating these, the average input current is $I_{in} = I_{out}(V_{out}/V_{in})$.[67]

Critical output current We've been assuming continuous inductor conduction in the waveforms of Figure 9.62, and also in deducing that the output voltage is simply the input voltage times the switch duty cycle. Look again at the graph of inductor current: its average current must equal the output current, but its peak-to-peak variation (call it ΔI_L) is completely determined by other factors (namely V_{in}, V_{out}, T, and L); so there is a *minimum output current* for which the inductor stays in conduction, namely when $I_{out} = \frac{1}{2}\Delta I_L$.[68] For output currents less than this critical load current, the inductor current reaches zero before the end of each cycle; the converter is then operating in discontinuous conduction mode, for which the output voltage would no longer remain stable at fixed duty cycle, but would depend on load current. Of greater importance, operating in DCM has a major effect on loop stability and regulation. For this reason many switching regulators have a minimum output current, in order to operate in CCM.[69] As the following expressions show, the minimum load current for CCM is reduced by increasing the inductance, increasing the switching frequency, or both.

[65] There is also hysteretic control, in which both pulse width and switching frequency may vary.

[66] Engineers like to say that the *volt–time product* (or the *volt–second product*) must average to zero.

[67] In real converters the efficiency is reduced by losses in the inductors, capacitors, switches, and diodes. It's a complicated subject.

[68] Operation at this current is called *critical conduction mode*.

[69] At load currents less than the minimum current for CCM they may enter other modes of operation, including "burst mode."

A. Buck converter equations (continuous-conduction mode)

From the preceding discussion and waveforms it is not terribly difficult to figure out that the ideal buck converter (Figure 9.61A), operating in continuous conduction mode, obeys these equations:

$$\langle I_{\rm in}\rangle = I_{\rm out}\frac{V_{\rm out}}{V_{\rm in}} = DI_{\rm out}, \tag{9.3a}$$

$$\Delta I_{\rm in} = I_{\rm out}, \tag{9.3b}$$

$$V_{\rm out} = V_{\rm in}\frac{t_{\rm on}}{T} = DV_{\rm in}, \tag{9.3c}$$

$$D = \frac{V_{\rm out}}{V_{\rm in}}, \tag{9.3d}$$

$$\begin{aligned} I_{\rm out(min)} &= \frac{T}{2L}V_{\rm out}\left(1-\frac{V_{\rm out}}{V_{\rm in}}\right) \\ &= \frac{T}{2L}V_{\rm out}(1-D), \end{aligned} \tag{9.3e}$$

$$\Delta I_{\rm C(out)} = \frac{T}{L}V_{\rm out}(1-D), \tag{9.3f}$$

$$I_{\rm L(pk)} = I_{\rm out}+\frac{T}{2L}V_{\rm out}(1-D), \tag{9.3g}$$

$$L_{\rm min} = \frac{T}{2}\frac{V_{\rm out}}{I_{\rm out}}(1-D), \tag{9.3h}$$

where $\langle I_{\rm in}\rangle$ represents the time-averaged value of input current, and $\Delta I_{\rm in}$ and $\Delta I_{\rm C(out)}$ are the approximate peak-to-peak ripple currents at input and output (important for capacitor selection[70]). The first equation holds regardless of mode (CCM or DCM). The expressions for minimum inductance and minimum output current represent the critical values to maintain CCM; for these expressions use the minimum output current and the maximum value of $V_{\rm in}$, respectively.

Exercise 9.8. Take the challenge: derive these equations (and be sure to tell us if we got them wrong). *Hint*: for $I_{\rm out(min)}$ and $L_{\rm min}$ use the fact that the output current $I_{\rm out}$ equals half the peak-to-peak inductor current variation $\Delta I_{\rm L}$, at the threshold of CCM, as easily seen from the $I_{\rm L}$ waveform in Figure 9.62.

B. Buck converter example – I

Let's do a buck regulator design, using a very simple (and inexpensive) controller chip, the MC34063 (Figure 9.63). This controller dates back to the 1980s and costs about $0.50. In spite of its ancient heritage, the MC34063 is quite popular for undemanding applications, because of its low price and simple design criteria; this 8-pin part is manufactured by a half-dozen companies, and is supplied in the usual package styles (DIP, SOIC, SOP). It includes an oscillator, error amplifier and voltage reference, current-limit comparator, and a Darlington output pair with access to both collector and emitter. Its operation is unsophisticated: it does not use the more usual PWM (in which the switch conduction time during each cycle is varied continuously, as in Figure 9.72). Instead, switch conduction cycles are enabled as long as the voltage at the feedback (FB) input is less than the +1.25 V internal reference; otherwise they are inhibited. You can think of this as a crude form of PWM, in which the modulation consists of turning on the switch for a full cycle, then skipping enough cycles to approximate the needed ratio of switch ON/OFF.[71] This feedback regulation scheme is known as *hysteretic* control.

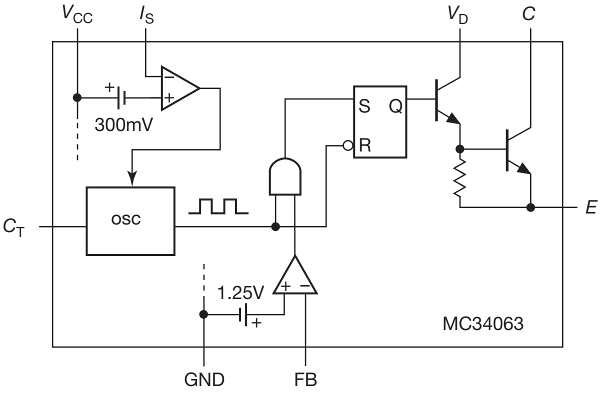

Figure 9.63. A popular $0.50 switching converter. The external connections to both collector and emitter of the 1.5 A switch make it easy to implement buck, boost, or inverting converters.

For our design let's assume a +15 V input, and produce a +5 V regulated output for load currents up to 500 mA. Figure 9.64 shows the circuit. The design is straightforward:

1. Choose an operating frequency: we picked 50 kHz, half the chip's recommended maximum. For that frequency the datasheet specifies $C_{\rm T} = 470\,$pF. The oscillator runs with a ratio $t_{\rm on}/t_{\rm off} = 6$, so the switch conduction time is $t_{\rm on} = 17\,\mu$s.
2. Calculate the inductor value so the converter operates

[70] Note that capacitor datasheets specify maximum allowed *rms* ripple current, rather than peak-to-peak. Be sure to allow a large safety margin in this parameter when selecting input and output capacitors for power conversion.

[71] This is analogous to "bang–bang" feedback control, as contrasted with proportional (or PID) control in which the feedback signal operates in a continual manner.

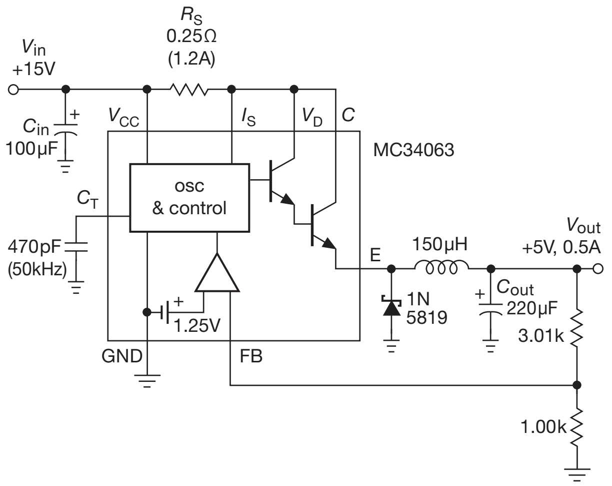

Figure 9.64. Step-down regulator using the MC34063. In contrast to proportional PWM, the chip's simple bang–bang control eliminates the need for feedback compensation components. But performance suffers.

in DCM,[72] assuming onset of CCM at minimum input voltage and maximum load current: at onset of CCM, the output current is half the peak inductor current, so, using $V = LdI/dt$ (and assuming a 1 V drop in the Darlington switch), we get $L = (V_{in} - V_{sw} - V_{out})t_{on}/2I_{out} = 153\mu$H. We'll use a standard value of 150 μH.

3. Calculate the value of sense resistor R_S to limit the peak current I_{pk} to somewhat greater than the expected 1 A, but no greater than the chip's 1.5 A rating: $R_S = 300\,\text{mV}/I_{lim} = 0.25\Omega$ (for a 1.2 A current limit).[73]

4. Choose an output capacitor value to keep the ripple voltage below some acceptable value. You can estimate the ripple by calculating the capacitor's voltage rise during one cycle of switch conduction (during which its current goes from 0 to I_{pk}), which gives a value $\Delta V = I_{pk}t_{on}/2C_{out}$. So an output capacitor of 220 μF results in a peak-to-peak ripple voltage of ∼40 mV.[74]

Several comments. (a) This simple design will work, but the performance will be far from ideal. In particular, the crude bang–bang control, combined with discontinuous-conduction operation, produces lots of output ripple, and even audible noise, caused by its intermittent pulsing. (b) The Darlington output connection prevents saturation in the output stage, with some loss of efficiency; this could be remedied by connecting the driver collector line (V_D) to the input supply, through a current limiting resistor of the order of 200 Ω. (c) The internal switch is limited to 1.5 A peak current, which is inadequate for output currents greater than 0.75 A; this can be remedied with an external transistor switch, for example a *pnp* transistor or *p*-channel MOSFET (for this buck configuration). The main attractiveness here is the combination of very low cost, and lack of worries about feedback stability and compensation. You'll see this part used in relaxed applications such as cellphone chargers and the like.[75]

C. Buck converter example – II

Fortunately, there are very nice integrated switchers that implement proportional PWM and, furthermore, make it really easy to do a circuit design (many are listed in Tables 9.5a,b, discussed later). For example, National Semiconductor (part of Texas Instruments) has a series of "Simple Switcher™" ICs, individually configured for buck, boost, or invert topologies, that include all the necessary feedback loop compensation components on-chip.[76] They cover a voltage range up to 40 V or more, with currents to 5 A, and have built-in current limit, thermal limit, voltage reference, fixed-frequency oscillator, and (in some versions) features such as soft-start (see §9.6.8G), frequency synchronization, and shutdown. Best of all, they make it dead simple to design a converter either by following the step-by-step recipes in the datasheets or by using free web-based design tools: you get the component values (including recommended component manufacturers' part numbers) and performance data.

Figure 9.65 shows such a design, in this case converting a 14 V input (from an automobile battery) to a +3.3 V output that can supply up to 5 A (to power digital logic). We followed the datasheet's recipe to get the component values and part numbers shown. With these components the efficiency is 80% and the output ripple is less than 1% of V_{out} (∼30 mV).

The LM2677 we used (and other "simple switcher" successors) follow on from the original LM2574,75,76 series

[72] That is, the inductor current ramps completely to zero during each switch cycle.

[73] If you find that the expected peak current is greater than the chip's limit, you will have to append an outboard transistor, or (better) use a different chip.

[74] The actual ripple voltage will be higher because of the capacitor's ESR, an effect that can also be estimated.

[75] Those who are struggling with an under-performing circuit based on an MC34063A should consider the NCP3063, a drop-in upgrade that operates to 150 kHz. This allows you to reduce the inductor size and deliver higher output currents.

[76] See for example the block diagram in the LM2677's datasheet, and associated patents for the active inductor (US patent 5,514,947) and active capacitor (US patent 5,382,918).

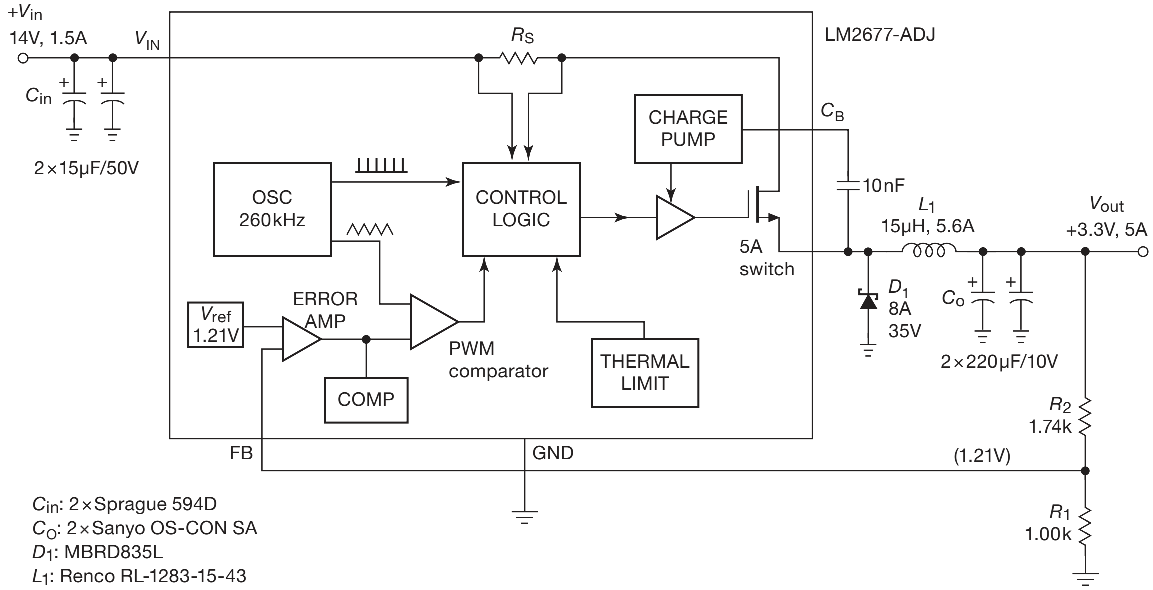

Figure 9.65. Step-down regulator using the LM2677 "Simple Switcher" (complete with elegant built-in compensation). We followed the datasheet's design recipe to get the component values and recommended part numbers shown.

(0.5 A, 1 A, and 3 A, respectively), which run at 52 kHz and which are widely popular "jellybean" parts – they are inexpensive and available from many manufacturers.[77] The LM2677 is a member of the improved LM2670 family, running at 260kHz, with output-current ratings to 5 A; it requires one additional capacitor (C_B in the figure) to drive the 5 A low-drop MOSFET.

Several comments:

(a) This converter provides ten times the output current of the previous design (Figure 9.64), and with significantly improved performance in terms of regulation, ripple, and transient response. That comes at a cost (literally), namely an IC that costs ten times as much (about $5, versus $0.50).[78]

(b) The good efficiency is due in part to the use of an *n*-channel MOSFET whose gate is driven from a voltage higher than V_{in}, thanks to an internal charge pump; that's the purpose of the boost capacitor C_B.

(c) Note the use of paralleled capacitors at the input and output. You see this often in switchmode converters, where it's important to keep ESR and ESL (equivalent series inductance) low: that reduces the voltage ripple caused by ripple current, and also keeps the capacitors within their ripple-current ratings.[79]

(d) For a standard output voltage like the +3.3 V here, you can save two resistors by selecting a fixed-voltage version (LM2677-3.3); but the adjustable version (LM2677-ADJ) lets you choose your output voltage, and you don't have to keep multiple versions in stock in your laboratory.

(e) Note that the input current is a lot less than the output current, representing a power-conversion efficiency of 80%; this is a major advantage over a linear regulator.

(f) Fixed efficiency means that if you increase the input voltage, the input current goes *down*: that's a negative resistance! This creates some amusing complications – for example you can get oscillation when the input is filtered with an *LC* network, a problem that applies to ac powerline input converters as well.

Exercise 9.9. What is the maximum theoretical efficiency of a linear (series pass) regulator, when used to generate regulated +3.3 V from a +14 V input?

Exercise 9.10. What does a step-down regulator's high efficiency imply about the ratio of output current to input current? What is the corresponding ratio of currents, for a linear regulator?

[77] And ON semiconductor has introduced the compatible NCV2576 family, low-cost parts rated specifically for the automotive market.

[78] Power converter ICs vary over an enormous price range; the approximate prices listed in this chapter's tables can provide some guidance in their selection.

[79] It also assists in creating a desirably low physical profile.

9.6.6 Step-up (boost) converter

Unlike linear regulators, switching converters can produce output voltages higher than their input. The basic non-isolated step-up (or "boost") configuration was shown in Figure 9.61B (repeated here as 9.66, and seen earlier, in Figure 9.55, in comparison with the linear regulator). During switch conduction (point Y near ground) the inductor current ramps up; when the switch is turned off, the voltage at point Y rises rapidly as the inductor attempts to maintain constant current. The diode turns on, and the inductor dumps current into the capacitor. The output voltage can be much larger than the input voltage.

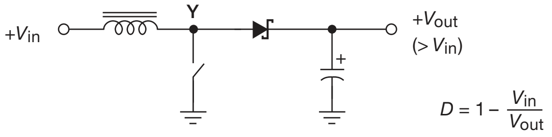

Figure 9.66. Basic boost (or "step-up") topology (non-isolated).

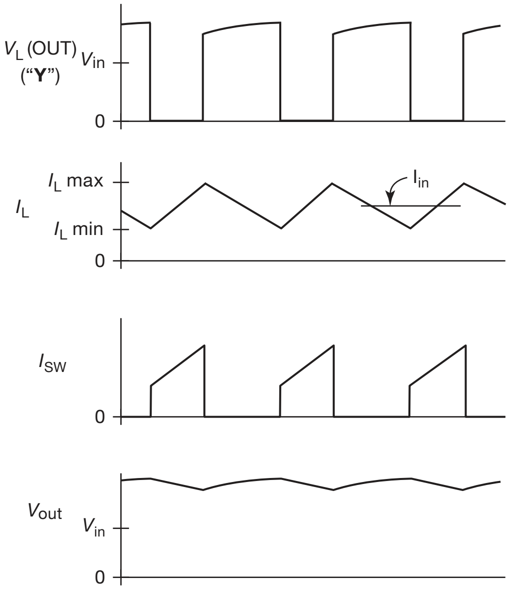

Figure 9.67. Boost converter operation. Inductor current ramps up during switch ON, and ramps down during switch OFF. The output voltage equals the input voltage divided by the fraction of the time the switch is OFF. In the case of continuous inductor current (CCM, as shown here) the input current is equal to the average inductor current.

A. Boost converter equations (continuous-conduction mode)

Figure 9.67 shows relevant voltage and current waveforms, assuming ideal components. As with the buck converter, it is not terribly difficult to figure out that the boost converter (Figure 9.61B), operating in continuous conduction mode, obeys these equations:

$$\langle I_{in}\rangle = I_{out}\frac{V_{out}}{V_{in}} = \frac{I_{out}}{1-D}, \tag{9.4a}$$

$$\Delta I_{in} = \frac{T}{L}V_{in}D, \tag{9.4b}$$

$$V_{out} = V_{in}\frac{T}{t_{off}} = \frac{V_{in}}{1-D}, \tag{9.4c}$$

$$D = 1 - \frac{V_{in}}{V_{out}}, \tag{9.4d}$$

$$\begin{aligned} I_{out(min)} &= \frac{T}{2L}\left(\frac{V_{in}}{V_{out}}\right)^2 (V_{out}-V_{in}), \\ &= \frac{T}{2L}V_{out}D(1-D)^2, \end{aligned} \tag{9.4e}$$

$$\Delta I_{C(out)} = \frac{I_{out}}{1-D}, \tag{9.4f}$$

$$I_{L(pk)} = \frac{I_{out}}{1-D} + \frac{T}{2L}V_{in}D, \tag{9.4g}$$

$$L_{min} = \frac{T}{2I_{out}}\left(\frac{V_{in}}{V_{out}}\right)^2 (V_{out}-V_{in}). \tag{9.4h}$$

The first equation holds regardless of mode (CCM or DCM). The expressions for minimum inductance and minimum output current represent the critical values to maintain CCM; for these expressions use the maximum value of V_{in} and (for L_{min}) the minimum output current.

Exercise 9.11. Continuing the challenge: derive these equations. *Hint*: for $I_{out(min)}$ and L_{min} use the fact that, at the threshold of CCM, the input current I_{in} equals half the peak-to-peak inductor current variation ΔI_L, as easily seen from the I_L waveform in Figure 9.67.

Exercise 9.12. Why can't the step-up circuit be used as a step-down regulator?

The design procedures for step-up (and inverting) converters are analogous to those for the buck converter, and so we will resist the temptation to display actual circuit examples.

9.6.7 Inverting converter

The inverting circuit (also known as an "inverting buck–boost," or "negative buck–boost") was shown in Figure 9.61C (repeated here as 9.68). During switch conduction, a linearly increasing current flows from the input into the inductor (point *Z*) to ground. To maintain the current when the switch is open, the inductor pulls point *Z* negative, as much as needed to maintain continuous current flow. Now, however, that current is flowing into the inductor from the filter capacitor (and load). The output is thus negative, and its average value can be larger or smaller in magnitude than the input (as determined by feedback); in other words, the inverting regulator can be either step-up or step-down.

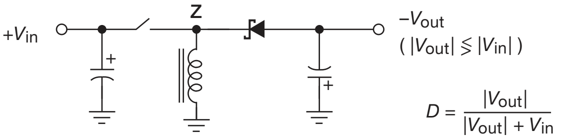

Figure 9.68. Basic inverting (or "inverting buck-boost") topology (non-isolated).

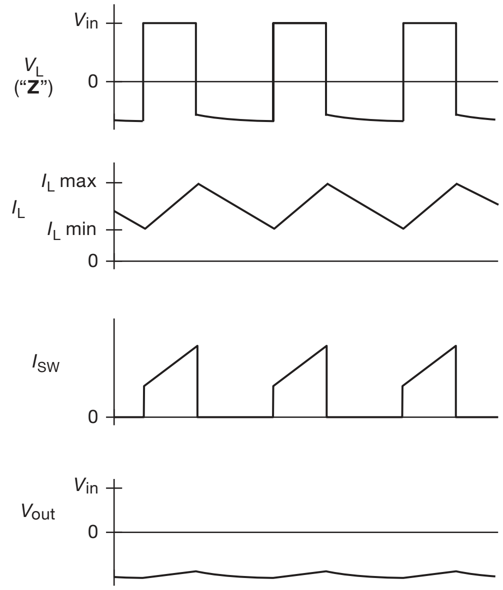

Figure 9.69. Inverting converter operation. Inductor current ramps up during switch ON, and ramps down during switch OFF. The output voltage is inverted in polarity, with a magnitude equal to the input voltage times the ratio of switch $t_{\text{on}}/t_{\text{off}}$ (for CCM, as shown here).

A. Inverting converter equations (continuous-conduction mode)

Figure 9.69 shows the relevant voltage and current waveforms of the inverting regulator, once again assuming ideal components. With more than a bit of struggle you can figure out that the inverting converter (Figure 9.61C), operating in continuous-conduction mode, obeys these equations:

$$\langle I_{\text{in}}\rangle = I_{\text{out}}\frac{V_{\text{out}}}{V_{\text{in}}} = -I_{\text{out}}\frac{D}{1-D}, \qquad (9.5a)$$

$$\Delta I_{\text{in}} = \frac{\langle I_{\text{in}}\rangle}{D}, \qquad (9.5b)$$

$$V_{\text{out}} = -V_{\text{in}}\frac{t_{\text{on}}}{t_{\text{off}}} = -V_{\text{in}}\frac{D}{1-D}, \qquad (9.5c)$$

$$D = \frac{|V_{\text{out}}|}{|V_{\text{out}}|+V_{\text{in}}}, \qquad (9.5d)$$

$$I_{\text{out(min)}} = \frac{T}{2L}V_{\text{out}}\left(\frac{V_{\text{in}}}{V_{\text{in}}+|V_{\text{out}}|}\right)^2$$

$$= \frac{T}{2L}V_{\text{out}}\,(1-D)^2, \qquad (9.5e)$$

$$\Delta I_{\text{C(out)}} = \frac{I_{\text{out}}}{1-D}, \qquad (9.5f)$$

$$I_{\text{L(pk)}} = \frac{I_{\text{out}}}{1-D} + \frac{T}{2L}V_{\text{in}}D, \qquad (9.5g)$$

$$L_{\text{min}} = \frac{T}{2}\frac{V_{\text{out}}}{I_{\text{out}}}\left(\frac{V_{\text{in}}}{V_{\text{in}}+|V_{\text{out}}|}\right)^2. \qquad (9.5h)$$

As with the buck and boost converters, the first equation holds regardless of mode (CCM or DCM). The expressions for minimum inductance and minimum output current represent the critical values to maintain CCM; for these expressions use the maximum value of V_{in} and (for L_{min}) the minimum output current. In these equations we've used the absolute value symbol ($|V_{\text{out}}|$) in the two places where the reader, unmindful of the opposite polarity of input and output voltage, could go seriously off the rails.[80]

Exercise 9.13. The final (and trickiest[81]) challenge: derive these equations. *Hint*: for $I_{\text{out(min)}}$ and L_{min} use the fact that, at the threshold of CCM, the average inductor current $\langle I_{\text{L}}\rangle$ equals half

[80] Readers who feel insulted by such lack of trust should replace "$+|V_{\text{out}}|$" with "$-V_{\text{out}}$." They can argue, with some justification, that their signed equation correctly describes also an inverting converter that produces a positive output from a negative input rail.

[81] Dare we confess? It flummoxed more than a few of us before we got it right.

the peak-to-peak inductor current variation ΔI_L. Now figure out how $\langle I_L \rangle$ is related to I_{in} (or to I_{out}), and take it from there.

9.6.8 Comments on the non-isolated converters

This is a good place to pause, before moving on to the transformer-isolated switching converters, to discuss and review some issues common to these converters.

A. Large-voltage ratios

The ratio of output to input voltage in the basic non-isolated converters depends on the duty cycle ($D = t_{on}/T$), as given in the formulas above. For modest ratios that works fine. But to generate a large ratio, for example a buck converter converting a +48 V input to a +1.5 V output, you wind up with undesirably short pulse widths (hence greater transistor stress, in the form of high peak voltages and currents, and lower efficiency). A better solution is to take advantage of a transformer, whose turns ratio provides an additional voltage transformation. We'll see soon how this is done, in the analogous isolated converter topologies (buck converter → forward converter; inverting converter → flyback converter).

B. Current discontinuity and ripple

The three basic converters behave quite differently in terms of input- and output-current pulsation. In particular, assuming the preferred continuous-conduction mode, the buck converter has continuous current being supplied to the output storage capacitor, but pulsed input current from the $+V_{in}$ supply; the boost converter has pulsed output current, but continuous input current; and the inverting converter has pulsed current at both input and output. Pulsed (discontinuous) currents are generally undesirable at high power levels because they require larger-value storage capacitors, with lower ESR/ESL, for comparable performance. There are some interesting converter topologies (discussed presently, §9.6.8H) that address these problems; in particular, the Ćuk converter (Figure 9.70) boasts continuity of current at both input and output.

C. Regulation: voltage mode and current mode

We've talked little about the details of feedback and voltage regulation in switchmode converters, though the examples above illustrate two approaches: the simple bang–bang pulse-skipping scheme of the MC34063-style regulator (Figure 9.64); and the more commonly used proportional PWM scheme implemented in Figure 9.65. In fact, PWM control can be done in two ways, known as *voltage mode* and *current mode*: in voltage-mode PWM, the error signal is compared with the internal oscillator's sawtooth (or triangular) waveform to set the switch-ON duration. By contrast, in current-mode PWM the switch's current, ramping according to $V = LdI/dt$, replaces the sawtooth, and is compared with the error signal to terminate the switch's ON state, as shown below in Figure 9.71. We'll go into a bit more detail in §9.6.9.

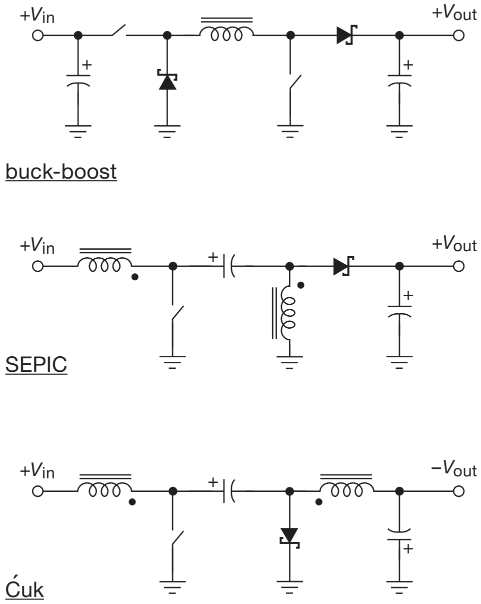

Figure 9.70. Converters allowing overlap of input and output voltage range. Both switches are operated together in the buck–boost (or "non-inverting buck–boost") configuration (A). The SEPIC (B) and Ćuk (C) configurations each use a single switch, but two (optionally coupled) inductors. The Ćuk "boost–buck" is inverting.

D. Low-noise switchers

Switchers are noisy! Figure 9.53, which compared linear and switching 5 V power converters, shows several characteristics of this undesirable "feature": first, there is plenty of noise at the switching frequency, which typically falls in the 20 kHz–1 MHz range; second, the switching frequency may vary,[82] causing interference over a range of frequencies; and, third, (and most distressingly) the switching signals can be nearly impossible to eliminate, propagating both as radiated signals and through ground currents.

[82] This is often done intentionally, in order to meet regulatory standards on interference (EMI) by "spreading" the emitted switching signals over a range of frequencies (see Figures 9.53 and 9.54). Although there is some rationale for resorting to this measure when other options are exhausted, we're not wild about this practice, which paradoxically encourages sloppy design that emits *more* total radiated power. As NASA engineer Eric Berger remarked, "When I first heard about this practice, I was appalled. The radiated energy is not reduced, just the peaks in the frequency domain are. This is like getting rid of a cow pie by stomping on it."

Figure 9.53 illustrates this latter point well: the switching noise can be heavily bypassed *at one point*, as in Figure 9.53B; but just put your 'scope probe a few inches away (Figure 9.53C and D) and *they're back!*

This problem is widely recognized, and there are various approaches to cleaning up switcher noise. At a simple level, a low-dropout regulator at the output helps considerably, as does a simple *LC* output filter. A more sophisticated approach is to use converter topologies that avoid current pulsations at the input and output (for example the Ćuk converter, §9.6.8H), or that exploit the resonant properties of inductance and capacitance so that the switches are brought into conduction at moments when the voltage across them is near zero ("zero-voltage switching," ZVS), and are opened when the current is near zero ("zero-current switching," ZCS). Finally, some converters (typified by the LT1533, LT1534, LT1738, and LT3439) incorporate circuitry to limit the switching transistor's voltage and current slew rates, which reduces both radiated and ground-conducted switching noise.

When thinking about switching converter noise, keep in mind that it emerges in multiple ways, namely:
(a) ripple impressed *across* the dc output terminals, at the switching frequency, typically of the order of 10–100 mV peak-to-peak;
(b) *common-mode* ripple on the dc output (which you can think of as ground-line ripple current), which causes the kind of mischief seen in Figure 9.53C;
(c) ripple, again at the switching frequency, impressed onto the *input* supply;
(d) *radiated* noise, at the switching frequency and its harmonics, from switched currents in the inductors and leads.

You can get into plenty of trouble with switching supplies in a circuit that has low-level signals (say 100 μV or less). Although an aggressive job of shielding and filtering may solve such problems, you're probably better off with linear regulators from the outset.

E. Inductance tradeoffs

There's some flexibility in the choice of inductance. Usually you want to run PWM converters (but not bang–bang converters like the MC34063 in our first example) in continuous-conduction mode, which sets a minimum inductance for a given switching frequency and value of minimum load current. A larger inductor lowers the minimum load current, reduces the ripple current for a given load current, and improves the efficiency; but a larger inductor also reduces the maximum load current, degrades the transient response,[83] and adds physical size to the converter. It's a tradeoff.

F. Feedback stability

Switching converters require considerably more care in the design of the frequency-compensation network than, say, an op-amp circuit. At least three factors contribute to this: the output *LC* network produces a "2-pole" lagging phase shift (ultimately reaching 180°), which requires a compensating "zero"; the load's characteristics (additional bypass capacitance, nonlinearities, etc.) affect the loop characteristics; and the converter's gain and phase versus frequency characteristics change abruptly if the converter enters discontinuous-conduction mode. And, to add a bit more complexity into an already-complex situation, there are important differences between voltage-mode and current-mode converters: for example, the latter, which are better behaved in terms of *LC*-network phase shifts, exhibit a "subharmonic instability" when operated at switch duty cycles greater than 50% (this is addressed by a technique called *slope compensation*).

The easiest approach for the casual user is to choose converters with built-in compensation (for example, the Simple Switcher series, as in Figure 9.65), or converters that provide complete recipes for reliable external compensation. Regardless, the circuit designer (you!) should be sure to *test* the stuff you've designed.[84]

G. Soft start

When input voltage is initially applied to any voltage-regulator circuit, feedback will attempt to bring the output to the target voltage. In the case of a switching converter, the effect is to command maximum duty cycle from the switch, cycle after cycle. This generates a large inrush current (from charging the output capacitor), but, worse, it can cause the output voltage to overshoot, with potentially damaging effects on the load. Worse still, the magnetic core of the inductor (or transformer) may saturate (reaching maximum flux density), whereupon the inductance drops precipitously, causing the switch current to spike. Core saturation is a major cause of component failure; you don't want it.

These problems are most severe in converters that run

[83] Transient speed is a major reason to use low inductance values in switching converters that power microprocessors, where you see the concept of *critical inductance*, i.e., an inductance small enough to handle the load step transients.

[84] When testing for stability, don't forget about the negative-resistance input characteristic of switching converters; be sure to test with whatever input filters you plan to use.

from the ac powerline, where the transformerless input stage (diode bridge and storage capacitor) causes additional inrush current, and where that input power source can deliver plenty of peak current. Many switching controller chips therefore incorporate "soft-start" circuitry, which constrains the switch duty cycle to ramp up gradually upon initial startup; these are indicated in the "soft start" column of Tables 9.5a,b and 9.6.

H. Buck–boost topologies

For the buck converter, V_{out} must be less than V_{in}, and for the boost converter V_{out} must be greater than V_{in}, required in both cases to reset the inductor current. Sometimes you'd like a converter that permits the input voltage to vary around both sides of the output voltage (for example in a battery-operated device with 2.5 V digital logic, powered by two AA cells, which begins life with 3 V input, and ends at about 1.8 V; or an automotive application, powered from a 12 V car battery, supplying 13.8 V running, but as little as 8 V starting and as much as 40 V in "load dump").

Although the inverting (buck–boost) converter (Figure 9.61C) allows the output voltage to be larger or smaller than the input, its polarity is reversed. Figure 9.70 shows three interesting configurations that allow overlap of the input- and output-voltage ranges. The first one is particularly easy to understand: both switches are operated simultaneously for a time t_{on}, applying V_{in} across the inductor; during t_{off} the inductor's current flows through the diode pair to the output. The output voltage, from the inductor's required volt–time equality (and ignoring voltage drops in the switch and diodes), is then simply $V_{\text{out}} = (t_{\text{on}}/t_{\text{off}})V_{\text{in}}$. Typical examples of buck–boost converter ICs are the LTC3534 (internal MOSFET switches) and the LTC3789 (external MOSFET switches); both use synchronous MOSFET switches in place of Schottky diodes, i.e., four MOSFETs in all. For other converters with synchronous switching see the "synchronous" column in Tables 9.5a,b on pages 653 and 654 and 9.6 on page 658.

The SEPIC (single-ended primary-inductance converter) and Ćuk[85] converters have the advantage of requiring only a single controllable switch. And the Ćuk converter has the remarkable property of producing *zero* output ripple current when the inductors are coupled (wound on the same core). This latter property was discovered accidentally, but is now part of the vocabulary of switchmode practitioners, who call it "the zero-ripple phenomenon." And while we're praising the Ćuk, it's worth noting that both input- and output-current waveforms are continuous, unlike the buck, boost, inverting, SEPIC, or buck–boost.

9.6.9 Voltage mode and current mode

There are two approaches to implementing pulse-width modulation, as we mentioned earlier in §9.6.8C; look at Figure 9.71.

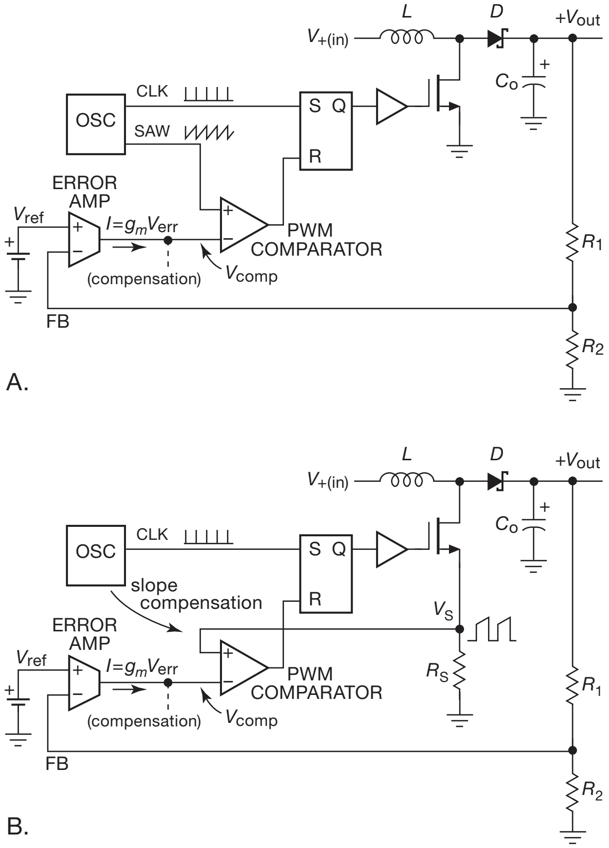

Figure 9.71. Pulse-width modulation in switchmode regulators. (A) Voltage-mode PWM compares the integrated error signal ($V_{\text{err}}=V_{\text{ref}}-\text{FB}$) with the oscillator's sawtooth whereas (B) current-mode PWM substitutes the switch's ramping current waveform.

At the top level, both methods compare the output voltage with an internal voltage reference to generate an error signal. That is, both methods are *voltage* regulators (don't confuse "current mode" with current *regulator*). The difference is in the way the error signal is used to adjust the pulse width: in *voltage-mode* PWM, the error signal is compared with the internal oscillator's sawtooth waveform to control the switch's ON duration.[86] In *current-mode* PWM, by

[85] Invented by Slobodan Ćuk (pronounced "chook") in 1976.

[86] Typically by using a *pulse* output from the oscillator to start the conduction cycle, and the output of the PWM comparator (which compares the error signal with the same oscillator's sawtooth) to end the conduction cycle, as shown in Figures 9.71A and 9.72.

contrast, the ramping current in the inductor replaces the sawtooth, with the internal oscillator used to *initiate* each conduction cycle[87] (Figures 9.71B and 9.72). Tables 9.5a,b and 9.6 indicate whether the SMPS IC employs a voltage-mode or current-mode control loop.

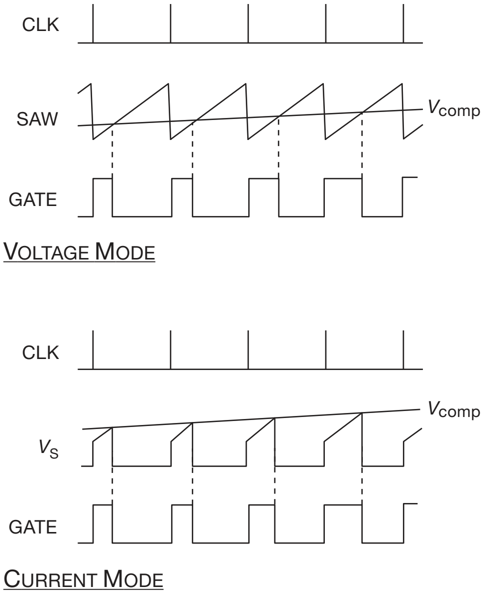

Figure 9.72. Waveforms in voltage-mode and current-mode PWM.

How to choose? Before comparing their relative merits, we offer this sensible advice: select the switching regulator chip that has the features you want (in terms of voltage and current ratings, ease of design, price and availability, component count, etc.), and don't worry about how the chip designers did their job.

Now for the comparison.

A. Voltage mode

This has been the traditional form of PWM. Its advantages include
(a) the simplicity of analyzing a single feedback path,
(b) low output impedance from the power stage, and
(c) good noise margins (because of the internally generated ramp).

Its disadvantages include
(a) the need for careful loop compensation (because of the 2-pole *LC* output filter),[88]
(b) slow loop response (especially in response to input changes), and
(c) the need for separate current-limiting circuitry for the switch transistor(s).

B. Current mode

Current-mode control became popular beginning in the 1980s when its benefits became apparent. They include
(a) rapid response to input changes,
(b) inherent pulse-by-pulse current limiting of the switch current,
(c) improved phase margin in the outer voltage-feedback loop (because the power stage's output, being current-like, effectively removes the inductor's phase shift; i.e., one pole instead of two in the feedback loop), and
(d) the ability to parallel the outputs of several identical converters.

The disadvantages of current-mode control include
(a) the greater difficulty of analyzing two nested feedback loops (mitigated by widely separating their characteristic frequencies),
(b) intrinsically higher output impedance of the power stage (the output is more affected by load changes because the fast loop tends toward a constant-current output),
(c) susceptibility to noise, particularly at low load, and to resonances (because the PWM depends on the current-derived ramp),
(d) premature termination of switch's ON-state caused by the leading-edge current spike (from parasitic capacitances and diode recovery effects), and
(e) instabilities and subharmonic resonances at high duty cycle.

Clever fixes Circuit designers are clever, and they've figured out some nice tricks to address the problems of each method. The slow response of voltage-mode controllers to input changes can be fixed by adding an input feedforward signal to the sawtooth ramp, and the slow loop response can be alleviated by running at a higher switching frequency. For current-mode control the bag of tricks includes leading-edge blanking (to ignore the switch-ON current spike), and "slope compensation" (to restore stability at high duty cycle).

Choice of control mode: both are viable In contemporary practice both modes are viable, and plenty of controller ICs are available using either technique. As a general statement, voltage-mode converters are favored
(a) in noisy applications, or in applications with light load

[87] And to generate the "slope-compensation" ramp signal.

[88] As the LT3435 datasheet succinctly puts it, "A voltage fed system will have low phase shift up to the resonant frequency of the inductor and output capacitor, then an abrupt 180° shift will occur. The current fed system will have 90° phase shift at a much lower frequency, but will not have the additional 90° shift until well beyond the *LC* resonant frequency. This makes it much easier to frequency compensate the feedback loop and also gives much quicker transient response."

Notes: (a) all have integrated power switch(es), current-sensing, and (in some cases) loop compensation; listed in order of increasing switch current. (b) number of fixed voltages available; all except NCP1400A have adjustable versions. (c) H=hysteretic mode; P=PWM fixed frequency; T=min t_{off}, max t_{on}; V2=ONsemi "V^2" control. (d) adjustable current limit. (e) B=BJT; M=MOSFET. (f) see LMZ23608 for V_{in} to 36V. (g) typical number of external parts (not counting bypass caps); two numbers indicate fixed/adjustable. (h) 60V for HV suffix. (m) adjustable current limit. (n) no adjustable version. (o) restart threshold. (p) CS51411 for 260kHz. (q) reduced freq or pulse skipping at low load. (s) parts with SHDN can have UVLO added with an ext circuit. (t) typical. (u) plus I_{sw}/50, etc., when the switch is ON (a power-dissipation issue if used with high V_{supply}). (v) plus BJT switch drive current, on BOOST pin, taken from low-voltage buck output. (x) runs down to 0.9 volts. (y) runs down to 0.3 volts. (z) runs down to 0.5 volts.

Comments: 1: pin compatible with LTC1375. **2:** many second sources. **3:** NCP3126 and 3127 for lower current. **4:** negative V_{out} to –35V (see datasheet); V_{in} comp; LT1076 for 2A. **5:** featured in text. **6:** NCP1402 for 200mA. **7:** 96% effy, low-batty comp. **8:** single-cell stepup.

conditions, or

(b) where multiple outputs are derived from a common power stage (that is, in converters that use a transformer with multiple secondary windings).

Current-mode controllers are favored

(a) where fast response to input transients and ripple is important,

(b) where it is desirable to parallel multiple power supplies (e.g., for redundancy),

(c) where you want to avoid the complexities in designing a proper pole-zero loop compensation network, and

(d) in applications where fast pulse-by-pulse current limiting is important for reliability.[89] Tables 9.5a and 9.5b list selected "integrated" switching regulators, i.e., with *internal* power switch(es). See also Table 9.6 on page 658 for switching regulators that drive external MOSFETS, Table 3.4 (MOSFETS, page 188), and Table 3.8 (drivers, page 218).

9.6.10 Converters with transformers: the basic designs

The non-isolated switching converters of the previous sections can be modified to incorporate a transformer within

[89] Evidently SMPS integrated circuit designers (and presumably their larger customers) prefer current-mode control over voltage-mode, as reflected in the shortened length of Table 9.5a compared with Table 9.5b, and by the paucity of voltage-mode controllers in the "control mode" column of Table 9.6.

Notes: (a) listed by increasing switch current; all have integrated switch, current-sensing, and in some cases loop compensation; all have shutdown capability except LM2577; all have thermal shutdown. (b) no power shutdown function; also UC2577. (c) H=hysteretic curr mode; M=Fixed peak current, with a minimum off time; O=var freq fixed off time; P=PWM fixed freq. (d) non-isolated boost higher voltages with a transformer. (e) with external parts. (f) suffix HV for 18V version. (g) typical number of external parts (not counting bypass caps); two numbers indicates fixed/adjustable. (h) suffix HV for 60V version. (k) 5A for LM2587. (m) maximum. (n) also negative, –2.5V. (o) restart threshold. (p) reduced freq or pulse skipping at low load. (r) reduced frequency during low V_{out}. (s) parts with SHDN can have UVLO added with an external circuit. (t) typical. (u) plus $I_{SW}/50$, etc., when the switch is ON (a power-dissipation issue if used with high V_{supply}). (v) plus BJT switch drive current, on BOOST pin, taken from low-voltage buck output. (w) low side. (x) transformer output.

Comments: **1:** invert OK, especially +5V to –5V converter. **2:** 60V transients OK. **3:** 60V OK for 100ms; 3.3V, 5V, and adj versions. **4:** ADP2301 for 1.4MHz. **5:** just add external inductor; 11 fixed voltages, from 1.0V to 3.3V. **6:** 5V and ADJ, see LT1507 for 3.3V. **7:** "simple switcher" nano. **8:** buck plus LDO, ext sync to 2.5MHz. **9:** power-good output; 500kHz for "A" version. **10:** adj OFF time. **11:** 100μA no-load I_Q. **12:** 80μA no-load I_Q; transients OK to 60V. **13:** boost single-cell to 1.8V–5.5V out; 3.3V, 5V, and adj versions. **14:** good for LED constant current drive. **15:** single-cell boost or flyback. **16:** "simple switcher" nano. **17:** boost from single Li-ion cell. **18:** operates down to 0.5V input; 40μA in burst mode. **19:** can regulate output using transformer's primary voltage (no feedback resistors required). **20:** low-noise, slew-rate control. **21:** 12V, 15V, and ADJ versions. **22:** 3.3V, 5V, 12V, and ADJ versions. **23:** programmable slew rate, very quiet.

the switching circuitry. This serves three important purposes: (a) it provides galvanic isolation, which is essential for converters that are powered from the ac line; (b) even if isolation is not needed, the transformer's turns ratio gives you an intrinsic voltage conversion, so that you can produce large step-up or step-down ratios while staying in a favorable range of switching duty cycle; and (c) you can wind multiple secondaries, to produce multiple output voltages; that's how those ubiquitous power supplies in computers generate outputs of +3.3 V, +5 V, +12 V, and −12 V, all at the same time.

Note that these are not the heavy and ugly laminated-core transformers that you use for the 60 Hz ac powerline: because they run at switching frequencies of hundreds to thousands of kilohertz, they do not require a large magnetizing inductance (the inductance of a winding, with all other windings open-circuited), and so they can be wound on small ferrite (or iron powder) cores. Another way to understand the small physical size of the energy-storage devices in switchmode converters – that is, the inductors, transformers, and capacitors – is this: for a given power output, the amount of energy passing through these devices in each transfer can be much less if those transfers are taking place at a much higher rate. And less stored energy ($\frac{1}{2}LI^2$, $\frac{1}{2}CV^2$) means a smaller physical package.[90]

9.6.11 The flyback converter

The *flyback* converter (Figure 9.73A) is the analog of the inverting non-isolated converter. As with the previous non-isolated converters, the switch is cycled at some switching frequency f (period $T = 1/f$), with feedback (not shown) controlling the duty cycle $D = t_{\text{on}}/T$ to maintain regulated output voltage. As with the previous converters, the pulse-width modulation can be arranged as voltage mode or current mode; and the secondary current can be either discontinuous (DCM) or continuous (CCM) from each cycle to the next, depending on load current.

What is new is the transformer, which in the flyback converter topology acts simply as an inductor with a tightly coupled secondary winding. During the switch-ON portion of the cycle, the current in the primary winding ramps up according to $V_{\text{in}} = L_{\text{pri}}\, dI_{\text{pri}}/dt$, flowing into the "dotted" terminal; during that time the output diode is reverse biased because of the positive voltage on the dotted terminals of both windings.

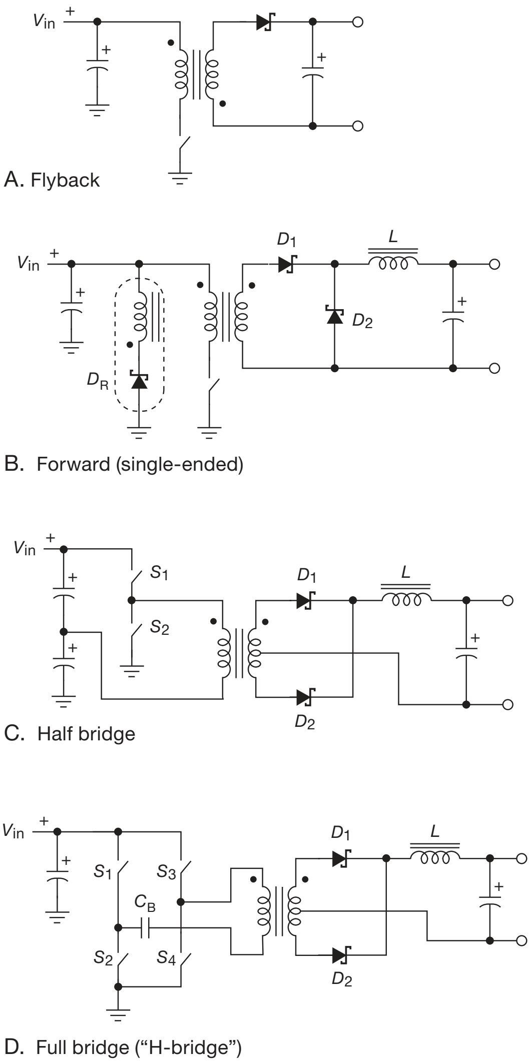

Figure 9.73. Isolated switching converters. The flyback converter (A) uses an energy-storage inductor with a secondary winding, whereas the forward and bridge converters (B–D) each use a true transformer with no energy storage (and thus require an output energy-storage inductor). The diode D_{R} and tertiary winding in the forward converter is one of several ways to reset the core in this single-ended design. The dc blocking capacitor C_{B} in the H-bridge prevents flux imbalance and consequent core saturation; for the half-bridge the series pair of capacitors serves the same function, while acting also as the input storage capacitor.

During this phase the input energy is going entirely into the magnetic field of the transformer's core. It gets its chance to go somewhere else when the switch turns OFF: unlike the situation with a single inductor, with *coupled* inductors the requirement of continuity of inductor current

[90] For the particular case of the flyback converter, discussed next, you can think of the transformer as formed by a second winding on the already-small inductor used for energy storage in the non-isolated inverting (buck–boost) converter.

is satisfied if the current continues to flow in *any* of the windings. In this case the switch-ON current, flowing into the dotted terminal, transfers itself to a similarly directed current in the secondary, but multiplied by the turns ratio $N \equiv N_{\text{pri}}/N_{\text{sec}}$. That current flows to the output (and storage capacitor), ramping down according to $V_{\text{out}} = L_{\text{sec}}\, dI_{\text{sec}}/dt$. From equality of inductor volt-seconds, the output voltage is simply

$$V_{\text{out}} = V_{\text{in}} \frac{N_{\text{sec}}}{N_{\text{pri}}} \frac{t_{\text{on}}}{t_{\text{off}}} = V_{\text{in}} \frac{N_{\text{sec}}}{N_{\text{pri}}} \frac{D}{1-D} \quad \text{(in CCM)}. \qquad (9.6)$$

And, as usual, efficiency is high, so power is (approximately) conserved:

$$I_{\text{in}} = I_{\text{out}} \frac{V_{\text{out}}}{V_{\text{in}}}. \qquad (9.7)$$

You can wind additional secondaries, each with its diode and storage capacitor, to create multiple output voltages (as set by the turns ratios). And, because the output windings are isolated, you can as easily generate negative outputs. Having chosen one of the outputs for regulating feedback, however, the others will not be as tightly regulated. The term "cross regulation" is used to specify the output-voltage dependencies.

A. Comments on flyback converters

Power level Flyback converters have full pulsations of input and output current. For this reason they are generally used for low- to medium-power applications (up to ~200 W). For higher power you usually see designs using the *forward* converter, or, for really high power, *bridge* converters.

The transformer is an inductor The input energy each cycle is first stored in the transformer core (during switch-ON), then transferred to the output (during the switch-OFF). So the transformer design must provide the correct "magnetizing inductance" (acting as an inductor), as well as the correct turns ratio (acting as a transformer). This is quite different from the situation with the forward converter and the bridge converters, below, where the transformer is "just a transformer." We won't go into further detail about transformer design here, simply noting that the design of the "magnetics" is an important part of switching converter designs in general, and flybacks in particular. You have to worry about issues such as core cross-section, permeability, saturation, and deliberate "gapping" (in general, energy-storage inductors are gapped, whereas pure transformers are not). Extremely helpful resources for design are found in IC datasheets and design software (usually available at no charge from the manufacturer) that provide specifics about the choice of magnetics. We explore this important topic further in §*9x.4*.

Snubbers With ideal components, the primary current would transfer completely to the secondary when the switch turns OFF, and you wouldn't have to worry about bad things happening on the dangling drain terminal of the switch. In reality the incomplete coupling between primary and secondary creates a series "leakage inductance," whose craving for current continuity generates a positive voltage spike at the switch, even though the secondary is clamped by the load. This is not good. The usual cure is to include a *snubber network*, consisting of an *RC* across the winding, or, better, a "*DRC*" network of a diode in series with a parallel *RC*.[91]

Regulation Flyback converters can be regulated with conventional PWM, either voltage mode or current mode, with a free-running oscillator calling the shots. Alternatively, you will see inexpensive designs in which the transformer itself becomes part of a *blocking oscillator*, thereby saving a few components. We cracked open some samples of low-power (5–15 W) "wall warts" and found, well, just about *nothing* inside! We reverse engineered them to look at the circuit tricks (Figure 9.74). They seem to work just fine.

Off-line converters This final circuit (Figure 9.74) is an example of a power converter that *requires* galvanic isolation. The transformer provides isolation for the power flow; in addition, the feedback signal from the dc output must be isolated as well on its way back to the primary side. This can be done with an optocoupler, as here, or with an additional small pulse transformer. We discuss these offline converters briefly in §9.7, and in Chapter *9x* we discuss high-efficiency ("green") power supplies, including a graph comparing the performance of this 5 W supply (whose standby power is 200 mW) with others.

9.6.12 Forward converters

The *single-ended forward converter* (Figure 9.73B) is the transformer-isolated version of the buck converter. It is helpful to refer back to the basic buck circuit (Figure 9.61A), to see how it goes. The transformer converts

[91] Leakage inductance values are typically ~1% of the magnetizing inductance. You can reduce leakage inductance greatly by splitting one of the windings (say primary) into two, with the other (secondary) sandwiched in between. And *bifilar* windings (wind primary and secondary as a pair of wires together) can reduce the leakage inductance to a low value. However these techniques increase inter-winding capacitance, and bifilar windings suffer from poor voltage insulation ratings.

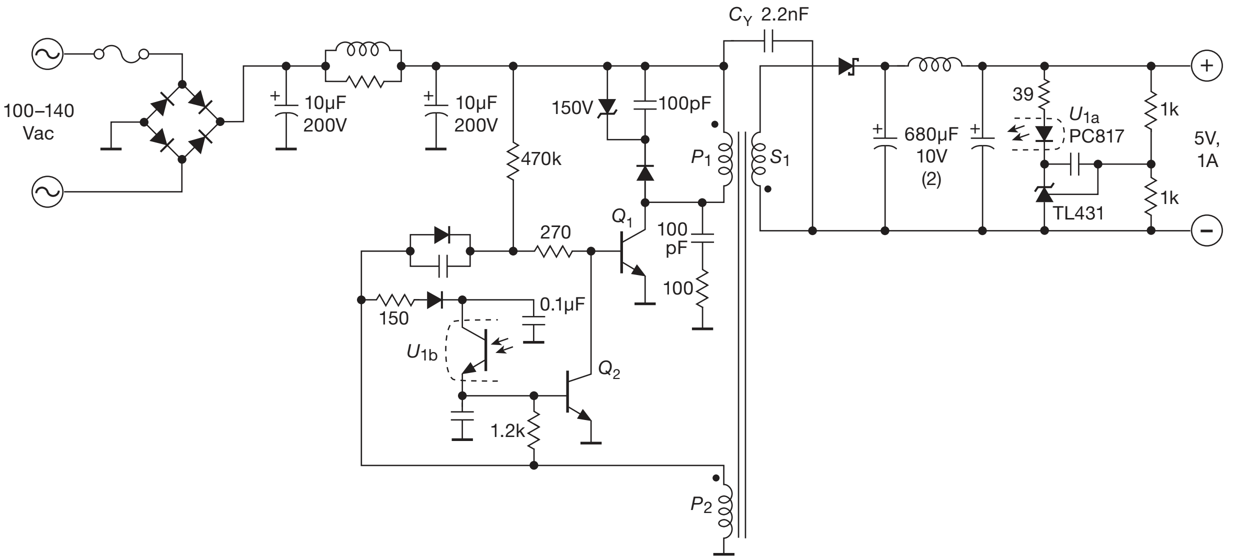

Figure 9.74. An inexpensive 5 W flyback converter, powered from 115 Vac line voltage, that uses a self-excited "blocking oscillator." Winding P2 provides positive feedback to sustain oscillation. The output voltage is sensed and compared with the TL431 shunt regulator, fed back via the optocoupler U_1 to adjust the conduction cycle.

input voltage V_{in}, during primary switch conduction, to a secondary voltage $(N_{\text{sec}}/N_{\text{pri}})V_{\text{in}}$. That transformed voltage pulse drives a buck converter circuit, consisting of catch diode D_2, inductor L, and output storage capacitor. The extra diode D_1 is needed to prevent reverse current into the secondary when the switch is OFF. Note that here, in contrast to the flyback converter, the transformer is "just a transformer": inductor L provides the energy storage, as with the basic buck circuit. The transformer does not need to store energy, because the secondary circuit conducts at the same time as the primary (energy goes "forward"), as you can see from the polarity marking.

Analogous to the buck converter, (eq'ns 9.3a–9.3h), the output voltage is simply

$$V_{\text{out}} = V_{\text{in}} \frac{N_{\text{sec}}}{N_{\text{pri}}} \frac{t_{\text{on}}}{T} = D \frac{N_{\text{sec}}}{N_{\text{pri}}} V_{\text{in}} \quad \text{(in CCM).} \qquad (9.8)$$

Resetting the core In contrast to the flyback circuit, there's an additional winding in Figure 9.73B, which is needed to *reset* the transformer's core.[92] That is because the volt-second product[93] applied to the transformer must average zero (i.e., no average dc input) in order to prevent a continual buildup of magnetic field; but the input switch alone always applies voltage in one direction only. The tertiary winding fixes this by applying voltage in the opposite direction during the switch-OFF portion of the cycle (when diode D_R conducts, from continuity of current in the winding as the magnetic field collapses).[94]

Additional comments (a) As with the flyback, and indeed with any transformer-coupled converter, the forward converter allows multiple independent secondaries, each with its inductor, storage capacitor, and pair of diodes. Regulating feedback then holds one output particularly stable. (b) The transformer isolates the output in a forward converter, if you happen to need isolation (as in a powerline-input converter); in that case you must galvanically isolate the feedback signal as well, typically with an optocoupler (as in the block diagram of Figure 9.48, or the detailed diagrams of Figures 9.74 and 9.83). On the other hand, if you do not need isolation you can have a common ground reference, and bring the error signal back to the PWM control circuit directly.

[92] Reset is inherent in the flyback, but not in the single-ended forward converter, as will become evident.

[93] Sometimes call "volt-time integral."

[94] There are clever circuits that reset the core without requiring a tertiary winding: one method uses a pair of primary switches, one at each end of the winding, in collaboration with a pair of diodes, to reverse the voltage across the single primary (see if you can invent the circuit!). Another method uses instead a second switch to connect a small capacitor across the primary during main switch-OFF; this clever method is known as "active clamp reset," and was devised independently by Carsten, Polykarpov, and Vinciarelli. It has the virtue of *reversing* the magnetic field in the transformer core, providing better performance by allowing double the normal flux excursion.

Notes: (a) all require external power switches (see listings in **Table 3.4**); all have undervoltage lockout (UVLO) and internal voltage references; listed within groups in approximate order of increasing drive current. (aa) I - current mode, V - voltage mode, P - fixed peak current, M - multiple modes. (b) uncommitted BJT output, sinks 200mA, 40V max. (c) P=PWM fixed freq; Q=quasi-res; R - resonant; V=var freq fixed width; (d) peak driver current, for controllers. (e) ext parts. (ex) lower voltage for x=3 or 5, higher voltage for x=2 or 4. (f) fixed only. (f3) three switching-frequency options. (g) unused footnote. (h) 2V for x=3 or 5. (i) adjustable current limit. (j) 25V zener clamp for V_{CC}. (k) to V_{CC} or voltage shown, whichever is less. (m) maximum. (n) nominal. (o) turn-on threshold. (oo) even with LEB (leading-edge blanking) an *RC* filter or at least a 100pF capacitor is often recommended. (p) ref pin is current-sourcing. (pp) [same note as integrated tables]. (q) reduced freq or pulse skipping at low load. (r) 0.7V for the '11. (s) helps stabilize the control loop against sub-harmonic oscillations. (t) transformer output. (u) a minimum off time (450ns) limits the duty cycle. (v) may not include dynamic gate-charge currents, etc. (w) for V_{out} below 30V, above 30V a current-sense resistor is required. (x) OVP = line over-voltage protection. (y) synchronous possible with low-voltage non-isolated flyback transfomer. (z) finds resonant frequency.

Comments: **1:** LTC1772, LTC3801 second-source. **2:** fixed 5V version available. **3:** automotive. **4:** hi-side sense. **5:** LTC3832 goes down to 0.6V. **6:** single inductor, foldback current limit. **7:** jellybean. **8:** improved UC384x. **9:** UC384x with LEB, SS, low I_Q. **10:** impressive 52V, LED drive. **11:** use with flyback xfmr. **12:** to 1.8V, slope-comp, soft-start, expensive. **13:** to 1MHz, advanced. **14:** HV pin, to 100V for startup. **15:** SOT23, low power, cute. **16:** can boost inputs as low as 1V. **17:** fixed voltage versions only, five choices 1.9V to 5.0V. **18:** quasi-resonant. **19:** inexpensive, ATX power supplies etc. **20:** freq dither. **21:** 25V zener clamp for V_{CC}. **22:** legacy, inexpensive, second sourced. **23:** programmable gap/overlap. **24:** legacy, inexpensive, flexible. **25:** also UC3525 etc. **26:** feed-forward ramp. **27:** resonant, use with FET driver IC. **28:** HV pin, to 500V for startup. **29:** optimized for inverting, V_{out} from –0.4V to –150V or more.

(c) As with all switchmode converters, snubber networks are needed to tame the voltage spikes caused by parasitic inductances (including particularly transformer leakage inductance).
(d) As with other converter types, PWM control can be either voltage mode or current mode. An alternative is to use pulse *frequency* modulation (PFM), with approximately constant pulse width, to take advantage of resonant behavior (thus avoiding "hard switching" by allowing the resonant ringing to charge and discharge parasitic capacitances, and thereby come closer to the ideal of zero-voltage/zero-current switching). (e) Single-ended forward converters are popular in the medium-power range (∼25–250 W).

9.6.13 Bridge converters

The last two transformer-isolated converters in Figure 9.73 are the *half-bridge* and *full-bridge* (H-bridge) converters. As with the single-ended forward converter, the transformer acts simply to effect voltage transformation and isolation; the secondary circuit's inductor does the energy storage, serving the same purpose as it does in the basic buck converter or single-ended forward converter. In fact, you can think of the bridge converters approximately as "double-ended forward converters." In both bridge circuits the capacitor(s) on the input side allow the voltage at the undotted end of the transformer primary to move up or down as needed to achieve zero average dc current, preventing transformer core saturation.

To understand the half-bridge converter, imagine first that switches S_1 and S_2 are operated alternately, with 50% duty cycle and with no gap or overlap. The voltage at the junction of input capacitors will float to half the dc input voltage, so what you've got is a center-tapped full-wave rectifier circuit, driven by a square wave. Power is transferred forward during both halves of each cycle, and the output voltage (ignoring diode drops) is just

$$V_{\text{out}} = V_{\text{in}} \frac{N_{\text{sec}}}{4N_{\text{pri}}}, \qquad (9.9)$$

where the factor of 4 arises from the factor of $\frac{1}{2}$ for the applied input voltage and the same factor from the output center-tap. The operation of the full-bridge converter is similar, but its four switches enable it to apply the full dc input voltage across the primary during each half-cycle, so the 4 is replaced by 2 in the denominator.

Regulation With the switches operating in opposition, at 50% duty cycle, the output voltage is fixed by the turns ratio and the input voltage. To provide regulation you need to operate each switch for less than a half-cycle (Figure 9.75), with a conduction gap ("dead time") whose length is adjusted according to the error signal. You can think of each half-cycle as a forward converter, of duty cycle $D{=}t_{\text{on}}/(t_{\text{on}}{+}t_{\text{off}})$, causing the converter to produce an output voltage (assuming CCM) of

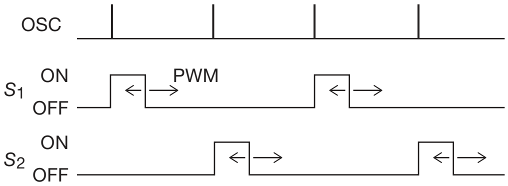

Figure 9.75. Pulse-width modulation in the half-bridge switching converter. The internal oscillator initiates switch conduction on alternate cycles, with feedback providing regulation by ending each switch's conduction according to the error signal.

$$V_{\text{out}} = D\,V_{\text{in}} \frac{N_{\text{sec}}}{4N_{\text{pri}}}. \qquad (9.10)$$

Bridge converters are favored for high-power conversion (∼100 W and above), because they make efficient use of the magnetics by conducting during both halves of each cycle, and they cycle the magnetic flux symmetrically. They also subject the switches to half the voltage stress of a single-ended converter. By adding another pair of switches, you can convert it to a full-bridge (or H-bridge), in which the full dc input voltage is applied across the primary each half-cycle. (See the comments below, however, about flux balance.) The full-bridge configuration additionally allows another form of regulation, called "phase-shift control," in which a 50% duty cycle is maintained in each switch pair, but the relative phase of one pair is shifted relative to the other, to effectively produce a variable duty cycle.[95]

Additional comments (a) As with the single-ended forward converter, it is essential to maintain zero average voltage (or volt-time integral) across the transformer's primary. Otherwise the magnetic flux will grow, reaching destructive saturation. The H-bridge in Figure 9.73D includes a blocking capacitor C_{B} in series with the primary for this purpose; the pair of input capacitors serves the same function for the half-bridge (Figure 9.73C). That capacitor can be quite large, and it has to endure large ripple currents; so it would be nice to eliminate it, for example by connecting the bottom of the winding to a fixed voltage of $V_{\text{in}}/2$ (which is available automatically in an offline voltage-doubling input bridge). That configuration is known as "push-pull."

[95] Some phase-shift controller ICs we like are the UCC3895 from TI and the LTC3722 from Linear Technology.

However, without the blocking capacitor it is easy to violate the flux-balance condition. One solution is the use of current-mode control, in which cycle-by-cycle (or, more accurately, half-cycle by half-cycle) current limiting prevents saturation. In any case, be aware that flux imbalance in bridge converters is really bad news.

(b) In bridge converters the power switches are connected in series across the dc input supply. If there is conduction overlap, large currents can flow from rail to rail; this is known as "shoot-through" current. What you need to know is that you don't want it! In fact, turn-off delays in MOSFETs, and more seriously in BJTs, require that the control signals provide a short time gap to avoid shoot-through.

(c) Once again, snubbers are needed to tame inductive spikes.

(d) Full-bridge converters are favored for high-power converters, to 5 kW or more.

(e) At high load currents the output filter inductor has a continuous current flowing through it. During primary conduction cycles this is, of course, supplied either by D_1 or D_2, by normal transformer action. But what happens during primary *non*-conduction (the gaps in Figure 9.75)? Interestingly, the continuing inductor current flows through *both* D_1 and D_2, forcing the transformer secondary to act like a short-circuit (even though its primary is open), because equal diode currents flow in the same direction out of both ends of the center-tapped winding.

9.7 *Ac-line-powered ("offline") switching converters*

With the exception of Figures 9.48B and 9.74, all the switching converters and regulators we've seen so far are *dc-to-dc* converters. In many situations that's exactly what you want – for battery-operated equipment, or for creating additional voltages within an instrument that has existing dc power.[96]

Apart from battery-powered devices, however, you need to convert incoming powerline ac to the necessary regulated dc voltages. You could, of course, begin with an unregulated low-voltage dc supply of the sort in Figure 9.49, followed by a switching regulator. But the better approach is to eliminate the bulky 60 Hz step-down transformer by running an isolated switching converter directly from the rectified (unregulated) and filtered ac power, as shown earlier in Figure 9.48.[97]

Two immediate comments. (a) The dc input voltage will be approximately 160 volts[98] (for 115 Vac power) – this is a dangerous circuit to tinker with! (b) The absence of a transformer means that the dc input is not isolated from the powerline, so it's essential to use a switching converter with an isolated power stage (forward, flyback, or bridge), and with isolated feedback (via an optocoupler or transformer).

9.7.1 The ac-to-dc input stage

A. Dual-voltage configurations

Figure 9.76 shows two common input-stage configurations. The simple bridge rectifier of Figure 9.76A is perfectly OK

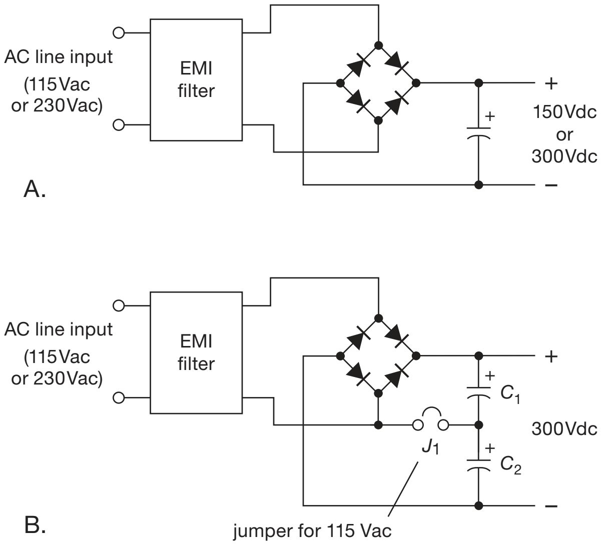

Figure 9.76. Switching power supplies run from the ac powerline (offline converters) use directly rectified dc to power an isolated converter. The jumper in the lower circuit selects bridge or voltage doubler configurations, so that either line voltage produces the same ∼300 V dc output.

[96] A common application is within a computer, where the processor may require something like 1.0 V at 100 A (!). That's a lot of current to be running around a printed circuit board! What is done, instead, is to bring a higher "bus" voltage (usually +12 V) into the vicinity of the processor, where it powers a half-dozen or so 12 V-to-1.0 V buck converters that surround the power-hungry chip and that run in multiple phases to reduce ripple. This is called "point-of-load" power conversion. The benefit, of course, is the lower current in the bus, about 8 A in this example, combined with tight voltage regulation at the load itself.

[97] A story to prove us wrong: we routinely disassemble all sorts of commercial electronic gadgets, just to see how the other half lives. Imagine our surprise, then, when we cracked open a cellphone charger and found. . . a tiny ac power transformer, bridge rectifier, and low-voltage storage capacitor, followed by an MC34063 switching converter! Goes to show you.

[98] And, more commonly, 320 volts; see below.

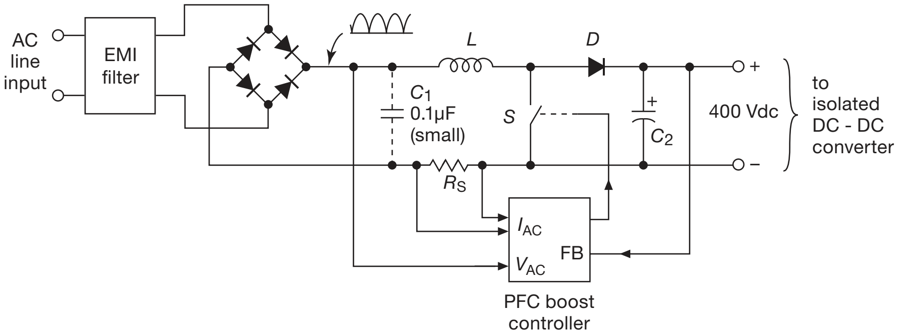

Figure 9.77. The direct rectifier circuits of Figure 9.76 create undesirable current pulses each half-cycle (low power factor). This is remedied with a power factor correction front end, consisting of a boost converter running from the (unfiltered) full-wave rectified line-voltage waveform, controlled by a special PFC chip that operates the switch to maintain the input current approximately proportional to the input voltage.

for devices intended for either 115 Vac or 230 Vac use, in which the switching converter that follows is designed for either ∼150 Vdc or ∼300 Vdc input, respectively. If you need a supply that can be switched to run on either input voltage, use the nice trick shown in Figure 9.76B: it's a simple full-wave bridge for 230 Vac input, but with the jumper connected it becomes a voltage doubler for 115 Vac input, thus generating ∼300 Vdc on either continent. (The other popular approach is to design the switching converter to accommodate a wide dc input range; most low-power chargers for consumer devices like laptop computers and cameras work this way. Check the label, though, before you plug in to 230 Vac power. And don't expect more power-hungry electronic devices to work automatically on "universal" power; they usually have a recessed slide switch that is the jumper in Figure 9.76B.)

B. Inrush current

When you first turn on the power, the ac line sees a large discharged electrolytic filter capacitor across it (through a diode bridge, of course). The resulting "inrush" current can be enormous; even a tiny "wall-wart" can draw 25 A or more of instantaneous current when first plugged in. Commercial switchers use various soft-start tricks to keep the inrush current within civilized bounds. One method is to put a negative-tempco resistor (a low-resistance thermistor) in series with the input; another method is to actively switch out a small (10 Ω) series resistor a fraction of a second after the supply is turned on. The series inductance provided by an input noise filter helps somewhat, as well. But a very nice solution comes in the form of an input power-factor correction circuit, discussed next.

C. Power-factor correction

The pulsed current waveform of rectified ac, as seen for example in Figure 9.51, is undesirable because it produces larger resistive (I^2R) losses compared with the ideal of a sinusoidal current waveform that is in phase with the voltage. (This is why it's easy to make the mistake of choosing too small a fuse rating, as discussed earlier in §9.5.1B.) Another way to say it is that a pulsed current waveform has a low *power factor*, which is defined as the power delivered divided by the product $V_{\rm rms} \times I_{\rm rms}$. Power factor made its first appearance in Chapter 1 in connection with reactive circuits, in which the phase-shifted (but still sinusoidal) current created a power factor equal to the cosine of the phase difference between the ac voltage and current. Here the problem is not phase, it's the high rms/average ratio of the pulsed-current magnitudes.

The solution is to make the power supply's input look like a passive resistor, by devising a circuit that forces the input current waveform to be proportional to the input voltage over the ac cycle. That is known as a power-factor correction (PFC) circuit, and it is connected between the full-wave rectified ac input (but with the usual storage capacitor omitted) and the actual dc–dc converter, as shown in Figure 9.77. It consists of a non-isolated boost converter, operating at the usual high switching frequency, with the switching duty cycle continually adjusted to keep the sensed input current ($I_{\rm ac}$) proportional to the instantaneous ac input voltage ($V_{\rm ac}$) over the ac cycles. At the same time, it regulates its dc output to a voltage somewhat greater than the peak ac input, usually +400 V. This dc output then powers an isolated dc–dc converter to produce the final regulated voltages.

Power-factor correction is becoming standard in most moderate-to-high-power offline switching power supplies (>100 W, say), and is required by various regulatory standards. It is quite effective, as can be seen in Figure 9.78, where we dusted off a vintage desktop computer and compared its input current waveform with that of a contemporary unit running at the same time and from the same wall outlet.

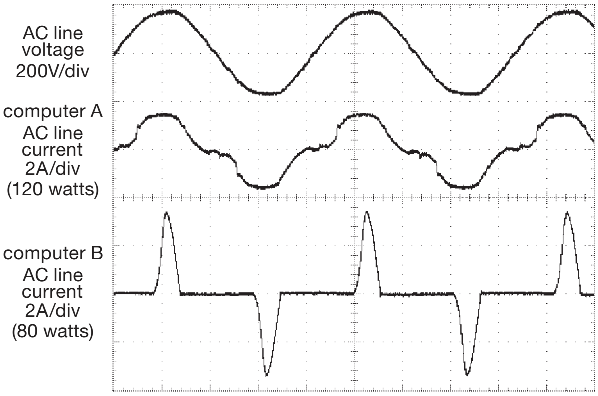

Figure 9.78. A tale of two computers. Computer A has a PFC-input power supply, causing its input current to track the input voltage. The power supply in computer B, built ten years earlier, lacks PFC; its input bridge rectifier charges the storage capacitor with short-duration current surges. Horizontal scale: 4 ms/div.

9.7.2 The dc-to-dc converter

There are some extra issues to contend with in the design of offline converters.

A. High voltage

Whether power-factor corrected or not, the dc supply to the converter–regulator will be at a substantial voltage, typically 150 V or 300 V, or somewhat higher if PFC is used. The converter itself provides the isolation, typically using one of the transformer configurations of Figure 9.73. The switch must withstand the peak voltages, which can be significantly larger than the dc supply. For example, in the forward converter with 1:1 tertiary reset winding (Figure 9.73B) the MOSFET drain swings to twice V_{in} during reset; and for the flyback the drain flies up to $V_{\text{in}}{\cdot}T/t_{\text{off}}$. Note also that these peak voltages assume ideal transformer behavior; leakage inductance and other non-ideal circuit realities further exacerbate the situation.

B. Switching losses

High-voltage MOSFETs do not have the extremely low R_{on} of their lower-voltage brethren. For high-voltage MOSFETs of a given die size, R_{on} increases at least quadratically with voltage rating (see Tables 3.4 and 3.5). So designers have to worry about the *conduction loss* during the conduction portion of the cycle, namely $I_{\text{D}}^2 R_{\text{on}}$. You can, of course, reduce conduction losses by choosing a larger MOSFET, with reduced R_{on}.[99] But larger transistors have higher capacitances, which contribute to *dynamic losses*, which become increasingly important when switching high voltages: imagine, for example, a forward converter in continuous-conduction mode; when the switch is turned ON, it must bring its drain (and attached load) from $+2V_{\text{in}}$ to ground. But there is energy stored in the switch's drain capacitance, as well as the parasitic capacitance of the transformer's winding, to the tune of $E=\frac{1}{2}CV^2$, which is squandered as heat each switching cycle. Multiply that by the switching frequency, and you get $P_{\text{diss}}=2fCV_{\text{in}}^2$. It goes up quadratically with operating voltage, and it can be substantial: an offline forward converter, running from +300 V rectified line voltage, switching at 150 kHz, and using a 750 V MOSFET with drain (and load) capacitance of 100 pF would be dissipating 3 W from this dynamic switching loss alone.[100]

There are clever ways to circumvent some of these problems. For example, inductances can be exploited to cause the drain voltage to swing close to ground (ideally, zero-voltage switching) before the switch is activated; this is called "soft switching," and is desirable for reducing both $\frac{1}{2}CV^2$ switching losses and the component stress caused by hard switching. And the $V_{\text{D}}I_{\text{D}}$ switching loss during transitions can be minimized by driving the gate hard (to reduce switching time), and by exploiting reactances to bring about zero-current switching. These problems are not insurmountable; but they keep the designer busy, dealing with tradeoffs of switch size, transformer design, switching frequency, and techniques for soft switching. This kind of circuit design is not for the casual electronics tinkerer, nor for the faint of heart.

C. Secondary-side feedback

Because the output is deliberately isolated from the hazardous powerline input, the feedback signal has to cross

[99] Or, for high-enough voltages, use an IGBT instead; see §3.5.7.

[100] A second kind of dynamic switching loss occurs during the ramp-up and ramp-down of switch voltage, during which the instantaneous transistor power dissipation is the product of drain voltage and drain current. This is basically a dynamic conduction loss associated with switching *transitions*, to be distinguished both from the *static* conduction loss during the switch's ON state, and from the dynamic "hard-switching" losses associated with charging and discharging parasitic capacitances.

back over the same isolation barrier. The configuration in Figure 9.74 is typical: a voltage reference and error amplifier (here implemented with a simple shunt regulator) drives the LED of an optocoupler at the output, with the isolated phototransistor providing guidance to the switch control (usually PWM) on the drive side. A lesser-used alternative is a pulse transformer, driven from a "secondary-side controller" circuit. A third alternative, if a high degree of output regulation is not needed, is to regulate the output of an auxiliary winding that is not on the "output" side (for example, a winding like P2 in Figure 9.74); because it returns to the input-side common, no isolation of its feedback signal is needed. This is called *primary-side* regulation. Typically you'll get something like ±5% output regulation (over a load-current variation from 10% to 100% of rated current), compared with ±0.5% or better with secondary-side feedback.

D. The isolation barrier

Transformers and optocouplers provide galvanic isolation. Simple enough, it would seem. But, as with life itself, there's usually plenty of nuance lurking below the surface (and, as will become evident, *along* the surface as well).

There are two mechanisms by which an isolation barrier can be breached:
(a) High voltages can create a spark directly across an air gap (or through an insulating sheet); this kind of breakdown is called "arcing" (or "arc-over"), so you have to ensure a minimum *clearance* distance, defined as the shortest distance in air between a pair of conductors.
(b) A conductive path can develop on the surface of insulating material that separates a pair of conductors; this kind of breakdown is called "tracking,"[101] best prevented by ensuring a minimum *creepage* distance, defined as the shortest distance along the surface of insulating material between two conductors; see Figure 9.79. As will become evident, creepage is generally the greater worry (compared with clearance) in high-voltage circuit layouts.

It's bad news when there's breakdown of an isolation barrier; it will likely cause damage or destruction to downstream powered electronics. Worse yet, there's human safety – an electronic device whose isolation from the ac line power is lost can kill you. For these reasons there are guidelines and strict standards that govern the design of isolation barriers (codified by IEC, UL, DIN/VDE, etc.). Publications like IEC 60950 and IEC 60335 include extensive tables of minimum clearance and creepage, and websites like www.creepage.com have delightful online calculators to keep your designs reliable and safe.

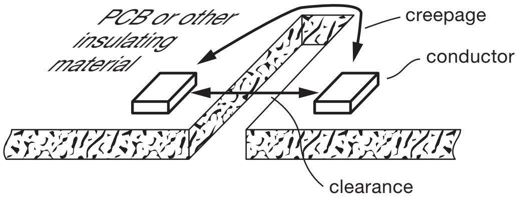

Figure 9.79. Two paths for breaching an isolation barrier: rapid arcing across the airgap (defined by the *clearance* distance), and conductive "tracking" along a path on the surface of the insulating material (defined by the *creepage* distance).

Generally speaking, clearances of 2 mm or so, and creepage distances of 4–8 mm or so, are appropriate for 120 Vac powered converters. However, there are additional variables that affect the required spacings. An example is "pollution degree" (referring to the presence of conductive dust, water, etc.); and there is the overall category of intended insulation (ranging from the merely "functional" to the strictest safety level of "reinforced"). Another factor is the intended application: for example, there are separate safety standards for products intended for household use (IEC 60335), and there are particularly strict standards for medical devices (IEC 60601). A full discussion of the subject is well beyond the scope of this book. The following treatment aims to alert the reader to the seriousness of high-voltage isolation, and some of the techniques that are used to deal with it.

The variables: insulation type, voltage, material group, pollution degree

These are the parameters you use with the tables or calculators.

Insulation type The overall level of required effectiveness, in five steps (functional, basic, supplementary, double, reinforced).

Voltage Arc-over in air or through an insulating sheet is rapid, so it's the *peak* voltage (or peak transient) that matters. By contrast, the deterioration or contamination that causes conductive creepage is slower, so you use rms or dc voltages when consulting the tables.

Material group This refers to the susceptibility of the particular insulating material to surface breakdown; the groups are called I, II, and III, going from least to most susceptible. Some standards prefer analogous parameters called "comparative tracking index" (CTI) and "performance level categories" (PLCs).

[101] A colorful term that describes well the little carbonized tracks you tend to find in postmortem forensics of a high-voltage device that has failed.

Pollution degree A curious term, which refers to the quality of air: degree 1 is clean and dry air; degree 2 is the normal home or office environment; degree 3 is nasty, with conductive dust, condensing moisture, and the like – basically it applies to service in heavy industrial or farming environments.

Increasing the creepage distance

If you've got a compact design, such that there's insufficient space to provide adequate creepage distances, you can use various measures. You'll frequently see gaps or slots cut through a printed circuit board, as in the offline switcher of Figure 9.80. You can also provide a protruding barrier to lengthen the surface-clinging path, a technique used in high-voltage optocouplers, transformer windings, and the like (see next paragraph). A conformal insulating coating applied over a populated circuit board is a particularly effective technique (but it must not delaminate, or it can be worse than no coating at all). Related techniques for individual components involve potting or molding.

Creepage considerations in component packaging and design

Components that bridge the isolation barrier, such as transformers and optocouplers, must be designed and packaged with appropriate clearances and creepage distances, both in the external leads and in the internal insulation. An example is the isolation-straddling Y-capacitor, with one foot on each side. As the photograph of Figure 9.81 shows, the leads of the disc-geometry Y-capacitor are oriented at right angles and coated with a continuation of the same conformal insulation that covers the capacitor body. Components housed in DIP-style cases can achieve greater separation of input and output sections by omitting intermediate pins[102] (thus a "DIP-8" that's missing pins 2,3,6, and 7). An example of a fully specified high-voltage part comes from Avago, whose datasheet for an optocoupler (ACNV260E) includes an abundance of clearance and creepage specifications: both "external" and "internal" clearances (13 mm and 2 mm, respectively), and likewise for creepage distances (13 mm and 4.6 mm, described as "measured from input terminals to output terminals, shortest distance path along body" and "along internal cavity," respectively).

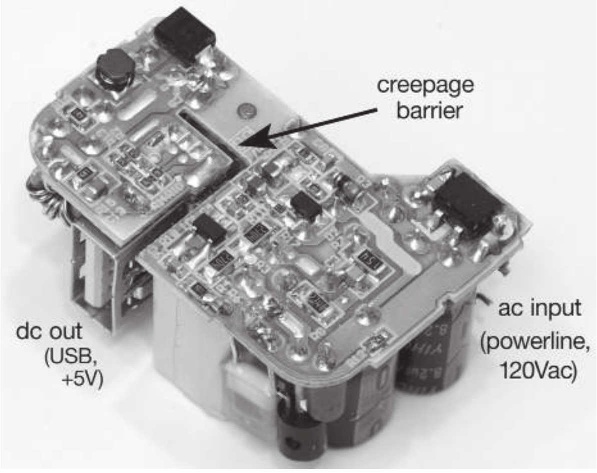

Figure 9.80. The designers of this switching converter included an L-shaped slot in the circuit board, greatly lengthening the creepage distance from the powerline circuitry to the isolated 5 V output.

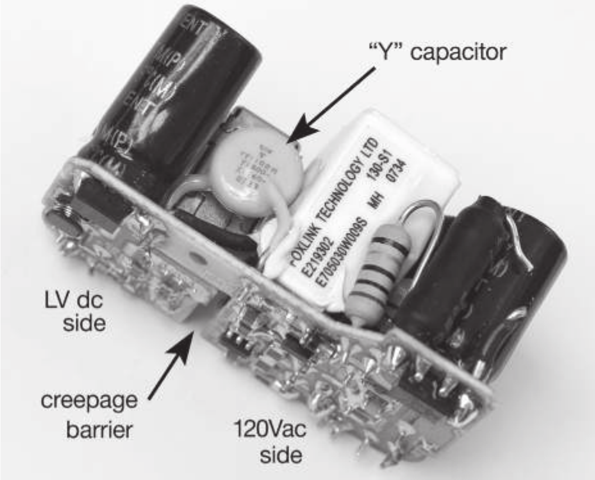

Figure 9.81. This edgewise view of the same converter reveals that the Y-capacitor's widely spaced leads preserve the 8 mm minimum creepage; by contrast, the converter's minimum *clearance* is just 1.5 mm.

The leads of the switching transformer must similarly maintain adequate spacing and creepage distance. Equally important, the inter-winding insulation and winding geometry must create both appropriate insulation (by a sufficient number of layers of insulating tape, etc.) and also appropriate creepage standoff. To meet the creepage requirements, the windings may be arranged side-by-side (rather than coaxial), and separated with an insulating sheet that extends outward beyond the windings. This is good for creepage, but bad for the magnetic design, as it increases the leakage inductance. With a magnetically preferable coaxial geometry, the creepage distance can be extended by

[102] See for example the datasheets for the Vishay CNY64 coupler, the ON Semiconductor NCP1207 PWM controller, or the Power Integrations LNK-403 driver.

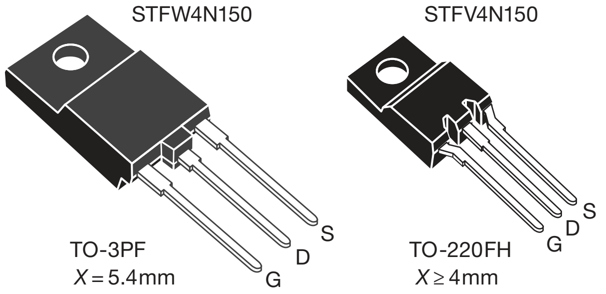

Figure 9.82. These 1500 V MOSFET packages employ shaped and grooved insulation to lengthen the creepage path length. (Adapted with permission of STMicroelectronics)

allowing the inter-winding tape to extend beyond the windings, or to wrap back around the outer winding.

Creepage effects are present whenever you deal with high voltage, whether or not an isolation barrier is involved. An example is shown in Figure 9.82, illustrating the pin configuration of two package styles of a 1500 V MOSFET. For the larger TO-3PF package (5.4 mm lead spacing) an extension of the plastic package material around the drain lead provides adequate creepage distance; for the smaller TO-220FH package (2.5 mm lead spacing) there's a grooved structure and offset lead geometry.

9.8 A real-world switcher example

To convey the additional complexity involved in a production-model line-powered switching power supply, we disassembled a commercial single-output regulated switching supply[103] (Astrodyne model OFM-1501: 85–265 Vac input, 5 Vdc @ 0–3 A output), another in our series of "Designs by the Masters," revealing the circuit of Figure 9.83.

9.8.1 Switchers: top-level view

Let's take a walk through the circuit to see how a line-powered switcher copes with real-world problems. The basic topology is precisely that of the switching converter in Figure 9.48, implemented with flyback power conversion (Figure 9.73A); there are, however, a few additional components! Let's take it first at the broad-brush level, circling back later to delight in the refinements.

At this very basic level it goes like this: the line-powered bridge rectifier D_1 charges the 47 μF storage capacitor[104] (rated at 400 Vdc, to accommodate the 265 Vac maximum input), providing the unregulated high-voltage dc input (+160 Vdc or +320 Vdc, for 115 Vac or 230 Vac input, respectively) to the high side of the 70-turn primary winding of T_1. The low side of the winding is switched to input common (the $\perp$ symbol) at fixed frequency (but with variable pulse width) by the PWM switchmode controller chip U_1, according to feedback current at its FB terminal. On the secondary side the 3-turn paralleled secondaries are rectified by Schottky diode D_5, with "flyback" polarity configuration (i.e., nonconducting during the primary ON period). The rectified output is filtered by the four low-voltage storage capacitors (totaling 2260 μF), creating the isolated 5 Vdc output. This supply uses secondary-side regulation, comparing a fraction (50% nominal) of V_{out} with U_2's internal +2.50 V reference, turning on the LED emitter of optocoupler U_3 when the output reaches its nominal 5 Vdc. This couples to phototransistor U_{3b}, varying the feedback current into switchmode controller U_1, thus varying the ON pulse width to maintain regulated +5 Vdc output.

At this point we've accounted for perhaps a third of the components in Figure 9.83. The rest are needed to cope with issues such as (a) auxiliary power for the controller chip; (b) powerline filtering, mostly of *outgoing* switching noise; (c) protection (fusing, reverse polarity); (d) feedback loop compensation; and (e) switching transient snubbing and damping. And, although not obvious from the schematic, but most essential to the design – the choice of transformer parameters: core size and "gapping," turns ratios, and magnetizing inductance[105] L_{M}.

Before looking into those details, though, let's see how the basic converter works. We'll be able to figure out things like the voltage and current waveforms, peak voltages and currents, and the duty cycle as a function of input voltage and output current.

9.8.2 Switchers: basic operation

The control chip operates at a fixed frequency f_{osc} of 100 kHz, adjusting its primary switch conduction duty cycle ($D = t_{\text{on}}/T$) according to voltage feedback. We've drawn ideal waveforms for one cycle (duration $T = 1/f_{\text{osc}}$) in Figure 9.84. These are what you might expect in the

[103] Pictured in the northeast corner of Figure 9.1.

[104] The input storage capacitor is often called the *bulk capacitor*.

[105] The conventional symbols for magnetizing inductance and leakage inductance are L_m and L_l, respectively. But the lower-case L subscript can be hard on the eyes, especially in a footnote. In the interest of readability, therefore, we've adopted small upper-case subscripts: L_{M} and L_{L} throughout.

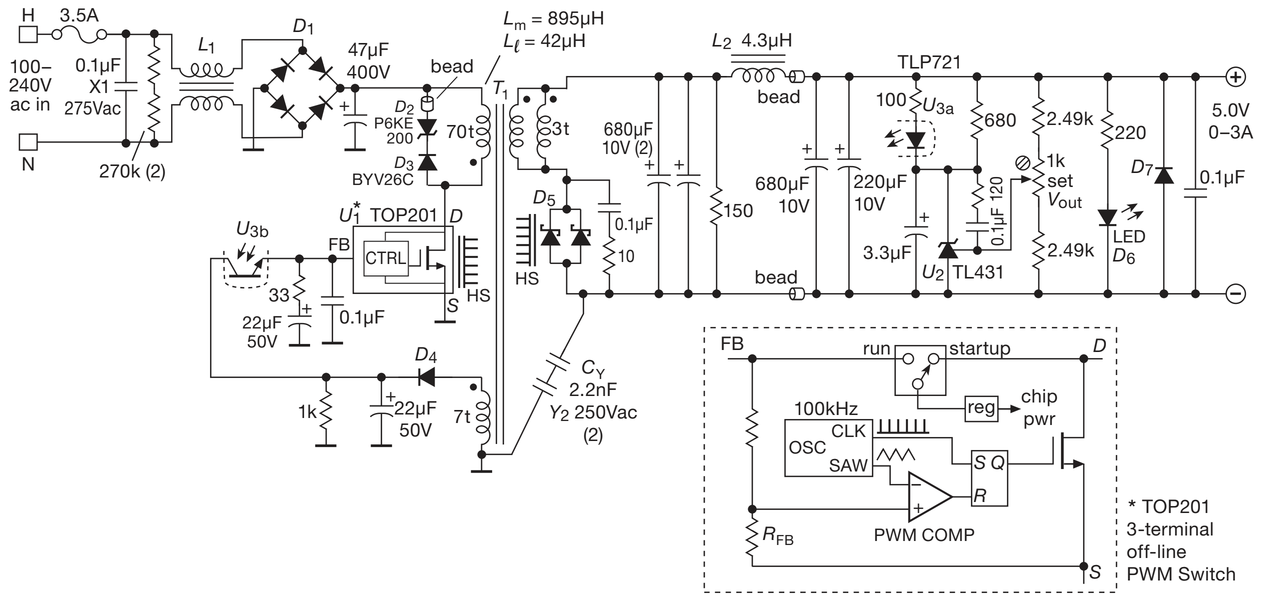

Figure 9.83. “Real-world” line-powered switching power supply. The circuit is relatively uncomplicated, thanks to its low power rating (15 W), and to the elegant 3-terminal switchmode controller U_1 from Power Integrations (with on-chip high-voltage power MOSFET). This is the open-frame “15W ac/dc switcher” shown in Figure 9.1.

absence of parasitic effects such as leakage inductance and switch capacitance.

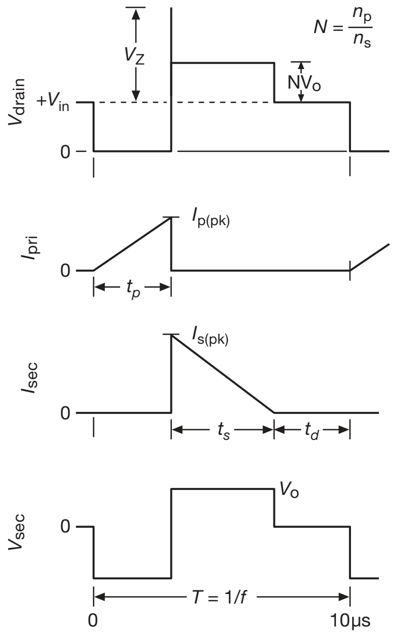

Figure 9.84. Ideal waveforms for an isolated flyback switching supply, operating in discontinuous-conduction mode.

A. The waveforms

We’ll do the calculations shortly, but look first at the waveforms. (We’ve assumed the converter is operating in discontinuous-conduction mode, which will be borne out when we do the numbers.) During switch conduction the drain voltage is held at ground, putting $+V_{\rm in}$ across the transformer primary and causing a ramp-up of primary current, according to $V_{\rm in} = L_{\rm M}{\cdot}dI_{\rm pri}/dt$, where $L_{\rm M}$ is the primary “magnetizing inductance” (the inductance seen across the primary, with all other windings disconnected). That current ramps up to a peak value $I_{\rm p}$, at which time there is a stored energy of $E = \frac{1}{2}L_{\rm M}I_{\rm p}^2$ in the transformer’s core. When the switch turns off, the persistent inductive current transfers to the secondary winding, delivering that stored energy E to the output as the secondary current ramps down to zero, according to $V_{\rm out}{=}L_{\rm M(sec)} \cdot dI_{\rm sec}/dt{=}(1/N^2)L_{\rm M} \cdot dI_{\rm sec}/dt$ (where $L_{\rm M(sec)}$ is the magnetizing inductance seen at the secondary[106]). For the rest of the cycle there is no transformer current flowing.

The voltage waveforms are instructive. When the primary switch is turned off, at time $t_{\rm p}$, the drain voltage rises

[106] Most of the time it’s the magnetizing inductance seen at the *primary* that matters, for which we simply use $L_{\rm M}$; in the few situations where we refer to the magnetizing inductance seen at the *secondary*, we add (sec) to the subscript: $L_{\rm M(sec)}$.

well beyond the input supply voltage V_{in}: that is because the inductor tries to continue sourcing current into the drain terminal. The voltage would soar, but the secondary circuit goes into conduction instead (notice the polarity of "dotted" windings in Figure 9.83), clamping its output to V_{out}, which reflects back to the primary via the turns ratio N (shorthand for $N_{\mathrm{p}}/N_{\mathrm{s}}$). The brief spike shown in the figure is caused by some primary inductance[107] that is not coupled to the secondary, and therefore not clamped. This terrifying voltage spike is ultimately clamped by the zener clamp D_2 seen in the schematic (more on this later). When the secondary current has ramped down to zero, the voltage drop across both windings goes to zero; so the drain terminal sits at $+V_{\mathrm{in}}$, and the voltage across the secondary winding goes to zero. Note that the latter is negative during primary switch conduction; it's a requirement that the "volt-time integral" (or "volt-second product") across any inductor average to zero, otherwise the current would rise without bound. That holds true for the primary also.

B. The calculations

Let us assume for simplicity that the converter is running at full load (5 V, 3 A) with nominal input voltage (115 Vrms or 160 Vdc).[108] We will calculate the switch duty cycle $D{=}t_{\mathrm{p}}/T$, the secondary conduction duty cycle t_{s}/T, and the peak currents $I_{\mathrm{p(pk)}}$ and $I_{\mathrm{s(pk)}}$. It's easiest to take these in reverse order, doing the calculations from a simple energy standpoint.

The parameters We measure the magnetizing inductance seen at the primary to be $L_{\mathrm{M}}{=}895\,\mu\mathrm{H}$, and the number of turns of primary and secondary to be $N_{\mathrm{p}}{=}70\mathrm{t}$ and $N_{\mathrm{s}}{=}3\mathrm{t}$. From this we get the turns ratio $N{=}N_{\mathrm{p}}/N_{\mathrm{s}}{=}23.3$, which sets the voltage and current transformation ratios. Finally, from the turns ratio we get the magnetizing inductance as seen at the secondary side: $L_{\mathrm{M(sec)}}{=}L_{\mathrm{M}}/N^2{=}1.65\,\mu\mathrm{H}$ (impedances scale as N^2; see Chapter *1x*). A final parameter that we will use later is the measured primary leakage inductance $L_{\mathrm{L}}{=}42\,\mu\mathrm{H}$.

Peak currents The output circuit is delivering 15 W to the load; but, taking account of rectifier drop ($\sim$0.5 V) and the combined resistive losses in the secondary winding and filter inductor L_2 (10 mΩ), the transformer secondary is delivering an average power of approximately 6 V×3 A, or 18 W. So, at a switching frequency of $f_{\mathrm{s}}{=}100\,\mathrm{kHz}$, the transformer must deliver an energy increment of $E{=}P/f_{\mathrm{s}}{=}180\,\mu\mathrm{J}$ during each switch cycle.

The rest is easy: we equate E to the magnetic energy in the core's magnetizing inductance, as seen at the secondary (because that's where it emerges). That is, $E{=}\frac{1}{2}L_{\mathrm{M(sec)}}I^2_{\mathrm{s(pk)}}$, from which we get $I_{\mathrm{s(pk)}}{=}14.8\,\mathrm{A}$. Dividing by the turns ratio ($N{=}23.3$), we find that the peak primary current is $I_{\mathrm{p(pk)}}{=}0.64\,\mathrm{A}$.

Conduction timing The primary switch stays on for a duration that ramps its current up to this peak current. That is, $t_{\mathrm{p}}{=}L_{\mathrm{M}}I_{\mathrm{p(pk)}}/V_{\mathrm{in(dc)}}{=}3.6\,\mu\mathrm{s}$. The secondary conduction commences when the primary switch turns off, and continues for the time duration t_{s} needed to ramp its current down from $I_{\mathrm{s(pk)}}$ to zero: $t_{\mathrm{s}}{=}L_{\mathrm{M(sec)}}I_{\mathrm{s(pk)}}/V_{\mathrm{sec}}{=}4.1\,\mu\mathrm{s}$. Note that the successive conduction of primary and secondary totals 7.7 μs, which is less than the cycle time of 10 μs; that is, the converter is running in discontinuous conduction mode, as we assumed at the outset (and drew in Figure 9.84). There is a "dead time" of about 2.3 μs before the next switch conduction.

C. Comparison with reality

How well did we do with this basic model? To find out, we measured voltage and current waveforms of this converter, at nominal input voltage and full output load. They are shown in Figure 9.85. The good news is that the timing and peak currents are in very good agreement with our

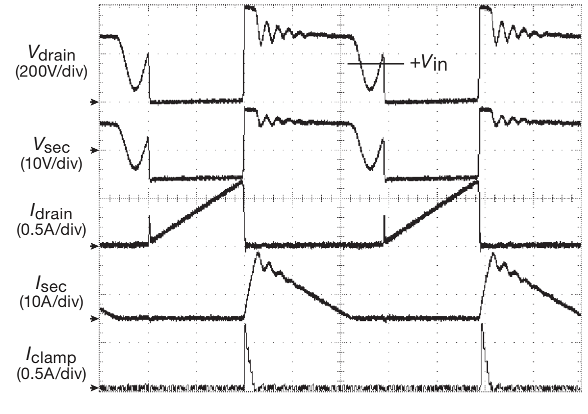

Figure 9.85. Measured waveforms for the switcher of Figure 9.83, running at full load (5 V, 3 A) and nominal input voltage (115 Vrms; $V_{\mathrm{in}}{=}160\,\mathrm{Vdc}$). The arrows mark the location of zero voltage and current for each trace. Horizontal scale: 2 μs/div.

[107] This is in fact the infamous "leakage inductance" L_{L}. As with magnetizing inductance, we use the unadorned L_{L} to refer to leakage inductance seen at the primary winding; for secondary leakage inductance we add (sec) to the subscript: $L_{\mathrm{L(sec)}}$.

[108] Of course, a full design analysis must consider operation at the extremes, in particular at minimum input with maximum load (hence maximum duty cycle), and for the full range of output current with maximum input.

calculations. The bad news is that there are some real-world "features" that are absent from our basic waveforms of Figure 9.84. Most prominent are

(a) a substantial drain voltage spike at turn-off, followed by
(b) some fast ringing on both windings during secondary conduction, and
(c) slower ringing during the dead time at the end of the cycle.

Visible also is

(d) a drain current spike at turn-on.

These are caused by non-ideal behavior of the MOSFET switch and the transformer, as we'll discuss soon; but, to put some names onto them, these effects are due to

(a) primary leakage inductance,
(b) resonance of drain (and other) capacitances with primary leakage inductance,
(c) resonance of drain (and other) capacitances with primary magnetizing inductance, and
(d) "hard switching" of the voltage across the drain and other capacitances.

9.8.3 Switchers: looking more closely

Let's go back and fill in the missing pieces. In the real world you cannot ignore important effects such as the voltage and current transients that we saw in Figure 9.85, and numerous other details that account for all the components you see in the circuit diagram.

A. Input filtering

Beginning at the input, we find the obligatory fuse, and then an across-the-line "X" capacitor (§9.5.1D and following) and a series-coupled inductor pair, together forming an EMI and transient filter. It's always a good idea, of course, to clean up the ac power entering an instrument; here, however, filtering is additionally needed to keep RF hash generated *inside* the power supply from radiating *out* through the powerline.[109] This is not merely an act of altruism; there are regulatory standards governing permissible levels of radiated and conducted EMI.[110] The pair of 270k resistors discharges the X capacitor's residual voltage when the unit is unplugged.

B. Voltage range, inrush current, PFC

Note that this low-power (15 W) supply operates directly from a wide input voltage range (3:1), without a dual-voltage range switch in the manner of Figure 9.76B. Such wide-range operation is particularly convenient in chargers and power bricks for consumer electronics. It does, however, impose constraints on the design, because the converter must operate over a wide range of switch conduction duty cycle, and because the components must be sized for the wider range of peak voltages and currents. Absent, also, are any circuit elements to limit the inrush current during initial charging of the line-side storage capacitor. That's permissible in a small supply like this; but even with the relatively small 47 μF storage capacitor the specified typical inrush current is a hefty 20 A at 100 Vac input (and twice that for 200 Vac). Note also the absence of a PFC frontend; it's common practice to omit PFC in small supplies, but PFC is usually found in supplies of 50 W or more, at least in part from regulatory pressures. Note, by the way, that a PFC front-end reduces peak inrush current.

C. Auxiliary supply

Moving to the right, we see the interesting configuration of the "auxiliary supply," needed to power the internal circuits of the regulator–controller chip with low-voltage, low-power dc. An unattractive possibility would be to use a separate little linear supply, with its own line-powered transformer, etc. However, the temptation is overwhelming to hang another small winding (with half-wave rectifier D_4) on T_1, thus saving a separate transformer. That's what's been done here, with the 7-turn winding, which generates a nominal +12 V output.

Sharp-eyed readers will have noticed a flaw in this scheme: the circuit cannot start itself, because the auxiliary dc is present only if the supply is already running! This turns out to be an old problem,[111] solved with a "kick-

[109] The important filter parameter here is not the converter's basic switching frequency, but rather the parasitic RF ringing frequency. If the latter is 2.5 MHz, for example, a lowpass filter with 250 kHz cutoff will attenuate the RFI by approximately $(f_{\rm RFI}/f_{\rm LPF})^2$, or 100×. With the 100 nF "X1" capacitor shown, the series inductance of the common-mode choke (its transformer leakage inductance) need be only $L{=}1/(2\pi f_{\rm LPF})^2 C_{\rm X}{=}4\,\mu$H. Higher frequencies will be attenuated more, up to the frequency at which the PCB's wiring inductance and the choke's winding self-capacitance take over.

[110] In the US, electronic equipment must meet FCC Class A (for industrial settings) and Class B (more stringent, for residential settings) limits; in Europe the analogous standards are set by VDE.

[111] For example, designers of traditional CRT-based television sets faced the same quandary, when they derived all their low-voltage dc supplies from auxiliary windings on the high-frequency horizontal drive transformer, the latter itself activated by those same supplies.

start" circuit that powers initially from the high-voltage unregulated dc, switching over to its auxiliary dc power after things are running. We'd like to show you how this is implemented in detail, but we are frustrated in that worthy goal because in this supply those functions (and others) are cleverly integrated into the TOP201 controller chip (shown in simplified block diagram form in the dashed box).[112]

D. Controller chip: bias and compensation

Moving next to the controller chip itself, we see its internal high-voltage MOSFET (drawn explicitly, for clarity), which switches the low side of the primary to input common. The switch operates at fixed 100 kHz rate, varying the duty cycle according to the feedback, in a voltage-mode regulator. The chip is packaged in a 3-pin TO-220 plastic power package, and requires a small heatsink. Think about that – a *3-pin* switching regulator! Impossible, you say: it needs pins at least for common, drain, feedback, and chip power ("bias"). Surprisingly, this clever chip does it with just three, with the feedback terminal doing double duty as a bias pin. Feedback takes the form of a current into the FB pin, with an internal voltage divider to create the voltage-feedback signal that is presented to the PWM (duty-cycle) comparator, and a linear regulator to create the (higher) internal bias voltage. The remaining components on the primary side are for loop compensation (the series *RC* and *C* shunting the FB terminal), and for clamping and damping the inductive spike at the end of the conduction cycle (the 200 V zener transient suppressor and ferrite bead).

E. Input transient clamp (snubber)

At first you might reason that no clamp is needed, because the secondary circuit clamps the flyback voltage (as transformed to the secondary side by the turns ratio) to the output voltage. That is, after all, how a flyback works: the magnetic energy added to the core during switch conduction is stored in the transformer's magnetizing inductance ($E_M = \frac{1}{2}L_M I_p^2$), and released to the secondary circuit when the switch is turned OFF. But there is also "leakage inductance" (L_L, see Chapter *1x*), an effective series inductance caused by incomplete magnetic coupling between the windings.[113] The magnetic energy stored in L_L ($E_L = \frac{1}{2}L_L I_p^2$) is *not* transferred to, nor clamped at, the secondary, which is why you need the zener clamp on the primary side. (You can think of this unclamped energy as arising from the magnetic field of the primary that is not linked by the secondary.) This energy can be substantial – we'll see just how robust a zener is needed, even for this low-power switcher, when we do the clamp calculations in the next paragraph. It's worth noting that the effects of leakage inductance loom particularly large in a line-powered supply, because the required high-voltage insulation between primary and secondary mandates that the windings be physically well separated, causing incomplete flux coupling.

Let's take a moment to understand the drain voltage spike waveform in Figure 9.85. The primary-side leakage inductance, here measured to be 42 μH, though a smallish fraction (∼5%) of the magnetizing inductance of 895 μH, stores that fraction of the total energy put into the transformer during primary switch conduction, and it is not transferred to the secondary; instead, it comes back out and is dissipated in the zener clamp D_2. That's about 0.84 W, which accounts for the robust zener that the designers chose. We can estimate the time duration of the primary current ramp to zero (call it t_{clamp}), mediated by the zener clamp. Look at Figure 9.86: the leakage inductance sees a clamp voltage equal to the zener voltage minus the reflected secondary voltage, which acts to ramp the primary

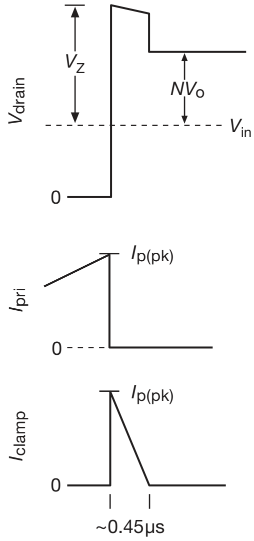

Figure 9.86. Drain-voltage spike caused by transformer leakage inductance. The zener clamp, whose voltage is higher than the reflected secondary output voltage, ramps the current to zero according to $V_Z - NV_{\text{out}} = L_L\, dI_D/dt$.

[112] Look in our second edition, where we devote six pages (pp. 361–366) to a complex offline switcher, if you want to see the gory implementation details of these and other features.

[113] Referring all inductances to the primary side, the magnetizing inductance L_M is what you measure across the primary terminals with all other windings left open-circuited, and the leakage inductance L_L is what you measure with all other windings short-circuited.

current down to zero from its starting value of $I_{\mathrm{p(pk)}}$. So, from $V{=}LdI/dt$ we get $V_{\mathrm{Z}}{-}NV_{\mathrm{out}}{=}L_{\mathrm{L}}I_{\mathrm{p(pk)}}/t_{\mathrm{clamp}}$, so $t_{\mathrm{clamp}}{=}0.45\,\mu$s. This is in good agreement with the measured waveforms of Figure 9.85.

A final note on the clamp network: the zener D_2 is not a normal zener, but rather a "transient voltage suppressor" type (TVS; see discussion in Chapter *9x*), designed and specified to absorb large pulses of energy. The series diode D_3 is needed to prevent conduction during the switch-ON cycle, when the zener would conduct as a normal diode. There's an interesting problem associated with D_3, namely the fact that ordinary diodes have a "reverse recovery time" after forward conduction, which is due to charge storage effects, before they become non-conducting (this is the origin of the curious microsecond-scale spikes seen in a simple 60 Hz unregulated power supply; see §*9x.6*). For this reason D_3 in this circuit is a "fast soft-recovery" rectifier: the "fast" means that it turns off quickly (<30 ns), and the "soft" means that it does so smoothly, not abruptly. That's useful, because an abrupt current transition to nonconduction produces large inductive spikes ($V = LdI/dt$). In addition, the designers added a ferrite bead to damp and suppress such effects.

F. The transformer

In a flyback converter the primary and secondary conduction cycles do not overlap (as they do in, say, a forward converter). So all the energy that is being moved from primary to secondary must take up temporary residence in the transformer's core. That is, in a flyback converter the transformer is not "just a transformer": in addition to the usual transformer functions (voltage and current transformation by the turns ratio, and galvanic isolation), it is also an *inductor*, storing energy from the primary cycle in its magnetizing inductance to the tune of $E{=}\frac{1}{2}L_{\mathrm{M}}I_{\mathrm{p(pk)}}$. In fact, it's probably more accurate to think of it as "an inductor with a secondary winding." To enhance the energy storage functions, such transformers are usually designed with a deliberate gap in the magnetic material, which has the effect of raising the stored energy for a given applied volt-second product. This particular transformer is evidently gapped, because its value of A_{L} (the ratio of magnetizing inductance to turns squared) is low: $A_{\mathrm{L}}{=}L_{\mathrm{M}}/N_{\mathrm{p}}^2{=}183\,\mathrm{nH/t^2}$, compared with a value of the order of 1500 for an ungapped ferrite core of this size. (The nonconducting ferrite core is used to eliminate eddy current losses at the high operating frequency.)

As we discovered above, this converter runs in discontinuous conduction mode at nominal input voltage and full load current. In fact, it stays in DCM even at minimum input voltage (90 Vrms) and full load current, which is the combination that brings it closest to CCM. With a bit more transformer inductance it would enter CCM; presumably the design choice was based on the desire to keep it small, and also to avoid some issues associated with CCM.[114]

As we hinted earlier, the transformer's inductances are responsible for the ringing seen in the waveforms of Figure 9.85. Let's do a simple calculation of what frequencies we expect. During secondary conduction (immediately following primary switch turn-off) the primary circuit looks like a parallel *LC*, with leakage inductance L_{L} in parallel with the parasitic capacitances of the MOSFET and other components (clamp diode, primary winding). A reasonable estimate for the combined capacitances is something like 75 pF, due mostly to the transformer wiring and the clamp zener. So the parallel *LC* formed with the leakage inductance of 42 μH resonates at about 2.8 MHz, in good agreement with the observed ringing (~2.5 MHz). At the completion of secondary conduction, the primary side no longer sees the leakage inductance (because the secondary is no longer clamped by the load); instead it sees the magnetizing inductance L_{M} of 895 μH (because the secondary is now open-circuited).[115] The new calculated resonant frequency then drops to about 615 kHz. You can see the first half-cycle of this slower resonance in the measured waveforms, centered on the +160 V dc input voltage, and interrupted by the onset of the next conduction cycle. (We later ran the converter at 25% load, which allowed three cycles of ringing at ~600 kHz, in excellent agreement with this estimate.)

While we're on the subject of parasitic capacitances, this is a good time to note the ~0.3 A current spikes at switch turn-on. This occurs because the switch is abruptly shorting a charged capacitor (the parallel capacitance of

[114] Most notably some tendency for the output voltage to overshoot when there is an abrupt drop in load current (owing to a larger required inductance in a CCM design, perhaps influenced also by the nonzero magnetic field throughout the cycle), and also a change in the feedback loop behavior (because of the different functional dependence of output voltage versus duty cycle, and, more interestingly, the fact that in CCM the duty cycle is fixed, for a given output voltage, and is independent of load current). Given this last fact, it may seem paradoxical that regulation against changes in load current is even possible! What happens is that, once in CCM, a change in load current causes a *transient* change in duty cycle, such that the baseline (minimum) primary current moves up or down to accommodate the changed load current; having established that new baseline current, the duty cycle then returns to the fixed value appropriate to the regulated output voltage.

[115] Somewhat overdamped by the reflected impedance of about 5 kΩ in series with ~200 pF from the 10Ω+0.1 μF secondary snubber network.

the switch itself, plus attached components). This is called "hard switching," and is responsible for significant power losses in converters running at high switching frequencies. Here, for instance, we can estimate the power dissipated in the switch by multiplying $\frac{1}{2}CV^2$ by the switching frequency, giving $P_{\text{diss}} \approx 0.15\,\text{W}$. That's not too serious at this modest switching frequency of 100 kHz, being just 1% of the output power; but its relative contribution is greater at low load current, and in any case it contributes to switch dissipation and stress. And it becomes increasingly important as you try to increase the switching frequency (in order to reduce size). The solution is to strive for "soft switching," in which the voltage across the switch is brought close to zero before switch activation (by exploiting reactive currents to discharge parasitic capacitances); this goal is called "zero-voltage switching" (ZVS).

G. Secondary power train

Moving to the secondary side, the rectifier is a Schottky type, which has both low forward voltage drop and zero recovery time (absence of charge storage).[116] Schottky rectifiers (also known as *hot carrier* rectifiers) are available at voltages up to ∼100 V; above that you'd use a "fast-recovery" (or "fast soft-recovery," like D_3) rectifier. Power rectifiers often come packaged as duals for applications that require two; here they've simply connected them in parallel. Note the heatsink: 3 A of average load current flowing through a 0.5 V (Schottky) forward drop dissipates 1.5 W, enough to merit a small heatsink. The series *RC* provides some damping and attenuation of switching transients, as do the ferrite beads. The series inductor L_2 filters ripple at the switching frequency: its reactance at the 100 kHz switching frequency is 2.7 Ω, compared with an impedance of ∼0.1 Ω (dominated by series resistance) for the downstream storage capacitors.

H. Secondary regulation

This power supply uses the popular TL431 "shunt regulator," which includes an internal voltage reference and error amplifier, and which goes into heavy conduction when the reference pin reaches 2.5 V above the ground pin. That turns on the optocoupler U_3's LED emitter, for currents above about 2 mA (the threshold set by the 680 Ω resistor). The resistive divider and trimmer allow ±0.4 V output adjustment, and the series *RC* around the TL431 is a compensation network to prevent oscillation. The large shunt capacitor limits the loop bandwidth, and also accomplishes "soft-start" at power-on: this it does by tricking the opto-emitter into thinking that the TL431 is conducting, when in fact the LED current is coming from the ramp-up of output voltage. It's easy to verify that an output ramp-up of 1.5 V/ms produces a sinking current of 5 mA at the cathode of the optocoupler LED, thus stretching the startup to about 3 ms, and therefore setting the secondary current needed to charge the four output storage capacitors to ∼3.4 A, roughly equal to the supply's maximum current rating.

I. Other design features

There are just a few additional goodies in this circuit. Capacitor C_Y is used to suppress conducted EMI. Because it bridges the isolation barrier, it must have appropriate "Y-capacitor" safety ratings (see §9.5.1). Rectifier D_7 protects against reverse polarity, in case some misbehaving load decides to create mayhem. The small output capacitor ensures low output impedance at high frequencies, where the large electrolytic capacitors become less effective (owing to internal inductance and ESR). And, finally, the switchmode controller itself (U_1) includes a host of nice features: internal oscillator requiring no external timing components, internal cycle-by-cycle current limit, overtemperature protection, automatic restart, internal regulator and dc source switching, and on-chip high-voltage power MOSFET, all integrated in an elegant 3-terminal configuration. Its high level of integration stole our thunder: it robbed us of the opportunity to show these important circuits explicitly!

9.8.4 The "reference design"

This is a nice power supply. We've bought a lot of them, and they work reliably and well. The circuit design might seem forbiddingly complicated, certainly for those inexperienced in offline switchmode supply design. In fact, we recommend strongly that the *user* of such supplies should not try to design and build them – *buy* them from the expert folks who do this for a living (see below).

But, how did those experts come up with this particular design? As it turns out, the manufacturers of interesting ICs have a great interest in making it painless to use their products. For this noble objective they provide what are known as *reference designs*, which basically consist of a complete circuit example (usually available from them as a "development board" or "evaluation board"). For the regulator chip used in this particular power supply, for example, Power Integrations (the TOP201 manufacturer) provides four example circuits, with increasing levels of regulation

[116] To deal with the high 15 A peak current in D_5, the designers selected a YG802C04 Schottky rectifier with its pair of 40 V 10 A sections paralleled (each of which specifies a forward drop of 0.53 V at 7 A), attached to its own heatsink.

stability (called "minimum parts count," "enhanced minimum parts count," "simple optocoupler feedback," and "accurate optocoupler feedback"). And in a pair of "Application Notes"[117] they provide a step-by-step recipe for these designs, complete with flowcharts, formulas, and graphs. You can hardly go wrong. The supply of Figure 9.83, in fact, closely follows the "accurate optocoupler feedback" design, differing primarily in the inclusion of soft start, ferrite beads, and reverse polarity protection. This is not to say that the design is a trivial exercise – the implementation of the transformer, the packaging and layout, and the process of testing and regulatory approval are all major challenges.

9.8.5 Wrapup: general comments on line-powered switching power supplies

- Line-powered switchers are ubiquitous, and for good reasons. Their high efficiency keeps them cool, and the absence of a low-frequency transformer makes them considerably lighter and smaller than the equivalent linear supply. As a result, they are used almost exclusively to power industrial and consumer electronics.
- Switchers are noisy! Their outputs have tens of millivolts of switching ripple; they put garbage onto the powerline; and they can even scream audibly! One cure for output ripple, if that's a problem, is to add an external high-current *LC* lowpass filter; alternatively, you can add a low-dropout linear post-regulator.[118] Some commercial converters include this feature, as well as complete shielding and extensive input filtering.
- Switchers with multiple outputs are available and are popular in computer systems. However, the separate outputs are generated from additional windings on a common transformer. Typically, feedback is taken from the highest current output (usually the +3.3 V or +5V output), which means that the other outputs are not particularly well regulated. There is usually a "cross-regulation" specification, which tells, for example, how much the +12 V output, say, changes when you vary the load on the +5 V output from 75% of full load to either 50% or 100% of full load; a typical cross-regulation specification is 5%. Some multiple-output switchers achieve excellent regulation by using linear post-regulators on the auxiliary outputs, but this is the exception. Check the specs!
- Line-powered switchers, like other switching converters, may have a minimum load-current requirement. If your load current could drop below the minimum, you'll have to add some resistive loading; otherwise the output may soar or oscillate.
- When working on a line-powered switcher, *watch out!* This is no empty warning – you can get yourself killed. Many components are at or above line potential and can be lethal. You can't clip the ground of your 'scope probe to the circuit without catastrophic consequences! (Use a 1:1 isolation transformer at the input, if you must go poking around.)
- Switchers usually include overvoltage "shutdown" circuitry, analogous to our SCR crowbar circuits, in case something goes wrong. However, this circuit often is simply a zener sensing circuit at the output that shuts off the oscillator if the dc output exceeds the trip point. There are imaginable failure modes in which such a "crowbar" wouldn't crowbar anything.[119] For maximum safety you may want to add an autonomous outboard SCR-type crowbar.
- Switchers used to have a bad reputation for reliability, but recent designs seem much better. However, when they decide to blow out, they sometimes do it with great panache! We had one blow its guts out in a "catastrophic deconstruction," spewing black crud all over its innards and innocent electronic bystanders as well.
- Line-powered switchers are definitely complex and tricky to design reliably. Our advice is to avoid the design phase entirely, by *buying* what you need! After all, why build what you can buy?
- A switching supply, operating at roughly constant efficiency, presents a load that looks like a negative resistance (averaged over the ac wave) to the powerline that drives it. It can cause some crazy effects, including (but not limited to) oscillations, when combined with the input reactance of noise filters.

9.8.6 When to use switchers

Luckily for you, we're not bashful about giving advice! Here it is.

[117] AN-14: "TOPSwitch Tips, Techniques, and Troubleshooting Guide"; AN-16: "TOPSwitch Flyback Design Methodology."

[118] You can get a switcher and LDO combined as a single regulator IC, for example in the Micrel "High Efficiency Low Dropout" (HELDO™) series.

[119] A personal anecdote: we smelled smoke, and found a dead 'scope in our lab one day. We opened it up, and found that the PFC's output storage capacitor (470 μF, 450 V) had failed, exuding lots of gooey stuff. No problem, we thought, we'll just replace it; especially since a new supply costs $800! Power on, looks good, go to lunch…come back, *smoke!* Turns out the PFC controller chip failed in a way that prevented both regulation and overvoltage shutdown, so the boost circuit just kept boosting, until the capacitor cried uncle.

- For *digital* systems, you usually need something like +2.5 V, +3.3 V, or +5 V, often at high current (10A or more). *Advice:* (a) Use a line-powered switcher. (b) Buy it (perhaps adding filtering, if needed).
- For analog circuits with low-level signals (small-signal amplifiers, signals less than 100 μV, etc.). *Advice:* Use a linear regulator; switchers are too noisy – they will ruin your life.[120] *Exception:* For some battery-operated circuits it may be better to use a low-power dc–dc switching converter.
- For high-power anything. *Advice:* Use a line-powered switcher. It's smaller, lighter, and cooler.
- For high-voltage, low-power applications (photomultiplier tubes, flash tubes, image intensifiers, plasma displays). *Advice:* Use a low-power step-up converter.

In general, low-power dc–dc converters are easy to design and require few components, thanks to handy chips like the Simple Switcher series we saw earlier. Don't hesitate to build your own. By contrast, high-power switchers (generally line-powered) are complex and tricky, and extremely trouble-prone. If you must design your own, be careful, and test your design very thoroughly. Better yet, swallow your pride and buy the best switcher you can find.

9.9 Inverters and switching amplifiers

The benefits of switchmode power conversion – high efficiency and small size – can be applied to the generation of a *time-varying* output voltage. You can think of this as "dc-to-ac" conversion, as contrasted with a dc-to-dc power converter. In essence, you can imagine substituting an input *signal* for the fixed dc voltage reference of a switchmode dc regulator; the output will follow the input signal as long as the input signal bandwidth is well below the switching frequency.

Switching converters of this sort are used widely, for example to provide multiphase ac power for motor driving, or to generate the individual winding currents for microstepping motors. A variable-frequency motor driver lets you control the motor speed. Powerline-frequency dc-to-ac converters are often called *inverters*, such as those used in uninterruptible power supplies (UPSs) for computers. At higher power levels such inverters are used to generate powerline-frequency ac from the high-voltage dc that is shipped across the countryside (at dc voltages up to a *mega*volt, would you believe?). And, closer to home, switching audio amplifiers (known as "class-D" amplifiers; see §2.4.1C) are dominant in consumer electronics. In that application a passive *LC* lowpass filter smooths a rail-to-rail switching waveform (typically at frequencies of ~250 kHz or higher) whose duty cycle is modulated in accordance with the input signal. See Figure 2.73 for waveforms from a low-power class-D audio amplifier.

To get just a taste of this subfield of power electronics, take a look at Figure 9.87, where we've captured waveforms from two styles of uninterruptible 120 Vac power supplies, along with the raw 120 Vac wallplug power in our lab. You might guess that the clean middle waveform is the utility power, but in fact that waveform is the loaded output from a UPS that boasts "low-distortion sine wave." The top waveform is the wallplug power, showing rather typical levels of distortion. The 3-level waveform at the bottom is euphemistically called a "modified sinewave," and is typical of less-expensive inverters and UPSs. It isn't handsome, but it does the job: if switched to ± 170 V rails 25% of the time, and to zero (or unpowered) in between, it's easy to figure out that it has the same rms voltage (120 Vrms) and peak voltage (170 Vpk) as a 120 Vrms sinewave.[121] So it delivers the same power to resistive loads, etc., and it

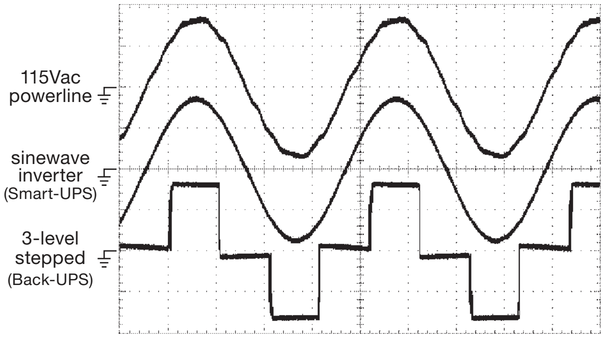

Figure 9.87. A true sinewave inverter generates a cleaner sinewave than wallplug ac. The 3-level waveform (sometimes called *modified sinewave*), though hardly a sinewave, has the same rms and peak voltages, and suffices for most loads. For these measured waveforms we loaded the APC UPSs with a 75 W incandescent lamp. Vertical: 100 V/div; horizontal: 4 ms/div.

[120] *Really!* Here's a pithy quote from James Bryant (from the Analog Devices "Rarely Asked Questions" series), in answer to the question "How can I prevent switching-mode power supply noise from devastating my circuit performance?" Answer: "With great difficulty – but it can be done." He continues: "Switching-mode power supplies are inherently the noisiest circuits imaginable. A large current from the supply is being turned on and off at high frequency with very fast dI/dt. There are inevitably large fast voltage and current transients."

[121] Just add up the squared voltages in equal time intervals, then take the square root of their average: $V_{\text{rms}} = \left[(V_1^2 + V_2^2 + \cdots + V_n^2)/n\right]^{1/2}$.

charges the input side of dc power supplies or converters to the same voltage as would the 120 Vrms utility line power.

There's more to think about than simply having the same rms and peak voltage, of course. There's *distortion*: the 3-level waveform has no even harmonics, but it has strong harmonics at all odd multiples of the fundamental frequency (there are various multilevel schemes to address this problem). Then there's the worry about systems that exploit zero crossings of the incoming ac power for timing, for which the 3-level waveform (or any stepped waveform with an odd number of levels) would wreak havoc.[122] There's plenty more to think about, even limiting ourselves to the subject of multilevel inverters.[123]

This area of power electronics is a rich subject; but, sadly, life is finite, and so (barely) is the size of this book.

9.10 Voltage references

Quite apart from their use in integrated voltage regulators, there is frequently the need for good voltage references within a circuit. For instance, you might wish to construct a precision regulated supply with characteristics better than those you can obtain using the best integrated regulators. Or you might want to construct a precision constant-current supply. Other applications requiring precision references (but not a precision power supply) include A/D and D/A converters, precision waveform generators, and accurate voltmeters, ohmmeters, or ammeters.

Integrated voltage references come in two styles: *2-terminal* (or *shunt*), and *3-terminal* (or *series*). Two-terminal references act like zener diodes, maintaining a constant voltage drop when current is flowing; the external circuit must provide a reasonably stable operating current. Three-terminal references (V_{in}, V_{out}, GND) act like linear voltage regulators, with internal circuitry taking care of biasing the internal reference (whether a zener diode, or something else). In Tables 9.7 and 9.8 (on pages 677 and 678, respectively) we've listed an abundance of currently available references of both types.

There are four different technologies used in currently available voltage references, all of which exploit some physical effect to maintain a well-defined and stable voltage – *zener diodes*, *bandgap references*, *JFET pinchoff references*, and *floating gate references*. They are all available as stand-alone (2-terminal or 3-terminal) components; they are also commonly incorporated as an internal voltage reference within a larger IC such as an A/D converter. Let's take them in order.

9.10.1 Zener diode

The simplest form of voltage reference is the zener diode, a 2-terminal device we introduced in §1.2.6A. Basically, it is a diode operated in the reverse-bias region, where current begins to flow at some voltage and increases dramatically with further increases in voltage. To use it as a reference, you simply provide a roughly constant current; this is often done with a resistor from a higher supply voltage, forming the most primitive kind of regulated supply.

Zeners are available in selected voltages from 2 to 200 volts (they come in the same series of values as standard 5% resistors), with power ratings from a fraction of a watt to 50 watts, and tolerances of 1% to 20%. As attractive as they might seem for use as general-purpose voltage references (being simple, inexpensive, passive 2-terminal devices), zeners lose their luster when you look a bit more closely: it is necessary to stock a selection of values, the voltage tolerance is poor except in high-priced precision zeners, they are noisy (above 7 V), and the zener voltage depends on current and temperature. As an example of the last two effects, a 27 V zener in the popular 1N5221 series of 500 mW zeners has a temperature coefficient of +0.1%/°C, and it will change voltage by 1% when its current varies from 10% to 50% of maximum.

There is an exception to this generally poor performance of zeners. It turns out that in the neighborhood of 6 volts, zener diodes are quiet, become very stiff against changes in current, and simultaneously achieve a nearly zero temperature coefficient. The graphs in Figures 9.88 and 9.89 illustrate the effects.[124] If you need a zener for use as a stable voltage reference only, and you don't care what voltage it is, one possibility is to use one of the compensated zener references constructed from a 5.6 V zener (approximately) in series with a forward-biased diode – if you can find one! (Read on...) The zener voltage is chosen to give a positive coefficient to cancel the diode's temperature coefficient of −2.1 mV/°C. Temperature compensation can be

[122] One solution is a 6-interval, 4-level waveform: V_{pk}, $V_{\text{pk}}/2$, $-V_{\text{pk}}/2$, $-V_{\text{pk}}$, spending twice as much time at $V_{\text{pk}}/2$ as at V_{pk}, and never dwelling at zero. This eliminates the 3rd harmonic (as well as all the even harmonics), and produces 120 Vrms if $V_{\text{pk}}=170$ V.

[123] A nice review is found in J. Rodriguez *et al.*, "Multilevel inverters: a survey of topologies, controls, and applications," *IEEE Trans. Indus. Electronics.*, **49**, 724–738 (2002), complete with 78 references.

[124] This peculiar behavior comes about because there are two competing mechanisms going on in zener diodes: zener effect at low voltages, with negative tempco; and avalanche breakdown at high voltages, with positive tempco.

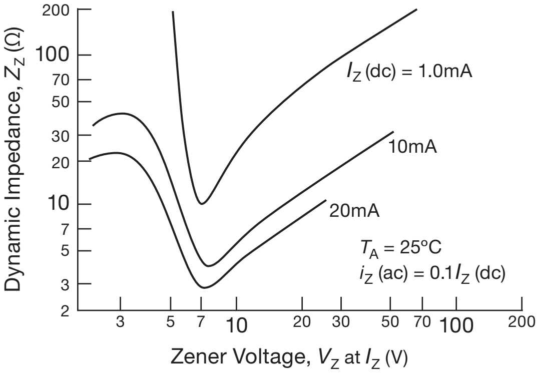

Figure 9.88. Zener diode dynamic impedance for zener diodes of various voltages. (Courtesy of Motorola, Inc.)

accomplished for other zener voltages also, for example in the 1N4057–85 series, which go from 12 V to 200 V, with tempcos of 20 ppm/°C.

Let's follow this thread – which, as we'll see, will lead us to a far better solution in the form of fully integrated voltage references (including those with a temperature-compensated zener on-chip) with superior characteristics. In fact, temperature-compensated zeners, as *discrete* devices, have become largely an extinct breed.

A. Providing operating current

A compensated zener could be used as stable voltage reference within a circuit, but it must be provided with constant current.[125] The tightly specified[126] 1N4895, for example, is specified as 6.35 V±5% at 7.5 mA, with a tempco of 5 ppm/°C (max) and incremental resistance of 10 Ω (max). So a change in bias current of 1 mA can change the reference voltage by 10 mV, three times as much as a change in temperature from 0°C to +100°C. You can, of course, rig up a separate current source circuit to bias the zener; but you can do better – Figure 9.90 shows a clever way to use the zener voltage itself to provide a constant bias current. The op-amp is here wired as a noninverting amplifier in order to generate an output of +10.0 V. That stable output is itself used to provide a precision 7.5 mA bias current. This circuit is self-starting, but it can turn on with either polarity of output! For the "wrong" polarity, the zener operates as an ordinary forward-biased diode. Running the op-amp from a single supply, as shown, overcomes this nuisance problem.[127] Be sure to use an op-amp that has common-mode input range to the negative rail ("single-supply" op-amps).

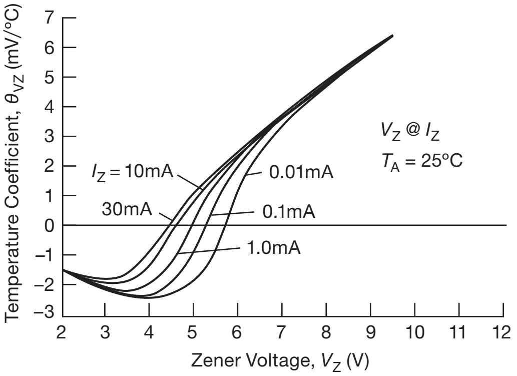

Figure 9.89. Temperature coefficient of zener diode breakdown voltage versus the voltage of the zener diode. (Courtesy of Motorola, Inc.)

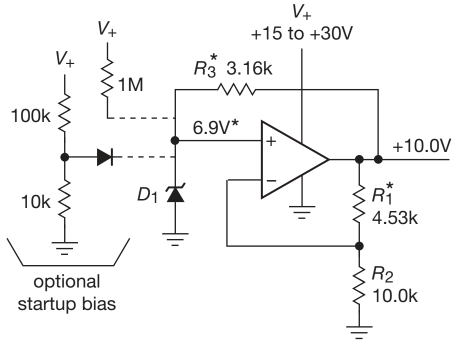
There are compensated zeners available that characterize the stability of zener voltage with *time*, a specification that normally tends to get left out. The 1N4895, for example, specifies stability of better than 10 ppm/1000h. The ultimate example is probably the LTZ1000, a 7.15 V integrated zener whose datasheet specifies an astonishing long-term stability of 0.15 ppm/$\sqrt{\text{kHr}}$ (typ). This puppy includes an on-chip temperature stabilizing heater, and claims to deliver a tempco as low as 0.05 ppm/°C, if treated with respect.[128] Such zeners are not cheap: the LTZ1000 will set you back $50.

[125] Most small zener diodes are specified at an operating current of 20 mA (though you can run them at lower currents). But, happily for those seeking low-current zeners, there's the 1N4678 to 1N4713 family (MMSZ4678–4713 for surface-mount SOD-123 package), specified at 50 μA.

[126] And individually tested for 1000 hours! It's available only from the manufacturer, Microsemi.

[127] With a caveat: the circuit could get stuck at zero output if the op-amp's input offset voltage is greater than the ground-saturated output voltage. This could happen with a rail-to-rail CMOS output stage, which is why we chose a BJT op-amp (whose saturation voltage is at least a few millivolts from ground). If you select a CMOS op-amp (say a precision chopper), or if you're losing sleep over the remote possibility of a stuck circuit, you can force the circuit to start correctly with either of the dotted supplements to the circuit.

[128] An example of appropriate respect is the prevention of thermal gradients: a junction of two dissimilar metals (a "thermocouple") generates a thermal EMF, about 35 μV/°C for the connection of the LTZ1000's Kovar-alloy leads to a circuit board. That's about 7 ppm per °C temperature *difference* in the two leads, which is a hundred times larger than that of the chip's zener itself!



Op-amp:			
	LT1077	2μV/°C max	$2.08
	½LM358A	15μV/°C max	$0.14

op-amp	LM358A	←	LT1077	→	

* values shown for LM329B

Figure 9.90. Stable output voltage provides a stable zener bias current over varying supply voltages V_+. The op-amp must operate to the negative rail. For a jellybean zener like the 1N5232 you can use an inexpensive op-amp like an LM358; but use a precision op-amp (e.g., the LT1077) to preserve the low tempco of a precision reference like the LM329 or LM399. Don't use a split supply here, because the output could happily settle to a negative output.

B. IC zeners

We hinted that precision-compensated zeners as *discrete* devices have largely disappeared; you can check this out for yourself by going to a site like Octopart.com, looking for once-popular parts like the 1N4895 or 1N821–29 series.

That's the bad news. The good news is that excellent compensated zeners now come in integrated form, as the internal reference within a variety of IC voltage references. Table 9.7 lists several of these, from the inexpensive (less than $1) LM329 to the spectacular LTZ1000. These include additional circuitry to yield improved performance (most notably, constancy of terminal voltage with applied current), in the form of an integrated circuit; it looks electrically just like a zener, with just two terminals, although internally it includes additional active devices. Being zener-based, these devices operate around the sweet spot of 7 V, although some (like the LT1236 in the table) include internal amplifier circuitry to create a round-number 10.0 V "zener."[129]

The jellybean LM329 is worth keeping in mind when you need only a "good-enough" zener reference; it has low noise, a zener voltage of 6.9 V, and in its best version it has a temperature coefficient of 10 ppm/°C (max), when provided with a constant current of 1 mA. Where better performance is needed, consider the LT1236A or the thermally regulated (on-chip heater) LM399A, the latter with an admirable 1 ppm/°C worst-case tempco!

When thinking about 2-terminal zener references, don't overlook the other voltage reference technologies that are available as 2-terminal (shunt) devices (see Table 9.7 on the facing page). From the outside they behave just like zener diodes, but they use other tricks (e.g., a V_{BE} drop) internally to create their stable reference voltage. Among other benefits, such devices come in desirable low voltages (1.25 V and 2.5 V are common), and some can operate at currents as low as 1 μA. Read on!

And remember always not to limit yourself to *2-terminal* references – there are excellent 3-terminal references, both zener based and otherwise. A fine example is the LT1027B, a zener-based 5.0 V reference with excellent tempco (2 ppm/°C, max) and low noise (3 μVpp typ, 0.1–10 Hz). A nice feature of most of the integrated references (both 2-terminal and 3-terminal) is the convenient output voltages they provide: instead of having to deal with something like V_{out}=6.95 V±4% (the voltage specification of the excellent LM399 temperature stabilized 2-terminal zener reference), you get precise round-number output voltages like 1.25 V, 2.50 V, 5.0 V, and 10.0 V, factory trimmed to an accuracy as good as ±0.02% (see Tables 9.7 and 9.8).[130]

[129] Zener diodes can be very noisy, and some IC zeners suffer from the same disease. The noise is related to surface effects, however, and *buried* (or *subsurface*) zener diodes are considerably quieter; this is the technology that is used to achieve the very low noise of parts like the LT1236 and LTZ1000 references.

[130] Also powers-of-2 voltages (2.048 V, 4.096 V) to set round-number LSB steps in ADCs and DACs.

Notes: (a) generally listing best accuracy grade.; sorted by type and increasing accuracy. (b) wired as a zener. (c) at 10mA. (C_L) load capacitor — R: >10nF required; N: not required but allowed, or recommended for transient-loads; µF = min required if more than a small cap is added, see datasheet; blank = no comment. The ac output impedance rises with frequency and will resonate with the load capacitor's reactance. A small resistor (22 to 100Ω, etc.) can isolate the capacitor and lower the resonance Q. (d) 5-10mA. (e) at I_Z=7.5mA. (f) ΔV (mV) over temp. (g) for the 2.5V version (the 1.2V version is generally less). (h) for the 1.225 version, or V_{ref} for the adj version. (k) an RC is suggested, e.g. 22Ω. (m) min or max. (n) nominal. (na) not available. (o) of the 1.24V ref, gained up to V_{clamp}. (p) also TLVH431A. (q) minimum operating current (maximum, i.e., worst-case); often higher for higher fixed voltages. (r) usually at 1mA, but not current dependent. (s) see datasheet. (t) typical. (u) spec'd over operating range. (v) 6V for TI's TLV431, 16V for Onsemi TLV431 or TI TLVH431. (w) see datasheet for exact value, chosen for minimum tempco. (x) scaled to 1.0V output; multiply listed value by V_{out}.

Comments: **1:** two resistors set V_{clamp}. **2:** I_{ref}=4µA max. **3:** I_{ref}=0.5µA max; complementary to LM385-adj. **4:** I_{ref}=0.5µA max; TLV432 is alternate pinout. **5:** LM336 has voltage-trim pin. **6:** multiple-source jellybean. **7:** -BX version is 30ppm/°C; I_{ref}=15nA. **8:** dual: bandgap and 7V zener (1.6%, 40ppm/°C typ, 90Ω), common neg terminal. **9:** lowest V_{ref} shunt ref. **10:** 1.235V is 0.3% tol, 2.45V is 0.8% tol. **11:** TI's -CDR suffix costs $0.25 (qty 25). **12:** nanopower, min I_Z=1µA; 40ms turn-on settling time with 1.2µA bias and 10nF cap. **13:** MAX6007, 08, 09 for other voltages. **14:** LM336 upgrade. **15:** non -A version. **16:** -B, -C, -D suffix looser tolerance. **17:** -A suffix 0.2% tolerance. **19:** -C suffix for looser tolerance. **20:** nanopower. **21:** -A suffix is 5ppm/°C typ, 10ppm/°C max. **22:** series ref used in shunt mode. **23:** on-chip heater; lowest guaranteed tempco. **24:** factory purchase. **25:** low-voltage zeners are poor! **26:** optimum zener voltage. **27:** tested 1k hours; "reference zener," spec'd at 7.5mA only. **28:** temp comp zener reference.

Notes: (a) sorted approximately by tolerance, tempco and 0.1-10Hz noise; generally listing best accuracy grade. (b) other packages: M - TO-99 metal can; P - DPAK power pkg; S - small (micro8, MSOP); T - tiny (DFN, LCC). (c) B: bandgap; F: floating gate; J: JFET pinchoff; Z: zener. (d) tabulated data corresponds to the voltage choice indicated by a large bullet. (e) 10Hz-1kHz. (f) in LCC pkg. (g) for 2.5V version. (h) qty 3k. (j) adjustable via external resistors. (k) qty 1k. (m) min or max. (n) nominal. (o) 15nV/√Hz with C_{NR}=1uF. (p) peak-to-peak. (q) over V_{in} range. (r) 10Hz to 100kHz. (s) 100μV with 10nF filter cap. (t) typical. (u) 0.1μF for V_{out}≥3V. (v) up to 10uF with recommended pole-zero network. (w) a minimum of 0.1uF or C_{out}, whichever is larger. (x) ESR must fall in min-max range, see datasheet. (y) no min or max for all except the 2.5V version, which may oscillate with 400pF<C_{out}<2μF when sinking between 1mA and 6mA. (z) a "-" means no minimum or maximum; in all cases consult datasheet for details.

Comments: **1:** inexpensive LDO reg/ref. **2:** inexpensive LDO reg/ref with dropout flag; can add ext BJT. **3:** lowest V_{ref}; op-amp FB input for V_{out} from 0.4V to rail. **4:** other suffixes for relaxed tempco and accy. **5:** -A grade for 0.2% accy; temp output (in 8-pin pkgs). **6:** temperature output. **7:** load regulation 20ppm/mA or better. **8:** no suffix for relaxed tempco and accy. **9:** low noise, low tempco. **10:** a favorite. **11:** pin selectable V_{out}; ext resistors for variable V_{out}. **12:** ISL21007 for V_{in}=2.7-5.5V and I_Q=75μA. **13:** 10mV no-load dropout. **14:** can use in shunt mode. **15:** low noise, wide supply. **16:** very low noise, low tempco. **17:** low noise, low tempco. **18:** lowest noise and tempco.

Well, you say, I could do that with the circuit of Figure 9.90, which lets me set the dc output voltage via the ratio of R_1/R_2. Sure. But hold on – standard metal-film resistors come in 1% precision, with tempcos in the range of ±50 ppm/°C. You *can* get fixed resistors and arrays with tempcos down in the ±1 ppm/°C territory (see §5.6), but you'll pay a dear price, and the resistance selection is sparse. And don't forget that you've still got to trim the gain to reach the precise round-number output voltage. Use a trimpot? Not a good idea, because the tempco will suffer, and you will have to worry about resistance stability (wiper resistance, mechanical stability, etc.). You're likely to conclude that an on-chip factory-trimmed resistive divider (matched tempcos, thus very low tempco of gain) is the way to go. And it is.

9.10.2 Bandgap (V_{BE}) reference

This method exploits the ∼0.6 V base–emitter voltage drop of a transistor operating at constant collector current (it should properly be called a V_{BE} reference), as given by the Ebers–Moll equation. Because that voltage has a negative temperature coefficient, the technique involves the generation of a voltage with a positive temperature coefficient the same as V_{BE}'s negative coefficient; when added to a V_{BE}, the resultant voltage has zero tempco.

Figure 9.91 shows how it works. We start with a current mirror with two transistors operating at different emitter current densities (typically a ratio of 10:1). Using the Ebers–Moll equation, it is easy to show that I_{Q2} has a positive temperature coefficient, because the difference in V_{BE}'s is just $(kT/q)\log_e r$, where r is the ratio of current densities (see the graph in Figure 2.62). You may wonder where we get the constant current to program the mirror. Don't worry – you'll see the clever method at the end. Now all you do is convert that current to a voltage with a resistor and add a normal V_{BE} (here Q_3's V_{BE}). R_2 sets the amount of positive-coefficient voltage you have added to V_{BE}, and by choosing it appropriately, you get zero overall temperature coefficient.[131] It turns out that zero temperature coefficient occurs when the total voltage equals the silicon bandgap voltage (extrapolated to absolute zero), about 1.22 V. The circuit in the box is the reference. Its own output is used (via R_3) to create the constant mirror programming current we initially assumed.

The classic bandgap reference requires three transistors, two for ΔV_{BE} and the third to add a V_{BE}. However, Widlar and Dobkin cleverly created a two-transistor version, first used in the LM317, see Figure 9.13.

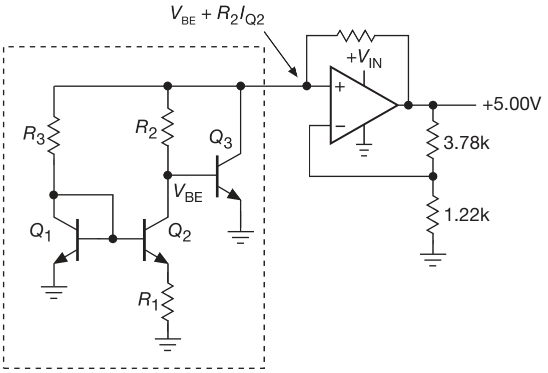

Figure 9.91. Classic V_{BE} bandgap voltage reference. The transistor pair Q_1Q_2 is a ratio current mirror, typically $I_{Q1} = 10I_{Q2}$; that ratio puts 60 mV across R_1, which sets the PTAT current I_{Q2}.

IC bandgap references

An example of an IC bandgap reference is the inexpensive (about $0.50) 2-terminal LM385-1.2, with a nominal operating voltage of 1.235 V, ±1% (the companion LM385-2.5 uses internal circuitry to generate 2.50V), usable down to 10 μA. That's much less than you normally run zeners at, making these references excellent for micropower equipment.[132] The low reference voltage (1.235 V) is often more convenient than the approximately 5 V minimum usable voltage for zeners (you can get zeners rated at voltages as low as 1.8 V, but they are pretty awful, with very soft knees). The best grade of LM385 guarantees 30 ppm/°C maximum tempco and has a typical dynamic impedance of 1 Ω at 100 μA. Compare this with the equivalent figures for a 1N4370 2.4 V zener diode: tempco = 800 ppm/°C (typ), dynamic impedance ≈3000 Ω at 100 μA, at which the "zener voltage" (specified as 2.4 V at 20 mA) is down to 1.1 V! When you need a precision stable voltage reference, these excellent bandgap ICs put conventional zener diodes to shame.

If you're willing to spend a bit more money, you can find bandgap references of excellent stability, for example, the

[131] The complete expression for V_{ref} is therefore $V_{ref}=V_{BE3} + (V_{BE1}-V_{BE2})R_2/R_1$.

[132] But note that low-current references tend to be noisy: the LM385-2.5 (20 μA min) running at 100 μA has a noise voltage density of 800 nV/$\sqrt{\text{Hz}}$, compared with 120 nV/$\sqrt{\text{Hz}}$ for the analogous LT1009 or LM336-2.5 references (400 μA min) running at 1 mA. And, if you're willing to squander more operating current, the LTC6655 low-noise 3-terminal bandgap reference (with a quiescent current of 5 mA) has an output noise density of just 50 nV/$\sqrt{\text{Hz}}$, and, impressively, with a $1/f$ noise corner below 10 Hz.

2-terminal LT1634A (2.5 V or 5 V, 10 ppm/°C max, about \$6), or the 3-terminal AD586 (5 V, 2 ppm/°C max, about \$9).

One other interesting bandgap-based voltage reference is the extremely popular TL431. It is an inexpensive (less than \$0.10 in large quantities) 2-terminal shunt regulator–reference, but with a third terminal to set the voltage. You hook it up as shown in Figure 9.92. The "zener" turns on when the control voltage reaches 2.50 V; the device draws only a few microamps from the control terminal, and gives a typical tempco of output voltage of 10 ppm/°C. The circuit values shown give a zener voltage of 10.0 V, for example. This versatile device comes in TO-92, mini-DIP, and a half-dozen surface-mount packages, and can handle currents to 100 mA and voltages to 36 V. Its low-voltage and low-power (80 μA min) cousins, the TLV431 and TLVH431, work the same way, but with a 1.25 V internal bandgap reference and limited output voltage and current.[133] Both types come in accuracy grades of ±2%, ±1%, and ±0.5%.

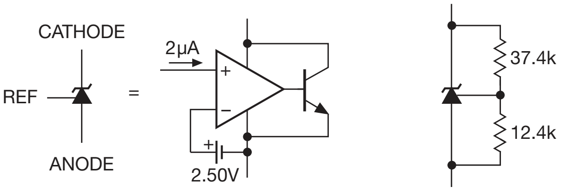

Figure 9.92. TL431 adjustable shunt regulator–reference. The resistive divider in the application circuit on the right sets the "zener" voltage to 10.0 V.

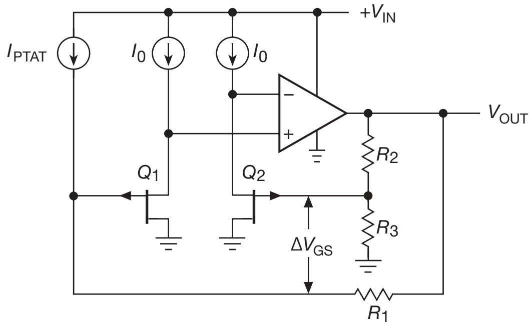
Bandgap temperature sensors

The predictable V_{BE} variation with temperature can be exploited to make a temperature-measuring IC. In Figure 9.91, for example, the difference in V_{BE}'s of $(kT/q)\log_e r$ implies that the current through Q_2 (and also Q_1) is proportional to absolute temperature (PTAT). The circuit can be rearranged (the Brokaw circuit) to produce simultaneously both an output voltage proportional to temperature, and a (fixed) bandgap voltage reference of 1.25 V. This is the case with a number of bandgap references, for example the AD680, a 2.50 V reference with an additional TEMP pin whose output voltage is 2.0 mV/K (thus 596 mV at 25°C). If you want only a temperature sensor, and don't need the bandgap reference, you can get nice stand-alone temperature sensors, for example the LM35, a 3-terminal sensor with 10 mV/°C output (0 V at 0°C), or the LM61, whose output is offset by +600 mV so it can measure from −30°C to +100°C. The LM61 costs a half dollar, compared with \$3 for the 8-pin multifunction AD680.

9.10.3 JFET pinch-off (V_{P}) reference

This recent technique is analogous to the V_{BE}-based bandgap reference, but uses instead the gate-source voltages of a pair of JFETs. A single JFET operating at fixed drain current has a wicked tempco of V_{GS}, but this can be circumvented by cleverly using a JFET pair. Figure 9.93 shows the configuration used in the ADR400-series of "XFET" voltage references from Analog Devices. The JFET pair Q_1Q_2 have identical geometry and run at equal drain currents; but their different channel doping produces a gate-voltage *difference* of ∼0.5 V that is quite stable, with a relatively small tempco of −120 ppm/°C. That's much smaller than the tempco of a V_{BE} drop (roughly −3000 ppm/°C), and requires only a small dose of positive tempco correction, here applied by the voltage drop across R_1.



$$V_{\mathrm{OUT}} = (\Delta V_{\mathrm{GS}} - R_1 I_{\mathrm{PTAT}})\left(1 + \frac{R_3}{R_2}\right)$$

Figure 9.93. JFET voltage reference. The asymmetrically doped JFET pair, running at the same drain current, generates a difference voltage ΔV_{GS} between the gates. The relatively small tempco is compensated by a current derived from a bandgap-type reference (not shown).

The result is a voltage reference with excellent tempco (e.g., 3 ppm/°C or 10 ppm/°C for the two grades in the ADR400-series). An important benefit of this technique is its unusually low noise (1.2 μVpp for the 2.5 V part[134]).

[133] 6 V and 15 mA for the TLV431; 18 V and 80 mA for the TLVH431. The adjustable LM385 works similarly, but with an operating current range of 10 μA–20 mA, and voltages to 5.3 V.

[134] Better specified as 0.5 ppm(pp), because the noise voltage scales linearly with output voltage.

Bandgap references cannot match this sort of noise performance, because the process of compensating for their large intrinsic temperature coefficient introduces the lion's share of their output noise.

9.10.4 Floating-gate reference

This most recent entry into the voltage reference sweepstakes is, well, bizarre. If you were challenged to come up with an idea that would most likely fail, you might invent the "floating-gate array" (FGA) reference. Intersil did that, but they made it succeed! The idea is to put some charge onto the buried and well-insulated gate of a MOSFET, during manufacturing, which puts it at some voltage (thinking of it as a capacitor); the MOSFET then acts as a voltage follower (or op-amp input) to create a stable output voltage.

The stability over time depends, of course, on the tiny capacitor not losing or gaining any charge. That's a tall order – you'd like it to remain stable to perhaps 100 ppm over several years, over the full operating temperature range. A gate capacitance of 100 pF charged to 1 V, for example, would require that gate leakage be no more than 10^{-22} A; that's about two electrons per hour!

Somehow the folks at Intersil have made it work. They also dealt with stability over temperature, with several tricks: one method uses capacitors of different construction to cancel the already-small tempco of approximately 20 ppm/°C; another method uses capacitors of one type only, cancelling the small residual tempco by adding a voltage of known tempco (as in the bandgap and JFET references).

The results are impressive: the ISL21009 series claim long-term stabilities of order 10 ppm per square-root-kilohour; tempcos of 3 ppm/°C, 5 ppm/°C, and 10 ppm/°C (max) for the three grades;[135] noise of 4.5 μVpp; and very low supply current of 0.1 mA (typ). They come in preset voltages of 1.250 V, 2.500 V, 4.096 V, and 5.000 V, each available in several grades of accuracy and tempco.

9.10.5 Three-terminal precision references

As we remarked earlier, these clever techniques make possible voltage references of remarkable temperature stability (down to 1 ppm/°C or less). This is particularly impressive when you consider that the venerable Weston cell, the traditional voltage reference through the ages, has a temperature coefficient of 40 ppm/°C. There are two methods used to make references of the highest stability.

A. Temperature-stabilized references

A good way of achieving excellent temperature stability in a voltage reference circuit (or any other circuit, for that matter) is to hold the reference, and perhaps its associated electronics, at a constant elevated temperature. In this way the circuit can deliver equivalent performance with a greatly relaxed temperature coefficient, because the actual circuit components are isolated from external temperature fluctuations. Of greater interest for precision circuitry is the ability to deliver significantly improved performance by putting an already well-compensated reference circuit into a constant-temperature environment.

This technique of temperature-stabilized or "ovenized" circuits has been used for many years, particularly for ultrastable oscillator circuits. There are commercially available power supplies and precision voltage references that use ovenized reference circuits. This method works well, but it has the drawbacks of bulkiness, relatively large heater power consumption, and sluggish warm-up (typically 10 min or more). These problems are greatly reduced if the thermal stabilization is done at the chip level by integrating a heater circuit (with sensor) onto the IC itself. This approach was pioneered in the 1960s by Fairchild with the μA726 and μA727 temperature-stabilized differential pair and preamp, respectively.

This technique is used in the LM399 and LTZ1000 references, which claim stabilized tempcos below 1 ppm/°C (max). Users should be aware that the subsequent op-amp circuitry, including gain-setting resistors, may degrade performance considerably unless extreme care is used in design. In particular, low-drift precision op-amps and matched-tempco resistor arrays are essential. These aspects of precision circuit design are discussed in Chapter 5.

B. Precision unheated references

Clever chip design has made possible unheated references of nearly comparable stability. For example, the MAX6325 series from Maxim have tempcos of 1 ppm/°C (max), with no heater power or warm-up delays. Furthermore, they exhibit low noise and long-term drift. Their chief drawback is the difficulty in getting them! These high-stability references (LTZ1000, LM399, and MAX6325) all use buried zeners.

[135] But see the paragraph and footnote about ionizing radiation on page 684.

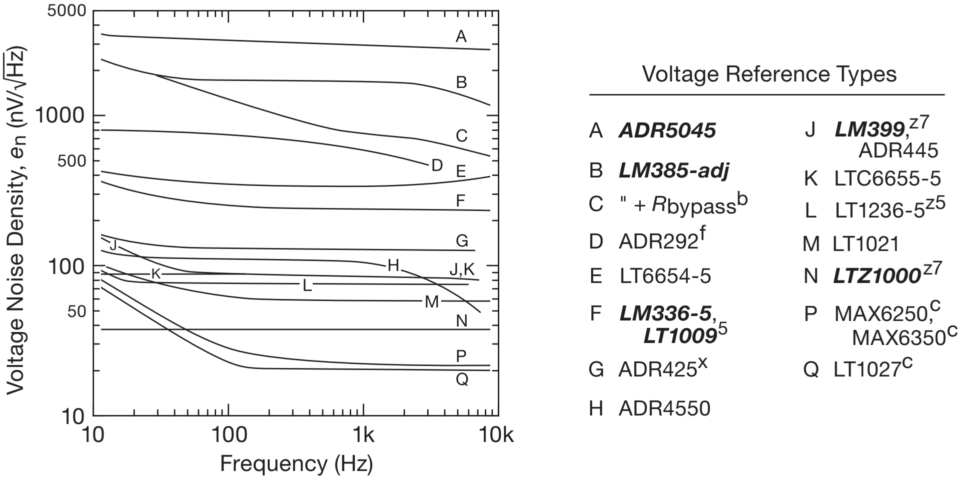


Figure 9.94. Noise density (e_n) versus frequency for a selection of voltage references. All are for 5 V output, except as noted; **boldface** part numbers are shunt type (2-terminal), the rest are series type (3-terminal). The LTZ1000 is operated at 4 mA. *Notes*: (5) 2.5 V reference, curve shown is 2× datasheet's e_n plot; (b) upper resistor bypassed; (c) with 1 μF noise reduction cap; (f) 4.096 V part; (x) "XFET" reference; (z5) buried zener, 5 V buffered output; (z7) 7 V buried zener.

9.10.6 Voltage reference noise

We mentioned briefly the business of *noise*, in connection with low-power references on page 679. You can always add filtering to suppress power supply or reference noise at higher frequencies (see the discussion of the *capacitance multiplier* in §8.15.1), but there's no substitute for a quiet reference at low frequencies, where the noise properties of the reference set a lower limit on output noise. The listings in Table 9.7 on page 677 and 9.8 on page 678 include datasheet values for integrated low-frequency noise (0.1–10 Hz, in units of μVpp), as well as rms noise voltage at somewhat higher frequencies (usually 10 Hz–10 kHz). In Figure 9.94 we've plotted noise-density curves (e_n, in units of nV/$\sqrt{\text{Hz}}$) for those references whose datasheets are considerate enough to provide such information. It's often useful to normalize the specified noise voltage values by the reference's voltage, to get a fair comparison among competing devices.

You can add lowpass filtering to reduce the noise from a voltage reference. Some references bring out an internal node on a "filter" pin (or "bypass," or "noise-reduction" pin) that you can bypass to ground; Table 9.3 indicates those in the "filter pin" column. Often the datasheets for such parts include numeric or graphical information to guide you in the choice of filter capacitor.[136]

Another technique you can use is the addition of an external lowpass filter, with an op-amp follower. Figure 9.95 shows this simple scheme, with an interesting twist: the basic lowpass filter is R_2C_2, with a time constant of 2.2 seconds (3 dB rolloff at 0.07 Hz). But why on earth is it perched atop C_1?! That's done in order to eliminate C_2's leakage current (which would produce an accuracy-damaging voltage drop across R_2) by bootstrapping the low side of C_2 – cute! The inclusion of R_1C_1 affects the rolloff and settling waveform, putting the 3 dB rolloff at 0.24 Hz and producing an 8% overshoot with a lengthened settling time (30 seconds) to 0.1%.[137] For this application you need a pretty good op-amp: input bias current low enough to prevent error from $\Delta V = I_B R_2$, and noise voltage low enough to add only insignificantly to the filtered reference's output. The OP-97E or LT1012A are similar and do the job well (or you could use a smaller R and larger C, permitting larger op-amp input current).

Generally speaking, a reference that runs at very low current will exhibit more noise, a trend evident in

[136] One of the more interesting pieces of such guidance appears in the LTC1844 datasheet, which cautions "Additionally, some ceramic capacitors have a piezoelectric response. A piezoelectric device generates voltage across its terminals due to mechanical stress, similar to the way a piezoelectric accelerometer or microphone works. For a ceramic capacitor the stress can be induced by vibrations in the system or thermal transients. The resulting voltages produced can cause appreciable amounts of noise, especially when a ceramic capacitor is used for noise bypassing." See the discussion in §*1x.3*.

[137] That is, with $R_1 = R_2$ and $C_1 = C_2$ the 3 dB rolloff frequency becomes $f_{-3\text{dB}} \approx 3.3/2\pi RC$, and the settling time to 0.1% (if you care) is approximately $\tau \approx 14RC$. Put a diode across R_2 to shorten the turn-on time.

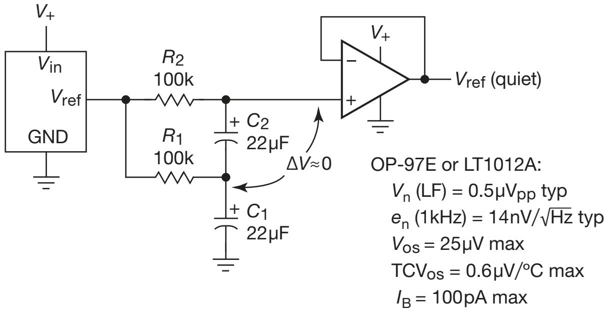

Figure 9.95. External lowpass filter with dc bootstrap quiets any voltage reference, while suppressing error from capacitor leakage currents. Use a quiet op-amp follower with low input current.

Table 9.8. This is easy to understand in the case of a bandgap (V_{BE}) reference, because BJT voltage noise decreases as the square root of collector current (see §8.3). You might conclude from this that a given shunt (2-terminal) IC reference would be quieter when biased at higher currents; but you would be wrong – a shunt reference runs its internal bandgap circuit at a current close to the part's "minimum operating current" (with corresponding noise voltage), and so running the reference at a higher current doesn't help.

9.10.7 Voltage references: additional Comments

As should be evident from Tables 9.7 and 9.8, there are lots of things to think about when selecting a voltage reference. Here are some bits of advice, to help the bewildered circuit designer (that's *you*).

Accuracy and drift There's *initial* accuracy, of course, often with a choice of grades designed by a suffix (-A, -B, etc.), with prices to match. But parts *age*, and a well-specified part will include a "long-term drift" figure (usually parts-per-million per thousand hours, or, perhaps more properly,[138] per $\sqrt{\text{kHr}}$), and sometimes a "thermal hysteresis" specification (the voltage offset after thermal cycling over the part's operating temperature range). Taking the LTC6655B (best grade) as an example, the initial accuracy is ±0.025%, the tempco is 1 ppm/°C (typ) and 2 ppm/°C (max), the long-term drift is 60 ppm/$\sqrt{\text{kHr}}$ (typ), and the thermal hysteresis is 35 ppm (typ) for thermal cycling between −40°C and +85°C. From these figures it's clear that initial accuracy is only a part of the story.

A caution about "temperature coefficient": most often we've used the description in terms of *slope*, i.e., ppm/°C (or μV/°C, etc.), giving perhaps a typical and a maximum (worst-case) value. But you'll sometimes see the description in terms of maximum deviation over the part's temperature range; an example is the LM385, where the specified worst-case *average* tempco of 150 ppm/°C is described in a footnote: "The average temperature coefficient is defined as the maximum deviation of reference voltage at all measured temperatures from T_{MIN} to T_{MAX}, divided by $T_{MAX}-T_{MIN}$." A maximum tempco so defined is guaranteed to be smaller than the maximum value of "slope" tempco (i.e., the maximum value of $\Delta V/\Delta T$ over the same temperature range), as you can convince yourself by drawing some wiggly curves. Figure 9.96 shows an example, adapted from the datasheet for the ADR4520–50 series of 3-terminal precision references.

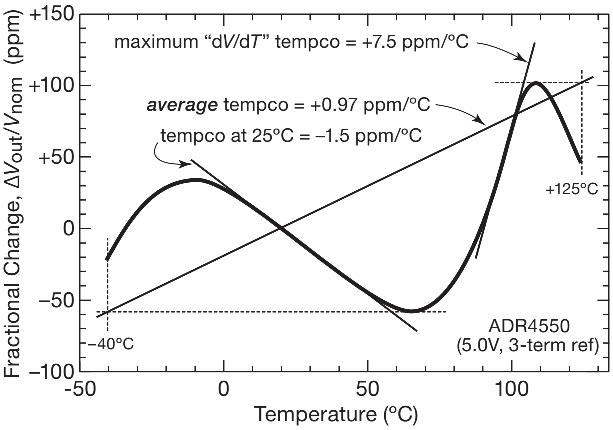

Figure 9.96. Three ways of defining the temperature coefficient of a voltage reference, illustrated with the ADR4550's serpentine datasheet curve. The datasheet's specified tempco is stated as 2 ppm/°C (max) over the full temperature range.

Some references include a "trim" terminal, which sounds like a great idea. But, as with op-amp offset trim configurations, it often provides *too much* trim range! You can try to remedy this by reconfiguring the trim network

[138] From the LTC6655 datasheet: "Long-term stability typically has a logarithmic characteristic and therefore, changes after 1000 hours tend to be much smaller than before that time. Total drift in the second thousand hours is normally less than one-third that of the first thousand hours with a continuing trend toward reduced drift with time. Long-term stability is also affected by differential stresses between the IC and the board material created during board assembly." Another bit of advice from LTC: "Significant improvement in long-term drift can be realized by preconditioning the IC with a 100–200 hour, 125°C burn in." A typical long-term drift spec is 60 ppm/$\sqrt{\text{kHr}}$. The datasheet for the REF5025 is instructive: it shows lower drift for the MSOP-8 package than an SO-8, 50 versus 90 ppm/$\sqrt{\text{kHr}}$, and it further shows 50 ppm/$\sqrt{\text{kHr}}$ for the first 1000 hours and 5 ppm/$\sqrt{\text{kHr}}$ for 1000 to 2000 hours. Better improvement than one gets from aging wine!

to supply less current. But a caution: some parts require that the external trim circuitry exhibit a specified temperature coefficient. Perhaps you're better off, as with op-amps, simply by choosing a reference with a tighter spec; a reference of better initial precision usually provides better tempco as well.

Self-heating Voltage references are happiest when they are only lightly loaded. If a reference IC is used to power a load, on-chip heating produces thermal gradients that can seriously degrade the part's accuracy and drift. For such applications it's best to buffer the output with an op-amp. Most good op-amps have lower noise and offset voltages than the voltage reference itself (you can do the calculation!), so it does not degrade the reference voltage. Quite the opposite, in fact, considering the degrading effect of substantial load current with an unbuffered reference – that's the whole point. And even middle-of-the-road op-amps have far lower tempcos of offset voltage than most voltage references (but use a precision op-amp for a precision reference, as we did in Figure 9.90).

An op-amp buffer also provides an ideal opportunity to add an *RC* noise filter; see §9.10.6, with its unusual filter configuration (Figure 9.95).

External influences As the footnote on the previous page suggests, you can seriously degrade a precision reference's accuracy by physically stressing the package; the stability is also compromised by the gradual infiltration of humidity through the plastic package. Sometimes you'll see improved specs for hermetically sealed package versions: the LT1236LS8 is packaged in hermetic LCC, and offers an improved drift specification relative to the plastic LT1236 version. And the most stable references are offered exclusively in hermetic metal packages to circumvent these problems: for example the LM399 (thermally stabilized buried zener reference) comes only in a TO-46 metal can; it specifies an excellent long-term drift specification of 8 ppm/$\sqrt{\text{kHr}}$ (typ). Pretty good – but handily outdone by the LTZ1000 "Ultra Precision" shunt reference (also in a metal-hermetic package), with a spectacular 0.3 ppm/$\sqrt{\text{kHr}}$ (typ)!

A recent contribution to the gallery of badnesses is the exposure of floating-gate references (§9.10.4) to ionizing radiation, most seriously in the form of airport luggage inspection x-ray machines or PCB post-assembly x-ray inspection. According to Intersil's Application Note,[139] by actual experiment at US airports the voltage shift for nine samples of a 5.0 V floating-gate reference (ISL21009) after six passes through carry-on x-ray machines averaged 25 ppm (negative); this is small compared with the initial accuracy of ±100 ppm, but in the same ballpark as the specified long-term (1000 hour) drift and hysteresis specs (both 50 ppm, typ).

Line and load regulation You've got to worry about regulation against input-voltage variations ("line regulation") for a voltage reference that is powered from unregulated dc, for example in a battery-powered application. For such use, a reference isn't suitable that boasts a worst-case tempco of 3 ppm/°C, but whose output varies 200 ppm per volt of input change (these are the specs of an entry in Table 9.8), though that reference would be fine if powered from a reasonably regulated dc rail. For this reason we've listed the worst-case line regulation for the references in Table 9.8 – these vary over nearly a 1000:1 range!

Load regulation matters also if you are using the reference as a voltage regulator, i.e., to power a load that draws a few milliamps, perhaps with load-current variation. But we discourage such use of a precision reference, because it produces on-chip heating and drifts; for that reason (and lack of space) we've not listed load regulation specifications in the tables.

9.11 Commercial power-supply modules

Throughout the chapter we have described how to design your own regulated power supply, implicitly assuming that is the best thing to do. Only in the discussion of line-operated switching power supplies did we suggest that the better part of valor is to swallow your pride and buy a commercial power supply.[140]

As the economic realities of life would have it, however, the best approach is often to use one of the many commercial power supplies sold by companies such as Artesyn, Astec, Astrodyne, Acopian, Ault, Condor, CUI, Elpac, Globtek, Lambda, Omron, Panasonic, Phihong, Power-One, V-Infinity, and literally hundreds more. They offer

[139] Intersil App Note #1533, 23Feb2010, *X-Ray Effects on Intersil FGA References*, which explains "The floating gate capacitor is susceptible to radiation degradation from various particles and photons in excessive doses, as the electrons generated in the silicon dioxide are collected in the storage cell. Normal radiation from cosmic rays or radon which exist in small amounts on earth will not cause the FGA reference voltage to drift appreciably for over 100 years. Artificial sources of radiation such as X-ray machines are capable of high enough doses to cause output voltage shift. Note that Flash memory devices are also susceptible to X-ray radiation degradation, although to a lesser degree as they are not precision analog devices."

[140] "Dude, this is a league game."

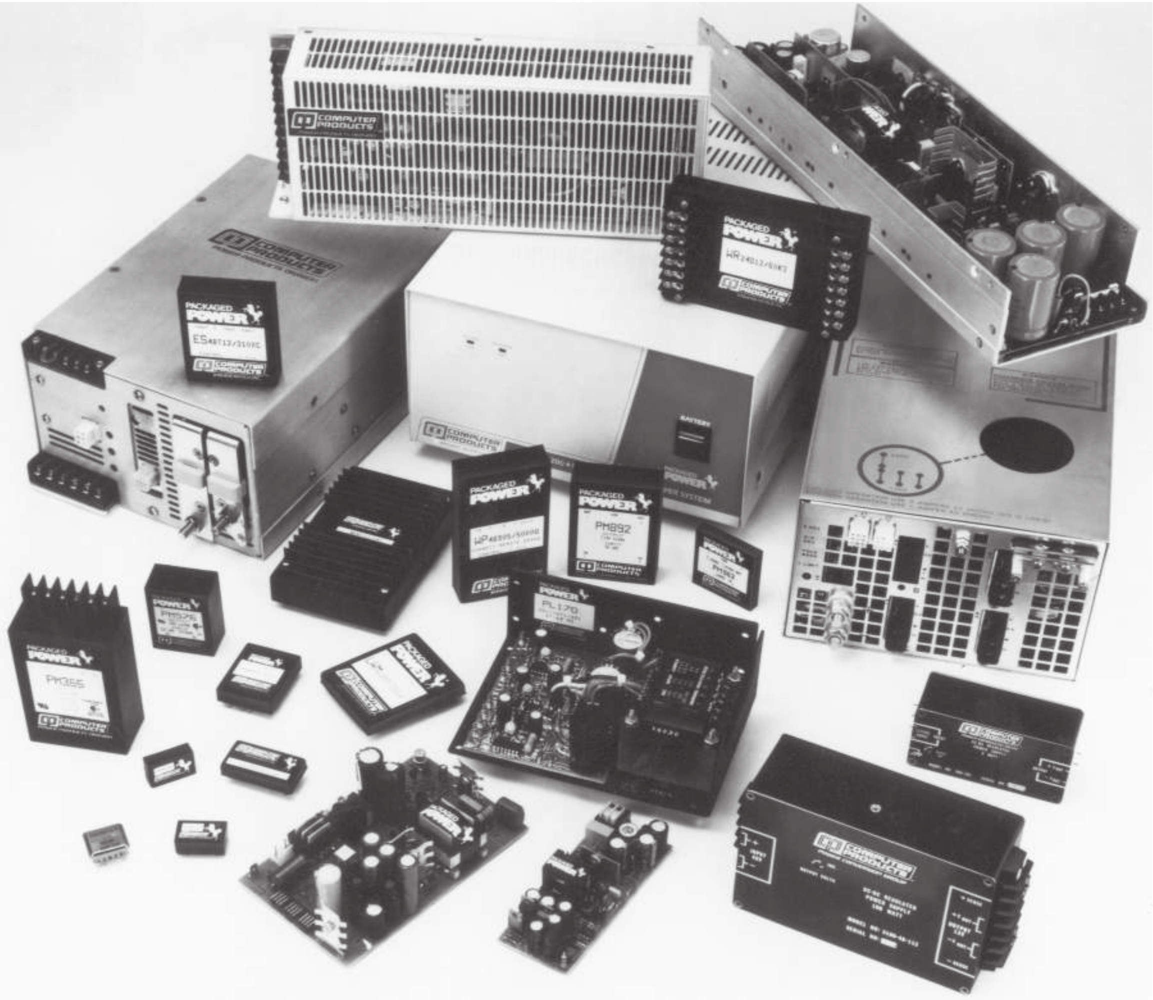

Figure 9.97. Commercial power supplies come in a variety of shapes and sizes, including potted modules, open-frame units, and fully enclosed boxes. (Courtesy of Computer Products, Inc.)

both switching and linear supplies, and they come in several basic packages (Figure 9.97).

- “Board-mount” supplies: these are relatively small packages, no more than a few inches on a side, with stiff wire leads on the bottom so you can mount them directly on a circuit board. Both ac–dc supplies and dc–dc converters come in this style, and they may be of “potted” or open construction. You can get linear or switchers, and they come with single or multiple output voltages. A typical PC-mounting open-case ac–dc triple-output switching supply provides +5 V at 2 A and ±12 V at 0.2 A and costs about $30 in small quantities. Linear board-mount supplies fall in the 1 W to 10 W range, switchers in the 15 W to 50 W range. In the dc–dc category (which are always switching converters) you can get isolated or non-isolated converters.[141] These are commonly used to generate additional needed voltages (e.g., ±15 V from +5 V), as we’ve seen in this chapter. But another important use is point-of-load (POL) conversion, for example to create +1.0 V at 75 A right at the chip’s pins, to power a high-performance microprocessor. POL converters come

[141] Common package styles include the “full-brick,” “half-brick,” and “quarter-brick” configurations (4.6″×2.2″, 2.3″×2.2″, and 1.45″×2.3″, respectively), originated by Vicor; these span the range of 50–500 W, and may include an aluminum baseplate for heatsinking.

in regulated and unregulated versions, the latter with a fixed reduction ratio from a regulated dc input.[142]

- "Chassis-mount" supplies: these are larger power supplies, intended to be fastened to the inside of a larger instrument. They come in both "open frame" and "enclosed-case" styles; the former have all the components on display, whereas the latter (for example, the "ATX" power supplies you find in a desktop or server computer) are wrapped in a perforated metal box. They are available in an enormous variety of voltages, both single and multiple outputs. Chassis-mount linear supplies fall in the 10–200 W range, switchers in the 20–1500 W range.
- "External adapters": these are the familiar black "wall-wart" and desktop ("desk-wart"?) that come with small consumer electronic gadgets, and which are widely available from dozens of manufacturers. They actually come in three varieties, namely (a) step-down ac transformer only, (b) unregulated dc supply, and (c) complete regulated dc supply; the latter can be either linear or switcher. Some of the switching units allow a full 95 to 252 Vac input range, useful for traveling instruments.
- "DIN-rail mount" supplies: a popular way of mounting some kinds of industrial electronics (relays, circuit breakers, surge protectors, connectors, terminal blocks, and the like) is the European-originated DIN rail, which consists of a length of formed metal rail, 35 mm in width. Rail mounting makes it easy to assemble electrical equipment in industrial settings, and you can get a variety of switching supplies in this style.

9.12 Energy storage: batteries and capacitors

No chapter dealing with regulators and power conversion would be complete without a discussion of portable power. That usually means batteries (replaceable or rechargeable), sometimes assisted by energy-storage capacitors. Contemporary life is awash in portable electronic devices, which have driven the development and availability of improved batteries and capacitors. In this section we provide an introduction to battery choices and properties, and to the use of capacitors for energy storage. Because this chapter is already, well, *huge*, we defer further discussion of the care and feeding of batteries to Chapter *9x* in the advanced volume.[143]

As we remarked in the previous edition, the (now out-of-print) Duracell "Comprehensive Battery Guide" listed 133 off-the-shelf batteries, with descriptions like zinc-carbon, alkaline manganese, lithium, mercury, silver, zinc-air, and nickel-cadmium. There are even subclasses, for example Li/FeS_2, Li/MnO_2, Li/SO_2, Li/$SOCl_2$, and "lithium solid state." And from other manufacturers you can get sealed lead-acid and gel-type batteries. For the truly exotic application you might even want to consider fuel cells or radioactive thermal generators. What are all these batteries? How do you choose what's best for your portable widget?

The foregoing list divides into so-called *primary* and *secondary* batteries. Primary batteries are designed for a single discharge cycle only, i.e., they're nonrechargeable. Secondary cells (lithium-ion, nickel metal-hydride, and sealed lead-acid gel-type), by comparison, are designed to be recharged, typically from 200 to 1000 times. You usually make your choice among battery types based on trade-offs among price, energy density, shelf life, constancy of voltage during discharge, peak current capability, temperature range, and availability. Once you've picked the right battery chemistry, you figure out which battery (or series combination of batteries) has enough energy content for the job.

Fortunately, it's pretty easy to eliminate most of the batteries in the catalogs, if you follow our first suggestion: *Avoid hard-to-get batteries*. Besides being hard to find, they're usually not fresh. So it's usually better to stick with the varieties available at the drugstore, or perhaps photography store, even if it results in somewhat less than optimum design. We particularly recommend the use of commonly available batteries in the design of any consumer electronic device; as consumers ourselves, we shun those inexpensive marvels that use exotic and expensive batteries. (Remember those early smoke detectors that used an 11.2 V mercury battery? They're better forgotten...)

[142] Although *unregulated* POLs might be expected to deliver poor "regulation," in fact they can surprise you: for example, Vicor's VTM series of high-efficiency fixed-ratio "current multipliers" (i.e., voltage step-down) include a unit rated at 130 A and 40:1 stepdown (thus 1.0 Vdc output from 40 Vdc input) with a worst-case output impedance of 0.00094 Ω at 100°C (thus < 0.1 V output change for a 100 A current step). Not bad. And you can always add feedback to the regulated supply that delivers the +40 Vdc input, to further stiffen the output for load change variations within the loop bandwidth. Moreover, these converters operate at 1.2 MHz switching frequency, so the residual ripple is at 2.4 MHz, conveniently bypassed with relatively small filter capacitors. In fact, the datasheet shows pretty good output-voltage waveforms with 0–130 A load steps, exhibiting essentially no overshoot even when the output is not filtered or bypassed with any external capacitor at all.

[143] See also the expansive discussion in Chapter 14 of the previous edition of this book.

9.12.1 Battery characteristics

If you want a primary (non-rechargeable) battery, your choices are essentially alkaline ("Zn/MnO_2") or one of the lithium chemistries ("Li/MnO_2," "Li/FeS_2," or "Li/$SOCl_2$"). Lithium batteries have a higher single-cell terminal voltage (∼3 V), higher energy density, flatter discharge curves (i.e., constancy of voltage as their life ebbs, see Figure 9.98), better performance at low temperatures (where alkaline batteries just fade away) and higher price. By contrast, the alkaline types (the basic grocery-store battery) are cheap and plentiful, and you can buy them inexpensively at "big-box" stores (if you don't mind getting them in packages of several dozen); they're fine for undemanding applications.

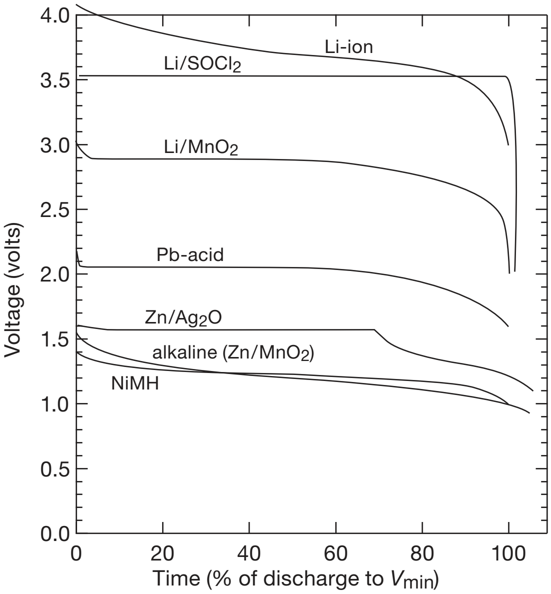

Figure 9.98. Battery discharge curves, as shown on the respective datasheets. In each case 100% discharge corresponds to the voltages as listed in the notes to Table 9.9.

Your choices for a secondary (rechargeable) battery are lithium-ion ("Li-ion"), nickel metal-hydride ("NiMH"), or lead-acid ("Pb-acid"). Li-ion batteries are lightweight, and provide the highest energy density and charge retention, but there are safety issues with lithium chemistries, and these aren't the kind of thing you buy off-the-shelf; they are the darlings of the manufacturers of smartphones, tablets, and laptop computers. Nickel metal-hydride batteries are the more common "consumer" rechargeables, and they come in standard form factors (AA, 9V sizes); early formulations had discouraging memory effects and self-discharge rates (∼30%/month!), but recent versions ("LSD" – low self-discharge) are greatly improved. Lead-acid batteries are the heavy lifters, with their very low internal resistance; they are dominant in uninterruptible power supplies (UPSs) and other power-hungry devices (like boats and automobiles!); they don't come in tiny packages, but you can get them in sizes as small as D-cells.

Recharging secondary batteries can be a complicated business, particularly for fussy chemistries like Li-ion. Taking first the example of the humble lead-acid battery, a good charging method is the so-called two-step technique: after a preliminary "trickle" charge, you begin with a high-current "bulk-charge" phase, applying a fixed high current I_{max} until the battery reaches the "overcharge voltage," V_{OC}. You then hold the voltage constant at V_{OC}, monitoring the (dropping) current until it reaches the "overcharge transition current," I_{OCT}. You then hold a constant "float voltage," V_F, which is less than V_{OC}, across the battery. For a 12 V 2.5 Ah lead-acid battery, typical values are I_{max}=0.5 A, V_{OC}=14.8 V, I_{OCT}=0.05 A, and V_F=14.0 V.

Although this all sounds rather complicated, it results in rapid recharge of the battery without damage. TI makes some nice ICs, for example the UC3906 and BQ24450, that have just about everything you need to do the job. They include internal voltage references that track the temperature characteristics of lead-acid cells, and they require only an external *pnp* pass transistor and four parameter-setting resistors.

Charging Li-ion batteries requires a bit more care, but once again the semiconductor industry has responded with easy-to-use single-chip solutions. Figure 9.99 shows an example of the kind of thing that is commonly seen. Here the power from a USB port (+5 V nominal, able to supply 100 mA or 500 mA) is used to charge a single-cell 4.2 V Li-ion battery; the latter's output (which is down to ∼3.5 V when mostly discharged) is reduced to a stable +3.3 V logic-supply level with a linear LDO regulator. In this circuit the charger IC (U_1) takes care of the charging current and voltage profiles, and it includes safety features to sense over-voltage, short-circuit, and both chip and battery over-temperature (the latter uses the optional thermistor, which is found in many battery packs, or can be added externally). The cell temperature is also used to adjust the charging current or voltage when the temperature is outside the normal 10–45°C range, according to what's called JEITA standards. The ISET2 pin sets the input current limit as indicated; the USB protocol allows 100 mA drain initially, which can be increased to 500 mA by a negotiation through the USB data pins D− and D+ (this requires a microcontroller or other smart chip, not shown here). The LEDs indicate status (charging, input power good). The

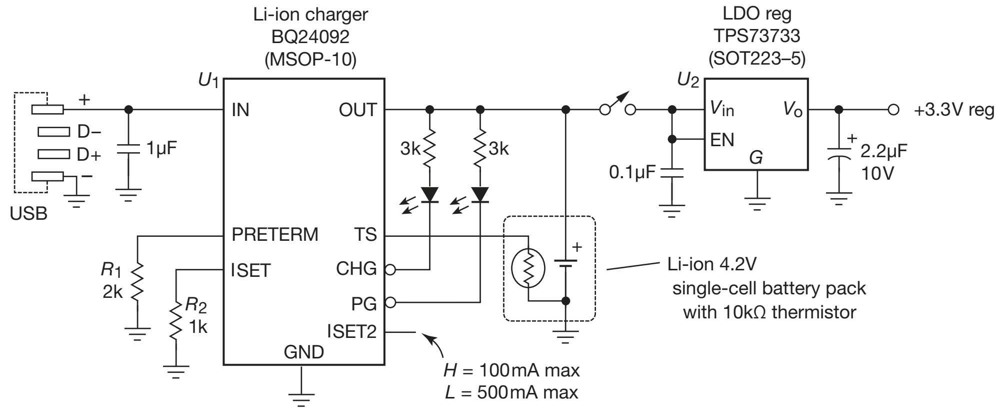

Figure 9.99. The +5 V provided by a USB port is ideal for charging a single-cell Li-ion battery; LDO regulator U_2 converts the battery's 3.5–4.2 V output to stable +3.3 V. See text for discussion of what to do with the USB's D+ and D− pins.

care and feeding of Li-ion batteries is discussed in more detail in §*9x.2*.

9.12.2 Choosing a battery

Table 9.9 lists characteristics of most of the batteries you might consider, and Figure 9.100 shows an assortment of common battery types. Here is a capsule summary of the most distinguishing characteristics of available batteries intended for use in electronic devices.

Primary Batteries (non-rechargeable)

Alkaline (Zn/MnO_2) Inexpensive; widely available (1.5V/cell AA, C, & D, and 9V pkgs); excellent shelf life; good low-temperature performance; sloping discharge.

Lithium (Li/MnO_2) High energy-density; good high-drain performance; 3V AA, C, & D, and 9V pkgs; excellent shelf life; excellent low-temperature performance; flat discharge.

Lithium (Li/FeS_2) Extraordinary shelf life (90% after 15 yrs); excellent low-temperature performance; flat discharge.

Lithium ($LiSOCl_2$) Extraordinary low-temperature performance (to −55°C); excellent shelf life; very flat discharge (but varies with $I_{\rm load}$).

Silver (Zn/Ag_2O) Button cells; very flat discharge.

Zinc-air (ZnO_2) High energy-density (it breathes); flat discharge; short life after seal is removed.

Secondary Batteries (rechargeable)

Lithium-ion (Li-ion) High energy-density; popular; 3.6V/cell; flat discharge; very low self-discharge; safety issues.

Nickel metal-hydride (NiMH) Inexpensive & popular; standard packages (AA, 9V); 1.2V/cell; flat discharge; recent formulations have low self-discharge.

Lead-acid (Pb-acid) High current (low $R_{\rm int}$); 2V/cell; flat discharge; moderate self-discharge.

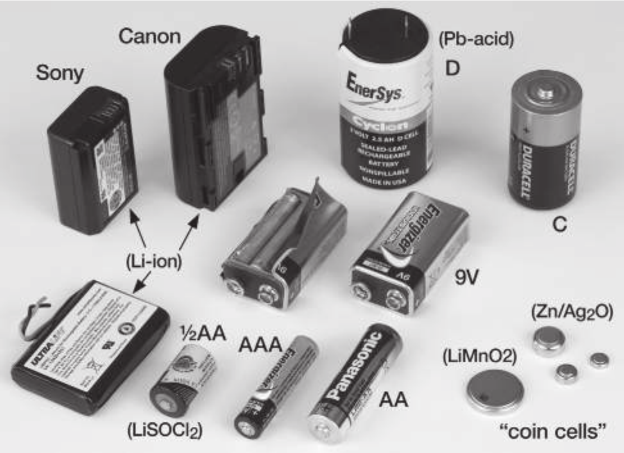

Figure 9.100. A collection of battery specimens. The Li-ion and Pb-acid types are rechargeable ("secondary"); the rest are nonrechargeable ("primary"). Those with unlabeled chemistry are alkaline. Some can opener activity revealed the 9 V innards – six itty-bitty alkaline cells.

9.12.3 Energy storage in capacitors

Batteries store energy *chemically*, either with reversible reactions (rechargeable batteries) or irreversible reactions (non-rechargeable). But batteries aren't the only way to store electrical energy: a charged capacitor stores $CV^2/2$ joules in its electric field, and a current-carrying inductor

stores $LI^2/2$ joules in its magnetic field. In quantitative terms these stored energies are dwarfed by those stored in batteries; but for some applications capacitors are just what you want. Among their other virtues, they have long lives, infinite endurance (charge/discharge cycles), the ability to be fully charged and discharged in seconds (or fractions of a second), and very high peak current capability (i.e., very low internal resistance, ESR). A storage capacitor, teamed with a conventional battery, can provide the best of both worlds: extraordinary peak power along with substantial energy storage. Furthermore, the energy density of recent "supercapacitors" is creeping up on the tail end of batteries. These points are seen nicely in a *Ragone plot* (Figure 9.101). To put numbers on it, we've collected data on some real-world representative capacitors and batteries; these are listed in Table 9.10. Capacitors excel in low ESR and high peak current (and therefore in high *power* density: W/gm or W/m^3), but batteries beat the pants off capacitors in *energy* density (Wh/gm or Wh/m^3).

9.13 Additional topics in power regulation

9.13.1 Overvoltage crowbars

As we remarked in §9.1.1C, it is often a good idea to include some sort of overvoltage protection at the output of a regulated supply. Take, for instance, a +3.3 V high-current switching supply used to power a large digital system. Failure of a component in the regulation circuit (even something as simple as a resistor in the output voltage sensing divider) can cause the output voltage to soar, with devastating results.

Although a fuse probably will blow, what's involved is a race between the fuse and the "silicon fuse" that is constituted by the rest of the circuit; the rest of the circuit will probably respond first! This problem is most serious with low-voltage logic and VLSI, which operate from dc supply voltages as low as +1.0 V, and cannot tolerate an overvoltage of as much as 1 V without damage.[144] Another situation with considerable disaster potential arises when you operate something from a wide-range "bench" supply, where the unregulated input to the linear regulator may be 40 volts or more, regardless of the output voltage. We've encountered some aberrant bench supplies that soar to their full output voltage, briefly, when you switch them off. But "briefly" is all it takes to ruin your whole day!

A. Zener sensing

Figure 9.102 shows three classic crowbar circuits – (A) is simple and robust, but inflexible; (B) uses an IC trigger circuit that lets you set the trigger point more accurately; and

[144] And sometimes much less: the datasheets for Xilinx's Virtex-5 and Virtex-6 FPGAs, for example, specify a core voltage of 1.0 V±5%, with an absolute maximum of 1.1 V! The Virtex-7 has the same 1.1 V limit and 1.0 V nominal core voltage, but it tightens the tolerance on the latter to ±3%; ouch!

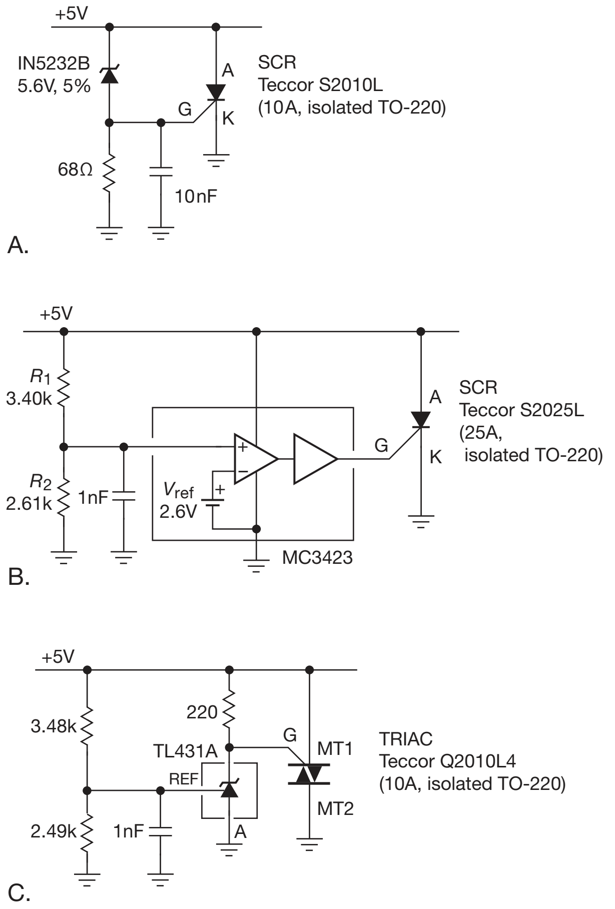

Figure 9.102. Overvoltage crowbars.

(C) uses a popular and precise 3-terminal "shunt regulator," with 1% setpoint accuracy.

In each case you hook the circuit between the regulated output terminal and ground; no additional dc supply is needed – the circuits are "powered" by the dc line they protect. For the simple circuit (Figure 9.102A) the SCR is turned on if the dc voltage exceeds the zener voltage plus a diode drop (about 6.2 V for the zener shown), and it remains in a conducting state until its anode current drops below a few milliamps. An inexpensive SCR like the S2010L can sink 10 amps continuously and withstand 100 amp surge currents; its voltage drop in the conducting state is typically 1.1 V at 10 A. The particular unit here is electrically isolated, so you can attach it directly to the metal chassis (SCRs usually connect their anode to the attachment tab, so normally you'd have to use an insulating spacer, etc.). The 68 Ω resistor is provided to generate a reasonable zener current (10 mA) at SCR turn-on, and the capacitor is added to prevent crowbar triggering on harmless short spikes.

There are several problems with this simple crowbar circuit, mostly involving the choice of zener voltage. Zeners are available in discrete values only, with generally poor tolerances and (often) soft knees in the *VI* characteristic. The desired crowbar trigger voltage may involve rather tight tolerances. Consider a 5V supply for digital logic, whose typical 5% or 10% tolerance demands a crowbar voltage at least 5.5V. But that minimum is raised because of transient overshoot of the regulated supply: the voltage can jump when there's an abrupt load current change, creating a spike followed by some ringing.

This problem is exacerbated by remote sensing via long (inductive) sense leads. The resultant ringing puts glitches on the supply that we don't want to trigger the crowbar. The result is that the crowbar voltage should be set not less than about 6.0 V, but it cannot exceed 7.0 V without risk of damage to the logic circuits. When you fold in zener tolerance, the discrete voltages actually available, and SCR trigger voltage tolerances, you've got a tricky problem. In the example shown earlier, the crowbar threshold could lie between 5.9 and 6.6 V, even using the relatively precise 5% zener indicated.

B. IC overvoltage sensing

The second circuit (Figure 9.102B) addresses these problems[145] by using a crowbar trigger IC, in this case the venerable MC3423, which has internal voltage reference (2.6 V±6%), comparators, and SCR drivers. Here we've set the external divider R_1R_2 to trigger at 6.0 V, and we've chosen a 25 A (continuous) SCR, also with an isolated mounting tab; it costs about a dollar. The MC3423 belongs to the family of so-called *power-supply supervisory* chips; the most sophisticated of these not only sense undervoltage and overvoltage, but can switch over to battery backup when ac power fails, generate a power-on reset signal on return of normal power, and continually check for lockup conditions in microprocessor circuitry.

The third circuit (Figure 9.102C) dispenses with a supervisor IC, using instead the wildly popular[146] TL431 shunt regulator to trigger a triac (a bidirectional SCR) when the voltage presented to the reference input exceeds the internal reference voltage of 2.495 V±1%; that causes heavy

[145] And others, for example the desirability of fast gate overdrive when crowbarring large capacitive loads; see ON Semiconductor MC3423 datasheet.

[146] A quick check of DigiKey's excellent website shows approximately a half million pieces in stock, in 134 variants, from five manufacturers. They cost as little as $0.09 in large quantities.

conduction from cathode (K) to ground, triggering the triac in what's known as "third quadrant" operation.[147] This circuit can be flexibly extended to higher supply voltages (the TL431 operates to 37 V); and, with the low-voltage TLV431 variant (whose internal reference is 1.240 V) to very low trigger voltages.

The preceding circuits, like all crowbars, put an unrelenting 1 V "short circuit" across the supply when triggered by an overvoltage condition, and it can be reset only by turning off the supply. Because the SCR maintains a low voltage while conducting, there isn't much problem with the crowbar itself failing from overheating. As a result, these are reliable crowbar circuits. It is essential that the regulated supply have some sort of current limiting, or at least fusing, to handle the short. There may be overheating problems with the supply after the crowbar fires. In particular, if the supply includes internal current limiting, the fuse won't blow, and the supply will sit in the "crowbarred" state with the output at low voltage, until someone notices. Foldback current limiting of the regulated supply would be a good solution here.

C. Clamps

Another possible solution to overvoltage protection is to put a power zener, or its equivalent, across the supply terminals. This avoids the problems of false triggering on spikes, because the zener will stop drawing current when the overvoltage condition disappears (unlike an SCR or triac, which have the memory of an elephant). However, a crowbar consisting of a simple power zener itself has its own problems. If the regulator fails, the crowbar has to contend with high power dissipation ($V_{\text{zener}}I_{\text{limit}}$) and may itself fail. We witnessed just such a failure in a commercial 15V 4A magnetic disk supply. When the pass transistor failed, the 16V 50W power zener found itself dissipating more than rated power, and it proceeded to fail too.

A better alternative, if you really want a power zener, is an "active zener" constructed from a small zener and a power transistor. Figure 9.103 shows two such circuits, in which a zener pulls the base or gate of a transistor into conduction, with a pull-down resistor to bring the zener current into the knee region at transistor turn-on. The TIP142 (in Figure 9.103A) is a popular Darlington bipolar power transistor, priced around $1, good for 75 W dissipation at 75°C case temperature, and with a minimum beta of 1000 at 5 A. For higher voltage and current, and where effective zener voltage accuracy is not critical, the MOSFET circuit (Figure 9.103B) is better: most MOSFETs do not have the second-breakdown-limited safe-operating areas of BJTs, and they are widely available in robust high-power versions. The circuit shown permits 130 W or 300 W dissipation at 75°C case temperature, for the IRF1407 or IRFP2907, respectively. These are "automotive" MOSFETs, rated at 75 V, and priced at $2.50 and $10, respectively. Note particularly the high peak current rating, limited only by transient thermal resistance (discussed in Chapter *9x*). One caution: a MOSFET clamp is prone to oscillation, particularly when implemented with a high-voltage (low-capacitance) part.

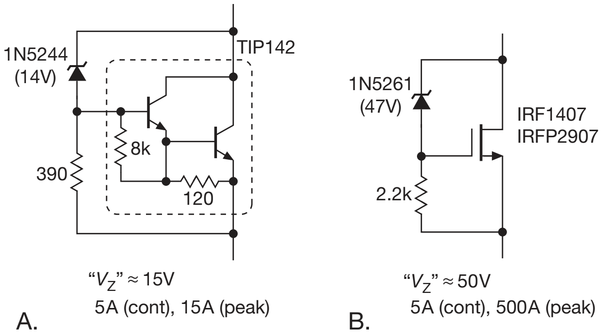

Figure 9.103. Active power zener.

D. Low-voltage clamp–crowbar

These techniques – zener crowbars, IC crowbars, and zener clamps – are generally inadequate for the low-voltage, high-current supplies used to power contemporary microprocessor systems; these may require +3.3 V (or lower) at 50–100 A: low-voltage zeners are imprecise and suffer from a soft knee, and crowbar trigger circuits like the MC3423 require too high a supply voltage (e.g., 4.5 V minimum for the 3423). Also, when an SCR triggers, it crowbars the supply until the power is cycled – not a good thing to do to a computer, particularly if the cause was a momentary (and harmless) transient.

We've wrestled with this problem, and, following the teachings of Billings,[148] have come up with a nice circuit for a low-voltage clamp–crowbar: it is adjustable, and it will operate down to 1.2 V. And (best of all) it operates in two steps – it *clamps* the transient, up to a peak current of 5–10 A; but if the transient persists, or rises above that current, it throws in the towel and fires a crowbar SCR that

[147] First and second quadrants have MT2 more positive than MT1, and trigger when the Gate is brought positive or negative with respect to MT1, respectively; third and fourth quadrants have MT2 more negative than MT1, and trigger when the Gate is brought negative or positive with respect to MT1, respectively. Quadrants two and four suffer from lower gate sensitivity.

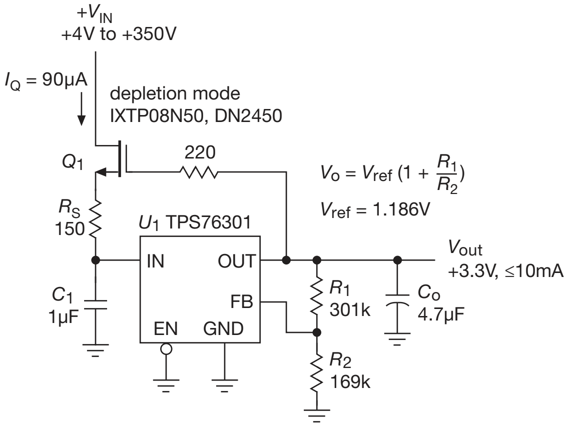
[148] "Overvoltage clamping with SCR 'crowbar' backup," in K. Billings, *Switchmode Power Supply Handbook*, McGraw-Hill, 2nd ed. (1999).

can handle 70 A continuous (1000 A peak). Because you may be dealing with a high-power system, it also has provision to switch off the ac input. *That* sure is a belt-and-suspenders solution! Because this is a bit off the beaten path, we've grouped this material with other advanced topics in Chapter *9x*.

9.13.2 Extending input-voltage range

As mentioned in §§9.3.12 and 3.6.2, linear regulators have a limited range of input voltage, typically +20 V to +30 V for BJT types, or as little as +5.5 V for CMOS types. Figure 9.104 (a completion of the block diagram in Figure 3.114) shows a nice way to extend the permissible range of $V_{\rm IN}$, to as much as 1000 V. Q_1 is a high-voltage depletion-mode MOSFET (see Table 3.6), here configured as an input follower to hold U_1's $V_{\rm IN}$ a few volts above its regulated output. For the parts shown, $V_{\rm GS}$ is at least -1.5 V, a comfortable margin for any LDO;[149] and their rated maximum $V_{\rm DS}$ of 400 V and 500 V provides plenty of input-voltage flexibility (substitute an IXTP08N100 if you want to go to 1 kV).

A few details. (a) In this circuit we've used a small gate resistor to suppress the oscillation tendency of high voltage MOSFETs. (b) The source resistor $R_{\rm S}$ sets an output current limit of approximately $V_{\rm GS}/R_{\rm S}$, which is essential here because this regulator by itself is capable of output currents to 350 mA, which would cause more than 150 W dissipation in Q_1 for $V_{\rm IN}$=500 V. Here we've chosen $R_{\rm S}$ for $I_{\rm lim}$~10 mA, thus 3.5 W maximum dissipation, handled easily with a modest heatsink attached to Q_1 in its TO-220 power package. (c) A power resistor could be added in Q_1's drain, to offload some of its power dissipation. (d) Low-dropout regulators specify (and require!) a minimum output capacitor $C_{\rm out}$ for stability (along with a specification of allowable range of its effective series resistance ESR); the value shown meets the specification for the TPS76301. (e) Some alternative choices for a fixed-voltage (+3.3 V; omit R_1 and R_2) low-power LDO are listed, with a few relevant parameters. All but the LM2936 are available also in adjustable versions, set with a resistive divider as we've done with the TPS76301 (but refer to their datasheets for $V_{\rm ref}$ and divider resistances).



Fixed 3.3V LDO choices for U_1

	$I_{\rm Q}$	$V_{\rm IN}$	$C_{\rm O}$	$V_{\rm DO}$		
	typ	max	min	max	@$I_{\rm load}$

TPS71533	3.2	24	0.47	740	50	SC-70

Figure 9.104. Extending LDO input-voltage range. The listing includes some other low-power 3.3 V fixed-voltage LDO choices.

9.13.3 Foldback current limiting

In §9.1 we showed the basic current-limit circuit, which is often adequate to prevent damage to the regulator or load during a fault condition. However, for a regulator with simple current limiting, transistor dissipation is maximum when the output is shorted to ground (either accidentally or through some circuit malfunction), and it exceeds the maximum value of dissipation that would otherwise occur under normal load conditions. Look, for instance, at the regulator circuit of Figure 9.105, designed to deliver +15 V at currents up to 1 A. If it were equipped with simple current limiting, the pass transistor would dissipate up to 25 watts with the output shorted (+25 V input, current limit at 1 A), whereas the worst-case dissipation under normal load conditions is 10 watts (10 V drop at 1 A). And the situation is even worse in circuits in which the voltage normally dropped by the pass transistor is a smaller fraction of the output voltage.

You get into a similar problem with push–pull power amplifiers. Under normal conditions you have maximum load current when the voltage across the transistors is minimum (near the extremes of output swing), and you have

[149] The dropout voltage available from the depletion-mode FET can easily be increased (by a factor of 2× or 3× if necessary) by connecting the gate to a resistive divider between the LDO's output and the FET's source terminal. Note that this raises the minimum output load current.

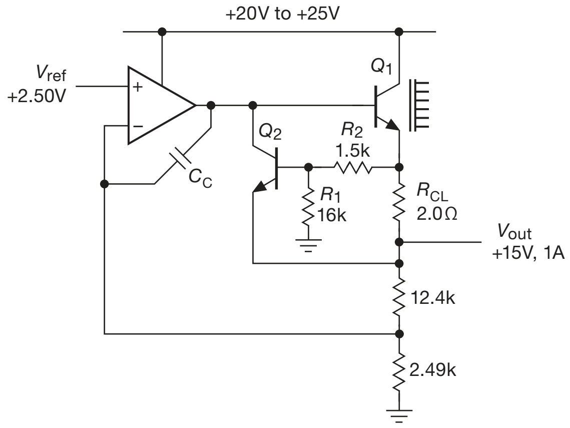

Figure 9.105. Linear regulator with foldback current limiting.

Figure 9.106. Foldback current limiting for the circuit of Figure 9.105.

maximum voltage across the transistors when the current is nearly zero (zero output voltage). With a short-circuit load, on the other hand, you have maximum load current at the worst possible time, namely, with full supply voltage across the transistor. This results in much higher transistor dissipation than normal.

The brute-force solution to this problem is to use massive heatsinks and transistors of higher power ratings (and safe-operating area; see §9.4.2) than necessary. Even so, it isn't a good idea to have large currents flowing into the powered circuit under fault conditions, because other components in the circuit may then be damaged. A better solution is to use *foldback* current limiting, a circuit technique that reduces the output current under short-circuit or overload conditions.

Look again at Figure 9.105. The divider at the base of the current-limiting transistor Q_2 provides the foldback. At +15 V output (the normal value) the circuit will limit at about 1 A, because Q_2's base is then at +15.55 V while its emitter is at +15 (V_{BE} is typically somewhat below the usual 0.6 V in the hot environment of power electronics). But the short-circuit current is less; with the output shorted to ground, the output current is about 0.3 A, holding Q_1's dissipation down to *less* (about 7.5 W) than in the full-load case (10 W). This is highly desirable, since excessive heatsinking is not now required, and the thermal design need only satisfy the full-load requirements. The choice of the three resistors in the current-limiting circuit sets the short-circuit current, for a given full-load current limit; see Figure 9.106.

An important caution: use care in choosing the short-circuit current, because it is possible to be overzealous and design a supply that will not "start up" into certain loads. Figure 9.107 shows the situation with two common nonlinear loads: an incandescent lamp (whose resistance rises with voltage), and a linear regulator's input (which begins as an open circuit, then looks like its load resistance while operating below dropout, and finally forms a constant-current load above dropout). As a rough guide, when designing a foldback circuit, the short-circuit current limit should be set no less than one-third to one-half the maximum load current at full output voltage.

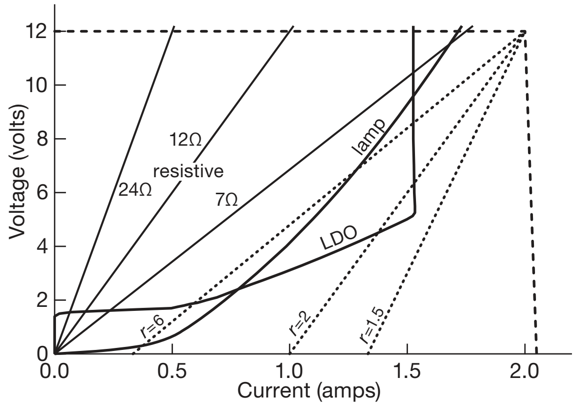

Figure 9.107. Excessive foldback may prevent startup into some loads. We measured VI curves for an automotive lamp (12 V, 21 W) and for a 5 V low-dropout regulator with 3.3 Ω load. The dashed line is normal 2 A current limiting, and the dotted lines show three values of foldback current limiting. A foldback current ratio of $r = I_{max}/I_{SC} = 6$ would fail to start up either load (it would get stuck at the lower intersection); for $r = 2$ the lamp is OK, but the LDO is not. A resistive load is never a problem.

9.13.4 Outboard pass transistor

Three-terminal linear regulators are available with 5 A or more of output current, for example the adjustable 10 A LM396. However, such high-current operation may be undesirable, because the maximum chip operating temperature for these regulators is lower than for power transistors, mandating oversized heatsinks. Also, they are expensive. An alternative solution is the use of external pass transistors, which can be added to integrated linear regulators like the 3-terminal fixed or adjustable regulators, whether of conventional or low-dropout configuration. Figure 9.108 shows the basic (but flawed!) circuit.

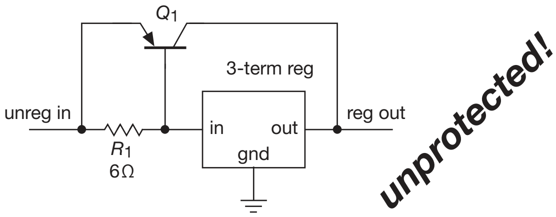

Figure 9.108. Basic three-terminal regulator with current-boosting outboard transistor. *Don't build this* – it has no current-limiting circuitry!

The circuit works normally for load currents less than 100 mA. For greater load currents, the drop across R_1 turns on Q_1, limiting the actual current through the 3-terminal regulator to about 100 mA. The 3-terminal regulator maintains the output at the correct voltage, as usual, by reducing input current and hence drive to Q_1 if the output voltage rises, and vice versa. It never even realizes the load is drawing more than 100 mA! With this circuit the input voltage must exceed the output voltage by the dropout voltage of the regulator (e.g., 2 V for an LM317) plus a V_{BE} drop.

In practice, the circuit must be modified to provide current limiting for Q_1, which could otherwise supply an output current equal to β times the regulator's internal current limit, i.e., 20 amps or more! That's enough to destroy Q_1, as well as the unfortunate load that happens to be connected at the time. Figure 9.109 shows two methods of current limiting.

In both circuits, Q_1 is the high-current pass transistor, and its emitter-to-base resistor R_1 has been chosen to turn it on at about 100 mA load current. In the first circuit, Q_2 senses the load current via the drop across R_{SC}, cutting off Q_1's drive when the drop exceeds a diode drop. There are a couple of drawbacks to this circuit: for load currents near the current limit, the input voltage must now exceed the regulated output voltage by the dropout voltage of the 3-terminal regulator plus two diode drops. Also, the small resistor values required in Q_2's base makes it difficult to add foldback limiting.

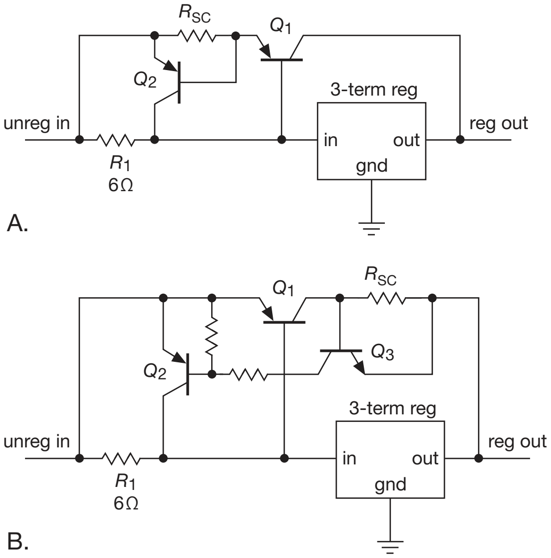

Figure 9.109. Outboard transistor booster with current limiting.

The second circuit helps solve these problems, at the expense of some additional complexity. With high-current linear regulators, a low-dropout voltage is often important to reduce power dissipation to acceptable levels. To add foldback limiting to the latter circuit, just tie Q_3's base to a divider from Q_1's collector to ground, rather than directly to Q_1's collector. Note that in either circuit Q_2 must be capable of handling the full current limit of the regulator.

A caution: With an external pass transistor you do not get the overtemperature protection that is included in nearly all integrated regulators. So you have to be careful to provide adequate heatsinking for both normal and short-circuit load conditions.

9.13.5 High-voltage regulators

Some special problems arise when you design linear regulators to deliver high voltages, and you often need to resort to some clever circuit trickery. This section presents a few such techniques.

A. Brute force: high-voltage components

Power transistors, both bipolar and MOSFET, are available with breakdown voltages to 1200 volts and higher, and they're not even very expensive. And IGBTs are available at even higher voltage ratings, up to 6000 volts.

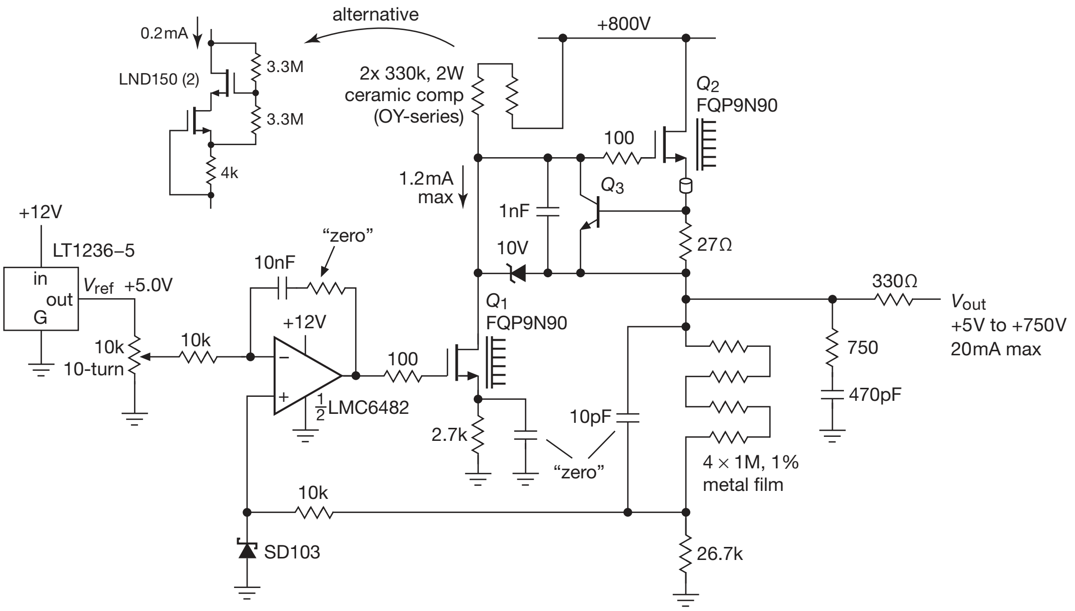

Figure 9.110. High-voltage regulated supply. The current-source pullup on Q_1's drain is a preferable alternative to the simpler resistive drain load; see §9.3.14C. See also Figure 3.111.

ON Semiconductor's MJE18004, for example, is a 5 A *npn* power transistor with conventional (V_{CEO}) collector-to-emitter breakdown of 450 V, and base back-biased breakdown (V_{CEX}) of 1000 volts; it costs less than a dollar in single quantities. And power MOSFETs are often excellent choices for high-voltage regulators owing to their excellent safe operating area (absence of thermally induced second breakdown); they are widely available with 800–1200 V ratings, and currents up to 8 A or more. For example, the FQP9N90 *n*-channel MOSFET (9 A, 900 V) from Fairchild costs about $1.75. See listings in Tables 3.4b and 3.5.

By running the error amplifier near ground (the output-voltage-sensing divider gives a low-voltage sample of the output), you can build a high-voltage regulator with only the pass transistor and its driver seeing high voltage. Figure 9.110 shows the idea, in this case a +5 V to +750 V regulated supply using an NMOS pass transistor and driver. Q_2 is the series pass transistor, driven by inverting amplifier Q_1. The op-amp serves as error amplifier, comparing a fraction of the output with a precision +5 V reference. Q_3 provides current limiting by shutting off drive to Q_2 when the drop across the 27 Ω resistor equals a V_{BE} drop. The remaining components serve more subtle, but necessary, functions: the zener diode protects Q_2 from reverse gate breakdown if Q_1 decides to pull its drain down rapidly (while the output capacitor holds up Q_2's source); it also protects against forward gate breakdown, for example if the output is abruptly shorted. The Schottky diode likewise protects the op-amp's input from a negative current spike, coupled through the 10 pF capacitor.

Note the use of several resistors in series, to withstand the large voltages; the OY-series of 1 W and 2 W ceramic composition resistors from Ohmite are non-inductive, as are the precision metal-film resistors in the output sensing divider. The various small capacitors in the circuit provide compensation, which is needed because Q_1 is operated as an inverting amplifier with voltage gain, thus making the op-amp loop unstable (especially considering the circuit's capacitive load). Likewise, the 330 Ω series output resistor promotes stability by decoupling capacitive loads (at the cost of degraded regulation). And Q_2's series gate resistor and source-lead ferrite bead suppress oscillations, to which high-voltage MOSFETs are particularly prone. *An important caution:* Power-supply circuits like this present a real electrical shock hazard – use care!

We can't resist an aside here: in slightly modified form (reference replaced by signal input) this circuit makes a very nice high-voltage amplifier, useful for driving crazy loads such as piezoelectric transducers; see Figure 3.111 for a simple 1 kV amplifier configured this way. For that particular application the circuit must be able both to sink and to source current into the capacitive load. Oddly enough, the circuit (called a "totem pole") acts like a "pseudo-push-pull" output, with Q_2 sourcing current and Q_1 sinking current (via the diode), as needed. See §*3x.8* for a detailed discussion about capacitive loading of MOSFET source-followers.

If a high-voltage regulator is designed to provide a fixed output only, you can use a pass transistor whose breakdown voltage is less than the output voltage. For example, you could modify this circuit to produce a fixed +500 V output, using a 400 V transistor for Q_2. But with such a circuit you must ensure that the voltage across the regulator never exceeds its ratings, even during turn-on, turn-off, and output short-circuit conditions. A few strategically placed zeners can do the job, but be sure to think about unusual fault conditions such as an abrupt upstream short-circuit (a spark, or probing fault), as well as "normal" events like an output short. It's remarkably easy to have a pretty-good (and tested) high-voltage circuit fail, abruptly (and usually with a "snap" sound), leaving precious few clues as to the cause. Learn from our hard-earned experience here: use a MOSFET rated beyond the full supply voltage.

Exercise 9.14. Add foldback current limiting to Figure 9.110.

B. Transistors in series

Figure 9.111 shows a trick for connecting transistors in series to increase the breakdown voltage. In the circuit on the left-hand side, the equal gate resistors distribute the dc voltage drops across the series-connected MOSFETs, and the paralleled capacitors ensure that the divider action extends to high frequencies. (The capacitors should be chosen large enough to swamp differences in transistor input capacitance, which otherwise cause unequal division, reducing overall breakdown voltage.) The zener diodes protect against gate breakdown.[150] And the 100 Ω series gate resistors help suppress oscillations, common in high-voltage MOSFETs (use some ferrite beads on the source and gate leads, if there's an oscillation sighting).

For series-connected bipolar transistors you can distribute the voltage drops with resistors alone, as shown, because the rugged base–emitter junctions are not susceptible to damage analogous to the MOSFET's oxide punch-through (in the forward direction they simply conduct a small current; and the small reverse currents from the base divider are generally benign, and they can be prevented entirely with 1N4148-style small-signal diodes connected between base and emitter). Small-signal transistors like the 300 V MPSA42 and MPSA92 (*npn* and *pnp*, respectively) and 400 V MPSA44 (available in TO-92 and surface-mount packages) are usefully extended to higher voltages this way.

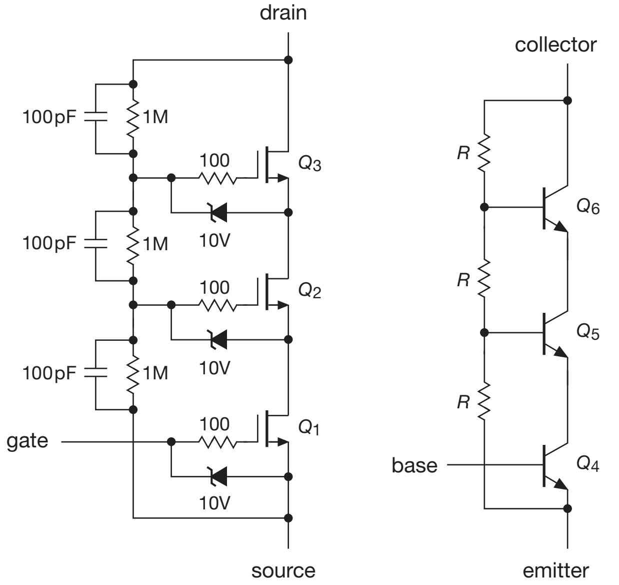

Figure 9.111. Connecting transistors in series to raise the breakdown voltage, to distribute the power dissipation, and (in power BJTs) to stay within the SOA.

Note that the series-connected string has considerably poorer saturation voltage than that of an equivalent high-voltage transistor: for three MOSFETs (as shown) the ON-voltage is $V_{\text{sat}} \approx 3V_{\text{DSon}} + 3V_{\text{GSon}}$; for the BJT circuit it's $3V_{\text{CEon}} + 3V_{\text{BE}}$.

Series-connected transistors can, of course, be used in circuits other than power supplies. You'll sometimes see them in high-voltage amplifiers, although the availability of high-voltage MOSFETs often makes it unnecessary to resort to the series connection at all.

In high-voltage circuits like this, it's easy to overlook the fact that you may need to use 1 watt (or larger) resistors, rather than the standard 1/4-watt type. A more subtle trap awaits the unwary, namely the maximum *voltage* rating of a resistor, regardless of its power-dissipation rating. For example, standard 1/4-watt axial-lead resistors are limited to 250 V, and often less for surface-mount types.[151] Another underappreciated effect is the astonishing voltage coefficients of carbon composition resistors, when run at

[150] Many designers use ordinary signal diodes, rather than zeners, assuming that there is no worry about *forward* gate breakdown, because the MOSFETs should turn on vigorously long before gate-channel breakdown. We're not so sure.

[151] Specifically, 200 V, 150 V, 75 V, 50 V, and 30 V for Vishay's CRCW thick-film resistors in sizes 1206, 0805, 0603, 0402, and 0201, respectively.

higher voltages. For example, in an actual measurement (Figure 9.112) a 1000:1 divider (10M, 10k) produced a division ratio of 775:1 (29% error!) when driven with 1 kV; note that the *power* was well within ratings. This non-ohmic effect is particularly important in the output-voltage-sensing divider of high-voltage supplies and amplifiers – beware! Companies like Ohmite (Victoreen division) and Caddock make resistors in many styles designed for high-voltage applications like this. See §*1x.2* for additional measurements and discussion.

Quite apart from their use in high-voltage applications, another motivation for series connection of multiple transistors is to distribute a large power dissipation. For such power applications, where you're not dealing with high voltages, you can, of course, use a *parallel* connection. But then you have to ensure that the current is divided approximately equally among the multiple transistors. For BJTs in parallel this is usually done with individual emitter-ballasting resistors, as we saw in §2.4.4. But that scheme is problematic with MOSFETs, because they have a spread of gate-source voltages, forcing you to allow an uncomfortably large voltage drop across the source resistors. This can be addressed, though, with some cleverness; see Figure 3.117 for a nice solution.

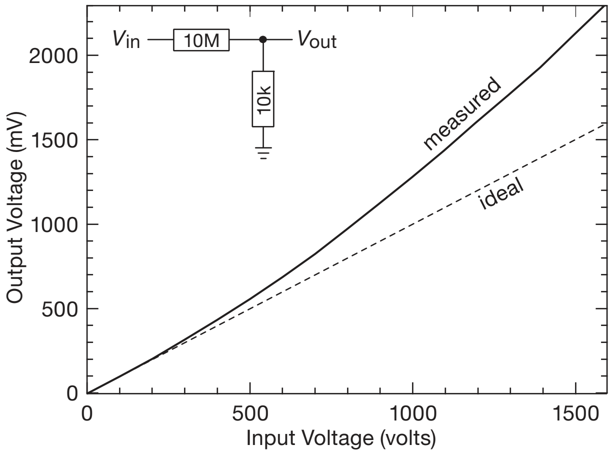

Figure 9.112. Carbon composition resistors exhibit a reduction in resistance as they approach their rated 250 V. Don't use resistors above their voltage rating!

C. Floating regulator

Another method sometimes used to extend the voltage range of integrated regulators, including the simple 3-terminal type, is to float the entire regulator above ground, for example as shown in Figure 9.113. Here the zener D_2 limits the drop across the 3-terminal regulator to just a few volts (the zener voltage minus Q_1's gate-source voltage), with outboard MOSFET Q_1 taking up the rest of the voltage drop. The LT3080 is a nice choice here, with its simple 10 μA programming current setting the output voltage. We used the trick of a pair of resistors (a "current divider," which you can think of as a current multiplier, viewed from the 10 μA source side) to raise the effective programming current to 1 mA, so we could use a 500k pot to set the voltage (rather than the awkward – and unobtainable – 50 megohms that otherwise would be needed); the boosted programming current serendipitously provides the LT3080's 0.5 mA minimum load current as well. Zener current is provided by the handy LND150 depletion-mode MOSFET from Supertex, here throttled down to 0.2 mA with a source self-biasing resistor.

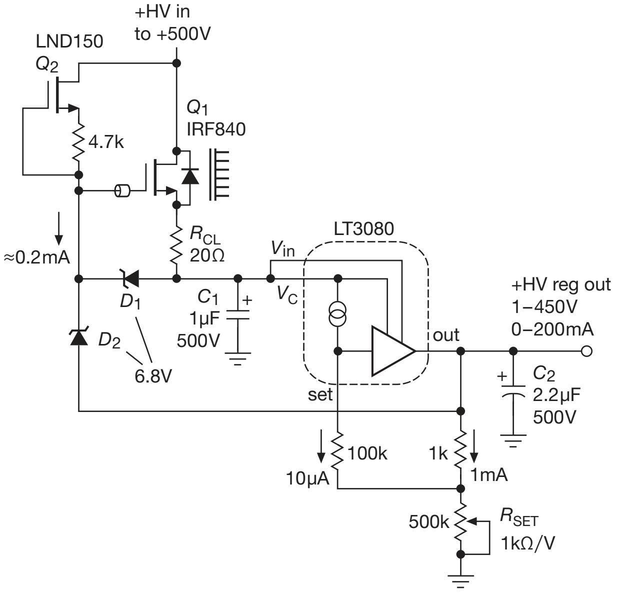

Figure 9.113. High-voltage floating three-terminal regulator.

The remaining components are easy to understand: D_1 protects Q_1's gate; the ferrite bead suppresses oscillations (you can use a 150 Ω gate resistor instead); and the LT3080 is outfitted with its minimum required input and output bypass capacitors. If there's an opportunity for the HV input to drop below the output voltage, add a diode across the LT3080 (heck, just do it anyway).

Exercise 9.15. Explore replacing Q_1 with a high-current depletion-mode MOSFET, like an IXTP3N50; see Table 3.6. Can you think of a way of using it to eliminate Q_2 and the zener diodes, despite the fact its $-V_{GS}$ may be less than the LT3080's required $V_{DO}(\max)=1.6$ V at high currents? *Hint*: an LM385-2.5 may be useful.

Review of Chapter 9

An A-to-K summary of what we have learned in Chapter 9. This summary reviews basic principles and facts in Chapter 9, but it does not cover application circuit diagrams and practical engineering advice presented there.

¶A. Voltage Regulator Taxonomy.

Voltage regulators provide the stable dc voltages needed to power all manner of electronic circuits. The simplest (and least noisy) type is the *linear* regulator (Figure 9.2), in which the output error signal, suitably amplified and compensated, is used to control a linear "pass transistor" (BJT or MOSFET) that is in series with a higher (and perhaps unregulated) dc input voltage. Linear regulators are not power efficient, with dissipation $P_{\text{diss}}{=}I_{\text{out}}(V_{\text{in}}{-}V_{\text{out}})$, and they are not able to a produce dc output that is larger than the input, nor a dc output of reversed polarity.

The *switching* regulator (or switching *converter*, *switch-mode power supply*, SMPS, or just "switcher," §9.6) addresses these shortcomings, at the cost of some induced switching noise and greater complexity. Most switching power supplies use one or more inductors (or transformers), and one or more saturated switches (usually MOSFETs) operating at relatively high switching frequencies (50 kHz–5 MHz), to convert a dc input (which may be unregulated) to one or more stable and regulated output voltages; the latter can be lower or higher than the input voltage, or they can be of opposite polarity. The inductor(s) store and then transfer energy, in discrete switching cycles, from the input to the output, with the switch(es) controlling the conduction paths; with ideal components there would be no dissipation, and the conversion would be 100% efficient. The output error signal, suitably amplified and compensated, is used to vary either the pulse width ("PWM") or the pulse frequency ("PFM"). Switching converters can be *non-isolated* (i.e., input and output sharing a common ground, Figure 9.61), or *isolated* (e.g., when powered from the ac powerline, Figure 9.73); for each class there are dozens of topologies, see ¶D below.

A minor subclass of switching converter is the *inductorless converter* (or "charge-pump" converter; see §9.6.3), where a combination of several switches and one or more "flying" capacitors is used to create a dc output that can be a multiple of the dc input, or an output of opposite polarity (or a combination of both). For many of these, the output(s) track the dc input (i.e., unregulated), but there are also variants that regulate the output by controlling the switching cycle. See Table 9.4 and Figures 9.56 and 9.57.

¶B. The DC Input.

Regardless of the kind of converter or regulator circuit, you need to provide some form of dc input. This may be poorly regulated, as from a battery (portable equipment) or from rectified ac (line-powered equipment, Figures 9.25 and 9.48); or it may be an existing stable dc voltage already present within a circuit (e.g., Figure 9.64). For a line-powered instrument that uses a linear regulator, the "unregulated" dc input (with some ac ripple) consists of a transformer (for both galvanic isolation and voltage transformation) plus rectifier (for conversion to dc) plus bulk storage capacitor(s) (to smooth the ripple from the rectified ac). By contrast, in a line-powered (confusingly called "off-line") switcher the powerline transformer is omitted, because a transformer in the isolated switcher circuit provides galvanic isolation and it is far smaller and lighter since it operates at the much higher switching frequency; see Figure 9.48.

A diode bridge and storage capacitor converts an ac input to full-wave unregulated dc, whether from a powerline transformer or directly from the ac line. Ignoring winding resistance and inductances, the dc output voltage is approximately $V_{\text{dc}}{=}1.4V_{\text{rms}} - 2V_{\text{diode}}$, and the peak-to-peak ripple voltage is approximately[152] $\Delta V_{\text{ripple(pp)}}{\approx}I_{\text{load}}/2fC$, where C is the capacitance of the output dc storage capacitor and f is the ac input frequency (60 Hz or 50 Hz, depending on geographic and political boundaries). The ac input current is confined to relatively short pulses during the part of the waveform leading up to the positive and negative peaks (see Figures 9.51 and 9.78). This low "power factor" waveform is undesirable, because it produces excessive I^2R heating and more stressful peak currents. For this reason all but the smallest switching converters use a power-factor correction (PFC) input stage (Figure 9.77) to spread out the current waveform and thus create an input current approximately proportional to the instantaneous ac input voltage.

Line-powered instruments need a few additional components, both for safety and convenience. These include a fuse, switch, and optional line filter and transient suppressor; these are often combined in an IEC "power entry module," see Figure 9.49.

¶C. Linear Voltage Regulators.

The basic linear voltage regulator compares a sample of the dc output voltage with an internal voltage reference (see ¶G, below) in an *error amplifier* that provides negative

[152] From $I = CdV/dt$, assuming approximately constant discharge current I.

feedback to a *pass transistor*; see Figure 9.2. The dc output voltage can be greater or less than the reference (Figures 9.4 and 9.5), but it is always less than the dc input. You can think of this as a feedback power amplifier, which is prone to instability with capacitive loads, thus the compensation capacitor C_c in Figure 9.2D,E. The final circuit in that figure shows a current limiting circuit (R_{CL} and Q_2), and also an *overvoltage crowbar* (D_1 and Q_3, see ¶J below) to protect the load in the event of a regulator fault.

All the components of the original 723-type linear voltage regulator can be integrated onto a single IC (Figure 9.6), forming a "3-terminal" fixed regulator, e.g., the classic 78xx-style (where "xx" is its output voltage). These require only external bypass capacitors (Figure 9.8) to make a complete regulator. There are only a few standard voltages available, however (e.g., +3.3 V, +5 V, +15 V); so a popular variant is the 3-terminal *adjustable* regulator (e.g., the classic 317-type, see Figure 9.9), which lets you adjust the output voltage with an external resistive divider (Figure 9.10). Figures 9.14, 9.16, and 9.18 show some application hints for this very flexible regulator. Both fixed and adjustable 3-terminal regulators are also available in negative polarities (79xx and LM337, respectively), as well as in low-current variants (78Lxx and LM317L, respectively).

One drawback of these classic linear regulators is their need for an input voltage that is at least ∼2 V greater than the output (its *dropout voltage*); that is needed because their pass transistor operates as an emitter follower (thus at least a V_{BE} drop) and the current-limit circuit can drop up to another V_{BE}. Two volts may not sound like a lot, but it looms large in a low-voltage regulator circuit, e.g., one with a +2.5 V dc output. To circumvent this problem, you can use a *low-dropout* (LDO) regulator, in which the pass transistor (BJT or MOSFET) is configured as a common-emitter (or common-source) amplifier, see Figure 9.20; the resulting dropout voltages are down in the tenths of a volt (Figure 9.24). LDOs are nice, but they cost more, and they are more prone to instability because their high output impedance (collector or drain) causes a lagging phase shift into the substantial load capacitance. LDOs may require significant minimum output bypass capacitance (as much as 10 μF or 47 μF), often constrained with both a minimum and maximum equivalent series resistance (ESR), e.g., 0.1 Ω min, 1 Ω max; see Table 9.3.

¶D. Switching Converter Topologies.

The basic *non-isolated* switcher topologies are the *buck* (or "step-down"), the *boost* (or "step-up"), and the *invert* (or "inverting buck–boost"); see §9.6.4 and Figure 9.61. The power train of these each uses one inductor, one switch, and one diode (or a second switch acting as an active rectifier), in addition to input and output storage capacitors. A complete converter requires additional components: an oscillator, comparator, error amplifier, drive circuits, and provisions for compensation and fault protection; see for example Figure 9.65. As with linear regulators, the semiconductor manufacturers have stepped in to provide most of the necessary components as packaged ICs, see Tables 9.5a,b and 9.6.

For the buck converter $V_{out} < V_{in}$, and for the boost converter $V_{out} > V_{in}$. The inverting converter produces an output of opposite polarity to the input, and whose voltage magnitude can be larger or smaller than the input voltage (this is true also of the remarkable Ćuk converter, §9.6.8H). The respective dc output voltages are $V_{out(buck)}=DV_{in}$, $V_{out(boost)}=V_{in}/(1-D)$, and $V_{out(invert)}=-V_{in}D/(1-D)$, where D is the switch-ON duty cycle $D=t_{on}/T$. There are also *non*-inverting buck-boost topologies that permit the output voltage range to bracket the input (i.e., able to go above or below the input). Examples are the 2-switch buck–boost (two switches, two diodes, one inductor), and the SEPIC (one switch, one diode, two inductors), see Figure 9.70. Of course, a switching converter with a transformer (whether isolated or not) provides flexibility in output polarity, as well as improved performance for large ratio voltage conversion.

Isolated switching converters use a transformer (for isolation), in addition to one or more inductors (for energy storage), see Figure 9.73. In the *flyback* converter (Figure 9.73A) the transformer acts also as the energy-storage inductor (thus no additional inductor), whereas in the *forward* converter and *bridge* converters (Figures 9.73B–D) the transformer is "just a transformer," and the diodes and inductor complete the energy storage and transfer. The respective dc output voltages are $V_{out(flyback)}=V_{in}[N_{sec}/N_{pri}][D/(1-D)]$ and $V_{out(forward)}=DV_{in}(N_{sec}/N_{pri})$. Speaking generally, flyback converters are used in low-power applications ($\lesssim$200 W), forward converters in medium-power applications (to ∼500 W), and bridge converters for real power applications.

¶E. Switcher Regulation: Hysteretic, Voltage Mode, and Current Mode.

There are several ways to regulate a switching converter's dc output voltage. Simplest is *hysteretic* feedback, in which the error signal simply enables or disables successive switching cycles. It's a form of simple "bang–bang" control, with no stability issues that require a compensation network; see Figure 9.64 for a buck converter design with the popular MC34063. Proportional PWM control is better, and comes in two flavors: voltage mode and current mode. Both methods compare the output voltage with a fixed reference to regulate the output voltage, but they do it in different ways. In *voltage-mode* PWM, the output voltage error signal is compared with the internal oscillator's sawtooth waveform to control the primary switch's ON duration, whereas in *current-mode* PWM the comparison ramp is generated by the rising inductor current, with the internal oscillator used only to initiate each conduction cycle. See §9.6.9, and particularly Figures 9.71 and 9.72. In either case the controller terminates a conduction cycle if the switch exceeds a peak current, the input drops below an "undervoltage lockout" threshold, or the chip exceeds a maximum temperature. Figure 9.65 shows a simple voltage-mode PWM buck converter.

Voltage-mode and current-mode control loops both require compensation for stability, and each has its advantages and disadvantages. Current-mode controllers appear to be winning the popularity contest, owing to their better transient response, inherent switch protection (owing to pulse-by-pulse current limiting), improved outer-loop phase margin, and ability to be paralleled.

¶F. Switching Converter Miscellany.

Switching conversion is a rich subject, many details of which are well beyond the scope of this chapter (or this book). Some topics – ripple current and inductor design, core saturation and reset, magnetizing inductance and snubbing, soft start, diode recovery, CCM and DCM conduction modes, switching losses, loop compensation, burst mode, inrush current, isolation barriers, PFC, switching *amplifiers* – are treated lightly here and in Chapter *9x*. Consider this chapter's treatment of switching converters as a lengthy introduction to a specialty field that can easily consume a professional lifetime.

¶G. Voltage References.

A stable voltage reference is needed in any voltage regulator, as well as in accurate applications such as precision current sources, A/D and D/A conversion, and voltage- and current-measurement circuits. Often a good voltage reference is included in a regulator or converter IC (see for example Table 13.1), but you may want the improved performance you can get with a high-quality external reference. And, often, you need a stand-alone voltage reference for other uses in a circuit.

The simplest voltage reference is the discrete *zener diode* (§9.10.1), but most voltage references are multi-component integrated circuits that behave externally either like an extremely good zener ("2-terminal," or *shunt*; Table 9.7), or like an extremely good linear regulator ("3-terminal," or *series*; Table 9.8). Shunt references must be biased into conduction (just like a zener) by supplying current from a higher-voltage rail (use a resistor or a current source), while series references are powered by connecting their supply pin directly to the dc supply. References of either type are available in a small set of standard voltages, typically in the range of 1.25–10.0 V.

The discrete 2-terminal zener is fine for non-critical applications, but its typical accuracy of ±5% is inadequate for precision circuits. Integrated references of either kind are far better, with worst-case accuracies in the range of 0.02% to 1%, and tempcos ranging from 1 ppm/°C to 100 ppm/°C, as seen in the tables. Most integrated references are based on a circuit that temperature compensates the $V_{\rm BE}$ of a BJT (a so-called "bandgap reference"), generating a stable voltage of approximately 1.24 V; but others use a buried zener diode with $V_Z \approx 7$ V. The latter are generally quieter, but bandgap references can operate from low supply voltages and are widely available in voltages of 1.24 V, 2.50 V, etc. Two newer technologies with surprisingly good performance are the *JFET pinchoff reference* from ADI (the ADR400 "XFET" references), and the *floating-gate* reference from Intersil. Both exhibit very good tempco and low noise. Other important characteristics of voltage references are *regulation* ($R_{\rm out}$ for shunt types, PSRR for series types), minimum *load capacitance* and stability into capacitive loads, *trim* and *filter* pins, and *package* style.

¶H. Heat and Power Dissipation.

Along with power electronics comes. . . *heat!* You remove it with a combination of convection (air flow) and conduction (thermal contact with a heat-dissipating *heatsink*). Conductive heat flow is proportional to the temperature difference between the hot and cold sides (Newton's law of cooling), $\Delta T = P_{\rm diss} R_\Theta$, where R_Θ is known as the "thermal resistance." For a succession of conductive joints the thermal resistances add; thus, for example, the junction temperature $T_{\rm J}$ of a power semiconductor dissipating $P_{\rm diss}$ watts is $T_{\rm J} = T_{\rm A} + P_{\rm diss}(R_{\Theta\rm JC} + R_{\Theta\rm CS} + R_{\Theta\rm SA})$, where $T_{\rm A}$ is the ambient temperature, and the successive R_Θ's represent the thermal resistances from junction to case, case to heatsink, and heatsink to ambient. Printed circuit foil patterns are often adequate for dissipation of a few watts or less (Figure 9.45); finned heatsinks or metallic chassis surfaces are used for greater heat removal, with forced airflow generally needed when the power dissipation reaches levels of 50 W or more (Figure 9.43). Semiconductor devices can withstand considerably greater power dissipation during short pulses; this is sometimes specified as a graph of *transient thermal resistance* (i.e., R_Θ versus pulse duration and duty cycle), or as elevated contours on a plot of Safe Operating Area (see ¶I).

¶I. Safe Operating Area.

A power transistor (whether BJT or MOSFET) has specified maximum values of voltage and current, and also (because of maximum allowed junction temperature) a maximum product $V_{\text{DS}}I_{\text{D}}$ (i.e., power dissipation) for a given case temperature; the latter is just $V_{\text{DS}}I_{\text{D}} \leq (T_{\text{J(max)}} - T_{\text{C}})/R_{\Theta\text{JC}}$. These limits define a *safe operating area* (SOA, §9.4.2), usually shown as contours on log–log axes of current versus voltage; see for example Figure 3.95. That plot shows two further features: (a) greater dissipation is allowed for short pulses; (b) the SOA of BJTs (but not MOSFETs) is further constrained by a phenomenon known as "second breakdown."

¶J. Overvoltage Crowbars.

Some failure modes of power converters cause output overvoltage, for example a shorted pass transistor in a linear regulator, or loss of feedback control in a switcher. This is likely to damage or destroy powered circuitry. An *overvoltage crowbar* (§9.13.1) senses overvoltage and triggers an SCR to short the output. A less brute-force technique shuts down conversion when an overvoltage is sensed; these are indicated in the "OVP" column in Table 9.5b.

¶K. Current Sources.

"Regulator" usually means a stable *voltage* source; but there are many uses for a controllable *current* source (§9.3.14). Three-terminal linear regulators are easily coaxed into current-source service (§9.3.14A). There are also dedicated current-source ICs like the LM334 and REF200. JFETs make convenient 2-terminal current sources, and depletion-mode MOSFETs make excellent current sources that can operate up to voltages as high as 1 kV, see §9.3.14C. And don't forget about the humble discrete BJT current source (§§2.2.6 and 2.3.7B), or the op-amp current-source circuits (§4.2.5: Howland; op-amp + transistor).

DIGITAL LOGIC

CHAPTER 10

10.1 Basic logic concepts

10.1.1 Digital versus analog

Thus far we have been dealing mainly with circuits in which the input and output voltages have varied over a continuous range of values: *RC* circuits, amplifiers, integrators, rectifiers, op-amps, etc. This is natural when dealing with signals that are continuous (e.g., audio signals) or continuously varying voltages from measuring instruments (e.g., temperature-reading or light-detecting devices, or biological or chemical probes).

However, there are instances in which the input signal is naturally discrete in form, e.g., pulses from a particle detector, or "bits" of data from a switch, keyboard, or computer. In such cases the use of digital electronics (circuits that deal with data made of 1s and 0s) is natural and convenient. Furthermore, it is often desirable to convert continuous (analog) data to digital form, and vice versa, using analog-to-digital converters (ADCs) and digital-to-analog converters (DACs), in order to perform computations on the data (with a computer or signal processor) or to store large quantities of data as numbers. In a typical situation a microprocessor or computer might monitor signals from an experiment or industrial process, control the experimental parameters on the basis of the data obtained, and store for future use the results collected or computed while the experiment is running.

Another interesting example of the power of digital techniques is the transmission of analog signals without degradation by noise: an analog audio or video signal, for instance, picks up "noise" while being transmitted by cable or wireless that cannot be removed. If, instead, the signal is converted to a series of numbers representing its amplitude at successive instants of time, and these numbers are transmitted as digital signals, the analog signal reconstruction at the receiving end (done with DACs) will be without error, providing the noise level on the transmission channel isn't great enough to prevent accurate recognition of 1s and 0s. This technique, known as PCM (pulse-code modulation), is particularly attractive where a signal must pass through a series of "repeaters," since digital regeneration at each stage guarantees noiseless transmission. The information and stunning pictures sent back by planetary deep space probes, for example the Pioneer 10 mission to Jupiter in 1973, were stored and transmitted with PCM. Digital audio and video are now commonplace in the home, for example in the form of the humble 12 cm optical CD,[1] in which music is stored in the form of a stereo pair of 16-bit numbers every 23 microseconds, (1.4 megabits/sec), 6 billion bits (gigabits, Gb) of information in all. And by contemporary standards this is a storage medium of low speed and capacity: the corresponding figures for DVDs and Blu-rays are 10 and 48 megabits/sec (maximum), with a total storage of 38 and 200 gigabits per layer.

In fact, digital hardware has become so powerful that tasks that would have seemed well suited to analog techniques are usually better solved with digital methods. As an example, an analog temperature meter might incorporate a microprocessor and memory to improve accuracy by compensating for the instrument's departure from perfect linearity; likewise for something as commonplace as a digital bathroom scale. Because of the wide availability of inexpensive (less than $1) microcontrollers, such applications are ubiquitous. The average home is awash in devices with "embedded" processors: in every music player, television set, cellphone, dishwasher, washing machine and dryer, fax, copier, microwave oven, coffee maker,.... The list is long, and sometimes surprising.[2] Rather than attempt to enumerate what can be done with digital electronics, let's just start learning about it. Applications will emerge naturally as we go along.

[1] And their video counterparts: DVDs and Blu-ray (BD) discs.

[2] One might encapsulate the history of the "conquest of digital over analog" something like this: the 1970s – planetary photographs sent digitally from 800 million kilometers away, but domestic life still ruled by analog; the 1980s – digital audio (CDs) and the personal computer invade the home; the 1990s – digital video (DVDs), cellphones, and MP3s; the 2000s – HDTV, digital wireless connectivity, digital photography and videography, high-speed Internet, and *Google*; and the 2010s (OK, OK, we know the old saying "It's difficult to predict... especially the future") – universal digital dissemination and fusion of information and media.

10.1.2 Logic states

By “digital electronics” we mean circuits in which there are only two (usually) states possible at any point, e.g., a transistor that can either be in saturation or be nonconducting. We usually choose to talk about voltages rather than currents, calling a level HIGH or LOW. The two states can represent any of a variety of “bits” (binary digits) of information, such as the following:

one bit of a number;
whether a switch is opened or closed;
whether a signal is present or absent;
whether some analog level is above or below some preset limit;
whether or not some event has happened yet;
whether or not some action should be taken;
and so on.

A. HIGH and LOW

The HIGH and LOW voltage states represent the TRUE and FALSE states of Boolean logic, in some predefined way. If at some point a HIGH voltage represents TRUE, that signal line is called “active HIGH” (or “HIGH true”) and vice versa. This can be confusing at first. Figure 10.1 shows an example. SWITCH CLOSED is true when the output is LOW; that’s an “active-LOW” (or “LOW-true”) signal, and you might label the lead as shown (a bar over a symbol means NOT; that line is HIGH when the switch is *not* closed). Just remember that the presence or absence of the negation bar over the label tells whether the wire is at a LOW or HIGH voltage state when the stated condition (SWITCH CLOSED) is true.[3] At first the idea of active-LOW may seem, well, *backward*; why not just keep it simple and outlaw this upside-down logic? As we’ll see, though, there are good reasons to do things “backwards” sometimes. Be patient.

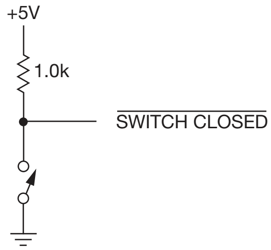

Figure 10.1. A LOW-true (“active-LOW”) logic level.

A digital circuit “knows” what a signal represents by where it comes from, just as an analog circuit might know what the output of some op-amp represents. However, added flexibility is possible in digital circuits; sometimes the same signal lines are used to carry different kinds of information, or even to send it in different directions, at different times. To do this “multiplexing,” additional information must also be sent (address bits, or status bits). You will see many examples of this very useful ability later. For now, imagine that any given circuit is wired up to perform a predetermined function and that it knows what that function is, where its inputs are coming from, and where the outputs are going.

To lend a bit of confusion to a basically simple situation, we introduce 1 and 0. These symbols are used in Boolean logic to mean TRUE and FALSE, respectively, and are sometimes used in electronics in exactly that way. Unfortunately, they are also used in another way, in which 1 = HIGH and 0 = LOW! In this book we try to avoid any ambiguity by using the word HIGH (or the symbol H) and the word LOW (or the symbol L) to represent logic states, a method that is in wide use in the electronics industry. We use 1 and 0 only in situations where there can be no ambiguity.

B. Voltage range of HIGH and LOW

In digital circuitry, the voltage levels corresponding to HIGH and LOW are allowed to fall in some range, according to the particular logic family.[4] For example, with high-speed CMOS (“HC” family) logic running from a +5 V supply, *input* voltages within about 1.5 volts of ground are interpreted as LOW, whereas voltages within 1.5 volts of the +5 V supply are interpreted as HIGH.[5] Those inputs are driven from the outputs of some other devices, for which typical LOW- and HIGH-state *output* voltages are usually within a tenth of a volt of 0 and +5 V, respectively (the output is a saturated transistor switch to one of the rails; see Figure 10.25). This allows for manufacturing spread,

[3] You’ll sometimes see the terms “positive-true” and “negative-true” used for HIGH-true and LOW-true, respectively. Those terms are OK, but they can be confusing to the inexperienced, especially since no negative voltages are involved.

[4] A “family” is a particular hardware implementation of digital logic, characterized by operating voltage, logic voltage levels, and speed. For historical reasons, most logic families name their standard logic parts with a prefix of 74, followed by a few letters that name the family, and ending with some numbers that specify the logic function. The logical functions themselves are the same across families. For example, a 74LVC08 is a 2-input AND gate (actually, four of them in one package) in the low-voltage CMOS (LVC) electrical family; the “08” designates a quad 2-input AND, and the “74” designates a logic chip for operation at standard temperatures.

[5] See the box “Logic Levels” for additional examples.

variations of the circuits with temperature, loading, supply voltage, etc., and the presence of "noise," the miscellaneous garbage that gets added to the signal in its journey through the circuit (from capacitive or inductive coupling, external interference, etc.). The circuit receiving the signal decides if it is HIGH or LOW and acts accordingly.[6] As long as noise does not change 1s to 0s, or vice versa, all is well, and any noise is eliminated at each stage, where "clean" 0s and 1s are regenerated. In that sense, digital electronics is noiseless and perfect.

The term *noise immunity* is used to describe the maximum noise level that can be added to logic levels (in the worst case) while still maintaining error-free operation. As an example, the formerly popular family of logic known as "TTL" (transistor–transistor logic) struggled with just this issue, because it has just 0.4 V of noise immunity: a TTL *input* is guaranteed to interpret anything less than +0.8 V as LOW and anything greater than +2.0 V as HIGH, whereas the worst-case *output* levels are +0.4 V and +2.4 V, respectively (see the accompanying box on logic levels). In practice, noise immunity will be better than the worst-case 0.4 V margin, with typical LOW and HIGH voltages of +0.2 V and +3.4 V and an input decision threshold near +1.3 V. But always remember that if you are doing good circuit design, you use worst-case values. It is worth keeping in mind that different logic families have different amounts of noise immunity. CMOS has greater voltage-noise immunity than TTL, whereas the speedy ECL (emitter-coupled logic) family has less. Of course, susceptibility to noise in a digital system depends also on the amplitude of noise that is present, which in turn depends on factors such as output-stage stiffness, inductance in the ground leads, the existence of long "bus" lines, and output slew rates during logic transitions (which produce transient currents, and therefore voltage spikes on the ground line, because of capacitive loading). We will worry about some of these problems in Chapter 12 (Logic Interfacing).

10.1.3 Number codes

Most of the conditions we listed earlier that can be represented by a digital level are self-explanatory. How a digital level can represent part of a number is a more involved, and very interesting, question. Put another way, we've seen *bits as indicators*; now we will see *groups of bits as a number*.

A decimal (base-10) number is simply a string of integers that are understood to multiply successive powers of 10, the individual products then being added together. For instance,

$$137.06 = 1\times10^2+3\times10^1+7\times10^0+0\times10^{-1}+6\times10^{-2}.$$

Ten symbols (0 through 9) are needed, and the power of 10 each multiplies is determined by its position relative to the decimal point. If we want to represent a number using two symbols only (0 and 1), we use the *binary*, or base-2, number system. Each 1 or 0 then multiplies a successive power of 2. For instance,

$$\begin{aligned}1101_2 &= 1\times2^3+1\times2^2+0\times2^1+1\times2^0\\ &= 13_{10}.\end{aligned}$$

The individual 1s and 0s are called "bits" (binary digits). The subscript (always given in base 10) tells what number system we are using, and often it is essential in order to avoid confusion, since the symbols all look the same.

We convert a number from binary to decimal by the method just described. To convert the other way, we keep dividing the number by 2 and write down the remainders. To convert 13_{10} to binary, therefore:

$$\begin{aligned}13/2 &= 6 \quad \text{remainder} \quad 1,\\ 6/2 &= 3 \quad \text{remainder} \quad 0,\\ 3/2 &= 1 \quad \text{remainder} \quad 1,\\ 1/2 &= 0 \quad \text{remainder} \quad 1,\end{aligned}$$

from which $13_{10} = 1101_2$. Note that the answer comes out in the order LSB (least significant bit) to MSB (most significant bit).

A. Hexadecimal ("hex") representation

The binary-number representation is the natural choice for two-state systems (although it is not the only way; we'll see some others soon). Because the numbers tend to get rather long, it is common to write them in hexadecimal (base-16) representation: each position represents successive powers of 16, with each hex symbol having a value from 0 to 15 (the symbols A–F are assigned to the values 10–15). To write a binary number in hexadecimal, just group it in 4-bit groups, beginning with the LSB, and write the hexadecimal equivalent of each group:

$$707_{10} = 1011000011_2\ (= 10\ 1100\ 0011_2) = 2\text{C}3_{16}.$$

[6] Sometimes digital signals are sent as a differential voltage pair, rather than "single-ended." This is particularly popular with longer high-speed signals, or signals that go off-board over some distance, for example fast serial buses such as USB, Firewire, and SATA; it is also commonly used to distribute high-frequency clock signals. A popular format is "LVDS" (low-voltage differential signaling), in which the differential signal amplitude is ∼0.3 V, centered at +1.25 V.

LOGIC LEVELS

The diagram in Figure 10.2 shows the ranges of voltages that correspond to the two logic states (HIGH and LOW) for popular families of digital logic. For each logic family it is necessary to specify legal values of both output and input voltages corresponding to the two states HIGH and LOW. The shaded areas above the line show the specified range of output voltages within which a logic LOW or HIGH is guaranteed to fall, with the pair of arrows indicating typical output values (LOW, HIGH) encountered in practice. The shaded areas below the line show the range of input voltages guaranteed to be interpreted as LOW or HIGH, with the arrow indicating the typical *logic threshold* voltage, i.e., the dividing line between LOW and HIGH. In all cases a logic HIGH is more positive than a logic LOW. Table 10.1 and Figure 10.26 provide additional information about these families, a subject we'll see in more detail in Chapter 12.

The meanings of "minimum," "typical,"and "maximum," in electronic specifications are worth a few words of explanation. Most simply, the manufacturer guarantees that the components will fall in the range minimum-to-maximum, with many close to "typical." What this means is that typical specifications are an approximate guide to use when designing circuits; however, those circuits must work properly over the whole range of specifications from minimum to maximum (the extremes of manufacturing variability). In particular, a well-designed circuit must function under the worst possible combination of minimum and maximum values. This is known as *worst-case design*, and it is essential for any instrument produced from off-the-shelf (i.e., not specially selected) components.

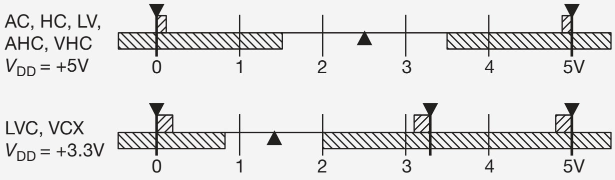

Figure 10.2. Logic levels of some popular logic families.

Table 10.1 Selected Logic Families

Family	Manufacturers	Supply voltage (V_{CC}) min (V)	Supply voltage (V_{CC}) max (V)	V_{in} max	t_{pd} (ns, typ)	@ Vcc (V)	Available packages DIP	SMT	1G,2G
74HC00	9	2	6	V_{CC}	9	5	●	●	●
74AC00	5	3	6	V_{CC}	6	5	●	●	-
74AHC00	2	2	5.5	V_{CC}	3.7	5	●	●	●
74LV00	2	1.2[a]	5.5	5.5	3.6	5	●	●	●
74LVC00	4	1.7	3.6	5.5	3.5	3.3[b]	-	●	●
74ALVC00	3	1.7	3.6	3.6	2	3.3[c]	-	●	-
74AUC00	1	0.8	2.7	3.6	0.9	1.8	-	●	●

Notes: (a) NXP only (TI specs to 2V only). (b) 6ns @ 1.8V. (c) 2.7ns @ 1.8V.

Hexadecimal representation[7] is well suited to the popular "byte" (8-bit) organization of computers, which are most often organized as 16, 32, or 64-bit computer "words"; a word is then 2, 4, or 8 bytes. So in hexadecimal, each byte is 2 hex digits, a 16-bit word is 4 hex digits, etc. For example, the memory locations in a microcontroller with 65,536 ("64K") bytes of memory can be identified by a 2-byte address, because 2^{16}=65,536; the lowest address in hex is 0000h (the trailing "h" means hex), the highest address is FFFFh, the second half of memory begins at 8000h, and the fourth quarter of memory begins at C000h.

A byte sitting somewhere in computer memory can represent an integer number, or part of a number. But it can also represent other things: for example, an alphanumeric character (letter, number, or symbol) is commonly represented as one byte. In the widely used ASCII representation (more in §14.7.8), lowercase "a" is represented as ASCII value 01100001 (61h), "b" is 62h, etc. Thus the word "nerd" could be stored in a pair of 16-bit words whose hex values are 6E65h and 7264h.

B. Binary-coded decimal

Another way to represent a number is to encode each decimal digit into binary. This is called BCD (binary-coded decimal), and it requires a 4-bit group for each digit. For instance,

$$137_{10} = 0001\,0011\,0111 \quad \text{(BCD)}.$$

[7] Alternative notations for a hexadecimal number (like $2C3_{16}$) are 2C3H, 2C3h, 2c3h, and 0x2C3.

Note that BCD representation is *not* the same as binary representation, which in this case would be $137_{10} = 10001001_2$. You can think of the bit positions (starting from the right) as representing 1, 2, 4, 8, 10, 20, 40, 80, 100, 200, 400, 800, etc. It is clear that BCD is wasteful of bits, because each 4-bit group *could* represent numbers 0 through 15, but BCD never represents numbers greater than 9. However, BCD is ideal if you want to display a number in decimal, since all you do is convert each BCD character to the appropriate decimal number and display it. For this reason, BCD is commonly used for input and output of numeric information. Unfortunately, the conversion between pure binary and BCD is complicated, because *each* decimal digit depends on the state of almost every binary bit, and vice versa. Nevertheless, binary arithmetic is so efficient that most computers convert all input data to binary, converting back only when data need to be output. Think how much effort and bother would have been saved if *Homo sapiens* had evolved with 8 (or 16) digits.[8]

Exercise 10.1. Convert to decimal: (a) 1110101.0110_2, (b) $11.01010101\ldots_2$, (c) $2A_H$. Convert to binary: (a) 1023_{10}, (b) 1023_H. Convert to hexadecimal: (a) 1023_{10}, (b) 101110101101_2, (c) 61453_{10}.

Table 10.2 4-Bit Signed Integers in Three Systems of Representation

Integer	Sign-magnitude	Offset binary	2's comp
+7	0111	1111	0111
+6	0110	1110	0110
+5	0101	1101	0101
+4	0100	1100	0100
+3	0011	1011	0011
+2	0010	1010	0010
+1	0001	1001	0001
0	0000	1000	0000
-1	1001	0111	1111
-2	1010	0110	1110
-3	1011	0101	1101
-4	1100	0100	1100
-5	1101	0011	1011
-6	1110	0010	1010
-7	1111	0001	1001
-8	-	0000	1000
(-0)	1000	-	-

C. Signed numbers

Sign–magnitude representation

Sooner or later it becomes necessary to represent negative numbers in binary, particularly in devices where some computation is done. The simplest method is to devote one bit (the MSB, say) to the sign, with the remaining bits representing the magnitude of the number. This is called "sign–magnitude representation," and it corresponds to the way signed numbers are ordinarily written (see Table 10.2). It is used when numbers are displayed, as well as in some ADC schemes. In general, it is not the best method for representing signed numbers (except for floating-point numbers), particularly where some computation is done, for several reasons: computation is awkward, and subtraction is different from addition (i.e., addition doesn't "work" for signed numbers). Also, there can be two zeros ($+0$ and -0), so you have to be careful to use only one of them.

Offset-binary representation

A second method for representing signed numbers is "offset binary," in which you subtract half the largest possible number to get the value represented (Table 10.2). This has the advantage that the number sequence from the most negative to the most positive is a simple binary progression, which makes it a natural for binary "counters." The MSB still carries the sign information, and zero appears only once. Offset binary is popular in A/D conversions, but it is still awkward for computation.

2's complement representation

The method most widely used for integer computation is called "2's complement." In this system, positive numbers are represented as simple unsigned binary. The system is rigged up so that a negative number is then simply represented as the binary number you add to a positive number of the same magnitude to get zero. To form a negative number, first complement each of the bits of the positive number (i.e., write 1 for 0, and vice versa; this is called the "1's complement"), then add 1 (that's the "2's complement").[9] As you can see from Table 10.2, 2's complement numbers are related to offset binary numbers by having the MSB complemented. As with the other signed-number representations, the MSB carries the sign information. There's only one zero, conveniently represented by all bits 0 ("clearing" a counter or register sets its value to zero). Because the 2's complement system is natural for computation, (i.e., it allows computers to treat negative and

[8] If the former, we'd be thumbless, thus spared the scourge of "texting."

[9] Alternatively, you can simply think of it as plain ol' (unsigned) binary, but with the MSB representing the negative of its usual value.

positive integers the same way), it is universally used for integer arithmetic in computers.[10]

D. Arithmetic in 2's complement

Arithmetic is simple in 2's complement. To add two numbers, just add bitwise (with carry), like this:

5+(−2)=3:

$$\begin{array}{rr} 0101 & (+5) \\ +1110 & (-2) \\ \hline 0011 & (+3) \end{array}$$

To subtract *B* from *A*, take the 2's complement of *B* and add (i.e., add the negative):

2−5=−3:

$$\begin{array}{rr} 0010 & (+2) \\ +1011 & (-5) \\ \hline 1101 & (-3) \end{array}$$

(Note in this last example that +5=0101, so its 1's comp is 1010 and its 2's comp is −5=1011.) Multiplication also "works right" in 2's complement representation. Try the following exercises.

Exercise 10.2. Multiply +2 by −3 in 3-bit 2's complement binary arithmetic. *Hint*: the answer is −6.

Exercise 10.3. Show that the 2's complement of −5 is +5.

Because an n-bit integer can represent only 2^n numbers, you can get overflow or underflow when you add or subtract two numbers of fixed word size. To be precise, an n-bit unsigned integer can take on values from 0 to 2^n-1, and an n-bit 2's complement signed integer can take on values from -2^{n-1} to $+2^{n-1}-1$. For 8-bit integers those ranges are 0 to 256, and −128 to +127. To determine if an unsigned add has overflowed (and is therefore incorrect), simply note if it generated a carry out of the MSB. For signed 2's complement numbers the analogous criterion is slightly weird: if the sign bit (the MSB) is changed *by carries* (that is, if a carry in to the MSB is not balanced by a carry out, or vice versa), the result is incorrect.

Exercise 10.4. Check this unlikely criterion by doing a 2's complement addition of each of the following signed-number pairs, assuming a 4-bit word size: $7+(-6)$; $7+7$; $7+4$; $-7+(-8)$. Then repeat the same sums with a 5-bit word size, in which all the answers should fit.

E. Gray code

The following code is used for mechanical linear and shaft-angle encoders and for certain ADCs, among other things. It is called a Gray code,[11] and it has the property that only one bit changes in going from one state to the next. This prevents incorrect codes at the transitions, which otherwise produce errors because there is no way of guaranteeing that all bits will change simultaneously at the boundary between two encoded values. If straight binary were used, it would be possible to generate an output of 7 in going from 3 to 4, for example. Here is a simple rule for generating Gray-code states: begin with a state of all zeros. To get to the next state, always change the single least significant bit that brings you to a new state.

State	Binary	Gray
0	000	000
1	001	001
2	010	011
3	011	010
4	100	110
5	101	111
6	110	101
7	111	100

Figure 10.3 shows how a Gray-coded angle encoder eliminates false codes at the transitions. Gray codes can be generated with any number of bits. They find use also in "parallel encoding" (also called *flash conversion*), a technique of high-speed A/D conversion that we will see later. We will talk about translation between Gray-code and binary-code representations in the next section (including a gate implementation in Figure 10.10).

10.1.4 Gates and truth tables

A. Combinational versus sequential logic

In digital electronics the name of the game is generating digital outputs from digital inputs. For instance, an *adder* might take two 16-bit numbers as inputs and generate a 16-bit (plus carry) sum. Or you might build a circuit to multiply two numbers. These are the kinds of operations a computer's processing unit should be able to do. Another task might be to compare two numbers to see which is larger, or to compare a set of inputs with the desired input to make sure that "all systems are go." Or you might want to compute a "parity bit" and attach it to a number to make the

[10] Note, however, that "floating-point" numbers are usually represented in a form of "sign magnitude," namely, sign-exponent-mantissa.

[11] Frank Gray, of the Bell Telephone Laboratories, received a patent for *Pulse Code Modulation* in 1953. It disclosed a "novel code" for A/D conversion, which he called a "reflected binary code," but known thereafter as a Gray code. These were evidently discovered earlier, however, by none other than Emile Baudot (from which "baud" derives), who used them in telegraphy in 1878.

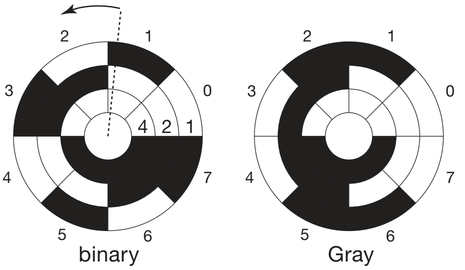

Figure 10.3. Two versions of a 3-bit angle encoder. Black or white sectors represent 1 or 0 for each of the three encoded bits (of value 4, 2, and 1 for the binary encoding). Binary encoding is prone to errors at transitions like 1→2 (shown), where more than one bit must change simultaneously; Gray code circumvents this problem.

total number of 1s even, say, before transmission over a data link; then the parity could be checked on receipt as a simple check of correct transmission. Another typical task is to take some numbers expressed in binary and display or print them as decimal characters. All of these are tasks in which the output or outputs are predetermined functions of the input or inputs. As a class, they are known as *combinational*[12] tasks. They can all be accomplished with devices called *gates*, which perform the operations of Boolean algebra applied to two-state (binary) systems.

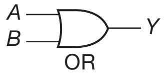
There is a second class of problems that cannot be solved by forming a combinational function of the inputs alone, but require knowledge of past inputs as well. Their solution requires the use of *sequential* networks. Typical tasks of this type might be converting a string of bits in serial form (one after another) into a parallel set of bits, or keeping count of the number of 1s in a sequence, or recognizing a certain pattern in a sequence, or giving one output pulse for each four input pulses, or controlling the state of a system as time goes on. All these tasks require digital memory of some sort. The basic device here is the "flip-flop" (the fancy name is "bistable multivibrator").

We begin with gates and combinational logic, since they're basic to everything. Digital life will become more interesting when we get to sequential devices, but there will be no lack of fun and games with gates alone.

B. OR gate

The output of an OR gate is HIGH if either input (or both) is HIGH. This can be expressed in a *truth table*, as shown in Figure 10.4. The gate illustrated is a 2-input OR gate. In general, gates can have any number of inputs, but, when packaged in the form of "standard-logic" ICs, you get from one to four gates in a single IC package.[13] For instance, a 4-input OR gate will have a HIGH output if any one input (or more) is HIGH.

The Boolean symbol for OR is $+$. "A OR B" is written as $A+B$ (in text), or as `A|B` (in the coding languages Verilog or C).

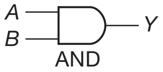


inputs		output
A	*B*	*Y*
0	0	0
0	1	1
1	0	1
1	1	1

Figure 10.4. 2-input OR gate and truth table.

C. AND gate

The output of an AND gate is HIGH only if both inputs are HIGH. The logic symbol and truth table are as shown in Figure 10.5. As with OR gates, AND gates are available with 3 or 4 (sometimes more) inputs. For instance, an 8-input AND gate will have a HIGH output only if *all* inputs are HIGH.



inputs		output
0	0	0
0	1	0
1	0	0
1	1	1

Figure 10.5. 2-input AND gate and truth table.

The Boolean symbol for AND is a dot (·); this can be omitted, and usually is. "A AND B" is written $A{\cdot}B$, or simply AB (in text), or as `A&B` (in Verilog or C).

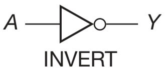
D. Inverter (the NOT function)

Frequently we need the complement of a logic level. That is the function of an inverter, a "gate" with only one input (Figure 10.6).

The Boolean symbol for NOT is a bar over the symbol,

[12] Sometimes called *combinatorial*.

[13] The alternative to standard logic is "programmable logic," in which you can connect up your own network of gates, up to hundreds of thousands within a single inexpensive IC. We'll have plenty to say about this later in the chapter, beginning at §10.5.4, and in detail in Chapter 11.



A	Y
0	1
1	0

Figure 10.6. Inverter (NOT gate) and truth table.

or sometimes a prime ($'$) symbol. "NOT *A*" is written $\overline{A}$ or A'. For the convenience of typesetters, the symbols /, *, $-$, and $'$ are often used in place of the overbar, to indicate NOT; thus, "NOT *A*" might be written as any of the following: A', $-A$, $*A$, $/A$, $A*$, $A/$. A given document will usually pick one of these alternatives and stick with it throughout. We have chosen the form A' for this book. In coding languages NOT is written `!` or ~ .

An aside: propagation time

In the real world, logic devices like gates and inverters do not operate instantaneously when presented with a changed input level: it takes a *propagation time* (t_p) for the news to get from the input to the output. Figure 10.7 shows actual 'scope traces for inverter outputs from five logic families, when driven with a 15 ns active-LOW pulse. The newer low-voltage families (74AUC, 74AVLC) are fastest, with propagation times of 2 ns or less.

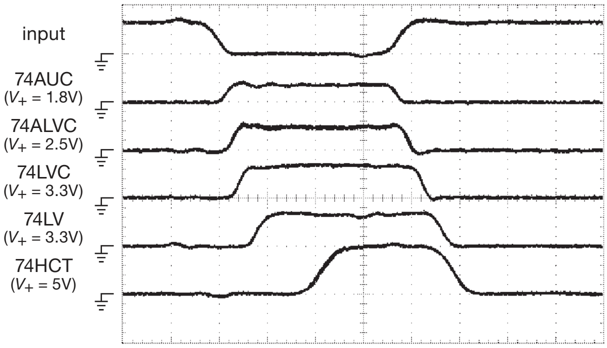


Figure 10.7. Real logic gates take a few nanoseconds to respond to a changing input. We drove inverters from five popular logic families with the active-LOW "input" pulse, and observed the outputs shown. The slowest family (74HCT, driven with a 5V swing) exhibits delays of 9 ns and 5 ns from leading and trailing edges, respectively, resulting in a shortened output pulse width. Vertical: 5 V/div; Horizontal: 4 ns/div.

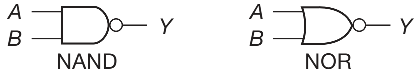
E. NAND and NOR

The INVERT function can be combined with gates, forming NAND and NOR (Figure 10.8), which are somewhat more popular than AND and OR (because, having an inversion, they can be morphed into any of the other gates, as we'll soon see).



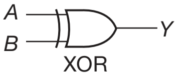
A	B	Y
0	0	1
0	1	1
1	0	1
1	1	0

A	B	Y
0	0	1
0	1	0
1	0	0
1	1	0

Figure 10.8. NAND and NOR, and truth tables.

F. Exclusive-OR

Exclusive-OR (XOR) is an interesting function, although less fundamental than AND and OR (Figure 10.9). The output of an XOR gate is HIGH if one or the other (but not both) input is HIGH (it never[14] has more than two inputs). Another way to say it is that the output is HIGH if the inputs are different. The XOR gate is identical with modulo-2 addition of two bits. The Boolean symbol for XOR is ⊕. "*A* XOR *B*" is written `A∧B` (in Verilog or C).[15]



A	B	Q
0	0	0
0	1	1
1	0	1
1	1	0

Figure 10.9. XOR and truth table.

Exercise 10.5. Show how to use the exclusive-OR gate as an "optional inverter," i.e., it inverts an input signal or buffers it without inversion, depending on the level at a control input.

Exercise 10.6. Verify that the circuits in Figure 10.10 convert binary code to Gray code, and vice versa.

[14] Well, hardly ever: the '1G386 claims to be a "3-input XOR gate," though we would call it a 3-input parity generator.

[15] Where, however, the ugly symbol ˆ is used, probably because it happens to be included on standard keyboards, there intended as a foreign language accent, but evidently hijacked by the playful authors of programming languages. In the text we use the nicer-looking "wedge" symbol ∧, ignoring the derisive howls of C-language purists.

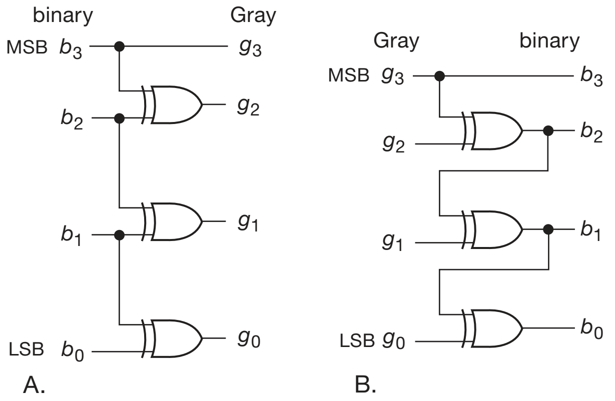


Figure 10.10. Parallel code converters: binary to Gray and Gray to binary.

	AND	OR	NOT	XOR
In text	A B	A + B	$\overline{\mathrm{A}}$	A ⊕ B
ABEL	A & B	A # B	!A	A $ B
Verilog	A & B	A | B	∼A	A ∧ B
VHDL	A and B	A or B	not A	A xor B

Figure 10.11. Syntax for logical operations, as expressed in hardware description languages or in running text. For these operators CUPL shares the same symbols as ABEL. Alternative symbols for use in text are are the following: for AND A·B; for NOT any of the following: A′, A*, *A, /A, A/, —A.

G. Basic logic: hardware description language

Thus far we've been using *schematic symbols* for the basic logic of gates. However, when you use *programmable* logic devices (PLDs: Chapter 11), rather than prefabricated standard logic, you have to enter, as text, the logic functions that you want to implement. This is done in a *hardware description language* (HDL), with names like Verilog or VHDL. Dedicated software then swallows and converts these expressions, creating a file that is used to program the actual part (or, for large volume applications, to create a "full custom" IC). The nomenclature shown in Figure 10.11 shows how these basic logical operations are expressed in the several programming languages used for programmable logic devices and custom ICs.

As a simple example, the Gray-to-binary logic shown schematically in Figure 10.10B could be written in the Verilog HDL (following some boring declarations) as:

```
assign b3 = g3;
assign b2 = g2∧g3;
assign b1 = g1∧(g2∧g3);
assign b0 = g0∧(g1∧(g2∧g3));
```

10.1.5 Discrete circuits for gates

Before going on to discuss gate applications, let's see how to make gates from discrete components. Figure 10.12 shows a diode AND gate. If either input is held LOW, the output is LOW. The output can go HIGH only when both inputs go HIGH. This circuit does work, but it has many disadvantages. In particular: (a) its LOW output is a diode drop above the signal holding the input LOW – obviously you couldn't use very many of these in a row! (b) there is no "fan-out" (the ability of one output to drive several inputs), since any load at the output is seen by the signal at the input; (c) it is slow, because of resistive pullup.

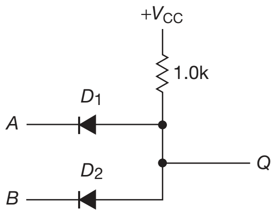

Figure 10.12. Diode AND gate.

Figure 10.13 shows how to fix some of these drawbacks, by using a pair of *npn* transistor switches to make a NOR gate, followed by an inverter to make it into an OR gate.[16] A HIGH at either input (or both) turns on at least one of the input transistors, pulling their common output LOW. Since this portion of the gate is intrinsically inverting (it's a NOR), you add an inverter, as shown, to make it into a (noninverting) 2-input OR gate.

Logic circuits using bipolar transistors have been almost entirely superseded by MOS circuits. Figure 10.14 shows the analogous NOR/OR gate circuit, with *n*-channel MOS transistor switches replacing the bipolar *npn* switches of Figure 10.13. The MOS implementation has the advantage of not requiring input current (though the input capacitance means that you do have to supply current during input transitions). But it still has some drawbacks, such as limited switching speed and significant power dissipation (due to

[16] This circuit was used in the family of logic known as RTL (resistor–transistor logic), which was popular in the 1960s because of its low price, but is now thoroughly obsolete.

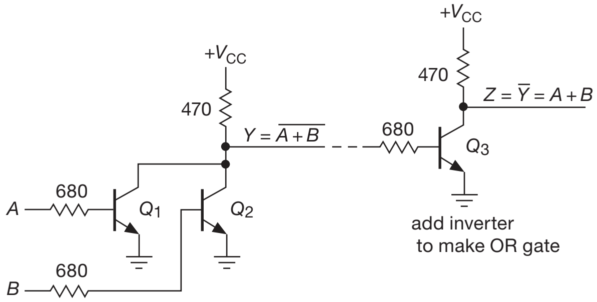

Figure 10.13. Resistor–transistor logic: NOR input stage, followed by inverter, makes a 2-input OR gate.

resistive pullup resistors). Both problems are elegantly finessed by the use of complementary MOS ("CMOS") transistors in a push–pull arrangement, as we discussed earlier in §3.4.4A.

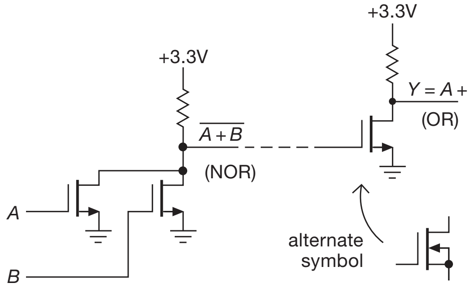

Figure 10.14. An nMOS OR gate. Digital circuit designers simplify the MOSFET symbol, always omitting the substrate terminal; they usually center the gate attachment, too, and indicate polarity instead with a bubble on the gate, as shown in the bottom pair of Figure 3.6.

Although the discrete gate circuits just illustrated are simple to understand, you wouldn't use them in practice because of their disadvantages. In fact, except in rare circumstances[17] you would never construct gates (or any other logic) from discrete components, since a full range of excellent logic is available as inexpensive and compact ICs, as we will see shortly. Currently nearly all IC logic circuits are built with complementary MOSFETs (CMOS). Look back at Figure 3.91 to remind yourself how you would make a CMOS NAND gate.

10.1.6 Gate-logic example

Let's work out a circuit to perform the logic we gave as an example in Chapters 1 and 2: the task to sound a buzzer if either car door is open and the driver is seated. The answer is obvious if you restate the problem as "output HIGH if either the left door OR the right door is open, AND driver is seated," i.e., $Q=(L+R)S$. Figure 10.15 shows it with gates. The output of the OR gate is HIGH if one OR the other door (or both) is open. If that is so, AND the driver is seated, Q goes HIGH. With an additional transistor, this could be made to sound a buzzer or close a relay.[18]

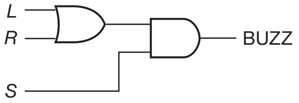

Figure 10.15. Car-door example: active-HIGH levels.

In practice, the switches generating the inputs will probably close a circuit to ground, to save extra wiring (among other reasons). This means, for example, that the inputs will go LOW when a door is opened. In other words, we have "active-LOW" inputs. Let's rework the example with this in mind, calling the inputs L', R', and S'.

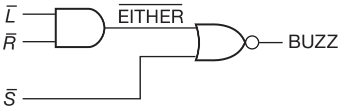

Figure 10.16. Car-door example: active-LOW levels cause confusion.

First, we need to know if either door input (L', R') is LOW; i.e., we must distinguish the state "both inputs HIGH" from all others. That's an AND gate. So we make L' and R' the inputs to an AND gate. The output will be LOW if either input is LOW; call that EITHER$'$. Now we need to know when EITHER$'$ is LOW and S' is LOW; i.e., we must distinguish the state "both inputs LOW" from all others. That's an OR gate. Figure 10.16 shows the circuit. We have used a NOR gate, instead of an OR gate, to get the same output as

[17] In some industrial and consumer applications, where ruggedness and simplicity are important, you'll find circuits like Figure 10.13, constructed from discrete components. For this purpose you can get transistors with integrated base resistors (or base divider); these are called "bias resistor transistors" (BRTs), "pre-biased transistors," or, sometimes, "digital transistors." They're ridiculously inexpensive, as little as $0.02 apiece in quantity. They're made by companies like ON semiconductor, Diodes Inc., and Rohm.

[18] This particular gate circuit just happens to be made, in a tiny minilogic package, as a 74LVC1G3208; they call it a "3-input positive OR–AND gate." But don't expect this level of service for all your gate circuit needs.

earlier, namely the Q output is HIGH when the desired condition is present. Something strange seems to be going on here, though. We have used AND instead of OR (and vice versa), as compared with the earlier circuit. Section 10.1.7 should clarify the matter. First, though, consider the following exercise.

Exercise 10.7. What do the circuits shown in Figure 10.17 do?

A. Gate interchangeability

When designing digital circuits, keep in mind that it is possible to form one kind of gate from another. For example, if you need an AND gate, and you have half of a 74LVC00 available (quad 2-input NAND), you can substitute as shown in Figure 10.18. The second NAND functions as an inverter, making AND. The following exercises should help you explore this idea.

Exercise 10.8. Using 2-input gates, show how to make (a) INVERT from NOR, (b) OR from NORs, and (c) OR from NANDs.

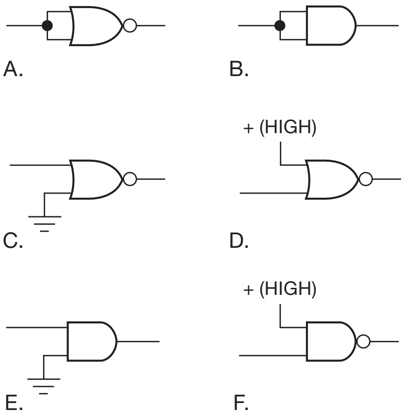

Figure 10.17. Gate configurations for Exercise 10.7.

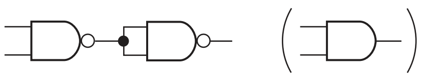

Figure 10.18. Making AND from NANDs.

Exercise 10.9. Show how to make (a) a 3-input AND from 2-input ANDs, (b) a 3-input OR from 2-input ORs, (c) a 3-input NOR from 2-input NORs, and (d) a 3-input AND from 2-input NANDs.

In general, multiple use of one kind of inverting gate (e.g., NAND) is enough to make any combinational function. However, this isn't true for a noninverting gate, because there's no way to make INVERT. This probably accounts for the greater popularity of NAND and NOR in logic design.

10.1.7 Assertion-level logic notation

An AND gate has a HIGH output if both inputs are HIGH. So if HIGH means "true," you get a true output only if all inputs are true. In other words, with active-HIGH logic, an AND gate performs the AND function. The same holds for OR.

What happens if LOW means "true," as in the last example? An AND gate gives a LOW if either input is true (LOW): it's an OR function! Similarly an OR gate gives a LOW only if both inputs are true (LOW). It's an AND function! Very confusing.

There are two ways to handle this problem. The first way is to think through any digital design problem as we did earlier, choosing the kind of gate that gives the needed output. For instance, if you need to know if any of three inputs is LOW, use a 3-input NAND gate. This method is still used by some misguided designers. When designing this way, you would draw a NAND gate, even though the gate is performing a NOR function on the (active-LOW) inputs. You would probably label the inputs as in Figure 10.19. In this example, CLEAR′, MR′ (master reset), and RESET′ might be active-LOW levels coming from various places in a circuit. The output, CLR, is active-HIGH and will go to the devices that are to be cleared if *any* of the reset signals goes LOW (true).

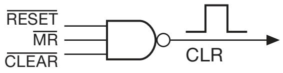

Figure 10.19. Confusing notation for OR function of active-LOW signals.

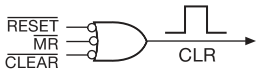

Figure 10.20. Use inverted input "bubbles" for active-LOW inputs.

The second way to handle the problem of active-LOW signals is to use "assertion-level logic." If a gate performs an OR function on active-LOW inputs, draw it that way, as in Figure 10.20. The 3-input OR gate with negated inputs is functionally identical with the preceding 3-input NAND. That equivalence turns out to be an important logical identity, as stated in DeMorgan's theorem, and we will spell out a number of such useful identities shortly. For now, it is enough to know that you can change AND to OR (and vice versa) if you negate the output and all inputs (see Table 10.3). Assertion-level logic looks forbidding at first, because of the proliferation of funny-looking gates. It is better, though, because the logical functions of the gates in the circuit stand out clearly. You'll find it friendly after you've used it for a while, and you won't want to use anything else.

Let's rework the car-door example again with assertion-level logic (Figure 10.21). The gate on the left determines if L or R is true, i.e., LOW, giving an active-LOW output. The second gate gives a HIGH output if both $(L+R)$ and S are true, i.e., LOW. From DeMorgan's theorem (after a while you won't even need that, you'll recognize these gates as equivalent) the first gate is AND and the second is NOR, just as in the circuit drawn earlier. Two important points.

1. Active-LOW (or LOW-true) is sometimes called "negative-true," but that doesn't mean that the logic levels are of negative *polarity*.[19] It means that the lower of the two states (LOW) stands for TRUE.
2. The symbol used to draw the gate itself assumes active-HIGH logic. A NAND gate used as an OR for active-LOW signals could be drawn as a NAND, or (better) using assertion-level logic, as an OR with negation symbols (bubbles) at the inputs. In the latter case you think of the bubbles as indicating inversion of the input signals, followed by an OR gate operating on active-HIGH input logic levels as originally defined.[20]

You might well ask why you shouldn't just keep things simple by doing all your designs with active-HIGH logic. In some cases you are constrained by the logic levels defined by the components themselves (for example, the common use of an active-LOW reset input on a microcontroller); and in other situations (like the car-door switches) it is better electrically to connect the common terminal to ground. In any case, you've got to be able to navigate in a digital world populated by both active-HIGH and active-LOW signals.

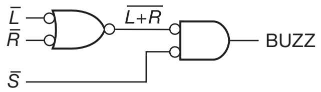

Figure 10.21. Car-door redux: assertion-level logic fixes confusing Figure 10.16.

10.2 Digital integrated circuits: CMOS and Bipolar (TTL)

Digital logic functions are implemented in hardware ICs, either as (small-scale) *standard logic* (e.g., the 74xx gates we've seen), or as *programmable logic* (e.g., an FPGA – field-programmable gate array; §11.2.3), or as a full-custom application-specific IC (ASIC, or ASSP[21]; e.g., a graphics processor). Because this book is intended primarily for the *circuit* designer (as opposed to the *chip* designer[22]), we will not discuss the design of ICs themselves.

CMOS dominates contemporary digital IC technology, having largely replaced the earlier bipolar ("TTL") logic. CMOS is faster, better adapted to operation at low supply voltage, and less power hungry. There are numerous families within CMOS (and also within bipolar); they offer the same logic functions, the differences having to do primarily with speed, supply voltage, and output drive capability. There are more than a half-dozen manufacturers of digital logic, with much duplication ("second sourcing"). For example, you can get a quad 2-input NAND in the popular LVC family (its part number is 74 LVC 00) from five manufacturers, and the largely similar 74 LCX 00 from three other manufacturers.

We discuss these family choices in some detail in §10.2.2 and §12.1.1. As a preview, though, and to get a sense of the march of technology, take a look at Figure 10.22, which shows the life cycle of most of the important digital logic families. Bipolar logic's days are numbered (except for BiCMOS – CMOS logic with bipolar output – and also some specialty families such as the speedy ECL).

Without going into detail now (see §12.1.1), we would suggest, for most purposes, either the mature HC(T) family, or the more recent (and faster) LVC/LVX family. The former is widely available, has an enormous variety of logic functions, and includes through-hole (dual in-line package or DIP) as well as surface-mount technology (SMT) packaging; the latter is faster, optimized for performance at lower supply voltages, but available in SMT only.

[19] A confusion that can lead to real damage: we loaned a digital frequency synthesizer to an inexperienced student, who read the manual and then applied −5 V to the programming inputs. He spent many days replacing burned-out circuitry.

[20] Logical AND and OR shouldn't be confused with the *legal* equivalents. The weighty legal tome known as *Words and Phrases* has over 40 pages of situations in which AND can be construed as OR. Among the more amusing is this gem: "OR will be construed AND, and AND will be construed OR, as the necessities of the case may require...." This isn't the same as DeMorgan's theorem!

[21] Application-Specific Standard Product.

[22] Sometimes you hear the terms *board-level* design and *chip-level* design.

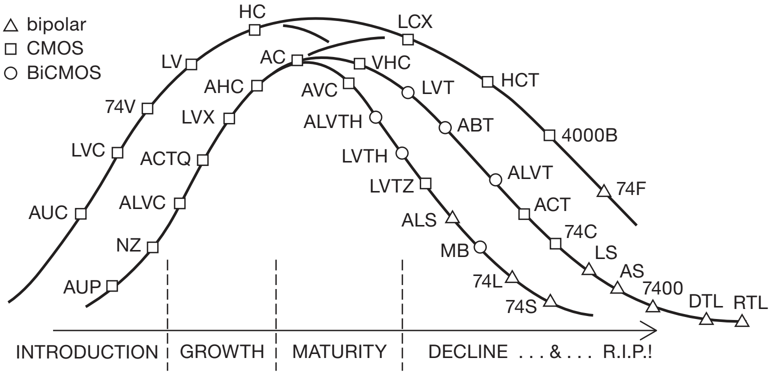

Figure 10.22. Life cycle of logic families, at a snapshot in time early in the third millennium. CMOS is in the ascendancy, bipolar in decline. We put this figure together by looking at analogous figures from NXP, TI, and others; by checking stock at distributors; and by factoring in our own biases.

10.2.1 Catalog of common gates

Table 10.3 shows the common gates you can get as standard digital logic. Each gate is drawn in its normal (active-HIGH inputs) incarnation, and also the way it looks for active-LOW inputs. These functions come in traditional 14- or 16-pin packages, with multiple gates per package (limited by total pin count); they are also available singly in tiny packages.[23] Figure 10.23 shows what these packages look like, going from the traditional through-hole DIP down to the tiny grain-of-sand CSP (chip-scale package) packages on the lower right; you could fit the latter parts nicely between any two leads of the former!

To fully specify one of these gates, you would form a part number beginning with 74, then add the several letters (like LVC, for low-voltage CMOS) to specify the family, then the numbers that designate the function (like 08, for 2-input AND). Additionally you would add some suffixes to specify package and temperature range, and perhaps a prefix like "SN" to specify the manufacturer: voilà, an SN74LVC08ADR, which is a quad 2-input AND in the LVC family, in reels of 2500 parts, packaged in a 14-pin "SOIC" (small-outline IC) temperature range of −40°C to +125°C, manufactured by Texas Instruments. For simplicity (and prevention of insanity) we routinely omit most of this detail, indicating digital IC types with an apostrophe, e.g., '08 for a 2-input AND function; in situations where the family type matters, we add the family designation, e.g., 'LVC08.

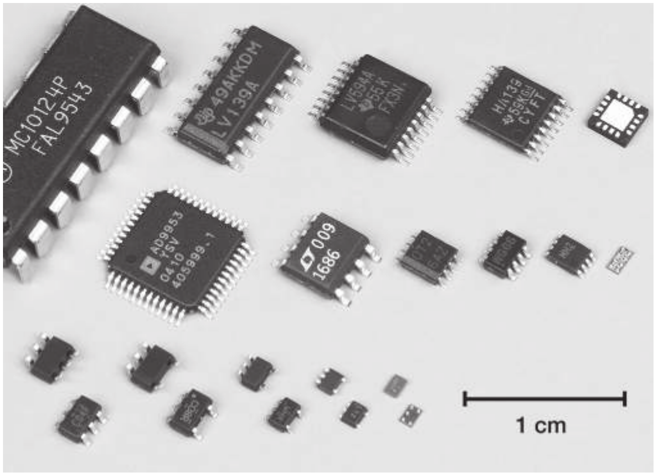

Figure 10.23. A selection of digital logic packages; all are surface mount, except for the DIP-16 cameo at upper left. Top row, left to right: DIP-16, SOIC-16, SSOP-16, TSSOP-16, QFN-16. Middle row: TQFP-48, SOIC-8, SSOP-8, SOT-23-8, US-8, WCSP-8 (DSBGA-8: die-size ball-grid array). Bottom row (two samples each): SOT-23-6, SOT-23-5, SC-70, SOT-533, WCSP-5 (DSBGA-5).

A. A "universal" gate?

Figure 10.24 shows an elegant trick, namely a tiny 6-pin part (called a '1G97) whose small block of logic lets you make any of nine logic functions, according to how you connect the inputs: inverter, noninverting buffer, 2-input multiplexer (MUX, see §10.3.3A), and six varieties of

[23] In a curious sort of inversion, the part numbers are shortest for the large parts, and vice versa. Here's an example: a 2-input NAND gate, packaged as a quad (4 gates) in a 14-pin package, has part number SN74LVC00DR; the same function, packaged singly in a 5-pin package, is called an SN74LVC1G00MDBVREP. (The "1G" portion specifies what we'll call "minilogic" – the packaging of single logic units in small-pin-count packages.)

Table 10.3 Standard Logic Gates in Popular Families[a]

Notes: (a) available gates/pkg listed as *m·n* etc.; e.g., a 2-input OR (‘32) in the AUC family is available with one or four gates in a package. (b) the digits signifying logic function follow the family designator (e.g., 2-input AND gates: *74LVC***08**, *74LVC1G***08**); common to all families except HV CMOS (4000B) and ECL (100E, EL, EP). (c) PP=push-pull (active pull-up & pull-down); OD=open-drain; 3S=3-state.

2-input gates (AND, OR, AND with one inverted input, OR with one inverted input, NAND with one inverted input, or NOR with one inverted input). The companion ’1G98 (same logic, but with inverted output) also has nine disguises, three of which are different (namely NAND, NOR, and MUX with inverted output). The smallest package for these parts is a mere 0.9 × 1.4 mm, way too small a space to print its part number.[24] Going one step further, the ’1G99 squanders two extra pins to give you (a) selectable output inversion (via an XOR) and (b) a “three-state” output

[24] Try it: a full part number is “SN74AUP1G97YZPR,” and this ◇ is the package size (actually it’s a bit generous, but we couldn’t find a small enough symbol in the LaTeX typesetting language).

(coming up in §10.2.4A). The similar ’1G57 and ‘1G58 gates have Schmitt-trigger inputs.

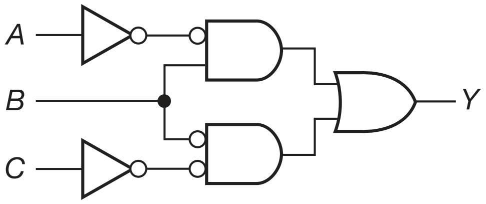

Figure 10.24. The ’1G97 and ’1G98 “configurable multiple-function gates” can perform any of nine logic functions. The ’1G97 is shown; the ’1G98 is identical, except with an inverted output.

Exercise 10.10. Show how to connect up a ’1G97 to make each of the nine functions just listed.

10.2.2 IC gate circuits

Although a NAND gate, for instance, performs identical logic operations in the various family versions, the logic levels and other characteristics (speed, power, input current, etc.) are quite different. In general, you have to be careful when mixing logic-family types. To understand the differences, look at the schematics of a NAND gate in Figure 10.25.

The CMOS gate (by far the most common family type) is constructed from enhancement-mode MOSFETs of both polarities, connected as switches (rather than followers). An ON FET looks like a low resistance (R_{on}) to whichever supply rail it is connected. Both inputs must be HIGH to turn on the series pair Q_3Q_4 and to turn off both of the pullup transistors Q_1Q_2. That produces a LOW at the output (marked X), i.e., it is a NAND gate. Q_5 and Q_6 constitute the standard CMOS inverter, thus completing the AND gate. From this example it should be evident how to generalize to AND, NAND, OR, and NOR with any number of inputs.

Exercise 10.11. Draw the circuit of a 3-input CMOS OR gate.

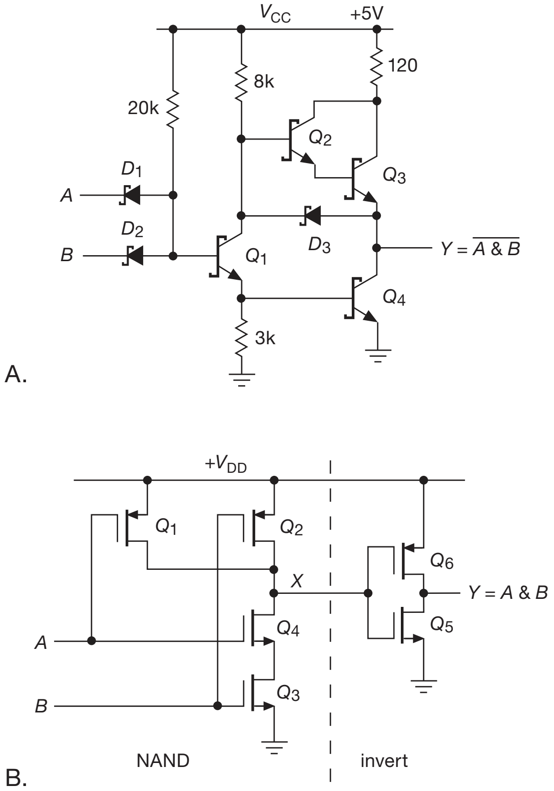

Figure 10.25. NAND/AND gates: two circuit implementations. A. Bipolar LS TTL NAND gate, with its “totem-pole” output stage; B. CMOS AND gate.

Bipolar-transistor logic families are no longer preferred because they are outperformed by CMOS families;[25] but it is instructive to look at the legacy “TTL” family.[26] The once-popular LS (low-power Schottky) NAND gate (Figure 10.25A consists basically of the diode–resistor logic of Figure 10.12 driving a transistor inverter followed by a push–pull output. If both inputs are HIGH, the 20k resistor holds Q_1 on, thus producing a LOW output by saturating Q_4 and shutting off Darlington Q_2Q_3. If at least one input is LOW, Q_1 is held off, thus producing a HIGH output by follower action of Q_2Q_3 combined with Q_4 being held off. (Note that the HIGH output, coming from a Darlington follower, is at least two diode drops below the +5 V supply.) Schottky diodes and Schottky-clamped transistors are used throughout for enhanced speed.[27]

Note that both CMOS and bipolar TTL gates have an output circuit with “active pullup” to the positive supply rail, unlike our discrete gate examples (Figures 10.12–10.14).

[25] With the exception of the extremely fast ECL types and the hybrid “BiCMOS” hefty bus-driver families.

[26] Among other reasons, its ghost hovers over much contemporary logic, in the form of “TTL-input level” limits of $\leq$0.8 V (LOW) and $\geq$2.0 V (HIGH), seen for example in several logic families in Figure 10.2.

[27] Schottky diodes have no stored charge and therefore no reverse recovery delay (see, e.g., §9.5.3B or §*9x.6*); and Schottky clamping prevents transistor saturation, which otherwise causes a turn-off delay.

10.2.3 CMOS and bipolar ("TTL") characteristics

This section might be subtitled "Analog aspects of digital circuits." The same logic function (e.g., NAND) can be implemented in different ways; these can differ in their *electrical* characteristics, while performing the same *logic*. In a nutshell – **Supply voltage**: CMOS can operate over a range, TTL requires +5 V; **Input current**: CMOS inputs draw no steady current, TTL inputs require current; **Input voltage**: the various families have varying logic thresholds and allowable input voltage, therefore incompatibilities; **Output**: CMOS outputs are rail-to-rail, TTL cannot reach V_+; **Speed and power**: CMOS has only *dynamic* power consumption (proportional to frequency), whereas TTL has substantial quiescent power; and the fastest families are low-voltage CMOS and bipolar ECL.

In somewhat greater detail (cracking open the nutshell):

Supply voltage: In Figure 10.26 we've plotted the supply-voltage ranges for most of the interesting logic families. The various CMOS families each have a healthy range of allowable supply voltages; for example, the LVC family is fully specified for supply voltages from +1.8 V to +3.3 V, and most family members support operation to 5 V.[28] Within its range a CMOS device runs faster at higher supply voltages (where there's more gate drive voltage). The bipolar families run on a single voltage: +5 V ±5% for TTL, and either −5 V (sometimes −5.2 V) or +5 V for ECL (called NECL and PECL, for negative and positive ECL, respectively).

Input – ***Current:*** CMOS devices have no quiescent input current (apart from leakage); however, like all devices, their input capacitance (of order 4 pF) draws current during switching ($I = CdV/dt$; so, for example, a 2.5 V input transition in 2 ns would require ∼5 mA of drive current). Bipolar logic does require quiescent input current: a TTL input held in the LOW state sources current into whatever drives it (e.g., 0.6 mA typ for the F family), so to hold it LOW you must sink current (in addition to the capacitive load current during switching).[29]

In general, logic families have adequate output-current capability to drive additional logic; what matters more is compatibility of logic-level *voltages*.

– ***Logic Levels:*** CMOS families generally put their input threshold voltage at half the supply voltage (though with considerable spread, typically 1/3 to 2/3 of the supply voltage); this is a good choice, since CMOS outputs swing all the way to both rails. However, for compatibility with legacy bipolar TTL output levels (where the HIGH output is well below the positive supply), many CMOS families have "TTL threshold" variants, often specified with a "T" in the family name: HC→HCT, VHC→VHCT. These families specify a maximum LOW threshold of +0.8 V and a minimum HIGH threshold of +2.0 V (see Figure 10.2, and the more complete Figure 12.6). These duplicate the bipolar-TTL specification, where the input logic threshold is about two diode drops above ground (about 1.3V).[30]

– ***Voltage Tolerance:*** The world has not standardized on a single logic supply voltage (nor should it), so in a typical digital system you'll usually have several supply voltages (e.g., +5 V and +3.3 V). Hence the question: can the output of logic running at one supply voltage (call it X) drive the input of logic at a different supply voltage (call it Y)? The short answer (we'll have a longer answer in Chapter 12) is that two things are required: (a) X's output levels have to satisfy Y's input logic-level requirements; and (b) if Y's supply voltage is less than X's, Y's inputs must tolerate X's (larger) output voltages. This latter is called input-voltage tolerance, and you've got to respect it! For example, you can see in Figure 10.2 that the legacy HC(T) family will not tolerate inputs greater than its supply voltage,[31] whereas the newer LVC family accepts inputs to +5.5 V regardless of its own supply voltage (including when it is unpowered). Input voltage tolerance is essential when digital signals cross over supply-voltage boundaries.

CMOS inputs are susceptible to damage from static electricity during handling. Unused inputs should be tied HIGH or LOW, as necessary (more on this in §10.8.3B).

Output: CMOS outputs are driven by a pair of MOSFET switches, either to ground or to V_+; i.e., "rail-to-rail." The TTL output stage, by contrast, is a saturated transistor to ground in the LOW state and a (Darlington) follower in the HIGH state (two diode drops below V_+). The datasheet will usually give more details, specifying typical and worst-case output voltages for some typical load currents.[32]

[28] For most LVC logic devices the datasheets say the "recommended" operating range extends only to +3.6 V, but some LVC parts extend that to +5.5 V, with their operating characteristics specified at 5 V.

[29] The niche bipolar ECL is strange stuff – its outputs are "bare emitters," which are deliberately terminated with 50Ω resistors to −2 V (NECL) or +3 V (PECL).

[30] This bit of history has cast its shadow all over the digital world, with "TTL input levels" pretty much established as standard for nearly all devices with digital inputs.

[31] More precisely, the inputs may not go more than 0.5 V above V_+ or below ground.

[32] CMOS devices usually specify output voltage at symmetrical pairs of

In general, the faster families (ALVC, LVC, LCX; F, AS) have greater output drive capability than the slower families (CD4000, HC(T); LS).

Speed and power: All CMOS families of standard logic consume zero quiescent current.[33] However, their power consumption rises linearly with increasing frequency, because switching the capacitance of internal nodes and external capacitive loads requires current ($I{=}C\,dV/dt$). CMOS operated near its upper frequency limit may even dissipate more power than bipolar logic (see Figure 10.27). It's common to see this *dynamic current*[34] specified in terms of an effective "power-dissipation capacitance," $C_{\rm pd}$, from which you can calculate the no-load dynamic power dissipation as $P_{\rm diss}{=}C_{\rm pd}V^2f$ (there are two transitions per cycle, which cancels the usual factor of 1/2). For example, a 74LVC00 (quad NAND gate) specifies $C_{\rm pd}{=}19$ pF per gate, from which you get a power dissipation of 0.2 mW/MHz per gate (for 3.3 V supply); so one such IC with all four gates churning along at 100 MHz would dissipate 80 mW internally (and additional power from switching the external load capacitances). The speed range of CMOS standard-logic functions goes from about 2 MHz (for the high-voltage CD4000 series running at a low 5 V) to about 100 MHz (for AHCT/VHCT at 5 V) to about 150 MHz (for LVC/LCX at 3.3 V) to about 350 MHz (for AUC at 2.5 V). In contrast to CMOS's zero quiescent current, the bipolar TTL families consume considerable quiescent current, more for the faster families (AS, F, ABT); the corresponding speeds go from about 25MHz (for LS) to about 100 MHz (for AS and F).

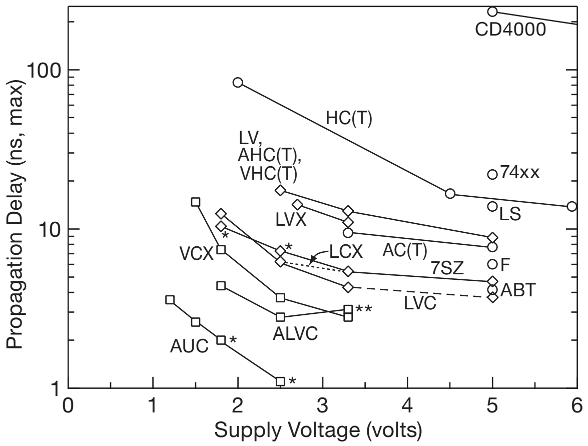

Figure 10.26. Gate speed versus supply voltage, for popular logic families. Maximum specified propagation delay ($t_{\rm pd(max)}$) is shown for the standard supply voltages at which each family is specified. (As a rough guide, "typical" delays are in the range of 35–75% of $t_{\rm pd(max)}$.) See the caption to Figure 12.3 for details.

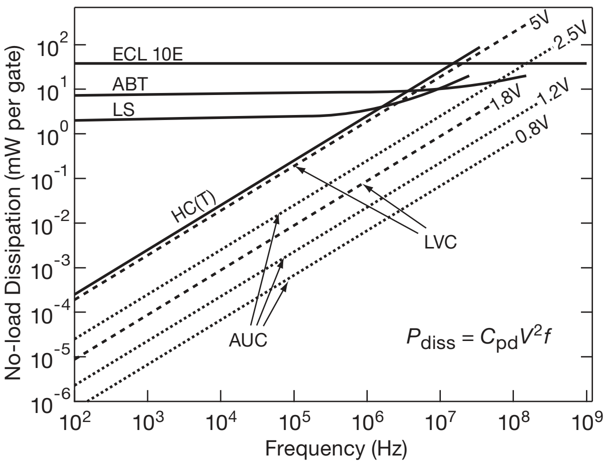

Figure 10.27. Gate internal power dissipation versus frequency for some CMOS and bipolar logic families. Note the dramatic (quadratic) dependence on power supply voltage, within any one family. See also Figure 12.2.

In Figure 10.26 (seen again as Figure 12.3, with additional commentary) we've plotted worst-case gate propagation delays for commonly used standard logic families.

In general, the nice characteristics of the CMOS families (zero quiescent current, rail-to-rail output swings, symmetrical sink–source output currents, and high speed) make them the logic of choice. Among them, the LVC and 7SZ families are nice,[35] with their 5 V tolerant inputs and good supply voltage ranges (1.8–3.3 V[36] and 1.8–5 V). For operation at 5 V the AHC(T), VHC(T), or LV families are

HIGH- and LOW-state load currents, for example at ±8 mA; TTL devices, with their unsymmetrical output, are usually specified at plenty of sink current, but very stingy source currents (e.g., at 8 mA and at −0.4 mA). This is important when a logic output is used to drive some external component, e.g., an LED indicator or solid-state relay: wire the component so the logic output *sinks* current (with the other end returned to the positive supply, through a current-limiting resistor if necessary).

[33] *Large-scale* CMOS circuits (for example gate arrays or microprocessors, as opposed to the basic "standard-logic" functions like gates and flip-flops) generally have nonzero (and sometimes quite substantial) quiescent current.

[34] When charging and discharging a capacitor from 0 to V at frequency f, the average current is $I{=}fCV$.

[35] The 7SZ and 17SZ families come only in minilogic packages.

[36] The maximum "recommended" supply voltage for some LVC devices is 5.5 V, whereas for others it is only 3.6 V; however, while the latter types give no specifications for operation above 3.6 V, *all* LVC devices grudgingly allow supply voltages to 5.5 V.

also good choices; their inputs are 5 V tolerant regardless of supply voltage (which can be 2.5–5 V). These parts are available only in surface-mount packages; if you want DIP through-hole parts for ease of breadboarding, use HC(T) or AC(T).

For unusual applications you might choose CD4000B series parts (supply voltages to 15 V, but *slow!*)), ECL logic (*fast!* – to 1 GHz), or the hybrid (BiCMOS) ABT series (output current to 64 mA, good for driving heavy loads such as buses).

Within any one logic family, outputs are designed to drive other inputs easily, so you don't often have to worry about thresholds, input current, etc. For instance, with bipolar TTL, any output can drive at least 10 other inputs (the official term for this is *fan-out*: TTL has a fan-out of 10), so you don't have to do anything special to ensure compatibility. In Chapter 12 we go into the issue of interfacing between logic families and between logic circuits and the outside world.

10.2.4 Three-state and open-collector devices

The CMOS and TTL gates we have just discussed have push–pull output circuits: the output is held either HIGH or LOW by an ON transistor. Nearly all digital logic uses this sort of circuit (called active pullup; in TTL it's also known as a totem-pole output) because it provides low output impedance in both states, giving faster switching time and better noise immunity, as compared with an alternative such as a single transistor with a passive collector-pullup resistor. It also results in lower power dissipation.

However, there are a few situations for which active pullup output is unsuitable. As an example, imagine a computer system in which several functional units have to exchange data. The central processor unit (CPU), memory, and various peripherals all need to be able to send and receive 16-bit words. It would be awkward (to put it mildly) to have separate 16-wire cables connecting each device to all others. The solution is the so-called *data bus*, a single set of 16 wires accessible to all devices. It's like the old-fashioned (now extinct?[37]) telephone "party line": only one device at a time may "talk" (assert data), but all may "listen" (receive data). With a bus system there must be agreement as to who may talk, and you'll see words like *bus arbitration* and *bus master*.

You can't use gates (or any other devices) with active pullup–pulldown outputs to drive a bus, since you couldn't disconnect your output from the shared data lines (you're holding it either HIGH or LOW at all times). What's needed is a gate whose output can be *open*. Such devices are available, and they come in two varieties, *three-state* devices and *open-collector* devices.

A. Three-state logic

Three-state logic, also called TRI-STATE® logic (a trademark of National Semiconductor Corporation, NSC), provides an elegant solution. The name is misleading; it is not digital logic with three voltage levels. It's just ordinary logic, with a third output state: open circuit (Figure 10.28). A separate *enable* input determines whether the output behaves like an ordinary active pullup output or goes into the "third" (open) state, regardless of the logic levels present at the other inputs. Three-state outputs are available on many digital chips, including counters, latches, registers, etc., as well as on gates and inverters. A device with three-state output behaves exactly like ordinary active pullup logic when enabled, always driving its output either HIGH or LOW; when disabled,[38] it effectively disconnects its output, so another logic device can drive the same line. Let's look at an example.

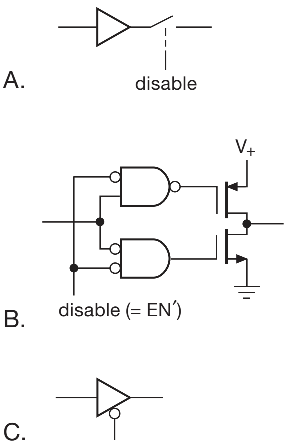

Figure 10.28. Three-state CMOS logic; A. Conceptual diagram. B. Realization with internal CMOS gates. C. Logic symbol.

B. A look ahead: data buses

Three-state drivers are widely used to drive computer data buses. Every device (memory, peripherals, etc.) that needs to put data on the (shared) bus ties onto it with three-state gates (or more complex functions such as "registers"). Things are cleverly arranged so that at most one device has its drivers enabled at any instant, all other devices being

[37] But playing a major role in the 1959 movie *Pillow Talk.*

[38] Mr. Lebowski is *disabled*, yes.

disabled into the open (third) state. In a typical situation the selected device "knows" to assert data onto the bus by recognizing its particular address on a set of address and control lines (Figure 10.29). In this simplified case the device is wired as port 6: it looks at address lines A_0–A_2 and asserts data onto data bus D_0–D_3 when it sees its particular address (i.e., 6) on the address lines *and* it sees a READ′ pulse. Such a bus protocol is adequate for many simple systems. Something like this is used in most microcomputers, as you will see in Chapter 14.

Note that there must be some external logic to make sure that three-state devices sharing the same output lines don't try to talk at the same time (that undesirable condition is officially called "bus contention"). In this case all is well as long as each device responds to a unique address.

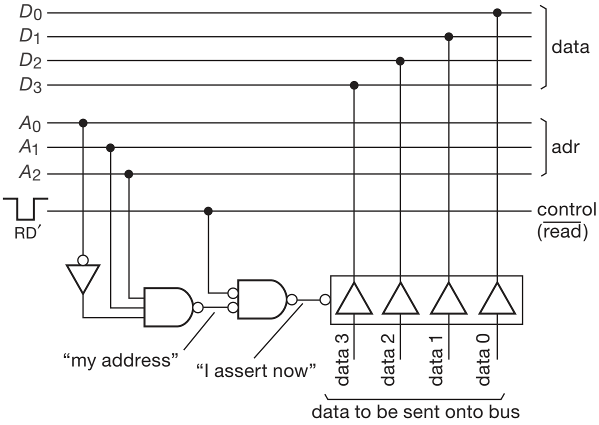

Figure 10.29. Data bus with address decode logic and three-state drivers.

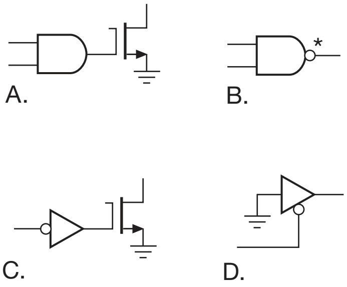

Figure 10.30. Open-drain logic: A. open-drain NAND; B. symbol; C. open-drain noninverting buffer; D. implementation with three-state buffer.

C. Open-collector and open-drain logic

The predecessor to three-state logic was "open-collector" logic, which allows you to share a single line among the outputs of several drivers. An open-collector (or open-drain) output simply omits the active pullup transistor of the output stage (Figure 10.30). The name "open-collector" is a good one. When you use such gates, you must supply an external pullup resistor somewhere. Its value isn't critical; a small-value resistor gives increased speed and improved noise immunity, at the expense of increased power dissipation and loading of the driver. Values of a few hundred to a few thousand ohms are typical. If you wanted to drive a bus with open-collector gates (rather than with three-state drivers), you would substitute 2-input open-collector NANDs for the three-state drivers of Figure 10.29, bringing one input of each gate HIGH to enable the gates onto the bus; note that the data bits then asserted onto the bus are inverted. Each bus line would need a single resistive pullup to the positive supply.

The disadvantage of open-collector logic is that speed and noise immunity are degraded, when compared with logic constructed with active pullup devices, because of the resistive pullup circuit. That's why three-state drivers are nearly universally favored for computer bus applications. However, there are three situations in which you would choose open-collector (or open-drain) devices: driving external loads, "wired-OR," and external buses. Let's look at them briefly.

D. Driving external loads

Open-collector (O/C) logic is good for driving external loads that are returned to a higher-voltage positive supply. You might want to drive a low-current lamp or relay that requires 12 V, or perhaps just generate a 15 V logic swing by running a resistor from a gate's output to +15 V, as in Figure 10.31. A popular O/C device is the ULN2003/4, a seven-channel open collector Darlington array with internal clamp diodes (for inductive loads); it accepts direct logic drive, has a 50 V breakdown rating, and can switch up to 500 mA (the 75468/9 is similar, but with 100 V breakdown). More on these subjects in §12.4.

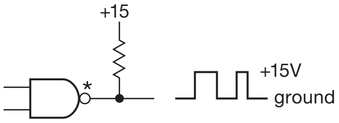

Figure 10.31. Open-collector logic as level translator.

E. Wired-OR

If you wire together some open-collector gates as shown in Figure 10.32, you get what's called "wired-OR" – the combination behaves in this case like a larger NOR gate, with the output going LOW if any input is HIGH. You can't do this with active pullup outputs, because there would be a contest of wills if all the gates didn't agree on what the output should be. You can combine NORs, NANDs, etc., with this kind of connection, and the output will be LOW if any gate asserts a LOW output. This connection is sometimes called "wired-AND," because the output is HIGH only if all gates have HIGH (open) outputs. Both names are describing the same thing: it's wired-AND for active-HIGH logic and wired-OR for active-LOW logic. This will make more sense to you after you've seen DeMorgan's theorem in the next section.

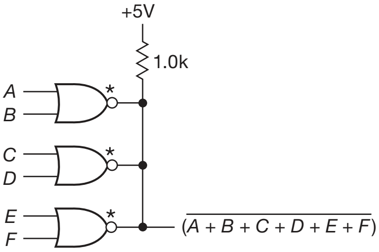

Figure 10.32. Wired-OR.

Wired-OR enjoyed some brief popularity in the early days of digital electronics, but it is not much used today, with two exceptions: (a) in the family of logic known as ECL (emitter-coupled logic) the outputs are what you might call "open-emitter," and can be wired-OR'ed painlessly; and (b) there are some shared lines in computer buses (most notably the line called *interrupt*) whose function is not to transfer data bits, but merely to indicate if *at least one* device is requesting attention; in that case you use wired-OR, because it does what you want and doesn't require external logic to prevent contention.

F. External buses

Where speed is not too important, you sometimes see open-collector drivers used to drive buses. Examples are the original SCSI bus used to connect disks and peripherals, and the IEEE-488 (also called general-purpose interface bus, GPIB) instrument bus. More on this in Chapter 14.

10.3 Combinational logic

As we discussed earlier in §10.1.4A, digital logic can be divided into *combinational* (sometimes called *combinatorial*) and *sequential*. Combinational circuits are those in which the output state depends on only the present input states in some predetermined fashion, whereas in sequential circuits the output state depends both on the input states and the previous history. Combinational circuits can be constructed with gates alone, whereas sequential circuits require some form of memory (flip-flops). In these subsections we explore the possibilities of combinational logic before entering the turbulent world of sequential circuits.

Table 10.4 Logic Identities

$ABC = (AB)C = A(BC)$
$AB = BA$
$AA = A$
$A1 = A$
$A0 = 0$
$A(B + C) = AB + AC$
$A + AB = A$
$A + BC = (A + B)(A + C)$
$A + B + C = (A + B) + C = A + (B + C)$
$A + B = B + A$
$A + A = A$
$A + 1 = 1$
$A + 0 = A$
$1' = 0$
$0' = 1$
$A + A' = 1$
$AA' = 0$
$(A')' = A$
$A + A'B = A + B$
$(A + B)' = A'B'$
$(AB)' = A' + B'$

10.3.1 Logic identities

No discussion of combinational logic is complete without the identities shown in Table 10.4. Most of these are obvious. The last two comprise DeMorgan's theorem, the most important for circuit design.

A. Example: exclusive-OR gate

We illustrate the use of the identities with an example: making the exclusive-OR function from ordinary gates. Figure 10.33 shows the XOR truth table. From studying this and by realizing that the output is 1 only when $(A, B) = (0, 1)$ or $(1, 0)$, we can write

$$A \oplus B = \overline{A}B + A\overline{B},$$

from which we have the realization shown in Figure 10.34. However, this realization is not unique. Applying the identities, we find

$$
\begin{aligned}
A \oplus B &= A\overline{A} + A\overline{B} + B\overline{A} + B\overline{B} \\
&\qquad (A\overline{A} = B\overline{B} = 0) \\
&= A(\overline{A}+\overline{B}) + B(\overline{A}+\overline{B}) \\
&= A(\overline{AB}) + B(\overline{AB}) \\
&= (A+B)(\overline{AB}).
\end{aligned}
$$

(In the first step we used the trick of adding two quantities that equal zero; in the third step we used DeMorgan's theorem.) This has the realization shown in Figure 10.35. There are still other ways to construct XOR. Consider the following exercise.

A	B	$A \oplus B$
0	0	0
0	1	1
1	0	1
1	1	0

Figure 10.33. XOR truth table.

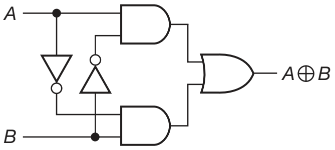

Figure 10.34. XOR realization.

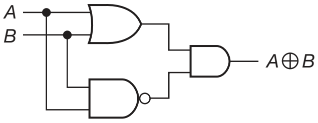

Figure 10.35. Another XOR realization.

Exercise 10.12. Show that

$$
\begin{aligned}
A \oplus B &= \overline{AB + \overline{A}\,\overline{B}}, \\
A \oplus B &= (A+B)(\overline{A}+\overline{B}),
\end{aligned}
$$

by logic manipulation. You should be able to convince yourself that these are true by inspection of the truth table, combined with suitable hand-waving.

Exercise 10.13. What are the following: (a) $0 \cdot 1$, (b) $0+1$, (c) $1 \cdot 1$, (d) $1+1$, (e) $A(A+B)$, (f) $A(A'+B)$, (g) A XOR A, (h) A XOR A'?

10.3.2 Minimization and Karnaugh maps

Because a realization of a logic function (even one as simple as exclusive-OR) isn't unique, it is often desirable to find the simplest, or perhaps most conveniently constructed, circuit for a given function. Many good minds have worked on this problem, and there are several methods available, including algebraic techniques widely available as software. For example, all of the "hardware description languages" (HDLs) used to enter circuitry going into programmable logic (see §11.2.6) include automatic logic minimization; you don't even see it happening.

Perhaps of historical interest only, you'll sometimes hear the term *Karnaugh map,* which is a simple tabular method for minimizing logic with four or fewer inputs; it also enables you to find a logic expression (if you don't know it) once you can write down the truth table.

We illustrate the method with an example (and then abandon it entirely!). Suppose you want to generate a logic circuit to count votes. Imagine that you have three active-HIGH inputs (each either 1 or 0) and an output (0 or 1). The output is to be 1 if at least two of the inputs are 1.

Step 1. Make a truth table:

A	B	C	Q
0	0	0	0
0	0	1	0
0	1	0	0
0	1	1	1
1	0	0	0
1	0	1	1
1	1	0	1
1	1	1	1

All possible permutations must be represented, with corresponding output(s). Write an X (= "don't care") if either output state is OK.

Step 2. Make a Karnaugh map. This is somewhat akin to a truth table, but the variables are represented along two axes. Furthermore, they are arranged in such a way that only one input bit changes in going from one square to an adjacent square (Figure 10.36).

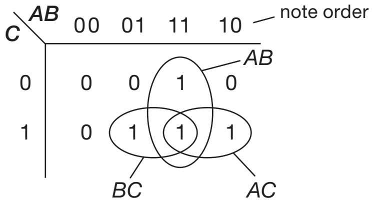

Figure 10.36. Karnaugh map for majority logic.

Step 3. Identify on the map groups of 1s (alternatively, you could use groups of 0s): the three blobs (called a "cover") enclose the logic expressions AB,AC, and BC. Finally, read off the required function, in this case

$$Q = AB + AC + BC$$

with the realization shown in Figure 10.37. The result seems obvious, in retrospect. We could have read off the pattern of 0s to get instead

$$Q' = A'B' + A'C' + B'C',$$

which might be useful if the complements A', B', and C' already exist somewhere in the circuit.

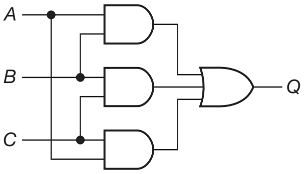

Figure 10.37. Majority (voting) logic.

Exercise 10.14. Just for fun, draw a Karnaugh map for logic to determine if a 3-bit integer (0 to 7) is prime (assume that 0, 1, and 2 are not primes). Show a realization with 2-input gates.

Exercise 10.15. Continuing Karnaugh-map fun: find logic to perform multiplication of two 2-bit unsigned numbers (i.e., each 0 to 3), producing a 4-bit result. *Hint*: use a separate Karnaugh map for each output bit.

10.3.3 Combinational functions available as ICs

With logic gates alone, you could construct logic to perform rather complicated functions such as binary addition or magnitude comparison, parity checking, multiplexing (selecting one of several inputs, as determined by a binary address), etc. In fact, that is just what is done when you implement complex logic in *gate arrays*[39] or in other forms of *programmable logic* (see §10.3.3F, §10.5.4, and Chapter 11.). Programmable logic (usually combined with a microcontroller) is quite often the method of choice when you want to make some digital (or combined analog/digital) system. We'll illustrate these techniques in the next chapter.

However, these functions are generally available also in the form of prefabricated MSI chips (medium-scale integration, upward of 100 gates on one chip), to be used as standard-logic functions. Although many interesting MSI functions involve flip-flops (i.e., *sequential* circuits, which we will get to shortly), there are a number of them that are combinational functions involving gates only. Let's see what animals live in the MSI combinational zoo.

A. 2-input select (multiplexer)

The 2-input select (also called a 2-input *multiplexer*, or "MUX") is a very useful function. It is basically a two-position switch for logic signals. Figure 10.38 shows the basic idea, with both a discrete gate implementation and an IC that packages four 2-input multiplexers (a "quad MUX") in one IC. When SELECT is LOW, the A inputs are passed through to their respective Y outputs; when SELECT is HIGH, the B inputs appear at the output. Holding ENABLE′ HIGH disables the device by forcing all outputs LOW. This is an important concept we'll see more of later. Here's the truth table, which illustrates the X (don't care) entry:

Inputs				*Outputs*
E'	SEL	A_n	B_n	Y_n
H	X	X	X	L
L	L	L	X	L
L	L	H	X	H
L	H	X	L	L
L	H	X	H	H

It can be written more compactly like this:

Inputs		*Outputs*
E'	SEL	Y_n
H	X	L
L	L	A_n
L	H	B_n

In a hardware description language the 2-input MUX logic function (without an ENABLE input) would be written as `Y = ~S & A | S & B`; with an ENABLE input it would become `Y = E & (~S & A | S & B)`.[40] Figure 10.38 and the preceding table correspond to the '157 quad 2-input select chip. The same function is also available with inverted output ('158) and with three-state outputs (true: '257; inverted: '258). It is also available as a tiny single-section MUX (without the EN′ input), with part numbers '1G157 and '2G157. These chips work electrically like gates – they do the logic and regenerate a logic level at the output accordingly. Another way to implement this function is with a few *transmission gates*, in which the appropriate input signal is simply passed through to the

[39] A function so implemented is sometimes amusingly referred to as having been "Gatorade."

[40] For a somewhat obscure reason (having to do with a "logic-race" condition) it's a good idea to add the redundant term `A & B` to these expressions; thus `Y = E & (~S & A | S & B | A & B)`.

output (via MOS transistors) without regeneration; we'll see this next.

Exercise 10.16. Show how to make a 2-input select, using a pair of 3-state buffers and whatever other logic you need.

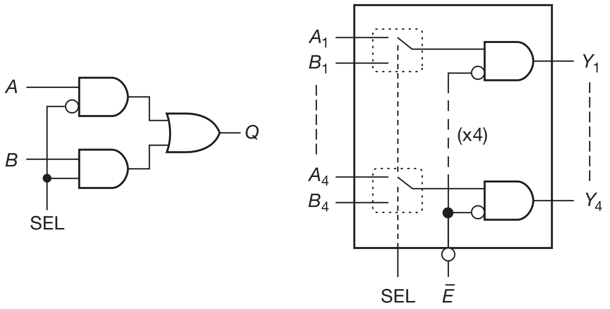

Figure 10.38. Two-input "select" gates: A. implemented with discrete gates; B. packaged together as a "quad," with a single SELECT line.

Although the function of a select gate can be performed by a mechanical switch in some cases, the gate is a far better solution, for several reasons:

(a) it is cheaper;
(b) all channels are switched simultaneously and rapidly;
(c) it can be switched, nearly instantaneously, by a logic level generated elsewhere in the circuit (most interestingly, from a microprocessor or other smart device);
(d) even if the select function is to be controlled by a front-panel switch, it is better not to run fast logic signals around through cables and switches, to avoid capacitive signal degradation and noise pickup.

With a select gate actuated by a dc level, you keep logic signals on the circuit board and get the bonus of simpler off-board wiring, namely a single line with pullup switched to ground by a single-pole single-throw (SPST) switch. Controlling circuit functions with externally generated dc levels in this manner is known as "cold switching," and it is a much better approach than controlling the signals themselves with switches, potentiometers, etc. Besides its other advantages, cold switching lets you bypass control lines with capacitors to eliminate interference, whereas signal lines cannot generally be bypassed. We'll see some examples of cold switching later.

B. Transmission gates

As we discussed in §3.4.1A, with CMOS it is possible to make "transmission gates," simply a pair of complementary MOSFET switches in parallel, so that an input (analog) signal between ground and V_{DD} is either connected through to the output through a low resistance (less than a hundred ohms) or open-circuited (essentially infinite resistance). As you may remember, such a device is bidirectional and doesn't know (or care) which end is input and which end is output. Transmission gates work perfectly well with digital CMOS levels, and in fact they are used extensively in the internal circuitry of CMOS digital devices. You can get them also as standard logic ICs. Figure 10.39 shows the layout of the popular '4066 CMOS "quad bilateral switch." Each switch has a separate *control* input: HIGH closes the switch, and LOW opens it. They are available also in compact single-section and two-section packages ('1G66, '2G66). Note that transmission gates are merely switches, and therefore have no fan-out; i.e., they simply pass input logic levels through to the output without providing additional drive capability.[41]

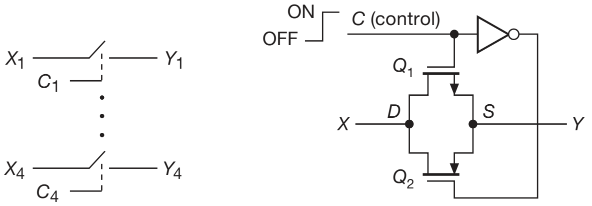

Figure 10.39. Quad transmission gate; a single gate, implemented with MOS transistors, is shown at right.

With transmission gates you can make 2-input (or more) select functions, usable with CMOS digital levels or analog signals. To select among a number of inputs, you can use a bunch of transmission gates (generating the control signals with a *decoder*, as will be explained later). This is such a useful logic function that it has been institutionalized as the multiplexer, discussed next.

Exercise 10.17. Show how to make a 2-input select with transmission gates. You will need an inverter.

C. Multiplexers with many inputs

Multiplexers are available with 4, 8, and 16 inputs. A binary address is used to select which of the input signals appears at the output. For instance, an 8-input MUX has a 3-bit address input to address the selected data input (Figure 10.40). The digital MUX illustrated is a '151. It has an active-LOW STROBE′ (another name for ENABLE′) input, and it provides true and complemented outputs. When the

[41] Transmission gates are attractive to IC designers because their simple design requires little area on the silicon die, and they do not incur the switching delay of a conventional gate.

```
wire [1:0] A; // 2 address ("select") input lines
wire [3:0] D; // 4 input data lines
wire Y, YBAR, ENBAR // outputs (true and complemented), and enable
assign Y = ~ENBAR & ( D[0] & ~A[1] & ~A[0]
                    | D[1] & ~A[1] & A[0]
                    | D[2] & A[1] & ~A[0]
                    | D[3] & A[1] & A[0] )
assign YBAR = ~ Y;
```

Figure 10.41. Verilog code for a 4-input multiplexer.

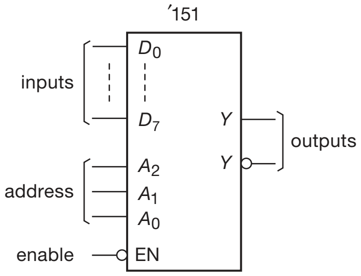

Figure 10.40. '151 8-input multiplexer.

chip is disabled (ENABLE′ held HIGH), Y is LOW and Y' is HIGH, independent of the states of the address and data inputs.

It's a good idea to become somewhat familiar with description languages used for logic entry, if for no reason other than anxiety reduction. Figure 10.41 shows what Verilog code looks like, for the simpler example of a 4-input multiplexer.

Electrically, two varieties of multiplexers are available. One type is for digital levels only, with an input threshold and "clean" regeneration of output levels according to the input state: an example is the '153 logic MUX (available in both CMOS and bipolar logic families). The other kind of MUX is analog and bidirectional; it's really just an array of transmission gates. These come only in CMOS families, and can be used for both logic and analog signals. The '4051–'4053 CMOS multiplexers work this way. Remember that logic made from transmission gates has no fan-out. Since transmission gates are bidirectional, these multiplexers can be used as "demultiplexers," or decoders. We discuss them next.

Exercise 10.18. Show how to make a 4-input multiplexer using (a) ordinary gates, (b) gates with three-state outputs, and (c) transmission gates. Under what circumstances would (c) be preferable?

You might wonder what to do if you want to select among more inputs than are provided in a multiplexer. This question comes under the general category of chip "expansion" (using several chips that have small individual capabilities to generate a larger capability), and it applies to decoders, memories, shift registers, arithmetic logic, and many other functions as well. In this case the job is easy (Figure 10.42). Here we have expanded two 74LS151 8-input multiplexers into a 16-input multiplexer (note that we've used lowercase designations for the input and output signals, to prevent confusion with the chip's similarly named pins).[42] There's an additional address bit, of course, and you use it to enable one chip or the other. The disabled chip holds its Y LOW, so an OR gate at the output completes the expansion. With three-state outputs the job is even simpler, because you can connect the outputs directly together.

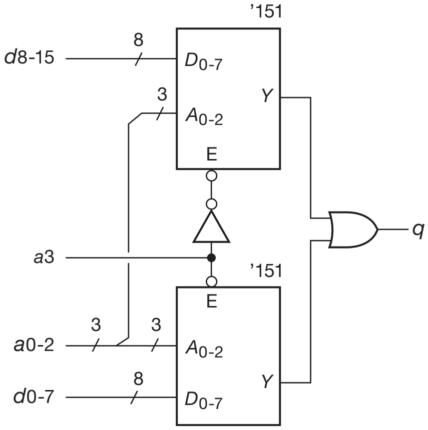

Figure 10.42. Multiplexer expansion.

D. Demultiplexers and decoders

A demultiplexer is the opposite of a multiplexer: it takes an input and routes it to one of several possible outputs,

[42] We've also introduced a common "bus" convention, namely the use of a single line with a diagonal slash to indicate a collection of similar signal lines; the number by the slash tells you how many signals are in the group, and the label tells you what they are.

```
wire [1:0] A; // 2-bit address: brackets show array range
wire [3:0] YBAR; // four active-LOW outputs
wire ENBAR; // active-LOW enable
assign YBAR[0] = ~(~ENBAR & ~A[1] & ~A[0]);
assign YBAR[1] = ~(~ENBAR & ~A[1] & A[0]);
assign YBAR[2] = ~(~ENBAR & A[1] & ~A[0]);
assign YBAR[3] = ~(~ENBAR & A[1] & A[0]);
```

Figure 10.44. Verilog code for one section of a ’139 dual 1-of-4 decoder.

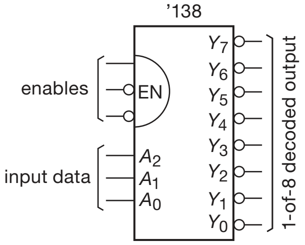

Figure 10.43. ’138 1-of-8 decoder.

according to an input binary address. The other outputs are either held in the inactive state or open-circuited, depending on the type of demultiplexer.

A decoder is similar, except that the address is the only input, and it is “decoded” to assert one of *n* possible outputs. Figure 10.43 shows an example. This is the ’138 “1-of-8 decoder.” The output corresponding to (addressed by) the 3-bit input data is LOW; all others are HIGH. This particular decoder has three ENABLE inputs, all of which must be asserted (two LOW, one HIGH); otherwise all outputs are HIGH.

Decoders are commonly used when interfacing to a data bus, to trigger different actions depending on the address; we’ll treat this subject in detail in Chapter 13. Another common use of a decoder is to enable a sequence of actions in turn, according to an advancing address given by the output of a binary *counter* (§10.4.2E). A close cousin of the ’138 is the ’139, a dual 1-of-4 decoder with a single active-LOW ENABLE per section. Figure 10.44 illustrates what its Verilog code would look like.

Figure 10.45 shows how to use a pair of ’138 1-of-8 decoders to generate a 1-of-16 decoder. No external gates are necessary, since the ’138 has ENABLE inputs of both polarities.

Exercise 10.19. More expansion: make a 1-of-64 decoder from nine ’138s. *Hint*: use one of them as an enabling switchyard for the others.

In CMOS logic, the multiplexers that use transmission gates are also demultiplexers, since transmission gates are bidirectional. When they are used that way, it is important to realize that the outputs that aren’t selected are open-circuited. A pullup or pulldown resistor, or equivalent, must be used to assert a well-defined logic level on those outputs (the same requirement as with TTL open-collector gates).

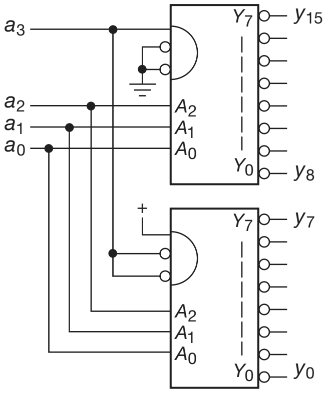

Figure 10.45. Decoder expansion.

Another kind of decoder is the ’47 “BCD-to-7-segment decoder/driver.” It takes a BCD input and generates outputs on 7 lines corresponding to the segments of a “7-segment display” that have to be lit to display the decimal character. This type of decoder is really an example of a *code converter,* but in common usage it is called a decoder.

Exercise 10.20. Design a BCD-to-decimal (1-of-10) decoder using gates.

Exercise 10.21. Design a “simple” encoder: a circuit that outputs the (2-bit) address telling which of 4 inputs is HIGH (all other inputs must be LOW).

Exercise 10.22. Figure out how to make a parity generator with XOR gates.

E. Other arithmetic chips

The *priority encoder* generates a binary code giving the address of the highest-numbered input that is asserted. It is particularly useful in “parallel-conversion” ADCs (see next chapter) and in microprocessor system design. An example is the ’148 8-input (3 output bits) priority encoder. The ’147 encodes 10 inputs.

Figure 10.46 shows a 4-bit *magnitude comparator.* It determines the relative sizes of the 4-bit input numbers A and B and tells you via outputs whether $A < B$, $A = B$, or $A > B$. Inputs are provided for expansion to numbers larger than 4 bits.

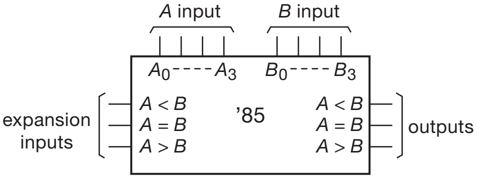

Figure 10.46. Magnitude comparator.

A *parity-generator* chip is used to generate a parity bit to be attached to a “word” when transmitting (or recording) data, and to check the received parity when such data are recovered. Parity can be even or odd (e.g., with odd parity the number of 1 bits in each character is odd). The ’280 parity generator, for instance, accepts a 9-bit input word, giving an even- and an odd-parity bit output. The basic construction is an array of exclusive-OR gates.

Figure 10.47 shows a 4-bit *full adder.*[43] It adds the 4-bit number A_i to the 4-bit number B_i, generating a 4-bit sum S_i plus carry bit C_o. Adders can be “expanded” to add larger numbers: the “carry-in” input C_i is provided to accept the carry out of the next lower adder.

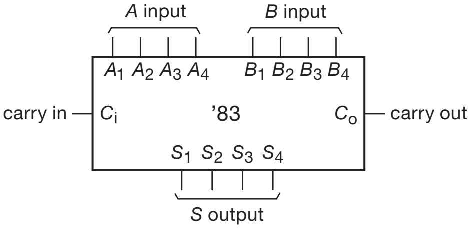

Figure 10.47. 4-bit full adder.

Figure 10.48 shows the Verilog code (here written out in somewhat longwinded form, for clarity) for a 4-bit full adder; see if you can understand how it figures out the sum.

A nice thing about languages like Verilog or VHDL is that they understand higher levels of abstraction (and you can, too, once you get the hang of them). In this case all the stuff after the `wire` declarations can be written as a single line, namely `assign {COUT,S} = A + B + CIN;`.

A device known as an *arithmetic logic unit* (ALU) can be used as an adder, though it has the capability of performing a number of different functions. For instance, the ’181 4-bit ALU (expandable to larger word lengths) can do addition, subtraction, bit shifts, magnitude comparison, and a few other functions. Adders and ALUs do their arithmetic in times measured in nanoseconds to tens of nanoseconds, depending on logic family. Other dedicated arithmetic chips include the *multiplier–accumulator* (MAC), which accumulates a sum of products, and the *correlator*, which compares the corresponding bits of a pair of bit strings, calculating the number of bits that agree.

However, owing to the development of large and fast microprocessors, contemporary digital design favors either general-purpose microprocessors or the more optimized digital signal processors (DSPs) for the kind of signal processing that involves extensive arithmetic functions. An attractive alternative is the FPGA, user-configurable to be just about anything; you can drop in a “soft” processor or other function, and you can get them with optimized “hard” functions already built in. We’ll talk about configurable logic in the next chapter, and microprocessors in Chapter 15.

F. Programmable logic devices

You can configure your own custom combinational (and sequential) logic on a single chip by using ICs that contain an array of gates with programmable interconnections. These are known generically as *programmable logic devices* (PLDs). The popular varieties are cPLDs (complex PLDs) and field-programmable gate arrays (FPGAs). Both flavors are high achievers, flexible, and a delight to use. They are a part of every designer’s toolbox of tricks. We’ll meet them later in this chapter, and again in the next.

10.4 Sequential logic

10.4.1 Devices with memory: flip-flops

All our work with digital logic so far has been with combinational circuits (e.g., arrays of gates), for which the output is determined completely by the existing state of the inputs. There is no “memory,” no history, in these circuits. Digital life gets really interesting when we add devices with memory. This makes it possible to construct counters, arithmetic

[43] We show the ’83 logic-family part number mostly from a sense of nostalgia. The part does not exist in the ’HC family, and the 7483 and 74LS83 parts are obsolete. In contemporary design such MSI (medium-scale integration) functions are most often implemented with some form of programmable logic (see §10.5.4 and Chapter 11). In fact, it is the very superiority of the latter that brought about the demise of many of the old MSI parts.

```
wire [3:0] A;
wire [3:0] B;
wire [3:0] S; // sum bits
wire CIN, COUT; // carrys
assign S[0] = A[0] ^ B[0] ^ CIN; // recall "^" means XOR
assign C01 = A[0] & B[0] | A[0] & CIN | B[0] & CIN;
assign S[1] = A[1] ^ B[1] ^ C01;
assign C12 = A[1] & B[1] | A[1] & C01 | B[1] & C01;
assign S[2] = A[2] ^ B[2] ^ C12;
assign C23 = A[2] & B[2] | A[2] & C12 | B[2] & C12;
assign S[3] = A[3] ^ B[3] ^ C23;
assign COUT = A[3] & B[3] | A[3] & C23 | B[3] & C23;
```

Figure 10.48. Verilog code for a 4-bit full adder.

accumulators, and circuits that generally do one interesting thing after another. The basic unit is the flip-flop, a colorful name to describe a device that, in its simplest form, looks as shown in Figure 10.49.

Assume that both A and B are HIGH. What are X and Y? If X is HIGH, then both inputs of G_2 are HIGH, making Y LOW. This is consistent with X being HIGH, so we're finished. Right?

$$X = \text{HIGH},$$
$$Y = \text{LOW}.$$

Wrong! The circuit is symmetrical, so an equally good state is

$$X = \text{LOW},$$
$$Y = \text{HIGH}.$$

The states X, Y both LOW, and X, Y both HIGH, are not possible (remember, $A = B = \text{HIGH}$). So the flip-flop has two stable states (it's sometimes called a "bistable"). Which state it is in depends on past history. It has memory! To write into the memory, just bring one of the inputs momentarily LOW. For instance, bringing A LOW momentarily guarantees that the flip-flop goes into the state

$$X = \text{HIGH},$$
$$Y = \text{LOW},$$

no matter what state it was in previously. You would describe it as an "SR flip-flop," which is Set or Reset with an active-LOW input pulse.

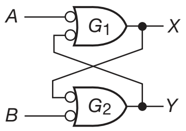

Figure 10.49. Flip-flop ("set-reset" type).

A. Switch debouncing

This kind of flip-flop (with a SET and RESET input, often labeled S and R) is quite useful in many applications. Figure 10.50 shows a typical example. This circuit is supposed to enable the gate and pass input pulses when the switch is opened.[44] The problem with this circuit is that switch contacts *bounce*. When the switch is closed, the two contacts actually separate and reconnect, typically 10 to 100 times over a period of about a millisecond. You would get the kind of waveforms shown; if there were a counter or shift register using the output, it would faithfully respond to all those extra "pulses" caused by the bounce.

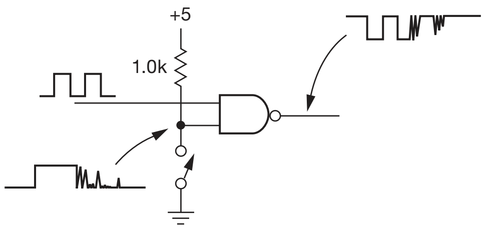

Figure 10.50. Mechanical-switch "bounce."

Figure 10.51 shows a cure. The flip-flop changes state when the contacts first close. Further bouncing against that contact makes no difference and SPDT (single-pole, double-throw) switches never bounce all the way back to the opposite position; the output is a *debounced* signal, as sketched. This debouncer circuit is widely used; the '279 "quad SR latch" lets you get four into one package, and the '1G74 (in a smaller package) can be used when only a single flip-flop is needed. Incidentally, the preceding circuit

[44] We generally like to tie a switch to ground (not +5V) for a couple of reasons: (1) ground is a convenient (and electrically "quiet") return path for switches and other controls; and (2) we got used to it, owing to a peculiarity of (current-sourcing) bipolar logic.

has a minor flaw: the first pulse after the gate is enabled may be shortened, depending on when the switch is closed relative to the input pulse train; the same holds for the final pulse of a sequence (of course, a switch that is not debounced has the same problem). A “synchronizer” circuit (see §10.4.4) can be used to prevent this from happening, for applications where it makes a difference.

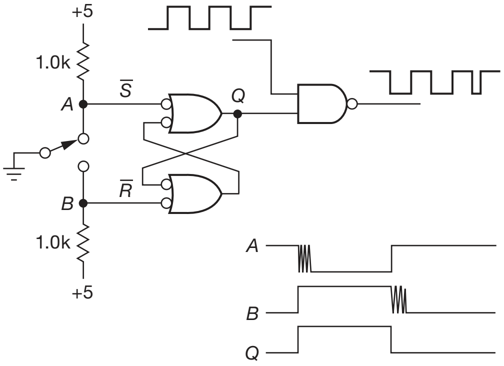

Figure 10.51. SR flip-flop switch debouncer. Note the damaged output waveform. The nodes labelled $\overline{S}$ and $\overline{R}$ are active-LOW SET and RESET inputs to the flip-flop.

Figure 10.52A shows a trick we use for making a simpler debouncer: the noninverting buffer (which could be made instead from an ’08 2-input AND, or two cascaded ’04 inverters, or whatever) holds its last state (just like a flip-flop). The switch, when thrown, momentarily overrides the buffer’s output; the latter, however, is wise enough not to fight inevitability, and it switches (without bounce) to agree. There’s a lot of output current during the momentary contention, which, however, lasts only during the gate transition time, of order a few nanoseconds. No harm done, and, despite one’s feeling of discomfort at such a dirty trick,[45] it works just fine. With a pair of cascaded inverters (Figure 10.52B) you can avoid the connection to V_{DD}.

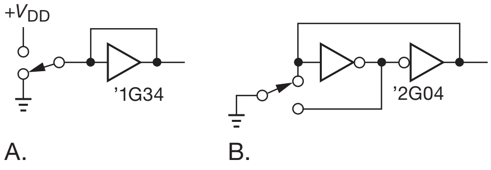

Figure 10.52. Simple switch debouncer.

B. Multiple-input flip-flop

Figure 10.53 shows another simple flip-flop. Here NOR gates are used; a HIGH input forces the corresponding output LOW. Multiple inputs allow various signals to set or clear the flip-flop. In this circuit fragment, no pullups are used, because logic signals generated elsewhere (by standard active pullup outputs) are used as inputs.

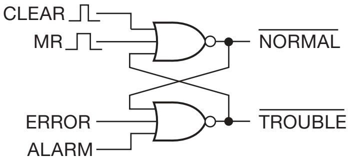

Figure 10.53. SR flip-flop with multiple inputs.

10.4.2 Clocked flip-flops

Flip-flops made with two gates, as in Figures 10.49 and 10.53, are known generically as *SR* (set–reset), or *jam-loaded*, flip-flops. You can force them into one state or the other whenever you want by just generating the right input signal. They’re handy for switch debouncing and many other applications. But the most widely used form of flip-flop looks a little different. Instead of a pair of jam inputs, it has one or two “data” inputs and a single “clock” input. The outputs will change state or stay the same, depending on the levels at the data inputs when the clock pulse arrives.

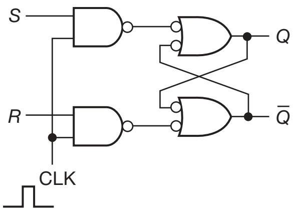

Figure 10.54. Clocked flip-flop: first approximation.

The simplest clocked flip-flop looks as shown in Figure 10.54. It’s just our original flip-flop, with a pair of added gates (controlled by the clock) to enable the SET and RESET inputs. It is easy to verify that the truth table is

S	R	Q_{n+1}
0	0	Q_n
0	1	0
1	0	1
1	1	indeterminate

where Q_{n+1} is the Q output after the clock pulse and Q_n is

[45] Timid engineers have been known to replace the feedback wire with a resistor, say 1 kΩ. This eliminates the momentary current spike on the power rail, simultaneously relieving your lingering anxiety.

the output before the clock pulse. The basic difference between this and the previous flip-flops is that *R* and *S* should now be thought of as *data* inputs (as opposed to flip-flop set–reset inputs). What is present on *R* and *S* when a short clock pulse comes along determines what happens to *Q*. The *R* and *S* inputs are otherwise ignored.

This flip-flop has one awkward property, however. The output can change in response to the inputs during the time the clock is HIGH. In that sense it is still like the jam-loaded *SR* flip-flop (it's also known as a *transparent latch*: the output "sees through" to the input when the clock is HIGH). The full utility of clocked flip-flops comes with the introduction of slightly different configurations: the master–slave flip-flop, and the edge-triggered flip-flop.

A. Edge-triggered: the type-D flip-flop

These are by far the most popular kind of flip-flop. The logic level present at the *D* (data) input just before[46] a clock transition, or "edge," determines the output state after the clock has changed.

Here's the truth table for the type-*D* flip-flop:

D	Q_{n+1}
0	0
1	1

You can think of the *D*-FF as copying the state of its input to its (latched) output. One of its many uses is, in fact, simply grabbing and holding a transient logic level,[47] as commanded by a separate clocking transition. These flip-flops are available as inexpensive packaged ICs and are always used in that form.

It is worth pausing for a moment to look at the innards of a *D* flip-flop, in order to understand what is going on. Figure 10.55 shows two circuit configurations, known as "master–slave" and "edge-triggered," respectively. The master–slave configuration is probably easier to understand. Here's how it works.

While the clock is HIGH, gates 1 and 2 are enabled, forcing the master flip-flop (gates 3 and 4) to the same state as the *D* input: $M{=}D$, $M'{=}D'$. Gates 5 and 6 are disabled, so the slave flip-flop (gates 7 and 8) retains its previous state. When the clock goes LOW, the inputs to the master are disconnected from the *D* input, while the inputs of the slave are simultaneously coupled to the outputs of the master. The master thus transfers its state to the slave. No further changes can occur at the output, because the master is now stuck. At the next rising edge of the clock, the slave will be decoupled from the master and will retain its state, while the master will once again follow the input.

The edge-triggered circuit behaves the same externally, but the inner workings are different. It is not difficult to figure them out. The particular circuit shown happens to be the ever-popular '74 rising-edge-triggered type-*D* flip-flop. Flip-flops are available with either rising- or falling-edge triggering.[48] (The preceding master–slave circuit transfers data to the output on the *falling* edge.) In addition, most flip-flops also have SET and CLEAR jam-type inputs. They may be set and cleared on HIGH or on LOW, depending on the type of flip-flop. Figure 10.56 shows four flip-flop examples. The wedge means "edge-triggered," and the little circles mean "negation," or complement. Thus the '74 is a dual type *D* rising-edge-triggered flip-flop with active-LOW jam-type SET and CLEAR inputs; the '4013 is a dual type-*D* rising-edge-triggered flip-flop with active-HIGH jam-type SET and CLEAR inputs; the '1G79 is a single type-*D* rising-edge-triggered flip-flop with no SET or CLEAR inputs and without a Q' output; and the '112 is a dual *JK* master–slave flip-flop with data transfer on the falling edge and with active-LOW jam-type SET and CLEAR inputs.

JK and type-T flip-flops

The *JK* and *T* flip-flops work on principles similar to those of the type-*D* flip-flop. Here are the truth tables:

J	K	Q_{n+1}
0	0	Q_n
0	1	0
1	0	1
1	1	Q'_n

T	Q_{n+1}
0	Q_n
1	Q'_n

Thus, if *J* and *K* are complements, *Q* will go to the value of the *J* input at the next clock edge. If *J* and *K* are both LOW, the output won't change. If *J* and *K* are both HIGH, the output will "toggle" (reverse its state after each clock pulse).

The *T* (toggling-type) flip-flop toggles at each clock if *T* is HIGH; *T* LOW makes it stick.

B. Divide-by-2

In digital circuits you often want to create a signal that toggles at a subdivision of some higher-frequency "clock" signal that is already present. For example, digital wristwatches use as their timebase a 32,768 Hz crystal oscillator; that peculiar frequency is chosen because its 2^{15}

[46] This vague wording can, and will, be made precise, when we visit *setup* and *hold* times in §10.4.2C.

[47] Or perhaps a bunch of separate bits (e.g., an 8-bit data byte) in an array of *D*-flops (which is called a *register*).

[48] Sometimes loosely called *positive edge* and *negative edge*, respectively.

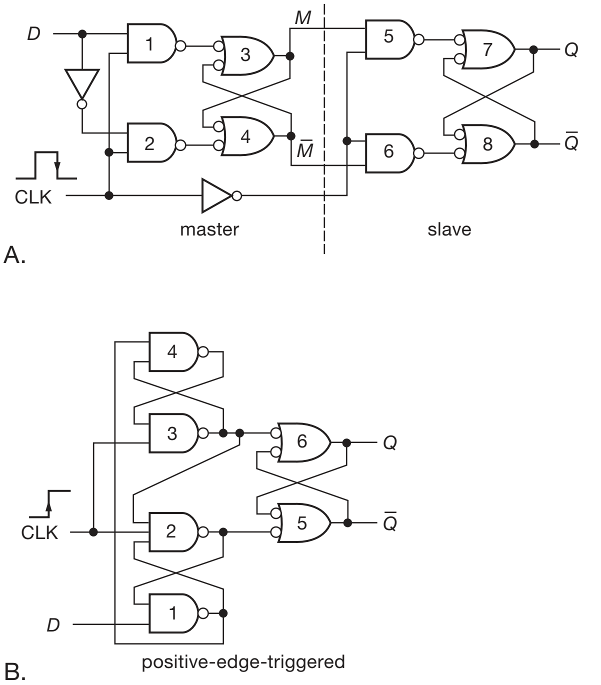

Figure 10.55. True clocked flip-flops: master–slave and edge-triggered type-*D* flip-flops.

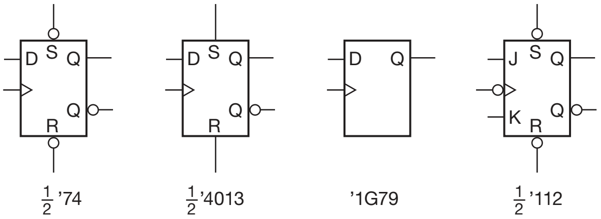

Figure 10.56. *D*-type and *JK* flip-flops.

subdivision is 1 Hz, just right for stepping the clock's second hand (or incrementing its displayed digital time). The basic trick here is to use the toggling capability of flip-flops: in Figure 10.57 the *D* flip-flop always sees, at its *D* input, the complement of its existing *Q* output. It therefore toggles at each clock pulse, generating an output at half the input clock frequency.

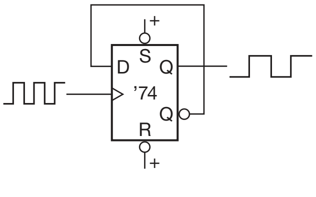

Figure 10.57. Toggling *D* flip-flop.

In Figure 10.58 you can see the essence of Verilog coding for the toggling *D* flip-flop.

```
wire CLKIN;
reg Q;
always @(posedge CLKIN)
 Q = ~Q;
```

Figure 10.58. Verilog code for the toggling *D* flip-flop.

C. Data and clock timing

This last circuit raises an interesting question: will the circuit fail to toggle, because the *D* input changes almost immediately after the clock pulse? In other words, will the circuit get confused, with such crazy things happening at its input? You could, instead, ask this question: exactly *when* does the *D* flip-flop (or any other flip-flop) look at its input, relative to the clock pulse? The answer is that there is a specified *setup time* t_s and *hold time* t_h for any clocked device. Input data must be present and stable from at least t_s before the clock transition until at least t_h after it, to guarantee proper operation. For the 74HC74, for instance, t_s=20 ns and t_h=3 ns (Figure 10.59). So, for the preceding toggling connection, the setup-time requirement is met if the output has been stable for at least 20 ns before the next clock rising edge. It may look as if the hold-time requirement is violated, but that's OK, also. The minimum *propagation time* from clock to output is 10 ns, so a *D* flip-flop connected to toggle as described is guaranteed to have its *D* input stable for at least 10 ns after the clock transition. Most devices nowadays have a zero hold-time requirement.

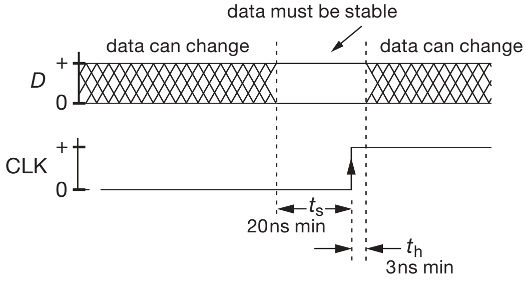

Figure 10.59. Data setup and hold times for the 74HC74 flip-flop.

D. Metastability

An interesting thing can happen if the level at the *D* input changes during the setup-time interval, namely a so-called *metastable* state in which the flip-flop can't make up its mind which state to go into. Figure 10.60 shows what happened when we deliberately violated the setup time for a 74HC74 type-D flip-flop (operating from a +3.3 V supply), bringing D_{in} HIGH at the last moment: the Q output took its good old time deciding which state to go to.[49] The 'scope trace accumulated about 2 seconds of data, during which there were some events in which the delay from clock to Q output stretched out to nearly 50 ns, compared with its normal value of about 16 ns; when we ran it for several minutes, its best cliffhanger clocked in at 75 ns (nearly at the right-hand edge of the screen). Faster logic families show a correspondingly shorter delay, and it is claimed that some are designed to be "metastable resistant."[50] We teased a 74LVC74 (at +3.3 V supply) into metastability (which occurred at $t_s \sim 0.4$ ns!), and measured a leisurely (!) propagation delay of 2–4 ns, compared with its frenetic normal delay of just 1.4 ns.[51]

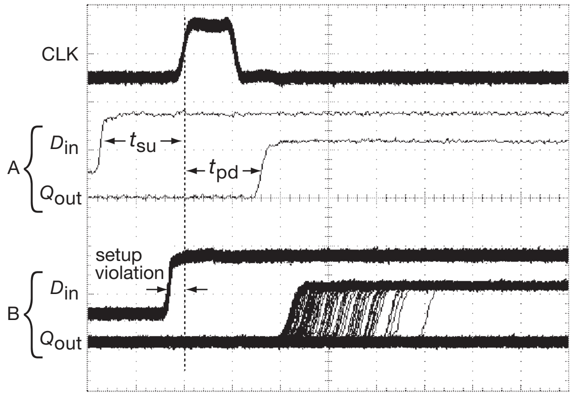

Figure 10.60. Timing violation produces metastability in clocked logic. Here a setup time violation at the D input of a 74HC74 (trace pair B) produces a much delayed output (Q_{out}) from CLK to Q compared with the normal delay of ∼16 ns (trace pair A). Horizontal scale: 10 ns/div.

Just for fun we measured the lengthening of "decision time" for the 74HC74 flip-flop, as we tortured it with less and less setup time; Figure 10.61 shows the results.

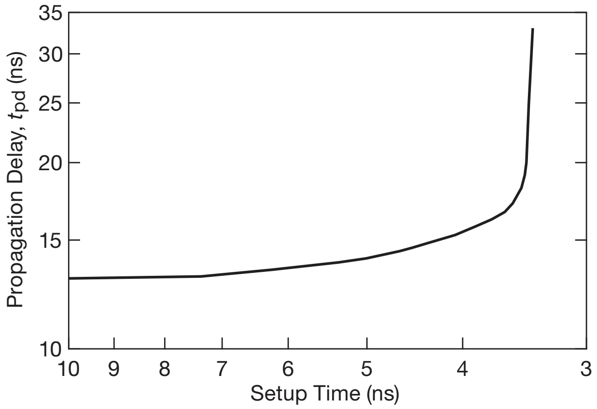

Figure 10.61. Twisting the dragon's tail: metastable propagation delay versus (violated) setup time for the 74HC74.

E. Divide by more

By cascading several toggling flip-flops (connect each Q output to the next clock input), it is easy to make a divide-by-2^n, or binary, counter. Figure 10.62 shows a three-stage *ripple counter*, which is a divide-by-8: the output waveform from the last flip-flop is a square wave whose frequency is 1/8 of the circuit's input clock frequency. Such a circuit is called a *counter* because the data present at the three Q outputs, considered as a single 3-bit binary number, goes through a binary sequence from 0 to 7, incrementing after each input pulse. (We've used the Q' outputs to clock successive stages, to make it count *up* rather than *down*.[52])

Figure 10.63 shows measured waveforms for this counter, zipping along at 50 MHz (the curved arrows were added to indicate what causes what, to aid in understanding): you can see the binary sequence of 3-bit numbers (0–7), where Q_A is the LSB, and Q_C is the MSB. You can also see that there is successive delay going from stage to stage (hence "ripple").[53]

In practice, the simple scheme of cascading counters by connecting each Q output to the next clock input creates certain problems related to the cascaded delays as the signal ripples down through the chain of flip-flops, and a *synchronous* scheme (in which all clock inputs see the same clocking signal) is usually better.[54] We'll see soon how to make a 3-bit synchronous counter.

The counter is a useful function, with many versions

[49] The abrupt Q output, buffered by the output stage, conceals the more interesting internal metastable behavior, in which the (unbuffered) voltage hovers between LOW and HIGH, balanced on a knife edge, trying to decide which way to fall.

[50] Metastable-*resistant* is not the same thing as metastable-*proof*; it's like water-resistant versus waterproof.

[51] The LVC family is a good overall choice for operation from 1.8–3.3 V, though by no means the fastest kid on the block (see Figure 10.26).

[52] There are two other configurations that produce an *up-counter*: (1) use the Q outputs to clock successive stages, but use the Q' signals as your binary outputs; or (2) use the Q outputs to clock successive falling-edge-triggered stages.

[53] In fact, the ripple delay is large enough here so that the count at any instant (i.e., a vertical slice through the traces) is never correct. This does not matter, however, if the counter is used only to generate an output of subdivided frequency, or if the counter is stopped prior to readout.

[54] However, if all you need is a 2^n subdivision of an input clock, with no

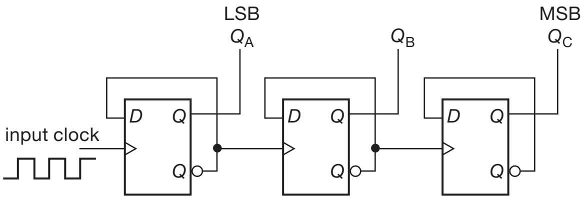

Figure 10.62. Three-stage binary ripple counter.

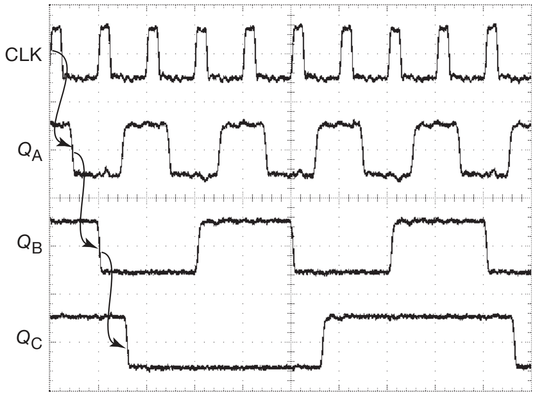

Figure 10.63. Ripple-counter waveforms. This ’scope trace (at 4 V/div vertical, 20 ns/div horizontal) shows a cascade of rising-edge triggered 74HC74 *D* flip-flops, clocked at 50 MHz, displaying successive ∼10 ns delays per stage. The counter, beginning at maximum count $(1,1,1)$, is clocked to all zeros by the rising edge of CLK at the extreme left edge. See Figure 10.71 for analogous waveforms of a fully-synchronous counter.

available as standard logic, including 4-bit, BCD, and multidigit counting formats. By cascading several such counters and displaying the count on a numeric display device (e.g., an LED digital display), you can easily construct an event counter. If the input pulse train to such a counter is gated for exactly 1 second, you’ve got a frequency counter that displays frequency (cycles per second) by simply counting the number of cycles in a second.

10.4.3 Combining memory and gates: sequential logic

Having explored the properties of flip-flops, let’s see what can be done when they are combined with the combinational (gate) logic we discussed earlier. Circuits made with gates and flip-flops constitute the most general form of digital logic.

A. Synchronously clocked systems

As we hinted in the previous subsection, sequential logic circuits in which there is a common source of clock pulses driving all flip-flops have some very desirable properties. In such a *synchronous system*, all action takes place just after each clocking pulse, based on the stable levels present just before each clock pulse. The system reaches its next stable state before the next clock pulse; it’s a nice way of managing feedback; and, by clocking all flip-flops simultaneously, it takes advantage of the relative lack of digital noise just before each clock pulse (the calm before the storm).

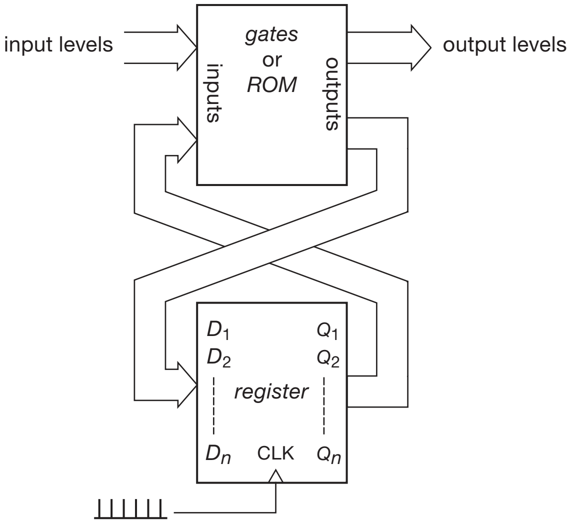

Figure 10.64. The classic sequential “state machine”: a set of clocked flip-flops (a *register*) plus combinational logic. This scheme is easily implemented with single-chip programmable logic devices (PLDs or FPGAs).

Figure 10.64 shows the general scheme. The flip-flops have all been combined into a single *register*, which is nothing more than a set of type-*D* flip-flops with their clock inputs all tied together, and their individual *D* inputs and *Q* outputs brought out; i.e., each clock pulse causes the levels present at the *D* inputs to be transferred to the respective *Q* outputs. The box full of gates looks at both the *Q* outputs and whatever input levels are applied to the circuit and generates a new set of *D* inputs and logic outputs. This simple-looking scheme is extremely powerful; it is the basis for general digital processors. Let’s look at an example.

B. Example: divide-by-3

Let’s design a synchronous divide-by-3 circuit with two *D* flip-flops, both clocked from the input signal. In this case,

particular phase relation to the input, a ripple counter is perfectly good; it is also simpler, and will operate to a higher maximum frequency.

D_1 and D_2 are the register inputs, Q_1 and Q_2 are the outputs, and the common clock line is the master clocking input (Figure 10.65). The trick is to rig up gating so that the D inputs are presented with the desired next state.

1. Choose the three states. Let's use

Q_1	Q_2	
0	0	
0	1	
1	0	
0	0	(i.e., first state)

2. Find the combinational logic network outputs necessary to generate this sequence of states; i.e., figure out what the D inputs have to be to get those outputs:

Q_1	Q_2	D_1	D_2
0	0	0	1
0	1	1	0
1	0	0	0

3. Concoct suitable combinational logic (gates), using available outputs, to produce those D inputs. In general, you can use a "lookup table" (LUT) in ROM (read-only memory), programmed to hold the next-state D values (and addressed by the current Q value, along with any external inputs).[55] This example is simple, so you can do it with one logic gate: you can see by inspection that

$$D_1 = Q_2,$$
$$D_2 = (Q_1 + Q_2)',$$

from which the circuit of Figure 10.66 follows.

It is easy to verify that the circuit works as planned. Because it is a synchronous counter, all outputs change simultaneously (unlike the ripple counter). In general, synchronous (or "clocked") systems are desirable, since susceptibility to noise is improved: things have settled down by the time of the next clock pulse, so circuits that look at their inputs only at clock edges aren't troubled by capacitively coupled interference from other flip-flops, etc. A further advantage of clocked systems is that transient states (caused by delays, so that all outputs don't change simultaneously) don't produce false output, because the system is insensitive to what happens just *after* a clock pulse. We'll see some examples later.

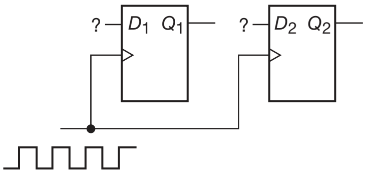

Figure 10.65. Divide-by-3: need logic!

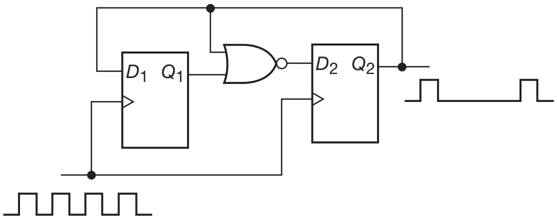

Figure 10.66. Synchronous divide-by-3.

C. Excluded states

What happens to the divide-by-3 circuit if the flip-flops somehow get into the state $(Q_1, Q_2) = (1,1)$? This can easily happen when the circuit is first turned on, since the initial state of a flip-flop is anyone's guess. From the diagram, it is clear that the first clock pulse will cause it to go to the state (1,0), from which it will function as before. It is important to check the excluded states of a circuit like this, since it is possible to be unlucky and have it get stuck in one of those states. (Alternatively, and better, the initial design procedure can include a specification of all possible states.) A useful diagnostic tool is the *state diagram*, which for this example looks like Figure 10.67. Usually you write the conditions for each transition next to the arrows, if other variables of the system are involved. Arrows may go in both directions between states, or from one state to several others.

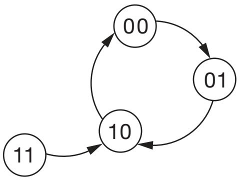

Figure 10.67. State diagram: divide-by-3.

The Verilog code for this circuit (this time a complete "module") is in Figure 10.68.

Exercise 10.23. Design a synchronous divide-by-3 circuit using two *JK* flip-flops. It can be done (in 16 different ways!) without any gates or inverters. *One hint*: when you construct the table of required J_1, K_1 and J_2, K_2 inputs, keep in mind that there are

[55] This example has no logic inputs, as you would have with, for example, an UP/DOWN counter, or a counter with a RESET input.

```
module divideBy3(CLKIN,Q1,Q2);
     input CLKIN;
     output Q1, Q2;
     reg Q1, Q2;
     always @(posedge CLKIN)
        begin
          Q1 <= Q2;               // the <= symbol is called a "nonblocking assignment"
          Q2 <= ~(Q1|Q2);    // it makes all steps happen at once, not sequentially
        end
endmodule
```

Figure 10.68. Verilog code for divide-by-3 circuit.

two possibilities for J,K at each point. For instance, if a flip-flop output is to go from 0 to 1, $J,K = 1,X$ ($X =$ don't care). Finally, check to see if the circuit will get stuck in the excluded state (of the 16 distinct solutions to this problem, 4 will get stuck and 12 won't).

Exercise 10.24. Design a synchronous 2-bit UP/DOWN counter: it has a clock input, and a control input (U/D$'$); the outputs are the two flip-flop outputs Q_1 and Q_2. If U/D$'$ is HIGH, it goes through a normal binary counting sequence; if LOW, it counts backward – $Q_2Q_1 = 00, 11, 10, 01, 00\ldots$.

D. State diagrams as design tools

The state diagram can be quite useful when designing sequential logic, particularly if the states are connected together by several paths. In this design approach, you begin by selecting a set of unique states of the system, giving each a name (i.e., a binary address). You will need a minimum of n flip-flops, or bits, where n is the smallest integer for which 2^n is equal to or greater than the number of distinct states in the system. Then you set down all the rules for moving between states, i.e., all possible conditions for entering and leaving each state. From there it is a straightforward (but perhaps tedious) job to generate the necessary combinational logic, because you have all possible sets of Q's and the set of D's that each leads to. Thus you have converted a sequential design problem into a combinational design problem.[56] Figure 10.69 shows a real-world example. Note that there may be states that don't lead to others, e.g., "with diploma."

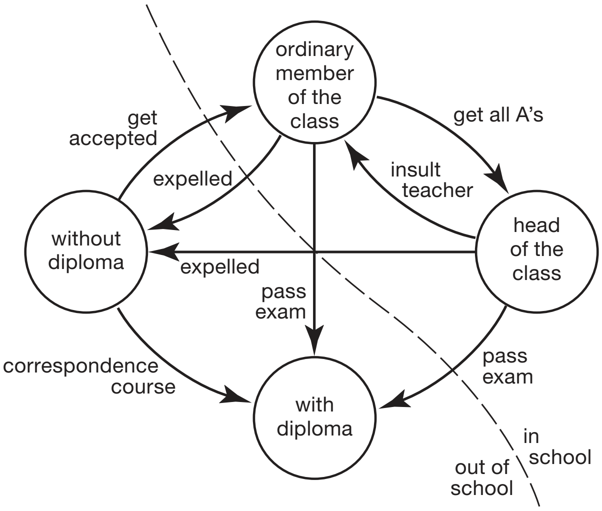

Figure 10.69. State diagram: going to school.

E. State machine design

Hardware description languages, used as algebraic entry tools for both programmable logic (cPLDs and FPGAs) and for full-custom integrated circuits (ASICs), provide a straightforward route to specify state machines. They include *if/elseif/else* statements that let you specify conditions for going to the next state, and for the outputs, given the current state and the inputs. The HDL software translates these specifications into a logic circuit, implemented with the usual gates and flip-flops.

One further point about state machines: the block diagram of Figure 10.64 allows for two possibilities, namely that (a) the outputs may depend on only the current state (defined by the Q's), and in fact may consist simply of the Q's themselves; or (b) for any given state of the Q's, the output may depend also upon the inputs, which are available to the combinational logic in the block labeled "*gates* or *ROM*." These are known as *Moore* and *Mealy* state

[56] You can always take the shortcut of using a lookup table, in the form of a ROM. Alternatively, there are design tools (e.g., hardware description languages (HDLs) used for programmable logic) that will minimize and instantiate the needed logic. Best of all, these HDLs always include an input syntax that lets you simply specify the states and their transition rules, so that you don't even have to figure out the necessary logic.

machines, respectively.[57] The Moore machine changes state only on clock edges, and, if the Q's themselves are considered the outputs, they are strictly synchronous. The Mealy machine responds asynchronously to input changes, regardless of the clock; it generally requires fewer flip-flops, because there are multiple possible outputs corresponding to a single state (defined by the Q's).

F. Synchronous binary counter

We promised we'd revisit our original 3-bit ripple counter (§10.4.2E) to make it fully synchronous. Figure 10.70 shows how it's done: the LSB always toggles, easily done by feeding back to its D an inverted Q. For higher-order bits the rule for counting in binary is to toggle only when all lower-order bits are 1s. Because an XOR is an "optional inverter," this is easily done by feeding each D input from an XOR, one of whose inputs comes from the corresponding Q, and the other from an AND of all lower-order Q's. It's worth seeing it also in a hardware description language:[58]

```
QA.d = !QA.q
QB.d = QB.q $ QA.q
QC.d = QC.q $ (QB.q & QA.q)
```

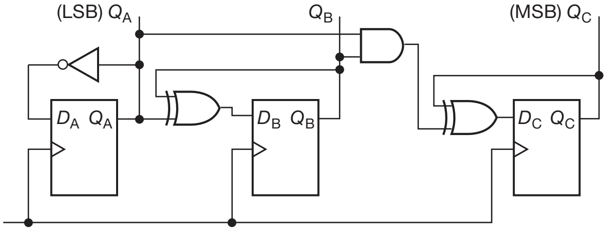

Figure 10.70. 3-bit synchronous binary counter.

As promised, the Q's all clock simultaneously,[59] as you can see in Figure 10.71, which shows measured waveforms for a 3-bit synchronous binary counter clocked at the same rate as the ripple counter of Figure 10.63. Here it is easy to see that the Q's of the successive clocked states are simply the numbers 0 to 7 in 3-bit binary.

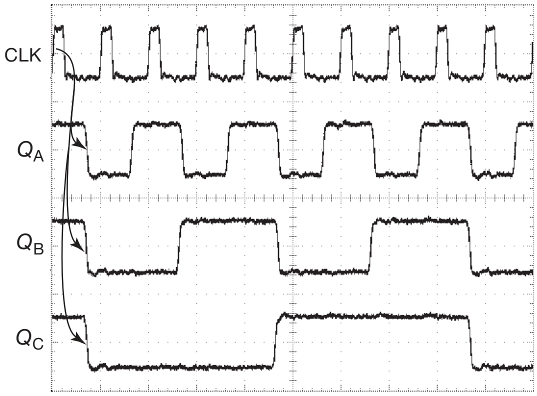

Figure 10.71. In contrast to a ripple counter (Figure 10.62), a *synchronous* counter (or, indeed, any synchronous system) has all flip-flops clocked from a common source. Here a 74HC161 4-bit synchronous counter (rising-edge triggered) displays a CLK-to-Q delay of about 14 ns, constant for all Q's, thus producing coincident changes. (Same conditions as Figure 10.63)

G. PLDs for state machine design

Programmable logic devices have just what you need for state machines – plenty of flip-flops and plenty of logic, all on one configurable (hence "programmable") chip. And the programming software includes tools that make state-machine design straightforward. We'll have much more to say about these remarkable devices in §10.5.4, and in the next chapter.

10.4.4 Synchronizer

An interesting application of flip-flops in sequential circuits is their use in a *synchronizer*. Suppose you have some external control signal coming into a synchronous system that has clocks, flip-flops, etc., and you want to use the state of that input signal to control some action. For example, a signal from an instrument or experiment might signify that data are ready to be sent to a computer. Because the experiment and the computer march to the beats of different drummers (in fancy language you would say they are *asynchronous* processes), you need a method to restore order between the two systems.

A. Example: pulse synchronizer

As an example, let's reconsider the circuit in which a debouncer flip-flop gated a pulse train (Figure 10.51 in §10.4.1A). That circuit enables the gate whenever the switch is closed, regardless of the phase of the pulse train being gated, so that the first or last pulse may be shortened. The problem is that the switch closure is asynchronous

[57] It's easy to get them mixed up; perhaps the mnemonic "Moore↔*O*utputs*O*nly" is helpful.

[58] We've chosen the primitive ABEL, rather than something sophisticated like Verilog, because it is "closer to the metal": it lets you specify D inputs and Q outputs, etc. In ABEL the XOR is written as $.

[59] Well, almost. At a fussier level of scrutiny you can worry about timing *skew*, the (relatively small) scatter of propagation times, among the various flip-flops, from the common clocking edge to the various Q outputs.

with the pulse train. In some applications it is important to have only *complete* clock cycles, and that requires a synchronizer circuit like that in Figure 10.72. When the switch creates a debounced HIGH on the D input, Q stays LOW until the next falling edge of the input pulse train. In that way, only complete pulses are passed by the AND gate. In the waveforms the curved arrows are drawn to show what causes what. You can see, for instance, that the transitions of Q occur slightly *after* the falling edges of the input.

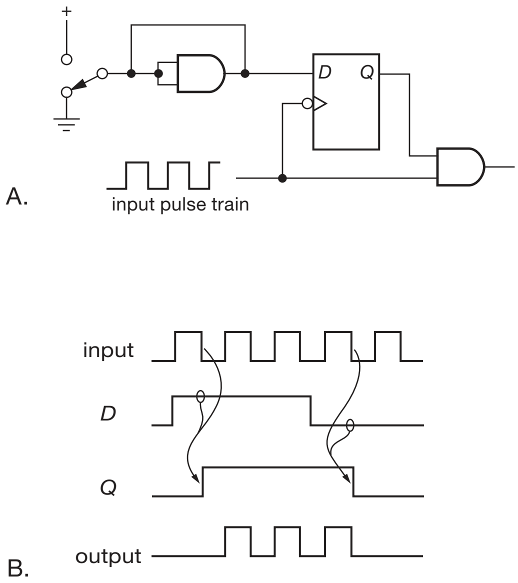

Figure 10.72. Pulse train synchronizer: A. circuit; B. timing diagram.

B. Logic races and glitches

This example brings up a subtle but extremely important point: what would happen if a *rising*-edge-triggered flip-flop were used instead? If you analyze it carefully, you'll find that things work OK at the beginning of the pulse train, but that a bad thing happens at the end (Figure 10.73). A short spike (or "glitch" or "runt pulse") gets through because the final AND gate isn't disabled until the flip-flop output has a chance to go LOW, a delay of about 20 ns for HC family logic. This is a classic example of a *logic race*. With some care these situations can be avoided, as the example shows.[60] Glitches are terrible things to have running through your circuits. Among other things, they're hard to see on an oscilloscope, and you may not know they are present. They can clock subsequent flip-flops erratically, and they may be widened – or narrowed to extinction – by passage through gates and inverters.

Exercise 10.25. Demonstrate that the preceding pulse-synchronizer circuit (Figure 10.72) does not generate glitches.

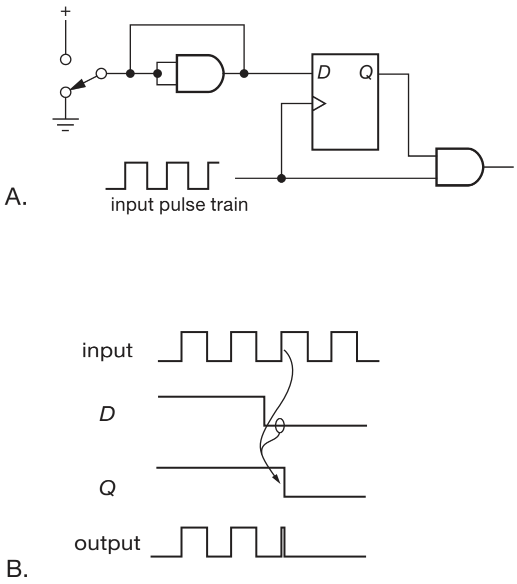

Figure 10.73. A logic race can generate a "runt pulse."

A few comments about synchronizers: the input to the D flip-flop can come from other logic circuitry, rather than from a debounced switch. There are applications in computer interfacing, etc., where an asynchronous signal must communicate with a clocked device; in such cases clocked flip-flops or synchronizers are ideal. In this circuit, as in all logic, unused inputs must be handled properly. For instance, SET and CLEAR must be connected so that they are not asserted (for a '74, tie them HIGH; for a 4013, they are grounded). Unused inputs that have no influence on the outputs can be tied to either level.

[60] That example required a falling-edge-triggered flip-flop, which is a rare species – but a rising-edge flip-flop creates the glitch! What to do? With some thought you will realize that the glitch-free condition is this: *the clock level that enables the gate must precede the edge that clocks the flip-flop*. OK, you say, "I'll clock the rising-edge flip-flop with the input pulse train, and I'll pass that same input through an inverter on the way to the AND gate." Sounds fine, but there's a new problem, namely a logic hazard at the *beginning* of the synchronized output train. Challenge yourself by figuring it out, and drawing a circuit that works properly with a rising-edge flip-flop.

10.4.5 Monostable multivibrator

In §7.2.2 we introduced what is really a *mixed-signal* device (combined analog and digital), the monostable multivibrator (also known as a "one-shot," accent on the *one*); see Tables 7.3 and 7.4 on pages 462 and 463. Although we counseled some caution when considering monostables, there are times when they do just what you want. Let's interrupt our narrative here to look at a nice example, namely, a triggerable pulse generator.

A. Pulse-generator example

Figure 10.74 shows a square-wave generator with independently settable rate and duty cycle (ratio of HIGH to LOW), along with an input that permits an external signal to start and stop the pulse train synchronously. Current source U_1–Q_1 generates a ramp at C_1, with slew rate proportional the resistance of panel potentiometer R_2. When C_1's voltage reaches the upper comparator's threshold of 3.0 V, the one-shot is triggered and generates a 100 ns LOW pulse, putting *n*-channel MOSFET Q_2 into conduction and discharging the capacitor. C_1 therefore has a sawtooth waveform going from ground to +3 volts, with the rate set by potentiometer R_2. The lower comparator generates an output square wave from the sawtooth, with duty cycle adjustable linearly between 2% and 98% via R_7. Both comparators have a few millivolts of hysteresis (R_{10} and R_{11}) to prevent noise-induced multiple transitions. The TLV3502 is a fast (4.5 ns) CMOS dual comparator with input common-mode range to both rails (ground and +5 V), and rail-to-rail outputs (see Table 12.2 on page 813 for more comparator types).

A feature of this circuit is its ability to synchronize (start/stop) to an externally applied control level. The ENABLE input lets the driven circuit start the oscillator at a predictable phase (the time of an output pulse's falling edge), and command the oscillator to stop after the next complete pulse.

A few instructive details (which can be skipped over on a first reading).

- The additional input to the 3-input NAND from the comparator output ensures that the circuit won't get stuck with C_1 charged up.
- The one-shot pulse width has been chosen long enough to ensure that C_1 is fully discharged during the pulse: you can estimate the discharge time from looking at both the 2N7000's saturation drain current with 5 V gate drive (about 350 mA), and its R_{on} (5 Ω) when the discharge is nearly complete; they correspond to approximate discharge times of 50 ns and 17 ns, respectively, from which we conservatively set a fixed discharge time of 100 ns.
- The 50 Ω resistor at the output provides "source termination" for a 50 Ω cable (see Appendix H).
- We've arranged things so that the top of the sawtooth waveform corresponds to the short duty-cycle setting; that's because the waveform has a 100 ns flat bottom (during discharge), whereas the top is an accurate sawtooth.
- Note that the oscillation frequency is, to a good approximation, independent of supply-voltage variations, being set ratiometrically (both the charging current and the peak amplitude are set as a fraction of V_+, nominally 5 V).
- The frequency-setting voltage applied to U_1 is bypassed to the *positive* rail, because that is the reference for the current source; at the low-frequency end of the range, the voltage at R_{15} is just 5 mV below the positive rail, thus rather sensitive to supply-voltage noise.
- We've specified a log-taper potentiometer for the frequency control R_2; otherwise the low-frequency end of the range gets squished.

10.4.6 Single-pulse generation with flip-flops and counters

In §7.2.2 we discussed the generation of pulses and time delays with monostable multivibrators, and some reasons to use caution when considering whether to use these partly–analog devices. When a clocking signal is present (which is almost always), there are purely digital alternatives. Figure 10.75 shows how to make a single glitch-free pulse whose width equals one clock cycle. You'll have fun drawing the timing diagram for this circuit – take the challenge!

Exercise 10.26. Take the challenge!

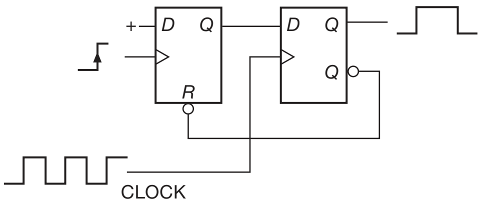

Figure 10.75. Single-pulse generator.

Figure 10.76 shows another case in which flip-flops and counters (cascaded toggling flip-flops) can be used in place of a monostable to generate a long output pulse. The '4060 is a 14-stage CMOS binary ripple counter (14 cascaded flip-flops). A rising edge at the input brings Q HIGH, enabling the counter. After 2^{n-1} clock pulses, Q_n goes HIGH,

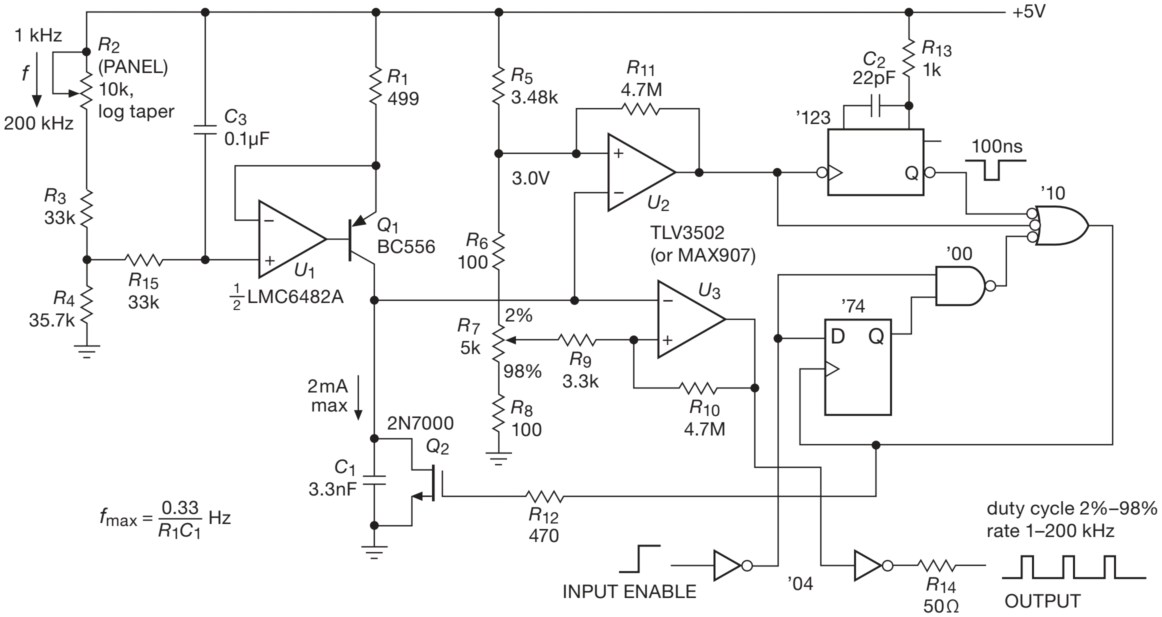

Figure 10.74. Autosynchronizing triggerable pulse generator. All digital logic is LVC family CMOS.

clearing the flip-flop and the counter. This circuit generates an accurate long pulse whose length may be varied by factors of 2. The '4060 also includes internal oscillator circuitry that can substitute for the external clock reference. Our experience is that the internal oscillator has poor frequency tolerance and (in some HC versions) may malfunction.

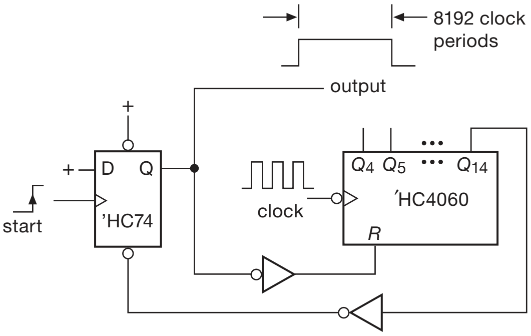

Figure 10.76. Digital generation of long pulses.

You can get complete ICs to implement timing with counters. The Maxim ICM7240/50/60 have 8-bit or 2-digit internal counters and the necessary logic to make delays equal to an integral number of counts (1–255 or 1–99 counts); you can set the number either with "hard-wired" connections or with external thumbwheel switches. The ICM7242 is similar, but with prewired divide-by-128 counter.

10.5 Sequential functions available as integrated circuits

As with the combinational functions we described earlier, it is standard practice to integrate various combinations of flip-flops and gates onto a single chip to create sequential "standard logic." In the following subsections we present a brief survey of the most useful types. *As we feel obliged to mention often, you can also get* uncommitted *arrays of gates and flip-flops, the interconnections to be programmed by the user. These are the hugely popular FPGAs and cPLDs, which we discuss later in this chapter and in Chapter 11.*

10.5.1 Latches and registers

Latches and registers are used to "hold" a set of bits, even if the inputs change. A set of individual *D* flip-flops constitutes a register, but it has more inputs and outputs than necessary. Because you don't need separate clocks, or SET and CLEAR inputs, those lines can be tied together, requiring fewer pins and therefore allowing eight flip-flops to fit in a 20-pin package. The popular '574 is an octal *D* register with rising clock edge and three-state outputs; the '273 is similar, but has a reset instead of three-state outputs. For larger data widths you can get the ’16374 (16-bit) and ’32374 (32-bit) *D* registers. Figure 10.77 shows a quad *D* register with both true and complemented outputs. The Verilog code that describes it is in Figure 10.78.

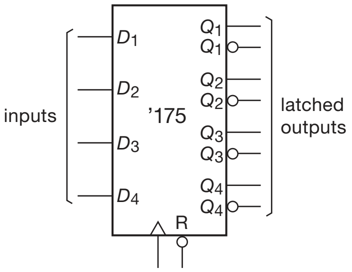

Figure 10.77. ’175 4-bit *D* register.

```
// 4-bit D-register with true and complemented
// outputs, and with active-LOW asynchronous reset
reg [3:0] D;
reg [3:0] Q;
reg [3:0] QBAR;
wire CLKIN;
wire RESETBAR;
always @(posedge CLKIN) or negedge RESETBAR
   if (!RESETBAR)
      begin
        Q <= 4’b0000;
        QBAR <= 4’b1111;
      end
   else
      begin
        Q <= D;
        QBAR <= ∼D;
      end
```

Figure 10.78. Verilog code for a quad *D*-register with true and complemented outputs.

The term “latch” is usually reserved for a special kind of register: one in which the outputs follow the inputs when enabled, and hold the last value when disabled. But the term “latch” has become ambiguous with use, so the terms “transparent latch” and “type-*D* register” are often used to distinguish these closely related devices. As an example, the ’573 is the octal transparent latch analogous to the ’574 *D* register, complete with three-state outputs. The 16-bit and 32-bit versions are called ’16373 and ’32373.

Some variations on the latch or register are as follows: (a) random-access memories (RAMs), which let you write to, and read from, a (usually large) set of registers, but only one (or at most a few) at a time; RAM ICs come in sizes up to 1 Gbyte or more, and are used primarily for memory in microprocessor systems (see Chapter 14); (b) addressable latches, a multibit latch that lets you update individual bits while keeping the others unchanged; (c) a latch or register built into a larger chip, for example a digital-to-analog converter; such a device needs the input applied only momentarily (with appropriate clocking edge), since an internal register can hold the data.

When choosing a register or latch, look for important features such as input enable, reset, three-state outputs, and *broadside* pinout (inputs on one side of the chip, outputs on the other); the latter is convenient when you are laying out a printed-circuit board (PCB).

10.5.2 Counters

As we mentioned earlier, it is possible to make a *counter* by connecting flip-flops together. There is available an amazing variety of such devices as single chips, some of which are listed in Table 10.5. Here are some of the features to look for.

A. Size

You can get BCD (divide-by-10) and binary (or *hexadecimal*, divide-by-16) counters in the popular 4-bit category. There are larger counters, up to 24 bits (not all of them available as outputs); the 74LV8154 is a nice example – it has a pair of 16-bit synchronous counters with output registers and separate clocking inputs, and an 8-bit three-state output that forwards any selected byte. There are also modulo-*n* counters that divide by an integer *n*, with the modulus *n* specified as an input. For some applications (e.g., timing) you don’t care about the intermediate bits, you just want a lot of internal stages, provided by chips like the ICM7240–60, MC14541, and MC14536; see §7.2.4D. You can always cascade counters (including synchronous types) to get more stages.

B. Clocking

An important distinction is whether the counter is a ripple counter or a synchronous counter. The latter clocks all flip-flops simultaneously, whereas in a ripple counter each stage is clocked by the output of the previous stage (Figures 10.62 and 10.63). Ripple counters generate transient states because the earlier stages toggle slightly before the later ones. For instance, a ripple counter going from a count of 7 (0111) to 8 (1000) goes through the states 6, 4, and 0 along the way. This doesn’t cause trouble in well-designed circuits, but it would in a circuit that used gates to look for

Table 10.5 Selected Counter ICs[a]

Part number (74xxx)	Supply voltage min (V)	Supply voltage max (V)	Bits	Synchronous?	U/D	BCD	Sync clear	f_{max} min (MHz)	@ V_{CC} (V)	DIP avail?
HC4024	2.0	6.0	7	no	-	-	-	30	4.5	•
HC4040	2.0	6.0	12	no	-	-	-	30	5	•
VHC4040	2.0	6.0	12	no	-	-	-	150	5	-
HC4060	2.0	6.0	14[b]	no	-	-	-	28	4.5	•
LV4060	1.2	5.5	14[b]	no	-	-	-	99[c]	3.3	(•)
HC40103	2.0	6.0	8	•	D	'102	•	15	4.5	•
74HC161	2.0	6.0	4	•	-	'162	'163	30	4.5	•
74AC161	1.5	6.0	4	•	-	-	'163	90[c]	3.3	-
74LV161	2.0	5.5	4	•	-	-	'163	165[c]	3.3	-
74LVC161	1.2	3.6	4	•	-	-	'163	200[c]	3.3	-
74HC191	2.0	6.0	4	•	•	'192	'193	30	4.5	•
74AC191	1.5	6.0	4	•	•	-	-	133[c]	5	-
74HC590	2.0	6.0	8[d]	•	-	-	-	33	4.5	•

Notes: (a) all are binary, async reset, count up, unless otherwise marked. (b) no output pins for bits 0, 1, 2, and 10. (c) typical. (d) with 3-state outputs.

a particular state (this is a good place to use something like a *D* register, so that the counter output state is examined only at a safe clock edge). Ripple counters are slower than synchronous counters, because of the accumulated propagation delays. That is, it takes longer for all bits to "settle" to their next state; on the other hand, a ripple counter has a higher maximum counting rate (for the same speed of flip-flop). Ripple counters clock on falling edges for easy expandability (by connecting the *Q* output of one counter directly to the clock input of the next); synchronous counters clock on the rising edge.

We favor the '160–'163 family of 4-bit synchronous counters for most applications that don't require a special feature (Figure 10.79). The four family members include BCD and binary, each available with either synchronous or asynchronous reset.[61] They can be parallel loaded, and are easily cascaded via the carry output and enable inputs.

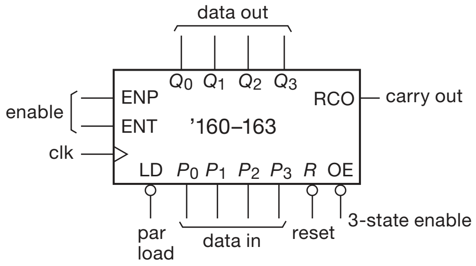

Figure 10.79. '160–'163 synchronous counters.

C. Up/down

Some counters can count in either direction, under control of some inputs. The two possibilities are (a) a U/D' input that sets the direction of count and (b) a pair of clocking inputs, one for UP, one for DOWN. Examples are the '191 and '193, respectively. The '579 and '779 are useful 8-bit up/down counters.

D. Load and clear

Most counters have data inputs so that they can be preset to a given count. This is handy if you want to make a modulo-*n* counter, for example. The load function can be either synchronous or asynchronous: the '160–'163 have synchronous load, which means that data on the input lines are transferred to the counter coincident with the next clock rising edge, if the LOAD′ line is also asserted LOW; the '190–'193 are asynchronous, or *jam-load*, which means

[61] With the reset input R' asserted, a counter with synchronous reset waits until the next rising clock to reset, whereas a counter with asynchronous reset clears upon assertion of the R' input, regardless of the state of the clock.

that input data are transferred to the counter when LOAD′ is asserted, independent of the clock. The term “parallel load” is sometimes used, since all bits are loaded at the same time.

The CLEAR (or RESET) function is a form of presetting. The majority of counters have a jam-type (asynchronous) CLEAR function, though some have synchronous CLEAR; for example, the ’160/’161 are jam CLEAR, whereas the ’162/’163 are synchronous CLEAR.

Example: divide-by-3 (again)

Let’s pause for a moment to look at this business of synchronous versus asynchronous control signals. Neither is “better” (after all, the ’160–’163 family gives you both choices, and at the same price) – the choice depends on the application. Let’s imagine we want to conscript a ’161/’163-style 4-bit synchronous binary counter into service as a divide-by-3 (a challenge we took on earlier, with discrete flip-flops, in §10.4.3B). Because these are *up*-counters only, we’ll use a NAND gate to detect the state count = 3, and use its active-LOW output to assert the RESET′ input of the counter. So it should count 0, 1, 2, and the next clock takes it to a count of 3, whereupon it is immediately reset. Because we want the reset to happen right away, we’ve chosen the ’161, with its asynchronous RESET′ input (Figure 10.80A).

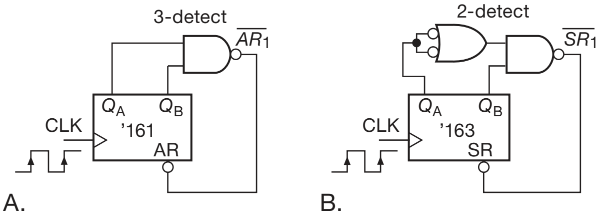

Figure 10.80. Two divide-by-3 circuits, from 4-bit synchronous counters: A. with asynchronous reset (’161); B. with synchronous reset (’163). We built both, with LV-A family logic running at 3.3 V; waveforms in Figures 10.81 and 10.82.

Sounds fine, and it does work, more or less. But there’s a bit of a problem: look at Figure 10.81, which shows measured waveforms, as we clocked it at about 12 MHz. You can see it clock successively through states 0, 1, and 2; then, just past halfway across the trace you see it reach state 3 (Q_A and Q_B both HIGH), whereupon the NAND gate generates a LOW pulse (AR_1'), which resets the counter to 0. The problem is that the RESET′ pulse contains the seeds of its own destruction, so to speak: it brings the count to zero, which makes it promptly disappear. So it’s possible for the pulse to be shorter than the minimum reset pulse width, which could result in incomplete resetting of all the counter’s flip-flops.[62]

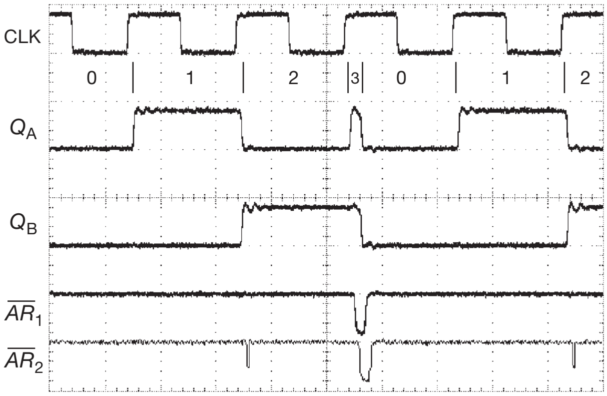

Figure 10.81. Measured waveforms from the divide-by-3 circuit of Figure 10.80A. The modified reset pulse AR_2' resulted from 39 pF additional loading on Q_A. Horizontal: 40 ns/div. Vertical: 4 V/div.

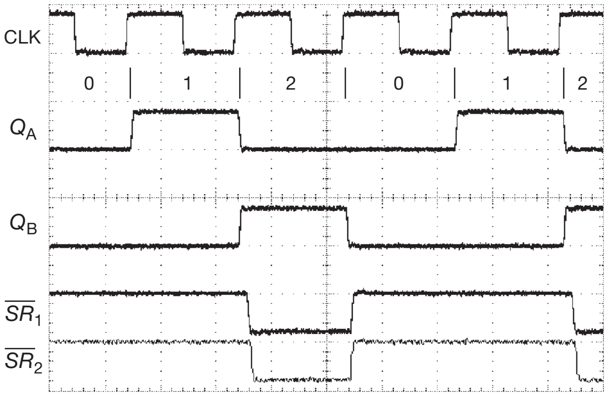

Figure 10.82. Measured waveforms from the divide-by-3 circuit of Figure 10.80B; same conditions as Figure 10.80A.

The scope trace shows another potential hazard of using asynchronous reset here: the trace labeled AR_2' is the NAND gate output when the Q_A output sees more capacitive loading than Q_B (we put 39 pF to ground); that delayed Q_A enough to produce a transient false “3” state during the 1→2 transition. In this circuit it wasn’t sufficient to prematurely reset the counter… but it sure looks bad!

The better solution is *synchronous* reset (Figure 10.80B), where the counter is reset at the rising clock *following* assertion of its RESET′ input. That means we need to detect count = 2 (rather than 3; i.e., $n-1$ rather

[62] Even if it works reliably in practice, you don’t want little runt pulses running around your circuit, right?

than n).[63] Figure 10.82 shows the waveforms, free of glitches and runt pulses (even with extra capacitive loading of Q_A, shown as the reset waveform SR'_2).

We'll see this issue again in connection with the n-pulse generator (§10.6.3).

E. Other counter features

Some counters feature latches on the output lines; these are always of the transparent type, so the counter can be used as if no latch were present. (Keep in mind that any counter with parallel-load inputs can function as latch, but you can't count at the same time as data are held, as you can with a counter/latch chip.) The combination of counter plus latch is sometimes quite convenient, e.g., if you want to display or output the previous count while beginning a new counting cycle. In a frequency counter this would allow a stable display, with updating after each counting cycle, rather than a display that repeatedly gets reset to zero and then counts up.

There are counters with three-state outputs. These are great for applications where the digits (or 4-bit groups) are multiplexed onto a bus for display or transfer to some other device. Examples are the '560/1, '590, and '779; the latter is an 8-bit synchronous binary counter whose three-state outputs also serve as parallel inputs; by sharing input–output lines, the counter fits in a 16-pin package. The '593 is similar, but in a 20-pin package. If you want a counter to use with a display, there are some that combine counter, latch, 7-segment decoder, and driver on one chip; an example is the 74C926 4-digit counter.[64]

10.5.3 Shift registers

If you connect a series of flip-flops so that each Q output drives the next D input, and all clock inputs are driven simultaneously, you get what's called a *shift register*. At each clock pulse the pattern of 0s and 1s in the register shifts to the right, with the data at the first D input entering from the left. As with flip-flops, the data present at the serial input just prior to the clock pulse are entered, and there is the usual propagation delay to the outputs. Thus they may be cascaded without fear of a logic race. Shift registers are very useful for conversion of parallel data (n bits present simultaneously, on n separate lines) to serial data (one bit after another, on a single data line), and vice versa. They're also handy as memories, particularly if the data are always read and written in order. As with counters and latches, shift registers come in a pleasant variety of prefab styles. The important things to look for are the following.

A. Characteristics

Size and Organization

The 4-bit and 8-bit registers are standard, with some larger sizes available (up to 64 bits or more).[65]

Shift registers are usually 1 bit wide, but there are also dual-, quad-, and hex-width registers. Most shift registers only shift right, but there are bidirectional registers like the '194 and '299.

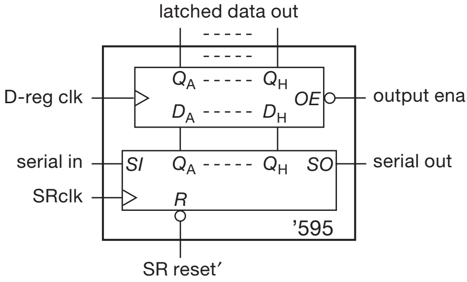

Figure 10.83. '595 octal shift register with output latch. A handy part for creating multiple latched outputs from a few pins of a microcontroller; the TPIC6595 variant has open-drain MOS drivers, good to 45 V and 250 mA, for driving heavy loads.

Inputs and outputs

Small shift registers can provide parallel inputs or outputs, and usually do; an example is the '395, a 4-bit parallel-in, parallel-out (PI/PO) shift register with three-state outputs. Larger registers may provide only *serial* input or output, i.e., only the input to the first flip-flop or the output from the last is accessible. In some cases a few selected intermediate taps are provided. One way to provide both parallel input and output in a small package is to share input and

[63] We could have ignored Q_A, and simply inverted Q_B (figure out why); however, for clarity we did full gating to detect Q_A=0 AND Q_B=1 for the synchronous reset signal SR'_1.

[64] We mourn the passing of the unusual TIL306/7, a counter *with display* on one chip: you just looked at the IC, which lit up with a digit telling the count! Another fine example of an integrated counter is Intersil's ICL7216, an 8-digit 10 MHz universal counter-on-a-chip (complete with 7-segment LED driver); it's shown in all its glory in our second edition (on p. 526). The bad news is that it was recently discontinued; but the good news is that you can do it yourself, in an FPGA or cPLD – see Chapter 11. (Maxim still makes the ICM7217 4-digit up-down counter with multiplexed LED drive, and the ICM7218 and 7228 8-digit-LED drivers are available from both Maxim and Intersil.)

[65] There are even variable-length registers (e.g., the 4557: 1 to 64 stages, set by a 6-bit input).

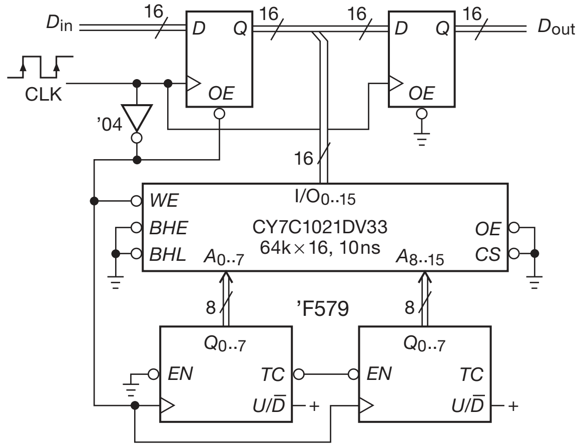

Figure 10.84. Large and wide shift register made from RAM plus counter; the slash indicates multiple lines, in this case 16-bit-wide data paths and a pair of 8-bit-wide addresses, for a total length of 65,536 16-bit words.

output (three-state) on the same pins, e.g., the '299, an 8-bit bidirectional PI/PO register in a 20-pin package. Some shift registers include a latch at the parallel input or output, so shifting can go on while data are being loaded or unloaded. A particularly nice example of the latter is the '595 8-bit shift register (Figure 10.83), nicely available in many logic families, including AHC(T), F, FCT, HC(T), LV, LVC, and VHC; it's great for creating a latched many-bit parallel output from a stingy bitstream coming from a microcontroller.[66] Similarly, the '597 is an 8-bit parallel-input shift register, convenient for getting data into a microcontroller via a single-bit serial input pin.

As with counters, parallel LOAD and CLEAR can be either synchronous or jam-load; for example, the '323 is the same as the '299, but with synchronous clear.

B. RAMs as shift registers

A random-access memory can always be used as a shift register (but not vice versa) by using an external counter to generate successive addresses. Figure 10.84 shows the idea. A pair of cascaded 8-bit synchronous counters generates successive addresses for a 64k-word×16-bit static RAM. The combination behaves like a 16-bit wide and 65,536-long shift register. By choosing a fast counter[67] and memory, we were able to achieve a maximum clocking rate of 27 MHz (see timing diagram, Figure 10.85), which is comparable to that of an integrated (but much smaller) standard-logic shift register. (It's worth spending a few minutes studying that calculation – a good exercise in setup and hold times, propagation delays, and memory access timing.) This technique can be used to produce very large shift registers, if desired.

Exercise 10.27. In the circuit of Figure 10.84, input data seem to go into the same location that output data are read from. Nevertheless, the circuit behaves identically to a classic 64k-word shift register. Explain why.

10.5.4 Programmable logic devices

We've said it before (and we'll be saying it again) – contemporary digital design is moving relentlessly toward user-programmable ICs, typically containing from hundreds to hundreds of thousands(!) of gates and flip-flops,[68] in which the *connections* are programmable. Design entry is done in a hardware description language, processed by software to generate the connection *netlist*, then loaded into the chip via a serial interface (usually JTAG). We'll have more to say about these in the next chapter; but they do so many logic jobs so well that we cannot end this chapter without a short summary.

A. The bad news

To use these little puppies you usually need to learn an HDL like Verilog or VHDL, and you need a programming "pod" (or other link to the computer where the HDL is processed). And these devices are universally (well, almost) packaged only in surface-mount packages, which makes rough-and-ready prototyping more difficult.

B. The good news

You can preserve an ignorance of HDL programming by using instead schematic-entry alternatives that are available, both from the PLD manufacturers and from third-party suppliers (§11.3.3A). And for most digital jobs, PLDs really hit the spot. Here are the most important uses and advantages of PLDs.

State machines

The PLD is a natural for an arbitrary synchronous state machine. You would be foolish to use an array of *D* flip-flops and discrete combinational logic when a PLD does the job in one inexpensive and powerful package.

[66] The wonderful do-it-all microcontroller is the subject of Chapter 15, where we'll show an example.

[67] The '579 is available only in a 5 V logic family. The rest of the circuit is powered from +3.3 V; however, signal levels are compatible throughout (that is, the logic running on 3.3 V has "5V-tolerant" inputs; and the 5V logic accepts 3.3 V input levels; see §12.1.2A).

[68] Sometimes supplemented with dedicated functions such as RAM, interfaces, and processors.

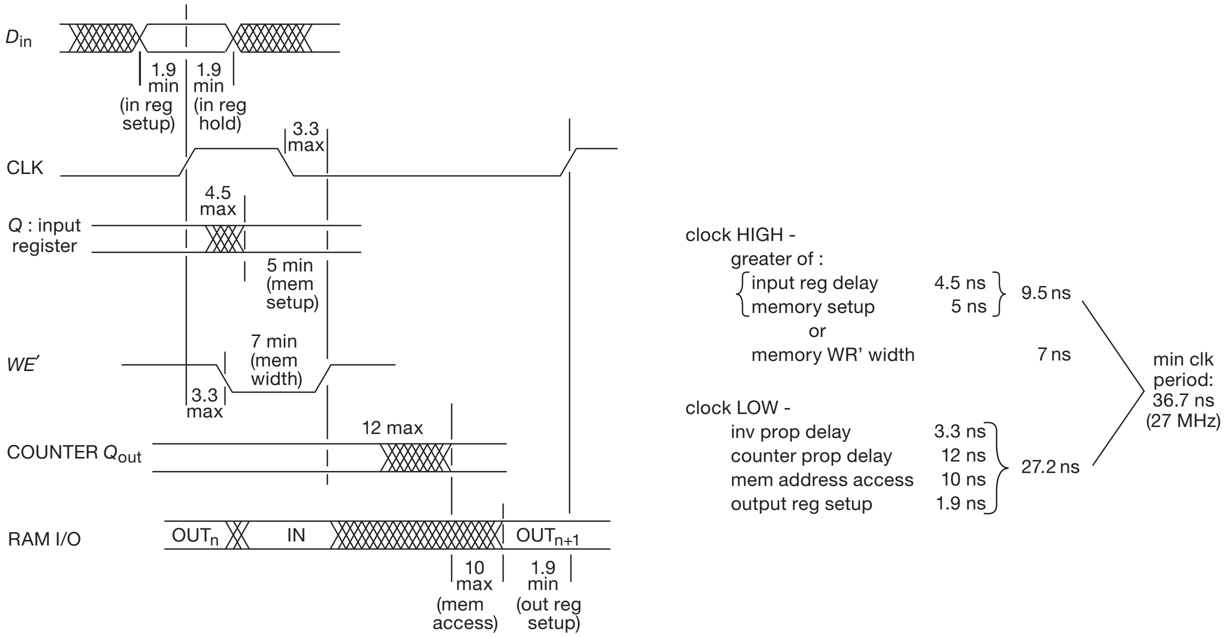

Figure 10.85. Timing diagram for the long shift-register implemented in RAM (the circuit of Figure 10.85), assuming worst-case timing specifications. This facilitates calculation of the maximum clock speed of 27 MHz.

Replacing "random" logic

Within many circuits you find little knots and tangles of gates, inverters, and flip-flops, scornfully referred to as *random logic*, or *glue logic*. A PLD will generally cut the package count by a factor of 10 or more.

Flexibility

Sometimes you're not quite sure how you ultimately want some circuit to work, yet you must finish the design so that you can play around with it. PLDs are great here, because you can reprogram them at some later stage, without the rewiring you'd have to do if you had used discrete logic. With PLDs, the circuit itself is a form of software.[69]

Multiple versions

PLDs make it possible to design a single circuit, then produce several different versions of the instrument by populating the board with differently programmed PLDs.

Speed and inventory

With PLDs you can generally get the design job done more quickly (once you've learned the ropes and set up your software tools). Furthermore, you need to stock only a few PLD types, rather than dozens of standard-function MSI logic types.

System-on-a-chip

The larger PLDs (in particular, FPGAs) have enough resources so that you may be able to do your whole design in one PLD. In particular, you can include functions such as an interface (Ethernet, USB, or whatever), memory, and even a microprocessor on the single FPGA. There are two possibilities: (a) if you include such functions in your HDL design and let the software implement them within the array of gates and flip-flops, you've got a "soft" implementation; that may include nicely implemented functions that you get from elsewhere, in which case it's called "intellectual property" (IP); (b) these functions may be hardwired into the FPGA (and not changeable) when you get it – that's a "hard implementation." More on this in the next chapter.

10.5.5 Miscellaneous sequential functions

With the relentless progress of the semiconductor industry, which routinely puts millions of transistors on a chip,[70] you

[69] More properly, *firmware*: in between unchangeable *hard*ware and easily changed *soft*ware.

[70] And *billions* in some of the larger microprocessors, graphic processors (GPUs), and FPGAs.

can get weird and wonderful gadgets all on one inexpensive chip. This brief subsection presents just a sampling.

First-in–first-out memory

A first-in–first-out (FIFO) memory is somewhat akin to a shift register in that data entered at the input appear at the output in the same order. The important difference is that with a shift register the data get pushed along as additional data are entered and clocked, but with a FIFO the data notionally *fall through* to the output queue. Input and output are controlled by separate clocks, and the FIFO keeps track of what data have been entered and what data have been removed.[71]

FIFOs are useful for buffering asynchronous data. The classic application is buffering a keyboard (or other input device, such as magnetic disk, or a fast external port such as Ethernet) to a computer or sluggish instrument. By this method, no data is lost if the computer isn't ready for each word as it is generated, provided the FIFO isn't allowed to fill up completely. The generic 7201–06 byte-wide series has been popular, and comes in several voltages and lengths; for example, 72V01–06 series of 3.3 V CMOS FIFOs has 0.5–16k words of 9 bits each, 40 MHz maximum speed, and zero *fall-through time* (an affliction suffered by early FIFOs, which were implemented as serial registers). You can get bidirectional FIFOs, synchronous FIFOs, and FIFOs up to 72 bits in width.

A FIFO is unnecessary if the device to which you are sending data can always get it before the next data arrive. In computer language, you must ensure that the maximum *latency* is less than the minimum time between data words. Note that a FIFO will not help if the data recipient is not able, *on the average*, to keep up with the incoming data.

Digital voltmeters

You can get complete digital voltmeters (DVMs) on a single chip (for some reason you'll find these things listed as "display drivers" when you go searching at distributors). They include voltage reference, high-impedance differential inputs, LCD drivers, and so on. An example is the MAX1495, a fully integrated $4\frac{1}{2}$-digit voltmeter in a 7 mm square package; it draws about a milliamp from a single 3–5 V supply. A popular generic part is the '7135 (TI, Intersil, and Maxim call it ICL7135; Microchip calls theirs TC7135; and TI also sells it as the TLC7135): it's a $4\frac{1}{2}$-digit voltmeter that runs from +5 V and drives 7-segment LED displays. The '7136 is $3\frac{1}{2}$-digit and drives 7-segment LCDs.

Special-purpose circuits

There are nice collections of large-scale integration (LSI) chips for arcane jobs like radio communications (e.g., frequency synthesizers), digital signal processing (digital filters, correlators, Fourier transforms, arithmetic units), data communications (UARTs, modems, network interfaces, data encryption–decryption ICs, serial format converters, wireless protocols), and the like. Often these chips are used in conjunction with microprocessor-based devices, and many of them cannot stand alone.

Consumer chips

The semiconductor industry loves to develop ICs for use in large-market consumer products. You can get single chips to make digital (or "analog") watches, clocks, locks, calculators, smoke detectors, telephone dialers, music synthesizers, rhythm and accompaniment generators, etc. The guts of radios, TVs, music and video players, GPS navigators, and cellphones are nearly empty these days, thanks to large-scale integration. Speech synthesis and recognition is well developed: that's why devices like GPS navigators can speak to us and understand our analog-generated replies.[72] Automobiles are laden with dozens of processors, for tasks like engine control, braking, collision-avoidance systems, navigation, and so on. Even the lowly toothbrush has a processor chip, running on a few thousand lines of computer code.[73]

Microprocessors

The most stunning example of the wonders of very large-scale integration (VLSI) is the microprocessor, a computer on a chip. At one extreme there are powerful number crunchers like the Intel eight-core Itanium, with more than 3 billion transistors; it has hundreds of internal registers, supports up to a petabyte (a million gigabytes) of RAM, and can be cobbled together into 512-processor architectures. At the other extreme are inexpensive single-chip processors with a rich load of input, output, and memory functions included on the same chip for stand-alone use.

[71] A FIFO can be implemented in software (as it usually is done in hardware) by creating a *ring buffer* in RAM, with a pair of pointers (write and read).

[72] One of the authors' children, enchanted with the talking Nissan Maxima we rented one summer, augmented its lexicon, which included messages such as "door is a-*jar*" and "tank is *low*," with his own: "You ran into a *di*nosaur."

[73] Check out the MC9RS08KA from Freescale Semiconductor, with internal 10 MHz oscillator and 2 KB of internal memory; it's "small enough to fit in the head of an electric toothbrush" and intended for "personal care appliances," among other uses. It costs a mere $0.40 in quantity.

An example (Figure 10.86) is the ARM7 LPC2458 from NXP (formerly Philips): 512kB/64kB memories, 72 MHz clock, 10/100 Ethernet, USB 2.0, 10-bit A/D and D/A, 2xPWM, 4 UARTs, 2xCAN, SPI, 2xSSP, 3xI^{2}C, I^{2}S, 136 bits of general-purpose I/O, and an external memory controller. This puppy costs just $10![74] This latter type is intended as a dedicated controller in an instrument rather than as a versatile computation device.

The microprocessor revolution hasn't begun to slow, and we have seen a doubling of computer power and memory size (now 8 Gbit per chip, compared with 1 Mbit/chip and 16 kbit/chip at the time the two previous editions of this book were written) every 18 months ("Moore's law"); at the same time, prices have dropped dramatically (Figure 10.87). Along with bigger and better processors and memory, recent activity in display devices, networking, and wireless data communication promises yet more excitement in coming years.

10.6 Some typical digital circuits

Thanks to the efforts of the semiconductor industry, digital design is wonderfully easy and pleasant. It's almost never necessary to "breadboard" a digital circuit, as so often is the case with analog design. Generally speaking, the only serious pitfalls involve timing and noise. We'll have more to say about the latter in Chapter 12.

This is a good place to illustrate timing with some sequential design examples. Some of these functions can be performed with LSI circuits or with programmable logic, but the implementations shown are reasonably efficient, and illustrate the kind of circuit design that's straightforward with widely available parts (and without mastery of any software languages or tools).

10.6.1 Modulo-*n* counter: a timing example

The circuit in Figure 10.88 produces one output pulse for every $n+1$ input clock pulses, where n is the 8-bit number you've set on the pair of hexadecimal thumbwheel switches. The '163s are 4-bit synchronous up-counters, with synchronous load (when LD′ is LOW) via the P_n inputs. The idea is to load the counters with the *complement* of the desired count, then count up to FF_H, reloading at the next clock pulse. Because we've generated the preload levels with pullups to the positive supply (with the switch common grounded), those levels are LOW-true for the displayed switch settings; that makes the preload values, interpreted as active-HIGH, equal to the 1's complement of the switch settings.

Exercise 10.28. Show that the last statement is true by figuring out the active-HIGH value that will be loaded for the switch settings in Figure 10.88.

Circuit operation is entirely straightforward. To cascade synchronous counters, you tie all clocks together, then tie a "maximum-count" output of each counter to an enable of the successive counter. For an enabled '163, the RCO (ripple-clock output) goes HIGH at maximum count, enabling the second counter via the enabling inputs ENT and ENP. Thus IC$_1$ advances at each clock, and IC$_2$ advances at the clock after IC$_1$ reaches F_H. The pair thus counts in binary until the state FF_H, at which point the LD′ input is asserted. This causes synchronous preload at the next clock. In this example we've chosen counters with *synchronous* load to avoid the logic race (and runt-pulse RCO) that you would get with a *jam*-loaded counter. Unfortunately, this makes the counter divide by $n+1$ rather than by n.

Exercise 10.29. Explain what would happen if jam-load counters (e.g. '191s) were substituted for the synchronous-load '163s. In particular, show how a runt pulse would be created. Demonstrate also that the foregoing circuit divides by $n+1$, whereas the asynchronous-load version would divide by n (if it worked at all!).

A. Timing

How fast can our modulo-n counter count? Let's use LV-family logic at 3.3 V, at which the 74LV163A specifies a guaranteed f_max of 70 MHz.[75] However, in our circuit there are additional time delays associated with the cascading connection (IC$_2$ has to know that IC$_1$ has reached maximum count in time for the next clock pulse) and also the load-on-overflow connection. To figure the maximum frequency at which the circuit is guaranteed to work, we have to add up the worst-case delays and make sure there is enough setup time remaining. Look at Figure 10.89, where we've drawn a timing diagram showing the load sequence that occurs at maximum count.

[74] NXP's LPC1768 is a low-power part that's popular with the prototyping crowd. It has most of the features of the LPC2458, but lacks the external memory controller. It has only 70 GPIO pins (we're sure you'll not miss the rest), and it comes in an easy-to-solder 100-pin QFP package (0.5 mm pin spacing). Notably it has a 12-bit ADC, a 10-bit DAC, and six general-purpose PWM outputs.

[75] The '1G04 isn't available in LV, so we'll use a 74LVC1G04.

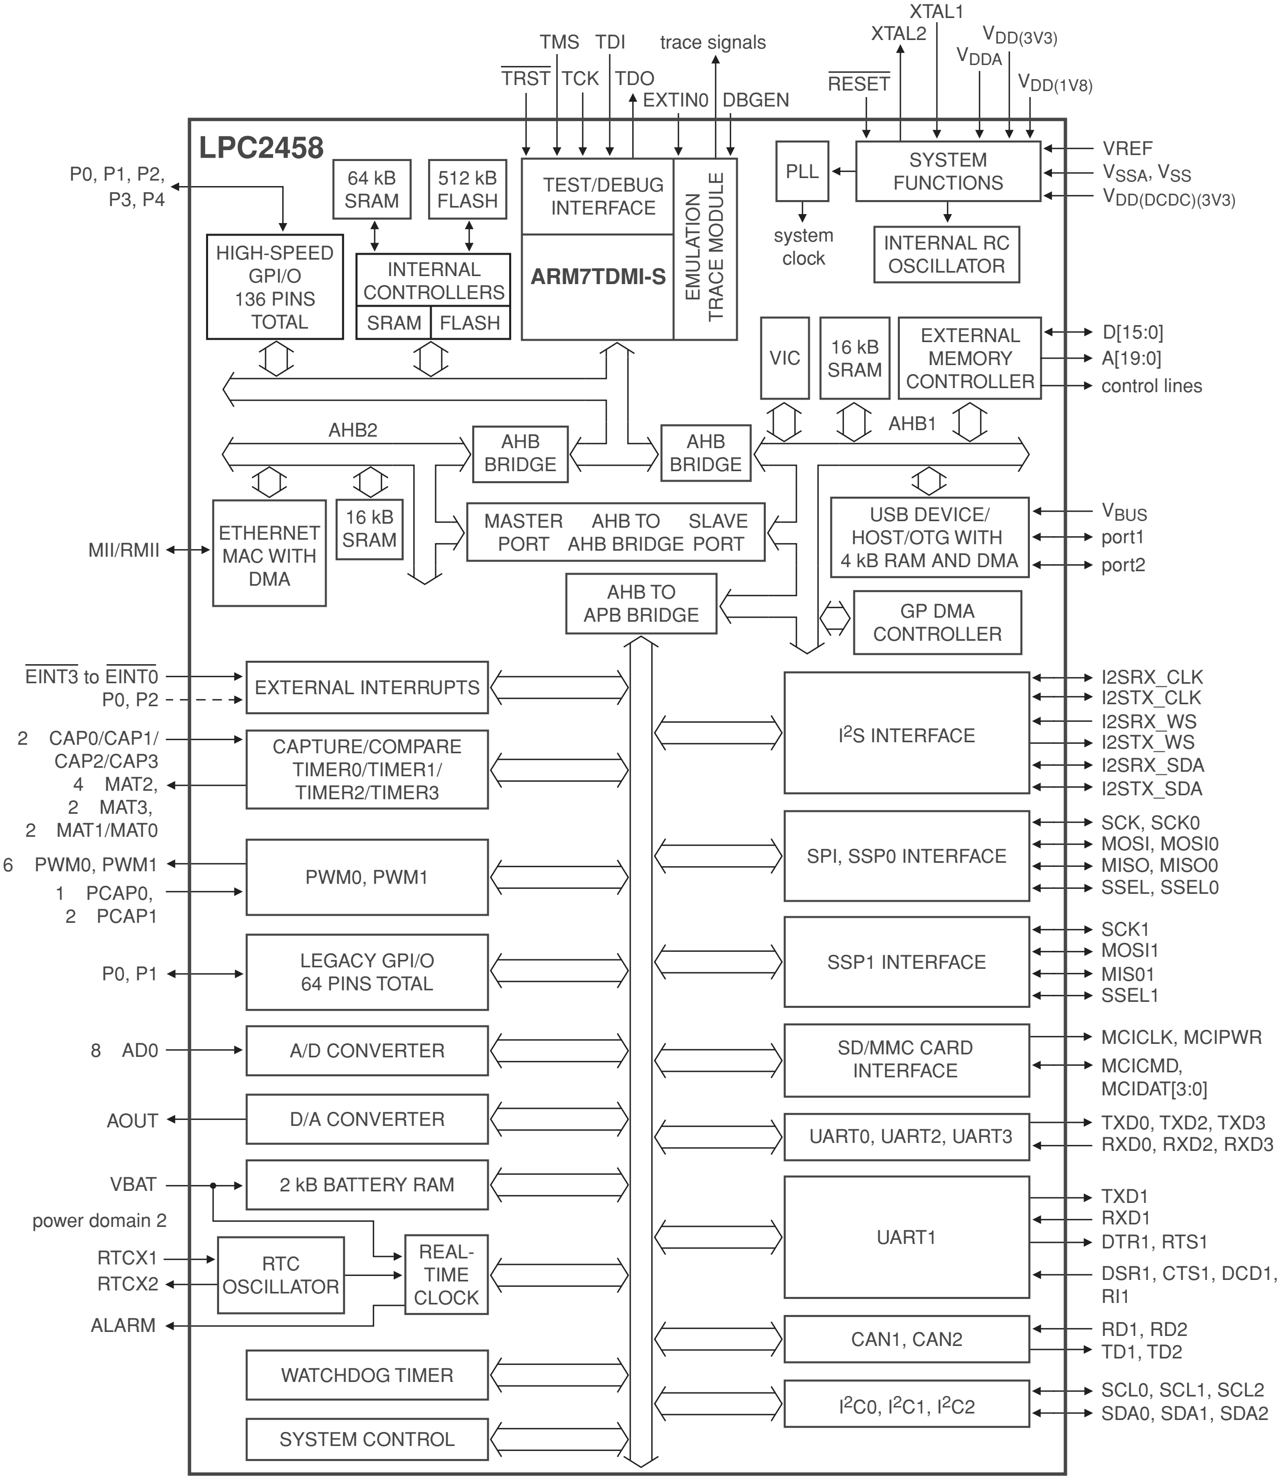

Figure 10.86. A preview of Chapter 13: an inexpensive microcontroller festooned with lots of cool stuff. Adapted from Document LPC2131_32_34 _36_38_4 ©NXP B.V. 2007)

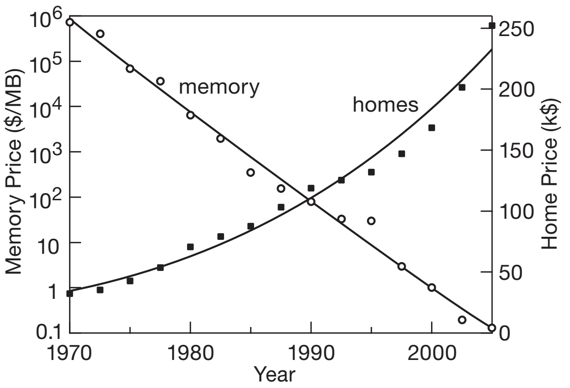

Figure 10.87. The law of Silicon Valley: thirty-five years of computer-memory retail prices, dropping 50% every 18 months. (The same law does not apply to median US new-home prices, which exponentiated nicely for many decades. But more recent events have demonstrated the hazards of a confident expectation of continuing exponential home prices.)

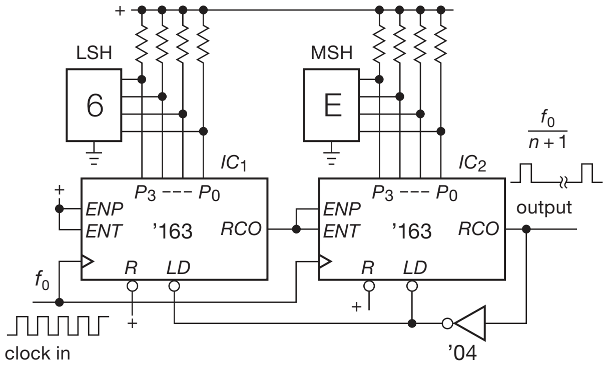

Figure 10.88. Modulo-n counter, with modulus set by thumbwheel switches.

A LOW-to-HIGH change on any Q output follows the rising edge of CLK by 15 ns max. That’s interesting, but not relevant, because the load sequence uses the RCO output; IC_1’s RCO follows the rising edge of the CLK pulse that brings it to maximum count by 16 ns max, and IC_2’s RCO follows its input enable (assuming, of course, that it is at maximum count) by 14.5 ns max. The LVC1G04 adds a delay of 3.3 ns max to generate LD′, which must precede CLK (t_{setup}) by 9.5 ns min. That brings us to the next CLK; therefore $1/f_{\max} = (16 + 14.5 + 3.3 + 9.5)$ ns, or $f_{\max} = 23.1$ MHz. This is considerably less than the 70 MHz maximum guaranteed counting frequency of a single 74LV163A.

	ns, max
① CLK to Q	15
② CLK to RCO	16
③ ENT to RCO	14.5
④ A to Y (‘04)	3.3
⑤ LD' setup to CLK	9.5 (min)

Figure 10.89. Timing diagram and calculation for modulo-n counter.

Exercise 10.30. Show by a similar calculation that a pair of synchronously cascaded 74LV163As (without load on overflow) have a maximum guaranteed counting rate of 40 MHz. Find the timing data you need by going to TI’s website.

Of course, if greater speed is needed, you can look for faster logic. Doing the same calculation for 74F logic (for which the maximum count rate of a single 74F163 is 100 MHz), we find $f_{\max}$=29 MHz. Here’s where the speedy ECL bipolar logic comes to the rescue: the MC100E016 is an 8-bit loadable synchronous counter, with a specified $f_{\max}$ of 700 MHz (!). What is the speed, though, in the modulo-n hookup? Since it’s 8-bit, we don’t need to cascade anything; also, its maximum count output (called TC′) is active-LOW, as is its parallel load control (called PE′), so we don’t need the inverter, either: TC′ connects directly to PE′. The CLK→TC delay is a mere 0.9 ns, and the PE→CLK setup is 0.6 ns, which calculates to a guaranteed modulo-n $f_{\max}$ of 667 MHz. Not bad. Even better, this chip planned ahead for modulo-n applications by including a “load-on-terminal count” input pin – by enabling that, you achieve the raw 700 MHz guaranteed speed (or 900 MHz “typical” speed) for modulo-n frequency division: 30 times faster than our pretty-good CMOS implementation!

Modulo-n counter devotees should take note of the ’HC40103, an 8-bit synchronous *down*-counter with

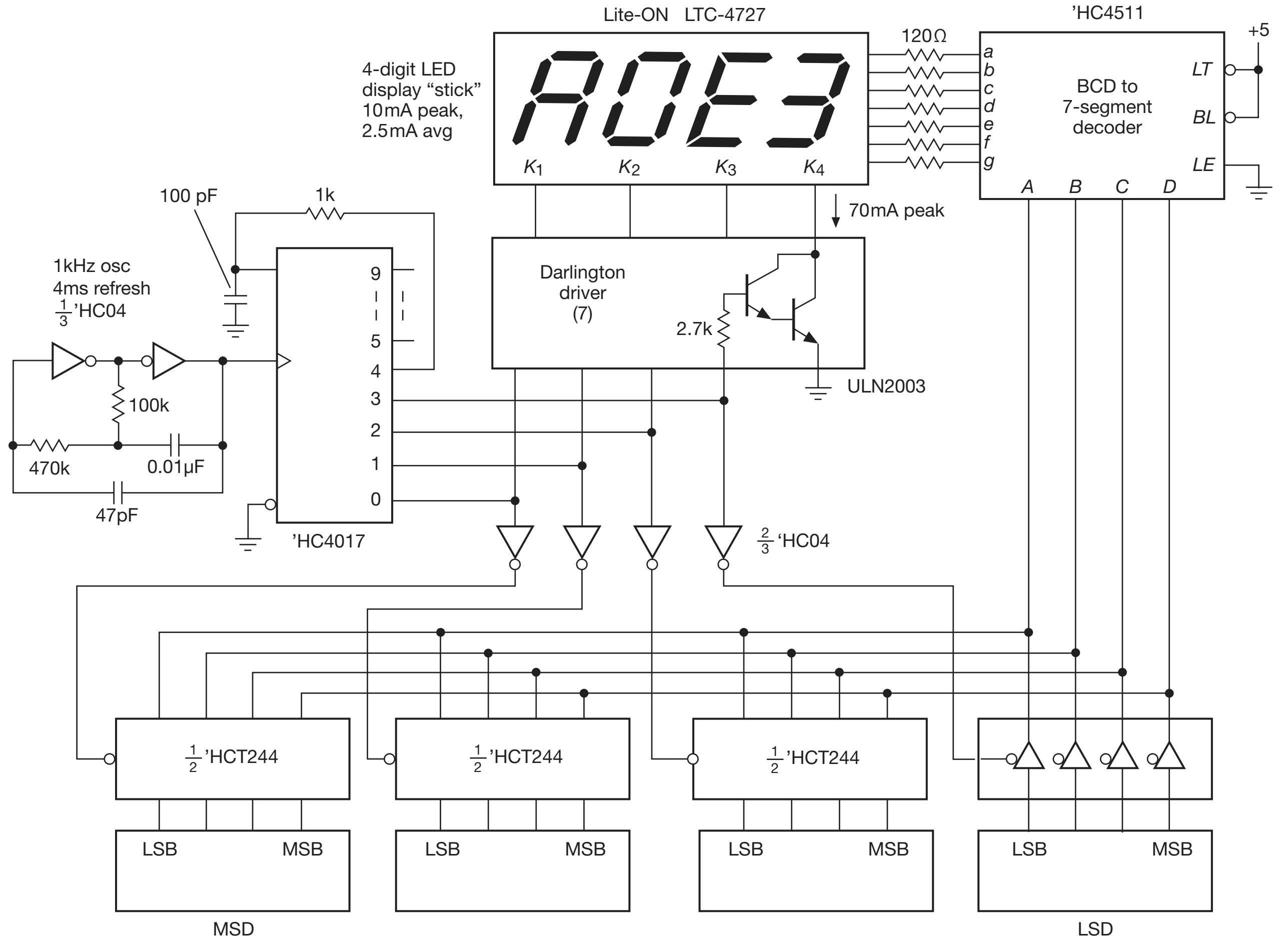

Figure 10.90. Four-digit multiplexed display. Whatever might that displayed quantity represent?

parallel load (synchronous *or* jam-load!), decoded zero-state output, and reset-to-maximum input.

10.6.2 Multiplexed LED digital display

This example illustrates the technique of display multiplexing: displaying an *n*-digit number by displaying successive digits rapidly on successive 7-segment LED displays (of course, the characters need not be numbers, and the displays can have a different organization than the popular 7-segment arrangement). Display multiplexing is done for reasons of economy and simplicity: displaying each digit continuously requires separate decoders, drivers, and current-limiting resistors for each digit, as well as separate connections from each register to its corresponding decoder (4 lines) and from each driver to its corresponding display (7 wires); it's a mess!

With multiplexing, there's only one decoder/driver and one set of current-limiting resistors. Furthermore, because LED displays come in *n*-character "sticks" with the corresponding segments of all characters tied together, the number of interconnections is greatly reduced. An 8-digit display requires 15 connections when multiplexed (7-segment inputs, common to all digits, plus one cathode or anode return for each digit), rather than the 57 that would be required for continuous display (and, since most LED displays come in multiplexed varieties, you'll probably find them to be the best choice anyway).

Figure 10.90 shows the schematic diagram. The digits to be displayed are resident in registers at the bottom; they could be counters (e.g., if the device happened to be a frequency counter), or perhaps a set of latches receiving data from a computer, or possibly the output of an ADC, etc. In any case, the technique is to assert each digit successively onto an internal 4-bit "bus" (in this case with four 4-bit three-state buffers, each half of an 'HCT244 octal buffer), and decode and display it while asserted on the bus (using the 'HC4511 BCD-to-7-segment decoder/driver).

We've used a pair of inverters to form a classic CMOS oscillator (Figure 7.2) operating at about 1 kHz, driving a 'HC4017 decimal counter/decoder. As each successive output of the counter goes HIGH, it enables one digit onto the bus and simultaneously pulls the corresponding digit's cathode LOW via the popular ULN2003 high-current open-collector Darlington driver. The 'HC4017 is rigged up to cycle through the states 0–3 by resetting when the count reaches 4 (with a bit of *RC* delay to ensure full reset). Display multiplexing will work with greater numbers of digits, and it is universally used in instruments with multidigit LED displays. Try rapidly shifting your eyes while viewing such a display – you get numeric alphabet soup!

One of the interesting design issues has to do with the LED "voltage budget": you've got a +5 V supply, and the LEDs that make up the segments have a voltage drop of ~2.2 V at the desired 10 mA drive current, so it would seem that there's nothing to worry about. A closer look (Figure 10.91) shows the problem, namely that the 'HC4511 anode drivers (which are a pMOS-*npn* hybrid) have one V_{BE} drop (about 0.7 V); and the ULN2003 Darlington digit sinks, running at 70 mA, have another V_{BE} plus some saturation voltage, for a total of about 0.9 V. Add the 2.2 V LED drop,[76] and you've got only 1.2 V left across the segment current-limiting resistors. So, for 10 mA LED current we needed 120 Ω resistors. That's pretty much OK, although you'd be forgiven for worrying that some scatter in the LED forward drops, etc., would produce significant percentage changes in the small remaining voltage across the resistors; i.e., you might see unacceptable brightness variations across the digits. If you're still not worried, consider the effect of a 10% drop in the +5 V supply. Note, also, that this LED drive circuit would not work at all with a +3.3 V supply.[77]

In an LED the maximum allowable current is limited only by overheating. So it's OK to use rather high peak currents in a multiplexed display, as long as the average current stays within the rated value. You have to be a bit careful, though: the thermal time constant of the small LED semiconductor chip is somewhere down around a millisecond, so for significantly longer ON times the peak current cannot much exceed the rated maximum average current. Another fine way to destroy a pulsed LED is to have the drive circuit get stuck in the ON state, for example caused by a program crash while debugging a microcontroller (firmware-driven) multiplexed display.[78]

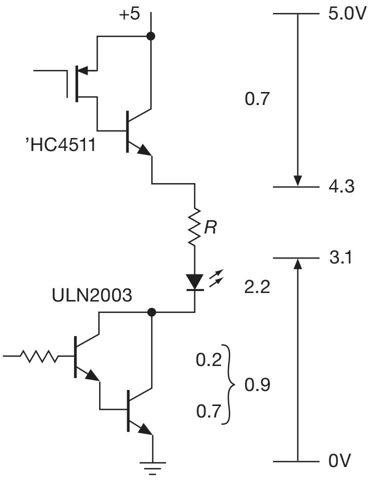

Figure 10.91. LED voltage budget.

Many LSI display-oriented chips, included in devices such as clocks, set-top (television) boxes, and the like, include on-chip display multiplexing (and even driver) circuitry. You can also get (though with some difficulty[79]) a stand-alone 6-digit display driver-multiplexer, the legacy 74C912; it accepts the 4-bit characters in sequence, and requires only the external digit driver.

10.6.3 An *n*-pulse generator

The *n*-pulse generator is a useful little test instrument. It generates a burst of *n* output pulses following an input trigger signal (or you can push a button), with a set of selectable pulse repetition rates. Figure 10.92 shows the circuit.[80] The 'HC190s are decade up/down counters (here wired to count down), clocked continuously by a selected power-of-10 subdivision of the fixed 10 MHz crystal oscillator, but disabled by having both the ALD′ (asynchronous load) inputs asserted and the EN′ (count enable) inputs disasserted. When a trigger pulse comes along, the first flip-flop enables the counter, and the second flip-flop synchronizes counting following the next rising edge of the clock.

[76] As specified for the yellow display stick shown in the figure; the forward drop of an LED depends on color; see Figure 2.8.

[77] Nor with a 5V supply and blue LED display, where the forward voltage $V_f \sim 3.5$ V.

[78] See §7.2.3 for a nice way to prevent this particular disaster.

[79] Jameco shows them in stock, $2 in unit quantity.

[80] Challenge for the reader: what is so "perfect" about the figure?

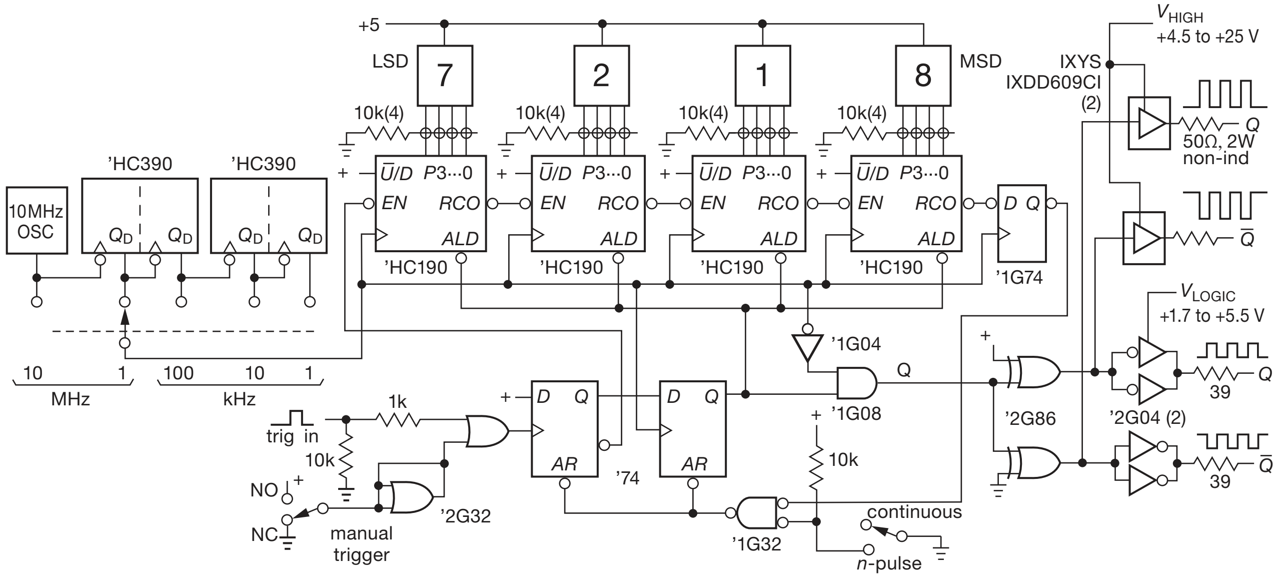

Figure 10.92. Perfect n-pulse generator. All logic is LVC family, running from $+5$ V, unless shown otherwise.

Pulses (during clock LOW) are passed by the AND gate until the counter reaches zero, at which state the RCO′ output[81] is latched for one clock, and both flip-flops are reset; this parallel-loads the counter back to $n-1$ from the BCD switches, disables counting, and readies the circuit for another trigger.[82] Note that the use of pulldown resistors in this circuit means that true (rather than complemented) BCD switches must be used. Note also that the manual trigger input must be debounced, as shown, since it clocks a flip-flop. That is not necessary for the continuous/n-pulse switch, which simply enables a continuous stream of output pulses.

The output stage delivers two pairs of true/complement signals: the XORs generate complementary logic signals with equal delay; the paralleled 'LVC2G04 inverters give normal rail-to-rail logic swings, settable from $+1.7$–5.5 V via an external dc supply input. We used two inverters in parallel to increase drive capability (the paralleled inverter sections can sink or source 32 mA, staying within 0.5 V of the rails, for V_+=3 V); the 39 Ω resistors, in combination with the ∼10 Ω inverter-stage output impedance, provide series termination for 50 Ω cable.

We added the boxed driver pair for serious driver tasks. It uses a hefty "MOSFET driver" chip, intended for rapid switching of highly capacitive MOSFET gate inputs. This particular specimen can sink or source up to 8 A, with a better-than-average switching time of ∼10 ns; it is noninverting, and accepts standard 5 V logic swings. The outputs are series terminated, with non-inductive 50 Ω 2 W resistors.[83]

10.7 Micropower digital design

Small battery-powered gadgets of all sorts need to operate on very small currents, ideally down in the microamp range. To appreciate the scale, consider that a 9 V battery has a capacity of about 500 mAh, thus about 20 days at 1 mA current drain; and a small "coin cell" like the

[81] Indicating a ripple-through "terminal count," which for a down-counter (as here) is the 4-digit state 0000. A peculiarity of the '190 is that RCO′ is enabled only during clock LOW.

[82] Because of the RCO′ latch, the output pulse train has n+1 pulses (rather than n), so you have to set the switches to one fewer than you want. Omitting that latch, however, would trade this *numerical* embarrassment for a *logical* one, namely the generation of a terminal output runt pulse. Challenge yourself by figuring out why. However, further removing the 1G04 clock inversion would eliminate the output runt, producing instead a much-shortened reload pulse, while retaining the $n+1$ counting "feature." There's nothing wrong, really, with a reload pulse whose width is determined only by logic propagation delays – it's just a bit, well, *ugly*; by contrast, the latched RCO′ for asynchronous reset–reload is neat and clean (and easy to see on a 'scope).

[83] Readers interested in constructing this circuit should consider, as an alternative to the '190 (or '192) counters, the elegant 'HC4059 4-decade loadable down-counter, which replaces four chips with one. If, however, *hexadecimal* counting is to your taste (perhaps you have 16 fingers?), use the 'HC191 (binary) alternative.

ever-popular CR2032 (stock check: nearly two million in stock at DigiKey today) delivers about 200 mAh at 3 V.

There are lots of micropower chips out there – both linear (op-amps, voltage references, oscillators, etc.) and digital (standard and programmable logic, ADCs and DACs, microcontrollers, etc.) – which is where any micropower design should start.

But if you're not careful it's easy to sacrifice the micropower performance of these excellent chips. The previous edition of this book[84] has a full chapter (Chapter 14) on micropower design. It includes lots of information on batteries and other power sources, and on both linear and digital micropower design; it makes good reading. But for reasons of space we are limited here to a brief subset of this important area, namely the business of micropower digital logic.

10.7.1 Keeping CMOS low power

There are several routine measures you should take to achieve low-current CMOS operation. In addition, it's worthwhile raising your CMOS pathology awareness.

A. Routine design considerations

- *Keep as few nodes as possible involved with high frequencies*. CMOS has no quiescent current (other than leakage), but current is required to charge internal (and load) capacitances during switching. Since the energy stored in a capacitor is $\frac{1}{2}CV^2$, and an equal amount of energy is dissipated by the resistive charging circuit, the power dissipated is

$$P = V_{\mathrm{DD}}^2 fC$$

  for a switching frequency f. Thus CMOS devices consume power proportional to their switching frequency, as we saw in Figure 10.27. At their maximum operating frequency they may use more power than equivalent bipolar-TTL logic. The effective capacitance C is often given on datasheets as the "power-dissipation capacitance," C_{pd}, to which you must add the load capacitance C_{L} before applying the formula above.
- *Within a circuit, be careful whenever mixing supply voltages*. Otherwise you may have current flowing through input-protection diodes. Even worse, you may force a chip into SCR latchup (see §10.8.3B).
- *Make sure logic swings go all the way to the rails*. CMOS outputs swing rail-to-rail. Outputs from other devices – bipolar TTL, oscillators, NMOS chips – may hover in between, causing class-A current and decreased noise immunity (recall Figure 3.93).
- *No open inputs*. Open inputs are the enemy of micropower operation, since there may be considerable class-A current (and even oscillation) as the input floats to the logic threshold (Figure 10.101). Tie all unused inputs to ground (or V_{DD}, if that disables something you don't want).
- *Arrange loads to keep normal-state drains low*. Pullups, pulldowns, LEDs, and output drivers should be wired so that current is minimum in the usual state.
- *Avoid slow transitions*. Again, class-A current is the culprit. A sinewave input driving a CMOS Schmitt trigger may cause a lot of supply current.
- *Put current-sensing resistors in the V_{DD} lead*. In certain failure modes, particularly those caused by static damage, a CMOS chip may draw excessive quiescent current; a 10 Ω resistor in series with V_{DD} on each board (Figure 10.93) makes it easy to see if that is happening (and you can use the stuck-node tracer in §4.8.2 to track down the offending component).

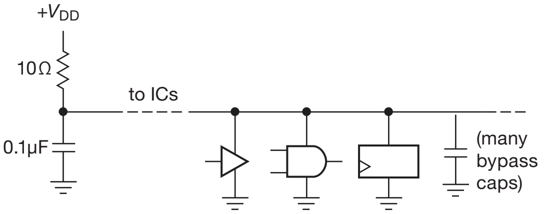

Figure 10.93. A "current spy" makes it easy to locate circuit subsections wherein lurks a current-hogging IC.

- *Quiescent current screening*. A typical CMOS logic chip (in any family – 4000B, HC, LVC, LCX, AUC, etc.) has a specified I_{Q} of 5–20μA *maximum*, but down around 0.04μA *typical* (if specified at all). Manufacturers evidently set a conservative spec on maximum leakage, probably because they don't want to bother testing to a much lower realistic value. Most of the time it is rare to have a quiescent current anywhere near the maximum, but it can happen. If you are operating at low switching frequencies (therefore low dynamic current), and require comparably low quiescent current, you may need to screen incoming chips. The use of small series resistors as recommended above makes the job much easier. We've noticed that in the case of CMOS LSI chips (such as large memories) the typical quiescent current may be close to the manufacturer's maximum leakage specifications – beware!
- *Time-out power switching*. You can save a lot of power by

[84] With continued (and perhaps perpetual) availability as an e-book.

making sure an instrument is turned off when no one is using it. Back in Chapter 7 we showed a simple timeout circuit, built with discrete logic, that turns off the switched +9 volt power an hour after the instrument has been turned on (§7.2.4A). Better yet, in any instrument with an embedded microcontroller (Chapter 15), use the controller's internal timer (or a programmed timeout loop) to command the power switching. In applications with limited battery energy, it's best to choose a micropower controller; alternatively, arrange for it to spend most of its time in a low-power mode (variously called "idle," "power-save," "power-down," "standby," "hibernate," or "sleep").

10.8 Logic pathology

There are interesting, and sometimes amusing, pitfalls awaiting the unsuspecting digital logician. Some of these, such as logic races and lockup conditions, can occur regardless of the logic family in use. Others (e.g., "SCR latchup" in CMOS chips) are genetic abnormalities of one logic family or another. In the following subsections we have collected our bad experiences in the hope that such anecdotes can help others avoid such problems.

10.8.1 dc problems

A. Lockup

It is easy to fall into the trap of designing a circuit with a lockup state. Suppose you have some gadget with a number of flip-flops, all going through their proper states. Everything seems to work fine. Then one day it just stops dead. The only way you can get it to work is to turn the power off and back on again. The problem is that there is a lockup state (an excluded state of the system that you can't escape from), and you got into it because of some powerline transient that sent the system into the forbidden state. It is important to look for such states when you design the circuit, and rig up logic so that the circuit recovers automatically. At a minimum, things should be arranged so that a RESET signal (generated manually, at startup, etc.) brings the system to a good state. This may not require any additional components (e.g., Exercise 10.23).

B. Startup clear

A related issue is the state of the system at startup. It is always a good idea to provide some sort of RESET signal at startup. Otherwise the system may do weird things when first turned on. One approach is to use an *RC* charging waveform, buffered by a Schmitt trigger (Figure 10.94). In addition to requiring several discrete components, however, this circuit has the drawback of not reliably responding to a momentary voltage dip.

A better approach is provided by a power-supply *supervisory* circuit IC. These chips come in many varieties. The simplest are 3-pin parts that create a reset pulse on power-up, for example, the venerable MC34164, which comes in a convenient TO-92 leaded transistor package (in addition to the usual tiny surface-mount configurations), and holds its open-collector output LOW until the supply voltage rises above 4.3 V (2.7 V for the 34164-3 part); it includes an internal voltage reference, and some hysteresis. A more flexible part is typified by the Maxim MAX700, which comes in 8-pin packages (including DIP), and which provides both RESET and RESET′ active pullup outputs; it lets you set the threshold in the range of 1.2–4.7 V with external resistors (you can also set the hysteresis), and it has an input for a manual RESET switch (Figure 10.95). The MAX823 and ADM823 families are "jellybeans" that are widely second-sourced. Other supervisory chips include the so-called *watchdog* function: You have to pulse it at least once per second, or it does a reset; these are intended to sense a processor crash, and force a reboot (a function often integrated into contemporary microcontrollers, as well).

Many of these supervisory parts are made by multiple

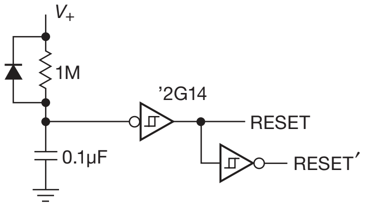

Figure 10.94. Simple power-on reset.

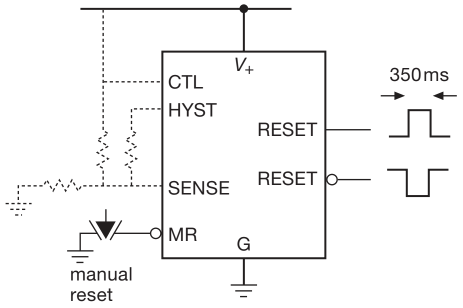

Figure 10.95. Supervisory IC provides power-on, voltage monitor, and manual reset functions. The optional (dotted) circuitry permits threshold and hysteresis adjustment.

manufacturers, but with different prefix part names. For example, the MAX809 is also available with APX, ADM, CAT, LM, STM, and TCM prefixes, and costs $0.14 in a roll of 3,000 pieces, thanks to all the competition. But be careful and read the datasheet before making a substitution! For example, NSC's MCP809 datasheet says it has a different pinout from the other '809 parts (it matches STM's jellybean STM1001). A drafting error? Maybe, but we warn you, be careful.

Advanced parts like the ADM690 series add features like supply switching to a backup battery, a second low-voltage warning comparator, and chip-enable gating. See Table 10.6 for characteristics of some favorite supervisory ICs.

Table 10.6 Selected Reset/Supervisors

Type	Pins	Package(s)	# Voltages[a]	Watchdog	Reset IN	Active High[c]	Supply current (μA)
MC34164	3	TO-92, SO-8	2	-	-	-	12
MAX809	3	SOT-23	7	-	-	'810	15
NCP303	5	SOT-23	7	-	-	'302	0.5
MAX700	8	SOIC-8	1[b]	-	●	both	100
ADM811	4	SOT-143	6	-	●	'812	5
ADM823	5	SOT-23, SC-70	7	●	●	'824	10

Notes: (a) Voltage is specified by a suffix. (b) External adjustment. (c) All have active-LOW output; part numbers listed have active-HIGH output instead; MAX700 has both.

10.8.2 Switching problems

A. Logic races

Lots of subtle traps lurk here. The classic race was illustrated with the pulse synchronizer in §10.4.4. Basically, in any situation where gates are enabled by signals coming from flip-flops (or any clocked device), you must be sure that a gate doesn't get enabled and then immediately disabled after a logic delay time. Likewise, make sure that signals appearing at flip-flop inputs aren't delayed with respect to the clock (another plus for synchronous systems!). In general, delay the clock rather than the data.

It is surprisingly easy to overlook a race condition. A classic example is the humble 2-input multiplexer: if you do the obvious thing, namely `Y=S&A|∼S&B`, as in Figure 10.96A, you are in trouble! The problem occurs when there is a HIGH level on both *A* and *B* inputs, and the SELECT input *S* transitions from HIGH to LOW, i.e., from selecting *A* to selecting *B*. The inverter's delay causes the lower AND gate to be disabled before the upper AND is enabled, producing a transient LOW glitch at the output. The solution is to add the redundant term `A&B`, as drawn in Figure 10.96B. (This is done correctly in any commercial IC. The problem comes when you want to put a MUX into programmable logic,[85] for which you spell out the logic in a hardware description language. You have to instruct it, sternly, not to "optimize" away the redundant term. You have to tell it that you are wiser than it. You can tell it, if all else fails, that you've read this book.)

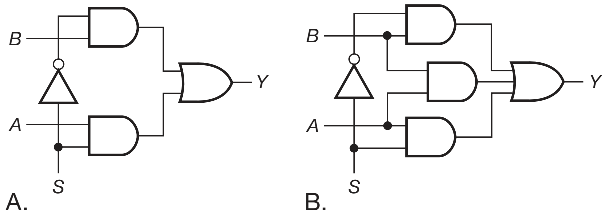

Figure 10.96. Adding a redundant term eliminates a logic-race glitch in the 2-input MUX.

B. Metastable states

As we discussed in detail earlier (§10.4.2D), a flip-flop (or any clocked device) can get confused if the data input changes during the setup-time interval preceding a clock pulse. As long as the flip-flop makes *some* decision promptly in this ambiguous case, all is well. However, there is a chance that the input may have changed at just the wrong time, at exactly the "moment of truth," such that the flip-flop can't make up its mind; its output can hover at the logic threshold for many times the usual propagation time (or it may sit in one logic state, then change its mind later, as in Figure 10.60).

This problem does not arise in properly designed synchronous systems in which setup times are always satisfied (by using logic fast enough so that inputs to flip-flops are stable by $t_{\rm setup}$ before the next clocking pulse). However, it can create problems in situations where asynchronous signals (e.g., going from device A, with its own clock, to device B, with a separate clock) must be synchronized. In these cases you cannot guarantee that input transitions do not occur during the setup interval; in fact, you can calculate how often they do![86] The metastability problem has

[85] The subject of the next chapter.

[86] The chance of landing in the "setup interval" Δt of the faster clock (from $t_{\rm su}$ before the clock to $t_{\rm h}$ after the clock) is $\Delta t/t_{\rm clkF}$, where $t_{\rm clkF}$=$1/f_{\rm clkF}$ is the period of the faster of the pair of asynchronous

been blamed for mysterious computer crashes, although we are skeptical. The cure generally involves a set of concatenated synchronizers, or a "metastable state detector" that resets the flip-flop. You may find claims of "metastable-resistant" logic, for example the AC(T) family of 5 V logic.

C. Clock skew

Clock skew problems arise when you have a clocking signal of slow rise time driving several interconnected devices (Figure 10.97). In this case two '595 octal shift registers have been cascaded to create a 16-bit parallel latched output; they are being clocked by a slowly rising edge, caused by capacitive loading of an anemic clocking signal (perhaps coming from a slow microcontroller's output pin). The problem is that the first register may have its threshold at a lower voltage than that of the second register (owing to process variations), and this causes it to shift earlier than the second register. The last bit of the first register is then lost. CMOS devices can display quite a spread of input threshold voltages, which compounds the problem (the threshold specification may be one-third to two-thirds of V_{DD}, and they mean it!). The best cure in such a situation is to drive the clock inputs from a nearby chip of adequate speed and without excessive capacitive loading. (Another way to fix the problem, if you've got clock skew, is to add some small delay in the data lines between successive clocked chips; but don't let that substitute for a clean clock.)

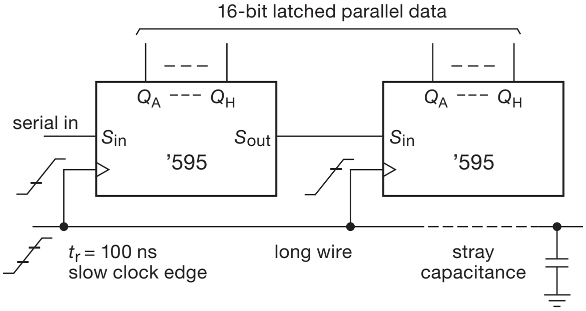

Figure 10.97. Slow risetimes can cause clocking skew, when the thresholds differ.

Speaking generally, edge-triggered clock inputs on any digital IC should always be treated with respect. For example, clock lines with noise or ringing should always be cleaned up with a gate (perhaps one with input hysteresis) before driving the clocked chip (but be careful not to violate setup- and hold-time requirements). You're especially likely to have problems with clock lines that come from another board, or from a different family of logic. For example, slow 4000B or 74C logic driving the faster HC or AC families is likely to exhibit problems of clock skew or multiple transitions; ditto for HC driving LVC, and so on.

Clock-skew problems can occur, surprisingly, even within a single chip of programmable logic. An example we've encountered is the venerable 9500-series of cPLDs, in which individual flip-flops can be clocked either by one of the chip's distributed *global clock* signals, or, alternatively, by the output of internal logic (these are called *product terms*). Sounds fine. But if you use a product term to clock a set of flip-flops in a shift register, say, the chip may malfunction. That is because of routing delays in bringing that clocking signal to the several flip-flops. A synchronous circuit like this is only guaranteed to work if clocked by a global clock.[87] This "gotcha" is not prominently featured on the datasheets.

D. Runt pulses

In §10.6.1 (modulo-*n* counter) we used synchronous-load counters ('163), rather than a jam-load alternative (like the '191), because with the latter you would need to add some delay to prevent a pulse of substandard width (since the counter's output causes it to clear itself). The same comment goes for LOAD pulses when you are using counters or shift registers. Runt pulses will make your life miserable, because you may have marginal operation or intermittent failures. Use the worst-case propagation delay specifications when designing.

E. Unspecified rules

As the semiconductor industry was finding its way, beginning with the simplest RTL ICs of the 1960s (see §12.1.1 for a brief chronology), then the improved TTL and Schottky families, to the modern high-performance CMOS families, there was an understandable lack of standardization of pinouts, specifications, and functionality. As examples, the 7400 (NAND) had its gates pointing "down," but the 7401 (open-collector NOR) was built with the gates going the other way. This created so much confusion that it had to be mutated into the 7403, which is a 7401 with 7400-style pinouts; a similar disaster happened with the 7490 (BCD ripple counter), with power-supply pins in the middle instead of at the corners. (Ironically, mid-chip power-

clocks. Meanwhile, the slower clock is ticking along at f_{clkS}. So it lands in the metastable interval, on average, at a rate of $f_{\mathrm{clkS}}f_{\mathrm{clkF}}\Delta t$ per second.

[87] Which, unfortunately, you cannot drive from a product term, except by bringing the signal out on one pin and back in (to a global clock) on another.

supply pins have made a comeback in fast CMOS, because of their reduced inductance.)

An important legacy of this early anarchy is the hodgepodge of "unspecified rules" that we're stuck with. For example, the ever-popular '74 type-*D* flip-flop exists in every logic family; asserting both SET and CLEAR makes both outputs HIGH in every family except 74C, where it makes both outputs LOW! That's not exactly an unspecified rule, since if you look carefully in the fine print you'll find the inconsistency; the technical term for it is a *gotcha*. Another of our favorite gotchas is the '96, a 5-bit shift register with tricky jam-load inputs: they can SET, but they cannot CLEAR!

A genuine unspecified rule, and in fact a very important one, is *removal time*: that's the amount of time you must wait after disasserting a jam-type input before a clocked device is guaranteed to clock properly. Chip designers didn't bother specifying this until the logic families of the early 1980s (though circuit designers always wanted to know it), specifically the advanced Schottky and fast CMOS families. If you're designing with earlier logic, our advice is to be conservative; for example, assume that the removal time is the same as the data setup time.[88]

10.8.3 Congenital weaknesses of TTL and CMOS

We divide this section into nuisance problems and really bizarre behavior.

A. Nuisance problems

Bipolar (legacy) TTL

You have to remember that TTL inputs *source* current when held in the LOW state (e.g., 0.25 mA for LS, 0.5 mA for F). That makes it difficult to use *RC* delays, etc., because of the low impedances necessary, and in general you have to give some thought when interfacing linear levels to TTL inputs.

The TTL threshold (and that of its imitators, HCT and ACT) is too close to ground, making the whole logic family somewhat noise prone (more on this in Chapter 12). The high speed of these logic families makes them recognize short spikes on the ground line; those spikes, in turn, are generated by the fast output transition speeds, making the problem worse.

Bipolar TTL makes demands on the power supply (+5V, ±5%, with relatively high quiescent power dissipation). Power-supply-current spikes generated by the active pullup output circuitry generally require liberal use of power-supply bypassing, ideally one 0.1μF capacitor per chip (Figure 10.98).

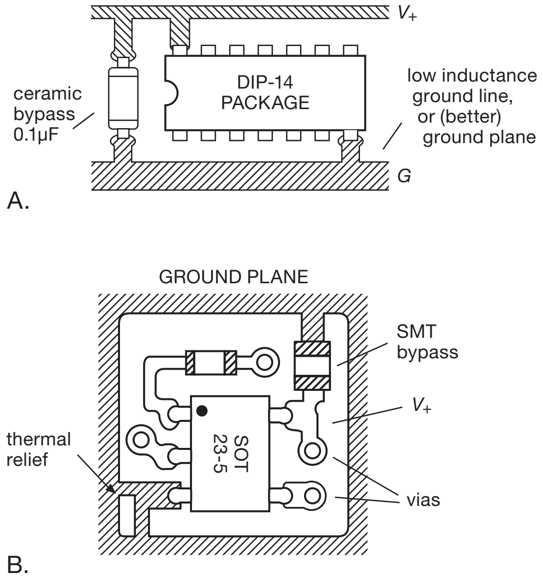

Figure 10.98. It's always a good idea to use robust low-inductance ground wiring, with liberal use of bypass capacitors. A. For an inexpensive two-sided board you should used gridded power and ground traces. B. Better yet, use a ground plane and surface-mount ceramic bypass caps. (The top layer is usually a signal layer, with power and ground planes stacked underneath, in a multilayer PCB. We've shown ground on top for clarity, though you might well do this in a two-layer PCB.)

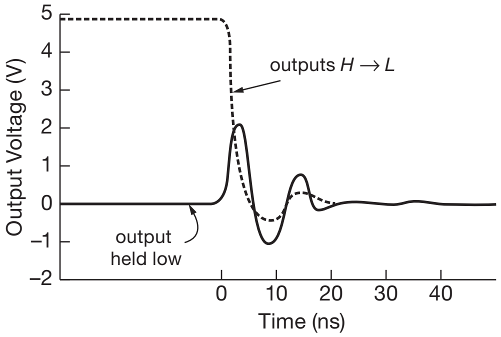

Figure 10.99. Ground bounce: 74AC244 octal buffer, driving seven 50 pF loads H→L, holding eighth output LOW. "Ground" is a copper foil plane (1 oz/ft^2). (After Figure 1.1-4, *TI Advanced CMOS Logic Designer's Handbook*.)

[88] It's usually less; for example, the 74HC74 *D*-type flip-flop specifies a minimum removal time (preset or clear to clock) of 5 ns, whereas the minimum data setup time is 20 ns.

CMOS

CMOS inputs have traditionally been prone to damage from static electricity, with mortality rates really climbing in winter. Recent families with polysilicon gates and effective input protection networks are much more rugged than their metal-gate ancestors. CMOS inputs show a large spread in logic threshold, which can lead to problems of clock skew (§10.8.2C). Logic outputs can even exhibit double transitions when driven with slowly rising inputs. CMOS requires all unused inputs, even those of unused gate sections, to be connected to HIGH or LOW.

An interesting congenital problem with fast CMOS families is the presence of *ground bounce*: a fast CMOS chip driving its capacitive load generates enormous transient ground currents, causing the chip's ground line to jump momentarily, and thereby carrying with it LOW outputs that happen to be innocent bystanders on the same chip. Figure 10.99 shows the sort of thing you see. Notice particularly the magnitude of the effect: 1 to 2 volts is not uncommon! When you consider that a 3 ns, 5 V transition into 50 pF amounts to a transient current $I = C\,dV/dt = 83$ mA, and that an octal buffer might drive eight such loads simultaneously (total current of 2/3 A!), this behavior isn't surprising. When fast AC(T) logic first appeared, clothed in the traditional DIP corner-pin power and ground packaging, this problem turned out to be harder to solve than anticipated, leading to a new set of AC(T) circuits with "center-pin" power and grounds (for lower inductance). Additionally, logic IC manufacturers made design improvements to limit peak slew rates (sometimes called *edge rates*), and thus the consequent $C\,dV/dt$ capacitive-load currents: logic families such as AC(T)Q ("Q" for "quiet") helped considerably, with little speed compromise.

A better solution has evolved, namely the move to smaller surface-mount packages (with less lead inductance), and the widespread use of multilayer circuit boards (with dedicated power and ground layers), combined with surface-mount bypass capacitors. Recent logic ICs sometimes specify self-induced noise levels.[89] And VLSI chips with lots of pins usually dedicate multiple pins (sometimes dozens![90]) to ground. Ground-bounce problems have not been banished, though. Users should be aware of this serious problem and take measures to keep ground inductance as low as possible (Figure 10.98). It's best to use circuit boards with dedicated power and ground planes, and plenty of low-inductance bypass capacitors. Better still, if you don't need the speed, stay away from the fastest logic families entirely.

B. Bizarre behavior

Bipolar logic

TTL doesn't do many really weird things.[91] However, some TTL monostables will trigger on a glitch on the supply (or ground) line, and they generally behave somewhat fidgety. A circuit that works well with LS TTL may malfunction when replaced with AS TTL, because of faster edge times and consequently larger ground-line currents and ringing (74F TTL seems better in this regard). Most weird TTL operation can be traced to noise problems.

ECL involves very fast transition times, and interconnections longer than a few centimeters must be treated as terminated transmission lines (see Appendix H, and §*1x.1*).

CMOS

CMOS logic can drive you crazy! Open inputs on CMOS chips are bad news: you might have a circuit that intermittently misbehaves. You put your 'scope probe onto a point in the circuit, and it shows zero volts, as it should. Then the circuit works fine for a few minutes – before malfunctioning again! What happened was that the 'scope discharged the capacitance on the open input, and it took a long time to charge back up to the logic threshold.

Another amusing stunt is when a CMOS chip goes into "SCR latchup," caused by forcing an input (or output) beyond the supply rails momentarily. The resultant current (50 mA or so) through the input-protection diodes turns on a pair of parasitic cross-connected transistors that are a side effect of the "junction-isolated" CMOS process. This effectively shorts $V_{\rm DD}$ to ground; the chip gets hot, and you have to turn off the power supply before it will behave itself again. If you let this happen for more than a few seconds, you'll have to replace the chip. Some of the newer CMOS designs claim immunity to latchup, even with input swings 5 V *beyond* the rails, and to operate properly for input swings 1.5 volts beyond the rails.[92]

[89] Sometimes called *quiet-output* logic levels, or *ringback*. These specify the maximum dynamic swing on an output that should remain in one logic state, while all other outputs from the same chip make a logic transition.

[90] Or even *hundreds*: we counted 423 ground pins on Xilinx's Virtex-7 FPGA in a 1761-pin package.

[91] A cynic might add that it doesn't do many *good* things, either.

[92] SCR latchup happens when input *current* exceeds some threshold: manufacturers often guarantee no latchup if $I_{\rm in}$ is kept below some maximum "input clamp current," e.g., 20 mA. The datasheet will say something like "the input and output voltage ratings may be exceeded if the input and output current ratings are observed." This is good to know, because you can use a series input resistor to prevent latchup even with input-voltage overdrive.

CMOS has some strange and subtle failure modes. One of the output FETs can "fail open," giving pattern-sensitive failures that are difficult to detect. An input may begin to sink or source current. Or the whole chip may start drawing substantial supply current. Putting a 1 Ω resistor in series with each chip's V_{DD} lead (with downstream bypassing) makes it easy to locate faulty CMOS chips that are drawing quiescent supply current (for power drivers or chips driving many outputs, use 0.1 Ω sense resistors). Most of the time you don't bother with this precaution; but it can be a good idea if you're making a battery-operated device, where microamps matter.

Besides the input threshold variation between chips, a single chip can exhibit different thresholds for several internal chip functions driven from a single input. For example, the RESET input of a CD4013 can bring Q' HIGH before it brings Q LOW. This means that you should not terminate a reset pulse based on the output at Q', because the runt pulse that will be generated may actually fail to clear the flip-flop.

Open inputs would be bad news anyway, even on unused gate sections. That's because the input can float up toward mid-supply, putting both *n*-channel and *p*-channel MOSFETs into conduction. This "class-A current" causes unwanted quiescent current (hey, CMOS is zero power, right?), and it can cause oscillations and (in come cases) enough power dissipation to destroy the IC. You can see how this goes in Figure 10.100, where we measured separately the sinking and sourcing currents in one section of a 74LVC04 inverter running on +3.3 V. As long as the input is within about 0.7 V of either rail, the corresponding MOSFET is fully OFF; but in between there is some simultaneous conduction, or "shoot-through" current. In this case that current peaks at about 20 mA for $V_{\mathrm{in}}\sim$1.4 V, causing 28 mW of dissipation in the inverter. If all six inverter sections floated, you could have nearly 200 mW of dissipation; and if the chip were running from a 5 V logic supply, the dissipation could reach destructive levels.

The maximum shoot-through current depends strongly on supply voltage, as shown in the measured data of Figure 10.101. At very low supply voltages, there is no input-voltage level that brings both MOSFETs into conduction simultaneously.

Here's the craziest of them all: you forgot to wire up the V_{DD} pin on a CMOS chip, but the circuit works just fine! That's because it is being powered by one of its logic inputs (via the chip's internal input-protection diodes from input to V_{DD}). You might get away with this for a long time, but suddenly the circuit reaches a state where all the logic inputs to the chip are simultaneously LOW; the chip loses its power and forgets its state. Of course, this is a bad situation anyway, since the output stage isn't adequately powered and can't source much current. The trouble is that this situation may produce symptoms only occasionally, and it can have you running around in circles until you figure out what's going on.

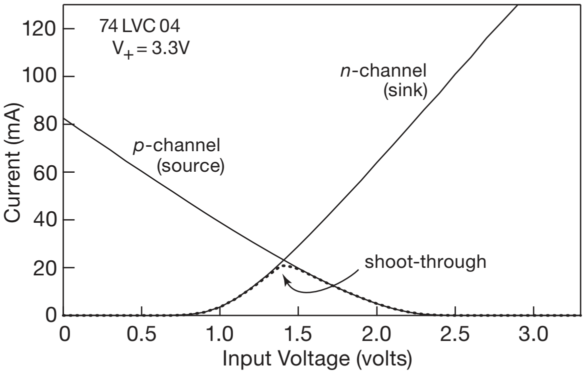

Figure 10.100. Measured sinking and sourcing currents in one section of a 'LVC04 inverter, as a function of logic input voltage. "Shoot-through current" is the colorful name given to simultaneous conduction, caused by a digital input voltage that is not near one of the rails.

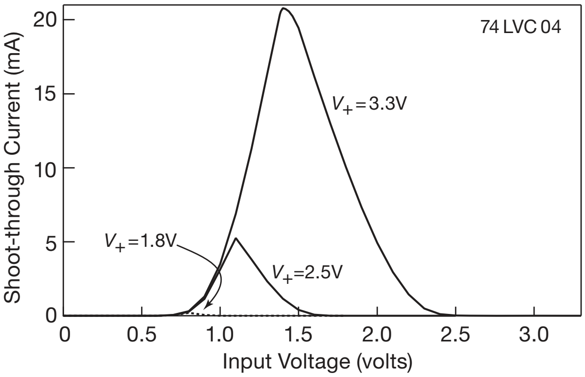

Figure 10.101. Measured shoot-through current versus digital input voltage level, for several supply voltages.

Additional Exercises for Chapter 10

Exercise 10.31. Show how to make a *JK* flip-flop by using a type-*D* flip-flop and a 4-input MUX. *Hint*: use the address inputs for *J* and *K*.

Exercise 10.32. Design a circuit that reads out, on 7-segment digits, how many milliseconds you've held a button down. The device should be smart enough to reset itself each time. Use a 1.0 MHz oscillator.

Exercise 10.33. Design a reaction timer. "A" pushes his button; an LED goes on, and a counter begins counting. When "B" pushes her button, the light goes out and an LED display reads the time, in milliseconds. Be sure to design the circuit so that it will function properly even if A's button is still held down when B's button is pushed.

Exercise 10.34. Design a period counter: a device to measure the number of microseconds in one period of an input waveform. Use a Schmitt comparator to generate logic levels; and use a 10 MHz clock frequency. Make it work so that pushing a button initiates the next measurement.

Exercise 10.35. Add latches to the period counter, if you haven't already.

Exercise 10.36. Now make it measure the time for 10 periods. Also, have it light an LED while it's counting.

Exercise 10.37. Design a true electronic stopwatch. Button *A* starts and stops the count. Button *B* resets the count. The output should be of the form *xx.x* (seconds and tenths); assume that you have a 1.0 MHz square wave.

Exercise 10.38. Some stopwatches use a single button (start, stop, reset, start, etc., each time it is pushed). Design an electronic equivalent.

Exercise 10.39. Design a nice frequency counter to measure the number of cycles per second of an input waveform. Include lots of digits, latched count while counting the next interval, and a choice of 1 s, 0.1 s, or 0.01 s counting interval. You might add a good input circuit with several sensitivities, a Schmitt trigger with adjustable hysteresis and trigger point (use a fast comparator), and a logic signal input for TTL signals. How about a BCD output? Multiplex the digits on output, as well as parallel output. Spend some time on this one.[93]

Exercise 10.40. Design a circuit, using LVC logic at 3.3 V, to time a speeding bullet. The projectile breaks a thin wire stretched across its path; then, some measured distance farther along its path, it breaks a second wire. Beware of problems like "contact bounce." Assume that you have a 10 MHz logic square wave, and design your circuit to read out, in microseconds (four digits), the time interval between breaking the two wires. A pushbutton should reset the circuit for the next shot.

Exercise 10.41. Invent a circuit to keep a running sum of successive 4-bit binary numbers that are input to it. Keep your result to only 4 bits (i.e., perform a sum modulo-16).[94]

Now add another feature to the circuit, namely, an output bit that is 1 if the *total number* of 1 bits in all the input numbers (since the last reset input) is odd, 0 if even. *Hint*: an XOR "parity tree" will tell you if the sum of 1s in each number is odd; figure it out from there.

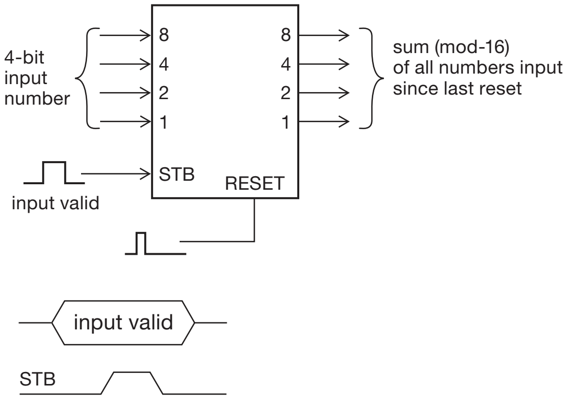

Figure 10.102. Checksum circuit block diagram.

Exercise 10.42. In Exercise 10.15 you designed a 2×2 multiplier by using a Karnaugh map for each output bit. In this problem you are to accomplish the same task by the process of "shift and add." Begin by writing out the product the way you would in elementary school (Figure 10.103). This process has a simple repeating pattern, requiring 2-input gates (what kind?) to generate the intermediate terms a_0b_0, etc., and 1-bit "half-adders" (adders that have a carry out but no carry in) to sum the intermediate terms.

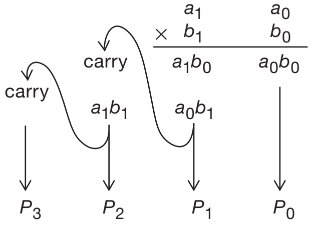

Figure 10.103. How to multiply.

[93] H & H did – this was one of our first joint projects, some forty years ago.

[94] More sophisticated variants of such a sum, e.g., a CRC code (cyclic-redundancy checksum) are useful as a validity check against errors introduced into data files intended for storage or transmission.

Review of Chapter 10

An A-to-H summary of what we have learned in Chapter 10. This summary reviews basic principles and facts in Chapter 10, but it does not cover application circuit diagrams and practical engineering advice presented there.

¶A. Digital Voltage Levels.

In contrast to analog electronics, where valid signals occupy some range of voltages (e.g., an op-amp's ±10 V output swing), the signals in *digital* electronics are confined to two (usually) states, called HIGH and LOW (or 1 and 0, or TRUE and FALSE). Each state has a nominal voltage level, and a defined valid range over which it will be properly interpreted by the input of a driven digital device (§10.1.2B, also §12.1.2). The signal may be single-ended (e.g., a +3.3 V CMOS output, with nominal levels of 0 and +3.3 V, see Figure 10.2), or it may be a differential pair (e.g., LVDS, whose current-mode drive produces a nominal 300 mV swing centered around +1.25 V, seen later in Figure 12.135). There are numerous *families* of digital logic, distinguished by their supply voltage range, input thresholds, speed, power dissipation, and the like; see ¶G.

¶B. Meaning of Digital Bits.

Individual logic bits may represent part of a larger quantity (e.g., bits in a data byte), or they may represent a state (e.g., RESET, or RUN). A group of n bits can be sent simultaneously as a *parallel* quantity (on n wires) or sequentially in time (on a single wire or pair) as a *serial* string, comprising a parallel or serial *bus*. Numeric quantities are represented as unsigned integers, 2's-complement integers, or floating-point numbers (§10.1.3), whereas alphanumeric characters use single-byte ASCII coding (or its two-byte extensions). Base-16 hexadecimal notation (0–9, a–f) is ordinarily used to write multibit binary quantities, with each hex character representing four binary bits (thus two hex characters per byte). Whether representing multibit quantities or single state bits, digital voltage levels in a circuit can be assigned as active-HIGH or active-LOW. For example, one might have an active-LOW signal to reset a microprocessor; it would be called RESET′, and would ordinarily stay *disasserted* at the HIGH voltage state, going LOW only when it asserts a reset operation.

¶C. Combinational Logic: Gates.

Digital circuits whose state depends only on present inputs (i.e., not on past history) are called *combinational*. Their logical operations are performed with *gates*, whose basic forms (§10.1.4) are AND, OR, and NOT (or *invert*), and whose standard graphic symbols and truth tables are shown in Figures 10.4, 10.5, and 10.6. These can be combined to form functions such as NAND and NOR (inverted-output AND and OR, Figure 10.8), or exclusive-OR (XOR, Figure 10.9). And they can be strung together to make any specified logical combinational output (or outputs) from a set of inputs.

¶D. Sequential Logic: Flip-flops.

The basic element of a sequential logic circuit is the *flip-flop* (§10.4), a device that maintains its state in the absence of external inputs; it is a "1-bit memory." The state of a circuit with flip-flops depends on both the present inputs and the previous state. For the ubiquitous *type-D* flip-flop ("*D*-flop"), the logic level present at the D (data) input at the time of[95] a clocking transition (edge) is captured and presented to the Q output. Once you have flip-flops, the world is your oyster – you can make counters, registers, arbitrary "finite-state machines" – and (drumroll) *computers!*

When a flip-flop is augmented with an *RC*, you get a *monostable*[96] *multivibrator* (or "one-shot") timing circuit, which generates an output logic pulse (of width set by the time constant *RC*) when triggered by an input edge. The one-shot is an example of a mixed-signal circuit, i.e., a combination of analog and digital techniques.

¶E. Sequential Logic: Registers and Counters.

A clocked *D*-flop captures and holds one bit; a collection of n *D*-flops with a common clock input is called a *register* (§10.5.1); it captures and holds n bits (a byte, for n=8). When combined with memory and gates, it can form a *finite state machine* (FSM, see Figure 10.64), just a step away from the microprocessor.

If the output bits Q_i of a *D*-register drive the subsequent inputs (i.e., Q_i is connected to D_{i+1}), you've got a *shift register*; these are handy for parallelizing a serial stream, or vice versa (if loaded in parallel and then shifted out the end). An interesting shift-register application is the generation of pseudo-random (noise-like) bit sequences, see §§8.12.4A and 13.14.

A collection of n *D*-flops can instead be connected to make an n-bit *counter*, such that successive input transitions cause the n-bit number represented by Q_0–Q_{n-1} to increment.[97] Simplest is the *ripple counter* (§10.4.2E), in

[95] More precisely, present and stable from a *setup time* t_s before the edge to a *hold time* t_h after the edge, to ensure proper operation.

[96] One-side stable, as contrasted with the ordinary *bistable* flip-flop (stable in either state), or the *astable* oscillator (stable in neither state).

[97] Or to decrement, for a *down counter*.

which the Q_i outputs drive the successive clock inputs; the alternative is a *synchronous* counter, in which all clock inputs are driven by the input signal, and gate logic is rigged up to present to the D inputs the levels corresponding to the next state. The latter is just a special case of a synchronous FSM. Synchronous counters (and synchronous systems in general) are favored, having the pleasant properties of simultaneous state changes (apart from *skew*), and of lack of digital noise in the setup interval before each system clock.

¶F. Standard Logic and Programmable Logic.

Digital logic is available as standard pre-wired functions (gates, flip-flops, counters, registers), in packages going from popular single-gate mini-logic "glue" in 5-pin or 6-pin packages, through the long-popular mid-sized (14-, 16-, or 20-pin) packages, to large multibyte-wide bus drivers in 48-pin or 96-pin packages; see, for example, the listings in Table 10.3 on page 716 (gates) and Table 10.5 on page 742 (counters).

These are good enough for many tasks; but an attractive alternative, particularly in a complex system, is the use of *programmable logic devices* (PLDs). These contain large numbers of uncommitted gates and flip-flops, whose interconnections are user-configurable (and re-configurable); see §10.5.4. The category known as *cPLDs* (complex PLDs) contain from a few dozen to a few hundred "macrocells" (a flip-flop and a collection of gates) and a few thousand gates, along with the non-volatile program memory, and they can replace much of the "random logic" (the tangle of gates and flip-flops) in a digital system; they are also ideal for implementing state machines. At a higher level of integration, the *field-programmable gate array* (FPGA) reigns supreme; the largest of these incorporate billions of transistors implementing millions of flip-flops, along with memory, serial transceivers, and all the resources needed to implement a microprocessor.

Most designers use a hardware description language (HDL), running on a PC platform, to specify the PLD's function, but there are available schematic-entry tools as well; these toolsets allow you to simulate the programmed functions, to verify that you've programmed what you intended. Contemporary PLDs are programmed in-circuit, usually via a JTAG serial port. We discuss PLDs in greater detail in Chapter 11.

Any discussion of digital logic must include *microcontrollers*, the increasingly capable and inexpensive computers-on-a-chip that can replace discrete and programmable logic devices in digital devices. Think of embedded microcontrollers not as exotic creatures, but simply as circuit components – they cost less than a precision op-amp, and they can do wonders. They are the subject of Chapter 15.

¶G. Logic Families.

Digital logic functions, whether standard logic or programmable logic, can be implemented in ICs with a variety of on-chip transistor technologies (§10.2). Earlier legacy families of standard logic (bipolar RTL, DTL, and TTL) have yielded their turf to the now-dominant CMOS logic families. The latter include the traditional 5 V HC[T] and AC[T] families (the T suffix indicates TTL thresholds, around 1.4 V), the high-voltage (but very slow) 4000B series, and a proliferation of CMOS families intended for lower-voltage operation; the latter include popular families like LVC (1.8–5 V) and AUC (1.2–2.5 V), among the dozens of choices. See Figures 10.22, 10.26, 10.27, and (in Chapter 12) §12.1 and Figure 12.2.

Programmable logic devices (cPLDs, FPGAs) and microcontrollers are invariably built with CMOS, with supply voltage ranging from as low as 1 V to as high as 5 V, and reflected in their speed and power dissipation. It is common to have separate "core" and I/O supply rails in many of these devices; for example a microcontroller or FPGA might have a 1.2 V core and a 1.6–3.6 V I/O (the latter for compatibility with external devices).

All these variations can be confusing. Chapter 12 deals in detail with logic family interfacing. At a simple level, though, what you need to know (summarized in §12.1.3, and encapsulated in Figure 12.9) is that (a) you can always make a direct connection between logic running at the same voltage; (b) logic running from a higher voltage (e.g., +5 V) can drive lower-voltage logic if the latter's input is "tolerant"; and (c) lower-voltage logic can drive higher-voltage logic if the latter has "TTL thresholds" and the former is powered from at least +2.5 V.

¶H. Digital Logic Cautions.

Digital design nicely sidesteps the complications inherent in linear circuits (biasing, thermal stability, etc.), and it's easy to become complacent, and lazy. But there are plenty of hazards in the digital playground, see §10.8. Among the *dc problems* are logical lockup states, SCR latchup, and undetermined startup states. More sinister are *switching problems* such as logic races and runt pulses, metastable states, clock and data skew, ground bounce, and power- and ground-conducted switching noise.

PROGRAMMABLE LOGIC DEVICES

CHAPTER 11

In the previous chapter we introduced the basics of digital electronics – gates and combinational logic, flip-flops and sequential logic – and we illustrated their application with some examples: a modulo-*n* counter, a multiplexed LED display, and an *n*-pulse generator. In that chapter we used primarily *standard logic*; that is, small blocks of logic (gates, flip-flops, counters, registers) packaged as single integrated circuits.

However, as we remarked often, there is an alternative (and usually better) way to implement those kinds of circuits, namely, the use of *programmable logic devices* (PLDs).[1] A PLD consists of a chip with lots of logic (gates and registers, and sometimes much more), in which the *connections* are programmable. But it's not a computer program: in a computer the program tells the processor *what to do*; in a PLD the program tells the chip *how to connect* its component pieces.

11.1 A brief history

The first PLDs (1975) were the Signetics' "Integrated Fuse Logic" devices, with a handful of uncommitted gates and a matrix of fuses (literally!) that could be selectively blown to leave the desired interconnections. You "programmed" the things with a chart of fuse links, or (later) by designating the fuse locations manually on a computer screen. In subsequent developments, Signetics added flip-flops to the mix, enabling sequential circuits; and Monolithic Memories devised a simplified family known as PALs (programmable array logic), with a more usable text-entry design language called PALASM. By the middle of the 1980s we had Lattice's GALs (generic array logic), which used electrically reprogrammable memory and a chameleon-like output cell that could be either a flip-flop or a gate. There were improved programming languages, too, namely CUPL and ABEL; these, and their successors, are all generically called *HDLs* (hardware description languages).

Around the same time Xilinx introduced the FPGA (field-programmable gate array), an alternative programmable logic scheme with a "finer-grained" architecture – many more gates and registers, organized as a fabric of logic blocks, surrounded by I/O blocks, with more flexible interconnections – and whose configuration programming was held off-chip in a separate small non-volatile memory device (a serial "configuration ROM"), and loaded into on-chip (and volatile) SRAM at power-up.

FPGAs and complex PLDs, improving nicely with time, are both part of the essential toolkit of circuit designers. Contemporary cPLDs (the "c" stands for "complex") have from 32 to 2000 macrocells, with tens of thousands of gates, and operate at clock speeds up to a few hundred megahertz; they use on-chip nonvolatile program memory, and can be programmed and reprogrammed in-circuit, using simple serial protocols (e.g., JTAG). There are variants[2] with essentially zero quiescent current. They have highly predictable timing.

Contemporary FPGAs are denser, topping out at around a million flip-flops, in packages (see Figure 11.1) with as many as 1738 pins (!). They may include blocks with dedicated memory, arithmetic modules (ALUs, MACs, other DSP), interface (USB, Ethernet, PCI), and other specialized functions. With such extensive capabilities, it's now routine to program in standard designs for large modules such as a video processor, PCIe controller, Bluetooth, or even a complete microprocessor (and peripherals), with plenty of programmable logic left over to form a "system-on-a-chip." These standard programmed ("soft") designs are known as "IP" (intellectual property, some of which you may have to license); if you put in an IP microprocessor, it is called a *soft processor* core.[3] An efficient alternative, if you want a processor inside your FPGA, is the use of a hybrid FPGA, with the microprocessor and peripherals already hardwired.[4]

[1] Officially "PLDs," but generally meant to include cPLDs (complex PLDs) and FPGAs (field-programmable gate arrays).

[2] Notably the Xilinx (originally Philips) CoolRunner™ series, and the Lattice ispMACH™4000Z series.

[3] Examples are the Xilinx MicroBlaze, the Altera Nios-II, the Lattice Mico, and the Actel ARM.

[4] Examples are the PowerPC (in Xilinx FPGAs), the AVR (in Atmel's FPSLIC), and the ARM (in Altera's FPGAs).

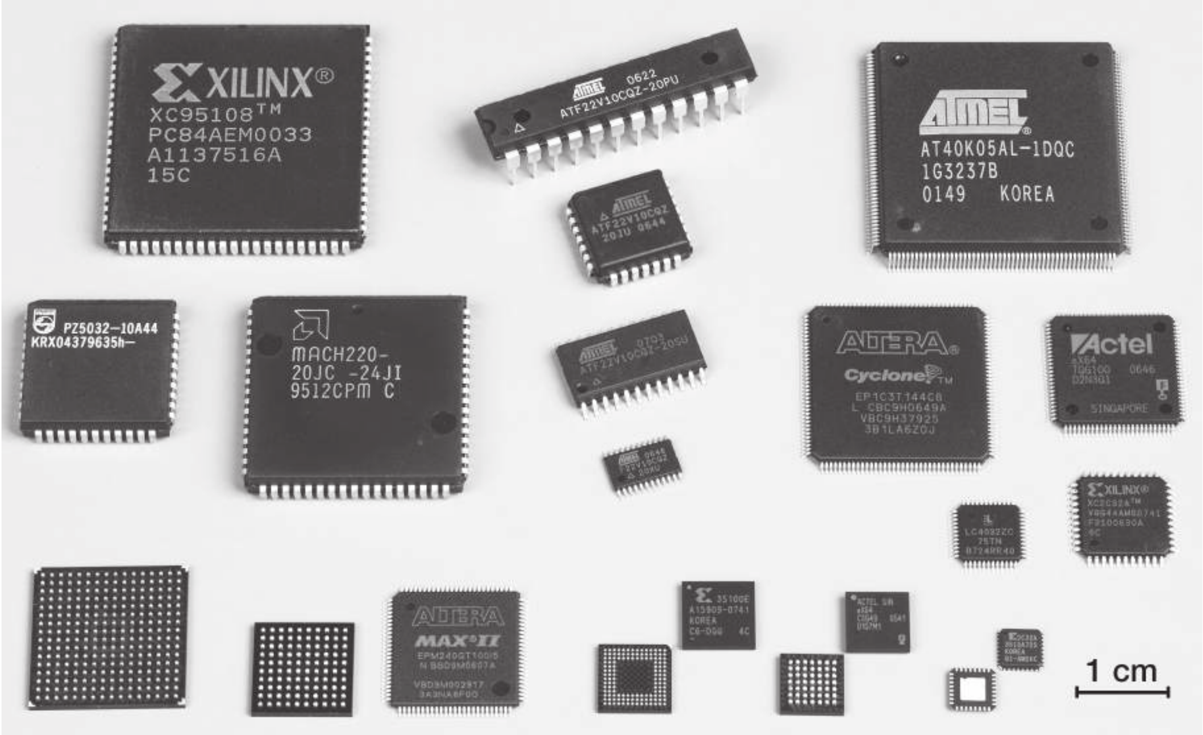

Figure 11.1. A selection of programmable logic packages. At upper left are three PLCCs (84, 68, and 44 pins), to be compared with their denser QFP brethren at upper right (going clockwise: PQFP-208, TQFP-100, VQFP-44, TQFP-48, and TQFP-144). Down the middle are displayed the same sPLD type (22V10) in four increasingly dense packages: DIP-24, PLCC-28, SOIC-24, and TSSOP-24. Across the bottom are the densest packages (left to right): FTBGA-256, FBGA-100 (and the same IC in a TQFP-100), BGA-132, BGA-49 (CSP-49), and QFN-32; for the last three both top and underside are shown.

For such complex devices, the legacy programming tools (CUPL, ABEL) that evolved with small PLDs are hopeless.[5] Current practice favors either graphical schematic entry, or one of the two contemporary and powerful text-based HDLs (called *Verilog* and *VHDL*); presently we'll illustrate both. For most digital designs, programmable logic is generally a better choice than standard logic, because (a) one chip replaces many – less wiring, smaller finished product, less inventory, lower cost; and (b) it is easy to reprogram the part if the initial design is flawed, or if you want to add features.

11.2 The hardware

Contemporary PLDs are fiendishly complex... and they're not getting any simpler. High-end devices already have upwards of 5 billion transistors (and counting). To make it all understandable, we'll take it in easy stages: first the classic simple PAL architectures (e.g., 22V10) and the more flexible PLAs (e.g., Xilinx CoolRunner-II), and then the complex and register-rich FPGAs.

11.2.1 The basic PAL

A good starting point is the basic PAL, an example of a simple PLD. The classic device is the 22V10, the part number signifying 10 output *macrocells* (more on this soon), among a total of 22 inputs and outputs (originally offered in a 24-pin package). The PAL circuit scheme consists of a programmable array of connections, whereby both inputs and feedback outputs can be selectively connected to a set of many-input AND gates; the outputs from a fixed number of such AND gates then feed an OR gate. Its output can be used directly (a combinational output), or it can feed a type-D flip-flop (a "registered" output); the circuitry for these output options is called an "output macrocell." Figure

[5] You *can* still get (from Atmel or Lattice) the classic small "sPLDs" (*simple* PLDs): 16V8, 20V8, 22V10, and 26V12, for which CUPL and ABEL are completely adequate.

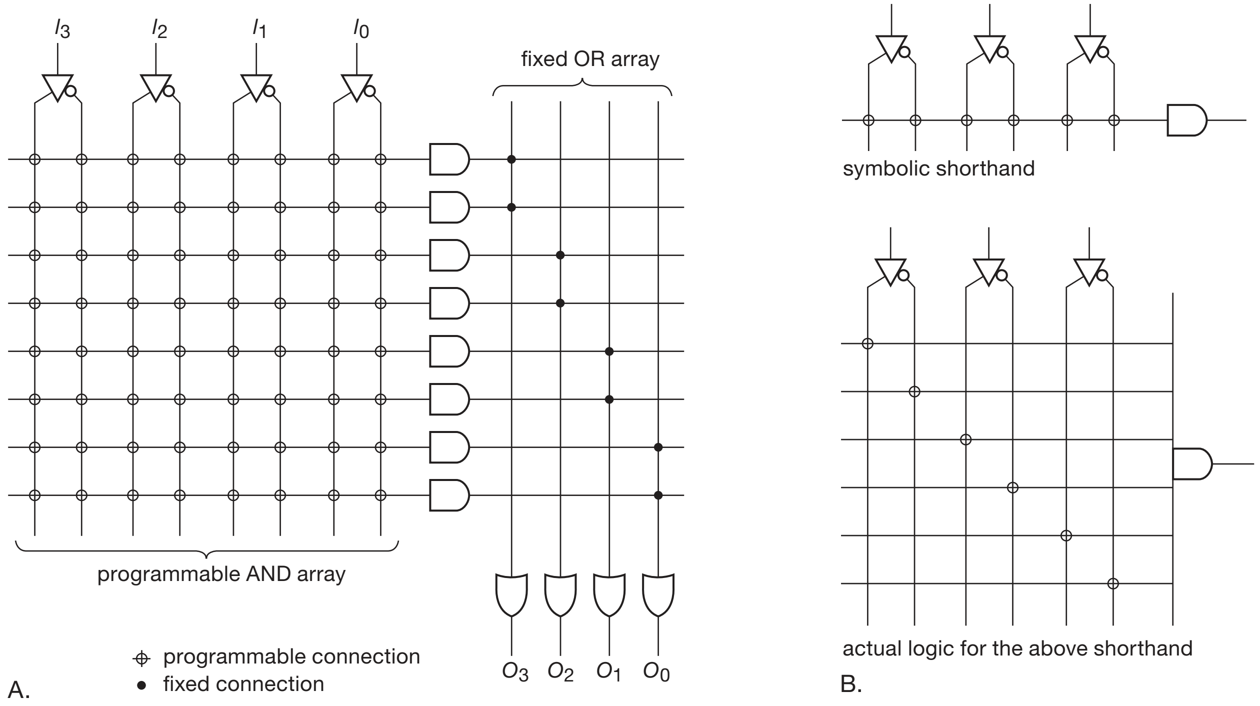

Figure 11.2. A. In a "PAL" (Programmed Array Logic) every available logic signal (or its complement) can be connected to many-input ANDs; the outputs of several such ANDs are OR-ed to form the logical outputs, each then passing through an output macrocell on the way to an output pin. B. Each AND gate has many inputs, shown in conventional shorthand and in fully expanded form.

11.2 shows the basic idea, in a simplified scheme with only four input signals; here each logic output comes from an OR gate fed from two of the 8-input ANDs, and that output would drive the output macrocell. (Note the shorthand notation used in Figure 11.2A for the many-input AND-gates and OR gates, shown expanded in Figure 11.2B.)

In real life a PAL has many more inputs and gates. Figure 11.3 shows the actual scheme for the 22V10, which, though impressive looking, is in fact tiny by contemporary standards. The 12 inputs (and their complements), along with feedback from the 10 outputs (and their complements) – thus 44 signals total – are all brought into the connection matrix, in which any set of them can be connected to any 44-input AND, whose output is then OR-ed with another 7 to 15 ANDs (more toward the center of the chip, fewer toward the ends) to create an output (one of ten). That output does not go directly off the chip, but rather gets massaged in an output macrocell (Figure 11.4), which consists of a bit of programmable logic that lets you latch the OR output in a flip-flop, or just pass it through without latching. You can see from Figure 11.4 that the output, whether "registered" or combinational, can be true or complemented, and further can be three-stated.

The 22V10 is adequate for many logic tasks: you can make a shift register, or a counter, or an address decoder, or just a collection of what's called "random logic." But by contemporary standards it is extremely limited, both by the small number of registers and I/O pins, and also by the constraint of a common CLK signal; you cannot, for example, make a ripple counter.

One evolutionary path has been the creation of what we might call a "super-PAL," in which the macrocells allow individual clocking from the logic array, and in which many more macrocells are packed into one IC. These often include schemes for expanding the logic by sharing product terms across macrocells. Such extensions of the basic PAL architecture are called "cPLDs" (complex PLDs), and are widely available.[6] They range in capacity up to 2000 or more macrocells (some of which may be "buried," i.e., available for internal interconnections but not connected to I/O pins), and they allow asynchronous clocking.

The "programmable-AND/fixed-OR" architecture

[6] For example, the Altera MAX7000 series, the Lattice Mach 4000 series, or the Xilinx CoolRunner-II series (the latter uses the more advanced PLA architecture; see §11.2.2).

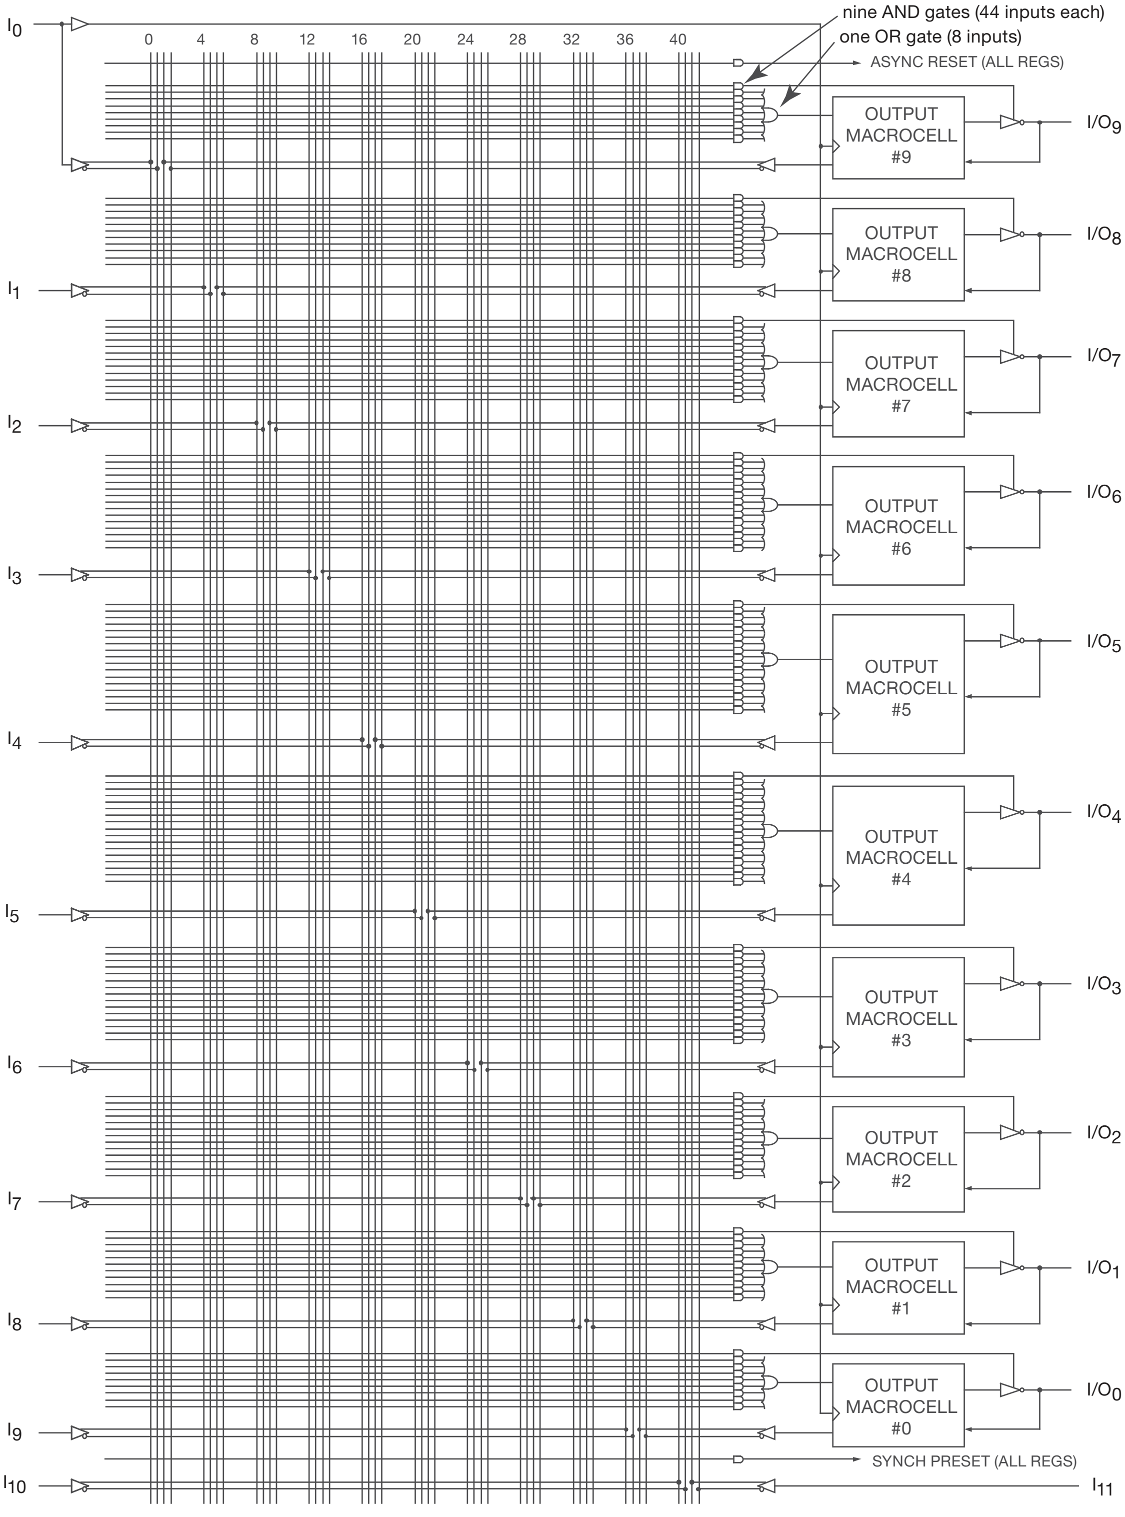

Figure 11.3. Logic array of the classic 22V10 PAL: programmable-AND/fixed-OR. The output macrocell can be programmed as a type-D flip-flop or a simple pass-through; see Figure 11.4. (Adapted from the Lattice ispGAL22V10 datasheet, ©Lattice Semiconductor Corporation, 2004.)

(sometimes called "sum of products") can be a limitation also, particularly when you want to implement a complicated bit of combinational logic, because it forces the implementation to be a single sum (OR) of several products (ANDs). The next step up in logical complexity is the programmed logic array (PLA).

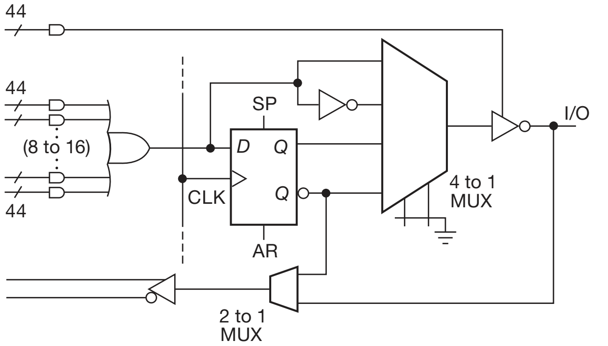

Figure 11.4. Programmable "macrocell" of the classic 22V10 PAL: true or inverted, registered or combinational, with three-state output and feedback into the logic array. The CLK, SP (synch preset), and AR (asynch reset) are common to all 10 macrocells, whereas a "product term" (a 44-input AND) is available for each macrocell's three-state control.

11.2.2 The PLA

In the PLA, the logic array consists of programmable ANDs feeding *programmable* (as opposed to fixed) ORs (Figure 11.5). Manufacturers don't generally distinguish these parts by calling them PLAs; they just call them cPLDs (same as the large PALs); you have to look in the datasheet to see what's really inside. A contemporary example is the Xilinx CoolRunner-II (XC2C) series of cPLDs, currently offered with 32 to 512 macrocells (the latter half buried, given its modest 324-pin package).

As we'll see soon, the software you use to program these parts pretty much hides their inner architecture from the user; you just write a bunch of HDL code, run the software, and see (a) if it fits, and (b) if it meets the speed and timing-delay requirements.

11.2.3 The FPGA

The PALs, PLAs, and cPLDs above are all examples of what might be called "logic-rich–register-poor" architectures. After all, with even the lowly 22V10 you have a dozen 44-input AND gates feeding each OR-gated macrocell – but only a handful (OK, *two* handfuls) of flip-flops.

A complementary approach is provided by FPGAs, which consist of a fabric of flip-flops, each fed from a modest bit of logic (typically just a four-input lookup table, or LUT), embedded in a vast array of interconnecting wiring. Here we're talking tens of thousands to millions of these cells, called variously "configurable logic blocks" (CLBs), or "logic elements" (LEs); and, these are often accompanied by blocks of memory (RAM), arithmetic functions such as multipliers or embedded processors, and interface elements such as PCIe or Ethernet. Such FPGA architectures are well characterized as "logic-poor–register-rich," or as "fine grained."[7] Figure 11.6 shows a typical logic cell, in this case from Altera's Cyclone-II FPGA family.

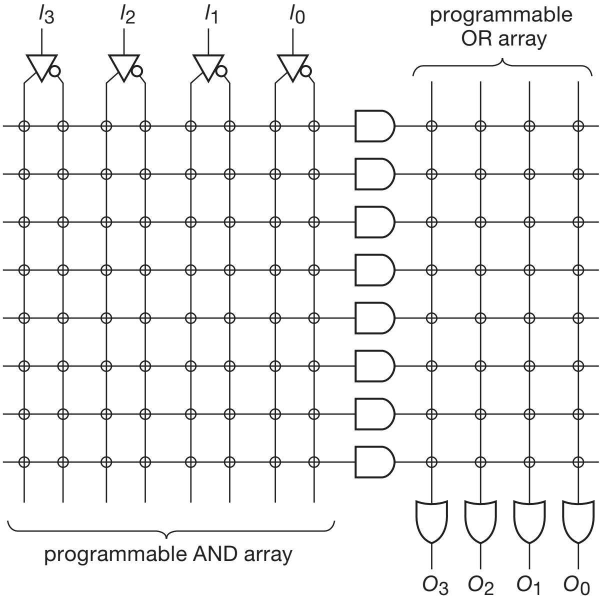

Figure 11.5. A PLA (Programmed Logic Array) is more flexible than the PAL (Figure 11.2), by allowing programming of both the AND and OR arrays.

You can think of FPGAs as highly advanced custom ICs that are configured by the user. The high-end FPGAs easily accommodate what you would normally think of as separate microprocessors and peripherals – a configurable "system-on-a-chip." And FPGA manufacturers compete vigorously to put the latest process technologies into their products. As a result, their products increasingly appeal to manufacturers as an alternative to full-custom ICs: the

[7] As luck would have it, this neat organization is challenged by some of the cPLDs that are actually chimeras, or FPGAs in disguise, for example the Altera Max-II cPLDs (which use 4-input LUTs), Cypress Delta39K cPLDs, or the Lattice MachXO "crossover cPLDs."

latter[8] involve a costly design cycle, provide less flexibility, and often delay the introduction of a new product into the marketplace. "Time-to-market" is critical in consumer electronics, making FPGAs cost effective, in spite of their higher per-unit costs. An additional benefit is the ability to upgrade their internal circuitry (for example to fix bugs, add signal processing options, or whatever).

Typically you'll pay a dollar or two for cPLDs and for small FPGAs, ten dollars or so for intermediate size FPGAs, and from hundreds of dollars up to a thousand dollars or more (!) for FPGAs of the largest size and highest performance. Traditionally FPGAs have not been low-power devices, with typical quiescent currents of the order of milliamps to tens of milliamps (and additional dynamic power dissipation, of course, when clocked rapidly). However, micropower FPGAs are becoming available, aimed squarely at portable applications: an example is the Actel IGLOO series, with quiescent power dissipation in the 5–50 μW range.

The big players in the high-end FPGA market are Altera and Xilinx (the originator), with smaller FPGAs from Actel, Atmel, Cypress, and Lattice.

11.2.4 The configuration memory

A programmable logic device has to have its program held *somewhere.* Traditionally, sPLDs and cPLDs have always kept their configuration on-chip, in non-volatile storage: the earliest PLDs (e.g., the original MMI PALs) used one-time on-chip fusible links, but they were quickly superseded by reprogrammable CMOS memory. Some early devices (e.g., the original Altera Max 7000) used UV-erasable (EPROM) memory (with a quartz window, so you could blast it with the appropriate amnesia-inducing dose – typically of 20 minutes duration – of ultraviolet light), but quickly enough the industry adopted *electrically*-erasable memory (EEPROM, or "flash" memory). That is how all sPLDs and cPLDs are now made; they can be erased in seconds, and reprogrammed typically in less than a minute. There are specifications for the minimum *data-retention* time of the on-chip memory (typically 20 years), and for its *endurance* (typically a minimum of 1000 to 10,000 program–erase cycles).

Early sPLDs had to be programmed in a *device programmer* (which you bought from a company such as BP Microsystems, Needhams Electronics, or DataIO), then placed in the target circuit. This worked OK for through-hole (DIP) packaged parts, for which you could provide sockets in the final resting place; but it was awkward for soldered-in-place surface-mount parts, because reprogramming required removal of the IC. The solution is "in-system" programmability, which was retrofitted onto some sPLDs (e.g., Lattice's ispGAL22V10, an ISP version of the standard 22V10). All contemporary cPLDs are in-system programmable, using a simple serial data protocol such as JTAG (IEEE 1149) boundary scan.[9] You connect to the serial programming pins with a "pod," connected to the host computer that holds the programming data via a USB connection. Pods typically cost around $100; see the discussion of JTAG in §14.7.4.

For *FPGAs* the situation is somewhat different. Traditionally, FPGAs had no on-chip ROM; instead they inhaled their configuration data at power-up from an external serial "configuration ROM," then held the configuration on-chip in static (volatile) memory. Although this is still the protocol for many FPGAs, there are now available some FPGA families with on-chip nonvolatile flash memory, for example from Actel, Lattice, and Xilinx. As with contemporary cPLDs, programming is done in-circuit, via a comparably priced pod.

11.2.5 Other programmable logic devices

It's worth remembering that a simple digital memory is "programmable logic": it produces a stored *n*-bit output for each possible *m*-bit (address) input. That is how it is used in the general state machine of Figure 10.64, and, at a simpler level, a small (e.g., 16×1) lookup table is used in the logic elements of an FPGA.

There are recent developments in the form of *mixed-signal* programmable logic; an example is the Cypress PSoC™ mixed-signal programmable family, which incorporates amplifiers, filters, and other analog components on a programmable chip that includes a microprocessor.

11.2.6 The software

To use programmable logic devices, you've got to learn some software tools. You begin with design *entry*, either with a hardware description language (HDL) or with schematic entry. Then you run a *simulation* tool, to verify that the design does what you intend. Next is *synthesis*, which converts the design to a "netlist," which describes the logical connections. The netlist is then fitted to the target device, a process called *place and route*. Finally,

[8] Sometimes called an *ASIC*, for application-specific integrated circuit.

[9] The IEEE has developed an industry standard data format for using JTAG for in-system configuration, known as IEEE 1532.

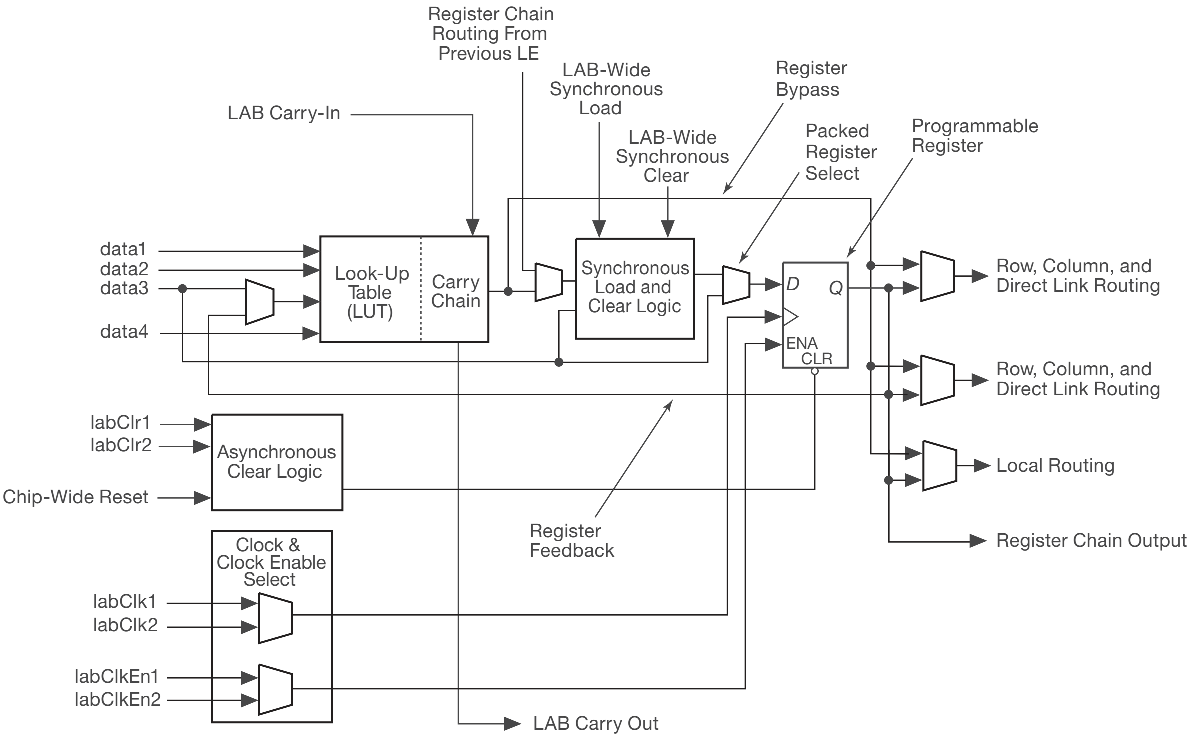

Figure 11.6. An FPGA logic element (LE), one of some tens of thousands in a typical FPGA, from the Altera "Cyclone II" family. The clocked flip-flop and lookup table (LUT) are decorated with extra logic and control signals from the larger logic array block (LAB), for flexible expansion. (Adapted from Altera Cyclone II Device Family datasheet, ©Altera Corporation, 2007.)

the fitted design is downloaded to the programmable logic chip, either to the chip itself (if it has on-chip non-volatile memory), or to a configuration ROM (from which it loads at power-up), or possibly hot-loaded from a processor directly to the powered-up chip.

FPGA manufacturers typically provide free software for their low-to-mid-range products,[10] but they may charge from several hundred dollars to several thousand dollars for software that supports their high-end offerings; some of the cost of the latter is attributable to the included software "cores" (code modules that creates blocks of useful hardware, sometimes called "IP," for intellectual property). There may be deep discounts offered to educational and nonprofit users.

These software tools are not terribly easy to learn, and they have a distressing tendency to change with time. They are often afflicted with bugs, requiring skillful workarounds. It can be a full-time job keeping up. It's always helpful, therefore, to have some company (which misery loves); that is, to use the same software tools as those the vastly more knowledgeable people around you are using.

We will not attempt to teach these tools. However, to illustrate the general process we next show an example of a complete circuit design done five different ways (§11.3), one of which is with a cPLD (§11.3.3).

11.3 An example: pseudorandom byte generator

The quickest way to see how a circuit idea can be implemented in several ways is, well, simply to see an example. Ours is what might be described as the ultimate gibberish machine,[11] namely a circuit that sends out a succession of pseudorandom bytes, as standard RS-232 serial data. In this section we begin with a *block diagram*, then we show the circuit implemented first in (a) *standard logic*, then in (b) *programmable logic* (with entry in two popular methods, namely graphic *schematic entry*, and text-based

[10] An example being the Xilinx "WebPACK," which you get directly over the Internet (if you have the patience to download and install the >5 GByte set of files!).

[11] Or the proverbial monkey-at-a-typewriter.

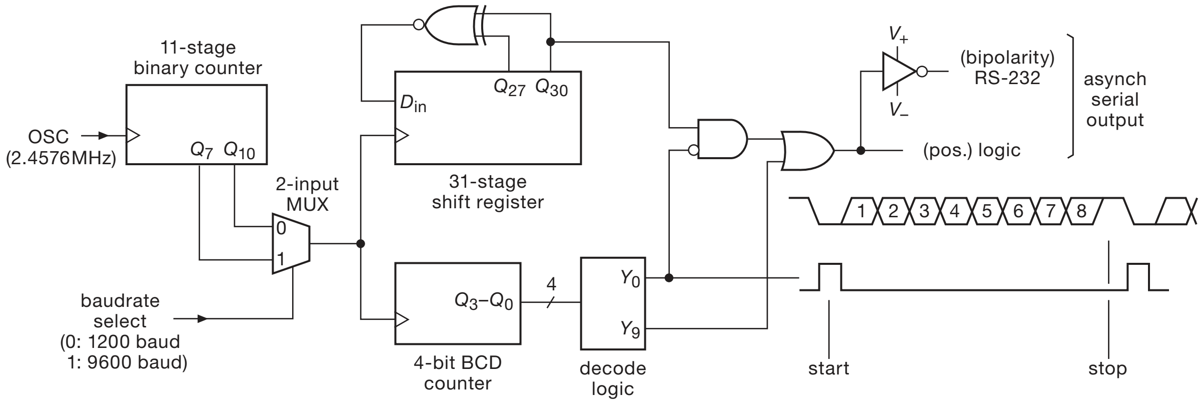

Figure 11.7. Block diagram of RS-232 pseudorandom byte generator. A 2-input MUX (multiplexer) selects the baudrate from a subdivided oscillator; the resulting clock shifts a maximal-length linear feedback shift register to produce pseudorandom bits, which are framed with START and STOP bits to produce 8n1-formatted serial bytes.

hardware description language.[12] Finally, we show how the same function is easily implemented with a *microcontroller*, the inexpensive (and indispensable) programmable computer-on-a-chip (complete with internal memory and I/O functions), intended for "embedded" use in any electronic device. Embedded microcontrollers are the subject of Chapter 15 – but we couldn't resist showing them now, simply because they are *the* attractive design alternative.

We wrap up this section with some advice – in particular, which hardware to use, paired with their appropriate design tools, and the pros and cons of each.

11.3.1 How to make pseudorandom bytes

Section 13.14 describes a simple method to produce a "pseudorandom" bit sequence (PRBS), using a shift register whose serial input comes from an XOR of two (or more) downstream bits.[13] The sequence so produced is *pseudo*random because, though it has many properties of randomness, it is not truly random; in fact, it is completely deterministic, with a repeat interval (with properly chosen XORed bits) of $2^n - 1$ for a register of n stages.[14]

Our example uses a register of length 31 (Figure 11.7), for which XOR feedback from bits 28 and 31 produces a maximal-length sequence. Its length ($2^{31} - 1$, or 2,147,483,647) corresponds to a repeat interval of 2.6 days at the maximum serial output rate of 9600 baud.[15] The shift register is clocked at a selectable rate of either 1200 or 9600 shifts/second, with the output bits grouped into 8-bit bytes, each of which is framed by a "START" and "STOP" bit pair. This is known as *asynchronous serial* communication, typified by the familiar RS-232C serial computer port. This circuit allows selection of baud rate (1200 or 9600), and formats the output as 8-bit data, no parity, and one stop bit (this is usually abbreviated "8n1").

As explained in §14.7.8, the actual voltage levels for serial port communication, described in the RS-232C specification, are (annoyingly) of both polarities, with ±5 V to ±15 V levels corresponding to the two logic states; to add a bit of confusion, those outputs are logically inverted, with logic HIGH corresponding to the negative signaling level, and vice versa.[16] The good news is that there are plenty of RS-232C driver–receiver interface chips available, most of which include internal charge-pump voltage generators so that you can power them from a single positive logic supply (usually +3.3 V or +5 V); an example is the MAX3232 shown in Figure 11.8.

[12] In particular, *Verilog* and *VHDL*, the two popular choices.

[13] Sometimes called a *linear feedback shift register*, or LFSR, and introduced earlier in §8.12.4A.

[14] It should be noted that there are far better computational algorithms for generating pseudorandom bit sequences; this method was chosen for its abject simplicity.

[15] Readers unhappy with the concept that a random sequence eventually *repeats* might prefer something a bit longer, say a shift register of length 71 (with XOR tap at 65), whose repeat interval is approximately 8 billion years (about half the age of the universe). *Real* purists can elect a longer register, say of length 167 (XOR tap at 161), which won't repeat for 10^{38} years (about 10^{28} times the age of the universe).

[16] Sometimes called *MARK* and *SPACE*, respectively.

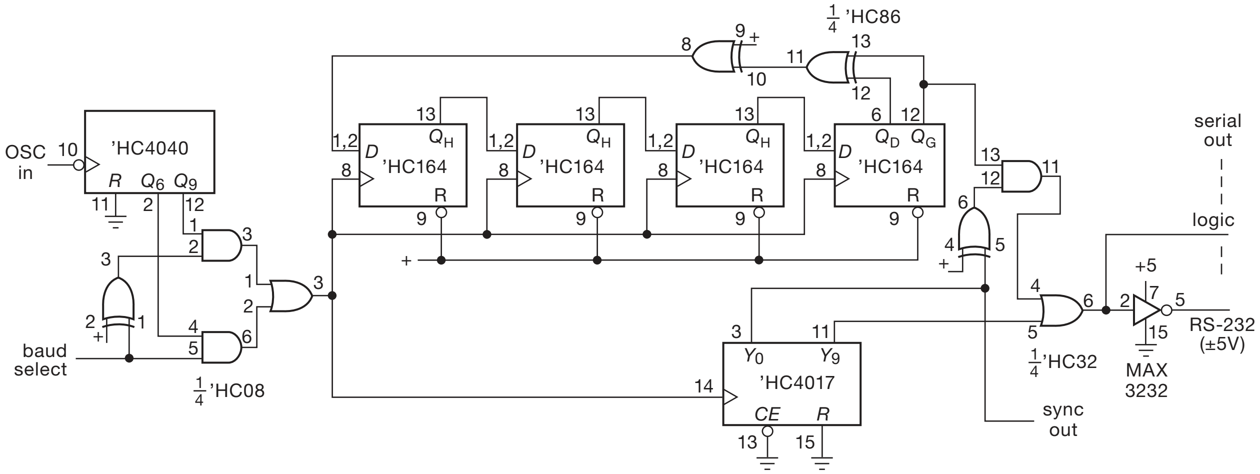

Figure 11.8. Implementation with standard logic (74HC family).

11.3.2 Implementation in standard logic

Gates, counters, shift registers – these are the stuff of "standard logic," most famously the legendary 74xxx logic family, with these discrete logic functions supplied in through-hole (DIP) or the many varieties of surface-mount (SOIC, SSOP, QFN, BGA) packages. In Figure 11.8 we've implemented the random generator in the 74HC subfamily (chosen for wide availability, adequate speed, low power, and DIP/SMT package options). We've indicated DIP pin numbers to emphasize that this is a complete and finished design.

Some comments.

- With standard logic you see tricks like unused XORs converted to inverters, to avoid extra components (such as a package of inverters). Another example is the use of discrete leftover gates (rather than an integrated 2-input MUX) for the baud-rate select.[17]
- We took advantage of some unusual packaged functions, for example the 'HC4017 fully decoded decimal counter, here used to frame the 8 data bits into 10-bit serial characters; the more conventional way would use a separate counter and decode logic. Another helpful packaged function is the 'HC4040 12-stage *ripple* counter (used for the clock subdivision), rather than a cascade of smaller synchronous counters.
- Even with tricks like these, this design required many IC packages (nine, to be exact, not counting the RS-232 driver) – a hallmark of digital implementations done in standard logic. Those nine ICs have to be wired; and, once wired, any changes require at least a wiring change. Furthermore, there are six different IC types, so for this kind of implementation you have to keep a substantial inventory of different IC functions.

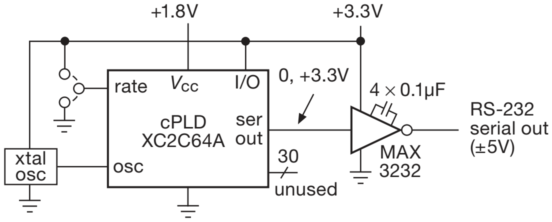

Figure 11.9. Programmable logic permits a far simpler circuit implementation. The connections within the cPLD can be specified, using software tools, either via graphical *schematic entry* or by a text-based HDL; we illustrate both. The resulting desired "fuse" configuration is programmed into the cPLD's internal non-volatile memory, with the cPLD in its actual circuit, via four dedicated pins (known as JTAG, not shown here).

11.3.3 Implementation with programmable logic

As we remarked, programmable logic devices usually provide a better hardware implementation of digital logic, and this example is no exception. Here programmable logic is

[17] Note, however, that you *can* get logic in convenient smaller bites, in the form of small pincount packages with 1–3 gates; these go by names like "TinyLogic™" (Fairchild's name), "PicoGate™" (NXP's name), "MiniGate™" (ON Semiconductor's name), "Little Logic™" (TI's name), Single Gate (ST's name), or LMOS™ (Toshiba's name). We'll call them all "mini-logic," a name evidently overlooked in the trademarking frenzy of the big guys. They come in handy when you need some glue between large digital chips.

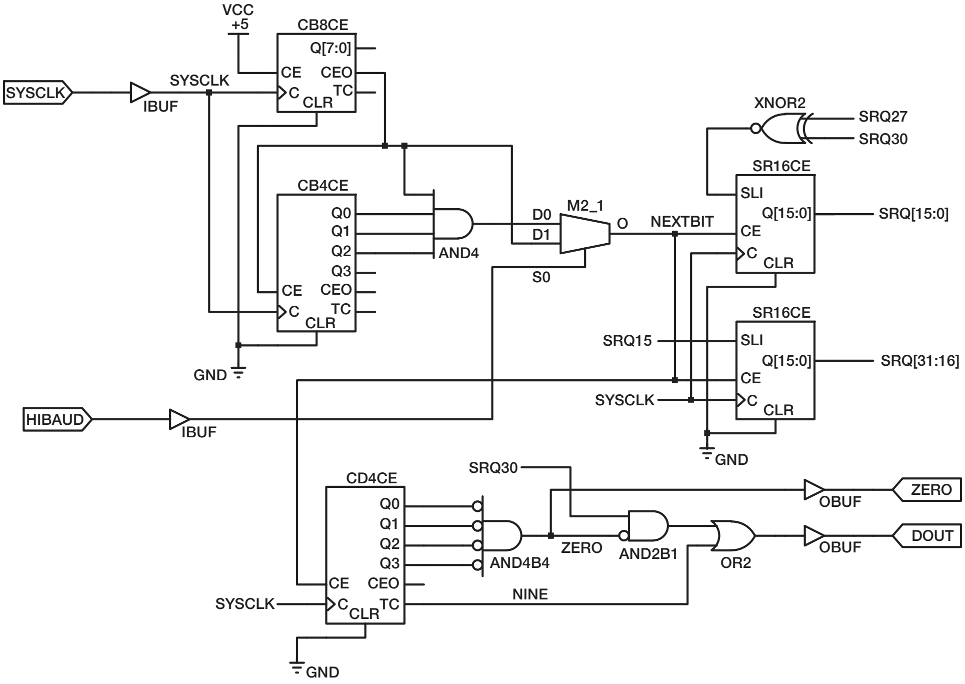

Figure 11.10. Graphical-entry schematic capture for programmable logic design, using Xilinx tools. The component blocks can be generic logic functions (e.g., CB4CE = counter, binary, 4 bits, with chip-enable), or specific standard logic part numbers (e.g., "163" = 74xx163 = 4-bit binary synchronous loadable counter with 3-state outputs and synchronous load and reset; not used in this design); or they can represent modules specified by a text-based hardware description language such as VHDL.

a *much* better choice than standard logic, with a single chip replacing nine; and, as with programmable logic generally, you can reprogram the circuit to fix errors, or to add features.

This design is small, about right for a cPLD, rather than the generally much larger FPGAs. Figure 11.9 shows the wiring, using a smallish cPLD (64 macrocells). The particular cPLD we chose runs its core at 1.8 V, but permits input and output operation from 1.5 V to 3.3 V. This task uses little of the chip's I/O capabilities; 30 pins (of 34 available) are unused. It does, however, use most of the 64 available flip-flops. The chip costs about $2.

A. Programmable logic – schematic entry

Many circuit designers favor a graphical "schematic-entry" technique for designing programmable logic. Figure 11.10 shows how it looks for our pseudorandom byte generator, entered using the tools supplied by Xilinx.

The individual symbols can be familiar gates (OR2: 2-input OR), or lopsided gates (AND2B1: 2-input AND with one bubbled input), or larger generic functions (CD4CE: counter, decimal, 4 bits, with chip enable). However, you can draw a modular block to represent a larger thing, for example a number of interconnected blocks. Here, for example, the entire figure could be represented by a block with two inputs (SYSCLK and HIBAUD) and two outputs (ZERO and DOUT); that block could then be used as a component in a larger system diagram. Furthermore, you can use text-based HDL entry (see below) to define the guts of a block, which you then connect up graphically just like the blocks here. And you can even create the HDL (which defines such a block) with graphical tools. For example, you can implement a state machine by entering the state-transition diagram in a tool like Xilinx's StateCAD (or Altera's Quartus); it generates HDL output (Verilog, VHDL, or ABEL), which can then be represented as a graphical block, with input and output pins.

Graphical-entry software tools let you simulate the design, to make sure it does what you intended; then it performs a "fit" or "place and route" to create the connection pattern for a particular hardware PLD (cPLD or FPGA). Finally, as described earlier, you program the part itself, either in a "device programmer" (from a company such as BP Microsystems) or (more commonly) with the part already

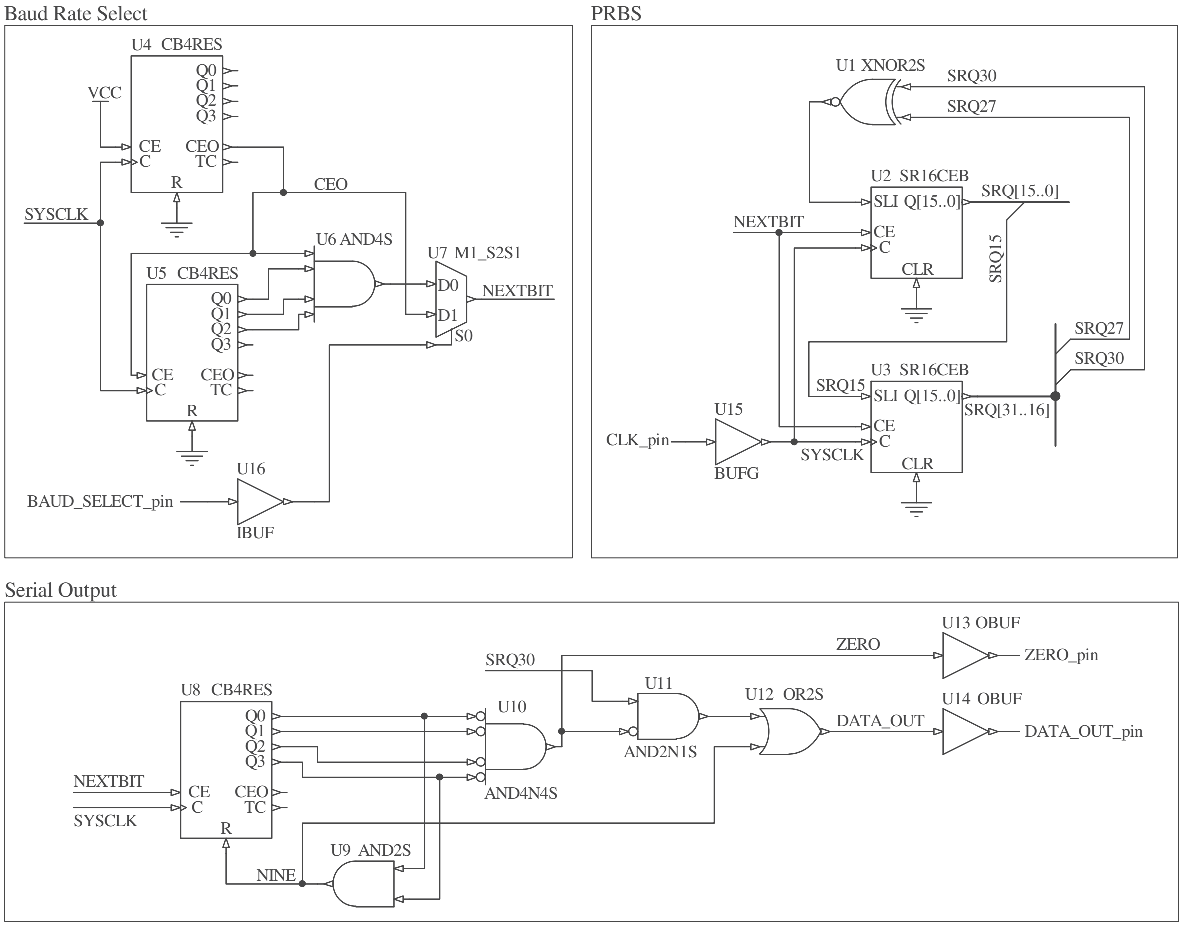

Figure 11.11. The same design as Figure 11.10, implemented with the Altium "Designer" software, and debugged using their NanoBoard development board.

mounted and powered in-circuit. The latter is done through a few dedicated programming pins, which you drive with a programming *pod* that connects to a computer running the design software (typically via USB).

In this example the schematic entry provides a reasonably readable circuit. The designer[18] chose a fully synchronous implementation (all clocked devices are driven from the same clock, namely the input oscillator), explaining that, for some PLDs, shift registers or counters are not guaranteed to work properly when driven from a derived clock (e.g., from the output of a ripple counter), even though this is normal practice when implemented with discrete standard logic.[19]

One traditional complaint with schematic entry has been that the software tools tend to be specific to one vendor's hardware (as in this example). That makes it hard to migrate a design to a different supplier's parts. But recently there have become available some reasonably priced schematic-entry and simulation suites that let you choose among several vendors' FPGAs. We've been trying out such a product – the "NanoBoard" series of hardware development boards supplied by Altium for use with their "Designer" software – that currently support FPGAs from Altera (Cyclone series), Lattice (ECP2 series), and Xilinx (Spartan and Virtex series). If you stick to the generic parts libraries, your design is portable. An example is shown in Figure 11.11, once again our friend the pseudorandom bit

[18] We thank Jim MacArthur for taking the challenge and producing both diagram and working chip in an hour or two.

[19] Evidently the signal delays as such a clock signal is routed in the PLD causes unacceptable skew (§10.8.2C); only the "global clock signals" are guaranteed to work reliably, a fact somewhat buried in the fine print.

generator. The designer[20] chose to group the design into functional modules, to keep the schematic readable. With the exception of the input and output buffers (which were taken from the Xilinx-specific library), all the parts are generic, and so the design is portable with little effort.

At a higher level of abstraction (and cost), you can get synthesis software toolsets like the elegant "Synphony HLS" (High-Level Synthesis) from Synopsys. You start your design with MATLAB and Simulink (from The MathWorks™), which let you snap together Lego-like functional modules from a toolbox of blocks (digital filter, FFT, sampler, etc.). Synphony takes this description and targets (by way of an HDL) either an FPGA or a full ASIC implementation, along with C-language code for functional simulation, test vector generation, and timing. This is far less laborious than traditional HDL design entry. And, because the initial high-level description is verifiable (and its functional blocks are reliably correct), the result is far less prone to errors than a similarly complex chip that is created from an HDL in the conventional manner. Note, however, that the resulting implementation may not be terribly efficient, in terms of use of silicon resources, speed, and power.

Advantages of schematic entry

Those who favor graphical schematic entry generally explain their choice as (a) they come from a schematic background, so it is natural; (b) they find it easier to learn, to understand, and to explain to others; (c) they like having a graphical schematic as documentation; (d) because modules can be HDL-in-disguise, it has all the power of HDL for complex designs where that is needed; and (e) graphical entry is used in graphical programming languages (GPLs) like LabVIEW, MATLAB®, and Simulink®.

11.3.4 Programmable logic – HDL entry

The alternative to graphical design entry is one of the text-based Hardware Description Languages. The current favorites are Verilog and VHDL, with lots of activity also in applying the C programming language to high-level design.

We think it may be helpful to show first how this design looks in the legacy ABEL HDL, whose statements tend to be "close to the hardware": in ABEL you define *pins* (input and outputs) and *nodes* (internal flip-flops or gates), and then you write *equations* that connect up the signals, for example the gates that determine the D input and clock source for a flip-flop. As with schematic entry, you can simulate (with *test vectors*), after which you run the *fitter* program that creates the connection netlist (called a *jedec file*) for your particular target PLD. Finally, you program the part itself, either in-circuit or (more rarely) in a separate standalone device programmer.

A. Programmable logic – HDL entry I (ABEL)

Figure 11.12 shows the ABEL source file for creating the pseudorandom byte generator, using a cPLD with 64 macrocells (each of which can implement a complicated logical function of available signals, delivering the result either combinationally or "registered" in a flip-flop).

A few explanatory comments (working from the top down): (a) lines end with a semicolon, and `//` signifies a comment; (b) the designations `com` and `reg_D` (or `reg_T`) following the directive `istype` specify outputs and nodes as combinational or registered (flip-flops); no designation means an input; (c) an array of signals (called a *set* in ABEL) is written as `[sr30..sr0]` (our 31-bit shift register); (d) NOT, AND, OR, and XOR are written as `!, &, #, $`; (e) variable names not declared as pins or nodes (like `baudclk`) are just *definitions*, to simplify later equations (like `[sr30..sr0].clk = baudclk`); thus, for example, `sr`*n* is the name we have chosen for the *n*th shift register bit, and not a reserved name in the ABEL language; (f) the several pins for a named flip-flop are designated by "dot extensions," for example, `sr0.d = !(sr30.q $ sr27.q)` creates the XOR of the *Q*-outputs of shift register bits 30 and 27 and connects it to the D-input of bit 0 (that's the XOR feedback that generates the pseudorandom bits).

It's worth spending a bit of time puzzling through the code to get a feeling for how you do a circuit in a text-based language; we've commented the code liberally to make it (somewhat) understandable. It's not the most efficient implementation (see below for a truly inspired method!), but it works.

B. Programmable logic – HDL entry II (Verilog)

Simple languages like ABEL were OK for simple cPLD designs (we used it for designs with up to 128 macrocells, with some pain), but somewhere between frustrating and hopeless for the really complex designs for which contemporary FPGAs are so well suited. Although both ABEL and CUPL evolved from their roots in PALASM to incorporate higher-level constructions (like "If-Then-Else"), they were finally abandoned in favor of contemporary languages, principally Verilog and VHDL. These have similar capabilities, but, sadly, divide humanity into two camps,

[20] The ever-clever Curtis Mead, to whom we owe thanks.

Figure 11.12. ABEL code for a pseudorandom byte generator.

with designers swearing passionate allegiance to one or the other.

To give a sense of these powerful text-based design languages, we've coded the pseudorandom byte generator design in both Verilog and VHDL.[21] Statements in these languages can be written in terms of the *structure* (e.g., what signals are connected to register inputs), or, at a somewhat higher level, in terms of *behavior* (e.g., what should happen next). These examples are primarily coded behaviorally, which is the mode generally favored by experienced users; but we show also a structural alternative for a small portion (the serial bit counter). Figure 11.13 shows the Verilog design, coded behaviorally; and Figure 11.14 shows alternative Verilog coding for the 4-bit BCD counter portion that is predominately structural.

Some explanatory comments. (a) The Verilog code is recognizably similar to the analogous ABEL code, particularly in the structural form. (b) The *wire* declaration creates an internal node, and *assign* makes a definition. (c) In common with computer programming languages, Verilog and VHDL make plentiful use of conditional structures like `if, else if, else`. (d) Designers tend to favor behavioral statements (being more compact and easily understood), at least through validation by simulation; however, structural coding often produces a more efficient implementation.[22]

A further detail: in this example there are two clocks – the fast ∼2.5 MHz input clock, and a subdivided clock at the baud rate (1.2 kHz or 9.6 kHz, according to the selected baud rate) for the serial bit counter. So the system is not fully synchronous (although each counter is synchronous, by itself). This is OK for a design that will be implemented as a full-custom IC, but it may create difficulties if targeted for a cPLD, or some FPGAs.[23] A clean solution is to use a single fast global clock for both counters, and then to enable the (slower) serial bit counter only at the subdivided rate.

C. Programmable logic – HDL entry III (VHDL)

The *other* popular HDL these days is VHDL, a more strongly typed language with roots in the programming language Ada (Verilog derives more closely from the C programming language). It tends to be more verbose. For the VHDL coding of the pseudorandom byte generator we've taken a fully synchronous approach; that is, the ∼2.5 MHz input clock is used for both the baud-rate divider and the serial bit counter, with the latter enabled only for one clock cycle (when `nextbit` is true). This mirrors the scheme used in the schematic entry examples of Figures 11.10 and 11.11. The (rather lengthy) code is shown in Figure 11.15.

Advantages of HDL entry

Those who favor text-based HDL entry generally explain their choice thus: (a) design entry is rapid, particularly when portions of previous designs are used; (b) the design is more concise (thus easier to know that it is right), and self-documented (as a textual description); (c) the design cycle is streamlined, as a design is being iterated through simulation and prototype; (d) it is particularly easy to change parameters (such as number of bits in a register, ALU, etc) by merely resizing arrays (compared with rearranging graphical modules); (e) the languages are standardized and universal (compared with proprietary schematic-entry tools); (f) good simulators are available and free of charge; (g) HDL languages are best suited for high-level synthesis of complex designs (like a microprocessor), and prefab open-source IP cores are provided as HDL;[24] (h) HDL entry is well suited to implementation as a *full-custom* IC (ASIC), which is often desirable for a circuit design destined for large-quantity manufacture and a high degree of optimization in speed and power (but which start out as an FPGA during development and small-quantity production); and (i) for those with a programming background, HDL entry is more natural.

11.3.5 Implementation with a microcontroller

Micro*controllers* (the subject of Chapter 15) are inexpensive processors intended for use in things *other than* computers. You should think of them more as a circuit component and less as a computer. Compared with a micro*processor* intended for a computer, microcontrollers are intended to stand alone, and therefore always include on-chip program and data memory, along with a selection of "peripherals" such as communications (USB, firewire, Ethernet, UART, CAN, SPI, I^{2}C), ADCs, digital I/O, comparators, LCD display drivers, pulse-width modulators, timers, and the like. Many also include an internal oscillator (all they need is dc power!), in some cases accurate enough for

[21] We are indebted to our colleagues GuYeon Wei and Curtis Mead, who kindly coded this example.

[22] An example might be a 32-bit counter, where a behavioral statement like "`count=count+1`" might compile to a register and 32-bit full adder, the latter receiving a constant 00000001(hex) as one of its inputs.

[23] Some FPGAs let you drive internal clock distribution lines from logic outputs, but some don't, for example the Virtex-5 and Spartan-3, respectively; for the latter you would have to bring the clocking signal out to a pad.

[24] But IP cores that must be licensed are encrypted.

```

   sbc[1] <= ~sbcnine & (sbc[0] ^ sbc[1]) & ~reset;
   sbc[2] <= ~sbcnine & ((sbc[0] & sbc[1]) ^ sbc[2]) & ~reset;
   sbc[3] <= ~sbcnine & ((sbc[0] & sbc[1] & sbc[2]) ^ sbc[3]) & ~reset;
end
// ------------------------------------------------------------------
```

Figure 11.14. Structurally-coded Verilog fragment for 4-bit BCD counter.

timing of on-chip serial ports (e.g., ±2%). They are programmed (and reprogrammed) in-circuit, by a serial connection like the JTAG boundary-scan protocol.[25] Recent designs include internal circuitry that permits run-time debugging in-circuit (by the same JTAG port used for programming).

Microcontrollers (sometimes abbreviated μC) are inexpensive (typically ranging from less than a half dollar up to ten dollars), and are available in literally thousands of versions from dozens of manufacturers; popular offerings are the PIC series (from Microchip), the AVR series (from Atmel), the ARM series (from multiple vendors), and evolved incarnations of the legacy Intel 8051 series (multiple vendors). Low-end μCs are usually 8-bit processors, with perhaps 1 kB of program memory and 128 bytes of RAM, and clock speeds of 20 MHz; at the high end there are 32-bit processors with 512 kB program memory, 64 kB of RAM, and many integrated peripherals.[26]

Microcontrollers are wonderfully versatile and capable, and they are found in nearly everything electronic, from toasters and toothbrushes to trucks and traffic lights. They can do a pseudorandom byte generator with the greatest of ease. Figure 11.16 shows the "circuit" – basically just dc power to the chip, and bytes out! The rest of the task is the programming, which we'll illustrate two ways.

A. Microcontroller programming – assembly code

Microcontrollers, and indeed all processors, perform a sequence of operations, specified as instructions that are stored in some form of electronic memory (see Chapter 14); in the case of μCs the program is held on-chip in non-volatile memory (thus retained when power is off). The instruction set is particular to the processor type, and includes operations such as arithmetic (e.g. `add`), logical (e.g. `shift`), data transfer (e.g. `move`), and branching (e.g. `brz`, branch if zero). The instructions themselves reside in memory as a set of bytes, fetched by the processor during program execution.

As with computer programming generally, programmers rarely deal with this *object code* itself (which is both tedious and error-prone), programming and debugging instead at a more humanly understandable level: either in *assembly language*, or in a higher-level language (usually C or C++). The code so written is then *assembled* or *compiled* (using software) to produce the μC-readable binary object code that will reside in the processor's program memory. There are nice software tools to help you get the code right – for example, *simulators* that let you see how the candidate program runs, step-by-step; and *run-time debuggers* that let you watch what the μC is actually doing, in-circuit, when it runs your program. The term *Integrated Development Environment* ("IDE") is used to describe a software suite that includes compiler, assembler, loader, and run-time debugger. You want one of these.

Figure 11.17 is a listing of assembly code for the pseudorandom byte generator implemented in the microcontroller circuit of Figure 11.16; not to worry, we'll see it coded in C, finally, in Figure 11.18.

Just a few notes of explanation (hey, this isn't a book on software!). (a) All microcontrollers include a bunch of internal "special-function registers," whose contents you must initialize to set up timer modes, interrupts, location of initial stack pointer, and so on. That's what the first seven `mov` operations do, here. This can be fussy code, particularly involving timer modes and baud rates (best to copy it from a program known to work correctly). And,

[25] A 4-wire serial protocol, which can be chained through a succession of ICs, and which permits run-time loading of, examination of, and bypassing of some internal registers in complex ICs; see §14.7.4.

[26] A current example is the ARM7 LPC2458 from NXP (formerly Philips), displayed in Figure 10.86: 512kB/64kB memories, 72 MHz clock, 10/100 Ethernet, USB 2.0, 10-bit A/D and D/A, 2xPWM, 4 UARTs, 2xCAN, SPI, 2xSSP, 3xI^2C, I^2S, 136 bits of general-purpose I/O, and an external memory controller. This puppy costs just $10! For higher clock speeds you would choose instead the faster ARM9.

Figure 11.15 continued.

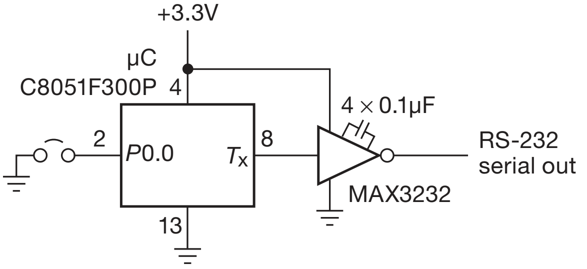

Figure 11.16. Microcontrollers represent a compact alternative to programmable logic, particularly when speed is not critical. This particular microcontroller choice (among literally thousands) includes an internal oscillator, so *no* external components are needed to generate the logic-level serial bitstream output.

surprise, there's absolutely no standardization across different microcontroller families. Fussy, fussy, fussy… (b) The program bookends `org 00h` and `end` tell the assembler where to put the first instruction, and where the code ends. That is, they are not instructions that the microcontroller executes, but rather directives to the assembler; they're sometimes called "pseudo-ops." (c) The rest of the code consists of arithmetic and logical operations, such as clear, copy (called `mov`), compare (`cjne`: compare and jump on not equal), loop counters (`djnz`: decrement and jump on nonzero), subroutine call (`acall`), and so on.

You really don't want to fall in love with this stuff – we show it mostly to warn you off!

B. Microcontroller programming – coding in C

Assembly language programming is fussy stuff, and it's easy to make trivial mistakes. Even when you get it right, it's tricky to modify. Large programs are laborious. The code must be rewritten if you want to use it with a different family of microcontroller. And, worst of all, you probably won't understand what you've written a few weeks later, when it needs to be changed.

For these reasons most programmers prefer a high-level language like C or C++ for coding.[27] It's easier to write and understand, and it's portable across microcontroller families (though with some changes required to accommodate architectural differences). Figure 11.18 list the PRBS generator, in the C programming language.

The programmer[28] noticed, in a burst of inspiration, that the PRBS could be coded to perform a full byte at a time, rather than the ponderous bit-at-a-time coding we assumed necessary in the earlier examples. That's because the shift register has, at any moment, all the downstream bits you need to calculate all the fresh bits up to the first feedback tap (in this case 27 bits). Given the byte organization of 8-bit μCs and the fact that the built-in serial-port UART expects a full 8-bit quantity before transmission, the smart thing is to create a new upstream byte, using the bytewide XOR instruction (bitwise XOR, without carry). The resulting program runs wicked fast! See if you can figure out the coding.

11.4 Advice

So, what should you do? Here's a brief summary of recommendations, which we think fairly represents the ups and downs of the various choices you have for digital (and mixed-signal) implementations.[29] We'll do this two ways, first by *Technology*, then by *User Community*.

11.4.1 By *Technologies*

- **Standard logic**
  - `Upside`: OK if you want to put a simple circuit together quickly and you have the parts on hand; useful for bus drivers, buffers, and small logic "glue" (for sticking large chips together, or for fixing logic errors); available in through-hole, so you can use a pluggable breadboard, or a solder (or wirewrap) protoboard; no software design tools needed.
  - `Downside`: unwieldy for complex circuits; multiple functions to inventory; inflexible.
- **Programmable logic (cPLD, FPGA)**
  - `Upside`: generally preferred (over standard logic) for most digital designs – reduced package count, easily reprogrammed, flexible and inexpensive, small inventory needed; favor cPLDs for predictable timing and for small designs, FPGAs for large designs (though small FPGAs are emerging); best choice for fast parallel logic and state machines; good for timing-critical functions (such as communications protocols), bit-level operations (CRC, Viterbi), and functions with lots of I/O; designs can be migrated across PLD families, and to full-custom ICs.

[27] Perhaps with small blocks of assembly code inserted where speed is critical, for example an interrupt service routine (see Chapter 13), within a larger program.

[28] Jason Gallicchio, to whom we are indebted for this code and for other assistance with the microcontroller discussion.

[29] Note, however, that it's usually smoother sailing if you adopt the methods that people around you are using – their experience base and toolsets accelerate learning and debugging – even if some different technique potentially offers other advantages.

Figure 11.18. C code for pseudorandom byte generator.

- `Downside`: time to learn software tools (often proprietary), and their cost; surface-mount parts only (requires custom PCB or adapter); cost of programming pod and design tools; short life cycle (supply problems).
- `PLD design--program tools`
  - ∗ *Schematic entry*
    - · `Upside`: easy to learn, understand, and explain to others (for circuit nerds especially); self-documenting; entry of parallel circuitry in a parallel way; analogous graphical programming languages (GPLs) used in tools like LabVIEW, MATLAB®, and Simulink®.
    - · `Downside`: proprietary design tools; cost; limited applicability.
  - ∗ *HDL (Verilog/VHDL)*
    - · `Upside`: natural migration for programmer nerds who can adapt to parallel thinking; concise and standardized; cost-free simulation and compilation tools; easy-to-iterate design modifications; can migrate across PLD families, and to full-custom ICs;

well suited for large complex designs; IP core availability.

- · `Downside`: time to learn, and lack of schematic documentation (especially for non-programmers).

- **Microcontrollers** (see Chapter 15!)
  - – `Upside`: programmable, flexible embedded computer; ideal for complex state machines with lots of decisional branching; rapid iteration of code and (in-circuit) debugging; many on-chip peripherals (communication,[30] conversion, interface,[31] other[32]); familiar programming language (C, C++); best for embedded control, especially involving user communication (display and control); enjoyable!
  - – `Downside`: slower than cPLD/FPGA; less suited to bit-level manipulation; less parallelism.
  - – μ`C program tools`
    - ∗ *Assembly language*
      - · `Upside`: can handcraft optimized code, for example an interrupt service routine.
      - · `Downside`: fussy and error prone; difficult to make major modifications; cannot port to a different processor family.
    - ∗ *C, C++*
      - · `Upside`: standardized and portable (though some processor-specific changes needed); widespread programming expertise; structured language facilitates changes and upgrades; libraries of useful functions; well suited for complex tasks.
      - · `Downside`: not much... compiled code may be less efficient in size and speed (can embed assembly code for critical loops and routines, and for access to special features); code can be hard to understand; requires compiler toolset (some are expensive, others are free).
    - ∗ *Other (Basic, Arduino Software; Java, Python)*
      - · `Upside`: easy to understand, good for entry level.
      - · `Downside`: limited range of microcontroller support, not generally portable across processor families, not for big projects.

11.4.2 By *User Communities*

All of the user communities are well served by *microcontrollers*, owing to low cost, ease of programming, and flexibility. Among these communities, the following additional technologies are favored.

- **High-volume production**[33]
  Here unit cost and time-to-market are critical. In large volumes, unit cost is minimized with ASICs (unique Application Specific full-custom Integrated Circuits) and ASSPs (generally available Application-Specific Standard Products), whereas time-to-market is generally shortened by using FPGAs to eliminate the ASIC design–debug cycle. In large production it is common to use high-density BGA (ball-grid array) packages and other fine-pitch surface-mount (SMT) devices, along with the necessary multilayer circuit boards and advanced assembly techniques. And, of course, always use microcontrollers.
- **Complex prototype and small production**[34]
  Here you usually cannot afford the delays and costs associated with both ASICs and high-density BGA packages. So the favored technologies are cPLDs and FPGAs, along with assorted support chips, all in surface-mount packages, and assembled on multilayer boards.[35] And, of course, always use microcontrollers.
- **Laboratory and "1-Off"**[36]
  Here it's important to be able to put together an instrument relatively quickly, and to modify and evolve its circuitry as the need arises. We favor through-hole prototyping boards, populated with through-hole components, and (where essential) with a small number of SMT devices (on through-hole adapters[37]). This constrains you to standard logic and interface, a limited selection of microcontrollers, and perhaps some cPLDs/FPGAs, along with analog components (op-amps, etc). You can make greater use of FPGAs if you take advantage of third-party pre-fabricated daughterboards from companies like Digilent, DLP Design, or Opal Kelly: these range from bare-bones boards (FPGA, program ROM, and USB or JTAG interface) up to complex boards with displays, Ethernet, and so on.[38]

[30] For example, UART, SPI, I^{2}C, CAN, USB, Ethernet, IrDA, WiFi, digital audio/video, Bluetooth, ZigBee.

[31] For example, keyboard, mouse, PCI, PCIe, PWM, SIM and Smart Card, GPS, PCMCIA/CF.

[32] For example, external DRAM/SDRAM, MMU, GPS, CCD/CMOS cameras, LCDs, graphic display.

[33] Cellphones, TV set-top boxes, etc.

[34] Oceanographic and scientific research instruments, MRI machines, experimental products, etc.

[35] If you need to use BGA or other high-pin-count parts, it's good to know about prototype assembly services such as Advanced Assembly™: they can handle fine-pitch BGA assembly (including X-ray inspection), and they will even take care of ordering the parts for you. Best of all, they don't mind orders of just a few boards.

[36] The *first* NMR, MRI, STM; atom traps, laser cooling, an astronomical telescope control, etc.

[37] For example from Aries Electronics, or Bellin Dynamic Systems.

[38] If you want to use FPGAs as building blocks in diverse projects, and

Alternatively, you can start with a fully populated microcontroller kit, including PLDs, that may include also unpopulated "prototyping" pads for a small number of additional devices.

- **Hobbyist**[39]
  Here the idea is to have lots of inexpensive fun. The basic unit is the microcontroller, either as part of a prefabricated kit,[40] or used on a through-hole protoboard, or perhaps a custom printed-circuit board.[41] Through-hole components (see *Laboratory and "1-Off", above*) are always easy to use, as are PLDs included in microcontroller kits.

you can't find what you want from companies like these, you can follow the lead of one of our colleagues: he designed a small daughterboard to hold his chosen FPGA, along with a couple of EEPROMs, an oscillator, a JTAG header, and voltage regulators (so it runs from +5 V power). It has a pair of 2×20-pin headers (connected to lots of FPGA pins) aimed downward, to plug into a custom board.

[39] Robots, remote control, lighting systems, audio/radio/video, etc.

[40] Supplied by the μC manufacturer, or from an independent supplier like Parallax, Digilent, DLP Design, or the Arduino project. It's pleasant, also, to loiter at websites like sparkfun.com and adafruit.com.

[41] There are freeware versions of layout tools, such as Eagle (from CadSoft); there are open-source tools; and there are inexpensive PCB fabrication houses, for example Advanced Circuits (www.4pcb.com), who also offer their "PCB Artist" free PCB layout software (which, however, produces files in their proprietary format).

Review of Chapter 11

An A-to-G summary of what we have learned in Chapter 11. This summary reviews basic principles, facts, and application advice in Chapter 11.

¶A. Programmable Logic Devices (PLDs).

PLDs are digital integrated circuits, typically containing thousands to millions of gates (and, sometimes, additional functional blocks such as transceivers, RAM, DSP, or general-purpose microcontrollers), whose circuit interconnections are determined by user programming (§11.2). That is, in analogy with a computer program (which tells the processor *what to do*), the program for a PLD tells the chip *how to connect* its internal component pieces. Some PLDs include non-volatile (and reprogrammable) memory that holds the programmed configuration; others read their configuration from an external non-volatile ROM at power-up, and hold it in on-chip (and volatile) memory; and many allow programming via a serial configuration port (commonly a JTAG port).

¶B. PLD Applications.

Small PLDs (tens to hundreds of macrocells, thousands of gates) are commonly used as "glue logic," replacing discrete gates, flip-flops, registers, and the like. Larger PLDs, and particularly FPGAs (field-programmable gate arrays), can implement nearly a complete system-on-a-chip. The largest FPGAs contain millions of flip-flops, megabytes of RAM, hundreds of I/O ports (LVDS, PCIe, etc.), and dozens of serial transceivers – resources adequate to hold a "soft" processor (i.e., configured from gates and flip-flops) running embedded Linux. (And when thinking of PLDs for some application, be sure to consider the alternative of a general-purpose *microcontroller* – they're increasingly capable, inexpensive, and easy to program.)

¶C. Programming Overview.

PLD design (§11.2.6) starts with the functional specification, where the choice is either *schematic entry* or a *hardware description language* (HDL). Next you run a *simulation*, to verify that the design works as intended. After that a *synthesis* process converts the design to a *netlist* (a full set of logical connections). The netlist is then "fitted" to the target PLD, a process known as *place and route*. Finally, the fitted design is downloaded to the PLD's memory – either to the PLD itself (if it has on-chip non-volatile memory), or to an external configuration ROM (from which the PLD loads at power-up), or possibly hot-loaded from an external processor directly to the powered-up PLD.

PLD design tools are provided by the PLD manufacturers, and by some third parties. For low-end PLDs the tools may be free, but they can be quite expensive for the high-end parts. Considerable time may be needed to master the PLD design tools (which have a distressing tendency to change with time), and the software can be (and usually is) buggy.

¶D. Schematic Entry.

Most comfortable to non-coders is schematic entry, in which you wire up familiar logic symbols (e.g., Figure 11.10) in the same manner as you would do when entering a circuit for a PCB layout. There's additional flexibility, because you can define larger functional blocks that are specified with either schematic entry or HDL text entry.

Another graphical entry method, at a higher level of abstraction, exploits software synthesis tools that convert a MATLAB/Simulink Lego-like functional-block description to an HDL source-code output; the latter can target a PLD or a full-custom (ASIC) implementation, as well as providing simulation, timing, and test vectors.

Those who favor graphical schematic entry generally explain their preference as (a) coming from a schematic background, they find it natural; (b) they find it easier to learn, to understand, and to explain to others; (c) they like having a graphical schematic as documentation; (d) because modules can be HDL-in-disguise, it has all the power of HDL, for complex designs where that is needed; and (e) graphical entry is used in graphical programming languages (GPLs) like LabVIEW, MATLAB®, and Simulink®.

¶E. HDL Entry.

Hardware description languages like Verilog and VHDL dominate the PLD-entry scene. Statements in either language can be *structural* (e.g., what signals are connected from some output to another input) or *behavioral* (e.g., which state follows another, and under which conditions). See the illustrative examples in §§11.3.4B and 11.3.4C.

Those who favor text-based HDL entry generally explain their preference as (a) coming from a programming background, they find it natural; (b) design entry is rapid, particularly when re-using portions of previous designs; (c) the design is more concise (thus easier to know that it is right), and self-documented (as a textual description); (d) the design cycle is streamlined, as a design is being iterated through simulation and prototype; (e) it is particularly easy to change parameters (such as number of bits in a register, ALU, etc) by merely resizing arrays (compared with rearranging graphical modules); (f) the languages are standardized and universal (compared with proprietary schematic entry tools); (g) good simulators are available, and free of charge; (h) HDL languages are best suited for high-level synthesis of complex designs (like a microprocessor), and prefab open-source IP cores are provided as HDL; and (i) HDL entry is well-suited to subsequent implementation as a *full-custom* IC (ASIC), following a prototype stage implemented initially as an FPGA.

¶F. Advice, by *Technology*.

(Paraphrased shamelessly from §11.4.1.)

- **Standard logic**
  - `Upside`: OK for quick assembly of simple circuits, and useful for bus drivers, buffers, and small logic "glue"; available in through-hole (for quick prototyping); no software design tools needed.
  - `Downside`: unwieldy for complex circuits; multiple functions to inventory; inflexible.
- **Programmable logic (cPLD, FPGA)**
  - `Upside`: better for most digital designs – reduced package count, easily reprogrammed, flexible and inexpensive, small inventory needed; favor cPLDs for predictable timing and for small designs, FPGAs for large designs; best choice for fast parallel logic and state machines; good for timing-critical functions, and functions with lots of I/O; designs can be migrated across PLD families, and to full-custom ICs.
  - `Downside`: time to learn software tools (often proprietary), and their cost; surface mount parts only; cost of programming pod and design tools; short life cycle (supply problems).
  - `PLD design/program tools`
    - ∗ *Schematic entry*
      - · `Upside`: easy to learn, understand, and explain to others; self-documenting; entry of parallel circuitry in a parallel way; analogous graphical programming languages (GPLs) used in tools like LabVIEW, MATLAB®, and Simulink®.
      - · `Downside`: proprietary design tools – cost; limited applicability.
    - ∗ *HDL (Verilog/VHDL)*
      - · `Upside`: natural migration for programmers; concise and standardized; cost-free simulation and compilation tools; easy to iterate design modifications; can migrate across PLD families, and to full-custom ICs; well-suited for large complex designs; IP core availability.
      - · `Downside`: time to learn, and lack of schematic documentation.
- **Microcontrollers** (see Chapter 15!)
  - `Upside`: programmable, flexible embedded computer; ideal for complex state machines with lots of decisional branching; rapid iteration of code and (in-circuit) debugging; many on-chip peripherals (communication, conversion, interface, other); familiar programming language (C, C++); best for embedded control, especially involving user communication (display and control); enjoyable!
  - `Downside`: slower than cPLD/FPGA; less suited to bit-level manipulation; less parallelism.
  - μ`C program tools`
    - ∗ *Assembly language*
      - · `Upside`: can handcraft optimized code, for example an interrupt service routine.
      - · `Downside`: fussy and error prone; difficult to make major modifications; cannot port to a different processor family.
    - ∗ *C, C++*
      - · `Upside`: standardized and largely portable; widespread programming expertise; structured language facilitates changes and upgrades; libraries of useful functions; well suited for complex tasks.
      - · `Downside`: not much... compiled code may be less efficient in size and speed (can embed assembly code where needed); code can be hard to understand; requires compiler toolset (some are expensive, others are free).
    - ∗ *Other (Basic, Arduino Software; Java, Python)*
      - · `Upside`: easy to understand, good for entry level.
      - · `Downside`: limited range of microcontroller support, not generally portable across processor families, not for big projects.

¶G. Advice, by *User Community*.

(Paraphrased shamelessly from §11.4.2.) *All* of the user communities are well served by *microcontrollers*, owing to low cost, ease of programming, and flexibility. Among these communities, the following additional technologies are favored.

- **High-volume production**

  Here unit cost and time-to-market are critical. In large volumes, unit cost is minimized with *ASICs* (unique Application Specific full-custom Integrated Circuits) and *ASSPs* (generally available Application-Specific Standard Products), whereas time-to-market is generally shortened by using *FPGAs* to eliminate the ASIC design–debug cycle. In large production it is common to use high-density *BGA* (ball-grid array) packages and other fine-pitch surface-mount (SMT) devices, along with the necessary multilayer circuit boards and advanced assembly techniques. And, of course, always use *microcontrollers*.

- **Complex prototype and small production**
  Because of the delays and costs associated with both ASICs and high-density BGA packages, the favored technologies are *cPLDs* and *FPGAs*, along with assorted support chips, all in surface-mount packages, and assembled on multilayer boards. And, of course, always use *microcontrollers*.
- **Laboratory and "1-Off"**
  To meet the goals of quick assembly and easy modification, we favor through-hole prototyping boards, populated with through-hole components, and (where essential) with a small number of SMT devices (on through-hole adapters). This constrains you to *standard logic* and *interface*, a limited selection of *microcontrollers*, and perhaps some *cPLDs/FPGAs*, along with *analog* components (op-amps, etc). You can make greater use of FPGAs if you take advantage of third-party pre-fabricated daughterboards. Alternatively, you can start with a fully populated *microcontroller kit*, including *PLDs*, and perhaps some unpopulated "prototyping" pads for additional devices.
- **Hobbyist**
  Here the idea is to have lots of inexpensive fun. The basic unit is the *microcontroller* (have we mentioned this before?), either as part of a prefabricated *kit*, or used on a through-hole protoboard, or perhaps a custom printed-circuit board. Through-hole components (see *Laboratory and "1-Off", above*) are always easy to use, as are PLDs included in microcontroller kits.

LOGIC INTERFACING

CHAPTER 12

Although sheer "number crunching" is an important application of digital electronics, the real power of digital techniques is seen when digital methods are applied to analog (or "linear") signals and processes. In this chapter we begin with a brief chronology of the rise and fall of digital logic families and a review of the input and output properties of the surviving (mostly CMOS) families that you are likely to use in circuit design. This is essential for understanding how to interface logic families to each other and to digital-input devices (switches, rotary encoders, keypads, comparators, etc.) and output devices (indicator LEDs, relays, power MOSFETs, etc.). We continue with the important subject of bringing digital signals on and off circuit boards, in and out of instruments, and through cables. We discuss optoelectronic devices (fiber-optic drivers and receivers, optocouplers, LCD and LED displays, and solid-state relays). And in the next chapter we discuss the major subject of conversion between analog and digital signals. Finally, with an understanding of these techniques, we look at a number of applications in which combined analog and digital techniques provide powerful solutions to interesting problems. Much of this material is applicable not only to "discrete" digital logic, but also to the PLDs and FPGAs of Chapter 11 and to the microcomputers and microcontrollers of Chapters 14 and 15.

12.1 CMOS and TTL logic interfacing

12.1.1 Logic family chronology – a brief history

In the prehistoric early 1960s, adventurous people who didn't want to build their logic from discrete transistors struggled with RTL (resistor–transistor logic), a simple logic family introduced by Fairchild and characterized by poor fan-out and poor noise immunity. Figure 12.1 shows the problem, namely, a logic threshold at one V_{BE} above ground and miserable fan-out (in some cases one output could drive only one input!) caused by passive pullup and a low-impedance current-sinking load. Those were the days of small integration, and the most complicated function you could get was a dual flip-flop, which would operate to 4 MHz (the MC790P, in case you want to look it up). We bravely built circuits with RTL; they sometimes malfunctioned when someone switched on a soldering iron in the same room.

The death knell for RTL came a few years later with the introduction by Signetics of DTL (diode–transistor logic) and, soon thereafter, Sylvania's SUHL – "Sylvania Universal High Speed Logic" – subsequently called TTL (transistor–transistor logic). Signetics had a popular mixture of the two, called 8000-series DCL Utilogic ("Designer's Choice Logic"). TTL caught on quickly, particularly in the "74*xx*" numbering system originated by Texas Instruments. (Although bipolar TTL is pretty much history now, the 74*xx* designations have remained healthy to this day, in contemporary CMOS incarnations.) These families used current-*sourcing* inputs with logic threshold at two V_{BE}'s and (usually) push–pull "totem-pole" outputs (Figure 12.1). DTL and TTL began the era of +5 V logic (RTL used +3.6 V), and offered speeds of 25 MHz and fan-outs of 10 (i.e., an output could drive 10 inputs). Designers rejoiced at the speed, reliability, and complex functions (divide-by-10 counters, for example) of these families. It seemed to us that you couldn't ask for more; TTL would live forever.

People are greedy, though. They wanted more speed. They wanted less power consumption. They soon got both, sort of. In the high-speed arena, a souped-up TTL (74H series; "High-speed" TTL) delivered roughly twice the speed, at twice the power! (It accomplished this underwhelming feat by cutting all resistor values in half.) Another family, ECL (emitter-coupled logic), delivered real speed (30 MHz in its original version), using a negative power supply and rather closely spaced logic levels (−0.9 V and −1.75 V); it consumed lots of power (30 mW/gate) and came only in small integration. For low power there was a souped-down TTL (74L series; "Low-power" TTL) with 1/4 the speed at 1/10 the power of the corresponding 7400 "standard" TTL.

Back at RCA, the first of the MOSFET logic families was developed, 4000-series CMOS. It had zero quiescent power consumption and a wide supply range (+3 V to

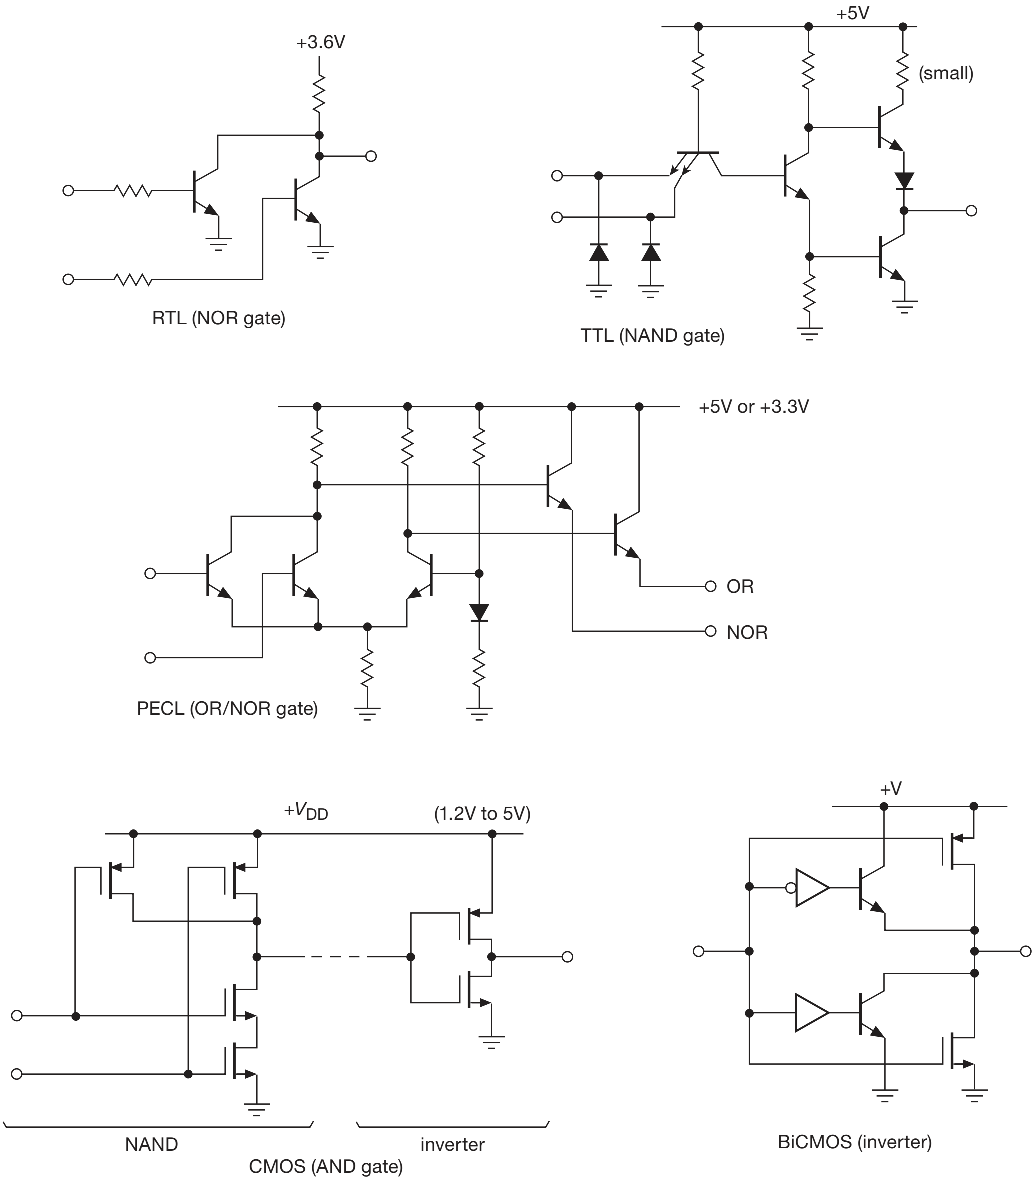

Figure 12.1. Simplified diagrams of several logic families.

+ 12V). The outputs swung rail-to-rail, and the inputs drew no current. That was the good news. The bad news was the speed (1 MHz at 5 V supply) and the price (about $20 for a package of four gates). In spite of the price, a whole generation of battery-powered instrument designers grew up on the micropower CMOS simply because there was no alternative. They learned the true meaning of static electricity as they worked with the easily damaged inputs.

This, then, was the situation at the beginning of the 1970s – two main lines of bipolar logic (TTL and ECL) and the extraordinary CMOS. The TTL variants were essentially compatible, except that 74L TTL had feeble output drive (3.6 mA sink) and could drive only two standard (74-series) TTL loads (whose inputs sourced 1.6 mA when held LOW). There was almost no compatibility between the major families (though a pulled-up TTL could drive CMOS, and 5 V CMOS could just barely drive a single 74L TTL load).

During the 1970s there were steady improvements on all fronts. TTL sprouted the nonsaturating "Schottky-

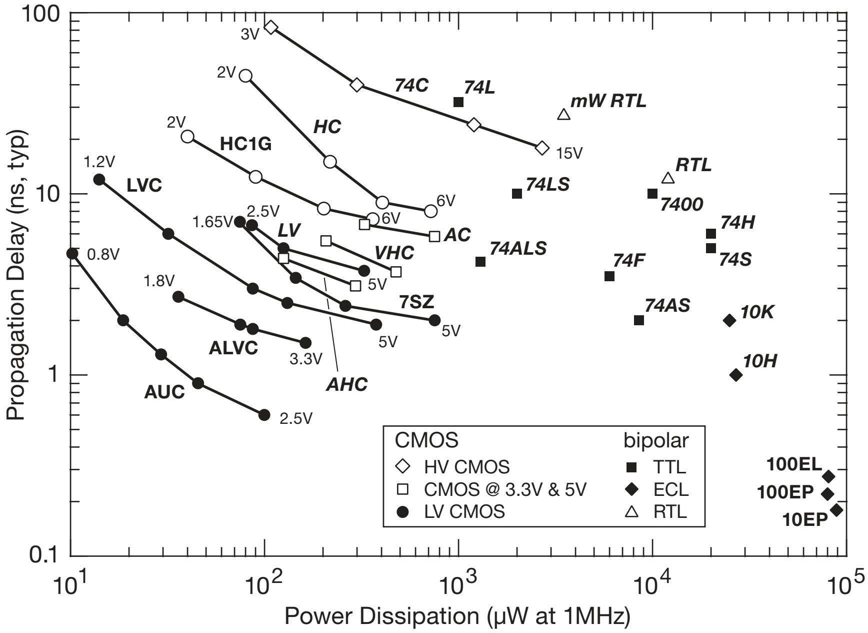

Figure 12.2. Gate delay versus power for various logic families. Power dissipation depends on supply voltage and frequency of logic switching: $P = C_{\mathrm{pd}}V_{\mathrm{cc}}^2 f$, where C_{pd} is called the "power dissipation capacitance." (C_{pd} does not include external wiring and load capacitances.) CMOS families permit operation over a range of supply voltages, whereas bipolar logic runs at a defined voltage (either 3 V or 5 V). Families in *italics* are available in DIP (through-hole packages). See also Table 10.1 and Figure 12.3.

clamped" families: first the 74S (Schottky) series, which made 74H obsolete by giving three times the speed at twice the power; then the 74LS ("Low-power Schottky"), which made the "standard" 74-series TTL obsolete by delivering slightly improved speed at 1/5 the power. Life with 74LS and 74S was nice, but then Fairchild came up with 74F (F for FAST: "Fairchild Advanced Schottky TTL"), which is up to 50% faster than 74S at 1/3 the power; it also has other improved properties that make it extremely nice to design with. Texas Instruments, the originators of many 74*xx* lines, came up with a pair of advanced Schottky families, 74AS ("Advanced Schottky") and 74ALS ("Advanced Low-power Schottky"); the former was intended to replace 74S, and the latter was intended to replace 74LS. All these TTL families have the same logic levels and plenty of output drive, and so they can be mixed within a circuit. Tables 10.1 and Figure 12.2 illustrate the speed and power of these families.

Meanwhile, the 4000-series CMOS evolved into the improved 4000B series, with wider supply range (3 V to 18 V), better input protection, and higher speed (3.5 MHz at 5 V). The 74C-series was essentially the same, with 74-family functions and pinouts to take advantage of the tremendous success of the 74-family bipolar logic. ECL sprouted the ECL II, ECL III, ECL 10,000, and ECL 100,000 series, with speeds to 500 MHz.

The situation in 1980, then, was this: most design was done with 74LS, with 74F (or 74AS) mixed in where higher speed was needed. This same TTL was used as "glue" to hold together nMOS microprocessor circuits, whose inputs and outputs are TTL compatible. Micropower design was always done with 4000B or 74C CMOS, equivalent and compatible with each other. And for the highest speeds (100–500 MHz), ECL was the only game in town. There wasn't much mixing between families, except occasional combination of CMOS and TTL, or perhaps TTL interfaces to an ECL high-speed circuit.

During the 1980s came the remarkable development of CMOS logic with the speed and output drive of TTL: first 74HC ("High-speed CMOS"), with the same speed as 74LS, and, of course, zero quiescent current; then 74AC ("Advanced CMOS"), with the same speed as 74F or 74AS. With rail-to-rail output swings, and input threshold at half the supply voltage, this logic combined the best features of previous TTL and CMOS, and it essentially replaced bipolar TTL. However, there was an incompatibility when both kinds of logic were used within a circuit, because the +2.4 V (minimum guaranteed) logic HIGH output of traditional TTL standard logic (and also of more complex functions that were being done in nMOS) was insufficient to drive an HC or AC input (with their requirement of +3.5 V, min).

To address this problem, each CMOS family offered a variant with the lower input threshold. These are named 74HCT and 74ACT ("High-speed CMOS with TTL threshold"). During the 1980s, also, complex large-scale integrated (LSI) and very large-scaled integrated (VLSI) devices (microprocessors, memory, etc.) evolved from nMOS to CMOS (with consequent low power and, usually, full-swing output CMOS compatibility), at the same time increasing speed and complexity. And at the extreme high-speed end, there was some development of GaAs (gallium arsenide) logic devices (by companies like GigaBit Logic and Vitesse) to reach speeds of ∼3 GHz.

Predictably, things just got better and better in the following two decades. The most important development was the improvement in CMOS performance, brought about by reduced feature size on the silicon chip ("scaling"). First, as the length scales were shrunk, it became possible to put many more transistors on a reasonable-sized chip – this led to the development of massive processor, memory, and other complex function (e.g., video) chips, with transistor counts going from millions to billions. Second, and perhaps as important, the scaling increased the speed and also reduced the operating voltage and the power per gate.[1] The result is new families of low-voltage CMOS logic parts (74LVC, 74AUC, and so on; see Figure 12.3) with pin-to-pin speeds in the several-hundred megahertz range (delay times down to 1 ns or less).

These fast CMOS families have proliferated, with a head-spinning menagerie numbering into the dozens. Most of them operate over a range of supply voltages (e.g., 1.8–5 V for 74LVC), and in most cases the input logic voltage can swing beyond the positive supply (e.g., 74LVC is "5 V tolerant," regardless of supply voltage; see Figure 12.3). With greater integration of most of the needed logic into the large VLSI components, there is little reliance on discrete logic, and these "standard-logic" parts are used mostly as occasional glue. For that purpose they come in small packages, holding one or two gates, or a single flip-flop, with names like TinyLogic, Little Logic, MiniGate, or PicoGate.

These packages share with other surface-mount ICs the advantage of low-inductance ground (and power) pins, which reduce "ground bounce" (§10.8.3 and Figure 10.99) and other transient symptoms caused by fast edge rates driving the combined capacitance of wiring and load. Ground bounce had become a serious headache in the decade of the 1990s, with the new 74AC and 74ACT families, which combined fast full-swing (between +5 V and ground) logic transitions in traditional DIPs with corner power and ground pins. Some manufacturers (notably TI) addressed this problem by adding extra power and ground pins, and moving them to the center (creating new part numbers like 74AC11004, a DIP-20 repinned version of the DIP-14 '04 hex inverter); others created "quiet" logic families with controlled edge rates (e.g., the 74ACTQ family from FSC/NSC). The situation improved considerably with the move to lower supply voltages, low-inductance SMT packaging, and good printed-circuit layout practices (especially the use of dedicated power and ground planes in multilayer PCBs). And the use of low-voltage differential signaling (LVDS) for fast signals and clocks pretty much eliminated the problem altogether, because of both the balanced current changes, and their relatively small swing (∼0.4 V).

All CMOS families of standard logic (beginning with the original 4000A, and extending through HC, LVC, AUC, and a dozen others) have the pleasant characteristic of zero "static" (i.e., nothing happening) power dissipation, with typical quiescent currents less than a microamp. But CMOS does draw "dynamic" current when logic levels are switching, because of the combined effects of (a) transient rail-to-rail conduction of internal push–pull pairs during the middle of the logic swing and (b) dynamic current needed to charge and discharge internal and load capacitances. Dynamic supply currents are proportional to switching frequency and can rival bipolar logic as you reach maximum operating frequencies, as we discussed in Chapter 10 – see Figure 10.27. Note, however, that many VLSI functions implemented in CMOS (e.g., FPGAs and cPLDs, see Chapter 11) often have substantial quiescent current; this situation is changing, however, with a trend

[1] To see how this goes, consider the process of shrinking the linear feature size (channel length L and width W) on a CMOS IC by a factor of k ($k<1$), while adjusting things to keep the electric field strengths constant; this is called "constant-field scaling." Then, with $L\propto k$ and $W\propto k$, constant-field scaling requires that $V_{\mathrm{DD}}\propto k$; that makes the gate oxide insulation thickness scale as $t_{\mathrm{ox}}\propto k$, which then makes the gate capacitance (which is proportional to LW/t_{ox}) go as $C_{\mathrm{g}}\propto k$. A consequence of the geometry scaling is that the saturation drain current goes as $I_{\mathrm{D}}\propto k$. Finally, with that drain current, a gate input can be driven through V_{DD} in a time $\tau\approx C_{\mathrm{g}}V_{\mathrm{DD}}/I_{\mathrm{D}}$, which therefore scales as $\tau\propto k$. Voilà – the gate delay time scales as k; i.e., the speed increases proportionally to $1/k$. Even better, the power ($V_{\mathrm{DD}}I_{\mathrm{D}}$) decreases as $P\propto k^2$; and a reasonable figure-of-merit $1/P\tau$ (speed/power) goes as $1/k^3$. Perhaps this explains some of the semiconductor industry's relentless zeal always to move to the next-generation scaling "node" (shrink factor of $1/\sqrt{2}$).

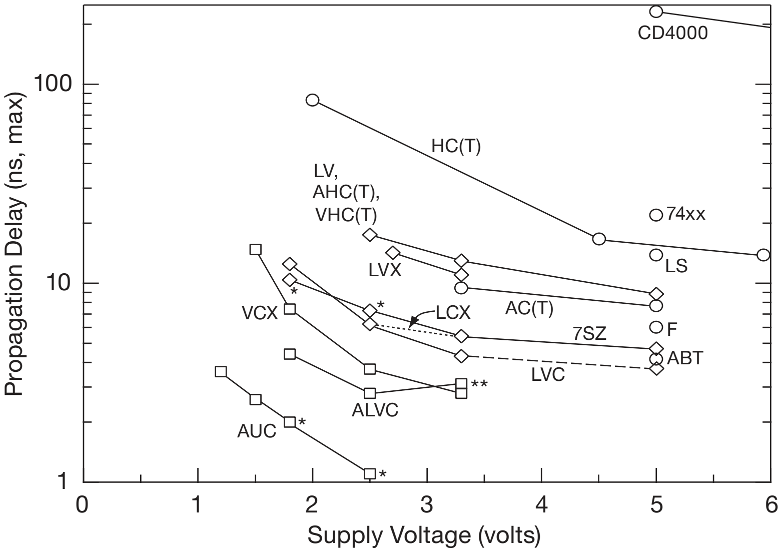

Figure 12.3. Gate speed versus supply voltage, for popular logic families. Maximum specified propagation delay ($t_{\text{pd(max)}}$) is shown for the standard supply voltages at which each family is specified. (As a rough guide, "typical" delays are in the range of 35–75% of $t_{\text{pd(max)}}$.) Open circles indicate families for which $V_{\text{in(max)}}$ is limited to V_{supply}, and data is for operation at 25°C; families with open diamonds have "5 V tolerant" inputs ($V_{\text{in}} \leq 5.5$ V, independent of supply voltage), and data is for operation over the "industrial" temperature range ($-40°$C to $+85°$C); families with open squares have "3.3 V tolerant" inputs ($V_{\text{in}} \leq 3.6$ V), data again over the industrial temperature range. Some families (e.g., LVC) have output-stage circuitry to ensure that the output does not load shared signal lines when unpowered. Plotted data is for load capacitance C_L=50 pF for 5 V and 3.3 V operation, 30 pF for 2.5 V and 1.8 V, and 15 pF for 1.5 V and below (except 50 pF for data points marked $**$, and 15 pF for $*$). The CMOS 4000-series logic runs to +15 V, at which $t_{\text{pd(max)}}$=70 ns. Only some LVC family members operate to +5V. Not shown are the speedy (and power-hungry) bipolar ECL families, operating at 5 V only: their maximum gate delays clock in at 0.6 ns (10E family), 0.44 ns (10EL), and 0.32 ns (10EP). Some families have evolved "enhanced" versions, for example LVC→LVCE, which operates down to 1.4 V and is 30% faster at low supply voltages. See also Figure 10.22 and §10.2.3.

toward micropower VLSI that is driven by battery-powered applications.

We wrap up our brief history with some recommendations.

- For simple logic circuits that are easy to assemble on a protoboard, and where blinding speed is not needed (nor desired), use 74HC or 74HCT logic (the latter for compatibility with either existing "TTL-level" signals, or with signals coming from low-voltage logic, e.g., powered from +3.3 V); you can substitute 74AC/74ACT/74ACTQ if you need the extra speed, but watch out for ground bounce.
- For low-voltage systems containing microcontrollers or other complex ICs, where some fast glue logic is needed, use a universal family like 74LVC, mindful that it is available only in surface-mount packages; these families are useful also for systems with several logic supply voltages.
- If you need to drive 5 V outputs (e.g., white LEDs, or solid-state relays) from a low-voltage system, use 74HCT
- for fast serial data and clock signals, use LVDS (or low-voltage PECL, "LVPECL") differential drivers, receivers, or SERDESs (serializer–deserializer).
- Choose the older 4000B/74C logic where the extended supply voltage range is needed and speed is unimportant (e.g., a portable device powered by an unregulated 9 V battery).
- Finally, use VLSI ICs (cPLDs, microcontrollers, ASSCs) rather than discrete logic – this reduces package count and wiring complexity and adds flexibility.

12.1.2 Input and output characteristics

Digital-logic families are designed so that the output from a chip can properly drive many inputs within the same logic family, powered from the same supply voltage. A typical fan-out capability is at least 10 loads, meaning that an output from a gate or flip-flop, for example, can be connected

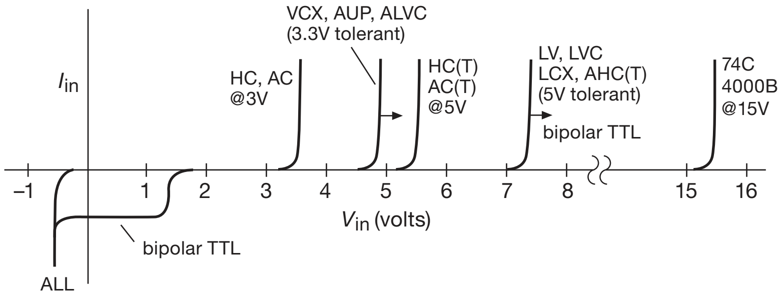

Figure 12.4. Logic gate input current versus input voltage. With the exception of bipolar "TTL," there is no static input current within the normal input-voltage range. All logic families include internal protective clamp diodes to ground. Some families (for example 74HC) clamp to the positive supply, and therefore draw input current when the input signal voltage exceeds a diode drop above V_+. More recent families (for example 74LVC or 74AUP) use internal zener-like protection, and permit inputs well above the supply voltage; these are called "5 V tolerant" or "3.3 V tolerant" (for example LVC and AUP, respectively), and permit such inputs even when unpowered (a situation in which a 74HC logic device would clamp at $+0.6V$ or, worse, cause the HIGH input to partially power the supply rail).

to 10 inputs and still perform within specifications.[2] In other words, in normal digital design practice you can get by without knowing anything about the electrical properties of the chips you're using, as long as your circuit consists only of digital logic driving more digital logic of the same type. In practice, this means that you don't often have to worry about what's actually going on at logic inputs and outputs.

However, as soon as you attempt to drive digital circuitry with externally generated signals, whether digital or analog, or whenever you use digital-logic outputs to drive other devices, you must face the realities of what it takes to drive a logic input and what a logic output can drive. Furthermore, when mixing logic families, or when you have logic running between different supply voltages, it is essential to understand the circuit properties of logic inputs and outputs. Interfacing between logic families is not an academic question. To take advantage of advanced VLSI chips, or special functions that are available in only one logic family, you must know how to mix logic types and voltages. In the next few subsections we will consider the circuit properties of logic inputs and outputs in detail, with examples of interfacing between logic families and between logic devices and the outside world.

A. Input characteristics

The graphs in Figures 12.4 and 12.5 show the important properties of digital-logic inputs: input current and output voltage (for an inverter) as functions of input voltage. We have extended the graphs to input voltages beyond the range normally encountered in digital circuits, because in interface situations the input signals may easily exceed the power-supply voltages. As the graphs imply, CMOS logic and bipolar TTL are normally operated with the negative supply pin connected to ground.

Input current (Figure 12.4)

Most logic these days is built with CMOS, where the inputs draw no current (except for leakage current, typically $10^{-5}\,\mu$A) for input voltages between ground and the supply voltage.[3] For voltages beyond the supply range, the input protection network looks like a clamping diode to ground, and either a diode to V_+ (e.g., the 74HCT family) or a zener-like clamp that permits input swings beyond the positive supply (e.g., the "5 V tolerant" 74LVC family); see Figures 12.3 and 12.4 for more details. Momentary currents greater than 20–50 mA through these diodes will damage or destroy the part, in some cases causing what's known as "SCR latchup" (§10.8.3B); you'll find such limits listed in the "Absolute Maximum Ratings" section of datasheets.

[2] For CMOS logic, which has zero dc input current, excessive loading merely slows down the transitions; in that sense the fan-out is "infinite." However, if you're driving bipolar logic, there's the additional issue of required dc input current (e.g., 1.6 mA for the 74LS family), which leads to a typical fan-out of 10.

[3] Note the peculiarity of the nearly obsolete bipolar TTL: an input sources a significant current (of order 0.1–1 mA) when held LOW, but draws only a small current when HIGH (typically a few microamperes, never more than 20 μA). To drive a TTL input, you must be able to sink a milliamp or so while holding the input below 0.4 V. Failure to understand this may lead to widespread circuit malfunction in interfacing situations!

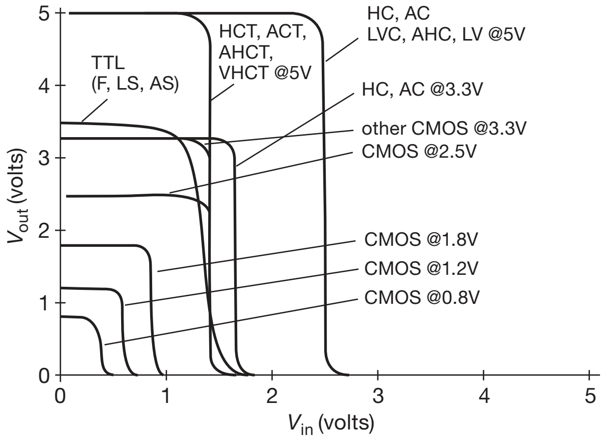

Figure 12.5. Output versus input ("transfer function") for logic inverters in commonly used families. In general, CMOS families that run at supply voltages of 2.5 V or less have their threshold at half the supply. At higher voltages most logic families (and many other more complex chips, such as microcontrollers and configurable logic) adhere to the "TTL" input specification, which guarantees that the threshold lies between 0.8 V and 2.0 V (and is typically 1.3–1.5 V). The HC/AC and 4000B families are exceptions, with their higher $V_+/2$ supply-tracking threshold.

Logic threshold (Figures 12.5 and 12.6)

The logic threshold voltage (the dividing line between logic LOW and logic HIGH inputs) depends on both the logic family, and on the supply voltage (for families where a range of supply voltages is permitted, as seen for example in Figure 12.3). The final authority is always the datasheet! But we can be of assistance here.

- Numerous digital devices adhere to what are known as "TTL thresholds," a legacy of the bipolar logic of the 1960s: $V < 0.8$ V is guaranteed to be interpreted as logic LOW, and $V > 2.0$ V is guaranteed to be interpreted as logic HIGH. (The voltages you send to such a logic device should stay outside those limits, to provide noise immunity; typically you'd provide a LOW level below 0.4 V, and a HIGH above 2.4 V.) The actual threshold voltage is typically around 1.35–1.5 V.[4] Common logic device families with TTL input thresholds (in addition to genuine bipolar TTL families such as 74F, 74LS, and 74AS) include the 74HCT, 74ACT, 74AHCT, and 74VHCT families; the "T" suffix signifies the family variant with (lowered) TTL thresholds, compared with the mid-supply ($V_+/2$) threshold of the non-T families (74HC, 74AC, 74AHC, 74VHC). Interestingly, many contemporary digital devices of high complexity, such as programmable logic (Chapter 11) and microcontrollers (Chapter 15) continue to adhere to both the TTL input threshold specification (LOW = 0.8 V or less, HIGH = 2.0 V or more), and the corresponding "TTL" output levels (LOW = 0.4 V or less, HIGH = 2.4 V or more).
- Logic inputs that are not of the "TTL-compatible" variety have their thresholds typically at mid-supply; that is, at $V_+/2$. This is true of the older CMOS families, for example 74HC and 74AC (which can operate with supply voltages from 2 V to 6 V) and the high-voltage 4000B/74C families (which can operate with supply voltages from 3 V to 18 V). It also generally holds for most newer low-voltage families like 74LVC and 74AUC. Note, however, that the actual threshold voltage for a logic part with a "mid-supply threshold" can vary considerably: the datasheet specifications typically permit a range from about one-third to two-thirds of V_+ (V_+ is often called V_{CC} or V_{DD}).

B. Output characteristics

The output circuit of CMOS logic devices almost invariably uses a pair of complementary MOSFETs, one ON and the other OFF (Figure 12.1). The output looks like a MOSFET r_{ON} to ground or to V_+ when it is within a volt or so of the respective rail, becoming something like a current source when you draw so much current that the output is forced more than a volt or two away from the supply rails. Typical values of r_{ON} are 30 Ω for 74HC(T) operating at +5 V, 12 Ω 74AC(T) operating at +5 V, 10 Ω/15 Ω (sinking/sourcing) for 74LVC operating at 3.3 V, and 200 Ω for 4000B operating at 15 V.[5]

The output circuit of bipolar-TTL devices (a disappearing species) uses an *npn* transistor switch to ground and an *npn* follower (or Darlington) to V_+ with a current-limiting resistor in its collector. One transistor is saturated and the other is off. As a result, a TTL device can sink a large current (8 mA for 74LS, 24 mA for 74F) to ground with a small (saturation) voltage drop, but when sourcing current

[4] We measured the threshold voltages for a sampling of "TTL threshold" inverters (by connecting the output back to the input), and here's what we found – 7404: 1.37 V; 74ACT04: 1.48 V; 74AS1004: 1.49 V; 74F04: 1.43 V; 74HCT04: 1.34 V; and 74LS04: 1.50 V.

[5] Watch out, though, for some "CMOS" digital functions (primarily older designs that operate from a +5 V supply, for example some cPLDs and microcontrollers) where the *p*-channel pullup switch is replaced with an *n*-channel source follower: for these devices the HIGH-state output does not reach the positive supply; instead it hovers around +3 V. You can recognize these parts from their datasheet's "DC Characteristics," which will say something like V_{OH}(min)=2.4 V, the telltale signs of an imitation legacy "TTL" output (where an *npn* follower forms the output pullup).

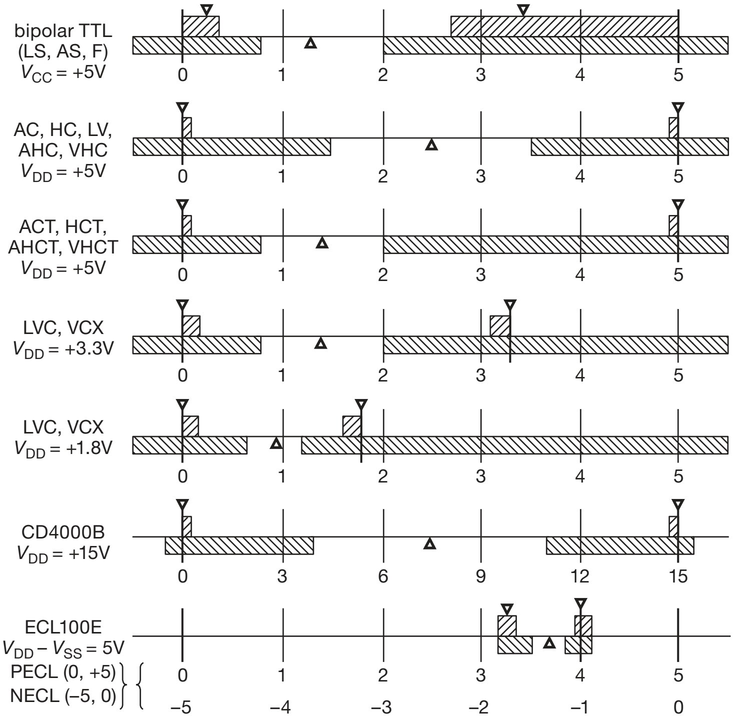

Figure 12.6. The range of voltages corresponding to the two logic states (HIGH and LOW) for popular families of digital logic. The shaded areas above the line show the specified range of output voltages within which a logic LOW or HIGH is guaranteed to fall, with the pair of arrows indicating typical output values (LOW, HIGH) encountered in practice. The shaded areas below the line show the range of input voltages guaranteed to be interpreted as LOW or HIGH, with the arrow indicating the typical *logic threshold* voltage, i.e., the dividing line between LOW and HIGH. In all cases a logic HIGH is more positive than a logic LOW. Table 10.1 and Figure 12.3 provide additional information about these families. See also Figure 12.135.

its output HIGH will be at least 1.5 V below the +5 V supply (see the 74AS and 74LS curves in Figure 12.7). The output circuit is designed to drive TTL inputs, or devices with "TTL input specifications" (<0.8 V guaranteed LOW, >2.0 V guaranteed HIGH) with a fan-out of 10.

In Figure 12.7 we have plotted the typical output voltage for both HIGH and LOW output states, against output current, for a selection of popular standard-logic families. To simplify the graph, output current is always drawn as positive. Note that true CMOS devices (that is, a complementary nMOS and pMOS push–pull switch pair) pull their outputs all the way to V_+ or ground, generating a full swing unless heavily loaded; so when driving only CMOS loads (zero dc current), the swing is fully rail-to-rail. Bipolar-TTL levels, by comparison, are typically 50–200 mV (LOW) or +3.5 volts (HIGH) when driving other TTL devices as loads. With a pullup resistor (discussed later), HIGH TTL outputs go all the way to +5 volts. We've also plotted two examples of MOSFET gate drivers, which accept a TTL-compatible logic-level input, and use a high-current CMOS output stage to generate an output swing between ground and a chosen positive V_{DD} supply; for the TC4420 series that can range from +4.5–18 V, whereas for the IXDD509 series the range is +4.5–30 V.[6]

In contemporary digital electronics we are increasingly exploiting the nifty capabilities of programmable logic devices (Chapter 11) and of microcontrollers (Chapter 15). So you really need to know what their outputs can do, in terms of driving external loads. Figure 12.8 shows the output drive characteristics of several popular PLDs (Altera MAX7000A, Lattice Mach 4000, Xilinx Coolrunner-II) and microcontrollers (Atmel ATmega, Microchip PIC16F, TI MSP430). These all use true CMOS

[6] Note, however, that MOSFET drivers do not operate at full logic speeds: although their timing is usually specified into the large capacitive loading characteristic of power MOSFETs, you're generally looking at propagation delays in the neighborhood of 10–25 ns or more (to be compared with $t_{pd}{\sim}2$ ns for standard-logic families like 74LVC).

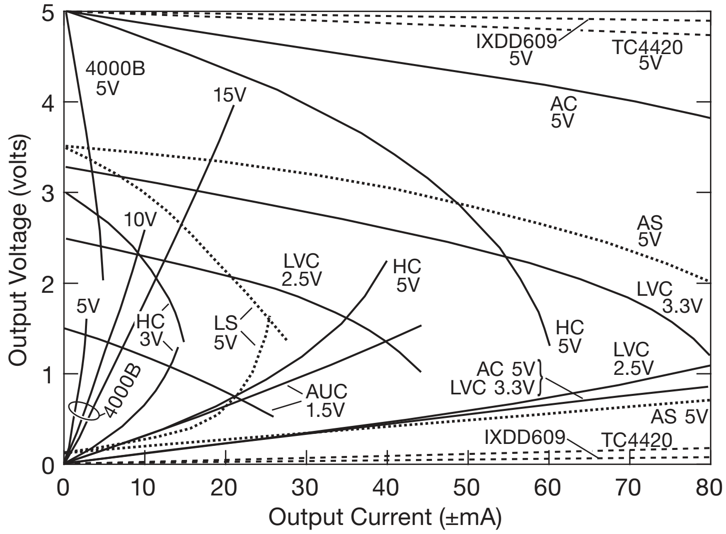

Figure 12.7. Logic gate output characteristics. The 74LS and 74AS families are 5 V bipolar TTL, with *npn* follower pullup, hence the ∼3.5 V HIGH output. All others are true CMOS, with rail-to-rail output swing. The TC4420/MCP1406 and IXDD609 are "MOSFET driver" ICs, with robust CMOS outputs that can source or sink up to 6 A and 9 A, respectively; they hardly even notice an 80 mA load.

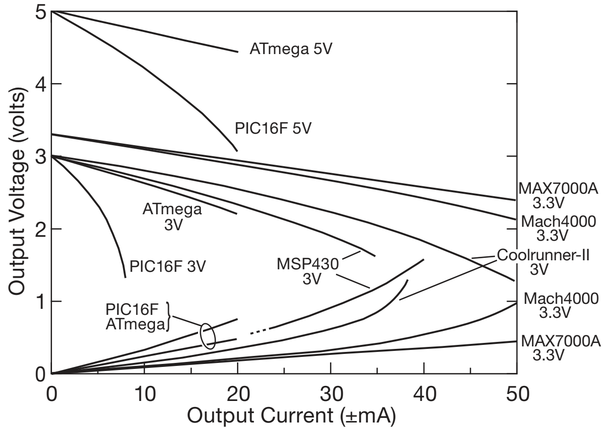

Figure 12.8. Output drive characteristics of selected PLDs and microcontrollers.

outputs with rail-to-rail voltage swing. As is evident from the graph, however, not all CMOS output stages are created equal.

12.1.3 Interfacing between logic families

It is important to know how to make different logic families talk to each other, because there are situations in which you must mix logic types, or portions of logic running from different supply voltages. In a typical situation you might want to use an output from a microcontroller running on +2.5 V to drive a 5 V single-gate inverter, so that the final 5 V full-swing output can drive a 5 V mechanical relay, or a solid-state relay (SSR), or a white LED. Or you might want to go the other way: a full-swing 5 V logic output needs to get to a low-voltage part running on 1.8 V.

The three things that can keep you from connecting any pair of logic chips together are (a) input logic-level incompatibility, (b) output drive capability, and (c) supply voltages. Rather than bore you with pages of rules and of explanations of what works and what doesn't, we've boiled down the interface problem to a simple set of recommended methods (Figure 12.9). Let's take a quick tour.

A. CMOS at same voltage

You can always make a direct logic connection between CMOS logic devices running from the same supply voltage. The output is full-swing, and therefore happily drives another CMOS device, regardless of the latter's particular threshold voltage.

B. "5 V logic" driving lower-voltage CMOS

CMOS running from 5 V can be connected directly to what's called "5 V-tolerant" logic (for example the 74LVC family) running at a lower supply voltage. As shown here, either CMOS (with its full-swing output), or "TTL" output-level devices (including true bipolar TTL, or ICs with nMOS follower pullups, either of which have a HIGH-state output of ∼3.5 V) satisfy the input voltage requirements

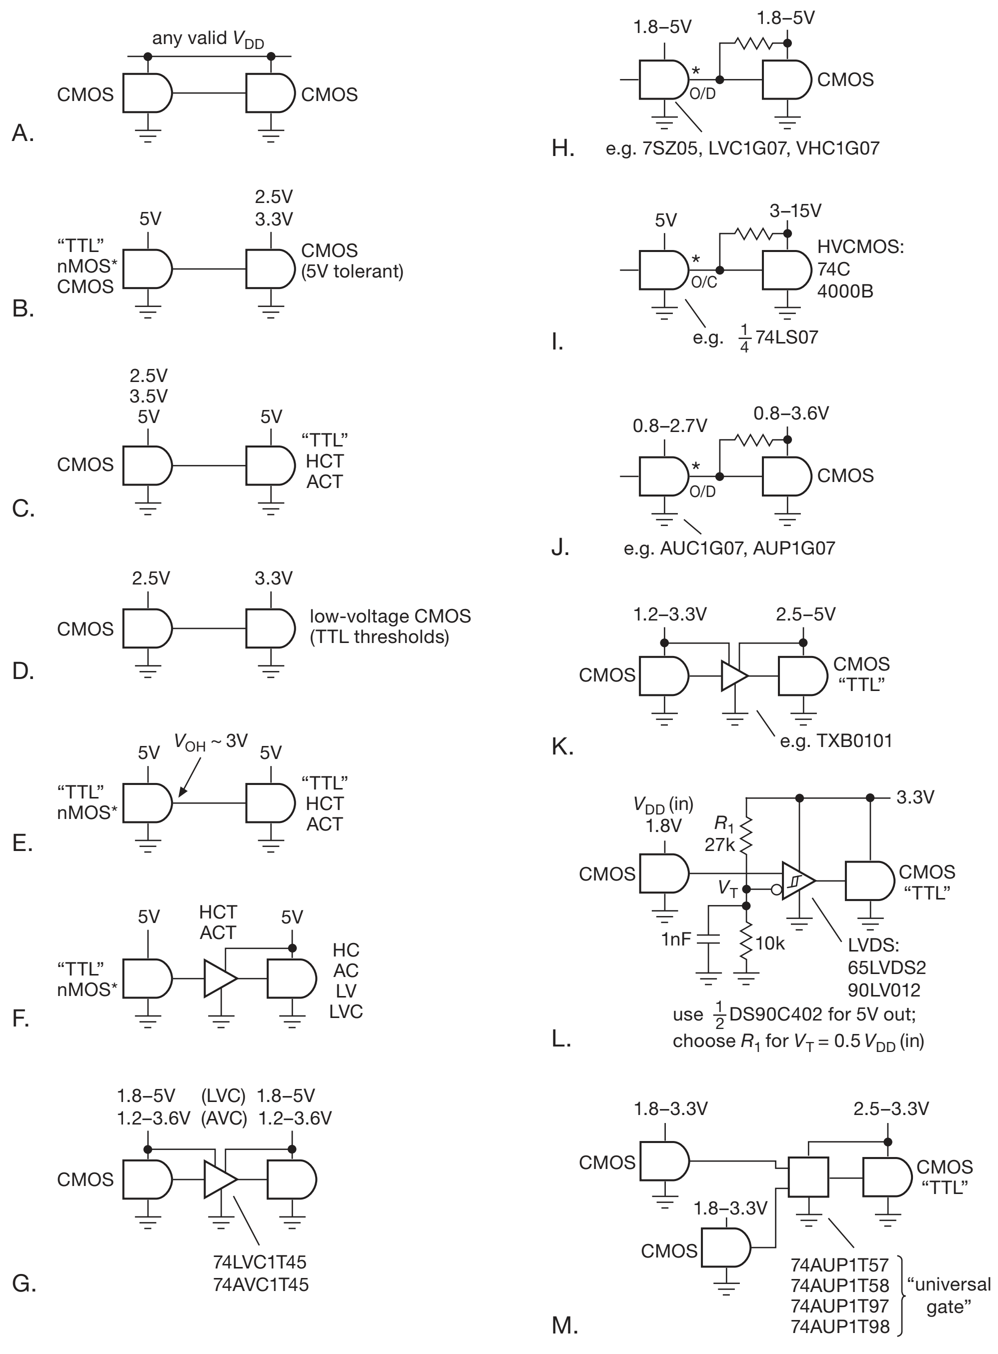

Figure 12.9. Logic family interconnections. See text for narrative.

of 5 V-tolerant CMOS running from supply voltages in the range of 2.5–3.3 V. There’s also the 74LV1T level-translating family, which can do both “down translation” (as here) or “up translation” (as in C).

C. Lower-voltage CMOS driving 5 V logic

You can drive “TTL input” (reduced-threshold) 5 V logic directly from CMOS outputs that swing at least to 2.5 V, as shown. In addition to true bipolar-TTL parts, some

5 V CMOS families (such as 74HC, 74AC, 74AHC, 74VHC) include TTL threshold variants (74HCT, 74ACT, 74AHCT,[7] 74VHCT). There's also the 74LV1T level-translating family.

D. CMOS at 2.5 V driving CMOS at 3.3 V

Nearly all CMOS families that can operate at 3.3 V supply voltage have TTL-compatible input levels (<0.8 V guaranteed LOW, >2.0 V guaranteed HIGH), so it's safe to drive them from the full-swing output of CMOS powered from 2.5 V.

E. 5 V "TTL outputs" driving reduced-threshold 5 V logic

To drive logic powered from 5 V, those outputs – LOW close to 0 V, but HIGH only ∼3.5 V (and only guaranteed to be >2.4 V) – must be paired with TTL-compatible inputs; that limits you to true 5 V bipolar TTL (e.g., 74F), or to 5 V CMOS logic families (or more complex 5 V digital chips) with TTL-compatible inputs (74ACT, 74HCT, 74AHCT, 74VHCT).

F. 5 V "TTL outputs" driving incompatible 5 V logic

If you're stuck with normal threshold 5 V logic (i.e., threshold at $V_{\mathrm{DD}}/2$, or ∼2.5 V), you can use a CMOS buffer or inverter with TTL thresholds (74HCT, etc) to convert the TTL swing to a 5 V full-swing signal. Note also that you can use instead a special level translator part like the 74LVC1T45 (Figure 12.9G).

G. Dual-supply level translator: 1.8–5 V and 1.2–3.6 V

There are some nice chips designed specifically for logic-level translation between a pair of supply voltages. The dual-supply 74LVC1T45 lets you translate between logic levels powered from 1.8 V to 5 V on either side (it is, in fact, bidirectional, controlled by a DIR pin input, just like the classic '245-style 8-bit bidirectional buffer). The lower-voltage 74AVC1T45 is similar, but operates from 1.2 V to 3.6 V on either side. You can also get these parts in duals (LVC2T45, AVC2T45). Note, however, that the LVC part, when operated at 5 V on its input side, has a "mid-supply" input threshold (guaranteed LOW <1.5 V, HIGH >3.5 V), and therefore cannot be driven from a TTL output level (with output HIGH only guaranteed to be ≥2.4 V). See also the TXB0101 dual-supply translator (Figure 12.9K).

H, I, J. Open-drain and open-collector

You can translate up or down in voltage level with an open-drain (or open-collector) buffer, though you pay a price in speed and quiescent current with the passive pullup resistor (the resistor value is a compromise – smaller is faster, but uses more power). Figure 12.9H shows translation between logic levels in the range 1.8–5 V on either side, using single gate '07 buffers in the wide voltage range logic families (7SZ, 74LVC, 74VHC), which support 5 V operation, and accept output pullup to 5 V. If you want a larger output swing, you can use the high-voltage open-collector 74LS07 (Figure 12.9I), which lets you pullup the output to +15 V. And if you need to translate from very low logic voltages, you can use a 74AUC1G07 or 74AUP1G07 (Figure 12.9J), which operates down to input logic levels as low as 0.8 V.

K. Low-voltage CMOS driving 2.5–5 V logic

The TXB0101 is another dual-supply translator (like the LVC/AVC1T45 in Figure 12.9G), but it has a couple of quirks. First, $V_{\mathrm{DD(B)}}$ (the righthand supply in the figure) cannot be less than $V_{\mathrm{DD(A)}}$. Second, it is bidirectional (like the 1T45), but it has no DIR control input; instead, it senses transitions on either side, responding by switching on the opposite port's CMOS drivers briefly, then maintaining that state weakly (∼4k series output resistor) with positive feedback (useful for switch debouncing, Figure 12.16).

L. Very low voltage CMOS to 3.3 V or 5 V logic

Here's a nice trick: an LVDS receiver accepts a differential digital signal pair, within a common-mode range from 0 V to +2.4 V, and with guaranteed switching down to an input amplitude of 200 mV. The (single-ended) output is full-swing CMOS, powered from 2.5–3.3 V (e.g., 65LVDS2) or from 5 V (DS90C402, DS90C032). So you can trick it into working for you as a level translator, by supplying a reference dc level halfway between logic states (with a small bypass capacitor) to the unused input. This will work down to very low input logic swings, for example as little as 0.5 V, where none of the other level translators dare to tread. LVDS interface chips are *fast*, too, often specified for data rates of 400 Mbps, with typical propagation delays <2 ns.

M. Low-voltage CMOS translator with configurable logic

The elegant "universal" gates that we mentioned in Chapter 10 (§10.2.1A) can be used to perform some logic while translating across logic voltage domains. When used this way, the gate runs from a single supply in common with the logic on the output side (which can range from 2.5–3.3 V), accepting inputs from logic that can be powered variously

[7] As an example, the 74AHCT1G125 is handy for converting a 3.3 V logic signal to a needed 5 V output swing; it comes in convenient SOT23-5 or SC70-5 packages, and costs less than $0.10.

from 1.8–3.3 V. These gates have Schmitt-trigger inputs, with about 0.4 V hysteresis centered about the threshold at ∼0.7 V.

A. Dynamic incompatibility: slow edge rates

Here's a problem that sometimes crops up when you drive an input of fast digital logic with a digital signal that does not slew through the threshold fast enough: the abrupt switching output of the driven device can couple back to the input (through the ground or power-supply connection, or internally on the chip itself, or just capacitively), causing multiple output transitions, as seen in the measured traces of Figure 12.10. To encourage such unseemly behavior we used a 74LS05 open-collector (OC) inverter with a lazy 5k Ω pullup to +5 V, driving a frenetic 74AC04 gate.[8] You can clearly see the disruption of the leisurely input waveform, as the fast inverter furiously switches its output.

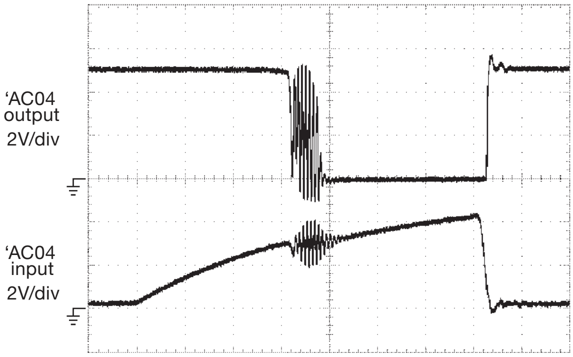

Figure 12.10. The relatively slow rising "edge" of a 'LS05 open-collector inverter with 5k Ω pullup (lower trace) drives a fast 'AC04 inverter, causing multiple output transitions. The trailing edge exhibits no bad behavior, because the open-collector falling edge is fast. Horizontal: 40 ns/div.

Multiple output transitions may be merely ugly; but this problem becomes devastating when you are driving edge-sensitive inputs (e.g., the clock input of flip-flops or counters). A flip-flop may fail to toggle; or a counter or shift register may clock several times at each edge. To illustrate this effect, we drove the clock input of a 74AC74 toggling flip-flop from the square wave output of a CD4001B NOR gate, with both powered from +5 V (and with a reset pulse applied to the flip-flop before the next clock). Figure 12.11 shows the messy result: sometimes the flip-flop toggles correctly, but sometimes it toggles twice in rapid succession.

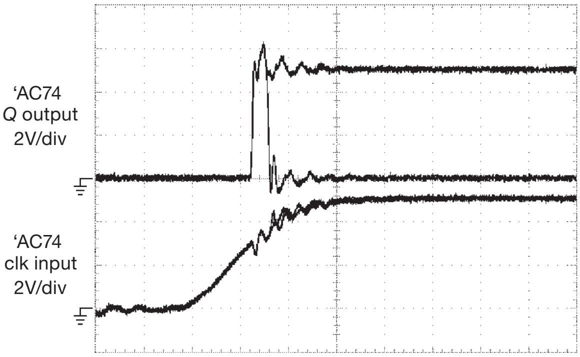

Figure 12.11. The slow rising edge of a CD4001B gate, loaded with 27 pF (a typical value of wiring and load capacitance), clocks a fast 'AC74 toggling flip-flop. The oscilloscope's persistence displays multiple clocking events, some more successful than others. Horizontal: 20 ns/div.

The lesson is clear: don't use slow edges to clock fast logic. It sometimes suffices to clean up the offending signal with a Schmitt-trigger inverter, available in most logic families as a '14 (e.g., 74LVC14). Figure 12.12 shows waveforms from the same setup as that of Figure 12.10, but with a 74AC14 (inverter with Schmitt) substituted for the 74AC04 (inverter without Schmitt). Better yet, stay away from slow edges completely.

You can get into the same kind of problems when you send digital signals between circuit boards, or between instruments, or over cables, an important set of topics we'll discuss presently (§12.9).

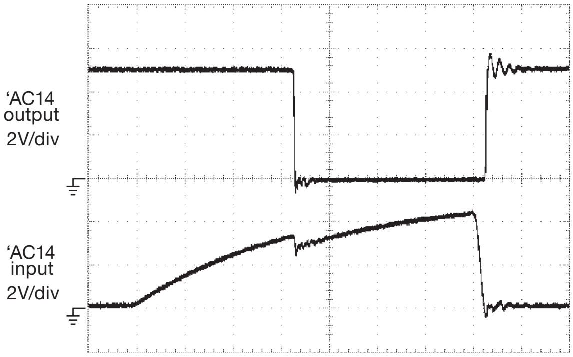

Figure 12.12. Same as Figure 12.10, but with the 'AC04 inverter replaced with an 'AC14 Schmitt-trigger inverter. The fast-switching output couples to the input, as before, but not enough to carry it back through the new (lower) threshold, thanks to the Schmitt's hysteresis. Horizontal: 40 ns/div.

[8] We've found that 74AC and 74ACT logic is fussy stuff, particularly in corner-pin power and ground incarnations packaged in through-hole DIP. Stay away from this stuff unless you need the speed; and then be sure to use a ground plane, keep ground leads short, and bypass close to the chip.

12.1.4 Driving digital logic inputs

A. Switches as input devices

It is easy to drive digital inputs from switches, keyboards, comparators, etc., if you keep in mind the input characteristics of the logic you're driving. The simplest way is to generate a valid logic level with a pullup or pull-down resistor (Figure 12.13). With CMOS logic, either is fine, because the inputs draw no current and the threshold is typically in the range of $0.3V_{\rm DD}$ to $0.5V_{\rm DD}$. It is usually more convenient to ground one side of the switch, but if the circuit is simplified by having a HIGH input when the switch is closed, the method with pull-down resistor will be perfectly OK. Be careful, though, with bipolar TTL: their inputs *source* a substantial current (e.g., a 74F family input sources 0.6 mA when held LOW), so it's best to use the configuration with a pullup resistor and the switch returned to ground.

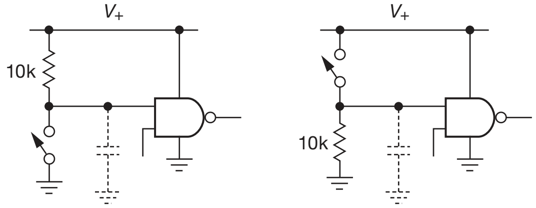

Figure 12.13. Mechanical switch to logic-level circuits (not debounced). If the switch is not close to the logic, it's common to see a small capacitor (~100–1000 pF) used to suppress capacitively coupled noise.

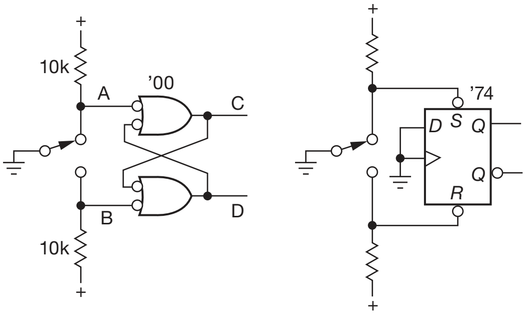

Figure 12.14. SR flip-flop switch debouncer, implemented either with cross-connected gates, or with a flip-flop with asynchronous SET and RESET inputs.

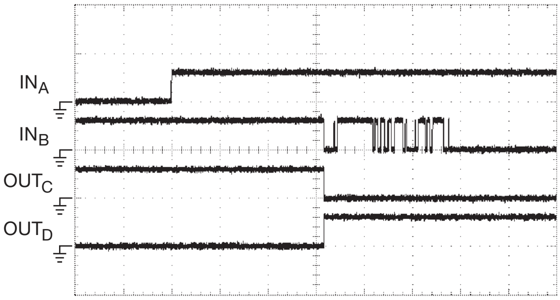

Figure 12.15. Waveforms from the debouncer of Figure 12.14, implemented with 3 V CMOS gates ('HC00) and a C&K 8121 SPDT (single-pole double-throw) pushbutton switch. Note the delay time from release of the *A* contact to the first closure of the *B* contact, as the switch's armature moves between the contacts. Vertical: 5 V/div; horizontal: 100 μs/div.

B. Switch bounce

As we remarked in Chapter 10, mechanical-switch contacts usually exhibit "bounce" after initial closure, with typical time scales of a millisecond. For physically large switches, the bounce can last as long as 50 ms. This can wreak havoc with circuits that are sensitive to changes of state, or "edges" (a flip-flop or counter would toggle many times if clocked directly from a switch input). In such cases it is essential to debounce the switch electronically. Here are a few methods:

- Use a pair of gates to make a jam-type *SR* flip-flop. Use pullups at the inputs to the debouncer, of course (Figures 12.14 and 12.15). Equivalently you can use a flip-flop with SET and CLEAR inputs (e.g., a '74); in that case, ground the clocking input.
- Use a noninverting buffer looped back into its input to make a latching "keeper" circuit, as in Figure 12.16. A buffer or noninverting gate (e.g., '1G34, '08, or '32) with its output looped back works fine. Timid circuit designers include a resistor in the feedback path (as shown) to limit the momentary transient current when the switch changes state; but, trust us, you can happily omit it.[9] The TXB0101 (§12.1.3, Figure 12.9K) is one of many "automatic" bidirectional level-shifter chips that hold their state, but can be overdriven by a change of state on either side.
- Use an *RC* slowdown network to drive a CMOS Schmitt trigger (Figures 12.17 and 12.18). The lowpass filter smooths the bouncy waveform so that the Schmitt-trigger gate makes only one transition. A 1 ms to 10 ms *RC* time constant is generally long enough. This method isn't

[9] It's always OK to override a logic output by shorting it to V_+ or ground, *providing the duration is kept short*. In this circuit there is no problem, because the output is forced for only a gate propagation delay, after which it contentedly holds itself in the new state.

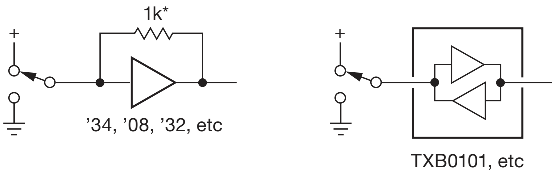

Figure 12.16. Switch debouncers using a "keeper" circuit that holds its logic state when the input is undriven.

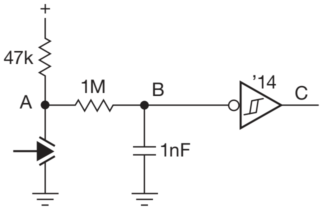

Figure 12.17. Debouncing an SPST (single-pole single-throw) switch with an *RC* smoothing circuit and a Schmitt trigger inverter.

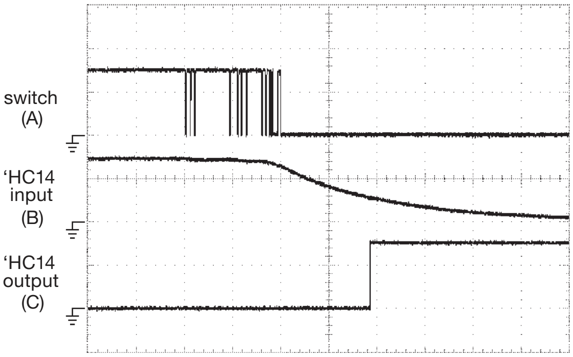

Figure 12.18. Waveforms from the debouncer of Figure 12.17, implemented with 3 V CMOS ('HC14) and a Microswitch 1PB13 pushbutton. Vertical: 2 V/div; Horizontal: 400 μs/div.

well suited to bipolar TTL because of the low driving impedance that TTL inputs require.

- Use a clocked circuit that samples the input level in a way that is not fooled by bounce. A simple way is to clock a *D*-type flip-flop with a period safely longer than the switch's bounce duration, e.g., with a clock frequency of 100 Hz (Figure 12.19). But there are dedicated debouncer chips, for example the MAX6816-8 (single, dual, and octal debouncers), which test for transition to a stable state for multiple clock periods (with internal oscillator, counters, and logic; effectively a digital lowpass filter) and generate a clean debounced output; they include internal pullup resistors, input protection to ±25 V, and operation from 2.7 V to 5.5 V. You just tie your SPST switches from input to ground – no external components needed (Figure 12.19). A similar part is the MC14490 hex (6-section) debouncer, which belongs to the CMOS 4000B-series and can run with supply voltages from 3 V to 18 V; it includes internal pullups, but it requires one external capacitor to set the clock rate. Another alternative is the so-called "power-supply supervisory" chip, which is ordinarily used to detect brownout (undervoltage) and to generate a clean reset pulse on power restoration (or initial power-up). Many of these chips include a manual reset input, to which you can connect a pushbutton, thus hijacking them into service as a debouncer.
- Use a microcontroller, with programming to carry out "software debounce" (Figure 12.20). Most microcontrollers include internal pullups; and simple code (either interrupt driven, or polled) can look for a stable change of state. This is a favorite method used by circuit designers for any gadget that needs a microcontroller anyway.
- Use a device with built-in debouncer. Keyboard encoders, for instance, are designed with mechanical switches in mind as input devices, and they usually include debouncing circuitry. Another example is shown in Figure 12.20, namely a pushbutton-controlled "digital potentiometer" (an internal resistor string, with tap selection via MOSFET switches). Each press of a button increments or decrements the internal counter, so it's got to be bounce free. And it is.

A few general comments on switches as input devices: note that SPDT switches (sometimes called "form C") are necessary with the first two methods (SR flip-flop, "keeper" circuit), whereas the simpler SPST switches ("form A") can be used with the other methods. Keep in

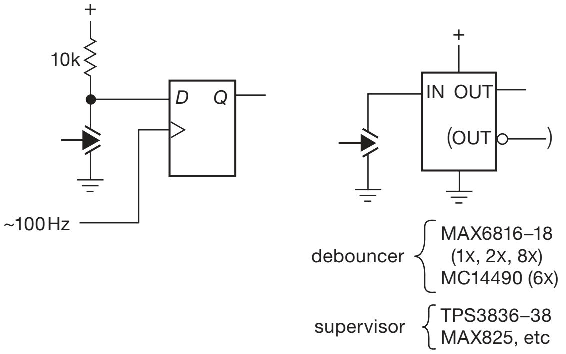

Figure 12.19. Clocked debouncers. Simplest is a slowly-clocked *D* flip-flop. There are better methods, embodied for example in special debouncer chips like the MAX6816-8 and MC14490, and in "supervisory" chips like the TPS3836-8.

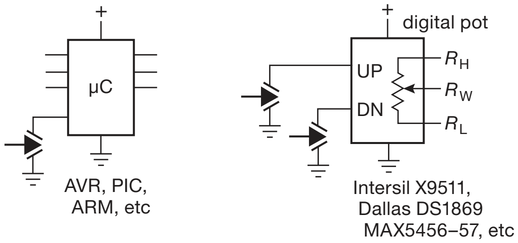

Figure 12.20. Debouncing with complex digital ICs: a microcontroller (μC) can use its user-written program (its *firmware*) to perform "software debounce"; and application-specific chips that accept pushbutton commands (like the digital potentiometers shown, with UP′ and DOWN′ inputs) often include internal pullup and debounce circuitry.

mind, also, that often it isn't necessary to debounce switch inputs, since they aren't always used to drive edge-sensitive circuitry. Another point: well-designed switches are usually "self-wiping" to maintain a clean contact surface (take one apart to see what that means), but it's a good idea to choose circuit values so that a current of at least a few milliamps flows through the switch contacts to clean them. With suitable choice of contact material (e.g., gold) and mechanical design, switches can be designed to avoid this "dry-switching" problem and will work properly even when switching zero current. More on this in Chapter *1x*.

12.1.5 Input protection

In these interfacing examples we've assumed that the signals being applied to the logic inputs are well behaved – that they do not have transient overvoltages or other destructive tendencies. That's not always the case. You can get into plenty of trouble with signals coming in from the outside, if you mount a connector on a box and casually hook it to the input of a logic gate (Figure 12.21A). A common source of transients is the static charge that accumulates readily in dry weather – those crackling sounds you hear when you take off a synthetic fleece jacket can elevate the body to a kilovolt or more. That voltage resides on the human capacitor (about 100 pF), and can take flight into a circuit input when you plug in a connector, or injudiciously touch components on a circuit board without first discharging yourself to ground.

The problem is well known in the electronics industry, and ICs are tested and rated for survival when subjected to electrostatic discharge. For this purpose the human body is modeled as shown in Figure 12.22. In the manner of the Physicist's "spherical cow," Electrical Engineers reduce all humans to a 100 pF capacitor in series with a 1.5 kΩ resistor,[10] and use that to test the robustness of their ICs. The usual charging voltages are 1–2.5 kV, but you see ICs rated up to 15 kV; for example, the MAX3232E RS-232 serial driver–receiver proclaims "ESD Protection for RS-232 Bus Pins – ±15 kV (HBM)." The figure shows the charged HBM (human body model) delivering a current pulse to the input of a logic-gate victim, which must sustain a transient current of an amp or more. That current is clamped to the supply rails, but the internal resistance of the clamp allows the input pin to go tens of volts beyond the rail (or below ground, for a negative transient), delivering a calculable energy to a very small area on the semiconductor die.

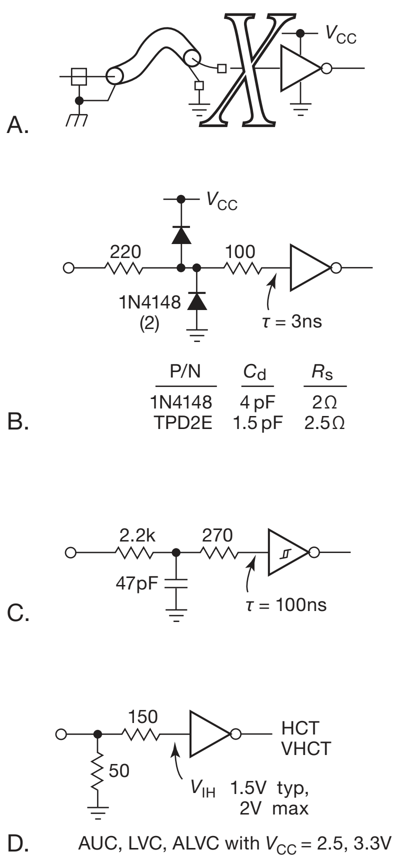

Figure 12.21. Protecting logic inputs from destructive transients: A. no protection; B. Diode clamps to V_{CC} and ground, or ESD protection array, with current-limiting series resistors; C. *RC* filtering plus Schmitt-trigger input; D. cable termination and series resistor, to dilute transient energy.

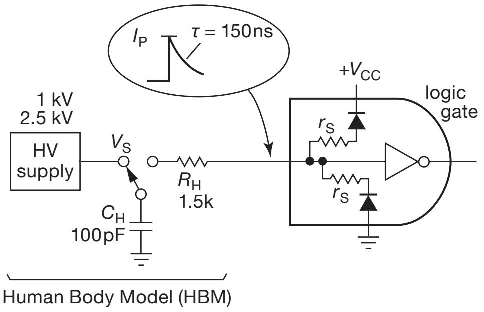
[10] JEDEC standard JESD22-A114D, dated 2006.



Peak Current and Clamp Energy

V_S	E_{CH}	I_P	E_{CLAMP} (r_S = 70Ω)
1kV	50μJ	0.67A	2.3μJ
2.5kV	310μJ	1.67A	15μJ

$E_{CLAMP} \approx \frac{1}{2} I_P^2 r_S \tau$

CIRCUIT	IC E_{CLAMP}
A	15μJ
B	0.1μJ
C	4μJ
D	1μJ

2.5kV

Figure 12.22. The Electrical Engineer's view of Biology: The "Human Body Model." ICs are tested and qualified at voltages of 1 kV, 2.5 kV, or more. The table lists estimated clamp energy values for the circuits in Figure 12.21. See also §3.5.4H.

ICs are rated to handle this. But plenty of damaged chips out there testify to the wisdom of adding external protection, especially if there's reason to expect exposure to high transient levels. Or inexperienced users. Look back at Figure 12.21. Circuit B is simple and effective. Ordinary diodes like the ubiquitous 1N4148 have more junction area than on-chip clamps, hence better clamping action; the upstream resistor limits the diode current, and the downstream resistor, fed from that clamped voltage, limits the chip's input current. You can get arrays of clamp diodes; these sometimes include a zener, as in Figure 12.23, for protecting differential logic like LVDS or RS-485.

Circuit C uses an *RC* transient filter to reduce the peak input current. To be effective, the time constant should be at least comparable to the HBM transient time scale, say 100 ns or so (and with an input resistance at least comparable to the HBM value of 1.5 k), and therefore should be followed by a Schmitt-trigger input. Circuit D takes a different approach: it combines a matched termination for 50 Ω coaxial cable (see Appendix H, and §12.10) with a larger series resistor, forming a "current divider." That dilutes the chip's transient input current by a factor of 4 (for the values shown), which is a 16× reduction of transient energy; and there's a further 2× to 5× reduction because the diluted energy is shared between the 150 Ω resistor and the chip's dynamic resistance during overvoltage. In Figure 12.22 we've estimated the delivered transient energy for each of these methods, compared with the 15μJ estimated value for a 2.5 kV HBM with no protection.

	V_B	I_L	(100A, 8/20μs) V_{clamp}	 r_{clamp}
SP03-3.3	3.3	1μA	15V	0.07Ω
SP03-6	6.8	25μA	20V	0.1Ω

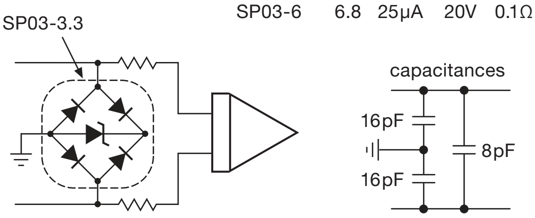


Figure 12.23. Diode protection arrays, like this one from Littelfuse, let you clamp single-ended or differential inputs, with very low clamp impedance. The internal zener sets the clamping voltage. You can get lower-current protection arrays with very low capacitance, for example the 5-volt CTLTVS5-4 from Central Semiconductor: it has a maximum 0.8 pF to ground (and 0.4 pF line-to-line) at zero volts, a peak current rating of 2.5 A, and it includes two protective bridges in a single SMT package.

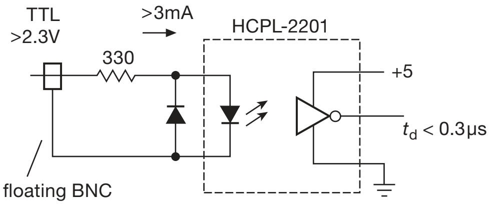

Figure 12.24. The ultimate in isolation: an optocoupler. This is more expensive than a diode clamp arrangement, but it's guaranteed to keep the bad stuff out.

Finally, for the ultimate in protection, use an optocoupler logic isolator, as in Figure 12.24. There's no galvanic connection at all (note the floating BNC connector), and these things can stand off potentials of many kilovolts (we'll see them later in the chapter, at §12.7). Note the current-limiting resistor and reverse protection diode; the latter is often omitted in error.

12.1.6 Some comments about logic inputs

A. Pullups and pull-downs

Most contemporary digital logic is CMOS, with essentially zero input current. So even a weak pullup (or pull-down) current is adequate to bring the input fully to V_+ (or to ground).[11] Watch out, though, for coupling of capacitive transients to such an input, for example from a panel switch with wiring that travels in proximity to signal-carrying lines. In such a case it's a good idea to add a small (∼1 nF) bypass capacitor near the high-impedance logic input. In the case of complex digital ICs (microcontrollers, FPGAs, and other application-specific standard products) it's common to see internal pullups for inputs that may come from switches, so no pullup or pull-down resistor is needed (though you may want to add a small bypass capacitor to suppress coupled transients).

B. Input overdrive

Digital-logic inputs include protection against overvoltage, usually in the form of a clamp diode to ground, and either a clamp diode to V_+ or a zener-like clamp (for devices with input tolerance beyond their supply voltage). The "Absolute Maximum" datasheet ratings tell you the limits of what you can get away with (e.g., 74LVC devices specify $-0.5\,\text{V} < V_{\text{in}} < 5.5\,\text{V}$, regardless of supply voltage: they are "5 V tolerant."). However, it's often the input *current* that does the damage, which is duly noted in the same table: "The input and output negative voltage ratings may be exceeded if the input and output current ratings are observed." And the latter (input clamp current, output clamp current) are specified, in this case, as −50 mA, maximum. Although it's a nice gesture to keep your input drive voltages within specified bounds, it's OK to go beyond if you have some series impedance to limit the current, as we've shown in Figure 12.21.

C. Unused inputs

Unused inputs that affect the logic state of a chip (e.g., a RESET input of a flip-flop) must of course be tied HIGH or LOW, as appropriate. Perhaps less obvious, even inputs that have no effect (e.g., inputs of unused gate sections in the same package) should be tied HIGH or LOW (your choice), because an open input to a CMOS device can float up to the logic threshold, causing the output to go to half the supply voltage, with both MOS output transistors conducting, thus drawing considerable class-A current. This can result in excessive supply current, and can even lead to failure in devices with hefty output stages. It can also cause oscillation.

12.1.7 Driving digital logic from comparators or op-amps

Comparators (and sometimes op-amps), together with analog-to-digital converters, are the common input devices by which analog signals can interface into digital circuits (recall §4.3.2). If your circuit has a microcontroller ("μC," Chapter 15), then you can take advantage of built-in ADCs or comparators, which are common features of most μCs. But you'll sometimes want to go from a comparator (or op-amp) output directly into digital logic. This is not terribly difficult – but you've got to respect the allowable voltage input range of the driven logic. Let's look at some examples (for which it may be helpful to look ahead to Table 12.1 on page 812 and Table 12.2 on page 813, to keep score in the detailed discussion that follows).

A. Comparator driving logic

Figure 12.25 shows some common ways to connect comparator outputs to logic (and we'll have lots more to say about comparator interfacing in §12.3). The ever-popular and seriously inexpensive LM311 (and improved versions, like the LT1011) has a flexible open-collector output stage with a "ground" pin that sets the LOW state (which can be anywhere between V_+ and V_-); the pullup resistor, of course, sets the HIGH state, as shown. These are designated as output type "FL" in the tables. Some comparators, like the AD790, use internal active pullup, but you get to set the HIGH output state at a logic voltage pin V_{L}. Many high-speed comparators that operate from lower-voltage supplies simply use the V_+ voltage for their output HIGH, while still providing a "ground" pin – the LT1016 (shown) is an example; we like it because its design makes it particularly resistant to multiple transitions and oscillations. Note that this part has "TTL" output levels, namely ground and approximately +3.5 V (though guaranteed only to be ≥2.4 V and ≤5 V), and so it cannot be connected to 5 V-intolerant logic. Next is a large class of low-voltage "single-supply" comparators (marked "CM to neg rail" in the tables; e.g., the TLC3702) that simply swing their outputs between ground and V_+. Finally, single-supply comparators that can run from higher voltages and that are not going for breakneck speed (e.g., the classic LM393) are usually configured with open-collector (or open-drain) outputs, with external

[11] However, be aware that bipolar-TTL devices are not so friendly: their inputs source significant current (up to a milliamp) in the LOW state, and sink a small (but nonzero) current (up to a few tens of microamps) in the HIGH state. Because of this asymmetry, external digital signals used as inputs will therefore nearly always have a pullup resistor and will pull LOW (sinking current) when active, a convenient arrangement because switches, etc., can use a common ground return. It also leads to greater noise immunity, since a line held near the bipolar V_+ of +5 V has 3 V of noise immunity, as compared with the ∼0.8 V of noise immunity of a line held near ground.

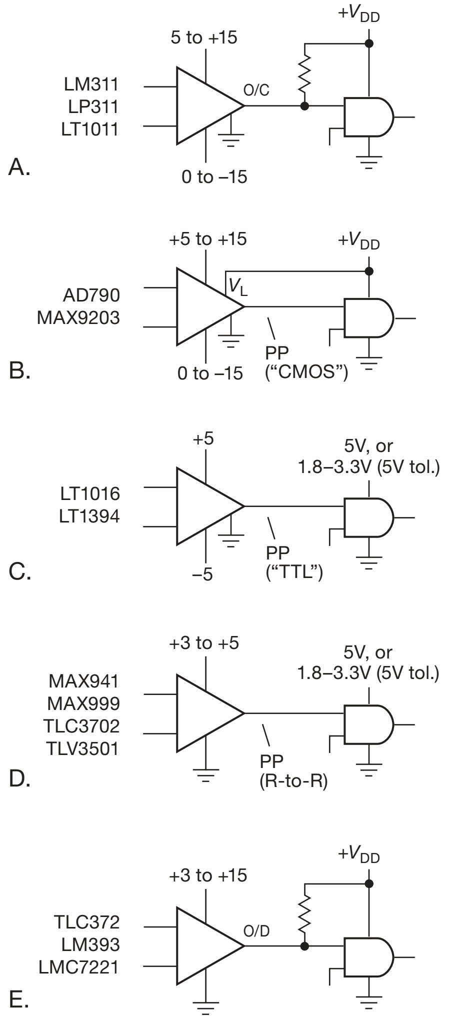

Figure 12.25. Driving digital logic from comparators.

pullup resistor as shown; these are marked as output type "OC" or "OD" in the tables.

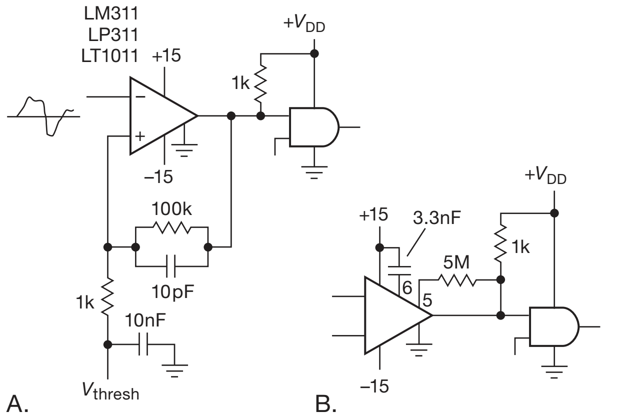

Figure 12.26. Threshold detector with hysteresis. A. Conventional circuit, for use with any comparator. B. Alternative method for the 311-type.

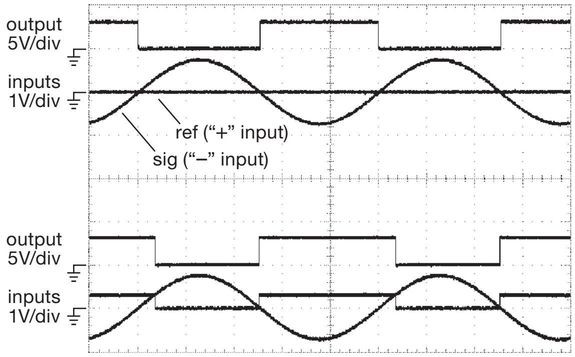

Figure 12.27. LM311 comparators driven with 1.5 V_{PP} 1 kHz sine wave, with output pullup to +3.3 V. Top: no hysteresis; bottom: 10% hysteresis (100k feedback, 11k to ground). Horizontal: 200 μs/div.

In Figure 12.25 we've ignored circuit configuration niceties like hysteresis, which we visited back in §4.3.2B. This is worth a reminder: Figure 12.26 shows the classic Schmitt-trigger threshold detector, configured with an amount of hysteresis equal to 1% of V_{DD}, and a small speed-up capacitor. In this circuit V_{thresh} must be provided from a low source impedance ($\ll$1k). That can be a serious disadvantage (although for slow or static V_{thresh} you can always use an op-amp buffer), in which case the alternative circuit shown may be just what you want. It takes advantage of the LM311's offset trim input terminals (pins 5 and 6) to produce both hysteresis (via the 5M resistor) and speed-up (via the 3.3 nF capacitor).[12] Figure 12.27 shows measured waveforms for an LM311 configured without and with 10% hysteresis. Note, in the latter case, the asymmetrical trigger points (and output waveform timing). Although it's not visible in the captured waveforms, you are asking for trouble when you send slow input waveforms to a comparator without hysteresis (trust us, we've been there!).

Finally, Figure 12.28 shows in detail the effect of a small speed-up capacitor in the feedback path of the Schmitt trigger. Without it, the positive feedback to the noninverting input is slowed by input and wiring capacitance, so an input signal with some low-level fast noise may produce multiple

[12] This trick, and variations on it, are nicely described in the LT1011 datasheet; there's some discussion, also, in National's extensive LM311 datasheet.

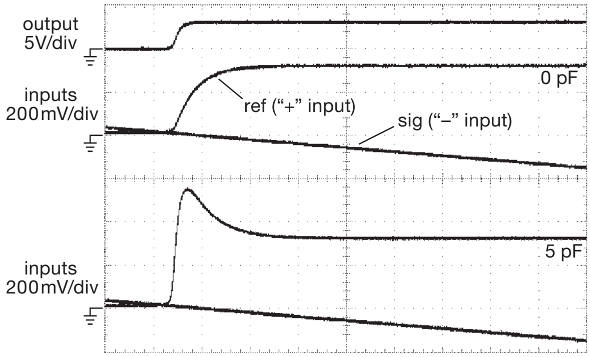

Figure 12.28. A small speed-up capacitor (bottom trace pair) compensates for the slowdown (middle trace pair) caused by input capacitance in the Schmitt trigger. Same circuit as Figure 12.27, but with expanded horizontal and vertical scales (to show detail of switching), and with 10 kHz sine wave input (so you can see the input signal's slope). Horizontal: 400 ns/div.

output transitions while the positive feedback is lollygagging along. The addition of very little feedback capacitance (here just 5 pF) fixes the problem (bottom trace pair). Don't overdo it, though – a large feedback capacitor generates a large hysteretic overshoot, with an undesirably long recovery time.

B. Op-amp driving logic

Op-amp driving logic – *what in heaven's name are you talking about?!* Well, sometimes you've used an op-amp section as a comparator, for example as a "battery-low" detector, or whatever. So its output swings between the rails, or nearly so (if it does not have a rail-to-rail output stage). All you want to do is get that output state into some digital logic. As with comparators, the only task is to make sure you respect the logic's input-voltage rules.

Figure 12.29 shows a few common situations. If the op-amp is running on a single low-voltage supply (in which case it likely has a rail-to-rail output stage) you can just connect it directly to logic that runs on that same V_+ voltage, or that is input tolerant to it. In the figure example, that could be 5 V logic, or 5 V-tolerant logic running on a lower supply (e.g., LV, LVC, or LVX: see Figure 12.3). If the op-amp has larger output swings, or swings both polarities, you need to limit it to logic bounds. One way is to interpose an nMOS inverter, as shown; alternatively you can use a passive clamp to the logic rail, combined with the logic's input protection negative clamp diode, as shown. We're not wild about this method, since it takes three components (and degrades the switching speed as well), but it does work. Whatever you do, be aware that the (analog and slew-rate-limited) op-amp output transitions will be much slower than normal digital-logic transitions. That is, don't expect clean logic switching; these interfaces are merely a way to get the op-amp's state into some digital logic.

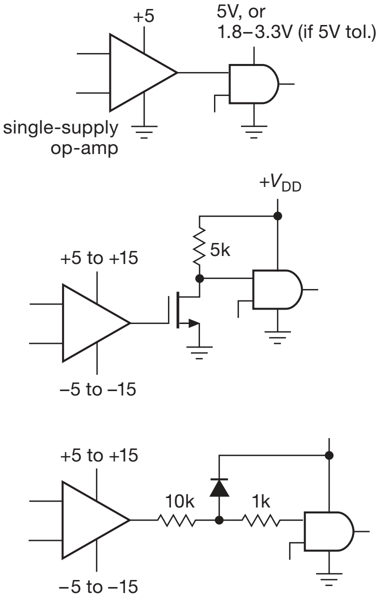

Figure 12.29. Driving digital logic from an op-amp's output.

C. Clock inputs: hysteresis

A general comment about driving digital logic from op-amps: don't try to drive *clock* inputs from these op-amp interfaces – the transition times are too long, and you may get glitches as the input signal passes through the logic threshold voltage. If you intend to drive clocking inputs (of flip-flops, shift registers, counters, monostables, etc.), it is best to use a comparator with hysteresis (e.g., Figure 12.26), or to buffer the input with a gate (or other logic device) with Schmitt-trigger input (e.g., a '14 Schmitt-trigger inverter). The same comment goes for signals derived from transistor analog circuitry.

12.2 An aside: probing digital signals

We've had envious queries ("How do you guys get such nice traces? How do you get rid of all the wiggles?") about the clean digital 'scope waveforms in this book:[13] It's pretty easy, once you realize that you can't get away with the same lazy techniques that work OK at low frequencies.

[13] Take a look at some examples from this chapter, for example Figure 12.18 (slow) or 12.108 (fast).

In particular, the fast edges on digital signals produce probing artifacts (ringing, and soft edges) when you try to use a standard 10× passive 'scope probe with its 6″ grounding lead.[14] Figure 12.30 shows how the same logic waveform looks when probed three different ways.

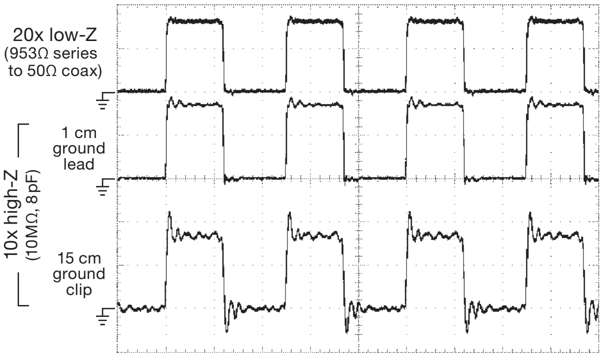

Figure 12.30. Logic waveform at 10 MHz from a 74AC14 inverter running at 3.3 V, as seen on a Tektronix TDS3044B 'scope when probed three different ways. Vertical: 2 V/div; horizontal: 40 ns/div.

This is a 10 MHz clock signal at the output of a 74AC14 inverter, wired up on a "solderless prototyping" board[15] (a dubious practice; but, hey, it works, most of the time anyway). We took the precaution of using an IC socket with integral SMT bypass capacitor, to put the best face on it. The bottom trace is business-as-usual, with a P6139A (500 MHz) 10× passive probe and 6″ ground lead. It's overshooting and ringing like crazy – can that be real, or is it an artifact of the probe's inductive ground path? You do considerably better by tossing the ground lead in the trash, removing the plastic sleeves, and using a little springy "ground tip contact." The middle trace shows the result: aha! Most of the ringing is gone. Better still, dump the 10× passive probe altogether (they don't come in speeds faster than 500 MHz anyway) and make your own by hooking a series resistor (we like 950 Ω) onto a length of skinny 50 Ω coax (we like RG-178); you temporarily solder the coax shield to a nearby ground, plug the other end into the 'scope (set for 50 Ω input) and voilà – a high-speed 20× probe![16] The top trace is about as clean as you can do, especially with through-hole (14-pin DIP) parts on a breadboard.

The homemade 50 Ω trick has the advantage of low cost, so you can do four traces easily; we used it for nearly all the digital 'scoping in this book. But because of its low input resistance, it is not useful for generalized circuit probing.

What happens with the more common configuration of surface-mount components on a printed-circuit board, and with much faster logic signals? Figure 12.31 shows what you see with four probing methods looking at the output of a 74AUC1G04 inverter, this time at 4 ns/div (and Figure 12.32 shows what the probes themselves look like).

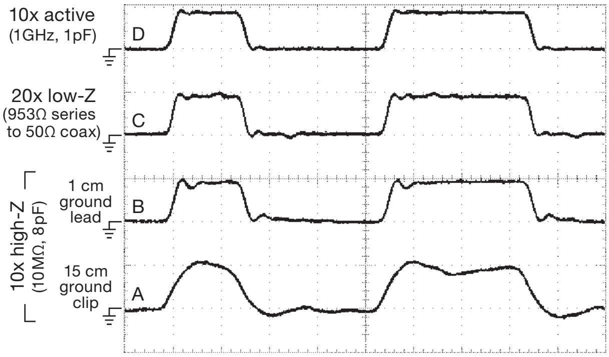

Figure 12.31. Logic waveform at a 6 ns clock rate from a 74AUC1G04 inverter running at 1.8 V, as seen on a Tektronix TDS3044B 'scope, when probed four different ways. The A–D labels match those in Figure 12.32. Vertical: 2 V/div; horizontal: 4 ns/div.

Here the passive-probe-with-ground-lead produces a mushy waveform (bottom trace) with moderate overshoot, considerably helped by using the shorter ground tip (next trace). The el-cheapo 20× trick looks better still. But best of all (if you've got the dough), is an "active probe" (an FET follower), with typical input capacitance less than 1 pF, and with speeds up into the high gigahertz (and prices to match). The top trace was made with a P6243 active probe (1 GHz bandwidth, less than – but not much less than – 1 kilodollar[17]).

12.3 Comparators

Comparators provide an important interface between analog (linear) input signals and the digital world, as we noted earlier in this chapter (§12.1.7A). In this section we would like to look at comparators in some detail, with emphasis on their output properties, their flexibility regarding power-supply voltages, and the care and feeding of input stages.

[14] *Leads?* Yeah, sure. I'll just check with the boys down at the crime lab... they've got four more detectives working on the case... they got us working in *shifts!*

[15] For example, Global Specialties type UBS-100, or 3M type 923252.

[16] You can get these as a commercial product, the Keysight (Agilent) 54006A "6 GHz Passive Divider Probe Kit." It includes resistors for 10:1 and 20:1, and has a probe-tip capacitance of just 0.25 pF (as little as 0.1 pF, if you trim the tip). You can create greater ratios (thus higher loading resistance) by substituting other values of Caddock MG710-type resistors.

[17] But ∼8 dB less expensive on used auctions.

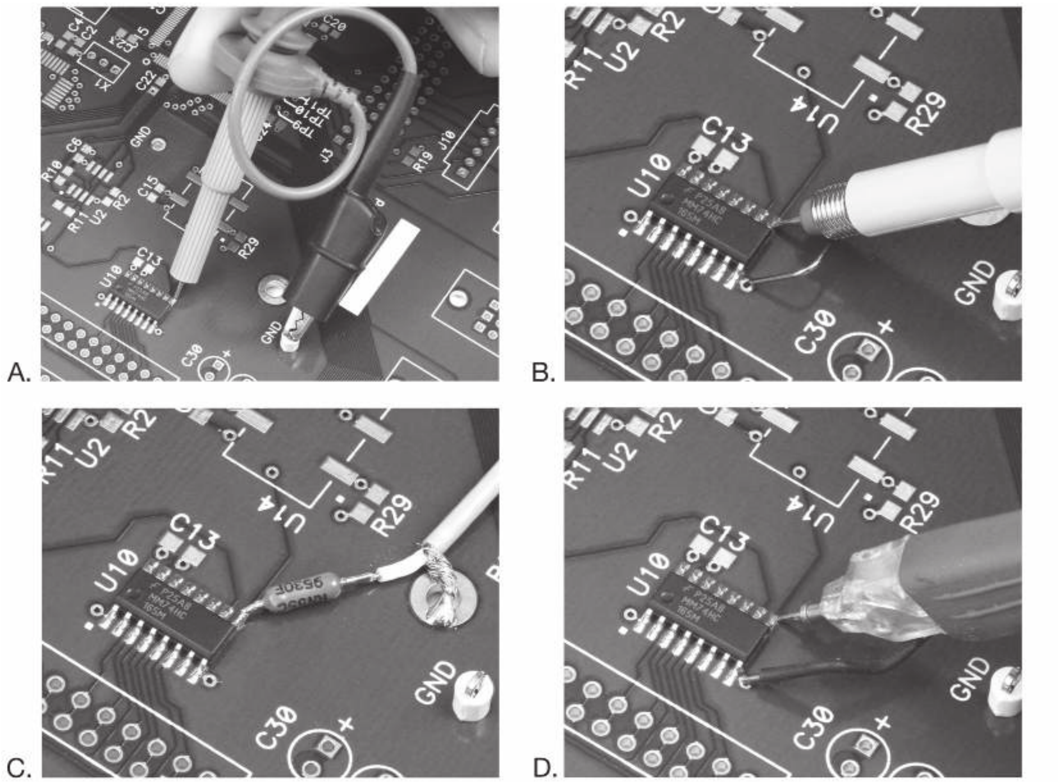

Figure 12.32. Probing digital signals: A. conventional 10× passive probe (Tektronix P6139A) with 6″ ground lead; B. short ground tip contact (Tek 016-1077-00) on 10× passive probe. C. Simple 20× passive "probe" for 50 Ω 'scope input: 953 Ω series resistor to coax; D. active probe (Tek P6243) with short ground tip. When probing fine-pitch ICs, it's a good idea to use a plastic guide (e.g., Tek "SureFoot" adapters) over the probe tip (not shown), so you don't short out adjacent contacts. The IC here is an SOIC-16, with 1.25 mm contact spacing.

Comparators were introduced briefly in §4.3.2A to illustrate the use of positive feedback (Schmitt trigger) and to show that special-purpose comparator ICs deliver considerably better performance than general-purpose op-amps used as comparators. These improvements (short delay times, high output slew rate, and relative immunity to large overdrive) come at the expense of the properties that make op-amps useful (in particular, careful control of phase shift versus frequency). Comparators are not frequency-compensated (§4.9) and cannot be used as linear amplifiers.

12.3.1 Outputs

We're used to op-amps, where the output can swing rail-to-rail (or nearly so), but where we usually stay in the linear region, deliberately avoiding saturation at the extremes of output swing. When the output is saturated, we're in trouble!

But comparators are different. Although the inputs are analog, the output is digital: it *lives* at the extremes. So what you care about is what the output does when LOW and when HIGH. As we've seen, the output may drive digital logic directly (Figure 12.25), in which case we need to bound its swing to that of the driven logic. Or we may want to drive an ON/OFF load, for example a relay (mechanical, or solid-state) or a bright LED, requiring plenty of output current, and perhaps powered from an external dc supply.

A. Output swing

Figure 12.33 shows the choices you've got to meet these various demands. In each case the comparator's analog circuitry is powered from a pair of supplies, V_+ and V_- (though for "single-supply" comparators, analogous to single-supply op-amps, the negative supply voltage V_- is ground). We'll have more to say soon about the input stage. What's interesting here are the output stages: one variety of comparators simply swing their output from rail to rail

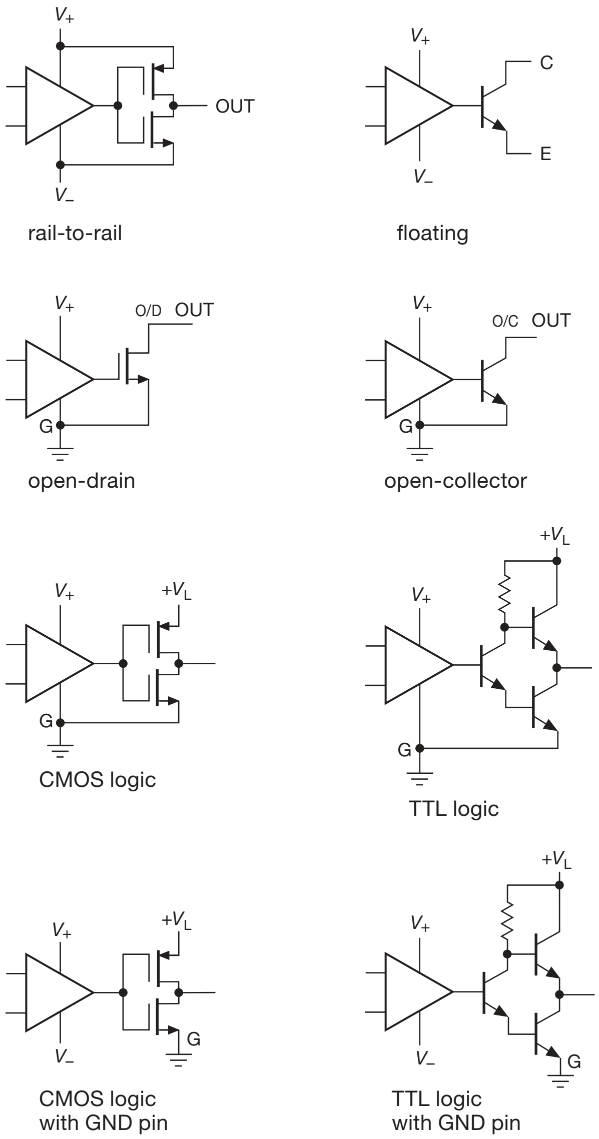

Figure 12.33. Don't let comparators confuse you: use this chart of simplified output stages, along with the listing in Tables 12.1 and 12.2.

("RR" in Tables 12.1 and 12.2), which is fine if that works for your application (e.g., if V_+ is +5 V, V_- is ground, and the output drives 5 V logic, or 5 V-tolerant logic; see Figure 12.25D). And the active pullup has the advantage of speed. But you may want to accommodate inputs that swing both sides of ground ("bipolarity") while driving digital logic (with its single positive supply), in which case you need to have V_- below ground; and so the right choice is either a comparator with floating output ("FL" in the tables) with resistive pullup (as in Figure 12.25A), or a comparator with separate GND and V_L (logic voltage) pins ("RR-G" and "TTL" in the tables), as shown in Figure 12.25B.

Finally, if you're interested in single-supply operation, with input signals only between ground and a positive supply V_+, you can use (a) logic-output types with active pullup to a logic voltage V_L ("RR-G" or "TTL" in the tables); or (b) if V_+ is a low logic voltage already, you can use a rail-to-rail comparator with V_- connected to ground (as mentioned above); or (c) you can use a comparator with open-drain or open-collector output ("OD" or "OC" in the tables), with pullup to a logic supply (as shown in Figure 12.25E). The open-collector style is nice for driving power loads, or loads connected to a high output voltage (e.g., the classic LM311 can sink up to 100 mA, and its output can be pulled up to +40 V); but passive pullup is slow (compared with active pullup), so you're better off with a logic-output type when driving digital logic, unless you don't care about speed.

B. Output current

Comparators vary widely in their output-current capability. When driving digital logic this doesn't much matter, but it's important when driving high current loads such as relays or LEDs. Figure 12.34 shows how it goes, for most of the open-collector and open-drain comparators in Table 12.1. You can see some interesting trends here: (a) comparators with MOSFET outputs (e.g., the TLC393) behave resistively (R_{on}) at low voltages, trending downward

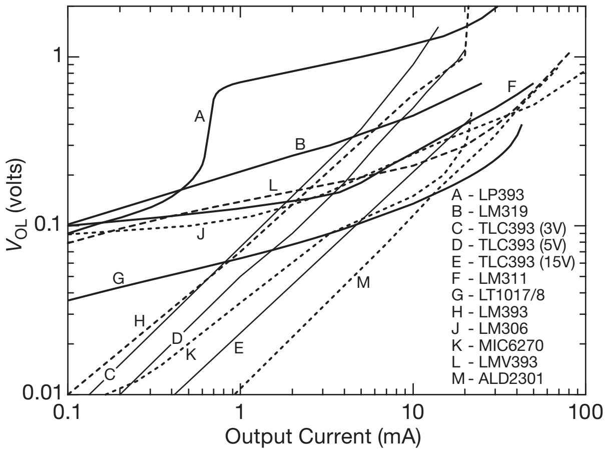

Figure 12.34. Saturated LOW output voltage versus sinking current, for a selection of open-collector and open-drain comparators. The popular TLC372-series is similar to the TLC393. Data are compiled from datasheet graphs, except for curve L and the low-current end of curves B and J, which were measured.

Table 12.1 Representative Comparators[a]

						Supply voltage						
			Input					Total				
	t_d	V_{OS}	current			V_+	V_-					
	typ	max	typ	CM to neg rail?	CM to pos rail?	max	max	min	max	Supply curr (mA)	Output type[b]	
Type	(ns)	(mV)	(nA)			(V)	(V)	(V)	(V)			Comments
LM393	600	5	25	●	-	36	-	2	36	0.4	OC	jellybean dual
TLC372	650	5	0.005	●	-	18	-	3	18	0.15	OD	cmos dual; quad=374
TLC3702	2500	5	0.005	●	-	16	-	3	16	0.02	RR	cmos dual; quad=3704
LM311	200	3	60	-	-	30	−30	4.5	36	5	FL	strobe, popular; dual=2311
LT1016	10	3	5000	-	-	7	−7	5	14	25	TTL	fast, stable
AD8561	7	7	3000	●		7	−7	3.5	14	5.6	TTL	improved 1016; quad=8564
TLV3501	4.5	6.5	0.002	●	●	5.5	-	2.7	5.5	3.2	RR	fast; dual=3502

Notes: (a) See also the more extensive listing in Table 12.2. (b) See "Comparators, Outputs" in text; FL = floating *npn* output, collector and emitter output pins; OC = open collector; OD = open drain; RR = rail-to-rail; TTL = logic swing, separate V_L pin.

to the left with unit slope; (b) comparators with bipolar *npn* output stages (e.g., the LT1017/8) tend toward a finite saturation voltage; and then there is (c) the LP393, which has a bipolar-output stage that behaves like a Darlington at higher currents (with saturation around a V_{BE}, or ∼0.6 V), but becomes a simple grounded-emitter switch at low currents, which explains the weirdly gyrating curve.

The LM311's curve is worth an additional comment. The designers used a cute "antisaturation" circuit in the output stage (Figure 12.35): the series-connected V_{BE} drops of Q_{13} and Q_{14} are poised to rob base current from driver Q_{12} if Q_{15}'s collector gets too close to its emitter. If R_{11} were zero, this would happen just as Q_{15} saturates (figure out why!). But adding R_{11} causes this clamping action to occur when there's still about 20% of a V_{BE} across Q_{15}. This prevents deep saturation, which has two benefits: (a) it eliminates excessive turn-off delay caused by stored base charge in the output transistor; and (b) it reduces power consumption, by providing no more base drive to Q_{15} than is needed to bring it nearly to saturation, for whatever load it is driving.

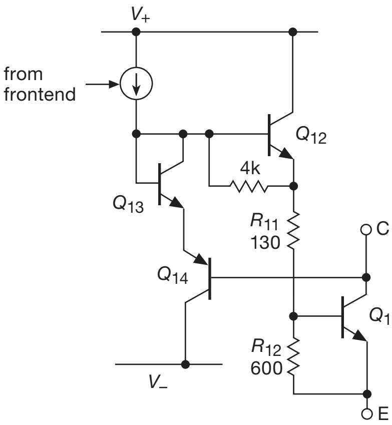

Figure 12.35. The output stage of the LM311 comparator incorporates a clever antisaturation circuit that limits base drive current when the output transistor is near saturation (V_{CE}≈100 mV). We've omitted here the output-stage current-limit circuit. Courtesy of Texas Instruments.

12.3.2 Inputs

A. Input common-mode range

Just as with op-amps, you've got to keep input voltages within the operating common-mode range. Comparators designed for low-voltage single-supply operation (in the range of 3–5 V; see Table 12.1) allow inputs to go to ground (or even a few tenths of a volt below), and some also work to the positive rail ("rail-to-rail" inputs). Examples are the TLC372/3702 and LMC7221/7211, respectively (with OD and RR versions listed in each pair). But these won't work with signals of both polarities (unless of course you tie the "ground" pin to a negative supply voltage, in which case you may be unhappy with an output that swings down to the negative supply). Instead you must use a dual-supply comparator (e.g., LM311, LT1016), many of which do not operate with inputs at or near the rails. Tables 12.1 and 12.2 include the common-mode operating range for the listed devices.

B. Offset voltage and trim

As with op-amps, garden-variety comparators have offset voltages in the millivolt range. You can do better with one of the "precision" comparators, from companies

Table 12.2 Comparators[a]

Notes: (a) ordered by supply voltage groups, then by speed. (b) note V_{diff}(max) ≪ Vsupply. (c) limited to 7V total analog supply voltage. (d) OK to rails, but 8.2kΩ for V_{diff} > 1V. (e) total, for listed part number. (f) back-to-back pairs of 2 clamp diodes, with 200Ω series resistor. (g) see "Comparators, Outputs" in text. (h) the first number corresponds to the listed part. (n) nominal. (t) typical.

like Analog Devices, Linear Technology, and Maxim; see Tables 12.1 and 12.2. A few comparators include external trim terminals; but, as with op-amps, an inexpensive trimmed comparator (e.g., an LM311) will have much larger tempco of V_{os} than an intrinsically accurate (i.e., precision) part. For example, the LT1011A "improved LM311" specifies a V_{os} tempco of 4 μV/°C, typ (15 μV/°C max), whereas for the generic LM311 none of the half-dozen manufacturers even bothers to specify it. In applications where you care about accurate input thresholds, it's always best to avoid heavy loads at the comparator's output.

Here's an interesting riff on offset voltage: thermal gradients set up on the chip from dissipation in the output stage can degrade input offset voltage specifications. In particular, it is possible to have "motorboating" (a slow oscillation of the output state) take place for input signals near zero volts (differential), because the state-dependent heat generated at the output can cause the input to switch.

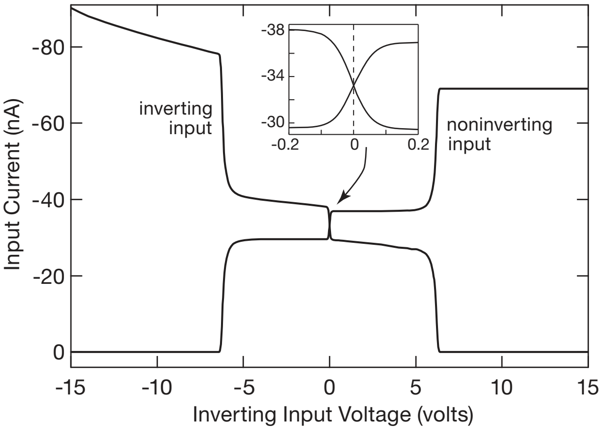

Figure 12.36. Measured input current of a specimen LM311N (NSC, with date code P134), with the noninverting input held at ground. The datasheet specifies an input current of 60 nA (typ), 100 nA (max).

C. Input current

Here, also, familiarity with op-amps can lead to trouble if you assume (incorrectly) that the inputs present essentially infinite impedance, and draw no current. An important feature of comparator inputs is the bias current at the input terminals and the way it changes with differential input voltage. For a wake-up call, look at Figure 12.36, a plot of measured current at the two inputs of the ever-popular LM311.[18] *It isn't zero!*

What's going on here? Many comparators use bipolar transistors for their input stages, with input bias currents ranging from tens of nanoamps to tens of microamps. Because the input stage is just a high-gain differential amplifier, the bias current changes as the input signal takes the comparator through its threshold. In addition, internal protection circuitry may cause a larger change in bias current a few volts away from threshold.

To see how this works in detail, look at the LM311's input circuit, which we've drawn in simplified form in Figure 12.37. The input stage consists of current-biased *pnp* followers driving an *npn* differential amplifier; the followers have an impressive $\beta{\approx}2000$, but even with that you've still got -35 nA of input current when the inputs are balanced. Of greater concern, the currents at the two inputs shift in opposite directions by roughly 10% when the inputs become unbalanced. This happens because the second-stage differential amplifier transfers its operating current over to one side or the other, unbalancing its base current loading on the first stage. (The current "step" at zero volts differential is actually a smooth transition taking place over 100 mV or so, as seen in the expanded inset graph, and represents the voltage change necessary to switch the input differential amplifier stage fully from one state to the other.) So, unlike an op-amp (where feedback keeps the inputs balanced), a bipolar comparator's input current shifts at the input transition, which can cause trouble if the signal driving it is not of low source impedance.

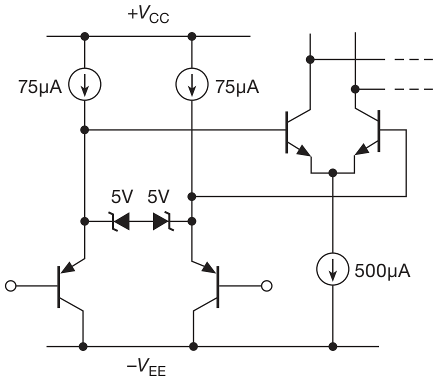

Figure 12.37. Simplified input stage of the classic LM311 bipolar analog comparator. Don't be alarmed by the 5 V zeners – the maximum allowed differential input is ±30 V.

For example, imagine you want to generate an output step when a slowly rising input signal (of finite source resistance) passes through zero volts. That's easy – you

[18] This is a true jellybean! A quick Internet search found at least a hundred 311 variants from a half-dozen manufacturers (Fairchild, NJR, National, ONsemi, ST, and TI), not even including "improved" 311s.

connect that signal to the inverting input, and you ground the noninverting input. Do this, and the output will likely exhibit fast multiple transitions as the input signal crosses through zero. The problem is that the drop in (negative) input current at zero volts causes the input voltage to reverse its rise, causing an extra transition; this continues several times, until the input signal has risen clear of the danger zone. Hysteresis (perhaps with a small speed-up capacitor) will generally cure this behavior, but it's helpful to understand its cause.

The graph in Figure 12.36 has some more surprises, namely the abrupt change in input currents when the differential input voltage reaches 6 V. This is caused by the symmetrical zener[19] clamp, included in the IC to prevent reverse base–emitter breakdown in the second-stage *npn* pair. Differential-input swings large enough to bring the clamp into conduction cause the *pnp* input transistor with the more negative input voltage to hog all the emitter current; so its base current doubles, and that of its twin drops to zero. The accurate graph of Figure 12.36 shows a feature you won't find in any of the official LM311 datasheets, namely the gradual increase in input current at large negative input voltages; this is evidently due to decreasing input-transistor beta at reduced V_{CE}. And a puzzle for the reader: why is this shape not mirrored in the noninverting input curve?

For comparator applications where extremely low input current is necessary, there are plenty of MOSFET-input comparators available, for example the TLC372, TLC3702, TLC393, and LMC7221. However, these are generally limited to a maximum total supply voltage of 16 V (compared with 36 V for "high-voltage" bipolar comparators); and, as with CMOS op-amps, they have poorer accuracy (V_{OS}) than precision bipolar comparators. In situations where the properties of a particular comparator are needed, but with lower input current, one solution is to add a matched-pair FET follower at the input.

D. Maximum differential-input voltage

Watch out for this one! Some comparators have a surprisingly limited differential input voltage range, as little as 5 V in some cases (e.g., the AD790, LM306, and LT1016), even though they can operate from a total supply voltage ($V_+ - V_-$) as high as 36 V. It may be necessary to use diode clamps to protect the inputs, because excessive differential input voltage will degrade beta, cause permanent input offset errors, and even destroy the base-emitter junctions of the input stage. General-purpose comparators that can operate from total supply voltages up to 36 V are generally better in this respect, with typical differential-input voltage ranges of ±30 V (e.g., the LM311, LM393, LT1011, etc.[20]).

E. Internal hysteresis

A little bit of hysteresis is usually a good thing. And some comparators (notably those intended for low-voltage single-supply operation) have a few millivolts of built-in hysteresis (see Tables 12.1 and 12.2). Some comparators (e.g., members of the ADCMP5xx and 6xx series from Analog Devices) permit adjustment of the amount of internal hysteresis.

12.3.3 Other parameters

A. Supply voltage

We've seen this already, because inputs have to stay in the "common-mode operating range," which at most extends slightly beyond the rails. Roughly speaking, there are three voltage ranges: (a) traditional bipolar comparators like the LM311 and LM393 can accept total supply voltages up to 36 V, and are now called "high-voltage" comparators; (b) a number of high-speed and CMOS comparators, for example the bipolar LT1016 and CMOS TLC/LMC parts, sit in a middle region, operating on total supply voltages up to 10–15 V; and (c) there has been a tremendous proliferation of "low-voltage" single-supply CMOS comparators like the LMV, TLV, and ADCMP600 series, which operate only to 6 V total supply. In the latter category there are some wickedly fast comparators (ADCMP572: 0.15 ns), and some micropower comparators (MCP6541: 0.6 μA typ; ISL28197: 0.8 μA typ). And there's pretty much everything in between.

B. Speed

It is convenient to think of a comparator as an ideal switching circuit for which any reversal in the differential-input voltage, however small, results in a sudden change at the output. In reality, a comparator behaves like an amplifier for small input signals, and the switching performance depends on the gain properties at high frequencies. As a result, a smaller input "overdrive" (i.e., more than enough signal to cause saturation at dc) causes a greater propagation delay and (often) a slower rise or fall time at the output. Comparator specifications usually include a graph of

[19] Implemented as a pair of back-to-back diode-connected transistors.

[20] These use integrated *pnp* input transistors, which tend to have high reverse emitter-base breakdown voltages, often more than 36 V (compared with typical *npn* breakdown around 6 V).

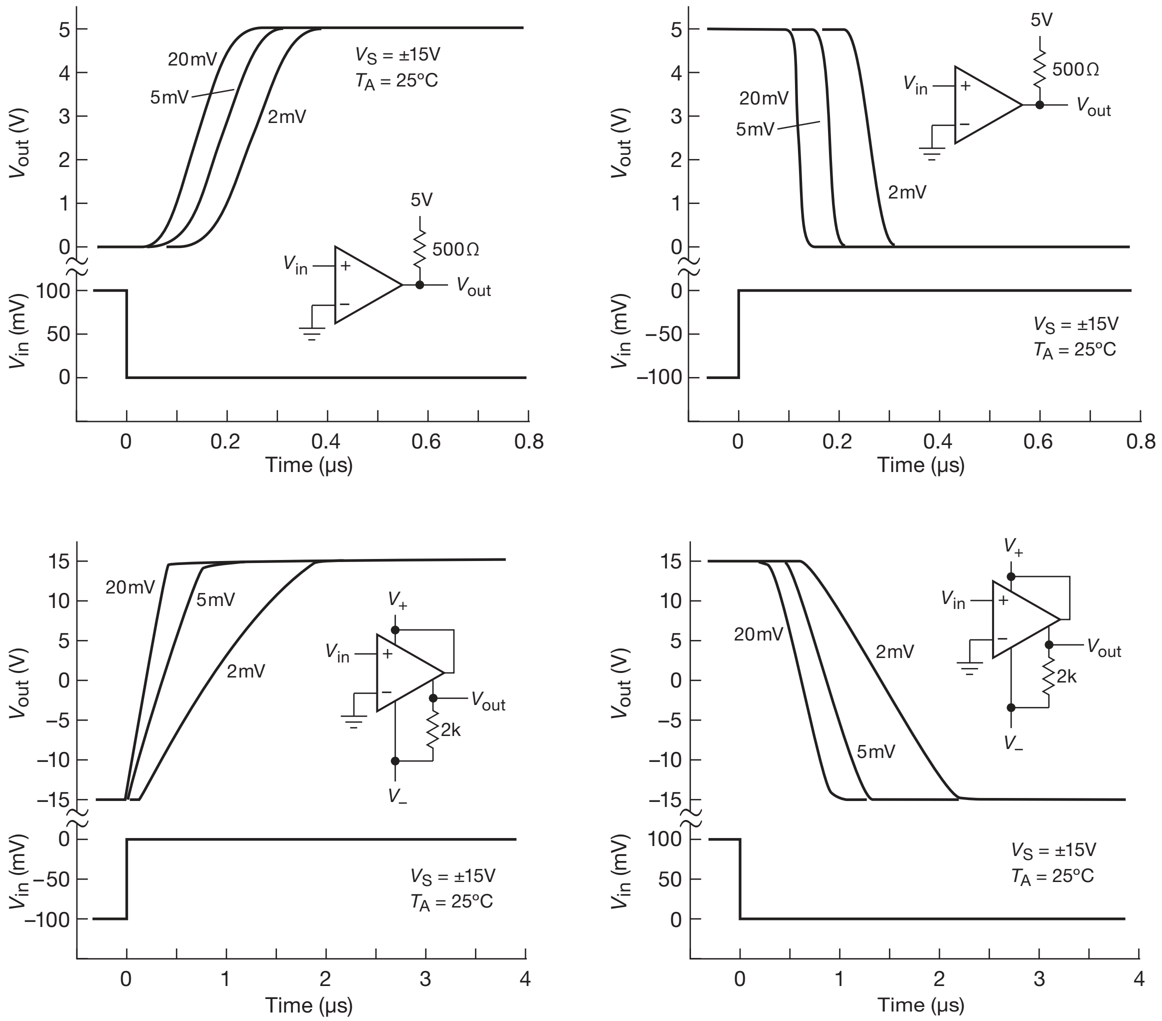

Figure 12.38. LM311 comparator response times for various input overdrives. Most comparators require considerable overdrive, 20 mV or more, for fast response. (Adapted from National Semiconductor Corp.)

"response times for various input overdrives." Figure 12.38 shows some for the LM311. Note particularly the reduced performance in the configuration in which the output transistor is used as a follower, i.e., with less gain. Increased input drive speeds things up because the amplifier's reduced gain at high frequencies is overcome by a larger signal. In addition, larger internal amplifier currents cause internal capacitances to charge faster.

The comparators in Tables 12.1 and 12.2 span a range of speeds (response time) from 0.3 ns to 300 μs – a ratio of a million to one! Haste makes waste – you pay the price in power dissipation (though low-voltage parts do much better), and in susceptibility to oscillations.

12.3.4 Other cautions

There are some general cautions concerning input circuits of comparators. Hysteresis (§4.3.2A) should be used whenever possible, because erratic switching is otherwise likely to result. To see why, imagine a comparator without hysteresis in which the differential-input voltage has just passed through zero volts, slewing relatively slowly, since it is an analog waveform. A mere 2 mV input differential causes the output to change state, with switching times of 50 ns or less. Suddenly you have 3000 mV fast digital-logic transitions in your system, with current pulses impressed on the power supplies, etc. It would be a miracle if some of these fast waveforms didn't couple into the input signal, at least to the extent of a few millivolts, overcoming the 2 mV input differential and thus causing multiple transitions and oscillations. This is why generous amounts of hysteresis (including a small capacitor across the feedback resistor), combined with careful layout and bypassing, are generally required for making sensitive comparator circuits function well. It is usually a good idea to avoid driving comparator inputs directly from high-impedance signals; use an op-amp output instead. It is also a good idea to avoid high-speed comparators, which only aggravate these problems, if speed is not needed. Then, too, some comparators are more troublesome in this regard than others; we have had plenty of headaches using the otherwise admirable LM311.

12.4 Driving external digital loads from logic levels

It isn't hard to use a logic-level output signal (coming from something as simple as a gate or a flip-flop, or from a fancier device like an FPGA or microcontroller) to control on/off devices like lamps (LEDs), relays, displays, and even ac loads. In some situations you can drive such loads directly from the logic-level signal; but more often you've got to add a few components to make it work. A classic example of the latter might be switching a load that returns to a *negative* supply voltage.

12.4.1 Positive loads: direct drive

Loads that don't require too much current and that return to a low-voltage positive supply can often be driven directly from a logic output. Figure 12.39 shows some methods. Circuit A shows the standard method of driving LED indicator lamps from logic running from a 3–5 V supply. You choose the current limiting resistor to set the LED current: LEDs behave like a diode with a forward drop of 1.5–3.5 V (depending on the semiconductor material and emitted color; see Figure 2.8). Contemporary high-efficiency LEDs look pretty bright at just a few milliamps, which is easy work for all logic-family outputs (as well as more complex digital chips such as FPGAs and microcontrollers); so the logic output stays valid even while driving the LED load (see the listed V_{OL} values). One caution here: the forward drop of ∼3.5 V of GaN-based LEDs (blue, white, and "bright green") requires 5 V logic, whereas lower-voltage LEDs can be driven by 3.3 V or 5 V logic.

For historical reasons connected with the highly asymmetrical output properties of earlier bipolar and nMOS logic families, designers tend to prefer the current *sinking* connection of Figure 12.39A; but for contemporary CMOS logic families it's OK to connect an LED in the sourcing configuration of Figure 12.39B. The output sourcing is somewhat less muscular than sinking (see the listed V_{OH}), but it's plenty good enough for the job.

Some panel-mount LEDs come with built-in current limiting resistors, intended for direct 5 V voltage drive. This saves a resistor, but the selection is limited, and you may not be happy with the manufacturer's choice of operating current (e.g., 10–12 mA for the CML 5100H-LC-series, or the Dialight 558-series).

You can drive small mechanical relays in a similar manner, providing their coil operating voltage is low (there are plenty of 5 V dc units, from Coto, Omron, Panasonic, Tyco-P&B, and other suppliers; and you can get relays that operate on as little as 1.5 V, for example the TXS2 series from Panasonic), and their operating current is low enough (i.e., high coil resistance). Figures 12.39C–F show several examples. "Signal" relays like the TXS2 series are intended for switching low voltage and current, and they have gold-plated contacts for "dry switching" (see §*1x.6*); their coil current of 10–20 mA can be sunk by the logic families shown (and others as well). You can also get logic-drivable relays that can handle power switching, for example the Omron G5- and G6-series 5 V-coil relays shown in the figure. These can handle up to 5 A when switching 115 Vac (or even 240 Vac) power.

For relays (and other loads) that require somewhat higher drive voltages or currents, you can use logic devices with open-collector outputs intended for that kind of job (Figures 12.39G,H). The venerable 74LS07 is an OC hex inverter good for output swings to +30 V and (LOW-state, sinking) load currents to 40 mA. The equally crusty (and wildly popular) ULN2003 is a 7-section ("heptal"?) grounded-emitter Darlington with input resistors (i.e., a logic inverter with open-collector) that can swing to +50 V and sink up to 350 mA; its equally muscular close cousin (the 75468) can swing to +100 V.[21] And if you want to drive these kinds of loads with a comparator, the vintage LM311 or LM306 can handle those kinds of currents, though the open-collector output swing is limited to 40 V above the negative supply, and +24 V above ground, respectively.

When driving relays and other power loads from a microcontroller (Chapter 15), it's worth knowing about a class of serial-input power registers. These are elaborations of the '595 8-bit serial-in parallel-out logic shift register, but

[21] On a more modest scale you can use the 75451–4 dual open-collector gates (AND, NAND, OR, and NOR, respectively) in 8-pin packages for loads to 30 V and 300 mA.

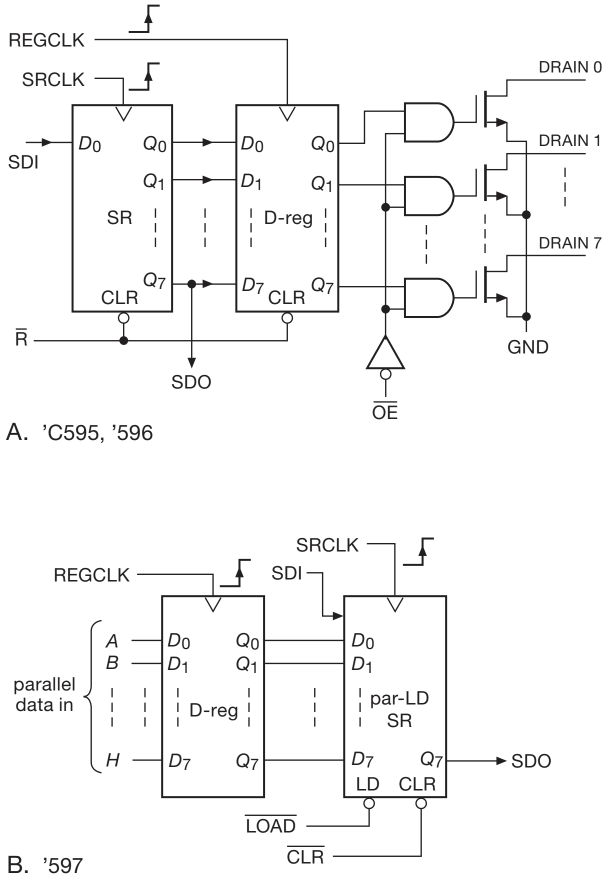
	V_{OH}(min)	V_{OL}(max)
'LVC (3V)	2.4V@16mA	0.4V@16mA
'LVC (4.5V)	3.8V@32mA	0.55V@32mA
'HC (4.5V)	4V@4mA	0.26V@4mA
'AC (4.5V)	3.9V@24mA	0.36V@24mA

Figure 12.39. Driving loads directly from logic outputs. Relay coils can demand a lot of drive current; be sure your choice of driver IC can deliver.

with open-drain outputs capable of sinking substantial currents, and with voltage ratings up to 50 V. Table 12.3 lists a nice selection of these, and Figure 12.40 shows what's inside these output devices, along with the companion '597 *input* register (i.e., parallel-in, serial-out). These are particularly helpful when you have a microcontroller with only a few I/O pins available because you can drive lots of power-hungry outputs (e.g., relays); and you can expand beyond eight outputs by chaining the SDO (serial data out) from one register to the SDI (serial data in) of the next. Figure 12.41 shows the basic idea.

A few points about relays in general, and these small easy-to-drive PCB-mounting relays in particular.

- Note that you don't ordinarily use a series resistor, because the coil's resistance sets the operating current at the rated operating voltage; add a series resistor, though,



A. ’C595, ’596

B. ’597

Figure 12.40. The ’595 and ’596 serial-input power registers accept a logic-level bit-serial input, clocked into an internal shift register; the contents can be latched in an output D-type register with substantial drive capability. The ’597 works the other way around, but accepts logic-level inputs only. See Table 12.3 for details.

if you’re running from a higher supply voltage (e.g., a 12 V relay operating from a 15 V supply). In any case, be sure to include the diode to clamp the inductive spike.[22]

- Relays are always available in the normal “single-side stable” (also known as *non-latching*) configuration, in which the contacts are held in the energized position only while coil power is being applied. But you can also get “latching” relays, which remain in whichever state they have been sent after the coil drive is removed. There are two varieties of latching relays: “dual coil” (you drive one or the other, to set and reset the state), and “single coil” (you apply one polarity or the other, to set and reset). Latching relays are a good choice for something like a battery-powered lamp timer, because you need to

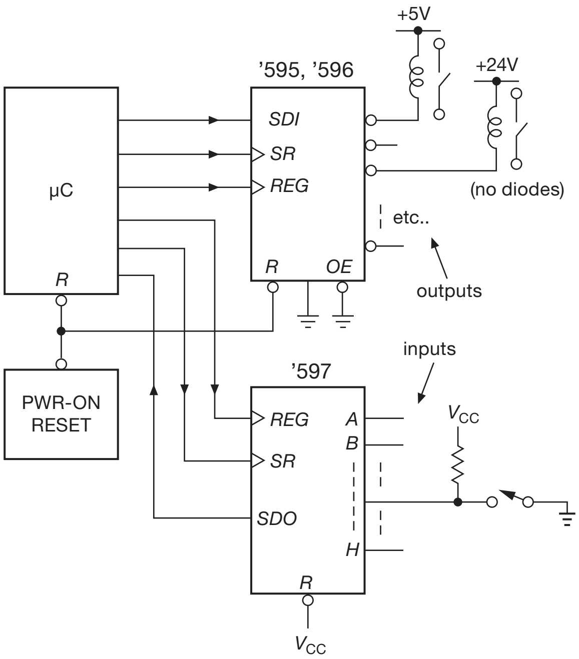

Figure 12.41. Driving relays and other power loads with a serial power register.

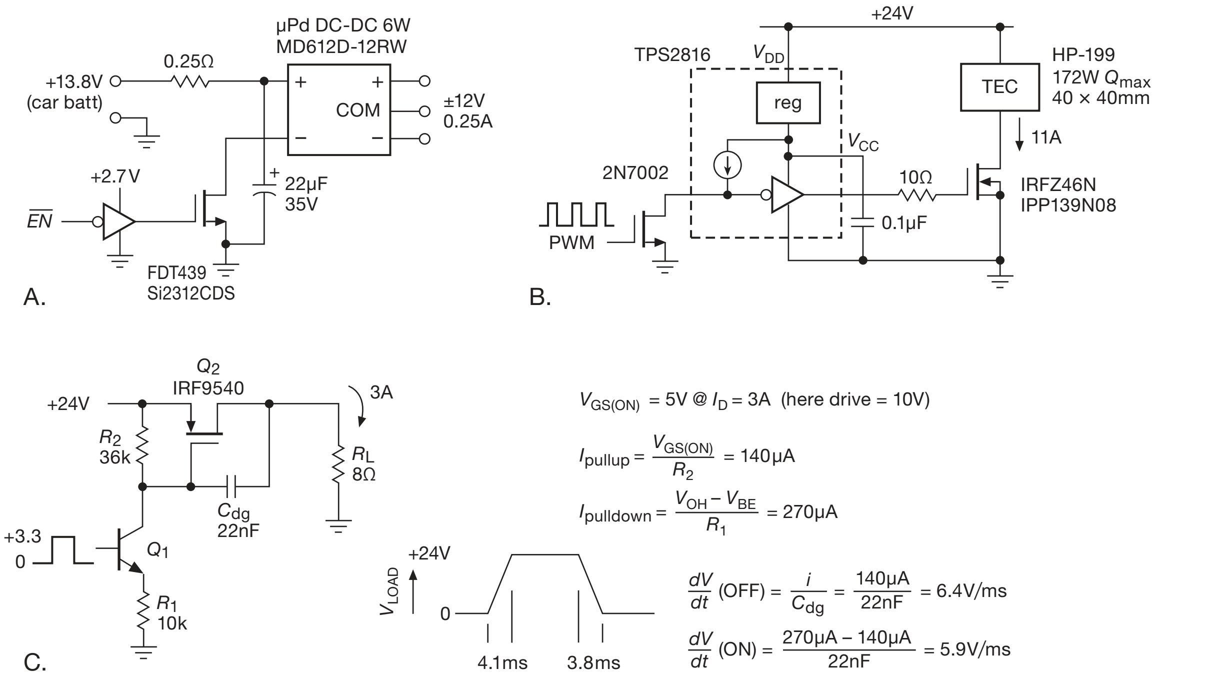
[22] Some driver parts include a diode, while other specifically give you an avalanche rating for the output MOSFET (with which to absorb the relay coil’s flyback spike). For example, the ’6B595 parts specify each output at 33 V and 30 mJ (some others allow 75 mJ), enough to handle the $E{=}LI^2/2$ inductive energy stored in a large coil. Always read the datasheet carefully.



$V_{GS(ON)}$ = 5V @ I_D = 3A (here drive = 10V)

$$I_{\text{pullup}} = \frac{V_{GS(ON)}}{R_2} = 140\mu\text{A}$$

$$I_{\text{pulldown}} = \frac{V_{OH} - V_{BE}}{R_1} = 270\mu\text{A}$$

$$\frac{dV}{dt}\text{(OFF)} = \frac{i}{C_{dg}} = \frac{140\mu\text{A}}{22\text{nF}} = 6.4\text{V/ms}$$

$$\frac{dV}{dt}\text{(ON)} = \frac{270\mu\text{A} - 140\mu\text{A}}{22\text{nF}} = 5.9\text{V/ms}$$

Figure 12.42. Some MOSFET switching examples: A. load with high inrush current (dc–dc converter); B. rapid (pulse-width modulation) switching of high-current thermoelectric module (the 2N7002 is needed because the TPS2816's internal pullup generates a 12 V input logic swing when powered from V_{DD}=24 V); C. high-side switching with controlled slew rate; the MOSFET Q_2 has full 10 V gate drive after a few milliseconds.

apply only a short energizing pulse (typically ∼10 ms minimum) to switch the load ON or OFF.[23]

- Single-coil latching relays evidently respect the polarity of the dc coil drive. But be aware that many of the normal (single-side stable) relays in these easy-to-drive PCB-mounting configurations also require that coil voltage be applied with correct polarity; it will be indicated on the datasheet, and usually with polarity markings on the relay body – and they mean it!

12.4.2 Positive loads: transistor assisted

With an external MOSFET or bipolar transistor you can drive just about anything. Look back at §3.5.3 (Figure 3.96) for some MOSFET drive circuits good for loads to hundred of volts and tens of amperes. MOSFETs (or insulated gate bipolar transistors, IGBTs; see §3.5.7) are the transistors of choice for such robust applications. They are also handy for "high-side" switching, as we saw in §3.5.6 (Figure 3.106).

Figure 12.42 shows some additional configurations. The challenge in the first circuit is to handle the relatively large inrush current at startup of the dc–dc converter (5 A peak, compared with 0.8 A while running at full power). The mighty FDT439, in its small SOT-223 case, guarantees a maximum R_{ON} of 0.08 Ω at V_{GS}=2.5 V (where its saturation drain current is around 20 A; see Table 3.4a). So it handles the inrush current with ease. The small input resistor and downstream bypass capacitor are included to filter switching noise and to isolate the turn-on transient to minimize disturbance of other electronic systems running from the car battery.

The challenge in circuit B is to do fast switching of a high power load (a thermoelectric cooling module), controlled by adjusting the duty cycle of its ON pulses (PWM, pulse-width modulation). Here we needed a hefty power MOSFET, and plenty of gate drive to switch the gate capacitance rapidly through its threshold (to minimize switching losses). The TPS2816 is a nice gate driver (see Table 3.8), with output HIGH voltage of +10 V (and peak current capability of ±2 A), and with a built-in regulator for

[23] We installed several Intermatic ST01C "Digital In-Wall Timers" to control our exterior home lighting. These puppies include enough brainpower to compensate for seasonal variations in dusk and dawn, and they happily switch 15 A 120 Vac loads, using only a single CR2 lithium battery. We could hardly wait to crack one open, and voilà – a latching relay!

operation from supply voltages to +40 V. The power MOSFETs shown are good to 30 A drain current, and come in power surface-mount packages (D^{2}Pak, TO-252, TO-262).

Finally, circuit C shows a high-side switch with controlled slew rate, to minimize production of transients. It's OK to switch power on time scales of milliseconds, as long as you don't try to do it at a high rate (as in PWM), and as long as the switch can handle the transient thermal pulse.[24] The slew rate is set by the gate drive current charging and discharging a "Miller capacitor" C_{dg}, here arranged for approximately equal net charging and discharging currents. The calculations in the figure say it all (five equations are worth a thousand words).

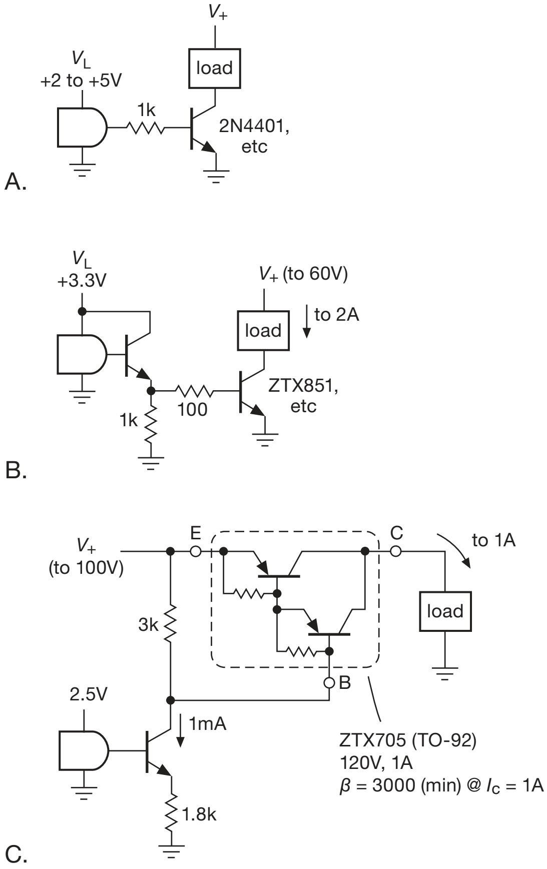


Figure 12.43. Bipolar transistors extend the voltage and current drive capability. Ditto for power MOSFETs – see Figures 3.96 and 12.42.

On a more modest scale you can use bipolar transistors (BJTs) for these same tasks, for example as shown in Figure 12.43. Something like a jellybean 2N4401[25] (about $0.06 in 100 qty) is good for up to +40 V and 500 mA; but beware – the minimum beta drops to 40 at that current, so you'll need to resize the series resistor to provide upward of 10 mA of base drive into the transistor's V_{BE}. And even then, the saturation voltage is not stunning: V_{CE}(sat)=0.75 V (max) at 500 mA with 15 mA of base drive (therefore 0.25 W transistor dissipation). A better choice for such currents is something like the ZTX851 from Zetex, which comes in a TO-92 variant that they call "E-line." It's good for 60 V and 5 A, minimum beta of 100 at 2 A, and V_{CE}(sat)=0.15 V (max) at 2 A with 50 mA of base drive. That's about the same dissipation as the 2N4401, but at four times the load current. To get the base drive you'd use an emitter follower driver, as in Figure 12.43B.

You can easily rig up a BJT as a high-side switch by using a logic-switched *npn* current sink to forward bias a high-side *pnp* switch (Figure 12.43C). Here we've used a Darlington from Zetex's excellent E-line series of BJTs, requiring only a milliamp of base drive to switch up to an amp of load current (where $V_{\mathrm{CE}}(\mathrm{sat}) \leq 0.75$ V).

In these examples we've not worried about protecting the switches from fault conditions such as a shorted load. This should not be ignored; and we won't – see §12.4.4, coming up shortly.

12.4.3 Negative or ac loads

Figure 12.44 shows some methods by which a logic input can control loads that return to a negative supply rail; also shown is a common interface from logic to an ac power load. In circuits A and B a HIGH output state turns on the *pnp* transistor switch, pulling the collector into saturation at one diode drop above ground. In circuit A, the resistor (or gate output-current limit) sets the emitter current, and therefore the maximum collector (load) current, whereas in the more powerful circuit B, an *npn* follower is used as a buffer, and a diode in series with the output keeps the load from swinging above ground. In both cases the maximum load current is equal to the drive current to the *pnp* transistor's emitter. Circuit C requires a low-voltage negative bias supply voltage ($-V_{\mathrm{bias}}$), but has the advantage of saturating cleanly to ground, and with a power MOSFET it can

[24] Datasheets specify a "transient thermal impedance" from junction to case, which for these transistors is about 0.5°C/W at millisecond time scales, fine for the 18 W (maximum) dissipation during switching. More on this in §*3x.13*.

[25] The 2N prefix is for the through-hole TO-92 package. For surface mount, the base part number becomes MMBT4401, with crazy suffixes for the different surface-mount packages (SOT-23, SOT-323/SC70, SOT-523, SOT-723).

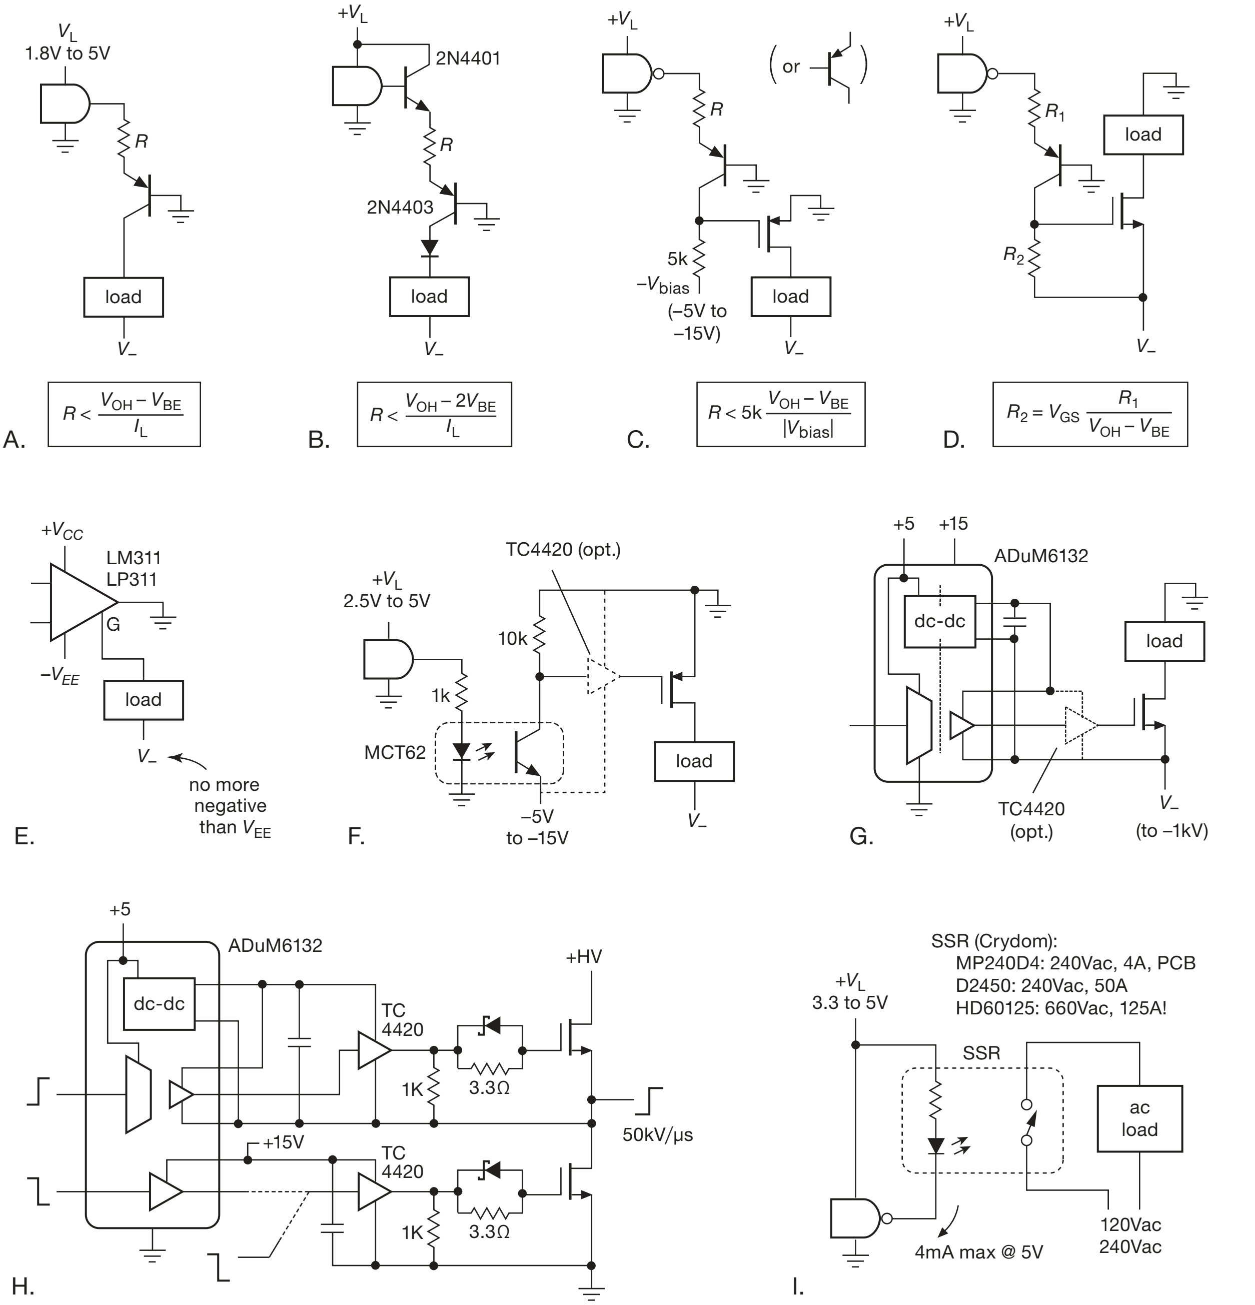

Figure 12.44. Driving negative and ac loads.

handle very large load voltages and currents, even when driven by low-voltage logic of minimal output drive current (but you may want to add a MOSFET gate driver IC, as in circuits F–H: its high current capability rail-to-rail output produces much faster switching into the MOSFETs large gate capacitance). Circuit D shows how to drive a ground-returned load to a negative voltage; this has the pleasant property of not requiring a separate low-voltage negative supply. Circuits like this do not provide protection against load faults; be sure to read §12.4.4, which deals with this important issue.

Comparators with a floating output (LM311 and cousins) can drive modest negative-referred loads, as in circuit E; but the negative return cannot be more negative than the comparator's negative rail, and the current is limited to 50 mA. Circuit F shows how to use an optocoupler (see §12.7) to translate a positive logic output to a negative-going level that can drive a *p*-channel power MOSFET gate directly (or through a MOSFET gate driver, for faster switching; see Figure 3.97). Because *n*-channel MOSFETs are better performers (lower $R_{\rm ON}$ and available up to 1000 V rating, compared with −300 V for pMOS), it's nice to be able to use them whenever you can. Circuit G does this by generating a gate drive signal down at the V_- rail, using the elegant ADuM6132 logic isolator from Analog Devices. The latter uses tiny on-chip transformers to generate both an isolated (floating) dc supply voltage, and also to couple the input logic signal to a similarly isolated output. Once again, you can interpose a MOSFET gate driver, powered by the same isolated power.

As an aside, circuit H shows how to use the same ADuM6132 to generate a *high-side* gate drive, so that you can use *n*-channel power MOSFETs for both switches in a high-voltage push–pull output stage. This isolator chip is notable for its ability to work properly even when the isolated output is flying around at slew rates up to 50 kV/μs. Note that the high-side MOSFET, though it looks like a follower, is actually a switch, because its gate is either at the same voltage as its source (when OFF), or it is 15 V above the source (when ON).

Finally, for driving ac loads the easiest method is to use a "solid-state relay," as in circuit I. These are optically coupled triacs, SCRs, or IGBTs with logic-compatible input and 1–50 A (or more!) load-current capability when switching a 115 Vac (or more!) load. The low-current varieties are available in SMT and DIP packaging (e.g., the photoMOS series from NAiS Aromat, the MOSFET relays from Omron, and the PV series of "photovoltaic switches" from International Rectifier; see §12.7.5 and 12.7.6 for more choices), while the heftier ones come as a chassis-mounting rectangular block roughly 2 inches square.[26]

Alternatively, you can switch ac loads with an ordinary relay, energized from logic. However, be sure to check the specifications, because most small logic-driven relays cannot drive heavy ac loads, and you may have to use a MOSFET or logic relay to drive a second larger relay. Most solid-state relays use "zero-crossing" (or "zero-voltage") switching, which is actually a combination of zero-voltage turn-on and zero-current turn-off; it is a desirable feature that prevents spikes and noise from being impressed onto the powerline. Much of the "garbage" on the ac powerline comes from triac controllers that don't switch at zero crossings, e.g., phase-controlled dimmers used on lamps, thermostatic baths, motors, etc. As an alternative to the optical coupling used internally in circuit I, you sometimes see a pulse transformer used to couple triggering pulses to a triac or an SCR.

12.4.4 Protecting power switches

In these switch examples we've sidestepped an important topic: when driving power loads, you must worry about any of a variety of possible "fault conditions," for example a short-circuited load. This can happen more easily than you might expect, particularly with external loads wired through connectors and cables. Without some protective circuitry, the MOSFET is easily (and rapidly) destroyed, perhaps taking with it some additional circuitry. Let's take a closer look.

Figure 12.45 shows three versions of a pMOS high-

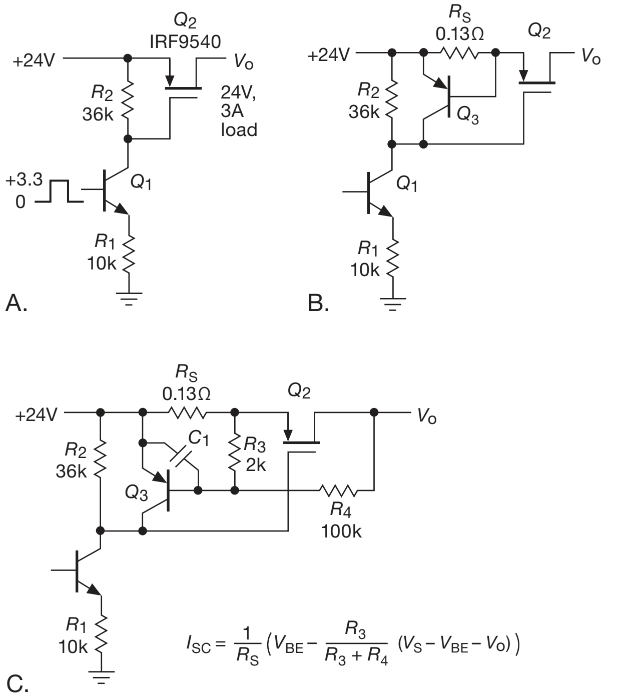

Figure 12.45. Current limiting the high-side switch: A. no protection; B. fixed 5 A current limit; C. foldback current limit.

[26] With high-current SSRs, the non-zero voltage drop can produce lots of power dissipation, requiring substantial heatsinks. For example, the 125 A HD60125 with its 1.7 V drop dissipates a bit over 200 W at full load! This is sobering: in spite of the no-moving-parts appeal of SSRs, you may decide that mechanical relays aren't so bad after all.

side power switch, intended for a ground-returned load that draws 3 A when powered by its rated +24 V. In all three circuits, *npn* transistor Q_1 converts the +3.3 V logic-level input into a 0.27 mA sinking current, which generates the $\sim$10 V negative-going gate drive for the *p*-channel power MOSFET Q_2. The IRF9540 has a maximum R_{ON} of 0.2 Ω at that gate drive, so there's at most 0.6 V drop at full load, or 1.8 W dissipation. You hardly need a heatsink.

What happens if the output is shorted? Circuit A has no protection, so the current is limited either by the capability of the +24 V supply or Q_2's saturation drain current, whichever is less. For the latter, the datasheet shows $\sim$50 A (at $V_{\text{GS}}=-10$ V and V_{DS}=24 V). For this 3 A application it's likely that the 24 V supply is less gutsy than that, perhaps good for 5–10 A. Taking the higher value, and using the datasheet's $R_{\text{ON}}=200$ mΩ at 25°C, we've got $I^2R_{\text{ON}}\sim 20$ W dissipation in Q_2 (rising to 30 W at 100°C), not a happy situation for a transistor that's ordinarily dissipating less than 2 W.

OK, you say, let's add *current limiting* (Circuit B). This is the usual circuit, with a current-sensing resistor R_{S} sized to generate a V_{BE} drop at the limiting current, thus bringing Q_3 into conduction, robbing gate drive and preventing further rise of current. It's best to set the limit current enough above the normal maximum load so that variations in V_{BE} with temperature don't cause premature limiting. Here the current limit is set at $\sim$5 A. The good news: we have a current limit. The bad news: it makes things worse for Q_2, whose dissipation into a short circuit rises to $I_{\text{lim}}V_{\text{in}}=120$ W.

OK, OK, you say, the problem with a simple current limit is that it permits a fault current at least equal to the maximum normal load current, and that with the full 24 V drop across the switch transistor. In other words, you'll always have at least 72 W dissipation (24 V times 3 A) into a short. So, let's rig up a better circuit that *reduces* the current limit when it sees the load dragging down the output; in other words, a protective circuit that permits full load current at rated output voltage, but reduced current at lower output voltage.

This is called *foldback current limiting*, and looks like circuit C. It behaves like the simple current limit when there's no significant drop across the switch; but if the output is held at ground (for instance), the voltage divider R_3R_4 creates about 0.5 V of forward bias across Q_3's base–emitter. So it takes only a bit over 1 A to bring Q_3 into conduction, limiting the current to that lower value and the dissipation to about 30 W. It's common to set the short-circuit current limit somewhere in the range of 25–35% of the full load current. Capacitor C_1 provides some delay before triggering current limit or foldback; a time constant of $\sim$1 ms guards against overzealous foldback while retaining protection.

Figure 12.46 shows the situation graphically. Among other things, you can see that the worst-case fault condition (in terms of transistor dissipation) occurs for a load that has a small resistance (rather than zero ohms). That's because the rising permitted load current more than compensates for the decreasing voltage drop across the switch. Even with this foldback scheme, we're once again faced with an enormous jump in switch dissipation: from 1.8 W (max) into a normal load, increasing to 34 W into a short, and 42 W into a 3 Ω fault-condition load. And foldback circuits have their disadvantages: if made sufficiently aggressive, they may prevent startup into a large capacitive load or other loads (like motors or dc–dc converters) that have a large inrush current.

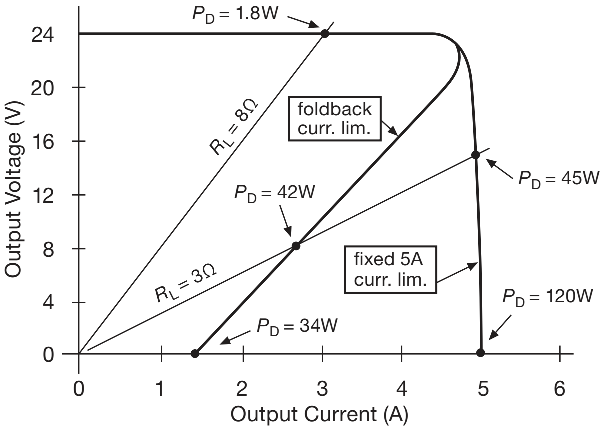

Figure 12.46. Foldback current limiting reduces the shorted-output switch dissipation by more than a factor of 3 compared with simple current limiting.

A. An easier way: protected switches

What to do? Foldback circuits can be made more precise,[27] for example by replacing Q_3 with a differential amplifier. And you can shape the foldback contour by including a zener in the feedback path. Then use a hefty heatsink, combined with temperature sensing to shut down the power when there's excessive heating, and you can make it all work reliably.

But there's a better way, in the form of "intelligent" pro-

[27] Our circuit suffers from uncertainties in V_{BE}, which is important: the short-circuit current is set by the *difference* between the actual V_{BE} and the 470 mV that the R_3R_4 divider creates during shorted output.

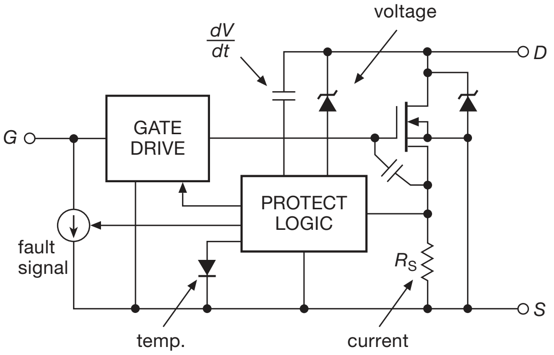

Figure 12.47. A protected MOSFET acts like an ordinary transistor, but it includes internal fault sensing and shutdown circuitry.

tected switches. One variety consists of *n*-channel MOSFETs, decorated with internal circuitry that senses overvoltage, overcurrent, and overheating, shutting down the gate drive accordingly (and providing an indication in the form of reduced gate input resistance). These devices come in standard 3-terminal transistor packages, but internally they have an integrated circuit watching over the power MOSFET (Figure 12.47). Table 12.4 lists a sampling of typical parts.

These are suitable for any application in which you would use a relatively low-voltage *n*-channel power MOSFET. For example, they would be fine for switching the low side of a load that returns to a positive supply, as in Figures 12.42A,B; or you could use one for switching a negative voltage to a ground-returned load, in the manner of Figure 12.44D.

Table 12.4 A Few Protected MOSFETS[a]

						Packages

Notes: (a) All are n-channel types, with active current and overtemp limits; all require 5V min gate drive, and signal fault conditions with excess gate current; BTS types have slow *dV/dt*, while VN types are faster but have controlled *dI/dt*. (d) dual. (s) slew-rate limit 1V/µs.

For a switching application like ours, though, you'd need a protected *p-channel* MOSFET, a breed that appears not to exist. For this application there's another variety of protected switches, intended specifically for *high-side* switching: these use an *n*-channel power MOSFET, suitably protected, with an internal charge pump and level-shifting circuitry to drive the gate ~10 V beyond the positive supply – see Figure 12.48. Once again there's sensing and protection against voltage, current, and temperature faults, sometimes responding also to undervoltage, reverse polarity, and loss of ground. So our problematic 3 A @ 24 V switching circuit becomes the thing shown in Figure 12.49: simple, inexpensive, and reliable.

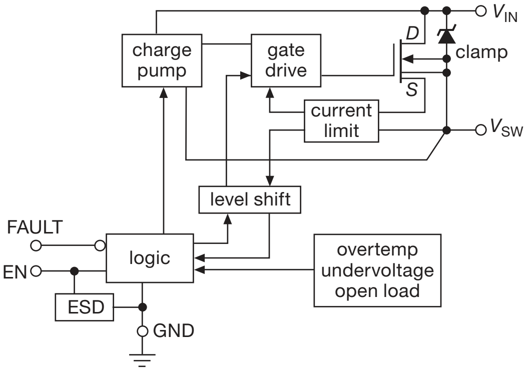

Figure 12.48. High-side intelligent switches have a charge pump and level-shifting circuits to drive the *n*-channel gate beyond the drain input supply; and they protectively monitor fault conditions such as overvoltage, overcurrent, and overtemp.

Table 12.5 lists the characteristics of selected high-side protected switches.[28] Within these there are two styles of logic input (Figure 12.50): one version accepts digital logic levels, relative to a ground pin; the other has no ground pin, instead requiring you to pull a current-sourcing pin to ground with a small external switch. This latter style provides a load-current indication, in the form of a "sense-output" pin that sources a current approximately proportional to load current.

[28] But a *caution*: the high-side intelligent-switch scene is strewn with discontinued parts. It's a healthy (but competitive) market sector (think automobiles), and new parts with improved performance (and pricing) are continually introduced. Table 12.5 gives a current list, and a sense of price and performance that's available; but you may have to look for comparable parts as these become consigned to the graveyard of obsoleted electronic components.

Notes: (a) all are *n*-channel switches, with charge pumps, unless marked; all have overcurrent and overtemperature protection. (b) transistor pair, not intelligent, add your own source and gate resistors. (c) adjustable 0.15-1.5A. (d) at 12V. (e) one pin signals load current and faults. (f) max. (g) shuts down after 10ms, retries every 160ms thereafter. (h) adjustable 0.4-2A. (n) Requires MOSFET closure to GND, sinking I_S.

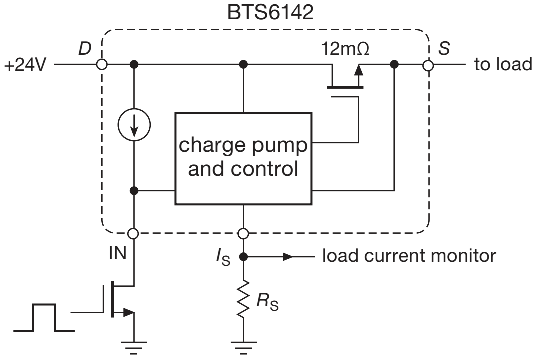

Figure 12.49. Problem solved! An intelligent high-side integrated switch provides a simple and reliable solution.

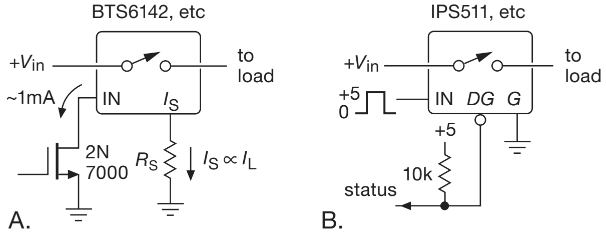

Figure 12.50. Two control schemes for high-side intelligent switches. A. No "ground" pin: enable by pulling input to ground, output current reported via proportional current-sourcing I_S pin. B. Logic-level voltage drive with respect to ground pin; active-LOW status output reports fault condition. This is the configuration shown in Figure 12.48.

12.4.5 nMOS LSI interfacing

Most LSI and VLSI circuits have true CMOS output drivers, with full rail-to-rail swings and with pretty much the same interfacing properties as the CMOS logic gates we just discussed. This is invariably true of ICs that operate from a supply voltage of +3.3 V or less. However, there are still useful ICs designed for 5 V supply operation that use a "totem-pole" *n*-channel MOSFET output stage (nMOS follower atop an nMOS switch; see Figure 12.51), thus producing a HIGH output voltage of only ~3.5 V, and

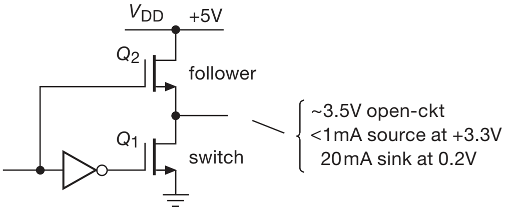

Figure 12.51. NMOS logic totem pole output circuit. The HIGH-state output voltage V_{OH} is around +3.5 V, with poor current-sourcing capability.

even that with hardly any sourcing current capability; you need to know about this quirky behavior. (The same goes for bipolar-TTL outputs, constructed with *npn* transistors in the same sort of totem pole.) While we're at it, we'll take a look also at a typical nMOS *input* stage, still widely used in ICs that can run over a range of supply voltages while maintaining an input logic threshold meeting the canonical TTL specifications (that is, anything less than +0.8 V is interpreted as LOW; anything above +2.0 V is HIGH).

A. nMOS and TTL outputs

The problem with an nMOS or TTL output is that its HIGH output, sitting anemically at ~3.5 V, is inadequate to drive loads like LEDs or relays; and it cannot even legally drive the input of a 5 V 'HC-logic device (with its mid-supply threshold). Taking the example of the XC95xx family of Xilinx cPLDs trying to drive a bright white LED, Figure 12.52 shows graphically the problem: the dashed curves show the output HIGH situation, where the cPLD's sourcing current versus voltage drops to zero around 3.4 V. We can figure out what will happen if we use that to drive a white LED whose cathode ("−" terminal) is grounded, by plotting on the same graph the "load line" of the LED; we've done that for a 70 Ω series resistor, and for no resistor at all. Either way we're lucky to get 4 mA of LED current, and without any confidence in the result. Contrast that with the *sinking* configuration (cPLD output connected to LED cathode, anode returned to +5 V via a series resistor), where a logic LOW output's clean saturation to ground produces a robust and predictable ~20 mA of drive with the series resistor (don't even *think* about omitting the resistor!). The results with a bipolar-TTL output structure are analogous (though with considerably poorer sourcing current).

The lesson is clear: when driving demanding loads directly from nMOS or TTL outputs, configure things so the output-LOW state does the heavy lifting.

If you insist on driving a load that returns to ground from one of these wimpy outputs, you've got several choices. The *wrong* way is to say "hmmm, I'll just add a current-boosting emitter follower" (Figure 12.53). Nice try, but the additional V_{BE} drop only makes things worse. Figure 12.54 shows several ways that do work. In circuit A the nMOS output LOW sinks 2 mA, driving the *pnp* transistor into hard conduction; you can use a discrete resistor plus transistor, or a combination "digital transistor" (also known as a "prebiased transistor" or "bias–resistor transistor") like the DDTA123, good to 100 mA load current.[29] Circuit B substitutes a low-threshold *p*-channel MOSFET (R_{ON}<100 mΩ at V_{GS}=−2.5 V), with a mild pullup resistor to ensure that output HIGH keeps the transistor OFF. Circuit C cheats a little, by interposing a CMOS inverter (or noninverting buffer) with TTL-compatible (therefore nMOS-compatible) input levels. The output can happily drive a 5 V load, sourcing (or sinking) tens of milliamps of current (see Figure 12.7). For more muscle, you can substitute a MOSFET gate driver like the ubiquitous TC4420-series (circuit D), which also lets you increase the output swing up to +18 V; these things hardly sweat at hundreds of milliamps source or sink (see Figure 12.7 again).

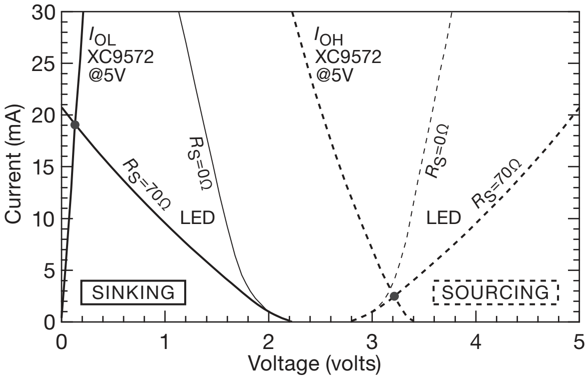

Figure 12.52. Driving a white LED with an nMOS output. The XC9500 5 V series of cPLDs provide good sinking all the way to ground, but weaker sourcing, and that only to ~3 V. Here we've used load lines (see Appendix F) to estimate the LED current for both the sinking and (undesirable) sourcing configurations, in each case with and without a series current-limiting resistor. (See Figures 2.8 and *1x.48* for LED *VI* curves.)

B. Weak CMOS outputs

Similar drive problems can crop up even with true CMOS rail-to-rail outputs. For example, look at the PIC16F sourcing (HIGH output) curve in Figure 12.8. We can use a

[29] Or the more than 300 alternatives in stock at DigiKey, from seven manufacturers.

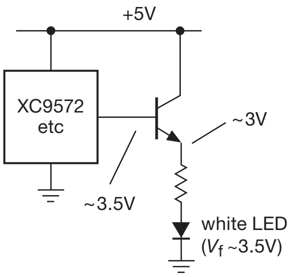

Figure 12.53. Don't do this! The low-hanging HIGH output voltage from an nMOS or TTL device is only made lower by the *npn* follower – it's a *black* LED.

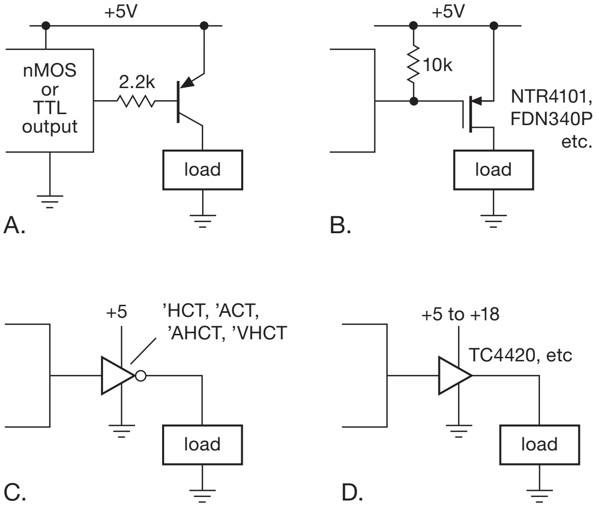

Figure 12.54. These nMOS logic outputs are driving loads that return to ground.

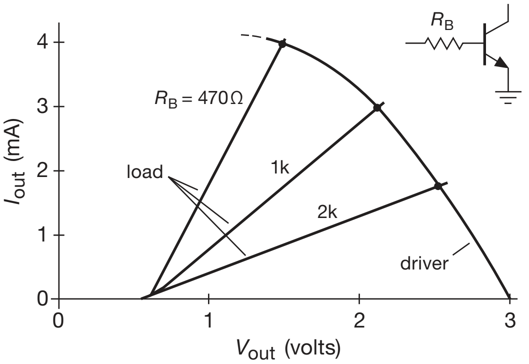

Figure 12.55. A weak CMOS output (here a PIC10F microcontroller, V_{DD}=3 V) can switch a "relay driver" transistor like the DRDNB16W (which includes both a 1k series base resistor and a clamp diode). Or you can use the resistorless DRDN005 with an external base resistor. Consider also an inexpensive 3-pin "digital transistor," which includes an integrated base resistor.

similar load-line graphical technique to see how such an output fares when driving a load like an *npn* switch with series base resistor (Figure 12.55), which you might use to switch on a 3 V relay coil (e.g., a Panasonic TXS2-3V, requiring 16.7 mA). The load lines are drawn for several choices of base resistor, allowing us to estimate the resulting base current from the intersection with the output-HIGH curve of the popular PIC10F microcontroller. Here a 2 kΩ series resistor produces about 1.7 mA of base drive, which (according to the transistor's datasheet) causes the collector to saturate at less than 50 mV with the relay coil as load. That's just fine – less than a milliwatt of transistor dissipation. But if you wanted to drive a heftier relay, for example the Omron G6RL-1A-3VDC, which has contacts rated at 8 A and 250 Vac, you'd have to contend with the 3 Vdc coil's resistance of 41 Ω, or 73 mA coil current. Now a 1 kΩ (or smaller) base resistor would be best: the >3 mA base drive produces a collector saturation voltage of ~100 mV, or 10 mW transistor dissipation.

C. nMOS inputs

You might think that nMOS is dead,[30] at the hands of the victorious CMOS. But you'd be wrong: many digital ICs that need to operate over a wide range of supply voltages use the simple input circuit of Figure 12.56. Q_1 is an inverter, and Q_2 is a small-geometry source follower providing pullup current (resistors take up too much space, so MOSFETs are universally used as drain loads); the alternative symbol shown for Q_2 is widely used. The threshold voltage of the input transistor is in the range of 1–1.5 V, fully compatible with the long-standing "TTL input level" specification. A classic example of an IC that works this way is a MOSFET gate driver like the TC4420 (and its many cousins), which runs from a single +V_{DD} positive

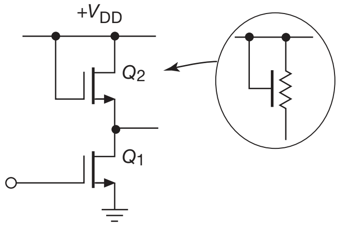

Figure 12.56. NMOS logic-input circuit.

[30] "She's not only merely dead, she's really most sincerely dead," as the Coroner proclaimed in *The Wizard of Oz*.

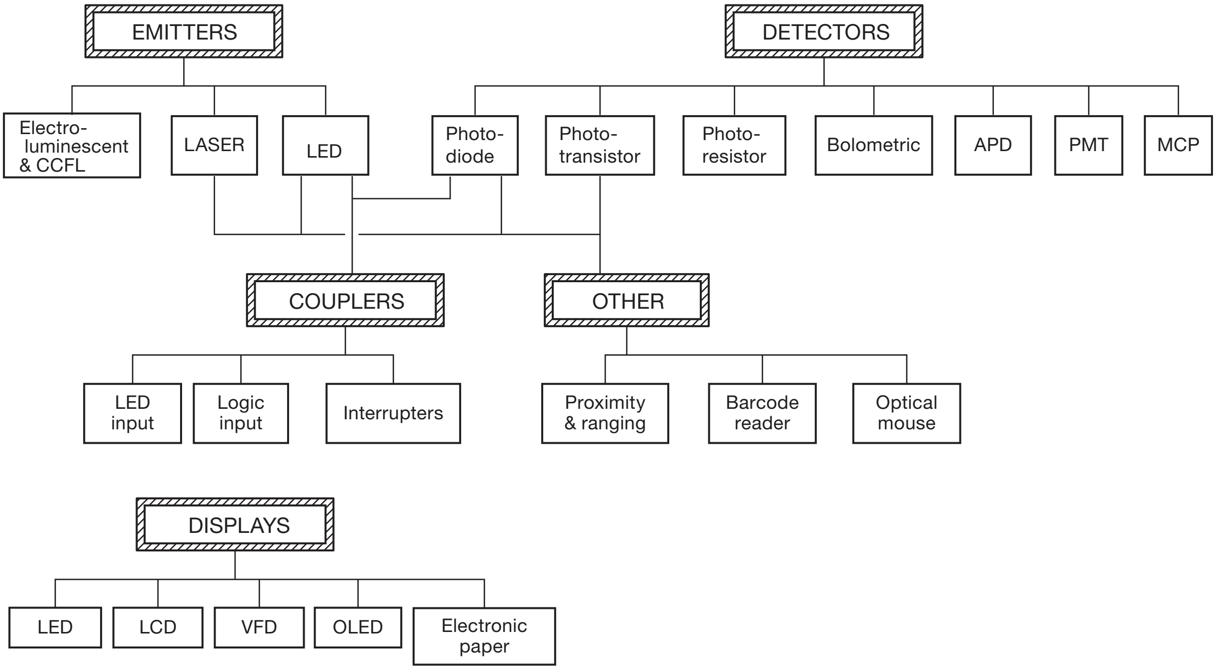

Figure 12.57. Optoelectronics family tree.

supply in the range of 4.5–18 V. Happily, such an input accepts pretty much any HIGH logic level you throw at it (including all the way to the elevated positive supply) while drawing essentially zero input current.

12.5 Optoelectronics: emitters

In the previous three chapters we have been using LED indicators and LED numeric display devices in various circuit contexts as we needed them. LEDs belong to the general area of *optoelectronics*, which includes displays based on other technologies as well, notably liquid crystals ("LCD") and gas discharge. It also includes optical electronics used for purposes other than indicators and displays: detectors (photodiodes and phototransistors), photomultipliers, array detectors such as "charge-coupled devices" (CCDs), light-coupled isolators ("opto-isolators"), solid-state relays, position and proximity sensors ("interrupters" and "reflective sensors"), diode lasers, image intensifiers, and a variety of components used in fiber optics.

Although we will continue to conjure up miscellaneous magic devices as we need them, this seems like a good place to pull together the area of optoelectronics, since it is related to the logic interface problems we have just been discussing.

To set the stage, we present a brief family tree of optoelectronics in Figure 12.57, and in the outline below. We've tried to make it inclusive, to provide perspective and orientation. And a family needs a *portrait*, so we gathered up a collection of optoelectronic goodies from our lab for Figures 12.58, 12.71, 12.80, 12.84, and 12.95. In the following sections we'll look at a subset of these devices, concentrating on the devices and techniques that are most important for day-to-day circuit and instrument design.

12.5.1 Indicators and LEDs

Electronic instruments look nicer, and are more fun to use, if they have pretty little colored lights on them. LEDs have replaced all earlier technologies (notably incandescent lamps) for this purpose. You can get red, yellow, green, blue, and white indicators, and you can get them in many packages, the most useful of which are (a) panel-mounting lights, and (b) PCB-mounting types. The catalogs present you with a bewildering variety of them, differing mostly in size, color, efficiency, and illumination angle. The latter deserves some explanation: a "flooded" (or "diffused") LED has some diffusing stuff mixed in, so the lamp looks uniformly bright over a range of viewing angles; that's usually best, but you pay a price in brightness.

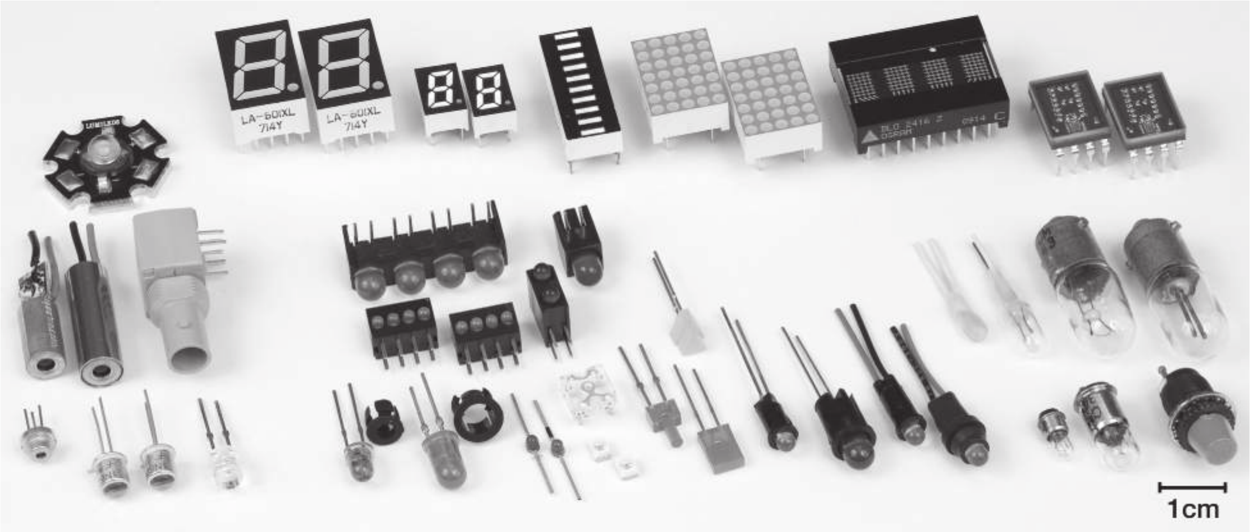

Figure 12.58. Optoelectronics: emitters and displays. At front center are visible LED indicators, in the popular 3 mm (T-1) and 5 mm (T-1$\frac{3}{4}$) panel-mount sizes (some with integral plastic mount), along with PCB-mount singles and arrays. To the left are three red lasers (bare, in 3-pin metal package; and with regulator-driver, in cylindrical housing), a few IR emitters, a fiber-optic ST-style transmitter, and a high-intensity white LED on an aluminum heat spreader. On the right are six legacy incandescent indicators and one NE-51 neon bulb. Along the rear are displays: 7-segment, bar graph, 5×7 dot matrix, 4-character dot matrix, and hexadecimal with latch–decoder–driver.

If the datasheet's "angle of half intensity" (or "viewing angle") specification is at least 90° (it may say "±45°"), and ideally 120° or more, it will look pretty good off-axis. Figure 12.59 shows a polar-plot comparison for LEDs with viewing angles of 30°, 60°, and 120°. These show relative intensity versus viewing angle, normalized to unit intensity on-axis (i.e., 0°). Without that normalization the plots for the 60° and 120° LEDs would shrink dramatically, as shown in the unnormalized plot of Figure 12.60.

An LED looks electrically like a diode, with a forward drop going from about 1.5 V (red) to 3.5 V (blue or white); they use semiconductors with a larger bandgap, and hence a larger forward drop, than silicon – see Figure 2.8 on page 76.[31] Panel-mount LEDs come mostly in 3 mm and 5 mm diameters (called T-1 and T-1$\frac{3}{4}$, respectively), sometimes with an integral mounting clip (see Figure 12.58). Typical flooded panel-type LED indicators look good at 4–10 mA forward current; on a board inside an instrument you can usually get away with 1 mA.

Figure 12.61 shows simple ways to drive small LED indicators. Basically you just need to provide a few milliamps of operating current through their forward voltage drop (V_F). That's usually just a series current-limiting resistor of value $R = (V_+ - V_F)/I_{LED}$, typically a few hundred ohms to a few kΩ. Some LED indicators come with internal current-limiting resistors (or even internal constant-

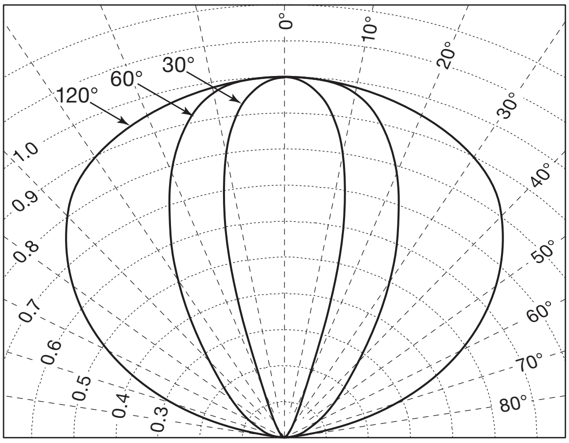

Figure 12.59. Intensity versus angle for three panel-mount LEDs with specified "viewing angles" (full-width to half-intensity) of 30°, 60°, and 120°, in each case "normalized" to unit intensity on-axis. *(After Vishay TLHx460, 520, and 640 series datasheets)*

[31] As an example, for the panel LEDs whose illumination patterns are plotted in Figure 12.59, the dependence of forward voltage V_F on wavelength is given approximately by $V_F(\text{volts}) \approx 1000/\lambda + 0.02 I_F$, where the wavelength λ is in nanometers, and the forward current I_F is in milliamps. The last term represents an effective series resistance of 20 Ω.

OPTOELECTRONICS FAMILY TREE

I. EMITTERS

LEDs (Light-Emitting Diodes) visible (red, yellow, green, blue, white) and infrared (IR); forward-biased diode, $V_{\rm F}$ ranges from $\sim$1–3.5 V, depending on color; panel-mount and PCB-mount; many configurations; available as displays

Laser diodes IR, red, and blue; fiber-optic transmitters, laser pointers, CD/DVD/Blu-ray players, barcode readers

Electroluminescent Night lights, "Indiglo"™ low-power backlight

II. DISPLAYS

LED-based 7-segment (numeric), dot-matrix (character), and "smart" (decoded–latched); organized as individual characters or as arrays ("sticks")

LCD-based (Liquid-Crystal Display) Bare LCD (standard or custom), or "smart" (decoded with memory; parallel and/or serial interface); character only, character plus configurable graphics, or full graphics; backlit transmissive, or "transflective"; varying quality (view angle and contrast)

VFD-based (Vacuum-Fluorescent Display) Smart LCD emulation, with superior readability; custom configurations for high-volume users

OLED (Organic LED) Inexpensive alternative to semiconductor LEDs; graphics, cellphone screens etc; larger sizes for best flat-screen TV

Electronic paper For example, E-Ink® microcapsule technology used in e-book readers; image retention at zero power except during erase–rewrite

III. DETECTORS

Photodiode *pn* (or PIN, positive–intrinsic–negative) diode junction; self-generated photocurrent into short ckt ("photovoltaic" mode), or when back-biased ("photoconductive" mode); fiber-optic receivers (speeds to gigabits/s); solar cells are large-area photodiodes

Arrays Linear (stripe); quad; proportional readout; full imaging array (CCD; CMOS)

Integrated Light → logic; light → voltage; light → current; light → frequency; synchronous detection pair

Phototransistor Transistor with base–emitter photodiode; higher current (factor of β), but slower; photo-Darlington even more so

Photoresistor Light-sensitive linear-resistive material (e.g., cadmium sulfide); slow response

Bolometric "Pyroelectric" material exhibiting large resistance change with temperature; motion detectors ("PIR", passive infrared)

APD (avalanche photodiode) High back-bias ($\sim$100 V) multiplies the collected charge per photon; can be linear, or saturating ("Geiger mode")

PMT (photomultiplier) Vacuum-tube device with a photocathode and array of electron-multiplying (gain$\sim10^6$) "dynodes"; operates at $\sim$1 kV

HAPD (hybrid APD) Vacuum-tube device, combination of photocathode and APD target; operates at >5 kV

Pixelated PMT Multi-anode PMT for coarse imaging; 4×4, 8×8 array

Microchannel plate Vacuum-tube device, combination of photocathode and electron-multiplying capillary array; an "imaging PMT"

IV. COUPLERS

LED-input LED→photodiode; LED→phototransistor; LED→photo-Darlington; LED→FET (via PV stack, "PV" = photovoltaic); LED→photoresistor; LED→SCR/triac (via PV stack): a "solid-state relay"; LED→logic output (active pullup, or open-collector)

Logic input Logic input→logic output

Interrupters With gap, or reflective

V. OTHER

Proximity and ranging Emitter plus position- or intensity-sensing detector: faucets, paper towel dispensers, LCD monitor power-down... and your iPhone (it needs to know that your cheek isn't trying to control the touch-screen)

Barcode reader

Optical mouse LED or laser emitter, plus smart detector

current circuits) – with these you omit the external resistor. For higher currents (large LEDs) use a transistor switch, as in Figures 12.61C–F.

We've listed some of our favorite panel LED indicators in Table 12.6. You can see them in the front row of Figure 12.58.

With the trend toward lower-voltage logic, along with the higher forward voltage of gallium nitride type LEDs

Table 12.6 Selected Panel-mount LEDs[a]

			Integral mount, front entry[b]			
	LED only (bare wire leads)		short bare leads		flying leads[c]	
Color	3mm (T-1)	5mm (T-1 3/4)	3mm	5mm	3mm	5mm
RED	TLHR4605	LX5093SRD/D	5111F1	5101H1	5110F1	5100H1
YELLOW	TLHY4405	LX5093LYD	5111F7	5101H7	5110F7	5100H7
GREEN	TLHG4605	TLHG6405	5111F5	5101H5	5110F5	5100H5
BLUE	LX3044USBD	LX5093USBD				

Notes: (a) all are diffused, without internal resistor. manufacturers: 51xx = CML; TLHxxx = Vishay; LXxxx = Lumex, with prefix SSL-. (b) Front-mounting: T-1 size take 5/32" (4.0 mm) hole, T-1 3/4 size take 1/4" (6.4 mm) hole. (c) Insulated, 24 gauge stranded, 15 cm long.

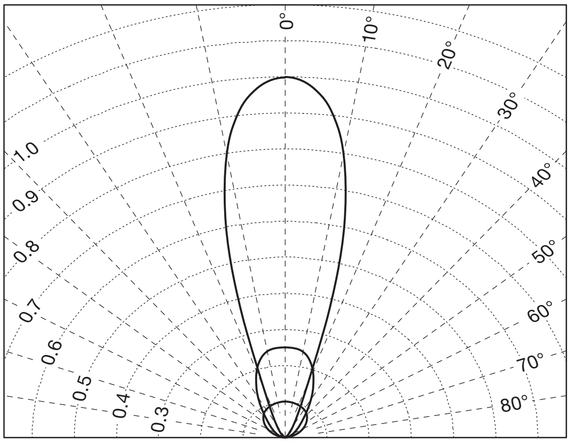

Figure 12.60. There's a price to pay in exchange for the pleasant appearance of a diffused ("flooded") LED, with its wide viewing angle. Here we've plotted intensity versus angle (relative to that of the 30° unit) for the same panel LEDs as in Figure 12.59, using datasheet values. It isn't quite as bad as it seems, though, owing to the eye's logarithmic-like sensitivity.

(used in blue, white, and bright-green LEDs – see Figures 2.8 and *1x.48*), you'll sometimes need a higher supply voltage. For example, +3.3 V is a popular supply voltage, but insufficient to drive a GaN-type LED. If you have a higher supply voltage (e.g., +5 V) available, use a transistor switch with pullup to that voltage (Figures 12.61E and F). If you don't, you'll need to generate the needed LED supply voltage. Figure 12.62 shows a few methods.

A favorite technique, particularly for driving several LEDs at once (e.g., a string of four or six white LEDs for backlighting) from a low supply voltage, is a non-isolated switching boost (step-up) converter, with feedback taken from a current-sensing resistor at the bottom of the LED string (Figure 12.62A). There are dozens of choices from many manufacturers; we've listed a few in the figure. These things will run on voltages as low as +1 V (i.e., a single cell), putting out tens of milliamps into 20 V or more, as needed to provide the LED operating current $I_{\text{LED}} = V_{\text{ref}}/R_{\text{CS}}$; and they're pretty efficient, typically 80% or more. Some variations include high-side sensing, internal current sensing (Figure 12.62B), linear intensity control, internal Schottky diode, and internal zener clamp.[32] Note well the latter: a zener clamp (D_Z in the figure) is *mandatory* if there's a way that the LED load might be disconnected; otherwise the output voltage runs away and destroys the IC.

You can get tiny individual LEDs, and arrays of LEDs – sticks of 2, 4, or 10 LEDs in a row – designed for PCB mounting. The latter are actually intended for linear "bar-graph" readouts. They come in upright or right-angle mounting. You can also get panel-mounting indicators with multiple colored LEDs in one uncolored package: red/green is inexpensive and common; you can also get red/blue/green and yellow/blue/green.[33] These make an impressive panel, with lights changing color to indicate good or bad conditions. When you turn on more than one LED you get "additive color," so, for example, you can generate *yellow* as red plus green, or *white* as red plus blue plus green. You can do this by switching each

[32] In addition to these *boost* (step-up) converters, you can get *buck* (step-down) converters for LED driving from a higher voltage supply; and you can get *buck–boost* converters that work with supply voltages higher or lower than the output voltage driving the LED load. You'll find more than a thousand varieties on the DigiKey website alone.

[33] Multicolor LEDs that include blue cost significantly more, and require the ∼3.5 V forward voltage characteristic of GaN-type LEDs.

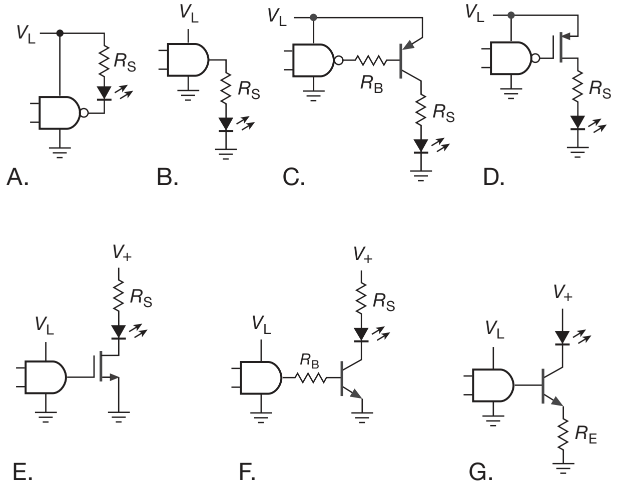

Figure 12.61. Driving LED indicators from logic – I: for LEDs with forward voltage V_F less than the logic supply voltage V_L, you can use the simple connections in circuits A and B to supply a few milliamps. For higher currents, use a transistor switch, as in circuits C–F (with V_+ tied to V_L). If you have a higher voltage available (e.g., +5 V) you can use circuits E–G to drive LEDs whose forward voltage is greater than the logic supply (e.g., a white LED from +2.5 V logic). Circuit G provides constant LED current, providing $V_+ \geq V_L + V_F$.

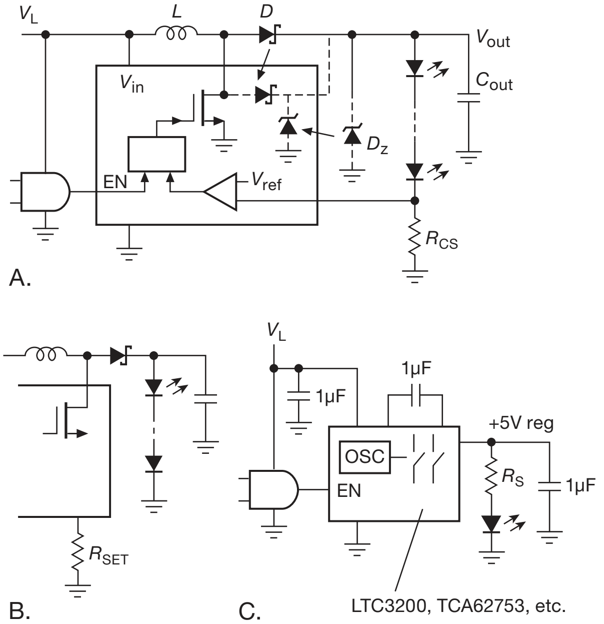
LED color fully ON or OFF; or you can produce intermediate levels of drive to each LED by varying the duty cycle (percentage of time ON) of a switching waveform (PWM). Multicolor LEDs come in both common-cathode (the – terminal) and common-anode (the + terminal) configurations; two-color LEDs also come as back-to-back diodes in a 2-pin package.



part #	V_{in}^a (V)	I_{out}^b max (mA)	C_{IN}/C_{OUT} min (μF)	V_{ref} (V)	D_Z max (V)	D	$ea (25pc)	notes

(a) V_{in} must be less than $V_{out.}$ (b) at V_{in} (min). (c) typical. (d) internal. (e) R_S on high side, LED(s) return to GND.

Figure 12.62. Driving LED indicators from logic – II: there are dozens (maybe hundreds) of switching boost converters designed specifically for constant-current driving of strings of LEDs from low supply voltages, as in circuits A and B. For a single LED you can use an inductorless (charge-pump) regulated doubler (circuit C).

A. Example: "Superlamp"

Thanks to Shuji Nakamura's enabling breakthrough in GaN technology, white LEDs have reached impressive intensities and efficiencies, and they're becoming the preferred alternatives to incandescent and fluorescent lights for "area lighting" applications. We had a leftover Intel CPU heatsink, and we got to thinking, "'Hmmm, what hot thing can we stick onto *that*?" Nice bright white LEDs, of course!

Figure 12.63 shows the circuit: a CMOS 555 oscillator running at 28 kHz (chosen to be above audibility) and configured for a 0–100% duty cycle (see §7.1.3B) is used to switch a power MOSFET, generating a 12 V rectangular wave. This drives four strings of three white LEDs each (Philips Lumileds "Luxeon Star," mounted three-up on hexagonal metal heat spreaders) with 2 Ω current-limiting resistors, generating an ON current of ~700 mA per string. A couple of design details. (a) The oscillator frequency is high enough to generate a modest amount of "switching loss" during the intervals when the MOSFET is transitioning between fully ON and fully OFF; adding a MOSFET gate buffer (like the TC4420) reduces the switching time, hence the loss, if that were a serious issue (it isn't). (b) The use of a current-limiting series resistor (rather than a current source) in each LED string has an interesting side effect – it cancels (approximately) the reduction of light output as the LED heats up (if anyone cares); that's because the LED's lower forward voltage (at higher temperatures)

Figure 12.63. Our old friend, the 555, is at the heart of this bright desk lamp with 0–100% PWM dimming.

causes more drop across the resistors, hence a compensating rise in LED current. The compensation is nearly perfect for the values shown.

Visitors are amused by this off-the-beaten-path "desk lamp." One of them pointed out that our creation (Figure 12.64), though charming, is completely outclassed by the brilliant "light engines" from Enfis Limited; they make dense LED arrays (e.g., the "quattro mini") that put out as much as 5000 lumens of white light from 144 power LEDs packed into a 2 cm × 2 cm array (and their other colors put out as much as 24 *watts* of light from the same area[34]). We're loyal to our re-educated heatsink. And the ∼30 W of dissipated power is child's play for this Xeon heatsink, which was intended to handle four times as much in its regular day job; we substituted a much slower fan, and throttled it down to a bare whisper.

B. LED fast high-current driver

You can drive an LED with brief very high current pulses (far above its continuous rating), for example in a flashlamp replacement application, exploiting the LED's thermal mass to absorb the energy. For this purpose you can use a series resistor to set the current (Figures 12.62 and 12.63), but an active current regulator is better. An example is LTC's LT3743, showing off its prowess in Figure 12.65, where it is being instructed to make steps to 2 A and 20 A. Even though the PWM is running at 500 kHz, it's able to switch the LED current in just 2μs. Amazing…check it out.

12.5.2 Laser diodes

We make a brief digression on semiconductor diode lasers. These are the heart of the ubiquitous handheld laser pointers, objects once exotic and expensive, but now commonplace and ridiculously inexpensive ($5 or less for a red pointer). They are also ubiquitous in optical storage devices such as CD, DVD, and Blu-ray players and recorders, as well as in fiber optic transmitters. Low-power red lasers come as little modules with circuitry to run on 3–5 V (e.g., Quarton VLM-650-03-LPA); or, for the adventurous, you can get the bare laser diode in a metal 3-lead transistor package (see Figure 12.58). These include an integral monitor photodiode, which is used as feedback to regulate the light output via the applied drive current. The threshold current at which laser action starts is somewhat variable, generally in the neighborhood of 20–40 mA; above that threshold the light output rises rapidly. This behavior is shown in Figure 12.66, a 'scope trace of emitted intensity versus linearly ramping laser-diode current. The output beam emerges directly from a tiny spot on the

[34] At a somewhat more mundane level, high intensity white LEDs are replacing residential incandescent bulbs, floodlights, and spotlights, delivering comparable illumination at 1/5 the ac wallplug power, and lifetimes of 25,000+ hours; many of these are selling for around $10. And the automotive industry has taken notice, using LEDs even for headlights (check out the Lumileds Altilon series).

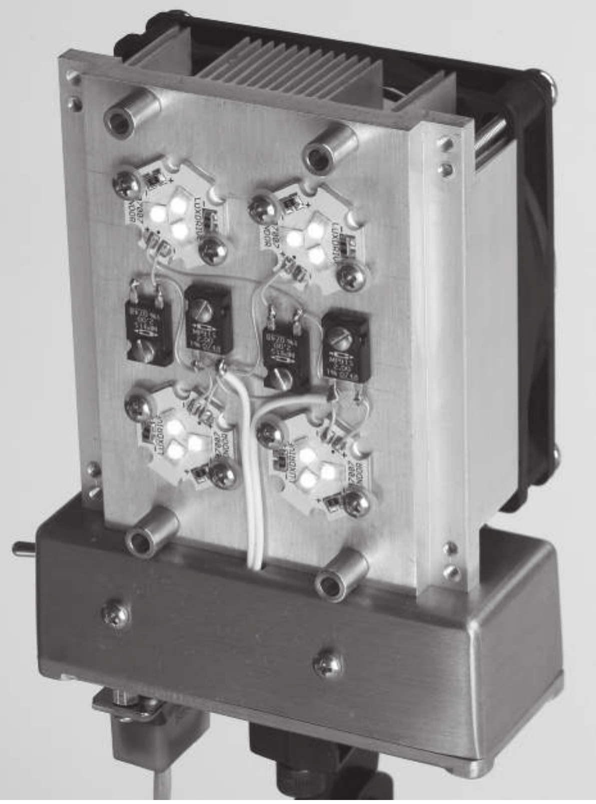

Figure 12.64. Computer CPU heatsink hijacked to make cool desk lamp. We cranked down the current so you can see the four sets of LED triples, along with the surface-mount ballasting resistors. At full brightness (1000 lumens) you can't look at this thing! The switching driver circuitry of Figure 12.63 lives in the box at bottom.

light-emitting semiconductor (GaAlAs for infrared) chip, diverging with an angle of about 10–20°; it can be collimated with a lens to form a parallel beam or a very small focal spot.

It's easy to rig up a decent drive circuit, without even resorting to op-amps or special driver circuits. Just compare the monitor photodiode current with a threshold, and adjust the drive current accordingly. It's a good idea to include a current limit, so you don't blow out the diode; and you'll need to compensate the feedback loop to make it stable. Figure 12.67 shows a "good-enough" driver circuit: it converts the monitor current to a proportional voltage (switchable between two levels by Q_3), compared with a diode-compensated 1.2 V reference voltage. Q_5 drives the laser, with current limiting via Q_4. C_C and R_C compensate the loop, with final "cut-and-try" values as shown. This simple circuit runs fine from dc up to 1 Mb/s.

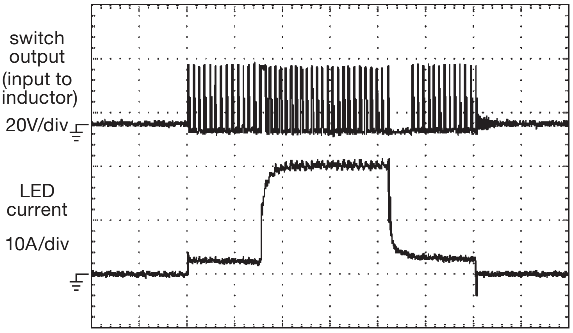

Figure 12.65. The LT3743 high-current LED driver uses cleverness to allow 2μs switching over a 3000:1 dimming range. Horizontal: 20μs/div. (adapted from LT3743 datasheet)

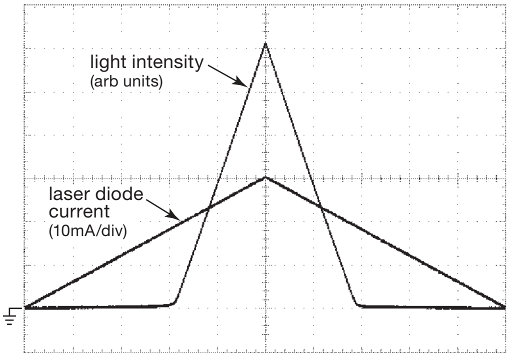

Figure 12.66. Diode laser output from a 0–30 mA triangular drive current. Horizontal: 100 μs/div.

For such ON/OFF control you hardly need the whole loop business. But it's necessary if you want true *linear* control of laser intensity. Figure 12.68 shows waveforms for this same circuit, with an *npn* current sink attached at point X (replacing R_3, R_4, and Q_3). Here the programming current I_{prog} is a 200 kHz triangle wave with a 4:1 ratio of peak-to-valley current; the laser output is accurately proportional. Note that the laser drive current has a large offset (all three traces are positioned relative to the same ground).

This circuit is a simple example, and not intended for high performance. The real challenges come when you're trying to modulate a laser at hundreds of megabits per second or more. For this it's best to use an IC designed for fast laser modulation;[35] better yet, just buy the laser+driver module as a complete unit (see §12.8 on fiber optics for some examples).

[35] For example, the Maxim MAX3735-series, Micrel SY88722, or ADI ADN2870-series. The MAX3975-series and 3930-32-series go to 10 Gb/s; get their *Fiber Design Guide* at `www.maxim-ic.com/design_guides/`.

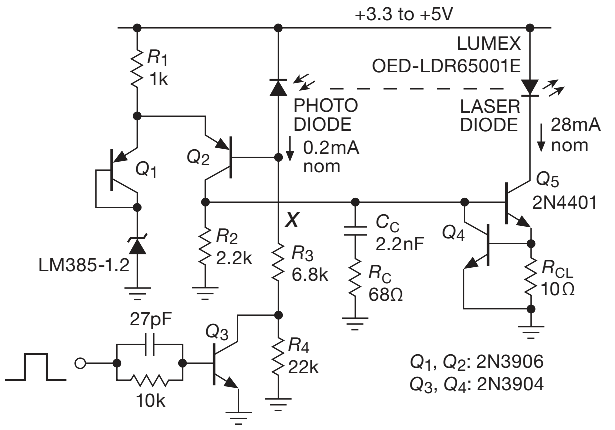

Figure 12.67. Simple laser drive circuit with monitor photodiode feedback and logic-level control.

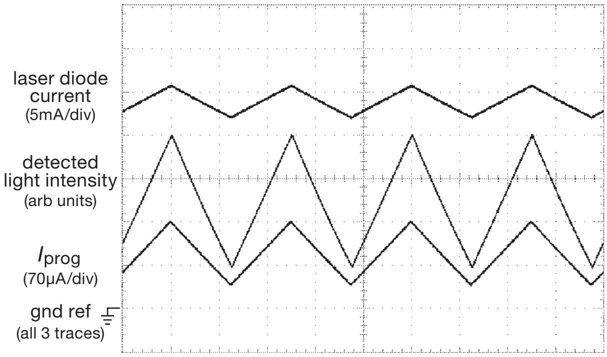

Figure 12.68. Linearizing the circuit of Figure 12.67 by replacing the components below "⊗" with an *npn* current sink: here a 200 kHz triangular programming current with 4:1 peak-to-valley ratio causes the offset laser current needed to produce an accurately proportional output intensity. Horizontal: 2 μs/div.

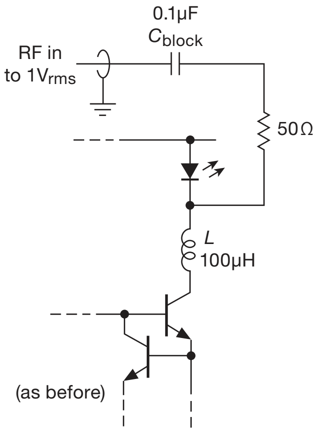

Figure 12.69. Adding a blocking capacitor, 50 Ω series resistor, and RF-isolating inductor to the laser drive circuit of Figure 12.67 provides a simple modulating input. We've used this circuit successfully with modulating frequencies up to ~1 GHz.

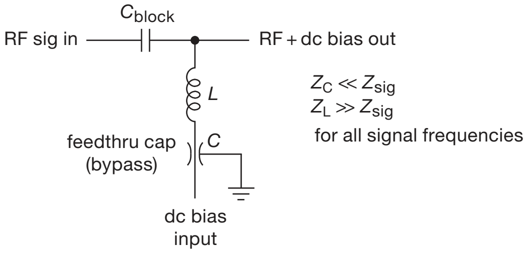

Figure 12.70. A "bias tee" lets you put a dc bias onto a signal (usually at radiofrequencies) that is coupled from input to output. Off-the-shelf bias tees are usually intended for line impedances of 50 Ω or 75 Ω, and they use careful inductor design for good performance over a wide frequency range (0.2 MHz to 12 GHz for the Minicircuits ZX85-12G, for example).

Figure 12.69 shows a simple alternative, if all you want is intensity modulation of a laser light source at some high frequency and you don't care much about linearity or response down to dc. The input signal, blocked by C_{block}, superposes a high-frequency variation of current at the laser diode, dc biased by the feedback circuit of Figure 12.67. Choose the blocking capacitor for the minimum modulating frequency (the value shown is good down to ~100 kHz), and be sure to bypass the supply rail effectively. The inductor L isolates the transistor's shunt capacitance, and should have a reactance greater than 50 Ω at all modulating frequencies. For good performance the inductor should be constructed from multiple series sections, cleverly designed (in the manner of a "bias tee," Figure 12.70) so that self-resonances do not produce low-impedance minima across the frequency range of interest.[36]

12.5.3 Displays

A *display* is an optoelectronic device that can show one or more numbers ("numeric" display); or the set of hexadecimal digits (0–9 and a–f, "hexadecimal display"); or any combination of letters, numbers, and punctuation ("alphanumeric display"); or most generally any graphic that can be represented by a dot matrix ("graphic display").

[36] Instead of suppressing resonances by dividing such an inductor into multiple sections, you can wind it in a *tapered* geometry; see, for example, the GL series of "Ultra Broad Band Inductors" from AVX. These have excellent performance from 1 MHz to 40 GHz.

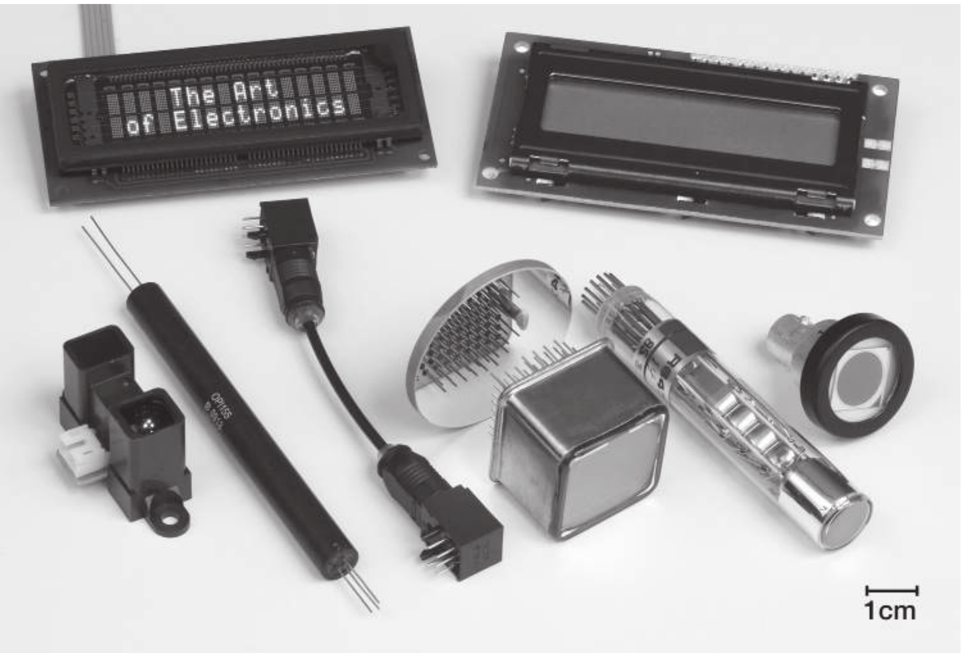

Figure 12.71. A collection of optoelectronic devices too large to fit in Figures 12.58, 12.80, and 12.84. At rear are VFD and LCD smart displays (Newhaven M0216SD-162SDARC-1 and Optrex DMC16207), the former with 3-wire serial interface. In front, left to right, are a ranging/proximity detector (Sharp GP2Y0D02YK0F), a 50 kV logic-output opto-isolator (Optek OPI155), a homemade TOSLINK isolator (Toshiba TOTX/TORX177PL), an 8×8 multianode photomultiplier (Hamamatsu R5900-00-M64), an end-on 13 mm PMT (Hamamatsu R647), and a 10 mm PIN-diode detector (OSI/UDT PIN-10D).

The dominant display technologies (in sizes relevant to electronic instruments) are LEDs, LCDs, VFDs (vacuum fluorescent displays), and OLEDs (organic LEDs). Figures 12.58 and 12.71 includes examples of all except OLED.

LED displays are bright, colorful, and available in large sizes; but they are power hungry, and not appropriate for graphics. LCD displays are quite popular – they are the monochrome yellowish or bluish backlit rectangular displays that commonly show one or two lines of 16 or 20 characters each. Depending on technology, backlit LCDs may be quite readable outdoors or in high ambient-lighting conditions (“transflective”), or they may look just terrible. LCDs intended for use without back-lighting (reflective) look pretty good. The clarity and off-axis readability depend considerably also on the liquid-crystal technology (active matrix versus passive matrix; “twisted nematic” versus “super-twisted nematic,” and so on). Apart from the backlight, LCD displays can run on extremely low power (think of a digital wristwatch); and you can have them made with custom shapes and symbols. VFD displays are similar to their LCD cousins (and emulate their interface), but they are self-luminous; we think they look terrific.[37] VFD display prices are coming down nicely – for example, the 2-row ×16 character alphanumeric “smart” display in Figure 12.71 costs $30 in single quantities; a bare 1-row ×20 character stick costs $7 in single quantities. OLEDs are making inroads, particularly in small sizes.[38] They are likely to be the large-screen display technology of the future (currently dominated by LCD and plasma), when manufacturing costs decline sufficiently to make them competitive.

[37] Some engineers have complained that they generate RF interference, and they avoid them in proximity to sensitive circuits.

[38] We are particularly impressed by the stunning clarity of the small ($\sim 1''$) white OLED graphic modules (available from hobby suppliers like Adafruit, as well as from standard distributors like DigiKey, Mouser, and Newark); they can run from a single +3.3 V supply, drawing some 20 mA, and they communicate via SPI or I^2C serial buses. They cost less than $20 in unit quantities.

A. LED displays

Figure 12.72 shows the choices you have in single-character LED displays (and the same layouts are used in integrated multi-character displays). The original 7-segment display is the simplest and can display the digits 0–9 and the hex extension (A–F), albeit somewhat crudely (the hex letters are displayed as "AbcdEF"). You can get single-character 7-segment displays in many colors and sizes, and in "sticks" containing 2, 3, 4, or 8 characters (generally intended to be "multiplexed" – the characters displayed one at a time in rapid sequence). Single-character displays bring out leads for the 7 segments and the common electrode; the two flavors are thus "common cathode" and "common anode." Multiple-character sticks bring each character's common electrode out, but tie the corresponding segments together, which is what you want for multiplexing. However, if you want to display lots of characters, you're usually better off choosing a so-called "smart" display: these accept input codes for characters (or graphic symbols), and they do their decoding, multiplexing, and displaying internally. We'll get to them shortly, in §12.5.3A.

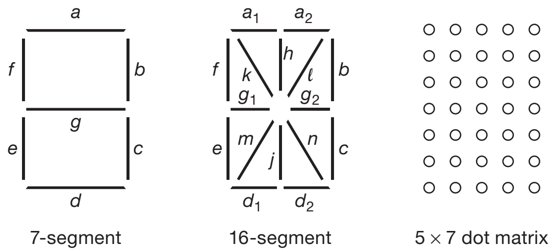

Figure 12.72. LED display layouts.

"Dumb" displays

Figure 12.73 shows how to drive a single-digit 7-segment common-cathode LED display. The 'HC4511 is a "BCD-to-7-segment latch–decoder–driver," able to source about 10 mA while holding its active outputs at +4.5 volts when powered from +5 V. The series resistors limit the segment drive current (to 2 mA or 4.7 mA, respectively, with 3 V or 5 V supply, assuming a typical LED drop of 1.5 V). Don't try to be clever and just stick a single resistor in the common cathode instead (why not?). You can get arrays of equal-value resistors in convenient SIPs (single in-line packages), in through-hole or surface-mount flavors.

You need only a single decoder–driver chip, even if you are displaying multiple digits, as long as you multiplex the display, i.e., illuminate only one displayed digit at a time. You do this by connecting the segment-driver outputs to all of the digits, then grounding the cathode of each digit in turn, simultaneously asserting the value to be displayed on decoder inputs D_0–D_3. Look back at Figure 10.90 (§10.6.2) to see how it's done in detail.

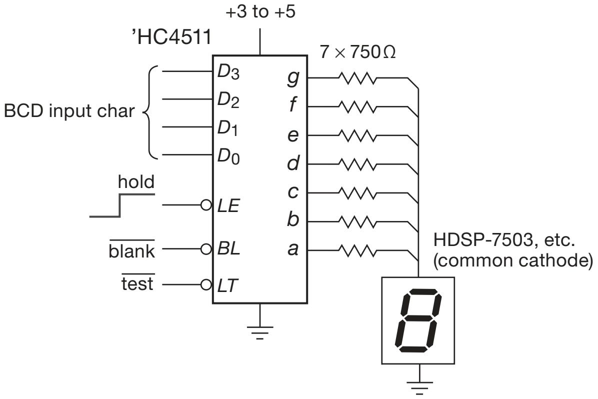

Figure 12.73. Driving a single 7-segment LED display from BCD (0–9) logic input.

Figures 12.74 and 12.75 show how to drive single-character LED displays in 16-segment or 5×7 configurations, respectively. Drivers for these displays generally assume you've got a microcontroller in your circuit somewhere, so they use serial input protocols such as SPI (serial peripheral interface; see §14.7.1). They include internal data registers, and current-source drivers programmed by a single external resistor. Note that the 16-segment driver in Figure 12.74 has no internal decoder – it just drives the segments you tell it to. So your microcontroller has to figure out which segments to drive; that's no big deal for these brainy parts, just be aware. The (smarter) 5×7 driver in

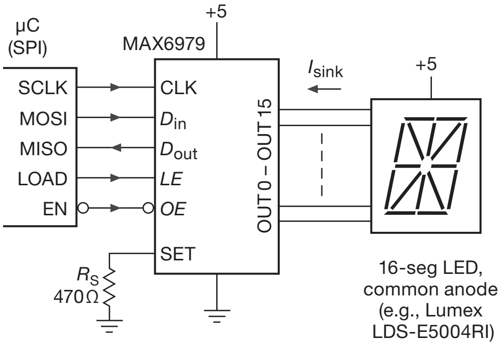

Figure 12.74. Driving a single 16-segment LED display from a serial (SPI) data input. There's no pre-stored character table in this particular driver chip; instead, you get to make up your own symbols, sending a HIGH or LOW bit for each segment.

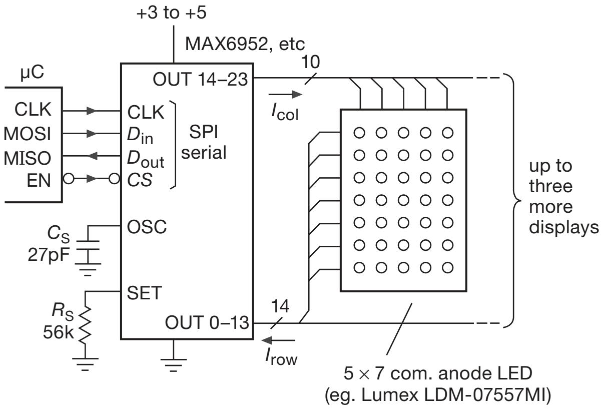

Figure 12.75. Driving up to four dot-matrix 5×7 LED displays from a serial data input (which can also control brightness and blinking). This driver has 104 predefined characters stored internally, and lets you create 24 more of your own.

Figure 12.75 *does* include an internal decoder with predefined character memory.

"Smart" displays

Except in high-volume applications that are cost-sensitive, it's usually a better idea to choose a display that integrates an array of characters (or graphics), with the decoders and drivers included. These come with LEDs, LCDs, VFDs, or OLEDs as the active display.

Single character LED The original smart display device is probably the single-character 5×7-dot LED, which delighted us back in the 1970s: you present it with a 4-bit code, and you can *see* (and latch) the result (Figure 12.76). These were made by HP and TI, and we liked them so much that we incorporated them in our electronic circuits lab course, confident that their ~$15 single-piece price would drop nicely over time. It didn't work out that way, and these puppies (still made by Avago Technologies, the optoelectronics spinoff of HP) now cost double that price in single quantities.

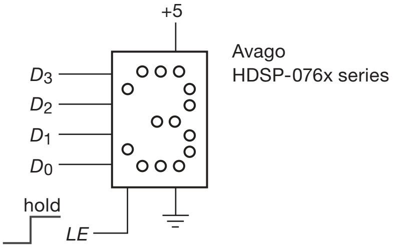

Figure 12.76. LED hexadecimal display with integral latch-decoder-driver. These are beautiful, and colorful, but expensive.

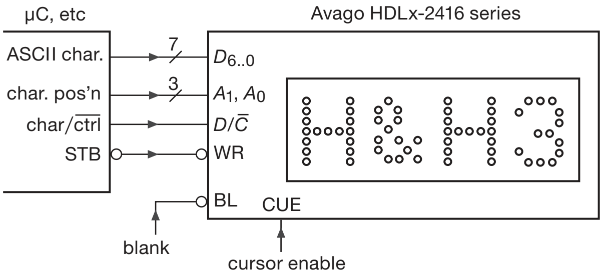

Figure 12.77. For half the price of Figure 12.76 you get a four-character smart LED display "stick." And you can display 128 ASCII characters with its built-in font ROM.

Several character LED Usually you want to display a few characters, at least: so there are handsome four-character smart display sticks (in the usual LED colors) that are as easy to use as the single-character display. Figure 12.77 shows one of these, originated by HP (now Avago) and available for about $15. These display a full character set (7-bit ASCII: upper-case and lower-case alphabets, numbers, and symbols), latched with a WR′ pulse and sent to the character position given by a 2-bit address (a simplified form of "parallel bus interface" that we'll learn about in Chapters 14 and 15). There are additional control functions (dimming, cursor), written by holding LOW the input D/C′ (which the datasheet oddly calls CU′, for cursor "select").

Many character LCD/VFD/OLED As we remarked earlier, the best way to display one or several lines of text is to use an intelligent (smarter than smart) LCD, VFD, or OLED "character" module (Figure 12.78). There's lots of competition,[39] with prices beginning at $10 or less (for a 16×2-character backlit LCD). They come in standard configurations of 1, 2, or 4 rows, with 16, 20, or 40 characters per row. They include built-in character sets, and many of them let you supplement that with a few (usually eight) custom characters. Alternatively, you can choose a full graphic version, consisting of a dot matrix (e.g., 64×260), which you program as a bitmap. That can be a chore if you want to display mostly text, so there are combination text-plus-graphics units that include a pre-stored character set in

[39] Here's an alphabetical list from our favorite suppliers (DigiKey, Mouser, Newark): 4D Systems, Adafruit, AND Displays, Batron, Displaytech, Electronic Assembly, Everbouquet, Hantronix, Lumex, Matrix Orbital, Microtips, Newhaven Display, Optrex, Powertip, Trident, Varitronix, and Vishay/Dale.

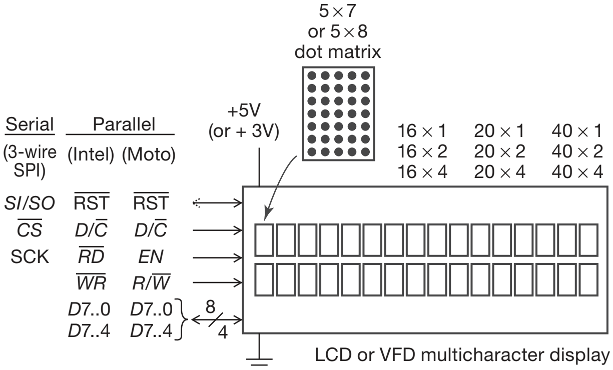

Figure 12.78. Better still, ride the popular wave with a smart LCD or VFD display stick. The character arrangements shown are standard. And some (as here) have both parallel and serial interfaces.

addition to full graphics capability. Examples of these, chosen from one company's offerings (Matrix Orbital, see Figure 12.79), are the LK162-12 (pre-stored text, plus eight user-defined symbols), the GLK24064-25 (full graphics, no built-in fonts), and GLK12232-25-SM (choice of pre-stored text or full set of user-defined symbols, plus full graphics).

To fully appreciate what these modules offer, it's important to understand that LCDs must be driven by an *ac* waveform; otherwise their liquid guts are ruined. So LCD driver chips usually have some way to generate a square-wave segment drive, synchronized to the LCD backplane waveform. An example is the 'HC4543, the LCD cousin of the 'HC4511 LED 7-segment latch–decoder–driver. Another complication, of course, is the need to continually drive the large array of dots with the pattern to be displayed. Add to that the need for an interface that lets you change individual displayed characters on command, or to scroll the display, or advance a cursor, and so on, and you can understand how complicated things can get. Fortunately, the manufacturers understand this, and therefore they provide complete displays that are more than intelligent; they're positively at the genius level.

These displays are invariably used in conjunction with a microcontroller, which communicates via a simple interface. The original LCD smart display sticks use a simple parallel interface, with 8 bits of data (either the character or control information, depending on a data/control′ line: D/C′ in the figure, but traditionally called "RS") and a few control lines.[40] Most now offer a 3-wire or 4-wire serial bus alternative, or provide both options (jumper selectable) on the same display, as in Figure 12.78 (which even offers a choice of "Intel" or "Motorola" parallel protocols, §14.3).

Figure 12.79. Display codes for an LCD alphanumeric "smart display" (Matrix Orbital LK-series) with a standard character set plus eight user-configurable characters (CG RAM). Reproduced with permission of Matrix Orbital.

We like these displays a lot; you can see both LCD and VFD types in the photograph (Figure 12.71), the latter expressing fluorescent joy in the completion of this weighty tome.

12.6 Optoelectronics: detectors

Figure 12.80 shows a selection of detectors, most of which are variations on a *photodiode* or *phototransistor*. We've seen these earlier, in the op-amp chapter (§4.3.1C), where we showed how to use a simple op-amp current-to-voltage ("transimpedance") circuit to convert the photocurrent to a proportional output voltage. In §8.11 we dealt in detail with the design of exceptionally fast and quiet photodiode amplifiers. And in §*4x.3* there's a discussion of the thorny problem of stability in transimpedance amplifiers, taking

[40] They allow a "nybble" mode, in which 8-bit data is sent as two successive 4-bit quantities.

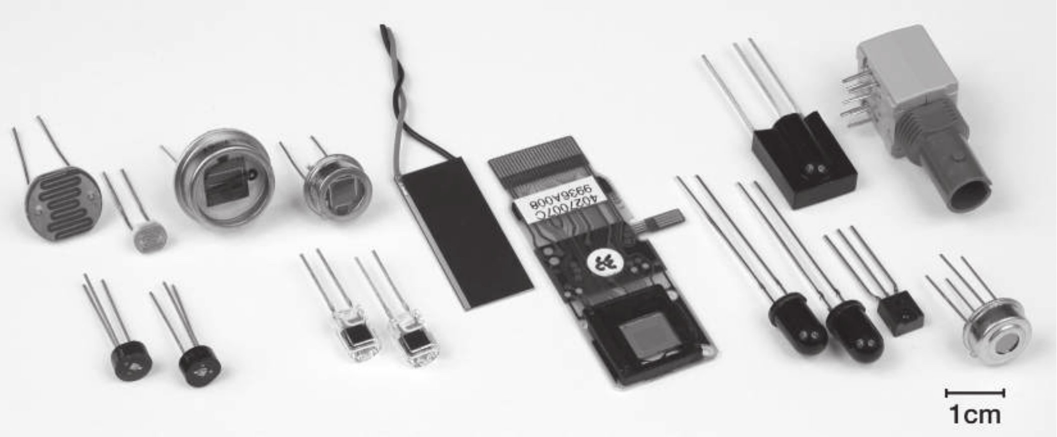

Figure 12.80. Optoelectronics: detectors. At left rear are a pair of cadmium sulfide photoresistive sensors, and a pair of photodiodes (GaAs, silicon) in hermetically sealed metal cases. Below them are plastic-case photodiodes (top- and side-looking), and to their right is a bare photodiode and a small CMOS image sensor (with attached flexible circuit connector) of the sort used in webcams and cellphones. The four opaque black objects toward the right are IR-detectors (filtered to eliminate interfering visible light); the small square one generates a logic-level output, and the large square one is used as a frequency selective (30–56 kHz) "clicker" receiver in consumer audio/video gear. At top right is an ST-style fiber-optic receiver, and below it is a pyroelectric thermal-IR sensor used in PIR motion detectors (featured in the geek movie classic "Sneakers").

into consideration the destabilizing effects of input capacitance.

Soon we'll see the ubiquitous use of photodetectors in the context of optocouplers (also called opto-isolators); and a bit later we'll see them again in connection with fiber optics. Here we simply summarize the earlier photodiode and phototransistor circuits (Figure 12.81), along with some nice parts you can get that integrate a photodiode with additional circuitry to produce either a digital-logic output, or a proportional output in the form of a voltage, a current, or a frequency.

This is a good place to say something also about *photomultipliers*: these sensitive and fast light detectors (two are shown in Figure 12.71) use a cascade of electron-multiplying electrodes (dynodes) to convert a single photoelectron (released, with about 20% probability, when a photon of light strikes the sensitive photocathode) into a fast (∼ns) pulse of 10^5–10^6 electrons. The resultant current pulse has thus been amplified sufficiently before reaching any circuitry, so that amplifier noise is not a problem: a million electrons in a nanosecond is nearly 0.2 mA!

12.6.1 Photodiodes and phototransistors

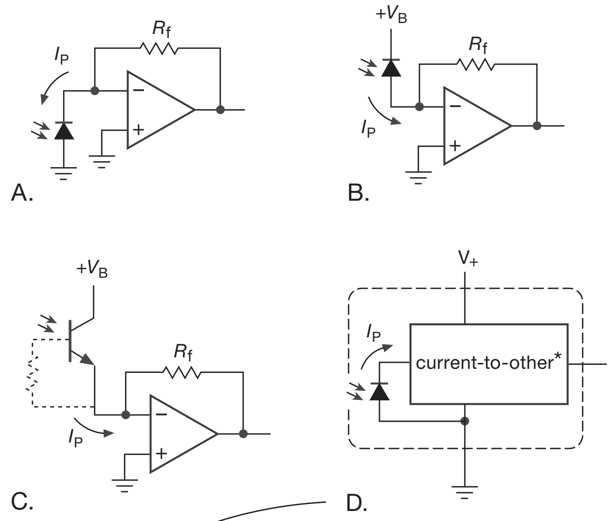
Figure 12.81 reviews the standard ways that photodiode and phototransistors are used. In circuit A the photodiode operates in *photovoltaic mode*; that is, generating a photocurrent into a short circuit. The transimpedance amplifier generates a positive output voltage ($V_{\text{out}} = R_f I_P$), so you can operate from a single positive supply. You might think the op-amp is unnecessary – after all, Ohm's law gives you the same answer – but you'd be wrong! First, the diode's self-generated photocurrent drops to zero if allowed to develop a diode drop of forward voltage, so you'd have to use a small resistive load, such that the maximum output voltage (with maximum light input) is less than ∼0.5 V; and second, the circuit would be slower, set by the time constant of the diode's capacitance and load resistance.

In circuit B the photodiode is back-biased (*photoconductive* mode), which increases the speed by reducing the diode's capacitance and by providing an electric field to sweep away charge. So this circuit is faster; but it's also noisier, and the diode's leakage current limits the low light-level performance. Capacitance can be a real problem in these circuits, especially when the photodiode sits at the far end of a connecting coax cable (§§8.11 and *4x.3*).

Circuit C uses a phototransistor, effectively boosting the photodiode current by the transistor's beta (the back-biased collector–base junction acts as a photodiode, whose photocurrent is multiplied by beta). So a small phototransistor under ordinary room illumination typically gives you currents in the ∼100μA range, compared with ∼1μA for photodiodes.[41] This configuration is the slowest of all, but

[41] Experimental data: we put an FPT110 phototransistor (lower left in

it can be speeded up by adding a base resistor. That produces a threshold, however, because the photodiode current must develop a diode drop across the base resistor in order to get the current amplification factor of beta. Pushing this further, you can get photo-*Darlington* detectors: lots more gain, but lots slower. Finally, Figure 12.81D shows some integrated possibilities, inexpensive and nicely engineered to save you time and pain.



*Function	Example Part Number, and (mfgr)
$E_V \to$ logic	QSE156-159 (FSC)
$E_V \to$ frequency	MLX75304, TSL230-series (Melexis, TAOS)
$E_V \to$ current	TPS851 (Toshiba)

12.6.2 Photomultipliers

Photomultipliers are favorite detectors for photon-counting applications, low light-level detection and integration, and X-ray or gamma ray detection (via a scintillator, which converts the energetic photon into a visible light pulse). There is ample sophistication, if you want to get really serious about these things; but the basic configurations are shown in Figures 12.82 and 12.83.

Simplest is the "photon-counting" configuration (Figure 12.82), in which the current pulse at the anode generates a (negative) fast pulse across the 50 Ω load resistor, amplified by a wideband amplifier of the sort used in RF applications (the UPC2710 costs about $1 and works fine: we've got a thousand of them running right now).

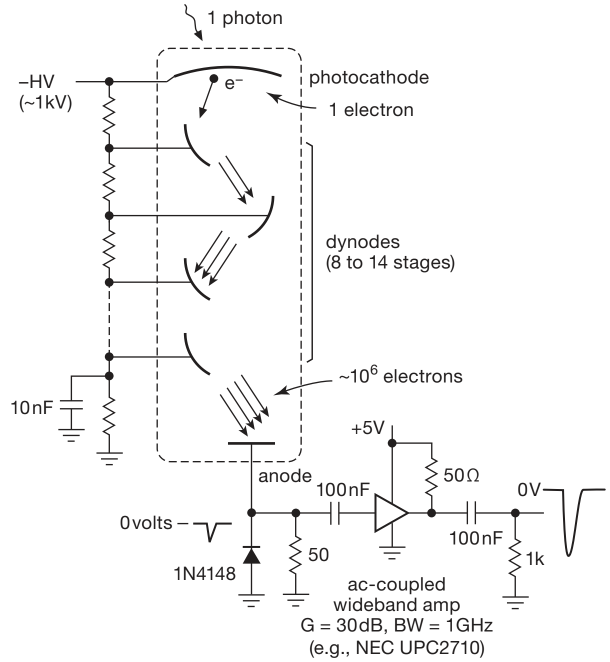

Figure 12.82. Photomultiplier "pulse counting" circuit. The cascade of electron-multiplying dynodes produces a ∼ns pulse of $\sim 10^6$ electrons for each detected photon of light, which develops a ∼mV negative pulse across 50 Ω.

If you want instead to detect accurately very low light levels, and don't need nanosecond speed, you probably want a bandwidth-limited "integrating" amplifier like the one shown in Figure 12.83.[42] Here the excellent (and nearly unique) OPA656 wideband low-I_B (JFET) op-amp converts the anode current to a voltage waveform. Even though we're aiming for only a few megahertz of bandwidth, we need a fast op-amp, as explained in §§8.11 and *4x.3*. For reasons of bandwidth and noise, it's especially

Figure 12.80) on our lab bench and measured its photodiode current as I_{CB}=0.4μA, compared with its phototransistor current (with 10 V bias) of I_{CE}=60μA. In hazy sunlight (an August day in Boston) the photodiode current was 250 times higher (100μA). Although the datasheet for this device doesn't tell you the active area, we measured it as 0.7 mm^2. That works out to an efficiency of about 5%, if you were to use the photodiode as a solar cell.

[42] This is similar to the amplifier designed for our colleague Lene Hau, and was used in her pioneering "slow-light" experiment in 1999: 17 m/s (38 mph), slower than a speeding bicycle!

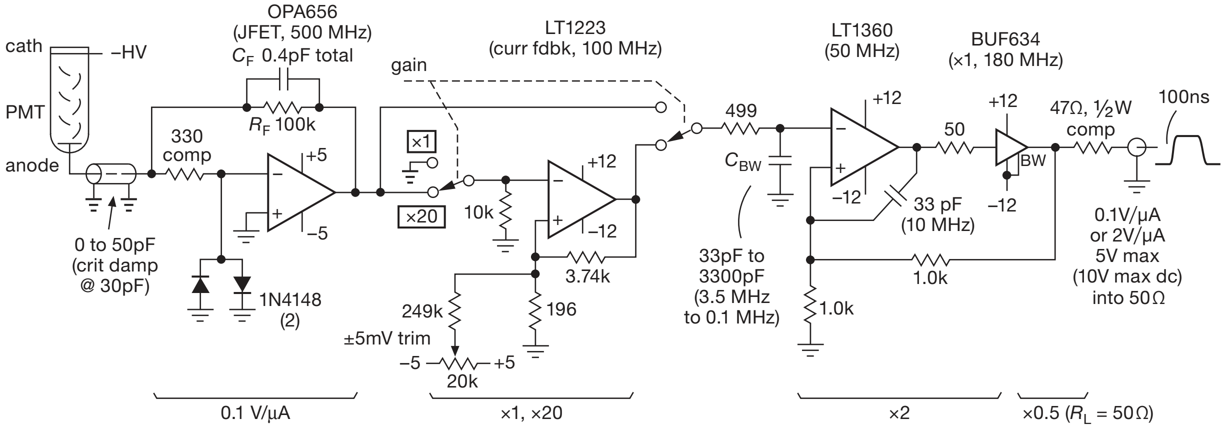

Figure 12.83. Low noise photomultiplier amplifier, with 3.5 MHz bandwidth and 2V/μA gain. See also the discussion in §8.11.

important to keep the input capacitance to a minimum, and to choose the stabilizing feedback capacitance C_F carefully.

The rest of the circuit is pretty straightforward: the series input resistor and clamp diodes protect the op-amp from input spikes, caused, for example, by PMT breakdown (it uses a kilovolt supply). The second stage is an optional ×20 gain boost, for which we used a current-mode op-amp. These have the interesting property that their closed-loop bandwidth is largely independent of closed-loop gain: the ratio of resistors sets the gain (as with the familiar "voltage-mode" op-amp), but the bandwidth is determined by the value of feedback resistor alone. For example, this particular op-amp has 100 MHz bandwidth with a 1k feedback resistor and G_{CL}=1, dropping modestly to 60 MHz for G_{CL}=30; by contrast, a voltage-feedback op-amp's gain would decrease inversely with closed-loop bandwidth. Here we chose a larger feedback resistor (3.74k), deliberately limiting the bandwidth to about 15 MHz, because that's all we need (and extra bandwidth just invites trouble).

This op-amp specifies ±3 mV (max) offset voltage, which, when combined with the ±2 mV (max) offset of the input stage, could produce as much as 100 mV of output offset; so we added an offset trim. There's a simple *RC* bandwidth-limiting lowpass on the way to the third stage; this could be elaborated into a switched set of 3 dB breakpoints, if desired. Note however that the maximum bandwidth of ~3.5 MHz is limited by the input-stage rolloff: BW=$(1/2\pi)R_FC_F$. Finally, the output stage consists of a wideband unity-gain power buffer (good to ±250 mA) enclosed within a gain-of-2 noninverting feedback stage. You need the op-amp, because the buffer alone does not have internal feedback to discipline its output: its offset is specified as ±100 mV (max). But you have to admire the brute – it's fast, and it's powerful.

12.7 Optocouplers and relays

An LED emitter, combined with a photodetector in close proximity, forms a very useful object known variously as an *optocoupler*, *opto-isolator*, or *photocoupler* (Figure 12.84). In a nutshell, optocouplers let you send digital (and sometimes analog) signals between circuits with separate grounds. This "galvanic isolation" is a good way to prevent ground loops in equipment that drives a remote load. It is essential in circuits that interact with the ac power mains. For example, you might want to turn a heater on and off from a digital signal provided by a microprocessor; in this case you would probably use a solid-state relay, which consists of an LED coupled to a high-current triac or SCR. Most ac-operated switching supplies (e.g., those used in computers, telecommunications, and instrumentation) use optocouplers for the isolated feedback path (see for example Figure 9.83 in §9.8). Similarly, designers of high-voltage power supplies sometimes use optocouplers to get a signal up to a circuit floating at high voltage.

Even in less exotic situations you can take advantage of opto-isolators. For example, an opto-FET lets you switch analog signals with essentially no charge injection (apart from effects of the fractional-pF isolation capacitance); the same goes for sample-and-hold circuits and integrators. Opto-isolators can keep you out of trouble when driving industrial current loops, hammer drivers, etc. Finally, the galvanic isolation of opto-isolators comes in handy in high-precision or low-level circuits: for example, it is difficult to take full advantage of a 16-bit analog-to-digital converter,

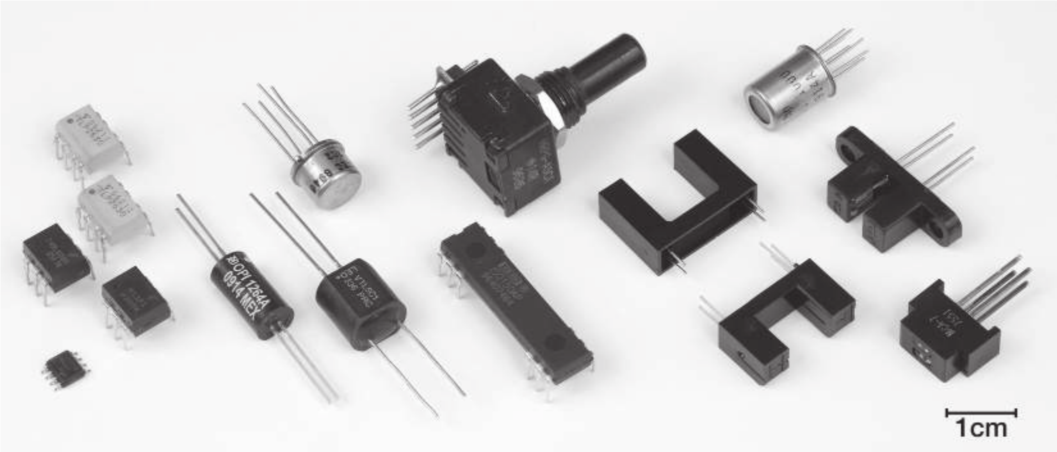

Figure 12.84. Optoelectronics: couplers and interrupters. The five ICs at left are optocouplers, with LED–photodiode pairs and (in some cases) logic inputs and outputs. They are good to several kilovolts or so of isolation, whereas the adjacent cylindrical object with whiskers is rated at 10 kV (and the stretch version in Figure 12.71 is good to 50 kV). The oval package (and metal can above it) are LED–photoresistor couplers, which use a CdS resistive sensor like the ones at top left in Figure 12.80. The stretched IC at center (ISO150) is also a digital isolator, but it uses a *capacitive* coupler; it doesn't belong at this party, but it's too elegant to omit! The three gapped objects to its right are opto-interrupters, and the boxy thing without a gap is a reflective sensor (as is the metal-can barcode reader at top). The panel control at top center is an optical incremental encoder, generating 120 quadrature cycles per turn.

because the digital output signals (and noise on the digital ground to which you connect the converter's output) get back into the analog front end. You can extricate yourself from "noise city" with optical isolation of the digital half. Optocouplers typically provide 2500 volts (rms) isolation, $10^{12}\ \Omega$ insulation resistance, and less than a picofarad coupling between input and output.

There are many varieties of optocouplers, the choice depending on the intended application – for example, the coupling of analog signals, or digital-logic signals, or ac power switching. In the sections below we've sorted these into seven categories, illustrated with examples of some of the more popular (or more interesting) parts currently on the market. The choice of categories is somewhat arbitrary, but it makes sense to us. They are (in order of appearance): I. Phototransistor output; II. Logic output; III. Gate driver output; IV. Analog-oriented; V. Solid-state relay with transistor output; VI. Solid-state relay with triac/SCR output; and VII. ac-input optocouplers.

12.7.1 I: Phototransistor output optocouplers

Figure 12.85 shows an assortment of optocouplers with bipolar transistor output. These are primarily intended for digital logic-level coupling (though it is possible to exploit the configuration in Figure 12.85C to make an approximately linear coupler; see Figures 12.88 and 12.89). The earliest (and simplest) is typified by the 4N35, an LED–phototransistor pair with 40% (min) current transfer ratio (CTR) as a phototransistor, and sluggish 5μs turn-off time ($t_{\rm OFF}$) into a $100\,\Omega$ load. Circuit A shows how to use it: a gate output and pullup resistor generate current-limited 8 mA drive, and a relatively large output-side collector resistor guarantees saturated switching between logic levels. Note the use of a Schmitt-trigger inverter, a good idea here because of the long switching times. You can get LED-phototransistor pairs with CTRs of 100% or more (e.g., the jellybean CNY17-4, with CTR=160% min), and you can get LED–photo-Darlingtons, as shown; they're even slower than phototransistors! To get improved speed, the manufacturers sometimes use separate photodiode and transistor, as shown in the 6N136 and 6N139 optotransistor and opto-Darlingtons. With optocouplers that provide access to the base, you can add a resistor from base to emitter to improve the speed (configurations B and F); however, this produces a threshold effect (as shown alongside circuit F), because the phototransistor doesn't begin to conduct until the photodiode current is large enough to produce a $V_{\rm BE}$ across the external base resistor. In digital applications the threshold can be useful, but in analog applications it is an undesirable nonlinearity.

12.7.2 II: Logic-output optocouplers

These preceding optocouplers are nice, but somewhat annoying to use because you have to supply discrete

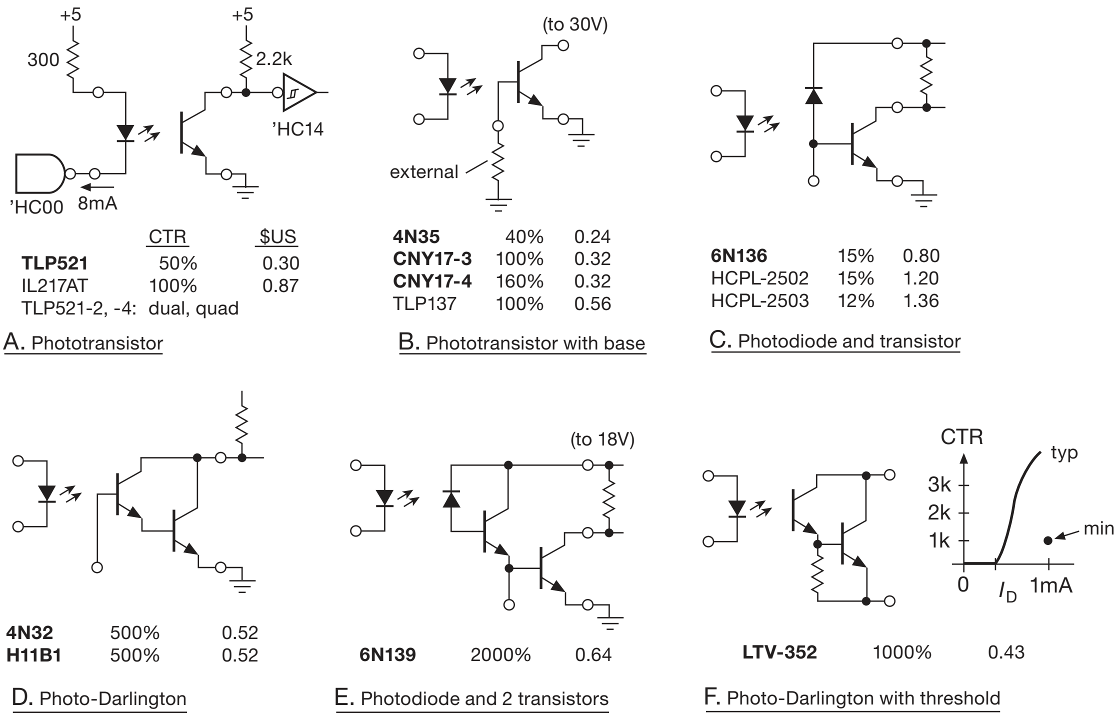

Figure 12.85. Optocouplers-I: Phototransistor output. Parts in **bold** are "jellybeans" – inexpensive and ubiquitous, though not necessarily the best performers.

components at both input and output. Furthermore, the current needed to drive the LED may exceed the drive capability of some logic families; and the passive pullup at the output side suffers from slow switching and mediocre noise immunity. To remedy these deficiencies the silicon wizards bring us "logic" optocouplers (Figure 12.86). The 6N137 and friends (configurations A and B) go halfway, with bare LED at the input, but buffered logic at the output. You still need plenty of input current (for the 6N137 it's specified as 6.3 mA, min, to guarantee output switching), but you get clean logic swings at the output (albeit open-collector), and speeds to 10 Mb/s. Note that you must supply +5 volts to the internal receive-side output-logic circuitry. Logic couplers with reduced drive are listed; among these are the classic (and curiously named) H11L1 and H11N1, descendants of the pioneering optoelectronic offerings from General Electric, happily enjoying great popularity well past their 30th anniversary. But note the cost penalty, particularly for high speed combined with low drive current.

As long as you have internal logic circuitry at the output, why not provide honest active pullup? Why not indeed. That's configuration B, among which you'll find improved versions, some faster, some with impressive isolation slewing rates, and some with three-state outputs; but note the "improved" pricing!

The optocouplers in configuration C bring us to the promised land (where, however, the real estate values are somewhat elevated): these accept logic-level inputs, and produce logic-level outputs with active pullup. Because of the internal logic circuitry at both input and output, both sides of the chip require logic supply voltages. Some varieties (e.g., the ACPL-772L) will happily run on either 3 V or 5 V supplies at both ends, in any combination. These couplers are pretty fast, up to 50 Mb/s.

We've listed also three isolating logic couplers that perform similarly, but that use capacitive or transformer-based isolation techniques in place of light. They are faster, but note one complication: their isolating methods are all *ac-coupled*, using short pulses to transfer changes of state across the gap. That is, they are not intrinsically "dc correct," and they may exhibit artifacts such as timing-delay skew, or require an initializing signal to force the output to a known state.

Figure 12.86. Optocouplers II: Logic output.

12.7.3 III: Gate driver optocouplers

Isolated optical coupling lets you float the output, relative to the input, at voltages up to the isolation rating of a few kilovolts (limited also by a maximum slewing specification, called “common-mode transient immunity,” typically a few kilovolts per microsecond). We know what you’re thinking now – whatever can such a high-voltage and swiftly moving load *be*?! Well, one important application that needs both isolation and fast slewing is “high-side drive” of MOSFETs or IGBTs (the latter favored for high-voltage power switching, see §3.5.7), where you have a push–pull pair going between ground and a high-voltage positive rail (see Figures 9.73C and D, and §*9x.10*). And what you need is an isolator that can deliver a full gate drive of +10 V or more, relative to the MOSFET source (or IGBT emitter) of the high-side transistor, which is acting like an nMOS follower. Because it’s a follower, rather than a switch, the latter is “flying” along with the output.

Figure 12.87 shows the basic gate-driver optocoupler. In block diagram form you might mistake it for a simple logic coupler; but its output stage consists of a robust push–pull driver that can source and sink currents of an amp or more, and operate from an output supply rail up to ∼30 V. When the coupler’s output goes HIGH, it switches on the IGBT, which promptly flies up to the positive high-voltage rail at a kilovolt or more, carrying the gate driver output along with it. That’s why you need both high-voltage isolation and common-mode transient tolerance.

Of course, the ∼20 V supply for the isolator’s output side has to fly also! Sounds like a serious problem – but there’s a terribly clever solution, which exploits the fact that the output is switching between ground and +HV: if you hook a high-voltage diode to the coupler’s V_{CC} from a plain ordinary +20 V supply (relative to circuit ground), as shown in Figure 12.87A, it will conduct during times when the output is LOW, charging up the bypass capacitor. Just make the latter large enough to keep the coupler’s output powered during the periodic HIGH states, and you’re done; that’s easy enough, because the coupler output-stage quiescent current is only a few milliamps. This is basically a high-side “charge pump,” sometimes called a “bootstrap supply.” You can use one of these couplers to drive the low side also; in that case just power it directly from the +20 V, omitting the diode.

High-voltage switching is fraught with peril, and is not a recommended activity for the faint of heart: a momentary output short can annihilate things in a hurry. You need to protect against such “faults,” for example with current-limiting circuitry. But even then you can destroy the IGBTs or MOSFETS, because a load short puts the full supply voltage across the high-side IGBT while it is running at that current limit. What you need to do is sense when the IGBT’s gate is being driven, but its output has not gone promptly into voltage saturation. Happily, there

	I_O	max V_{CC}	$US

B. Gate driver with fault shutdown

Figure 12.87. Optocouplers III: Gate driver output.

are improved gate-driver optocouplers with “desaturation” fault detection, as in Figure 12.87B: internal circuitry looks at the drop across the driven IGBT, and shuts off its gate drive during a non-saturating fault.[43] It also sends a fault indication back across the isolation gap, as shown.

12.7.4 IV: Analog-oriented optocouplers

So far we’ve seen only *switching* applications of optocouplers, where linearity is of little concern. But sometimes you need to isolate *analog* circuits. One method, of course, is to use a pair of converters, converting the analog quantity to a digital bitstream, coupling that via logic optocouplers, then converting back to analog. But there are analog-oriented optocouplers that do the job directly.

Figure 12.88 shows most of these. The classic H11F1 (another winner from the pioneers at GE, this one going back to 1979) is an opto-FET, in which the LED drive current affects the FET in the same way that a gate drive voltage would (we’re not exactly sure what’s inside this part). So increasing levels of LED drive increase the saturation current (that is, channel current at channel voltages greater than a few tenths of a volt or so), reaching about 1 mA for an LED drive of 25 mA. Notice that the output is completely symmetrical, and works up to ±30 V across the output terminals. And, as with ordinary FETs, the output terminals look approximately resistive for small voltages across the channel; here, however, the R_{ON} value is set by the LED drive current, and varies from $>$300 MΩ (with no LED drive) down to about 100 Ω (with 16 mA LED drive). Once again this property is symmetrical both sides of zero volts, but it’s not particularly linear beyond about ±50 mV, as seen in the graph of Figure 12.88A.

For really good linearity you can use an opto-photoresistor (configuration B), which is an LED illuminating a CdS photoresistor. The sensors are slow, and exhibit memory effects; but the output terminals behave like very linear resistors, with linearities of ∼0.01% for voltage swings up to ±1 V.[44] This would make an excellent amplitude limiter for a low-distortion Wien Bridge oscillator like the one in Figure 7.22.

There’s a small class of “video optocouplers,” which rely on the inherent linearity of LED intensity versus drive current (except at low currents), and the good linearity of photodiode current versus illumination. Figure 12.88C

[43] There’s time to do this: an IGBT’s thermal mass provides about 10 μs at its maximum conduction current, with full rated voltage across it, before damage occurs.

[44] Sadly, the continued availability of these nice devices is threatened by legislated restrictions on hazardous substances (RoHS): cadmium is not a nice material, and worries about its toxicity put it on the no-no list. Ironically, while the milligrams of cadmium in a CdS photocell are a target of RoHS legislation, such potential exposure (from *eating* the things?) is dwarfed by the general population’s exposure to cadmium via fossil-fuel burning and cigarette smoking. And, while we’re whining, how about the vast quantities of lead that are permitted in automobile batteries? These weigh 50 pounds or more, most of it lead, and about 100 million are manufactured annually: that’s more than a megaton of lead!

	R_{OFF}/R_{ON}	V_{max}	t_{ON}	t_{OFF}

HCPL7510	0.06%	5.75
HCPL7800	0.004%	10.80

Figure 12.88. Optocouplers IV: Analog-oriented output.

shows on example, with a claimed bandwidth of 17 MHz when used in the circuit of Figure 12.89. Another way to achieve reasonable linearity is to package a matched pair of photodiodes with an LED (Figure 12.88D), then use one of them to provide feedback on the driving side (Figure 12.90); the far-side photodiode will then exhibit linearity limited only by the degree of matching. The devices listed in Figure 12.88D achieve linearities of better than 1% in such a configuration.

Finally, there's an interesting class of linear optocouplers that integrate an A-to-D converter and a D-to-A converter, with digital coupling. These use "delta–sigma" conversion (sometimes called "1-bit" conversion), which we discuss later in §13.9. Figure 12.88E shows the scheme. These are very linear, but the delta–sigma process leads to significant output noise (∼30 mVrms, compared with 3 V full-scale output), and some signal delay (∼5 μs). These parts have found widespread use in half-bridge three-phase variable-frequency-drive motor-power systems, where they measure the current in each leg. As a result they generally have full-scale ranges of only 300 mV.

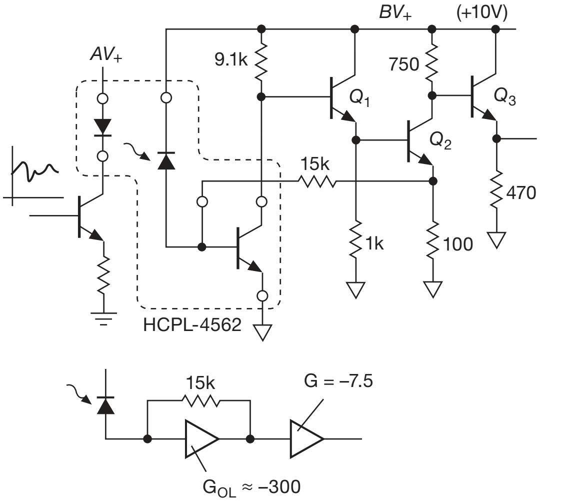

Figure 12.89. Using the HCPL-4562 "video optocoupler" in the datasheet's recommended transresistance configuration (∼17 MHz bandwidth to −3 dB).

12.7.5 V: Solid-state relays (transistor output)

Turning back again to couplers whose output is a switch, we have the class of "solid-state relays" (SSRs; Figures 12.91 and 12.92). These are characterized by isolated two-terminal outputs that are either open (nonconducting) or closed (conducting), depending on the state of input LED drive, and therefore can be thought of as substitutes for electromechanical relays (see §*1x.6*). They do not

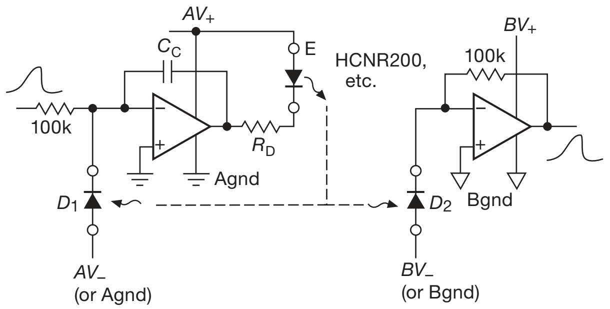

Figure 12.90. Linearizing an optocoupler with photodiode matched pair.

require any external source of supply voltage on the output side – they're "just a switch." One class of SSRs uses *thyristors* (SCRs and triacs) as the output switch; these devices, once triggered into conduction, remain conducting until the current is removed, and so they are suitable only for ac loads (where the current goes through zero twice per cycle). We treat these below, after looking at SSRs with MOSFETs as the output switches, which is the class of SSRs that is suitable for dc loads (and, as we'll see, these can also switch ac loads when configured as a series pair of MOSFETs).

To bring the output transistor(s) into conduction, MOSFET-output SSRs use a series string of a dozen or more photodiodes to generate the needed gate voltage. This "photovoltaic stack" is illuminated by the LED, generating 5–10 V of gate bias. It can supply only a few microamps to the gate, whose capacitance causes the turn-on and turn-off times to be typically in the range of 0.1–5 ms. You don't have to crack an SSR open to play with this portion of the relay, though, because you can buy it à la carte (Figure 12.91A). The datasheets for these devices don't tell you much about what's inside; but it's evident from the fast t_{OFF} specifications that most of them use an auxiliary bit of circuitry to discharge the gate for fast turn-off. This could be a *pnp* transistor that is pulled into conduction when the PV stack's output current ceases, perhaps aided by an SCR (indicated by dashed lines).

Most MOSFET SSRs use a series-connected pair of *n*-channel FETs, as shown in Figure 12.91D, driven by a photovoltaic stack.[45] For an ac load you use the top and bottom (drain) terminals. When the relay is OFF, one transistor or the other is acting as the open switch, depending on polarity; you need the series pair, because otherwise the reverse (body) diode would conduct. When the relay is ON, both transistors act as switches, characterized by an R_{ON}.[46]

You can of course use this same connection for a dc load, but you do better by using the transistors in parallel (connecting the drains together as shown), which reduces R_{ON} by a factor of 4 (at the cost of increased output capacitance, if that matters to you). Note that enhancement-mode MOSFETs give you a "normally OFF" (form A) relay, whereas depletion-mode MOSFETs (with the gates connected to the negative end of the PV stack) make a "normally ON" (form B) relay.

Keep in mind that these "relays" come in an enormous range of current capabilities, and that the small ones can be used effectively for low-level switching: parts like the AQY221N3 or NEC/CEL PS7801-1A, for example, have an R_{ON} of 10 Ω or less while presenting a mere picofarad of output capacitance. Unlike CMOS analog switches (§3.4.1A), they have *zero* charge injection (apart from the isolation capacitance, about 1 pF for most parts, but a mere ~0.3 pF for the PS7801A) – you may want to use them even when you don't need the isolation. For example, you might use one of these in a sample-and-hold or integrator circuit.

There are a couple of oddball FET relays listed in Figures 12.91B and C: the H11F1 (featured earlier as "analog oriented") is both fast (~15 μs) and symmetrical (good to ±30 V when OFF, ±100 mA when ON). We're not sure how they do it. And the LH1514 has an interesting configuration, intended for balanced ac signals: it uses a "T-switch" arrangement, with a pair of normally-open series switches on each line, bridged across with a normally-closed switch (a depletion-mode MOSFET, driven from the same PV stack). This results in good signal attenuation when OFF, even for signals at radiofrequencies (65 dB at 1 MHz).

12.7.6 VI: Solid-state relays (triac/SCR output)

For powerline ac switching, it's common to use a solid-state relay with a triac or a pair of SCRs (collectively *thyristors*) as the switching device. The low-current SSRs shown in Figures 12.92A and B are used primarily as trigger devices to activate a high-current thyristor, as shown in Figure 12.93. But the big gorilla in the room is the integrated SSR, which includes the optocoupler and (usually)

[45] Some SSRs, intended for dc loads only, use only a single MOSFET; examples are the AQV100- and AQZ100-series from Panasonic.

[46] In §3.5.6B we suggested a general-purpose roll-your-own version of this SSR circuit (Figure 3.107). The advantage of providing your own MOSFETs is that you can select low-resistance, high-current parts (to over 1kA pulsed, 100 A continuous), or common low-cost parts like an IRF640 (200 V, 12 A, 0.25 Ω), or amazing high-voltage parts (to 4.5 kV); a handy table is provided there.

D. Solid-state relay – MOSFET output

Figure 12.91. Optocouplers V: "dc solid-state relay" (transistor output).

zero-voltage-switching (ZVS) trigger circuit, along with a substantial output triac or SCR pair. This is good: when driving ac loads, it's best to switch on the load during a zero crossing of the ac waveform, to avoid putting spikes onto the powerline; and the triac or SCR inherently switches off at zero current.[47] So we've got "ZVS/ZCS."

Figure 12.92C lists just a few of the hundreds of available types. High-current SSRs aren't cheap, but they're delightfully easy to use. The larger ones (10 A or more) come in a panel-mount "brick" package (about 1.75″×2.25″×1″, intended for heatsinking), whereas the smaller ones come in several sizes of PCB-mounting "single in-line" packages (SIPs).[48]

[47] An exception is when switching powerline ac across a transformer primary: there ZVS is the *worst* case, because the full unipolarity half-cycle applied voltage brings the core closest to (or into) saturation, with enormous peak currents. Ideally you'd want to switch the ac close to its *peak* voltage. We encountered this effect in our lab, when powering a 20 A Variac (§1.9.5D) – about half the time when you switched it on, the 20 A circuit breaker on the wall would snap out (even though the Variac was unloaded); you had to be lucky and catch the ac waveform near a peak to successfully switch it on.

[48] But see our warning footnote in §12.4.3 about heatsinks. Be sure to

12.7.7 VII: ac-input optocouplers

Finally, there is a class of optocouplers intended for ac input drive (Figure 12.94). Some use a pair of LEDs back-to-back, coupled to a phototransistor or photo-Darlington. The output phototransistor conducts according to the magnitude of LED current, with typical current-transfer ratios of 20–100%; this is useful for detecting zero crossings of the ac powerline.

Input–output modules

There is a category of opto-isolating "input–output modules" used in industrial settings: The *input* modules monitor an ac or dc signal (with a selection of voltage ratings, up to powerline voltage), producing an isolated low-voltage open-collector logic output to go to a computer or other industrial controller; the *output* modules use a low-voltage logic signal from a computer or controller to switch an ac or dc load, typically at powerline voltages. In other words, the output modules are SSRs with thyristor or transistor outputs (ac and dc, respectively), and the input modules are ac-input optocouplers with open-collector outputs. These latter, therefore, are an easy way to use an ac powerline input to create an isolated logic-level swing (or higher, because the O/C output typically can go to +30 V), as shown in the figure. Note that these puppies include an internal *RC* filter, so the output indicates the presence or absence of an ac waveform, but does not capture the individual cycles. Input–output modules come in several standard upright module package sizes (e.g., 1.7″×1.25″×0.6″ and 1.7″×1″×0.4″), with a hold-down screw-fastener arrangement, and (often) an indicator LED on top.

12.7.8 Interrupters

You can use an LED–phototransistor pair to sense proximity or motion. An "optical interrupter" consists of an LED coupled to a phototransistor across an open slot. It can sense the presence of an opaque strip, for example, or the rotation of a slotted disk. An alternative form has the LED and photodetector looking in the same direction, and

consult the datasheet for the ON voltage drop when designing an SSR into a system.

it senses the presence of a reflective object nearby (most of the time, anyway!). As with optocouplers, you can get these with a simple phototransistor on the receive side, or you can get them with logic-level outputs (either open-collector, or active pullup). You can see some examples in Figure 12.84. Optical interrupters are used in mechanical devices such as printers, to sense the end of travel of the moving assembly. Optical interrupters can have problems when ambient light levels are high. A nice trick in such situations is to use *synchronous detection* (§8.14.1), making the detector selectively sensitive to the frequency at which the emitter is driven. Hamamatsu offers a nice selection (their S4282/89-, S6809/46/86-, and S7136-series) of detectors with built-in preamp and signal processing electronics. You can get optical "rotary encoders" that generate a quadrature pulse train (two outputs, 90° out of phase) as the shaft is rotated; there's an example of one in Figure 12.84. These provide a nice alternative to resistive panel controls (potentiometers) – see §15.5.

In any application where you're considering an optical interrupter or reflective sensor, take a look at Hall-effect sensors (not shown) as an alternative; they use solid-state magnetic-field sensors to indicate proximity. They're commonly used in applications such as automobile ignition systems (as an alternative to mechanical breaker points), antilock brakes (sensing wheel rotation), and brushless dc motors.

12.8 Optoelectronics: fiber-optic digital links

Fiber-optic transmission of digital signals provides a convenient galvanically isolated link, capable of carrying digital communications at rates to 10 Gb/s, over distances to 10 km,[49] without any susceptibility to interference, even in the most electromagnetically noisy environments (factory floor, automobile, mountaintop observatory). Although the sophisticated user may want to design 10 Gb Ethernet fiber-optic circuits, we're mostly interested here in rather more humble goals, for example, simply linking some instruments together over distances of 10 m (or perhaps 1 km), with data rates of megabits per second (or perhaps with fast Ethernet, at 100 Mb/s). Let's see what off-the-shelf components will do the job.

12.8.1 TOSLINK

A very simple and inexpensive short-range digital-fiber link is provided by the TOSLINK™ family of transmitter–receiver pairs (known generically as "EIAJ optical," "JIS F05," "ADAT optical," or "Digital Audio Optical Cable"), see Figure 12.95. The TOSLINK standard was originated by Toshiba,[50] and is widely used for digital-audio interconnections, for example between audio and video components. It is one of the two "digital-audio" jacks you see on the rear of DVD and Blu-ray players, sometimes la-

[49] The speed record at time of publication is 1 petabit/s (10^{15}b/s) over a 50 km length of fiber optic cable, achieved by a collaboration of NTT (Japan), Fujikara Ltd., Hokkaido University, and the Technical University of Denmark. The "cable" is a 12-core bundle, each fiber of which carries 84.5 Tb/s by multiplexing upon 222 separate wavelengths a signal rate of 380 Gb/s per wavelength (the latter achieved by modulating eight separate carriers, each with polarization multiplexed 32QAM).

[50] **Caution**: we've found current availability largely through second-source suppliers such as Comoss, Sys Concept, and FiberFin; the parts used for the examples in this section appear to be unavailable from distributors, and may have been discontinued by Toshiba.

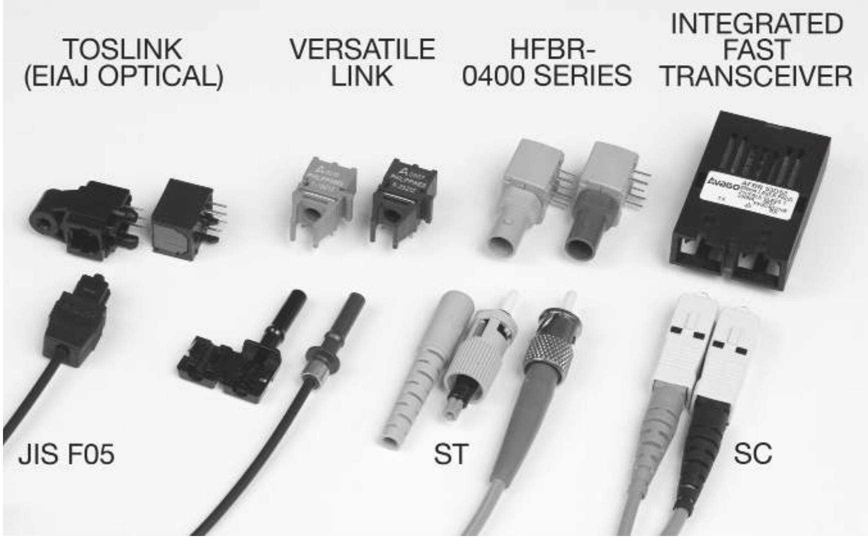

Figure 12.95. Some popular fiber-optic formats. The TOSLINK devices, widely used in consumer audio, are here shown in a shuttered PC-mount version (right), and a panel-mount unshuttered version (left). The other connector formats can be field terminated (bare connectors are shown for ST and Versatile Link), but it's easier to buy preterminated fiber cables.

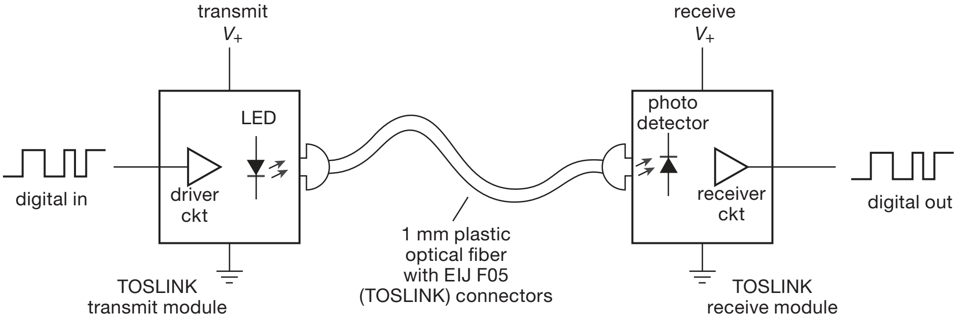

Figure 12.96. Inexpensive PC-mounting TOSLINK-style fiber-optic modules include all drive and receive electronics. They accept and reconstruct standard logic levels, at rates to 15 Mb/s over ranges to 10 m.

beled "digital optical" (the other being a coaxial electrical audio socket that is physically identical to the common "RCA" jack, usually placed alongside the TOSLINK connector, and that carries, electrically, the same digital stream as the optical port). TOSLINK uses visible red LEDs, operating at 650 nm; it's easy to see when it's working, and which end is the transmitter (unlike the case with invisible infrared fiber modules).

The charm of TOSLINK is its simplicity and low cost: the Toshiba TOTX147 and TORX147 are a typical transmitter–receiver pair, costing about $1 at each end (in small quantities). They run on a 2.7–3.6 V logic supply, with the transmitter accepting logic-level inputs, and the receiver replicating the logic levels at its output. That is, all the logic interface circuitry is built in; all you do is connect it up (Figure 12.96). They are intended for short-range links, operating up to 15 Mb/s over a distance of 5 meters or less. You use an inexpensive 1 mm plastic fiber (APF, for all-plastic fiber, or POF, for plastic optical fiber), which you can get as a 2.2 mm (or thicker) sheathed cable with TOSLINK jacks at each end; we've found such "patch-cords" (e.g., at Amazon.com) for as little as a dollar or less, and are standard equipment at audio–video supply stores. Figure 12.97 shows logic input and output from a TOSLINK pair running at +3.3 V, driven with a 15 Mb/s data stream, and connected with an 8-foot fiber patch-cord. You can get 5 V versions as well, e.g., Toshiba part numbers TOTX/TORX177 (analogous Sharp part numbers are

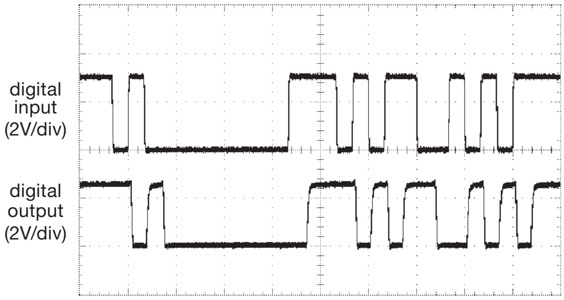

Figure 12.97. Transmitted and received data, sent through 8 feet of 1 mm plastic fiber at 15 Mb/s with TOSLINK digital-audio components (Toshiba TOTX141FPT, Sharp GP1FA352RZ). Horizontal scale: 200 ns/div.

GP1FA351TZ/RZ and GP1FA551TZ/RZ, for 3 V and 5 V transmitter–receiver pairs).

One drawback of these digital-audio TOSLINK components is that the receiver bandwidth does not extend down to dc, and is specified to operate properly only with a minimum data rate of 0.1 Mb/s.[51] Note that the transmitter end is dc-coupled; the problem is at the receiver end, where the optical signal's switching amplitude is used to establish the receiver's threshold. This is done to minimize pulse-width distortion: if a *fixed* threshold were used (as is common with other fiber protocols, for example the Versatile Link devices below), the receiver's output would show a widening or narrowing of the reconstructed data bits, according to the amplitude of the received optical signal (i.e., dependent on length of fiber and other losses).

If you need response down to dc, you can get true dc-coupled TOSLINK-style receivers, with generally improved performance: for example, the TOTX197 and TORX198 pair of "general-purpose" (as contrasted with "digital-audio") modules operate from dc to 6 Mb/s over a distance of 40 meters or less, using the same plastic-fiber cable and connector. The TOTX/TORX1350 series specify data rates of dc to 10 Mb/s over distances to 100 meters, again with all-plastic fiber (APF). And, by using a lower-loss plastic-clad glass fiber (PCF, with a fiber diameter of 0.2 mm) the range is extended to 1 km, for example, with the TOTX/TORX196 pair. As in life generally, there are tradeoffs: these devices exhibit greater pulse-width distortion (typically ±55 ns, compared with ±15 ns for the audio-style devices[52] with their adaptive threshold circuitry); also, you pay about twenty times as much for them ($20–25 or so, in small quantities).

A. Connectorless plastic-fiber components

If you dislike connectors, you can get connectorless fiber transmitters and receivers from Industrial Fiber Optics, Inc. These accept 1 mm plastic fiber, in a PCB-mount cinch-nut collet housing; you just cut the fiber, insert, and twist the thing tight. They make a range of power and speed grades, up to 155 Mbps; pretty colors (red, green, blue, and infrared) too! While you're shopping, you might pick up one of their nifty "Infrared Detection Cards" (part # IF-850052), with which you can tell if an IR LED (or laser) is working. You hold it in front of the emitter, and you see an orange-yellow spot on its target area.[53]

12.8.2 Versatile Link

The Versatile Link (VL) series of optical-fiber transmit and receive modules was introduced by Hewlett–Packard (then spun off as Agilent, and finally Avago) around 1990, and continues in wide use. It runs through the same 1 mm plastic fiber as TOSLINK, but with a somewhat different connector format, namely a cylindrical snap-in connector that engages a pair of plastic pincers (see the photograph, Figure 12.95). These modules use a similar visible red wavelength (660 nm), and come in several models, most usefully a 5 Mb/s dc-coupled pair (HFBR-1521Z/2521Z) that works out to 20 m distance, and a 40 kb/s dc-coupled pair (HFBR-1523Z/2523Z) that's good to 100 m. The receive end provides a logic-level output (using an external or internal pullup resistor); but the transmit end is a bare LED, so you have to provide a current-limiting resistor and a saturated switch to ground, or the equivalent (Figure 12.98). This provides some flexibility in transmitted optical level, but does require extra components. Both transmit and receive modules cost less than $10 in small quantities. You can get the optical cable with connectors attached; or you can roll your own, which turns out to be simple and quick, using the "crimpless" (i.e., no tooling required) HFBR-4531Z series of connectors; they cost about $0.50 apiece, in small quantities.

For greater link speeds you can get the faster HFBR-

[51] It is not required that the data stream have balanced quantities of 1s and 0s, just that there be transitions at frequent-enough intervals.

[52] There has been some grumbling in the audiophile community about jitter in this interconnection technology. Although this can be addressed with PLL clock regeneration or sample-rate conversion, it is an issue that does not arise with electrical (coaxial) interconnection of digital audio devices.

[53] Puzzle for the reader: converting a lower-energy photon into one of higher energy would appear to violate energy conservation. Figure it out!

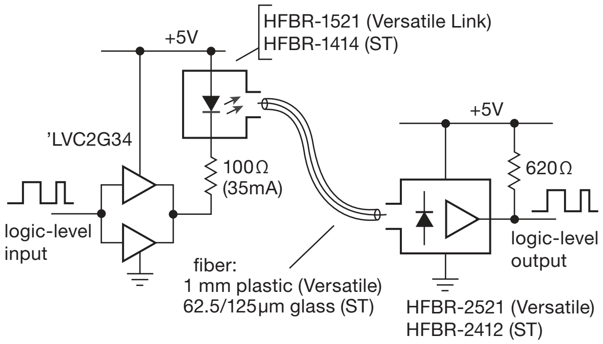

Figure 12.98. Typical drive and receive circuit for the Avago dc-coupled 5 Mb/s "Versatile Link" and ST-connectored fiber-optic series. For 3.3 V logic levels use 50 Ω and +3.3 V on the driver side, and pullup to +3.3 V on the receiver side. Operating currents shown here are suitable for lengths to 10 m (Versatile Link: plastic fiber) or 1 km (ST: glass fiber); they can be altered, depending on link length and maximum data rate (see Avago datasheets and App Note 1035).

1527Z/2526Z modules, which use the same fiber and connector geometry, and which permit signal rates to 125 Mb/s (but not dc-coupled). These, and analogous devices (e.g., the TODX2402 or TOTX/RX1701 in the TOSLINK series; or the HFBR-1424/2426 in the 820 nm ST/SC-connector devices from Avago that use all-silica graded-index fiber, see below) are popular as fiber-based fast serial links, for example to carry Ethernet signaling, or serialized data between a SERDES (serializer–deserializer) pair.

12.8.3 ST/SC glass-fiber modules

For many years we've used the HFBR-14xx/24xx series of fiber transmitters and receivers from Avago. These are more expensive (about $15 in small quantity) than the plastic-fiber devices above, but by using graded-index silica-clad silica fiber (sometimes called "ASF," all-silica fiber, or "AGF," all-glass fiber) at 820 nm wavelength, they work happily even through a kilometer or more of fiber. An added bonus is the robustness of the fiber cables, which, with their very thin glass core/cladding (62.5 μm/125 μm, in the most common variety) and tough jacket, can withstand plenty of bending and pulling without damage.

We use the ST connector style, which is a locking bayonet (see Figure 12.95). You can buy preterminated fiber cables as simplex (one fiber, ST termination at each end), or duplex (also called "zip cord": a pair of fibers, each with its own ST connector at each end), from companies like Tyco/AMP, 3M, and Amphenol, for a few dollars per meter. If you're willing to spend a few hundred dollars on a termination kit, and suffer a bit, you can even put the connectors on by yourself; look at connectors and tooling from companies like Tyco/AMP and 3M.

As with the Versatile Link components, you can get dc-coupled low-speed receivers, for example, the HFBR-2412Z, which goes to 5 Mb/s at distances to 2 km. Its open-collector output requires only a pullup resistor to generate the reconstructed digital logic levels. For high speeds use instead the HFBR-2416Z, which is good to 155 Mb/s at distances to 0.6 km. The latter provides a high-bandwidth "analog" output from its internal PIN-diode detector and preamp, which you ac-couple to external amplifier–comparator circuitry to generate the fast LVDS or ECL reconstructed digital stream. For either receiver you would use the HFBR-1414Z transmitter, which, like the analogous Versatile Link component, looks electrically like a bare LED; you have to provide the requisite drive, either with a transistor switch and resistor, or with a hefty logic gate like a 'LVC2Q34 (see Avago App Note 1123 and App Brief 78).

12.8.4 Fully integrated high-speed fiber-transceiver modules

Why not integrate *all* the logic-level interfacing within the fiber-optic module itself? Indeed. With widespread use of duplex fiber to carry fast serial data – for example as optical fast Ethernet (125 Mb/s), or firewire (rates to 250 Mb/s), or simply between a pair of SERDES parallel–serial chips – there are now plenty of easy-to-use fiber-optic-transceiver ("FOT") modules. These devices have both transmitter and receiver optical modules and connectors (usually in duplex SC or ST format, for glass fiber; or as the duplex "SMI" connector for plastic fiber), along with driver and receiver circuitry using fast differential signaling (usually 5 V or 3.3 V PECL); see Figure 12.99 (and the portrait in Figure 12.95).

Contemporary examples are the Avago AFBR-5xxx-series, which come in duplex SC or ST connector styles, and which can handle 100 Mb/s data rates for fast Ethernet (100Base-FX) or ATM (asynchronous transfer mode); you connect the transceiver's PECL ports directly to the corresponding inputs or outputs on an Ethernet, firewire, or ATM "PHY" (physical layer IC). A typical member of this family, the AFBR-5803, good to 125 Mb/s, currently costs about $30; the faster AFBR-53D5 can handle gigabit Ethernet and costs about $60. You can use a fast fiber transceiver to connect to a SERDES like the Cypress CY7C924 or HDMP-1636, to link a pair of widely separated parallel ports, with data rates of 20–100 Mbytes/s.

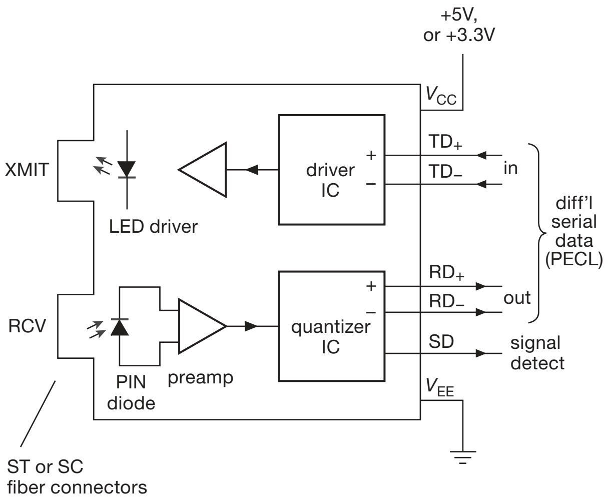

Figure 12.99. High-speed integrated fiber-optic transceivers like the Avago AFBR-5xxx-series, in the industry standard 1×9 SIP package, include all driver and receiver circuitry, to interface directly via 3 V or 5 V serial differential PECL.

For short links, fast transceivers that mate with plastic fiber are available, for example the Toshiba TODX2402 (PECL in–out, duplex SMI, rates to 250 Mb/s; about $25 in small quantity).

12.9 Digital signals and long wires

Special problems arise when you try to send digital signals through cables or between instruments. Effects such as capacitive loading of the fast signals, common-mode interference pickup, and "transmission-line" effects (reflections from impedance mismatching; see Appendix H) become important, and special techniques and interface ICs are often necessary to ensure reliable transmission of digital signals. Some of these problems arise even on a single circuit board, so a knowledge of digital transmission techniques is generally handy. We begin by considering on-card problems. Then we go on to consider the problems that arise when signals are sent between cards, on data buses, and finally between instruments via twisted-pair or coaxial cables.

12.9.1 On-board interconnections

A. Output-stage current transient

The push–pull output circuit for logic ICs consists of a pair of transistors going from V_+ to ground. As we remarked earlier (§3.4.4B and 10.8.3B), when the output changes state there is a brief interval during which both transistors are ON; during that time, a pulse of "shoot-through" current flows from V_+ to ground, putting a short negative-going spike on the V_+ line and a short positive spike on the ground line. The situation is shown in Figure 12.100. Suppose that IC$_1$ makes a transition, with a momentary large current from +5 to ground along the paths as indicated; with 74F*xx* or 74AC(T)*xx* circuits the current might reach 100 mA. This current, in combination with the inductance of the ground and V_+ leads, causes short voltage spikes relative to the reference point, as shown. These spikes may be only 5 ns to 20 ns long, but they can cause plenty of trouble: suppose that IC$_2$, an innocent bystander located near the offending chip, has a steady LOW output that drives IC$_3$ located some distance away. The positive spike at IC$_2$'s ground line appears also at its output, and, if it is large enough, it gets interpreted by IC$_3$ as a short HIGH spike. Thus, at IC$_3$, some distance away from the troublemaker IC$_1$, a full-size bona fide logic-output pulse appears, ready to mess up an otherwise well-behaved circuit. It doesn't take very much to toggle or reset a flip-flop, and this sort of ground-current spike can do the job nicely.

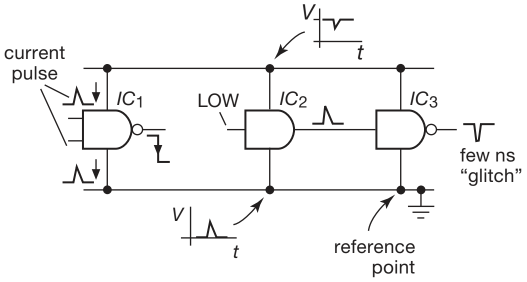

Figure 12.100. Ground-current noise, also known as *ground bounce.*

The best therapy for this situation consists of (a) using hefty ground lines throughout the circuit, or preferably a "ground plane" (one side of a double-sided PC board) or an inner layer of a multilayer PCB, and (b) using bypass capacitors liberally throughout the circuit. Large ground lines mean smaller current-induced spikes (lower inductance and resistance), and bypass capacitors from V_+ to ground sprinkled throughout the circuit mean that current spikes travel over only short paths, with the reduced inductance resulting in much smaller spikes (the capacitor acts as a local voltage source, since its voltage does not change appreciably during the brief current spikes). It is best to use a 0.1μF ceramic capacitor near each IC, although one capacitor for every two or three ICs may suffice. In addition, a few larger electrolytic capacitors (∼10μF or so) scattered throughout the circuit for energy storage and resonance damping[54] is a good idea. We can hardly emphasize enough the importance of bypass capacitors from power-supply lines to ground in any circuit, digital or linear. They help make the supply lines low-impedance voltage sources at high frequencies, and they prevent signal coupling between circuits via the power supply. Unbypassed power-supply lines can cause peculiar circuit behavior, oscillations, and headaches. *Don't do it!*

B. Spikes caused by driving capacitive loads

Even with the supplies bypassed, your problems aren't over, as we mentioned earlier in §10.8.3A. Figure 12.101 shows why. A digital output sees the stray wiring capacitance and the input capacitance of the chip it drives (5–10 pF, typically) as part of its overall load. To make a fast transition between states it must sink or source a large current into such a load, according to $I = C(dV/dt)$. For instance, consider a 74LVC*xx* chip in a +3.3 V logic system, driving a total load capacitance of 25 pF (equivalent to three or four logic loads connected with short leads). With typical output rise and fall times of ~2 ns, the current during the logic transition is 40 mA. This current returns through ground (HIGH-to-LOW transition) or the +3.3 V line (LOW-to-HIGH transition), producing those cute little spikes at the receiving end, as before. To get an idea of the effects of such current transients, consider the fact that wiring inductance is roughly 5 nH/cm. An inch of ground wire carrying this logic transition current would have a spike of $V = L(dI/dt) = 0.2$ V. And if the chip happened to be an octal buffer, with simultaneous transitions on a half dozen outputs, the ground spike would be over a volt; refer back to Figure 10.99. A similar (though generally smaller) ground spike is generated near the driven chip, where the drive-current spikes return to ground through the input capacitance of the driven device.

In a synchronous system, with a number of devices making output transitions simultaneously, the noise-spike situation can become so serious that the circuit will not function reliably. This is especially true in a large printed-circuit card, with long interconnections. The circuit may fail only occasionally, when a whole group of data lines unluckily happen to make a simultaneous HIGH-to-LOW transition, generating a momentary very large ground current.

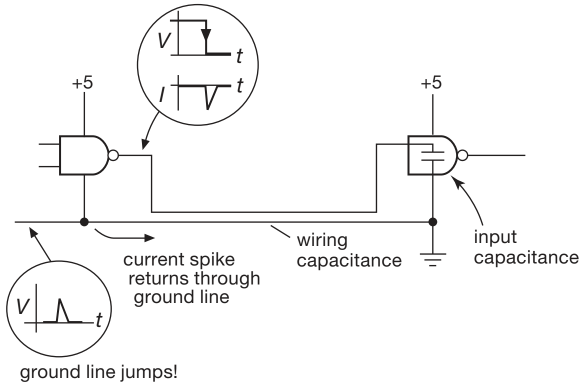

Figure 12.101. Capacitive-load ground current noise.

This kind of pattern sensitivity is characteristic of noise-induced error and is a good reason for running extensive memory tests on microprocessor systems (where you typically have 16 or 32 data lines and 32 address lines bouncing around in crazy patterns).

The best design approach is to use an internal ground-plane layer on a multilayer circuit board, or at least a perpendicular "gridded" arrangement of grounds on both sides of a simpler two-sided board. Copious use of bypass capacitors is mandatory. These problems have been mitigated considerably by measures such as (a) low-inductance surface-mount packages for discrete logic devices, (b) the use of multiple ground pins on complex logic devices,[55] (c) the nearly universal adoption of multilayer PC boards with dedicated power and ground planes, and with extravagant use of SMT chip bypass capacitors, and (d) controlled edge-rate chip designs (e.g., 74ACQ, 74ACTQ, or Gunning Transceiver Logic[56]) and redundant "center-pin" power–ground pinouts for situations in which fast logic chips will be used with less favorable layouts (i.e., through-hole packages, two-layer PCBs, etc.).

Because of these noise problems, it is generally best not to use a faster logic family than you need.[57] That's why we use 74HC(T) logic, rather than 74AC(T), for general-purpose use in our electronics course (where students put their circuits together using "solderless breadboards").

[54] A circuit with multiple 0.1 μF ceramic bypass capacitors, connected by inductive supply-bus wiring, is susceptible to ringing and even oscillation, owing to the multiple high-Q resonances; these are often in the 5–20 MHz range. They can be effectively damped by the equivalent series resistance (ESR) of one or more paralleled electrolytic capacitors.

[55] For example, the "Virtex-5" FPGA that we're using in our lab has 197 redundant ground pins; the larger "FF1760 package" version has 322!

[56] Read Fairchild's App Note AN-1072 to see how it works. GTL is a single-ended bus-driving logic family with reduced swing (<1 V) and controlled edge rates.

[57] This advice goes for *analog* circuits, too: don't use a 100 MHz op-amp, or a 2 ns comparator, when you don't need the speed.

12.9.2 Intercard connections

With logic signals going between circuit cards, the opportunities for trouble multiply rapidly. There is greater wiring capacitance, as well as longer ground paths through cables, connectors, card extenders, etc., so the ground spikes induced by drive currents during logic transitions are generally larger and more troublesome. It is best to avoid sending clocking signals with large fan-out between boards, if possible, and the ground connections to the individual cards should be robust. For fast signals (characteristic times of order a few nanoseconds, or less) the interconnections must be treated as constant-impedance *transmission lines* (see §12.10.1 and Appendix H), which may be single-ended (coaxial cable) or differential (twisted pair). We'll have much more to say about this soon (§12.10).

If clocking signals are sent between boards, it is important to use a gate (for single-ended signals) or a differential receiver (for differential signals such as LVDS) as an input buffer on each board. In some cases it may be best to use line driver and receiver chips, as we will discuss shortly. In any case, it is best to try to keep critical circuits together on one card, where you can control the inductance of the ground paths and keep wiring capacitance at a minimum. Fast signals (edge times of order 1 ns or less), and especially clocking signals, that go between the circuits on a single card will often be routed as "stripline" or "microstrip" transmission lines (§*1x.1.3*).[58] This can take the form of a single-ended trace above a ground plane (microstrip) or between ground planes (stripline); or it can be a differential pair, with two traces side-by-side or stacked vertically. Such constant-impedance routes will be terminated in their characteristic impedance, commonly 50 Ω (single ended) or 100 Ω (differential), either with "back termination" at the driving end, or with far-end termination, or both. The problems you'll encounter in sending fast signals around through several cards should not be underestimated; they can turn out to be the major headache of an entire project!

12.10 Driving Cables

You can't run digital signals from one instrument to another by just stringing a single conductor between them, because such an arrangement is prone to pickup of interference (as well as generating interference of its own), and also serious degradation of the digital signals themselves. Instead, digital signals are generally piped through coaxial cables, twisted pairs, flat ribbon cables (sometimes with ground plane or shield), multiwire bundled cables, and, increasingly, fiber-optic cables.[59] Let's look at some of the methods used to send digital signals between boxes of electronics, since these methods constitute an important part of digital interfacing. In most cases there are special-purpose driver–receiver chips available to make your job easier.

12.10.1 Coaxial cable

If you've never dealt with fast signals going through cables, you're in for a surprise.

A. The wrong way

Here's a typical mistake that we see again and again: you've got some digital signals coming out of a "Digital I/O" interface card, for example the PCI-6509 from the popular series of data acquisition products made by National Instruments. This puppy plugs into a computer motherboard's PCI slot, and gives you 96 bits of bidirectional digital I/O, grouped in 12 bytes, each byte of which can be configured as input or output. As an output, each bit generates full-swing 5 V CMOS logic levels (i.e., 0 V and +5 V), with plenty of drive capability (24 mA sink or source), enough to drive easily loads like solid-state relays, small mechanical relays, bright LEDs, and the like.[60]

The mistake is to connect this digital output to a length of coax, and expect it to arrive safely at the far end, as in Figure 12.102A. The thinking goes like this: we've got at least ±24 mA of drive, which should be able to drive the ~200 pF of a 2-meter length of coax (C=100 pF/m) just fine; after all, $I = C\,dV/dt$ predicts a rise time of ~20 ns, assuming a typical switching output current of ~40 mA into the capacitive load. So, what's the problem?

The problem is that we have to treat a coax cable as a transmission line, rather than as the low-frequency approximation of a lumped capacitance, when dealing with signals that are changing on a time scale comparable with (or shorter than) the round-trip delay time of the cable. If you try to use the logic output to drive the cable directly, you'll get a messy waveform at the far end, with overshoots and polarity reversals, producing incorrect recovery of the waveform (and even destruction of the far-end gate). But you can magically fix the problem by simply adding a 50 Ω

[58] This is mandatory, for example, with the fast logic families known as ECL-100K, ECL-100E, ECL-100EL, and ECL-100EP.

[59] Coaxial cables (affectionately called "coax") and twisted pairs are examples of *transmission lines*, discussed in detail in Appendix H.

[60] Look up the 74LVC4245A, if you want to see the specs on the voltage-translating (3 V ↔ 5 V) octal transceivers used in this product.

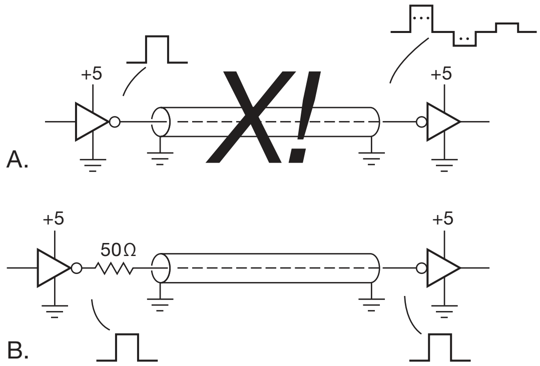

Figure 12.102. A. Driving a length of cable with a logic output produces a mangled waveform of overshoots and polarity reversals. B. Adding a ∼50 Ω series resistor effects a magic cure.

series resistor at the driving end (Figure 12.102B): the far-end waveform becomes a good replica of the driving waveform.

Let's look at this situation in more detail, beginning with the "wrong" way, then progressing through three configurations that solve the problem, each of which have advantages and disadvantages. We'll wind up with the magic fix of Figure 12.102B, known as "series termination," which is well suited to digital-logic signals.[61]

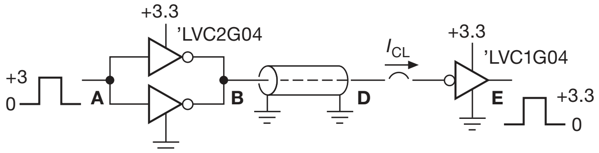

Figure 12.103. Test circuit that attempts to send digital logic signals directly through a length of cable whose far end is "unterminated". The disastrous results can be seen in Figures 12.104–12.106. *Don't do this!*

To illustrate the problem, we hooked up the circuit of Figure 12.103 and ran a pulse pattern through it. You can see the measured results in Figures 12.104–12.106. In Figure 12.104 the far end has been left unconnected: the first transition reaches the far end 12 ns later, where it bounces off the open end (with unchanged polarity), producing an output voltage nearly double the step size; things get messy as the signals bounce back and forth, reversed in polarity with each bounce off the source end, and decaying slowly with each bounce, but always adding the new source signal transitions. The signal at the far end looks terrible – and it swings to +8 V and −6 V, even though we are driving the cable with 0 V and +3.3 V only. Imagine what will happen when we connect a logic inverter at the far end!

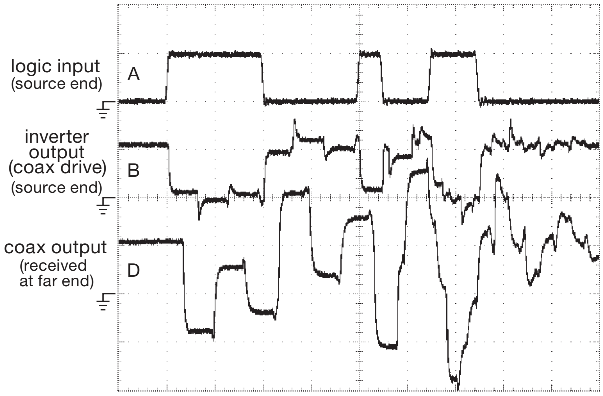

Figure 12.104. Waveforms seen in the circuit of Figure 12.103, when driven with a pulse pattern clocked at 20 ns, and with the far end of the 8 foot (2.4 m) RG-58 coax cable unconnected. The 3.3 V logic-level drive to the cable produces far-end swings of nearly 15 V peak-to-peak! Horizontal: 40 ns/div; Vertical: 3 V/div.

You needn't imagine. In Figure 12.105 we've attached the far end inverter, running also from +3.3 V. Its input protection diodes clamp the renegade waveform, limiting negative swings to roughly a diode drop, but allowing occasional positive swings to +8 V (the 'LVC1G04 has 5 V–compliant inputs, regardless of supply voltage). It's an ugly situation, and it's not surprising that the recovered logic output has some false transitions.

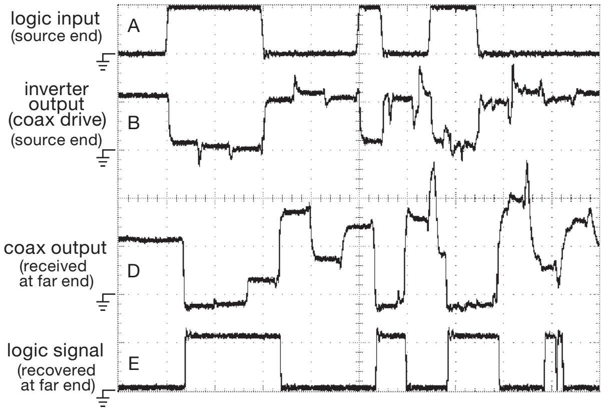

Figure 12.105. Same as Figure 12.104, but with the 'LVC1G04 inverter connected at the far end. The clamping effect of the inverter's input protection diodes reduces the swing at the coax output. This unhealthy situation produces some false transitions at the output; it can also destroy the output inverter.

[61] But not to *every* kind of signal: in the world of RF and video the method of "double-ended termination" is used universally.

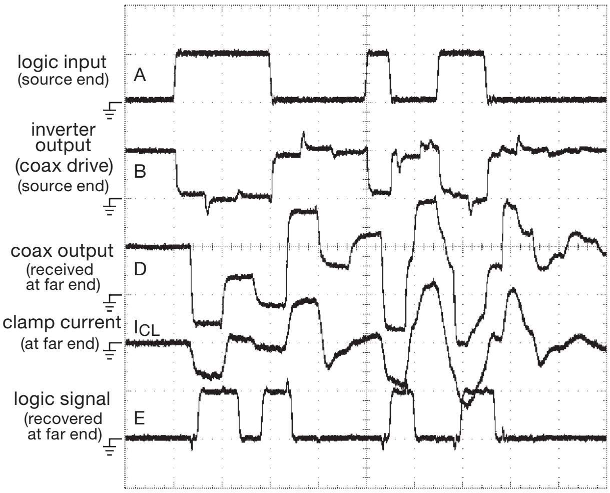

Figure 12.106. Same as Figure 12.105, but with 5 V logic ('LVC2G04 drivers, 'HCT04 far-end receiver). Note the substantial clamping currents, and the error-prone signal recovery. Horizontal: 40 ns/div; vertical: 5 V/div and 20 mA/div.

Turning now to the original scenario – a 2 m cable connecting a digital I/O card to some instrument – the driving signal comes from a hefty 5 V logic output, and the receiver (within some commercial instrument) is likely to be something like an 'HCT04 (5 V logic, with TTL threshold ∼1.4 V). Figure 12.106 shows what happens. It's not a pretty picture: once again the flailing far-end signal is partially clamped, but reaches peaks of +10 V and −5 V, with corresponding clamp currents of ±25 mA. This exceeds the "absolute maximum" input clamp current specification of ±20 mA.[62] And the recovered output is a mess. It's pretty clear that you just cannot hook things up this way.

12.10.2 The right way – I: Far-end termination

The solution is to *terminate* the cable in its *characteristic impedance* $\mathbf{Z}_0$ (see Appendix H), which for most coaxial cables is 50 Ω (resistive).[63] There are three different ways this can be arranged, namely far-end termination, double termination (both ends), and near-end termination ("series termination," "source termination," or "back termination").

Far-end termination is the easiest to understand; see Figure 12.107. The *amazing fact* about transmission lines (explained in Appendix H) is that the addition of a simple resistor of value $R = Z_0$ at the far end suppresses all reflections and, furthermore, makes the cable input look like a pure resistance equal to R. Amazing, because *all capacitance disappears*.

The good news is that this solves the problem. The bad news is that Z_0 is uncomfortably low, usually 50 Ω, which requires rather high driver output currents (20 mA per volt of drive). But you can do it, with hefty logic chips, typically several in parallel, operating with modest logic supply voltages (for example, +3.3 V or less).[64]

Figure 12.107 shows one way to do this, using several sections of 'LVC04 or 'AC04 in parallel to drive the near end of a length of 50 Ω coax that is terminated with a 50 Ω resistor at the far end. The 'LVC2G04 is fully specified at ±24 mA output current and 3 V supply; the corresponding figure for the 'AC04 is ±12 mA. So we're pushing things just a bit here, demanding +60 mA of source current. (No worry, however, if we replaced the single 50 Ω termination with a 100 Ω–100 Ω divider at the far end. That would require ±30 mA of drive, for which we could probably get away with a single 'LVC1G04.)

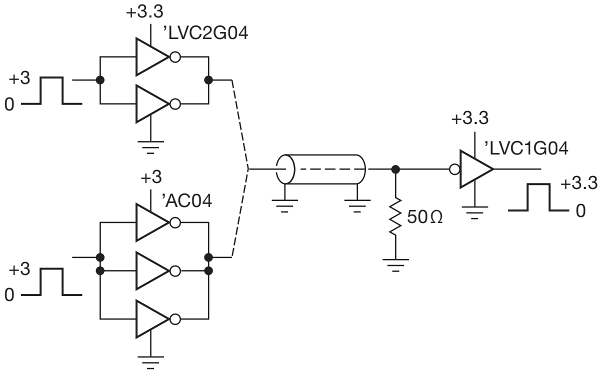

Figure 12.107. Digital logic levels driving end-terminated 50 Ω coax. Apart from losses, the received signals are full-swing replicas of the driving signal.

But it works: Figures 12.108 and 12.109 show the nice waveforms you get, in this case with a 10 m (33 foot) length, operating at the same 20 ns clocking rate. Note the clean waveforms throughout (with a small bit of ringing evident with the 'AC04 driver, probably caused by

[62] For which the datasheet warns "Stresses beyond those listed under 'absolute maximum ratings' may cause permanent damage to the device. These are stress ratings only, and functional operation of the device at these or any other conditions beyond those indicated under 'recommended operating conditions' is not implied."

[63] A big exception is the video community, which has chosen 75 Ω (typified by RG-59 coax); and in pulse circuits you occasionally see 93 Ω (RG-62).

[64] A nice trick that reduces the needed drive current by a factor of 2 is to use a pair of 100 Ω resistors at the far end, configured as a divider between the supply and ground.

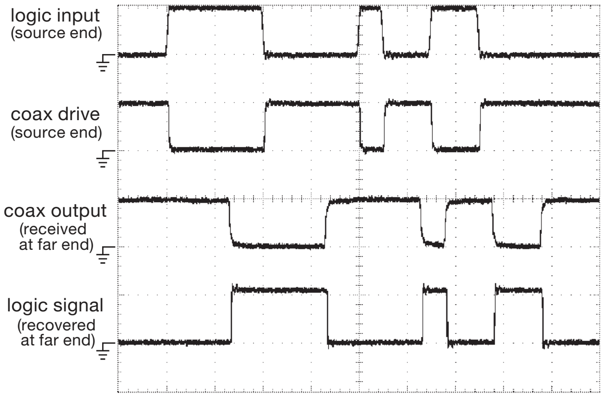

Figure 12.108. Waveforms from the circuit of Figure 12.107 ('LVC2G04 driver), with the same 20 ns clocked pulse pattern as in Figures 12.104–12.106, but with a 10 m length of coax. Horizontal: 40 ns/div; vertical: 3 V/div.

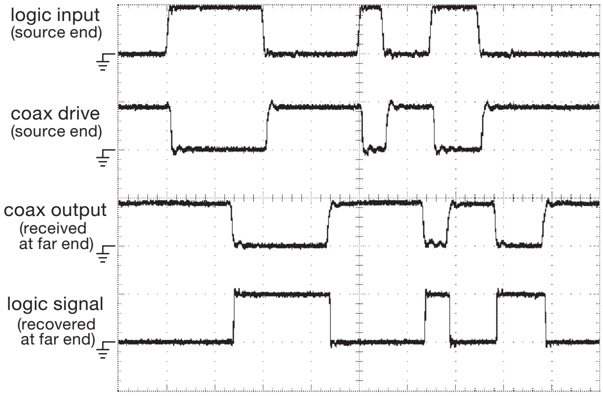

Figure 12.109. Same as Figure 12.108, but with 'AC04 driver.

the greater inductances in power and ground leads of its DIP-14 package, as compared with the compact SOT23-6 surface-mount package of the 'LVC2G04).

If you're worried about the substantial drive current needed to push full rail-to-rail logic-level swings into a 50 Ω load, and if you are not operating at maximum logic speeds, you can substitute a "MOSFET low-side driver" IC for the paralleled logic inverters we used. For example, the venerable TC4420-series of MOSFET drivers accept logic-level inputs, and generate a robust rail-to-rail output swing between ground and the supply voltage, which can range from +4.5 V to +18 V. The peak output current ranges from 1.5 A to 9 A in this series – no problem driving 50 Ω! These are dual drivers, available in many package styles (including DIP) and in inverting or noninverting flavors; they cost about a dollar in small quantity (see Table 3.8 on page 218). There are literally hundreds of MOSFET driver chips available, with some very nice choices from companies like Fairchild, IXYS, Microchip, ST, and TI, among others; most are happy to operate from 5 V supplies (where they have reduced output-drive capability, but they're still pretty muscular; the 9 A IXDD609, for example, can source or sink 2 A when powered from a 5 V supply). Don't be discouraged by the rather relaxed speed specifications on datasheets (e.g., rise and fall times of 20 ns or more), because these are usually specified into the horrendous capacitive loads (1000–10,000 pF, aided and abetted by the Miller effect) of switching power MOSFETs. You'll do much better when driving a 50 Ω far-end terminated coax, which presents a pure resistive load to the driver. For example, the IXYS IXDD509 9 A noninverting driver specifies ∼25 ns rise and fall, but that's into 10,000 pF! From the curves later in the datasheet, however, you'll discover rise and fall times of 4 ns or less for supply voltages anywhere between +5 V and +30 V.[65]

A. The right way – II: Double-ended termination

The high currents needed to drive end-terminated 50 Ω coax can be remedied somewhat by adding a series resistance at the cable's input, equal in value to its characteristic impedance (i.e., 50 Ω; see Figure 12.110). Then the driver sees a load of 100 Ω (the series resistor plus the 50 Ω seen at the cable's input). That's sometimes called "double-ended termination." It has an additional advantage, namely that any signals reflected from the far end are swallowed by the input resistor, which acts effectively as a termination for signals traveling backward.

It works, but now the output-signal amplitude is half that of the driver, because the cable's input resistance forms a voltage divider with the series resistor at the input. That's why we used 5 V logic at the input, combined with inverters at the output whose thresholds are in the range of 1.2–1.4 V: either the TTL threshold 'ACT04 (see Figure 12.111), or logic running from a lower +3 V supply (see Figure 12.112). The 'ACT04 specifies input logic levels of <0.8 V and >2.0 V; the corresponding figures for the 'LVC1G04 (powered from +3.0 V) are <0.8 V and >1.7 V.

[65] In spite of the good rise and fall times, there tend to be substantial delay times, regardless of load capacitance, at low supply voltages; for this IXYS part, the delay times are of order 30 ns with a +5 V supply, dropping to half that at V_S=10 V. From a practical point of view, this limits operation to speeds of a few megahertz. A more serious problem at high frequencies is the rising rail-to-rail supply current, and consequent power dissipation, at frequencies above a megahertz that are due to the high internal capacitance of the large output MOS devices. Some parts show plots of no-load supply current versus frequency in their datasheets.

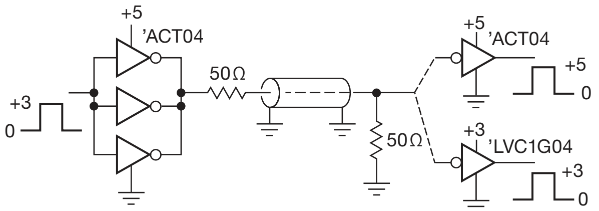

Figure 12.110. Digital logic driving double-end terminated 50 Ω coax. The received signal amplitude is half that of the driver logic output, therefore ∼2.5 V in this example.

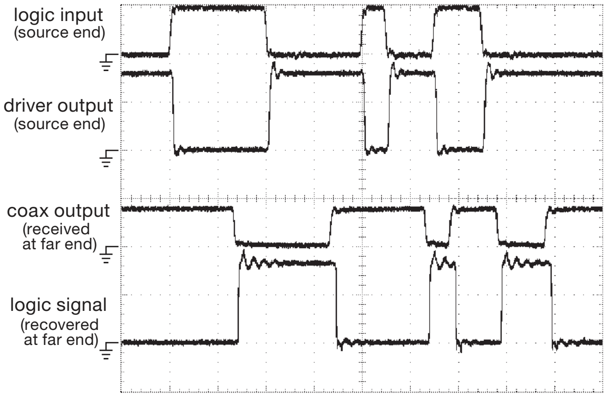

Figure 12.111. Waveforms from the circuit of Figure 12.110 ('ACT04 receiver), with the same 20 ns clocked pulse pattern as in Figures 12.104–12.109, and with a 10 m length of coax. Horizontal: 40 ns/div; vertical: 3 V/div.

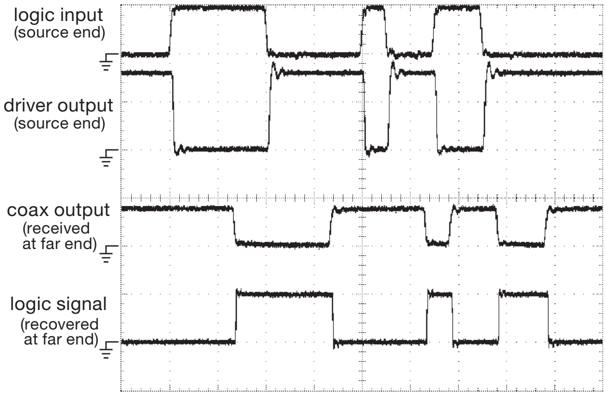

Figure 12.112. Same as Figure 12.111, but with 'LVC1G04 receiver.

The method of choice, for RF and video Because double-ended termination results in a received signal that is half the amplitude of the unloaded driver, it is not well suited for *digital logic* applications like this. It's better to use series termination (next subsection). Lest we leave the wrong impression, however, we note that the use of double-ended termination is *universal* in the RF and video worlds: all such signal sources are built with an output impedance equal to that of the cable impedance (50 Ω for RF, 75 Ω for video), and the far end of every cable is terminated in that same resistance. And the factor-of-two amplitude reduction is addressed by arranging the open-circuit amplitude of every signal source to be exactly twice what is ultimately needed at the (properly terminated) far end. You see this in signal and function generators – the output amplitude, as measured with a 'scope probe, is double what you've set it for (because it assumes you've attached a 50 Ω load resistor, or a cable with 50 Ω far-end termination). And in the video world you'll find plenty of "video buffer amplifiers" that provide a gain of exactly ×2, to compensate for the corresponding loss when driving a terminated cable. Figure 12.113 shows an example from LTC: their LT6553 is a triple video buffer (three independent amplifiers, to handle color analog video), with an internally set gain of 2, intended for driving 75 Ω video cable, as shown. It has impressive bandwidth (650 MHz) and slew rate (2500 V/μs), and can drive a ±3.5 V swing into the 150 Ω load it sees in this circuit, when powered from ±5 V supplies. Their companion LT6554 has the same specs, but with unity gain.

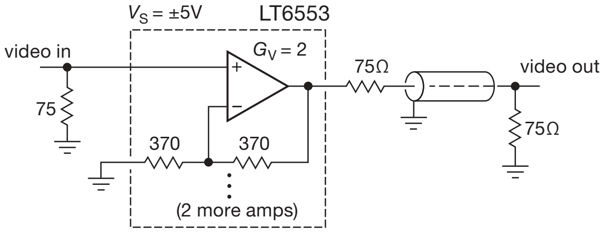

Figure 12.113. A video buffer amplifier drives a 75 Ω load through 75 Ω coax. The voltage gain of G_V=2 compensates for the ×2 signal attenuation caused by the series resistor at the amplifier's output.

B. The right way – III: Series termination

To summarize the previous methods: end termination with direct drive requires lots of drive current, but it delivers the full driver signal at the far end. Double-ended termination reduces the drive current, but attenuates the driver signal amplitude by a factor of 2.

There's a third way, which captures the best of each: use a series resistor at the source end and *no* termination at the far end. This is sometimes called "series termination" or "back termination" (Figure 12.114). It exploits a property of open-ended transmission lines, namely that there is a

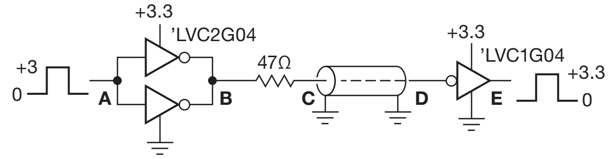

Figure 12.114. Series termination presents a load of twice the cable's characteristic impedance (therefore 100 Ω), while delivering the full driver amplitude at the far end. We recommend this method for logic outputs on instrument panels.

full-amplitude reflection from the far end, of the same sign as the incident signal, thus producing an output amplitude of twice the incident amplitude. But, because the incident amplitude is half the driver's output (owing to the voltage divider formed by the series resistor and the cable's input impedance), the net result is an output just equal to that of the driver. Voilà – full output swing, without the need to drive the cable's low impedance. And we don't get the ugly situation of signals bouncing back and forth (as in Figures 12.105 and 12.106), because the series resistor acts as a proper end termination for the backward-going signals. Instead you get one reflection off the far end, which gets swallowed at the source end, with the production of some steppy waveforms at the near end (Figure 12.115).

Series termination is the method of choice for piping logic signals through cable. This technique has the pleasant properties of (a) presenting a (less severe) load impedance equal to twice the cable's characteristic impedance, and (b) requiring *no* continuing drive current after a logic-level change has propagated down and back. To expand on this latter point: immediately after a step change, current flows from the driving gate, $I = V_{CC}/2Z_0$, or 50 mA for 5-volt logic driving a 50 Ω cable; but this ceases after a round-trip propagation delay. We have +50 mA for low-to-high steps, and −50 mA for high-to-low steps. Often we'll estimate the R_{OUT} of the driving gate and reduce the value of the added source resistor accordingly. But if the total source resistance is too low (less than 50 Ω), the returning echo will overshoot V_{CC} (for low-to-high steps) or undershoot ground (for high-to-low steps) for a time equal to a propagation delay. If the overshoot is high enough (i.e., more than 10% for a 5 V supply) it will cause current to flow in the gate's output clamp diode.

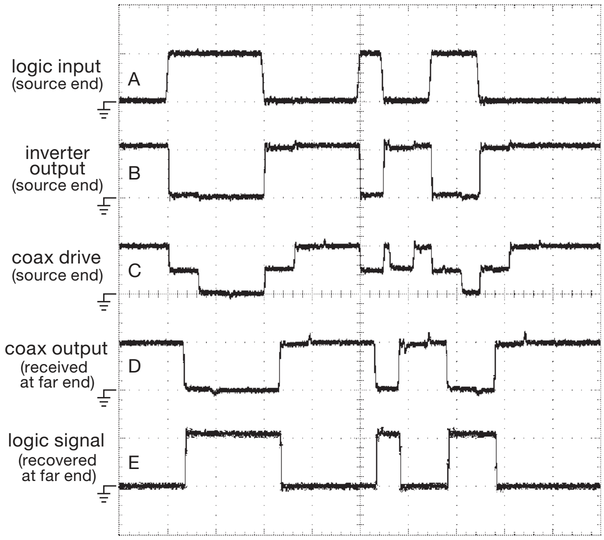

Figure 12.115. Waveforms from the circuit of Figure 12.114, with the same 20 ns clocked pulse pattern as in Figures 12.104–12.112, and with an 8-foot (2.4 m) length of coax. Horizontal: 40 ns/div; vertical: 3 V/div.

The logic family known as "AUC Little Logic" (one of TI's low-voltage logic families, one or two gates in 5-lead or 6-lead SMT packages) has an unusual output structure that is well suited for driving PCB traces or lengths of coax. Its output impedance is a reasonable approximation to a series termination, so you can drive a 50 Ω transmission line directly from the logic gate output, without any series resistor. The family is optimized for a +1.8 V supply voltage. As described in the Application Report[66] the output stage consists of three paralleled inverters, such that the driving impedance changes during a logic transition: it starts low (for high drive current), then becomes an approximate match to the transmission line, suppressing ringing or reflections. Also, there is no clamp diode from the output to the positive supply, so the output is "3.6 V tolerant" and is not damaged by back reflections from the open-ended transmission line.

Although they suggest cable or trace lengths only to 15 cm or so, we found that these devices work well for substantially longer runs of cable. Figure 12.116 shows the signals when driving a 30 cm length of 50 Ω cable (RG-316 "skinny" coax) with 100 MHz NRZ[67] data (twice the rate used in Figures 12.104–12.112 and 12.115). How far can you go with this driver, and at these speeds? Figure 12.117 shows the logic input pattern, and the (open-ended) coax output (points "A" and "D" in Figure 12.114), when driving lengths of 50 Ω coax[68] up to 5 m long. Looks pretty good, to us!

[66] *Application of the Texas Instruments AUC Sub-1-V Little Logic Devices*, SCEA027A (September 2002).

[67] "Non-return to zero," a fancy name for just sending each bit value, as a logic level, for one clock period.

[68] RG-141 for 500 cm, RG-316 for the rest.

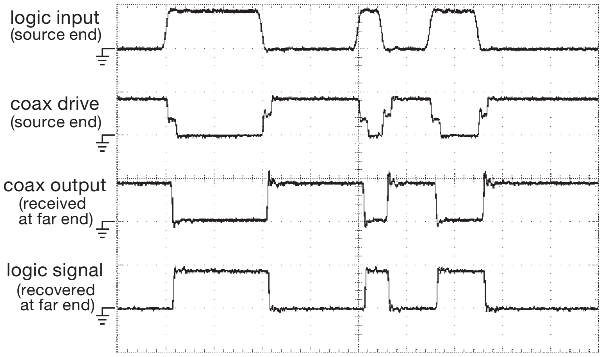

Figure 12.116. Waveforms from a 74AUC1G04 inverter operating at 1.8 V and directly driving a 30 cm length of coax, with the same pulse pattern as earlier, but at a 10 ns clock rate. The four traces (top to bottom) correspond to points A, C, D, and E in Figure 12.114, but with no resistor. The approximate half-step at the coax input confirms a drive impedance close to 50 Ω. Horizontal: 20 ns/div; vertical: 2 V/div.

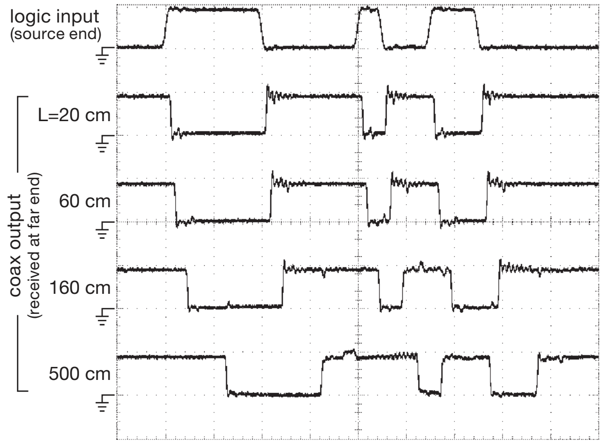

Figure 12.117. Same setup as Figure 12.116, showing received waveform at far end of coax cables with the indicated lengths. Horizontal: 20 ns/div; vertical: 2 V/div.

C. Driver pre-emphasis and receiver equalization

The measured waveforms above look pretty good. But we're not really pushing the limits, at these data rates of 50–100 Mbps NRZ. Things get pretty messy when you try to send upward of a few hundred megabits per second, because the coax cable itself becomes lossy and attenuates higher frequencies (see Appendix H). For example, the popular RG-58A (used for everybody's BNC patch cords) attenuates about 10 dB per 30 m at 500 MHz. You do better, of course, with cables of lower loss (e.g., RG-8 attenuates about 5 dB per 30 m). But these are bulkier – RG-8 cable is 10 mm in diameter, double that of RG-58.

Here's what you can do instead: at either the driver end or the receiver end (or both) you can compensate for the cable's loss (and phase shift) at higher frequencies. This is called *pre-emphasis* and *equalization*, respectively. Figures 12.130–12.132 later in the chapter show how it goes, in the case of a differential twisted-pair cable or printed-circuit differential stripline. For a (single-ended) coax line you could use a chip set like NSC's DS15BA101 and DS15EA101; the latter is a receiver with adaptive equalizer, which can apply up to 35 dB of boost at 750 MHz.[69] You can think of this trick as analogous to "turning up the treble," in an audio system, though here we need to worry about phase as well. It works quite well, owing to the very good signal-to-noise ratio of these large signal swings running through shielded (or twisted-pair) transmission lines. We'll see this next, in connection with LVDS signaling on differential pairs.

12.10.3 Differential-pair cable

There's another way to convey digital signals on cables, namely to use differential signaling, most often by way of a twisted-pair cable.[70] A common example of the latter is "Cat-5" (or Cat-6) Ethernet cable, which is an unshielded cable containing four independent twisted pairs, with characteristic impedances of 100 Ω. Some advantages of differential signaling are the suppression of common-mode interference and ground noise, the ability to use smaller signal swings (hence smaller drive currents),[71] and the large reduction of both radiated noise and signal-rate ground-current fluctuations (from the balanced differential swings, as well as the smaller amplitudes). Two popular differential signaling standards are RS-422 and LVDS. They differ in several ways. Roughly speaking, RS-422 is used for

[69] This chip, like other adaptive cable equalizers that are widely used in digital video systems (conforming to 75 Ω coaxial video serial digital interface standards with names like SMTE 259M, 292M, 344M, or 424M), is meant to be ac-coupled, and works only down to some minimum frequency of order 150 Mbps. See National Semiconductor's App Note AN-1909.

[70] Which may be shielded twisted pair ("STP") or unshielded twisted pair ("UTP"). It need not be twisted, however: you'll see adjacent wire pairs on a flat ribbon cable used for differential signaling, as well as parallel trace pairs ("microstrip," "stripline") on a printed circuit board.

[71] Because the signal is differential, it does not require accurate alignment of thresholds (as, for example, with the fussy single-ended 10K/100K ECL logic, whose ∼0.8 V swing mandates careful temperature compensation); the differential signal pair need stay only in the common-mode range of the receiver, e.g., 0 V to +2.4 V for LVDS, with its ∼0.35 V differential swing.

data rates up to a few megabits per second, and cable runs up to a kilometer. It uses differential *voltage* drive, and is common in industrial control applications. By contrast, LVDS is used for data rates to several gigabits per second, over distances to several meters. It uses differential *current* drive, and is common in short-range high-rate applications such as backplanes (e.g., PCIe[72]) and transmission of serial data (e.g., SATA, Firewire). Both are point-to-point connections, but provide multidrop variants (RS-422 → RS-485; LVDS → M-LVDS).

A. RS-422 and RS-485

These comprise a popular industrial data bus, improving on the venerable RS-232 data link standards (see discussion at §§12.10.4 and §14.7.8), and substantially extending the latter's capabilities, see Figure 12.134. The RS-422 and RS-485 standards[73] specify signal properties used in a differential voltage-drive arrangement like that shown in Figure 12.118. The differential outputs typically swing most of the way between ground and the +5 V rail, although the specification permits differential-output swings as small as ±2 V or as large as ±10 V. The receiver must respond to differential inputs as small as ±0.2 V, over a common-mode range of −7 V to +7 V (−7 V to +12 V for RS-485). The characteristic impedance of differential twisted pair cables is typically 100–120 Ω, so you've got to terminate the far end with that value resistor. You often see both ends terminated (as in Figure 12.118), which is not necessary (or desirable) with unidirectional RS-422, but required with the bidirectional (or multipoint) variant (RS-485).

Figure 12.119 shows measured signals traversing one of the four twisted pairs in a 140 m length of Cat-6 Ethernet cable, with a, by now, familiar bit pattern clocked at 10 MHz (i.e., an NRZ rate of 10 Mbps). Although this is ten times faster than allowed by the RS-422 specification (Figure 12.134), the differential nature of the received signal allows clean logic recovery nonetheless; note the propagation delay of ∼700 ns (mostly caused by the 4.7 ns/m signal velocity in the cable).

Differential signaling provides impressive immunity to common-mode interference. The latter may arise from nearby signal-carrying wires or from radiated signals (from intentional emitters like radio/TV, wireless networks, etc.); it's also common to see a difference in ground potentials between equipment that is plugged into different power outlets. We have seen as much as a volt or two of 60 Hz ac between instruments in the same room!

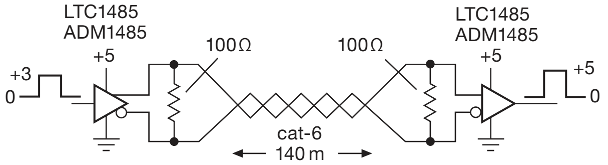

Figure 12.118. Differential voltage signaling with RS-422/485 over a length of unshielded twisted pair, using transceiver chips with 3-state outputs (each chip has a separately enabled Tx and Rx, sharing a common differential pair).

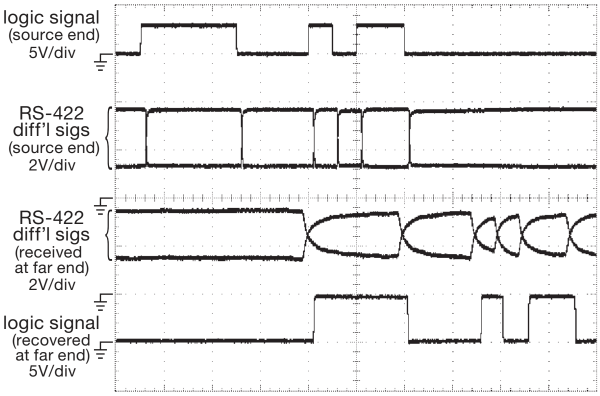

Figure 12.119. Waveforms from the circuit of Figure 12.118, with a 100 ns clocked pulse pattern, and a 140 m length of Cat-6 network cable. Horizontal: 200 ns/div.

We hooked up the circuit in Figure 12.120 to illustrate common-mode rejection in RS-422 signaling. The pseudo-random noise generator adds a ∼15 Vpp noise voltage into the (floating) ground of the signal source, as seen from the destination end. The results are shown in Figure 12.121: both the 5 V logic signal and the RS-485 differential pair signals are hopelessly noised up, reaching peak levels of −7 V and +12 V (the specified receiver common-mode range) as seen from the destination end. But the magic of common-mode rejection recovers the original logic intact. Note that the noise is very much "in-band," with wiggles on the time scale of the digital data. Although the figure captures a single-shot data burst, the result is robust – we ran it many times, with never an error.

Slew rate limiting If you don't need the speed, it's wise to choose driver ICs of lower slew rate because you get less signal coupling from signals on adjacent pairs. RS-422 and

[72] Shorthand for "PCI Express," itself shorthand for "Peripheral Component Interconnect Express."

[73] Officially known as ANSI TIA/EIA-422 and TIA/EIA-485; however, most engineers continue to use the original designations "RS-422" and "RS-485," or, more loosely, they'll just say "422" or "485." In context it's clear what they mean.

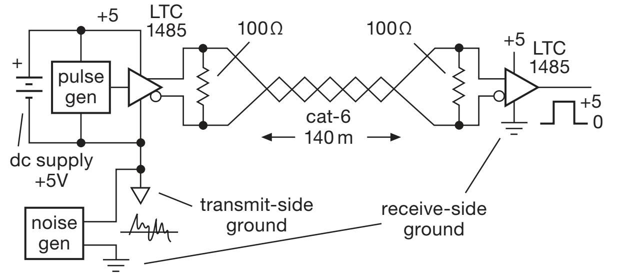

Figure 12.120. Torture test for RS-422 common-mode noise rejection. We floated the driver-side circuitry, and drove its "ground" with band-limited noise of ~15 Vpp amplitude, relative to far-side ground.

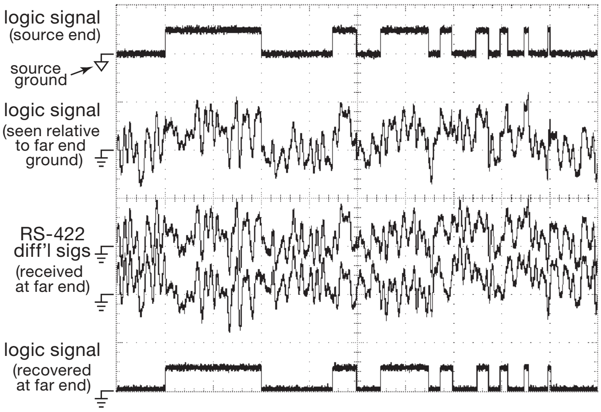

Figure 12.121. Waveforms from the circuit of Figure 12.120. As seen from the far end, the input logic signal is buried in the noise, extending from −7 V to +12 V. The individual differential signals are likewise a mess, but the recovered logic output is error free. The signal pattern includes pulses with widths from 200 μs down to 5 μs. Horizontal: 100 μs/div; vertical: 10 V/div.

RS-485 drivers are available with a selection of slew rates, for example the Maxim MAX3293-95 series, with specified rates of 250 kbps, 2.5 Mbps, or 20 Mbps. Other examples include the MAX481–489- and 1481-1487-series, the LTC2856–2858-series, and the 65ALS176 versus the 75ALS176B.

RS-422 versus RS-485 RS-485 is basically RS-422 with some additions that make it possible to have several drivers share a single signaling pair: this requires that the drivers have an ENABLE input, so they can be put into a high-impedance (noninterfering) state, analogous to the use of three-state drivers on a shared (single-ended) data bus line.[74] RS-485 interface chips (e.g., the classic 75ALS176, or LTC1485) usually combine a transmit–receive pair, sharing the same differential signal lines ("half duplex"),[75] with complementary ENABLE pins (called DE and RE′); such a *transceiver* chip looks like Figure 12.122.

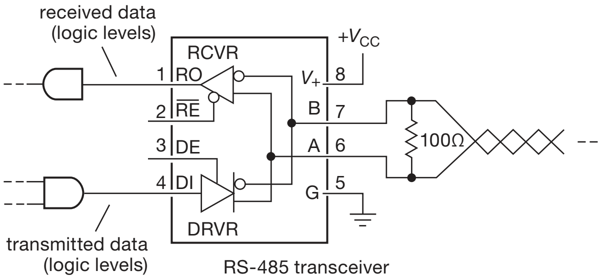

Figure 12.122. An RS-485 *transceiver* combines driver and receiver in one package, sharing a single twisted pair. Separate ENABLE pins (usually tied together) permit operation in either direction. The pin numbering shown is an industry standard.

Along with the ENABLE feature that is necessary for multiple drivers (called "multipoint"), the RS-485 specification beefs up some other RS-422 specifications: (a) it expands the receiver common-mode input range (−7 V to +12 V), thereby allowing symmetrical common-mode swings (up to ±7 V) around the traditional power-supply and signaling levels of 0 V and +5 V; (b) it lowers the minimum load resistance (to 54 Ω), which is necessary because a driver at either end requires end-termination at the other end (thus a 100–120 Ω at *both* ends). The RS-485 specification also (c) expands the allowable common-mode range that can be applied to a driver *output* (in the disabled state), from a diode drop beyond the rails (RS-422) to the full −7 V to +12 V range of an RS-485 input. This is necessary, of course, because the driver and receiver are both connected permanently to the signal lines in a typical bidirectional (or multipoint) arrangement; if the driver's output clamped to ground or the positive rail, it would defeat the receiver's wider common-mode range.

Most RS-485 transceivers satisfy also the narrower RS-422 specifications, so you might as well just use one of the hundreds of available RS-485 interface chips (from manufacturers like Analog Devices, Intersil, LTC, Maxim, or TI), even if you are sending data in only one direction; simply enable what you are using at each end. Some common choices are the 'ALS176 (and its many imitators –

[74] Good references: Analog Devices AN-960 and AN-727, National Semiconductor AN-759, Maxim AN-3776, and TI SLLA112.

[75] An interface chip that brings RS-485 driver and receiver pairs out separately is called "full duplex."

65LBC176, 65HVD1176, etc.), the 75176 and 75ALS180 classics, the LTC1480/5, and the ADM1485.

Isolated RS-422/485. Scenario: a "factory floor," with a host of automated machine tools and with products moving along on conveyor belts (think of a scene from the ever-informative "How It's Made" series on cable channels like Discovery Channel or Science Channel). Sensors send digital information through cables that snake along on overhead cable trays, and wind up at a central computer control; the same cables, or different ones, carry commands back to actuators. This centrally controlled network choreographs factory activities, ultimately directed toward the practical (and profitable) goal of… making stuff. It's common to see these signals piped around as differential RS-485 or a variant like the Process Field Bus (PROFIBUS®) that uses a similar "physical-layer" signal.[76]

These activities may be spread out over distances of hundreds of feet, and may go between buildings. Let's face it, with all that heavy machinery thumping along, you're likely to see common-mode transients that exceed even the "generous" specifications of RS-485.[77] The solution here is to use *isolated* interface chips, in which the RS-485 signals have their own independent ground, galvanically isolated from the ground of the logic signals. This requires a second dc power source, of course, floating with respect to the logic signal ground.

There are many isolated RS-485 interface chips to choose from. The clever designers use various tricks to make fast digital signals cross a gap that can withstand a kilovolt or so. For example, the LTC1535 (or MXL1535) "isolated RS485 Transceiver" uses small capacitors to couple the (modulated) digital signals (Figure 12.123). It also helpfully includes a high-frequency (∼420 kHz) oscillator, whose output you can use with a transformer to isolate and rectify to make the isolated dc for the RS-485 signal side. The ISO15/35 from TI is a less-expensive alternative, which omits the oscillator; you've got to provide isolated dc from scratch (either from an isolated dc–dc converter, or an ac-line-powered dc supply).[78]

Another approach is to couple with small (chip-scale) transformers. This technique is used in the ADM2485 series of isolated transceiver from Analog Devices, which also provides an oscillator output that can be used for generating the isolated dc (like the LTC1535). Or, you can add the popular MAX845 or MAX253 chips, which generate a pair of complementary square wave outputs at ∼0.75 MHz, suitable for directly driving a small isolation power transformer, good to a half-watt or so of isolated dc. The electronics industry makes it easy to use this part: major transformer companies even offer "MAX845 transformers."

An interesting technique is used in the IL3485 from NVE Corp, namely the "giant magnetoresistive effect" (GMR, widely used in hard-disk drives to sense the magnetically stored bits on the rotating platters). Instead of conventional transformer coupling, where a secondary winding senses flux *changes*, the NVE part uses GMR to sense the field directly.

Finally, isolated transceivers like the MAX1480/90 use optocouplers for the digital signals. And, to make your life really easy, they include an internal transformer to generate isolated dc power. These hybrid ICs include also the diodes and capacitor to complete the power circuit, so all you need to provide is a +5 V logic-side supply. That's the good news; the bad news is that these puppies will set you back twenty bucks (in small quantities), compared with $5–$8 for the capacitor- or transformer-coupled chips.

Ethernet PHY When thinking about moving digital data across isolation barriers, don't forget about the optical couplers and fibers earlier in this chapter, and also about isolation via pulse transformers, as used, for example, in local-area networks such as Ethernet. Figure 12.124 shows the physical layer ("PHY") of an Ethernet link, with pulse isolation transformers (which everyone just calls the "magnetics."). They provide excellent rejection of common-mode interference (and of course of differences in potential at the ends), using both a transformer and a common-mode

[76] PROFIBUS transceivers have higher maximum data rates, typically 30 Mbps or 40 Mbps, and generally meet the (less-rigorous) specifications of RS-422 and RS-485; check out parts like the 65ALS1176, ADM1486, ISO1176, or ISL4486. Some other industrial buses that use RS-485 signaling include BITBUS, Data Highway (DH-485), INTERBUS-S, Measurement Bus (DIN 66348), Optomux, P-NET, and Series 90 (SNP).

[77] As eloquently expressed in the MAX1480 datasheet, "The RS-422/485 standard is specified for cable lengths up to 4000 feet. When approaching or exceeding the specified maximum cable length, a ground-potential difference of several tens of volts can easily develop. This difference can be either DC, AC, at powerline frequency, or any imaginable noise or impulse waveform. It is typically very low impedance so that if a connection between the two grounds is attempted, very large currents may flow. These currents are by their nature unstable and unpredictable. In addition, they may cause noise to be injected into sensitive instrumentation and, in severe cases, might actually cause physical damage to such equipment." Amen.

[78] You sometimes see industrial RS-485 hookups with bused dc (+24 V or +48 V "telecom dc") bundled in the same cable as the RS-485 signal pair(s); hang an isolated dc–dc converter onto that, at each transceiver node, to power the RS-485 signal side of a transceiver like the ISO15/35.

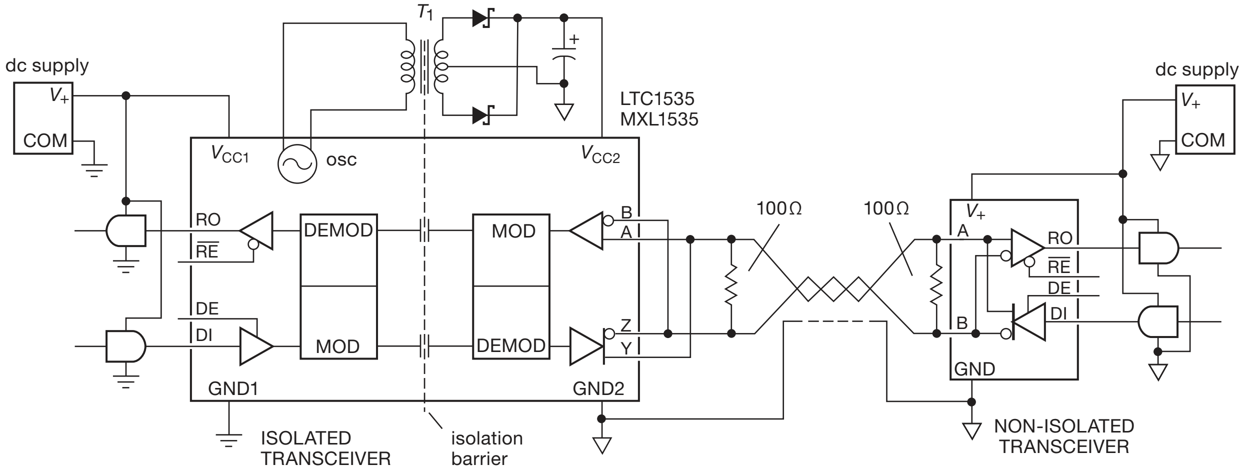

Figure 12.123. An “isolated” RS-485 transceiver galvanically separates the circuitry connected to the cable pair from the logic-level circuitry. The far-end ground (“GND2,” triangular symbol) is brought back to the isolated transceiver, but is never connected to the local ground (“GND1,” normal symbol). Such an arrangement prevents ground loops, and can accommodate common-mode and ground offset potentials of hundreds of volts. Additional isolated transceivers can be connected (“multidrop”) along the span, referenced to the same GND2, each with its own isolated RS-485-side power supply; such midspan “stubs” must be kept short in length, and without 100 Ω terminating resistors.

choke, as shown.[79] If you’ve got a microprocessor in your system already, why invent your own isolation hardware, when Ethernet works just fine? And, if you need to go greater distances, you can use a media converter to carry Ethernet signals on fiber. Check out the offerings from manufacturers like Allied Telesis.

B. LVDS

In contrast to RS-422, which is intended for modest data rates (10 Mbps and below) over relatively long cables (to 1 km), the LVDS (low-voltage differential signaling, also known as RS-644) standard is aimed at much higher data rates (to 1 Gbps and above) over shorter cables (to ∼10 m) or even shorter circuit-board trace runs. Rather than driving the wire pair with crisscrossing *voltages* of a few volts amplitude, LVDS switches *currents*: an LVDS driver sinks and sources 3.5 mA (nominal) into a wire pair that is terminated at the far end in its characteristic impedance (usually 100 Ω). That produces a differential voltage at the far end of ±350 mV. The driver is obliged to maintain a common-mode voltage, nominally +1.2 V; so the receiver sees crisscrossing voltages of approximately +1.0 V and +1.4 V. The relatively low common-mode voltage was chosen deliberately to accommodate both driver and receiver chips operating at low supply voltages. That’s important because digital chips are moving steadily to lower voltages, and the

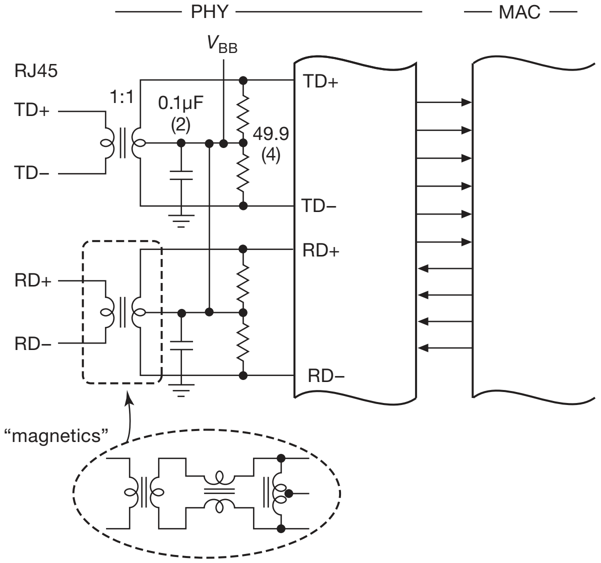

Figure 12.124. Ethernet uses transformer coupling and common-mode chokes for robust isolation of its differential signaling. Closest to the wiring is the physical layer (“PHY”), followed by the media-access control layer (“MAC,” as in “MAC address”).

[79] You get additional robustness by adding surge-protecting components, notably the Transient Blocking Units (TBU™) from Bourns. These are little 2-terminal elements that go in series with the signal leads from the transformer: they act like a low resistance, up to a critical current, at which point they go into a high resistance state.

LVDS interface is often incorporated right into a complex chip that wants to run at low voltages.

We hooked up the circuit in Figure 12.125 (analogous to Figures 12.120 and 12.121) to illustrate LVDS's rejection of common-mode interference. We injected a trapezoidal waveform at ~30 MHz into unused pairs of a network cable, and cranked up the amplitude until the received signal reached the specified common-mode receiver limits of 0 V and +2.4 V. The results are shown in Figure 12.126: You can see the two received signal voltages weaving busily past each other, at the command of the input signal (delayed by that speed-of-light nuisance, of course), cleanly recovered by the LVDS receiver.

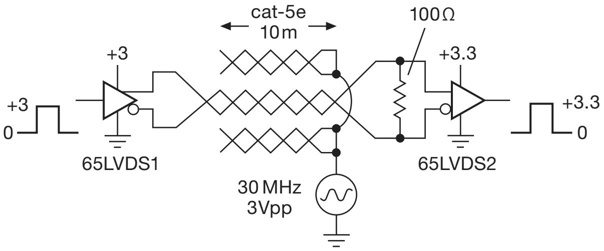

Figure 12.125. Torture test for LVDS common-mode interference rejection. We applied a ~30 MHz signal to two unused pairs at the far end of a 10 m length of Cat-5e network cable, while transmitting a pulse sequence (clocked at 20 ns) through a different pair.

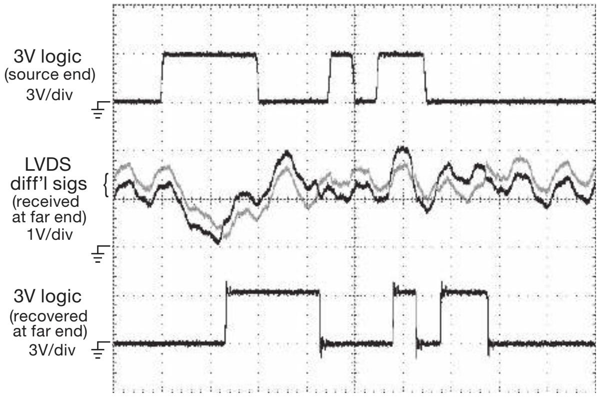

Figure 12.126. Waveforms from the circuit of Figure 12.125. The injected signal adds up to ±1 V of common-mode interference to the ~400 mV differential 50 Mbps received signal. Horizontal: 40 ns/div.

To illustrate the problem of conveying digital signals between instruments whose grounds differ by a small amount of 60 Hz ac, we rigged up the circuit of Figure 12.127. We "floated" the source device's ground, analogous to the arrangement earlier with RS-422 (Figure 12.120), then drove it with a 2 Vpp sinewave. The results are shown in Figure 12.128, where we've clocked down the data rate so you can see the powerline frequency. Note that LVDS permits only 2 Vpp of added common-mode signal, compared with 14 Vpp for RS-422/485; but with LVDS you get lots of speed, and compatibility with low-voltage logic.[80]

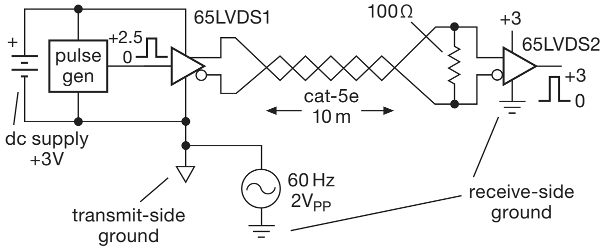

Figure 12.127. Powerline common-mode test setup, using a floating LVDS signal source (complete with pulse pattern generator and power supply).

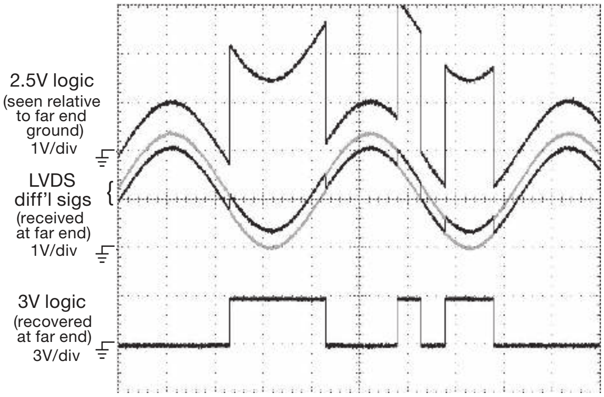

Figure 12.128. Waveforms from the circuit of Figure 12.127. The ~400 mV differential signal is superposed on the added 2 Vpp 60 Hz sinewave, reaching the specified receiver common-mode limits of 0 V and +2.4 V. Horizontal: 4 ms/div.

The LVDS protocol is widely used in serializer-deserializer links (see also §12.8.4, §12.10.5, and §14.7), in which a fast serial link connects a pair of separated parallel registers. At each end you think you're talking to a parallel port (and you are!), but in between the data travels as serial bits. A common data width is 10 bits, which lets you send a byte plus two extra bits to signify whatever you want (a new byte, or the beginning of a new "frame"

[80] You can get LVDS receivers with extended common-mode capability, for example the 65LVDS34, which specifies operating common-mode range of −4 V to +5 V (they do it with a resistive input divider, so R_{in}=250 kΩ).

of bytes). Figure 12.129 shows how it goes, in this case with a SERDES pair with a relatively relaxed speed specification: the transmit clock, which times the entry of 10-bit data symbols, can be in the range of 16–40 MHz. The serialized data bits that go over on the LVDS link are at ten times that rate, i.e., up to 400 Mbps.[81] You need only one LVDS differential pair, because the deserializer performs "clock recovery" from the transmitted bitstream. In the figure we've omitted some additional details having to do with modes and synchronization.

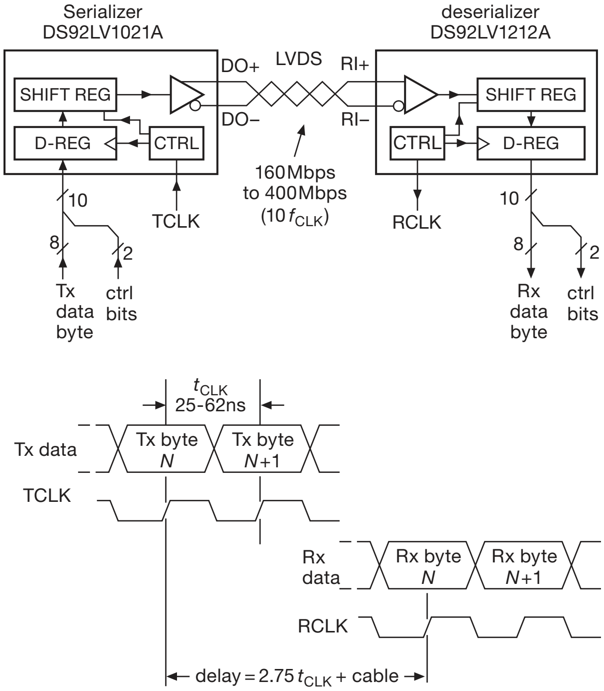

Figure 12.129. A serializer-deserializer pair lets you clock parallel data into a register at the transmit end; it appears, magically, as parallel data at the receive end. There are a few clock cycles of delay, but nothing to write home about.

LVDS signal conditioning As we remarked earlier (§12.10.2C), the use of transmit pre-emphasis and receive equalization can compensate for the frequency-dependent loss of the connecting cable. These *signal-conditioning* techniques reduced greatly the effects of data-dependent jitter, which is also known as *intersymbol interference*, or ISI.

This ISI effect is worth a few words of explanation: because of the lowpass filtering effect of the losses in cables or printed-circuit traces, particularly when operating at very high bitrates (gigabits per second), the initial received signal voltage at the beginning of each bit cell depends on the previous bit (or bits), and so the time to cross the threshold will vary somewhat, depending on the previous bit(s). Intersymbol interference plagues high-speed communication in all forms. You can see this effect in the 1.5 Gbps recovered LVDS waveforms in Figure 12.132, in which the 'scope traces, triggered by the clean clock signal, show the scatter of signal levels on the data line carrying a pseudo-random data pattern. This is called an "eye diagram;" it is a standard tool for visualizing noise and jitter in assessing signal quality in a clocked data stream.

The use of pre-emphasis and equalization can significantly extend bitrates and transmission distances, as we remarked earlier in §12.10.2C in connection with coaxial cables. Figure 12.130 shows the scheme, and Figure 12.131 shows how pre-emphasis boosts the voltage levels following each transition; and when combined with receiver equalization (high-frequency boost), the result is a clean replica of the original input signal. Such signal conditioning is used in various driver and receiver ICs, for example the DS25BR100/200/400 and DS25CP102 series from NSC; see their App Note AN-1957 for details and illustrative waveforms.

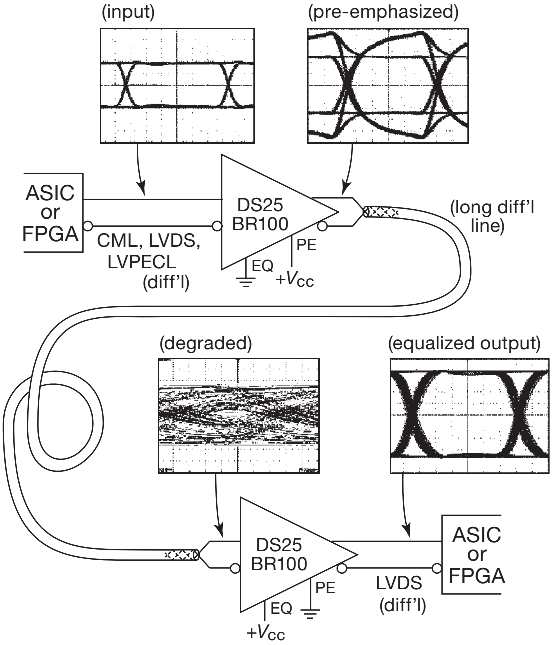

Figure 12.130. Driver pre-emphasis, receiver equalization, or both can compensate for cable losses when transmitting at high data rates over lossy media.

[81] The serial bitrate is actually 12 times the clock rate, because the serializer adds two clocking bits.

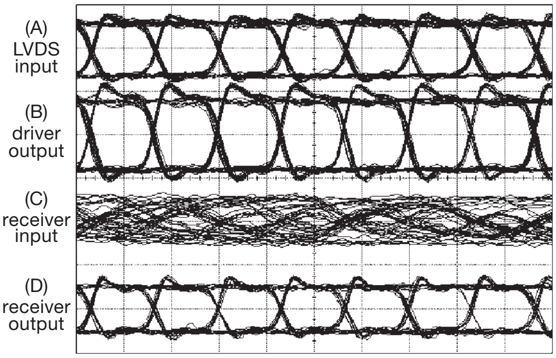

Figure 12.131. Waveforms from a 1.5 Gbps pseudorandom LVDS signal traversing a 2.5 m length of differential stripline on a printed circuit board. A. Input to DS25BR120 driver; B. Driver output, with pre-emphasis; C. Input to DS25BR110 receiver; D. Receiver output, with pre-emphasis and equalization. Vertical: 500 mV/div; horizontal: 500 ps/div.

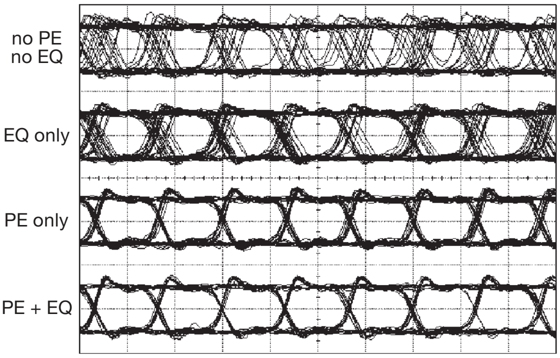

Figure 12.132. Receiver output waveforms ("eye diagrams") from the same setup as Figure 12.131, showing the effect of varying amounts of driver pre-emphasis and receiver equalization. The bottom trace represents PE=+9 dB and EQ=+8 dB at 1.5 GHz. Vertical: 500 mV/div; horizontal: 500 ps/div.

12.10.4 RS-232

This is a signaling format that goes back to the 1960s, intended originally for low-speed (<19.2 kbps) serial links between alphanumeric terminals (e.g., the legendary DEC VT-100) and computers. RS-232 has been revised several times and is now known officially as EIA232; although RS-232 ports are still seen on some computers and instruments, the standard is considered old-fashioned, and arguably headed for the trashcan. It's still with us, however (and perhaps always will be[82]). Although not part of the standard, the data is usually sent as asynchronous 8-bit serial data bytes, with a synchronizing START bit, and one or two STOP bits (these extra bits allow the receiver to resynchronize after each byte; see §14.7.8). The usual bit rates (also not specified in the RS-232 standard itself) are power-of-2 multiples of 300 bps (thus 300, 600, 1200, 2400, 4800, 9600, and 19,200 bps, supplemented with an interleaved set consisting of 14.4 kbps, 28.8 kbps, 57.6 kbps, and 115.2 kbps). Thus, for example, when you set up a serial port for "9600 8N1," you are sending groups of 8 bits, with one START and one STOP bit, and no parity, at 9600 bits/s. Note that the synchronizing bits (START and STOP) are included in the overall bitrate measure; for this example, then, you're sending a payload of 960 bytes/s.

What the standard *does* specify are the signaling voltages, load resistance and capacitance, and slew rates, along with the connector pinouts. We'll see RS-232 again, in the context of computer communications, in Chapter 14. But here we stick to the use of RS-232, at the physical level (hence the term "PHY"), as a way to drive cables with digital data. The RS-232 voltage levels are bipolarity, with legal driver output voltages of either −5 V to −15 V (logical 1, also known as "MARK"), or +5 V to +15 V (logical 0, also known as "SPACE"). RS-232 drivers and receivers are inverting, so MARK corresponds to logic HIGH at the input of a driver or at the output of a receiver (see Figure 12.135). As indicated in the figure, RS-232 is single ended; and, because of the relatively low signaling rates, the cable is unterminated. That's a terrible thing to do, normally, because rapidly changing signals (i.e., on a time scale shorter than the round-trip signal travel time) reflect from the open end, as we've seen. RS-232 finesses that problem by specifying a maximum slew rate (30 V/μs), which is slow enough for typical cable runs of fifteen meters (the original specified maximum, later replaced with a maximum load capacitance) or less. To be in compliance with the standards, the load capacitance must be 2500 pF or less;[83] and the load resistance is a nominal 5kΩ (±2kΩ). RS-232 drivers must withstand a continuous short to ground or to any dc voltage in the range ±25 V.

[82] It's hard to completely dismiss RS-232, when so many test instruments are happily working well with it, as one of their several interface choices. The move toward USB is being stolen by Ethernet instead (or other replacements), leaving an RS-232 connector as the easy-to-implement port. Unlike more advanced serial interfaces like USB and Firewire, RS-232 does not require any "smarts" – there's no initialization or negotiation needed. Partly for this reason, most microcontrollers include an easy-to-use serial port controller. And for connection to contemporary laptop computers and the like, you can get USB-to-RS-232 adapter pods, for example from FTDI.

[83] Which corresponds to 50 m of Cat-5 twisted pair (50 pF/m), or 25 m of 50 Ω coax (100 pF/m).

So, RS-232 rumbles along, slowly. The good news is that it can ride along in a multiwire unshielded cable, which need not act as a well-behaved transmission line; the limited slew rate minimizes both crosstalk and reflections. The bad news is that the driver needs both positive and negative supply voltages of at least ±5 V. The original driver–receiver chips (1488/1489, and their CMOS follow-ons DS14C88/89 and MC145406) required such dual supplies (±9 V, nominal), which is asking a lot in a digital system (like a computer motherboard) that runs on positive supply voltages only. Maxim was the first to introduce RS-232 drivers with an on-chip charge pump (flying capacitor) voltage doubler and voltage inverter, to generate ±10 V from a single +5 V; they named it (naturally) the MAX232. There are now dozens of such chips (some with the capacitors included in the package, e.g., the MAX203 or LT1039), spanning a range of maximum speed, power consumption, supply voltage, number of drivers and receivers in one package, and so on. As an example, the MAX3232E is a dual transceiver (two drivers, two receivers) that runs from a single +3 V to +5.5 V supply, requires four external 0.1 μF capacitors, and is guaranteed to meet RS-232 specifications to 120 kbps; it comes in five different packages (SMT and DIP). The -E suffix designates enhanced robustness to electrostatic discharge, namely ±15 kV ESD-protected, specified with the Human Body Model (HBM, recall §12.1.5) of a 100 pF charged capacitor in series with a 1.5kΩ resistor.

The RS-232 interface specification includes a number of additional control signals, intended for hardware "flow control" when a terminal is connected to a computer (see §14.7.8); these have names like Data Terminal Ready (DTR), Data Set Ready (DSR), Request to Send (RTS), and Clear to Send (CTS). You can ignore all of this if you simply want to use an RS-232 interface chip pair to send low-speed digital data over a wire connection. In fact, these are often ignored even in computer serial ports: you can simply use the transmit data (TD) and receive data (RD) lines, plus ground, and do the flow control with software (more on this in Chapter 14). Note, however, the curious (and confusing) official naming of the actual signal lines TD and RD: you would expect that TD is the output from a driver, which should be connected to RD of the (distant) receiver. Not so! In RS-232 nomenclature, a device is either Data Communications Equipment (DCE) or Data Terminal Equipment (DTE); the signal sent by the latter is called TD *at both ends of the link!* (and likewise for RD). Go figure. In practice, most engineers ignore this confusion; they call an outgoing signal TD and an incoming signal RD, at whichever end it's happening.

Figure 12.133 shows received RS-232 signals and the recovered +3.3 V logic-level digital data. We used a pair of MAX3232E dual RS-232 transceivers, powered from +3 V, and driven by a random byte generator[84] emitting standard serial-formatted data at 115.2 kbaud. The 'scope capture, triggering on the transition from negative STOP bit to positive START bit, shows many such bytes superposed, so the data bits attain both values. The recovered logic signal is clean after 10 m of twisted pair (approximately its rated limit), but after 140 m there is significant spread in the recovered data's edge timings, caused by intersymbol interference (§12.10.3B) in the slow-transitioning RS-232 signal. Here, the slow transition time is comparable to the time for one bit (1 "UI," or unit interval), causing the time to cross the 0 V threshold to vary somewhat, according to the preceding bit values. You can see this effect in the long cable data in Figure 12.133, where the received cable signal falls short of its asymptotic voltage levels (approximately ±4.5 V) by as much as a volt.[85]

When sending digital signals on wires over substantial distances, or in electrically noisy environments, there

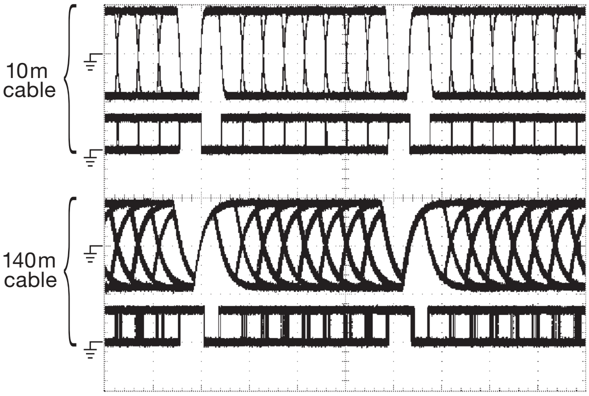

Figure 12.133. RS-232 signaling uses single-ended voltage drive, alternating between positive and negative voltage levels. These 'scope captures show received random bytes ("8N1") at 115 kbaud (top trace of each pair) after transmission through two lengths of Cat-5e/6 network cable; the drivers and receivers are inverting, as can be seen in the recovered logic signal (bottom trace of each pair). The marginal performance with the longer cable is consistent with Figure 12.134's limit of ~10 kbaud for this cable length. Driver/receiver: MAX3232E at +3 V. Horizontal: 20 μs/div; vertical: 5 V/div.

[84] The one used to generate the ~250 MB of random bytes on the *Numerical Recipes* CD-ROM.

[85] Users of RS-232 often use slower data rates, the most popular of which is 9600 baud, at which these effects are insignificant.

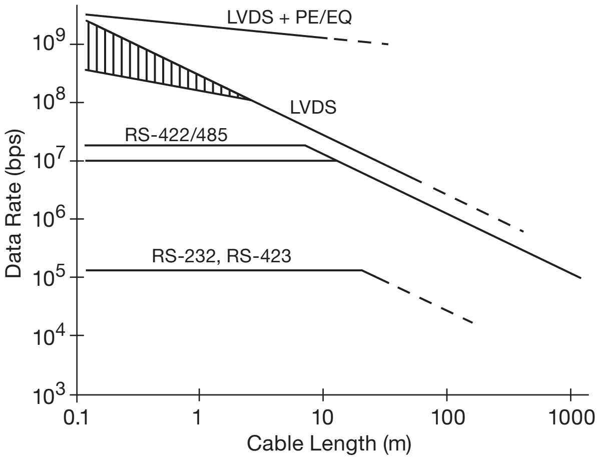

Figure 12.134. Approximate data rate limits versus cable length, for several signaling protocols. Your actual mileage may vary, depending on cable quality and interference environment. Note the speed improvement gained with pre-emphasis and equalization ("PE/EQ," see Figures 12.130–12.132).

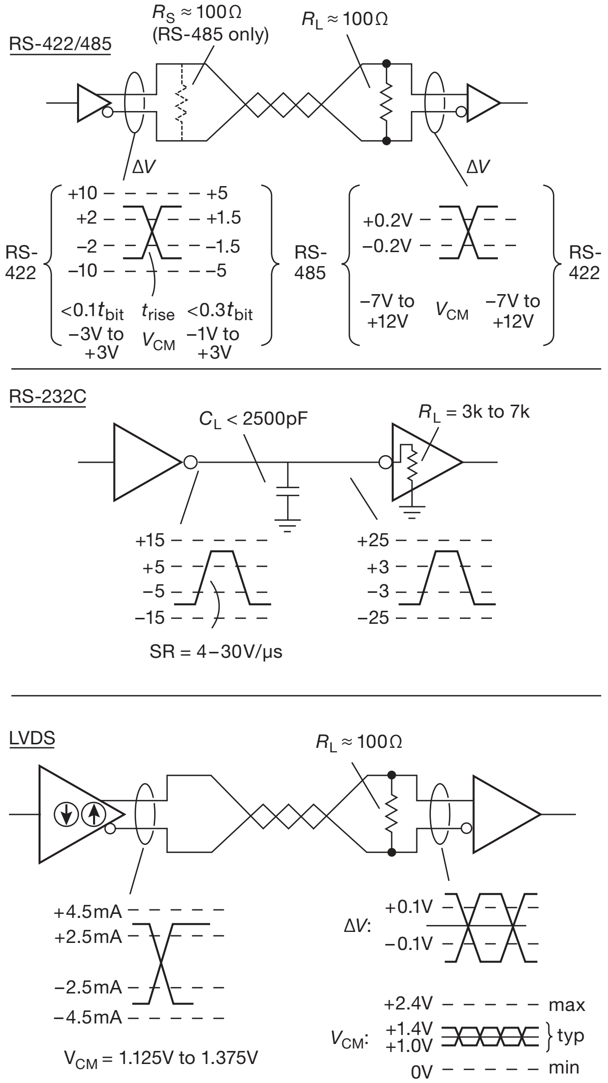

Figure 12.135. Allowable driver and receiver signal levels for LVDS, RS-422/485, and RS-232 signaling. Except for the bipolarity (and single-ended) RS-232, the output voltages from the drivers are of positive polarity only. LVDS outputs are *current-mode* drive (which are converted to a differential voltage signal at the cable's terminating resistance), at a common-mode voltage of +1.25 V; the others are *voltage-mode* outputs. All of the receivers respond to voltages, whether single ended (RS-232) or differential (LVDS, RS-422/485).

are always the problems of ground currents and of injected noise. Galvanic isolation is the best solution. Although RS-232 does not receive as much attention as RS-422/485, there is at least one good isolated driver, namely the ADM3251E from Analog Devices. It uses internal transformer coupling (with a modulator–demodulator pair) for the transmit and receive data, and an additional transformer (plus rectifier and regulator) to generate the isolated dc; the only external components are five 0.1 μF for the (internal) charge pumps.

One final comment: we've been talking mostly about the RS-232 *physical layer* (the actual voltages on the cable), with its awkward bipolarity signaling, as a simple tool for direct transmission of digital data. In the real world, RS-232 is ordinarily used in conjunction with asynchronous serial data sources, for example between a host computer's "serial COM port" and a device such as a modem or programming pod. In that role, you need to use driver and receiver interface chips (like the MAX3232) at each end, to translate between the logic-level signals and the RS-232 signals. Although we're less than enthusiastic about RS-232 signals, we believe that the use of the simple asynchronous serial data protocol *without conversion to RS-232 voltage levels* will continue to be useful. That's because it is the last of the uncomplicated serial interface standards – later serial protocols such as USB, Firewire, and SATA require substantial brainpower to negotiate and operate the link. Most microcontrollers include one or more serial ports (called UARTs, or COM ports), which are easy to use, and which can talk to any computer via a serial-to-USB converter such as the popular FTDI TTL-232R-3V3. This handy device plugs into a USB host at one end, and gives you a serial port with +3.3 V logic levels (for direct connection to a microcontroller, or whatever) at the other end.

12.10.5 Wrapup

In contemporary practice LVDS is quite popular, owing to its combination of high speed (to 3 Gbps and beyond), low emission of interference, low power, and compatibility across low-voltage logic families.[86] It's used widely for high-speed signal transport and distribution on circuit boards and backplanes, as well as through short runs ($\lesssim$10 m). You can get discrete drivers and receivers in small packages (e.g., 65LVDS1/2), and many complex ICs include LVDS driver/receivers for serialized data, for example a SERDES pair like the DS92LV1023/1224, or a complex FPGA like the Xilinx Spartan-3 or Altera Stratix series.

RS-422/485 is used for longer runs, often in industrial environments, where the data rates are lower (to 10 Mbps) but the common-mode noise is higher. And RS-232 survives, in spite of frequent predictions of its demise, for simple data links at low rates. For applications where the signal must be isolated from interference (both incoming and outgoing) you'll see shielded cables, either as shielded twisted pairs for differential signaling, or as coax cables for single-ended (or analog) signaling. It's also common to see galvanically isolated RS-485 interface chips, employing electrostatic (via capacitors), magnetic (via transformers, or GMR), or optical (via LEDs) techniques to bring the data across a several-kilovolt isolation barrier. Finally, fiber optics (§12.8) provides a totally noise-immune and galvanically isolated digital link, capable of very high data rates and long runs, in exchange for higher costs in driver–receiver components.

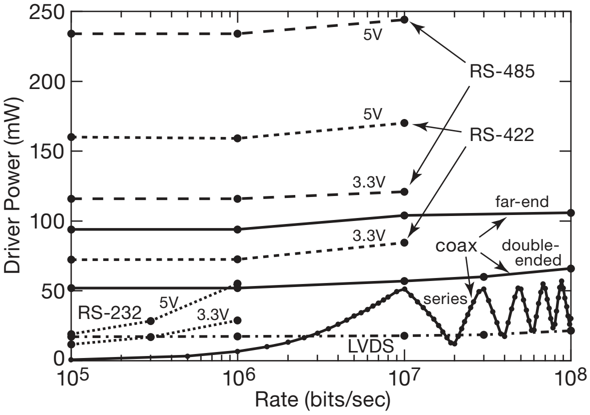

Figure 12.136. Measured driver power versus bitrate, for several single-ended (coax) and differential (twisted-pair) cable-driving configurations. All tests used a 10 m length of RG-58A coax or Cat-5e network cable, driven with alternating 1s and 0s (i.e., a square wave whose frequency is half the bit rate). The far-end termination resistance was 50 Ω for coax (except open circuit for "series" terminated), and 100 Ω for twisted pair (except 5 kΩ for RS-232) with another 100 Ω at the source end for RS-485. Note the effect of reflections from the mismatched end termination (5 kΩ) with RS-232, particularly evident here because of the single-frequency square-wave drive.

Figure 12.134 is a rough guide to speeds and lengths of LVDS, RS-422/485, and RS-232 signaling. Figure 12.135 summarizes the signal characteristics of these link standards. And Figure 12.136 compares their driver power requirements (i.e., the driver chip's supply voltage times current), along with that of 50 Ω coax.[87]

[86] There are several closely related protocols, namely PECL (positive emitter-coupled logic), LVPECL (low-voltage PECL), and CML (current-mode logic). The latter is used, for example, in digital-video links such as DVI and HDMI.

[87] The driver ICs we used for these power measurements were: coax – 74LVC2G04 (both sections in parallel); LVDS – 65LVDS1; RS-232 – MAX3232E; RS-422/485 – LTC1485 (5 V) or LTC1480 (3.3 V).

Review of Chapter 12

An A-to-S summary of what we have learned in Chapter 12. This summary reviews basic principles, facts, and application advice in Chapter 12.

¶A. Logic Interconnections.

The subject of this chapter is the interconnection of digital logic signals and logic devices to… *everything*, where "everything" includes (a) other logic devices, (b) input sources (switches, optoelectronics, cables), and (c) output devices (dc and ac power loads, optoelectonics, cables). So it's a long chapter, rich with multiple themes. Here we try to organize these diverse topics into manageable paragraphs.

¶B. Logic Families.

§12.1.1. Contemporary digital logic is owned by CMOS, with the minor exception of some emitter-coupled logic families (ECL, PECL, and LVPECL) and some BiCMOS (ABT, BCT). CMOS inputs draw no current, and their logic thresholds are usually close to mid-supply, except for the -T suffix types (HCT, ACT, AHCT, VHCT) where the threshold conforms to that of legacy bipolar TTL (∼1.4 V); see Figure 12.5.

The 74HC[T] logic is good for easy prototyping and general-purpose use, and is available in DIP or SOIC; substitute 74AC[T] or 74LV for applications needing higher speed. For lower-voltage applications at moderate speeds, use 74LVC or 74VCX (available in SOIC and mini-logic packages only). For operation up to 15 V you can use 4000B logic, but this stuff is *slow*. Finally, for differential signaling use LVDS (or LVPECL, if specified) drivers and receivers. See Figures 12.2 and 12.3 for logic-family speed versus power, and speed versus supply voltage.

¶C. Input and Output Characteristics.

§§12.1.2A and 12.1.2B. CMOS *inputs* draw no current when 0V $\leq V_{\text{in}} \leq V_{\text{DD}}$ (and even for inputs a few tenths of a volt beyond). For most logic families, the input protection diodes clamp to ground and V_{DD}, thus causing substantial input current for input voltages as much as a volt beyond V_{DD} or below GND; this can cause SCR latchup. However, some families use zener-like clamping, allowing input swings well beyond the rail (and even when unpowered); examples include 5V-tolerant 74LVC, and 3.3V-tolerant 74AUP. See Figure 12.4.

CMOS *outputs* swing to the rails, looking resistive for small load currents (Figure 12.7). The output current capability varies widely among families; within a family it increases with increasing supply voltage. See Figure 12.6 for a summary of thresholds, and valid input and output voltage ranges. Note that the outputs of (essentially obsolete) bipolar TTL logic (and also of digital ICs with nMOS outputs) do not saturate to the supply rail; see §12.4.5A.

¶D. Interfacing between Logic Families.

You can mix logic types as long as you respect logic-level input requirements. At the basic level this means that (a) you can always make a direct connection between logic running at the same voltage; (b) logic running from a higher voltage (e.g., +5 V) can drive lower-voltage logic if the latter's input is "tolerant"; and (c) lower-voltage logic can drive higher-voltage logic if the latter has "TTL thresholds" and the former is powered from at least +2.5 V. With dozens of logic families, most capable of operating over a range of supply voltages, you've got a lot of possibilities. Most are dealt with in §12.1.3, and presented pictorially in Figure 12.9.

¶E. Driving Digital Logic Inputs.

§12.1.4. A mechanical switch with pullup (§12.1.4A) generates the right logic levels, but with *bounce*. That may be OK for some applications; but for clean edges you need a debouncer, illustrated in a half-dozen variations in §12.1.4B. A logic input can come instead from a *comparator* (a subject summarized in ¶G below, and treated in detail in §12.3), whose output may have active pullup to the same V_{DD} as the driven logic, or it may come from an "open-drain" (or open-collector) terminal; in the latter case you need an external pullup to V_{DD}. Figure 12.25 shows representative circuit configurations.

When driving logic inputs from signals of any type, be careful not to overdrive the input (whether from a signal source of greater swing, or from transmission-line effects – see the egregious example in Figures 12.103 and 12.104); and do not leave unused logic inputs floating.

Contemporary logic devices are engineered to withstand substantial static-electricity insults (defined in terms of the human-body model, HBM, of 100 pF in series with 1.5kΩ, §12.1.5), but it's best not to tempt fate; be careful to discharge yourself, use antistatic materials, etc. See also the earlier discussion in §3.5.4H.

¶F. Driving External Loads from Logic Outputs.

§12.4. You can drive small loads (LEDs, SSRs, small mechanical relays) directly from logic outputs (§12.4.1 and Figure 12.39), taking care to respect the output drive capability (voltage swing, current), and, for a mechanical relay, adding a diode clamp across its coil. As shown in the figure, you can use an open-collector driver (ULN2003, 75468) to accommodate voltages and currents as high as 100 V and 350 mA respectively. There are analogous drivers for use with serial data (from a microcontroller), see Figures 12.40 and 12.41, and the listing in Table 12.3 on page 819.

For driving heftier loads you can append an external transistor or power-driving module. For driving *positive* loads see §12.4.2, and Figures 12.42 and 12.43. For driving *negative* or *ac* loads see §12.4.3 and Figure 12.44. Serious power switching requires *fault protection*, see §12.4.4 and Figures 12.45–12.48.

¶G. Comparators.

A comparator is a high-gain uncompensated differential amplifier, used to signal which of two analog voltage inputs is greater. It is an important interface between analog signals and the digital world. Comparators were introduced in §4.3.2, and treated in detail in §12.3 (with listings in Tables 12.1 on page 812 and 12.2 on page 813).

As with op-amps, comparators come in a range of speeds (<1 ns to tens of μs), supply voltages (total supply voltages from as little as 1.1 V to as much as 40 V), input offset voltages (0.25 mV to 10 mV), input bias currents (1 pA to $>10\,\mu$A), input common-mode voltage ranges (to both rails, one rail, or neither), and quiescent currents ($<1\,\mu$A to tens of mA). But, unlike an op-amp, which is normally operated in the linear region where the (analog) output voltage avoids saturation, a comparator's output is digital; it lives at the extremes. It may be used to drive logic, or it may drive an ON/OFF load like a relay or an LED. To accommodate various loads, comparator output stages come in a half-dozen variations (Figure 12.33), including (a) rail-to-rail (like an op-amp); (b) open-drain or open-collector; (c) logic-level with auxiliary logic-rail pin V_L; (d) logic-level with both V_L and GND pins; and (e) floating-transistor output stage.

Comparator miscellany: comparators are usually configured with some hysteresis (Schmitt trigger) to prevent multiple transitions and oscillation. Some comparators have quite limited differential input voltage ranges (as little as a few volts). For comparators with BJT input stages, the input currents may undergo an abrupt step at zero differential voltage (e.g., Figure 12.36). The delay and switching time of a comparator depends on the input overdrive (Figure 12.38).

¶H. Optoelectronics.

§12.5. Continuing the theme of "logic-to-everything," we must include among the latter *humans*, with senses that delight in visual presentations.[88] There's much richness here, including emitters, indicators, displays, detectors, and couplers, as illustrated in the photographs in Figures 12.58 (page 830), 12.71 (page 837), 12.80 (page 841), 12.84 (page 844), and 12.95 (page 853). To remind you of the breadth of optoelectronics, here is a condensed listing of devices (expanded in ¶¶I–M below) in the family tree:

Emitters: LED; Laser diode; Electroluminescent

Displays: LED-based; LCD-based; VFD-based; OLED; E-ink

Detectors: Photodiode; Phototransistor; Photoresistor; Bolometer; APD; PMT; HAPD; Microchannel plate

Couplers: LED-input or logic-input, with transistor-, thyristor-, or logic-output

Other: Opto-interrupter, proximity and ranging; Barcode reader; Optical mouse.

¶I. LED Indicators.

These have diode-like *I–V* curves, but with greater (and color-dependent) forward voltage drops (Figure 2.8). They come in many form factors (panel mount, PCB mount, arrays, 7-segment displays), sizes, viewing angles, and colors (§12.5.1). You can drive them from a logic signal of adequate swing, with a current-limiting series resistor (mindful that blue, bright-green, and white LEDs have forward drops of 3 V or more), or you can add an external transistor for higher voltage or current (see Figure 12.61). For serious illuminations purposes you're better off using a current-sensing dc-dc switching converter (Figure 12.62). By contrast, to drive *laser diodes* you use feedback from the integrated monitor photodiode to set the drive current (see Figure 12.67 and associated text).

¶J. Displays.

A popular device for numeric or hexadecimal data is the 7-segment (or 16-segment) *display* (§12.5.3A), available in multicharacter sticks of both "dumb" and "smart" varieties (see Figures 10.90 and 12.77, respectively). Once you've bought into the idea of a multicharacter display device, you should consider the multicharacter (and multiline) LCD smart display (Figure 12.78) and the nicer-looking (and compatible) VFD display, seen in Figures 12.71 and 15.25.

¶K. Detectors.

In the detector arena, *photodiodes* convert light to a proportional photocurrent, and can be operated in either of

[88] As a colleague once remarked, as we were admiring the sunset while walking along the beach, "nice graphics."

two modes – *photovoltaic* (self-generating, into a short circuit or virtual ground); or *photoconductive* (back-biased) – see Figure 12.81. The latter is faster, but suffers from leakage current and increased noise. A *phototransistor*, which operates only in photoconductive mode, combines a photodiode and transistor, for greater gain, but with reduced speed; similarly (and more so) for a *photo-Darlington*. The *avalanche photodiode* exploits the phenomenon of avalanche multiplication in a photodiode biased close to breakdown; each detected photon causes multiple electrons to be collected, thus providing higher gain (in linear operation), or (if biased still further) a full-sized "Geiger-mode" pulse for each detected photon. A different class of detector is the cadmium sulfide *photoresistive* sensor, which behaves like a linear resistance ($I \propto V$) that depends on illumination; CdS sensors are slow, and they are becoming a rarity owing to RoHS regulations (cadmium is not good for you), but they are useful in applications where you want a light-controlled linear resistance (see for example Figure 7.21). Finally, a still-popular old-school photodetector is the *photomultiplier* tube (PMT, §12.6.2), in which a photoelectron is accelerated and collides with successive electron-multiplying dynodes to produce a cascade of some 10^6 electrons at a collecting anode (Figures 12.82 and 12.83).

¶L. Optocouplers and Solid-state Relays.

Optocouplers (also known as opto-isolators, or photocouplers) consist of an opto-emitter combined with a detector in an opaque package (§12.7). They are used to convey digital (and sometimes analog) signals between circuits with separate grounds; such *galvanic isolation* prevents ground loops in sensitive circuits, it permits safe switching of ac powerline circuits, and it allows communication and control for circuits operating at a high voltage.

All optocouplers use an LED at the *input end*, in most cases simply providing the anode (+) and cathode (−) terminals (so you have to limit the driving current with an external resistor, see Figure 12.85A); some optocouplers include current limiting (e.g., SSRs, Figure 12.92C), while some others (e.g., high-speed logic-to-logic couplers, Figure 12.86C) accept a logic-level input signal. At the *output end* there are many configurations: transistor or Darlington (Figure 12.85), digital logic with open-collector or active pullup (Figure 12.86), active-pullup MOSFET-driver (Figure 12.87), ac-output SSR (Figure 12.92), and dc-output SSR in many flavors (Figure 12.91). There are also analog-oriented optocouplers (Figures 12.88, 12.89, and 12.90), ac-input optocouplers (Figure 12.94), and a whole range of industrial *input/output modules* (§12.7.7).

¶M. Opto-interrupters, Proximity Sensors, and Angle Encoders.

An *opto-interrupter* is an LED-detector pair with an open gap (Figure 12.84), widely used to sense end-of-travel in mechanical devices. An optical *proximity sensor* bounces a beam off an external object; the *distance measuring sensor* is a variant that incorporates a position-sensitive detector that uses parallax (triangulation) to measure object distance (to ∼1 m or so). Optical *shaft angle encoders* measure shaft position; they come in incremental (quadrature square-wave) and absolute versions, with resolutions of 32 to 128 counts per rotation (for panel controls) to 30,000 or more for high-resolution shaft encoders.

¶N. Fiber Optics.

Light travels happily, and unimpeded, through glass or plastic fiber. For long-haul high-datarate communications you use single-mode glass fiber (with rates to 100 Gbps or more per fiber); but for more modest data communications you can use multimode fibers, ranging from the simplest TOSLINK 1 mm plastic fiber to the very popular 62.5/125 μm graded-index glass fiber. Transmitter and receiver modules are widely available (§12.8.1–12.8.3), as well as high speed transceiver modules that include all necessary driver/receiver electronics (§12.8.4).

¶O. Digital Signals and Long Wires.

Fully 25% of the chapter (§12.9) is devoted to the problem of sending digital signals somewhere else, where the *somewhere* may be on the same PCB, or through a backplane, or through a cable to a remote electronic device. As simple as these may seem, numerous pitfalls await the unwary: for example, we were surprised (but should not have been) when encountering errors while sending parallel digital data of only modest speed (HC logic) through just 4″ of flat ribbon cable. Read the following paragraphs, to avoid membership in the club of the unwary.

¶P. Short Links.

For the *short links* that stay on a PCB, the distributed capacitive loading and consequent ground-current spikes cause logic glitches (§12.9.1A), requiring liberal power-supply bypassing (which is always salutory) and low-inductance ground plane layouts. The problem is less severe in synchronous systems; but it's more severe with fast logic, where interconnections may require constant-impedance transmission-line layouts (see §*1x.1.4*). These problems are more pronounced for signals moving between circuit boards or along backplanes, where you may need to use line driver and line receiver ICs, perhaps in combination with controlled impedance traces that are properly terminated; the latter is standard practice with LVDS (differential) signaling, as seen for example in Figure 12.127.

¶Q. Cable Runs.

Longer signal runs require *cable* (§12.10), usually *coaxial* (e.g., the ubiquitous RG58 BNC patch cords), multiwire *ribbon*, *twisted pair* (e.g., the comparably ubiquitous cat-5 or cat-6 network cable), or *fiber optic* (generally recognizable by their brightly colored svelte profile). With the exception of "slow" waveforms,[89] signal cables must be treated as *transmission lines* (Appendix H), with their *characteristic impedance*[90] Z_0. For coax, Z_0 is usually 50 Ω (but 75 Ω for video), while twisted-pair is usually 100 Ω. The significance of Z_0 is that *a signal applied to a cable, terminated with a load resistance equal to its characteristic impedance, is completely absorbed by the load*; it does not reflect. No other load impedance can make that statement.

¶R. Terminating Digital Coax.

So you can (a) put a 50 Ω resistor across the far end of a coax line (a "terminated line," or "matched line") and drive it with your digital signal (which sees a pure 50 Ω resistive load – the capacitance disappears!), as in Figure 12.107; or (b) drive such a terminated line with a signal of the same impedance, as in Figure 12.110, noting that the output signal amplitude is reduced by ×2; or (c) keep the matched source resistor but omit the load resistor, as in Figure 12.107, to preserve the full output amplitude. In the latter case there *is* a reflection of substantial amplitude, which however is hospitably absorbed by the source resistor – see the highly educational waveforms in Figure 12.115. See §12.10.1 for pretty pictures, and plenty of detail.

¶S. Differential Cable.

Differential signals are treated similarly, with a termination connected across the pair. For long hauls (to ∼1 km) and modest speeds (10 kbps–10 Mbps) the long-lived RS-422/485 protocol is popular, whereas the LVDS protocol is used for higher datarates (10 Mbps–1 Gbps) over shorter distances; see the speed limit contours in Figure 12.134. To achieve the highest datarates over significant lengths of cable one commonly uses driver *pre-emphasis* and receiver *equalization*, see Figures 12.130–12.132 and associated discussion.

[89] Those whose transition times are much longer than the round-trip travel time, $t=2L\sqrt{\varepsilon}/c$, where the factor $\sqrt{\varepsilon}$ accounts for the slower-than-light "velocity factor" of wave propagation in the cable.

[90] Which should really be called characteristic *resistance*.

DIGITAL MEETS ANALOG

CHAPTER 13

Here we meet the major subject of conversion between analog and digital signals – analog-to-digital (A/D) and digital-to-analog (D/A) converters (ADCs and DACs) – as well as the important "mixed-signal" phase-locked loop (PLL). And we cannot resist a look at the fascinating topic of pseudorandom noise generation.

We live in a largely analog (continuous) world – of sounds, images, distances, times, voltages and currents, and so on – which would seem to call for analog circuits (oscillators, amplifiers, filters, combiners, etc.). But we live also in a partly digital (discrete) world – of numbers and arithmetic, of text and symbols, and the like – which would seem to call for digital circuits (arithmetic logic and storage, etc.). And that's how it was, for many years: analog amplifiers and filters for audio and video; analog oscillators, tuned circuits, and mixers for radio and television; and even *analog computers*, for solving differential equations[1] or for real-time control of flight or weaponry. Meanwhile digital techniques (initially with mechanisms and relays, then with vacuum tubes, followed by discrete transistors, small-scale ICs, and finally the large and fast microprocessors with a billion+ transistors that we take for granted) were used for computational tasks like keeping track of money, and of words.

But the almost miraculous improvements in the speeds and densities of purely digital electronics have produced a major paradigm shift, namely, the use of digital conditioning and processing for nearly every "analog" quantity. For example, audio engineers now digitize the individual microphone signals at the time of recording, and perform all subsequent mixing and conditioning (e.g., the addition of reverberation) as arithmetic on those numbers; the same goes for digital video. And at the everyday level, digital techniques have invaded our lives: the authors' bathroom scales indicate to 0.1 pound (sometimes to our regret) – that's a resolution[2] of a part per thousand; our porch light is switched on and off by a digital wall switch that follows the seasonal variation of dusk and dawn; and our automobiles depend on a digital bus, to which are connected some 50 or more embedded digital controllers for functions like engine control and diagnostics, braking, air bags, entertainment, climate control, and so on.

The bottom line is that A/D and D/A conversion techniques have become central to every aspect of analog measurement and control. This is important stuff, and it is the major subject of this chapter. Let's go at it.

Our treatment of the various conversion techniques is not aimed at developing skill in converter design itself. Rather, we try to point out the advantages and disadvantages of each method, because in most cases the sensible thing is to buy commercially available chips or modules, rather than to build the converter from scratch. An understanding of conversion techniques and idiosyncrasies will guide you in choosing from among the thousands of available units.

13.1 Some preliminaries

13.1.1 The basic performance parameters

Before getting into lots of detail, we'd like to summarize the important performance parameters that you need to keep in mind when choosing ADCs and DACs. Knowing what you need makes it a lot easier to find what you want.

Digital-to-analog converters

Resolution: number of bits
Accuracy: monotonicity; linearity; dc stability
Reference: internal or external; multiplying DAC (MDAC)?
Output type: voltage output or current output
Output scaling: unipolarity or bipolarity; V_{out} ranges; I_{out} compliance
Speed: settling time; update rate

[1] There's a nice example of this in the section on Analog Function Circuits in Chapter *4x*: modeling the fascinating chaotic behavior of the system of nonlinear differential equations devised by Lorenz.

[2] To be distinguished from *accuracy* – recall the discussion in §5.1.1. Although the bathroom scale reads with a *resolution* of 0.1 pound, its accuracy is likely poorer (perhaps to ±1 pound), with some drift over time and temperature.

Quantity: single or multiple DACs/pkg
Digital input format: serial (I^2C, SPI, or a variant) or parallel
Package: module, through-hole, or various surface-mount packages
Other: glitch energy; power-on state; programmable internal digital scaling

Analog-to-digital converters
Resolution: number of bits
Accuracy: monotonicity; linearity; dc stability
Reference: internal or external
Input scaling: unipolarity or bipolarity; voltage range
Speed: conversion time and latency
Quantity: single or multiple ADCs/pkg
Digital-output format: serial (I^2C, SPI, or a variant) or parallel
Package: module, through-hole, or various surface-mount packages
Other: internal programmable gain amplifier (PGA); spur-free dynamic range (SFDR)

13.1.2 Codes

At this point you should review §10.1.3 on the various number codes used to represent signed numbers. Offset binary and 2s complement are commonly used in A/D conversion schemes, with sign-magnitude and Gray codes also popping up from time to time. Here is a reminder:

	Offset binary	*2s Complement*
+Full scale	11111111	01111111
+Full scale−1	11111110	01111110
↓	↓	↓
0+1 LSB	10000001	00000001
0	10000000	00000000
0−1 LSB	01111111	11111111
↓	↓	↓
−Full scale+1	00000001	10000001
−Full scale	00000000	10000000

13.1.3 Converter errors

The subject of ADC and DAC errors is a complicated one, about which whole volumes could be written. According to Bernie Gordon at Analogic, if you think a high-accuracy converter system lives up to its claimed specifications, you probably haven't looked closely enough. We won't go into the application scenarios necessary to support Bernie's claim, but it's worth a first look at the four most common types of converter errors: offset error, scale error, nonlinearity, and nonmonotonicity, nicely illustrated in the self-explanatory Figure 13.1. Rather than boring you with a long-winded discussion, though, we'll move directly to a description of D/A converter techniques and capabilities. Then we'll revisit the business of converter errors (§13.4), which will make a lot more sense in context.

13.1.4 Stand-alone versus integrated

Sometimes an ADC or DAC (or both) is integrated into a fancier IC. The most common example is the microcontroller (Chapter 15), where you frequently see both ADCs and DACs integrated on the same chip as the processor and its other I/O peripherals. As far as we can tell, the least-expensive stand-alone ADC costs significantly more than the least-expensive microcontroller-*with*-ADC.[3] Microcontrollers are fond of integrating lots of useful peripherals, along with program and data memory, so that you've got essentially a "system-on-a-chip." Be aware, though, that these converters that come bundled with inexpensive general-purpose microcontrollers do not attain the excellent performance of a good stand-alone converter: you can get 8-bit or even 10-bit performance; but you won't get 16 bits, and nothing approaching the 24-bit performance of a high-quality audio ADC.[4]

For some classes of IC, though, an integrated converter delivers excellent performance. One example is a direct digital synthesis (DDS) chip (§7.1.8), where on-chip phase counters and a sine lookup table create digital values of the synthesized sinewave output; these things can clock at speeds of 1 GHz or more, with an on-chip 14-bit (for example) DAC generating the analog output signal. Another example comes from the video world, where it's common to see digital video processing and conversion functions combined on a single high-performance IC. And in the audio business you see parts like the Cirrus CS470xx-series (their "All-In-One Audio IC" system-on-a-chip), which includes multiple 24-bit ADCs and DACs with 105 dB dynamic range, integrated onto a chip that has a 32-bit DSP (with 32 kB RAM), audio codecs and sample rate

[3] To wit: National's ADC0831 8-bit ADC costs $1.85, whereas Microchip's PIC10F with its 8-bit ADC and 2-input multiplexer costs $0.48 (both in quantity 25).

[4] A shining exception is provided by Analog Devices' series of "Analog Microcontrollers," with honest performance to 16 or 24 bits. You might think of these as consisting of a high-quality converter core, with a quiet microcontroller tacked on.

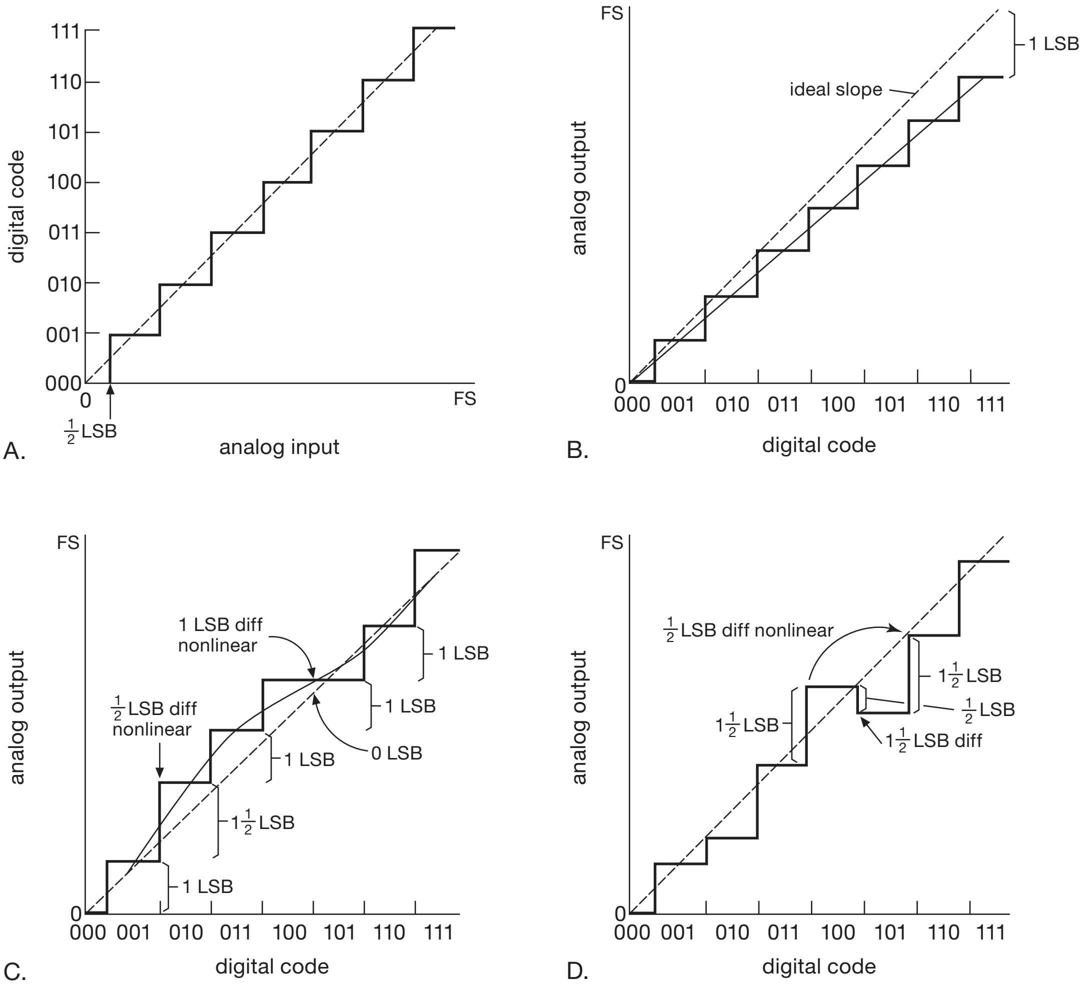

Figure 13.1. Graphs illustrating the definitions of four common digital conversion errors, for a 3-bit converter over its 8 levels from 0 to full scale (FS). A. ADC transfer curve, $\frac{1}{2}$LSB offset at zero. B. Linear, 1 LSB scale error. C. $\pm\frac{1}{2}$ LSB nonlinearity (implies 1 LSB possible error); 1 LSB differential nonlinearity (implies monotonicity). D. Nonmonotonic (must be $>\pm\frac{1}{2}$ LSB nonlinear). Used with permission of Texas Instruments Inc.

converters, digital audio ports (SPDIF), and an SPI/I^{2}C control port.

Stand-alone converters are dominant, though, in high-accuracy and high-linearity applications (voltmeters; quality audio gear). They also provide a tremendous selection range, in terms of the many parameters just listed, as compared with the rather limited selection of on-chip converters you find in microcontrollers.

13.2 Digital-to-analog converters

The goal is to convert a quantity specified as a binary (or multidigit BCD, see §10.1.3B) number to a voltage, or to a current, proportional to the value of the digital input. There are several popular methods: (a) resistor string with MOS switches; (b) R–$2R$ ladder; (c) binary-scaled current sources; and (d) delta–sigma (and other pulse-averaging) converters. Let's take them in turns.

13.2.1 Resistor-string DACs

This method is about as straightforward as you can get. A string of 2^n equal-value resistors is connected between a stable voltage reference and ground, creating a very tall voltage divider; and a set of MOSFET analog switches is used to route the selected tap's voltage to an output voltage buffer (Figure 13.2). The figure shows the configuration of TI's impressive DAC8564, a quad 16-bit DAC (four independent DACs in one package), each section having a string of 2^{16} (65,536) resistors connected between a precision internal +2.5 V reference and ground. Quoting from the terse description in the datasheet, "The code loaded into the DAC register determines at which node on the string the voltage is tapped off to be fed into the output amplifier by closing one of the switches connecting the string to the amplifier."[5]

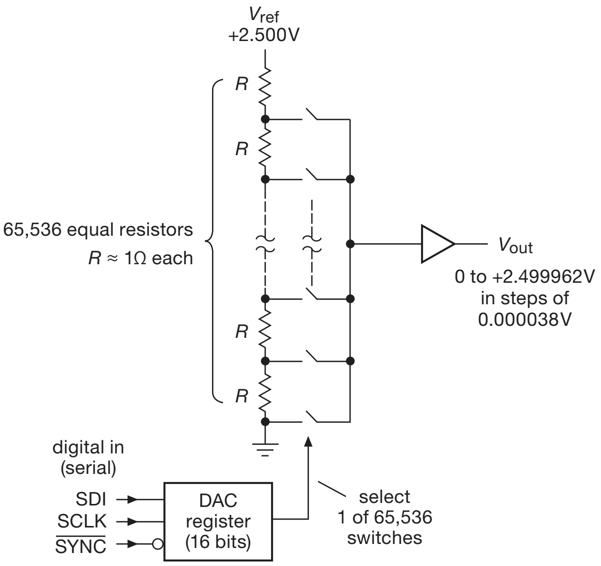

Figure 13.2. An easy-to-understand DAC: the digital input selects the corresponding MOSFET switch tap on a giant voltage divider. TI crams four of these into their DAC8564.

This method has the virtue of guaranteed monotonicity. As the datasheet puts it (even more tersely than before), "It is monotonic because it is a string of resistors." And this particular DAC exhibits other nice qualities, specifically low *glitch energy* (spikes that appear at the output during code transitions), excellent accuracy and stability (worst-case values of ±0.02% initial accuracy and 5 ppm/°C tempco), rail-to-rail output ("RRO") with a single positive supply (+2.7–5.5 V), and low power (1 mA, typ). This puppy costs about $12. The same method is used in DACs of more modest performance, for example National's DAC121: 12-bit, voltage output, micropower ($150\,\mu$A) single-supply with rail-to-rail input and output (RRIO). The latter is a single DAC without internal reference (full scale is the positive supply), and of course it has "only" 4096 resistors in its string; it costs under $2. Both of these (and most other converters these days) use a serial digital input, which for these particular converters is the simple 3-wire SPI (see §14.7). See also the discussion of digital potentiometers in §3.4.3E.

13.2.2 *R*–2*R* ladder DACs

A string of 2^{16} matched resistors and switches is a pretty impressive piece of engineering. But the exponential number of components eventually overwhelms engineering finesse. An attractive alternative is the *R*–2*R* ladder, which collapses the requirement to an array of just $2n$ matched resistors (versus 2^n) for an n-bit DAC.

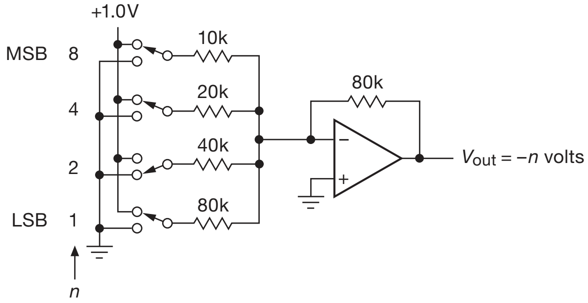

Figure 13.3. Summing scaled currents to create a simple DAC. Simple to understand, but never used in practice: an *R*–2*R* network is used instead.

To get started, consider the simple notional scheme shown in Figure 13.3: the resistor values are in a binary sequence, so their binary-weighted currents at the summing junction produce a binary-weighted voltage output. Simple, but not terribly practical with more than a few bits, because the resistor values must span a wide range, and with increasingly demanding accuracy for the lower resistance values; of greater worry still is the need for very low switch R_{on} corresponding to the low resistance values.[6]

Exercise 13.1. Design a 2-digit BCD DAC. Assume that the inputs are 0 or +1 volt; the output should go from 0 to 9.9 volts.

Instead, the scheme shown in Figure 13.4 is used. It's easy to convince yourself that this clever arrangement produces a binary-weighted current into the op-amp's summing junction, therefore a corresponding output voltage. And only two resistor values are needed (*R* and 2*R*, which, however, must both be accurately replicated and in a precise 2:1 ratio), regardless of the number of bits.

[5] These guys seem not to be fond of commas. We were tempted to add a few, to pace the breathless flow of the sentence. But, hey, a quote is a quote, right?

[6] This method does have the flexibility, however, of allowing arbitrary bit weights.

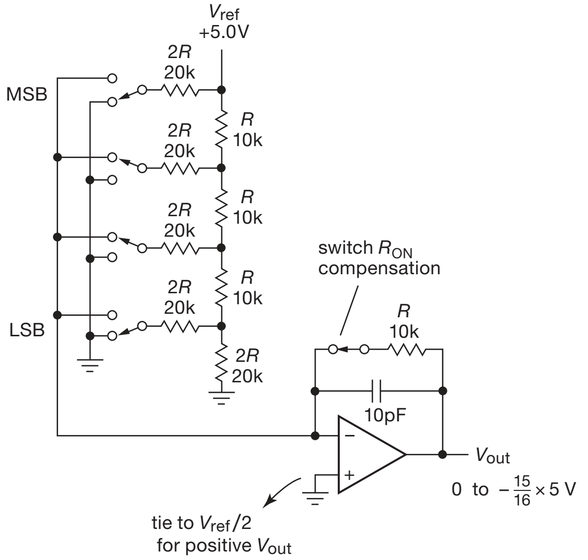

Figure 13.4. An R–$2R$ ladder network generates a binary-scaled output current into the op-amp's summing junction, producing a voltage-output DAC.

There are many excellent R–$2R$ DACs out there. For example, TI's DAC9881 is an 18-bit voltage-output DAC with an SPI serial input; it is guaranteed monotonic,[7] with integral linearity to ±2 LSB. It requires an external voltage reference (V_{ref}), which sets the full-scale voltage (the non-inverting input is biased at $V_{ref}/2$, for positive output polarity). It excels in accuracy and low noise, and costs about $30.

Exercise 13.2. Prove that the foregoing R-$2R$ ladder works as advertised.

In practice, most R–$2R$ DACs use the alternative configuration of Figure 13.5, in which the output of the R–$2R$ network is itself a voltage. For example, the TI DAC7611 is a 12-bit voltage-output DAC (+4.095 V full-scale output, popular for DACs that run from +5 V) with an SPI serial input and on-chip voltage reference; it's linear and monotonic to its full 12 bits, comes in an 8-pin package, and costs about $4.

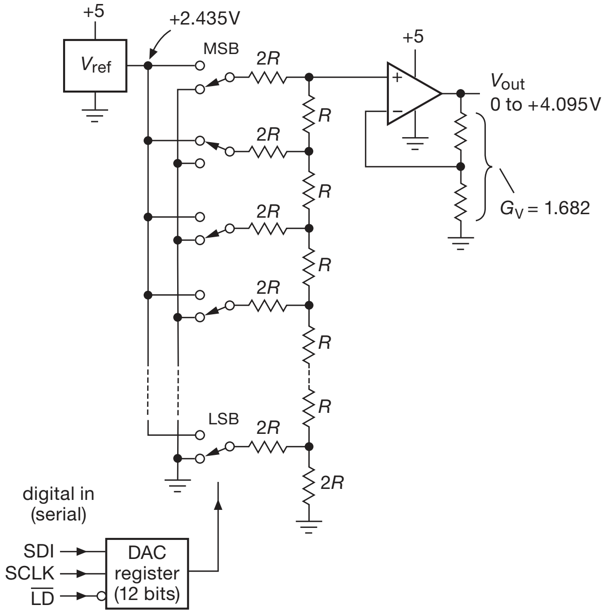

Figure 13.5. R–$2R$ voltage-output DAC, in the more common voltage-combining configuration.

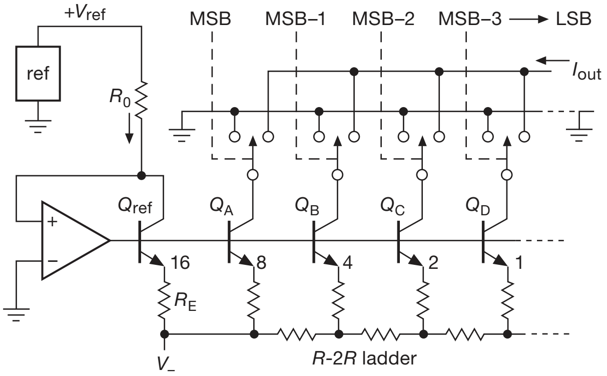

Figure 13.6. Classic current-switched DAC.

13.2.3 Current-steering DACs

The preceding converters generate *voltage* outputs. This is often most convenient, but the op-amp tends to be the slowest part of the converter circuit. In situations where you can use a converter with *current* output, you'll get better speeds, and usually at lower price. Some additional advantages of current-output DACs are: (a) flexible choice of current-to-voltage op-amp, for example to minimize noise, or to produce a larger output voltage swing; (b) the ability to combine several DAC outputs directly; and (c) the availability of *multiplying DACs* (see next subsection), in which

[7] Note that, unlike a resistor-string DAC, an R–$2R$ DAC is not *guaranteed* monotonic when resistor tolerances are taken into account. The semiconductor industry does a good job, however, and most R–$2R$ DACs are monotonic to 1 LSB.

the output current is the product of the digital input code and an analog signal applied to the V_{ref} input.

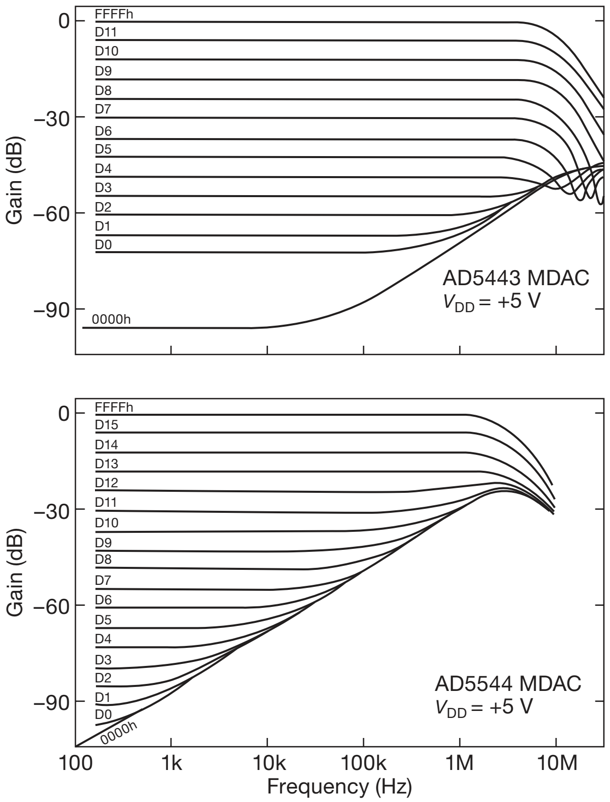

Figure 13.7. An MDAC's analog "reference multiplying bandwidth" listed in the datasheet is usually specified for the maximum digital input code only; for these Analog Devices MDACs those values are 2 MHz and 10 MHz. These graphs, found later in the datasheets, tell the whole story. Although the AD5544 and AD5443 are similar designs with similar part numbers, the latter has considerably better capability in the 0 dB to −40 dB region out to 10 MHz.

Figure 13.6 shows how these "current-steering" converters work. The currents can be generated by an array of transistor current sources with scaled emitter resistors, although IC designers usually use instead an *R*–2*R* ladder of emitter resistors. In most converters of this type, the current sources are ON all the time, and their output current is switched to the output terminal or to ground, under control of the digital input code. Watch out for limited output compliance in current-output DACs; it can be as little as 0.5 V, though values of a few volts are typical.

Some examples of current-steering DACs (with serial digital inputs and internal voltage references) are the LTC1668 (16 bits, 20 ns settling time into a 50 Ω load as "voltage out," output compliance to ±1 V, about $20) and the TI DAC5682 (dual, 16 bits, 10 ns settling time, output compliance to $V_+ \pm 0.5$ V, about $45). For *real* speed, there's the AD9739 (14 bits, 2500 Msps!). On a more modest scale there's the industry-standard DAC/LTC8043 (external voltage reference input, 12 bits, 0.25 μs settling time into 100 Ω, about $6), and the similar parallel-input AD/LTC7541.

13.2.4 Multiplying DACs

Note that these latter two converters require an external voltage reference, an apparent disadvantage that can be turned into an advantage: they accept a continuous range of V_{ref} input voltages, *of either polarity*. In other words, the (current) output is proportional to the product of the digital input and the analog reference voltage: it's a "multiplying DAC" (MDAC). Furthermore, the product can be positive or negative; so its full name is a "four-quadrant multiplying DAC." Examples of higher-resolution four-quadrant MDACs are the 16-bit DAC8814 (serial input) and closely similar DAC8820 (parallel input). Multiplying DACs specify both their conversion precision (linearity, monotonicity) and the bandwidth of the analog multiplying input (i.e., V_{ref}); for these two converters the "reference multiplying bandwidths" are 10 MHz and 8 MHz, respectively, with respective prices of $25 and $15.

Note that not all DACs are optimized for use in this way, so it is best to check the datasheets of the converters you're considering for details. A DAC with good multiplying properties (wide analog input range, high speed, etc.) will usually be called a "multiplying DAC" right at the top of the datasheet. Table 13.3 on page 894 lists selected Multiplying DACs.

A caution: the specified bandwidth can be seriously misleading, owing to the effects of capacitive feedthrough. Figure 13.7 shows this behavior, as illustrated in the respective datasheets of these two MDACs.

Multiplying DACs (and the ADC equivalent) open the possibility of *ratiometric* measurements and conversions. If a sensor of some sort (e.g., a variable-resistance transducer like a thermistor) is energized by the same voltage that also supplies the reference for the ADC, then variations in the reference voltage will not affect the measurement. This concept is very powerful, because it permits measurement and control with accuracy greater than the stability of voltage references or power supplies; conversely, it relaxes the requirements on supply stability and accuracy. The ratiometric principle is used in its simplest form in the classic *bridge* circuit, in which two ratios are adjusted to equality by nulling the differential signal taken

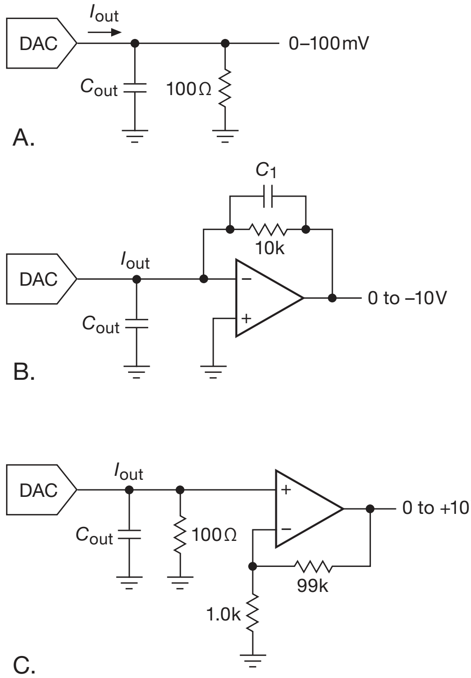

Figure 13.8. Generating voltages from current-output DACs.

between the two voltage-divider outputs. Devices like the 555 (see §7.1.3) achieve good stability of output frequency with large variations of supply voltage by using essentially a ratiometric scheme: the capacitor voltage, generated by an *RC* network from the supply, is compared with a fixed fraction of the supply voltage ($\frac{1}{3}V_{CC}$ and $\frac{2}{3}V_{CC}$), giving an output frequency that depends only on the *RC* time constant.[8] We will have more to say on this important subject in connection with ADCs later in this chapter.

13.2.5 Generating a voltage output

If you've chosen a voltage-output DAC, you're done! But with a current-output DAC you've got to use one of several schemes for generating a voltage output. Figure 13.8 shows some ideas. If the load capacitance is low and large voltage swings aren't needed, a simple resistor to ground will do nicely (but see warning, below). This is what's usually done with video DACs. For example, the THS8133 triple 10-bit video DAC generates full-scale output currents of 26.7 mA, which produce a standard 1.0 V analog video signal when driving doubly terminated 75 Ω coax. This method works fine also for general applications: with the usual 1 mA full-scale output current, a 50 Ω load resistor will give 50 mV full-scale output with 50 Ω output impedance. If the capacitance of the DAC's output combined with the load capacitance doesn't exceed 100 pF, you will get 50 ns settling time in the preceding example, assuming the DAC is that fast. When worrying about the effect of *RC* time constants on DAC output response, don't forget that it takes quite a few *RC* time constants for the output to settle to within $\frac{1}{2}$ LSB of the final voltage. It takes 7.6 *RC* time constants, for instance, to settle to within 1 part in 2048, which is what you would want for a 10-bit converter output.

To generate large swings, or to buffer into small load resistances or large load capacitances, an op-amp can be used in the transresistance configuration (current-to-voltage amplifier), as shown. The capacitor across the feedback resistor may be necessary for stability, because the DAC's output capacitance in combination with the feedback resistance introduces a lagging phase shift; unfortunately, that compromises the speed of the amplifier. It is an irony of this circuit that a relatively expensive high-speed (fast-settling) op-amp may be necessary to maintain the high speed of even an inexpensive DAC.[9] In practice, the last circuit may give better high-speed performance, since no compensation capacitor is needed. Watch out for offset voltage error, because the op-amp's input offset voltage is amplified by the voltage gain (here a factor of 100).

An Important Warning: when using current-output DACs, note that both the initial accuracy (e.g., full-scale I_{out}) and the stability of the current output may be grotesquely poor, relative to the DACs resolution. It is not uncommon to see a spread of as much as 2:1 (!) in the full-scale current. What to do? Most current-output DACs include a built-in feedback resistor, closely matched to the *R*–2*R* resistors, intended to be used with an external op-amp (Figure 13.9). If you don't use it, you may have gain errors of ±25% or more; and even if you trim away this gain error, there will be residual gain *drift* (not usually specified on datasheets) that typically will be 100 times larger than you get with the internal resistor.

To give an example, the LTC8043 is an improved version of the industry-standard DAC8043 12-bit multiplying

[8] We showed analogous ratiometric schemes in §§4.3.5, 4.6.4, 7.1.3D, and 10.4.5A.

[9] Some current-output DACs have surprisingly-high output capacitance, C_{out}, e.g., as much as 200 pF for the LTC7541 12-bit MDAC. So you need a stabilizing capacitor C_1, of value $C_1 > \sqrt{C_{out}/2\pi f_T R_f}$, as discussed before, see for example §§8.11.6 and *4x.3*. Choose an op-amp, then, with a high enough f_T so that C_1 is small enough for the desired speed. Some fast current-output DACs take pains to keep C_{out} small, as little as 5 pF.

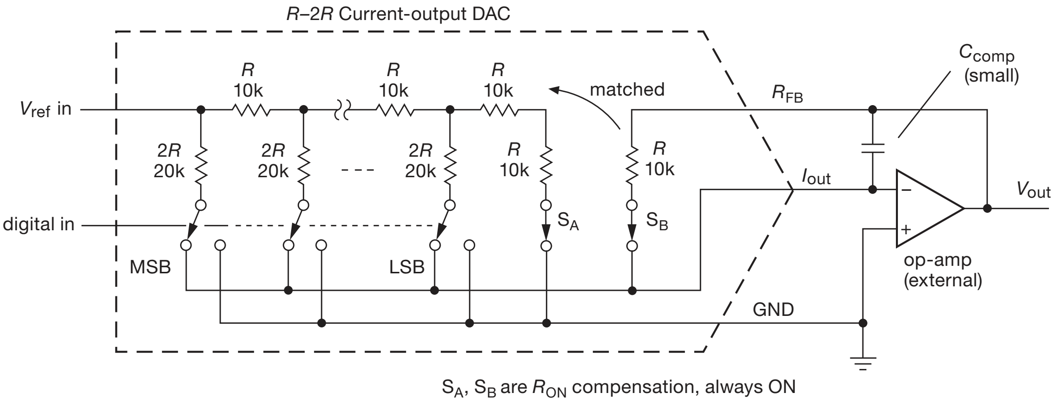

Figure 13.9. Current-output R–$2R$ DAC with internal feedback resistor matched to the precision network resistors both in initial resistance and in temperature coefficient. Ignore R_{FB} at your peril!

DAC. In the best grade (-E suffix) it specifies a gain error of ±1% (max), and a gain tempco of 5 ppm/°C (max). (It also guarantees maximum integral and differential nonlinearities of ±0.5%; see the discussion in §13.4.) Impressive specs. Note, however, that the gain specifications state "Using internal feedback resistor." What if you don't? The datasheet doesn't say! But you can tease the answer from what it *does* say, namely that the input resistance of the R–$2R$ network (seen at the V_{ref} input) is 11 kΩ (nominal), with limits of 7 kΩ (min) and 15 kΩ (max). That is, this DAC, which guarantees an admirable gain accuracy of ±0.024% when the matched internal feedback resistor is used in conjunction with an external op-amp, would deliver a shockingly poor[10] ±35% absolute gain error as a current-output device (or, equivalently, with an external feedback resistor and op-amp, for voltage output).[11]

Bottom line: if a current-output DAC gives you an internal feedback resistor, you need to think long and hard before deciding not to use it.

Another bottom line: if you want a bipolarity output-voltage range, you might be tempted to sink a reference current (derived from V_{ref}) from the summing junction in Figure 13.9. *Don't do it!* Instead, append a difference amplifier to V_{out}, using an offset of $V_{\text{ref}}/2$ for the other input.

13.2.6 Six DACs

To give a further sense of what's out there, let's look at a few examples of relatively simple DACs of modest performance. By "modest" we mean that these converters do not push close to the limits of speed or accuracy; rather, they're inexpensive, compact, and easy to use. You can drop them onto a circuit board, and off you go. Later, in §13.3, we'll look at some applications that demand DACs of greater performance; in those situations you'll need carefully designed surrounding circuitry to exploit fully the advanced capabilities of the converter.

Take a look at Figure 13.10, with reference to Table 13.1. These were chosen somewhat arbitrarily from the many thousands (no kidding!) of available DACs, though we did make an effort to select devices from multiple manufacturers. They range from 8 to 14 bits, with settling times of 4–10 μs. Except for E, they are all voltage-output devices.

Taking it from the top of Figure 13.10: A–C are single-supply low-voltage parts with serial interfaces, so they can fit into tiny SOT23 or (even tinier) SC70 packages. The pair in A use the supply voltage as reference, with the full-scale output voltage V_{FS} equal to the supply V_{DD}; one uses an SPI interface (with the usual chip select), whereas the other uses an I^{2}C interface (with the input pin A_0 selecting between factory preset bus addresses of decimal 76 or 77).[12] If you want a fixed and stable reference voltage, rather than using V_{DD}, a converter like the LTC2630 in B is a good choice. Its internal reference has adequate

[10] I'm shocked, shocked to find that gain inaccuracy and drift is going on in here!

[11] You might ask why an IC manufacturer whose chips deliver outstanding accuracy has a problem making resistors with even "pretty good" absolute accuracy. Good question. Turns out that the process is optimized for best *tracking*, with overall resistor scaling only of secondary importance.

[12] The DAC7512 from the same manufacturer substitutes SPI for I^{2}C; and the AD5601/11/21 are less-expensive 8- to 12-bit versions of the 14-bit AD5641.

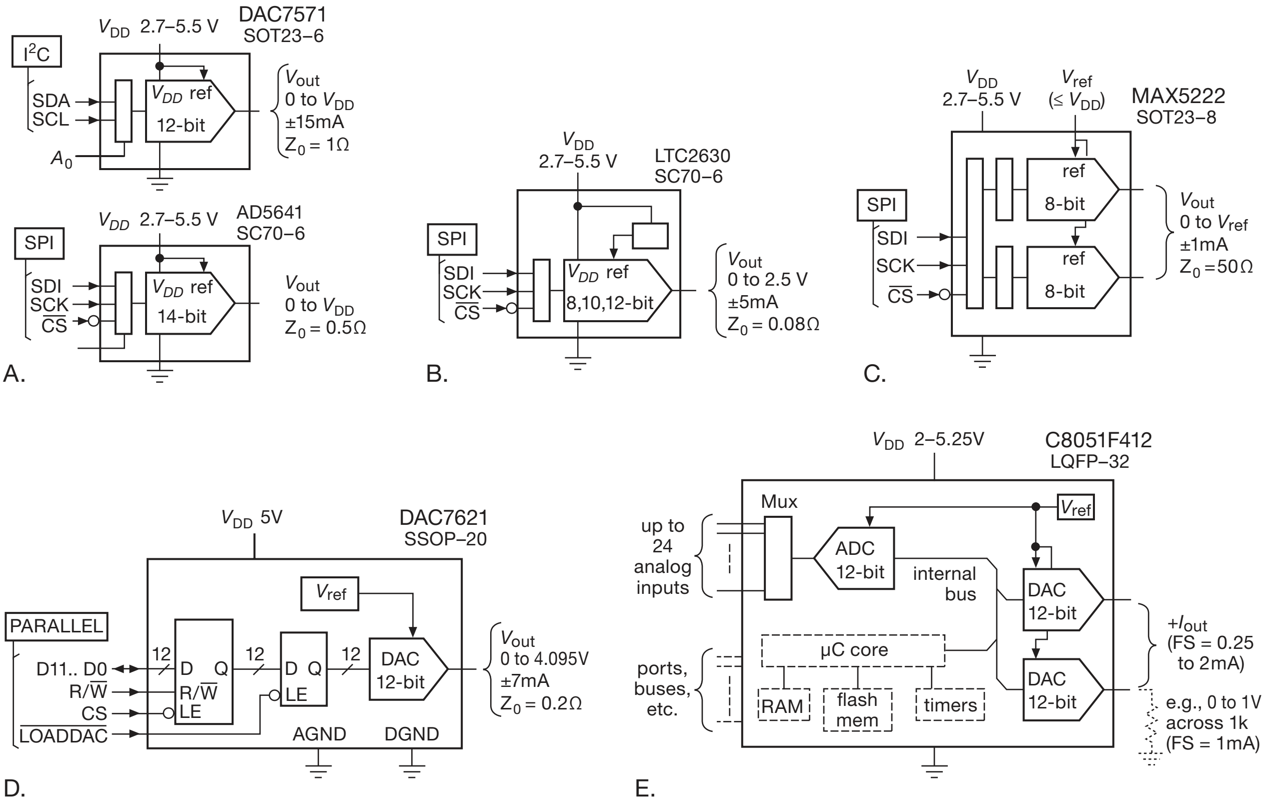

Figure 13.10. Six DACs, whose specifications are listed in Table 13.1. The DAC7571, LTC2630, and MAX5222 in the upper row are typical of inexpensive serial-input converters in small packages (see §14.7 for discussion of the SPI and I^{2}C serial interfaces). The DAC7621 uses a traditional parallel data input; and the C8051 is a general-purpose microcontroller that includes a pair of current-output DACs among its many internal assets.

stability for a converter of this precision (±10 ppm/°C, typ), though its absolute accuracy is only modest (full-scale error of ±0.2% typ, ±0.8% worst case). The LTC2630 family includes a "high-voltage" variant with a 4.096 V internal reference (thus 1.0 mV/LSB), for which the V_{DD} range is narrowed to 4.5–5.5 V (5 V nominal); it also includes 8- and 10-bit variants.

Although you *could* imagine squeezing two converters into a 6-pin package (e.g., with an I^{2}C 2-wire interface and no choice of address), the converter in C takes the rational choice of adding two pins, which both accommodates the SPI port (three wires, including CS′) and allows an external reference.[13] By reducing the lead pitch (from 0.95 mm to 0.65 mm) this 8-pin device fits in the same overall package size (1.6×2.9 mm) as the 6-pin SOT23-6.

The bottom row illustrates a converter with a parallel input port, an interface that has largely gone out of popularity except for converters that operate at the highest speeds (e.g., the 2500 Msps AD9739 in §13.2.3). But there are applications for which this is useful, even at modest speeds, for example if you want to use the *n*-bit output of a counter directly: no microcontroller, no programming... just wires.

Finally, the last "converter" E is actually just some carry-on baggage belonging to a full-function microcontroller, complete with on-chip program memory (flash ROM), SRAM, timers, ports (parallel, SPI, UART), accurate oscillator, and even a 24-channel (multiplexed) 12-bit 200 ksps ADC. The dual DACs use an internal reference, and produce a current-sourcing output (with programmable full-scale ranges of 0.25–2 mA, by factors of 2) with compliance to 1.2 V below the supply rail (which runs over a wide range of 2.0–5.25 V). Oh, and did we mention that this thing includes a computational core that runs at

[13] One small fly in the ointment here is the lack of double buffering along with an 8-bit data payload; thus the two channels cannot be updated to different values simultaneously.

50 million instructions per second? Or that it includes on-chip full-speed in-system debugging? Or that you can get it also in a diminutive 5 mm square QFN-28 package? Quite a performance!

13.2.7 Delta–sigma DACs

The final DAC technique is somewhat weird, and not so easily understood in all its richness. (See Table 13.11 on page 939.) We'll describe it in detail later in the chapter (§13.9). Very roughly speaking, the technique consists of generating a train of fixed-amplitude pulses, at a high clock rate, on a single output line. These pulses are all of the same width, and are either present or absent at each clocking interval, according to the digital input code. (You could imagine simply generating a regular train of pulses, with a duty cycle proportional to the input code; but the delta–sigma process is considerably more sophisticated, as explained in §13.9.) This pulse train is then lowpass filtered, with a cutoff well below the clock frequency, to generate the analog output.

This is sometimes called a "1-bit DAC." That's a seriously misleading name, though, because these things in fact deliver stunningly linear output signals of high resolution. They are widely used in professional audio. A nice example is the ADI AD1955 dual (stereo) ADC, which delivers 20-bit analog audio output (120 dB dynamic range) when clocked at 12 MHz.[14]

13.2.8 PWM as digital-to-analog converter

One last method of driving an analog system from a digital quantity is via *pulse-width modulation* (PWM). This is qualitatively different from the true DACs just described, because it does not generate an analog output directly; but it is widely used for power loads such as a heater. The idea is to run a repeating cycle of N clock cycles, during which the load is switched ON for some smaller number of clock cycles k, and OFF for the rest, with the fraction (duty cycle) k/N proportional to the digital input (Figure 13.11). This is easily done with a counter, magnitude comparator, and high-frequency clock (see Exercise 13.3). The slowly responding load does the averaging over the full cycle. This is more efficient than driving the load with a properly smoothed analog signal, because the driver is a switch, with very little dissipation; a switch is also simpler than a linear amplifier. This technique is popular in "class-D" audio power amplifiers (§2.4.1C) and in other power-control applications such as stepping motors and dc servomotors (§9.9). Many microcontrollers are configured with internal PWM timer modes; even lacking that, you can always program it in software.

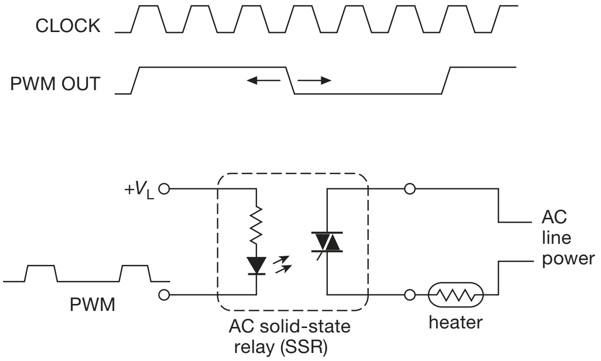

Figure 13.11. Pulse-width modulator (PWM) as time-averaged DAC, for slow power loads. For an ac-powered load (as shown) the clock should be synchronous with the powerline.

Although a simple lowpass filter could be used to generate an output voltage proportional to the average time spent in the HIGH state (i.e., proportional to the digital input code), pulse-width modulators are most often used when the load is itself a slowly responding system. The pulse-width modulator then generates precise parcels of energy, averaged by the system connected as a load. For example, the load might be capacitive (as in a switching regulator, see Chapter 9), thermal (a thermostated bath with heater), mechanical (a tape-speed servo, variable-speed motor, or stepping motor), or electromagnetic (a large electromagnet controller).

PWM outputs are attractive both for their simplicity and for their natural match to digital devices like counters and power-driving switches (MOSFETs); but there are some serious tradeoffs. For example, to get high PWM resolution for the k/N fraction, we need a large N. But the timer has a maximum clock rate f_{clk}, which sets a lower cycle rate $f_c = f_{\text{clk}}/N$. For a PWM that is within a feedback loop (as in the PWM discussion in §15.6) this implies reduced loop bandwidth and gain.

In practice you'll most likely encounter digital PWM hardware in a microcontroller. Sometimes you can choose a specific μC on account of its PWM capabilities, but more often not. For example, further along in §13.9.11B we choose TI's MSP430F2101 because it has an analog comparator. So, what kind of PWM does one get in the MSP430x2xx family? This information is not in the

[14] It does cheat, however, by generating several parallel 1-bit streams internally; it's a "multibit" delta–sigma ADC. More on this, and other delta–sigma amusements, in §13.9.

Table 13.1 Six Digital-to-Analog Converters

	Bits	Channels	Output	t_{settle} (μs)	Total V		I_S (μA)	bus/Mbps	Reference		Output		pkg	pins	Cost qty 1 $US
					min (V)	max (V)			type	error[m]	Z_{out} (Ω)	I_{out} (mA)			
DAC7571	12	1	V	10	2.7	5.5	140	I^2C / 4.8	V_{DD}	0.2%	1	±15	SOT23	6	4.65

Notes: (a) 10 bit and 8 bits avail, $2.63. (b) 5V logic OK. (c) choice of V_{DD} or V_{ref}, 2.5V or 4.096V avail. (d) double buffered. (e) software select 0.25mA to 2mA, by factors of 2. (f) compliance to V_{CC}–1.2V. (m) max.

52- or 88-page datasheets; we had to consult the 693-page "MSP430x2xx Family Users Guide," where 40 pages were devoted to Timers A and B.

Figure 13.12 shows the MSP430F2002 member of this microcontroller family (which has a 10-bit ADC instead of a comparator) driving a dc torque motor. We've arranged four MOSFETs with an H-bridge driver and the controller's PWM signal to set the current. Naively, you'd expect that a 50% duty cycle would correspond to zero motor current; but that's true only when the motor is stopped, because the motor's "back EMF" disturbs this simple concept. Here we've used two sense resistors to measure the forward or reverse currents, with a pair of G=80 instrumentation amplifiers (§5.15) to inform the μC's ADC so it can servo the PWM to set the desired motor current and torque.[15] The amplifiers can operate from a single supply if their output reference pin is at least +0.8 V (see Table 5.8 on page 363); here we used a 1.25 V zener-type IC reference.

The microcontroller has a pair of 16-bit timers with programmable input selectors and dividers. They can run as fast as 16 MHz, which results in a cycle frequency of f_c=244 Hz if we use the full 16-bit resolution. You can program the length N to less than 2^{16}, but remember that the timer's other users have to live with your choice. Timer A has two capture/compare registers (CCR1 and CCR2), which can be used in compare mode to generate two PWM outputs (CCR0 is already used to set N). For example, let's say we need a speedier cycle rate of f_c=10 kHz, and we stick with the maximum 16 MHz clock. We set the counter's modulus N=f_{clk}/f_c=1600 counts, and our PWM resolution will be limited to... about 10 bits. My goodness, only 10 bits?[16]

This example illustrates that a favorable alternative to PWM may involve attaching a few external DACs to a microcontroller. Another possibility is to drive the MOSFET switch with the internal bitstream (if provided on an external pin) of a delta–sigma DAC, with its improved resolution–bandwidth tradeoff (compared with $f_c = f_{clk}/N$ for the simple PWM).[17]

Exercise 13.3. Design a circuit to generate a 10 kHz train of pulses of width proportional to an 8-bit binary input code. Use counters and magnitude comparators (suitably expanded).

A. An unusual PWM DAC

We close the PWM discussion by mentioning an unusual DAC from Linear Technology. Their LTC2644 (dual) and 2645 (quad) are PWM-to-DAC converters (a DAC with a digital PWM input). Each channel measures the duty cycle (fraction of time HIGH) during each incoming PWM cycle, and immediately presents *and holds* the corresponding correct output voltage. These particular devices are available in 8-, 10-, or 12-bit resolution versions, with internal 10 ppm/°C voltage reference and monotonic rail-to-rail voltage output. They are a great improvement over the classic technique of lowpass filtering a PWM input. The possibilities are mind-boggling!

[15] You could instead use a differential amplifier between the two sense resistors, with a single ADC channel digitizing the resulting bipolarity signal.

[16] In motor-drive applications it's often desirable to keep the drive frequency above audibility, so you don't drive people nuts. In this example we'd have to use a modulus N=800 or less, throwing out another bit of control resolution.

[17] There are families of ICs, intended for speaker-driving audio power output stages, that accept a digital input stream in a standard audio format (such as I^2S), and create as output a $\Delta\Sigma$-like switching waveform to drive a MOSFET H-bridge. Some of these include the MOSFETs on-chip – a single-chip PCM-to-speaker solution.

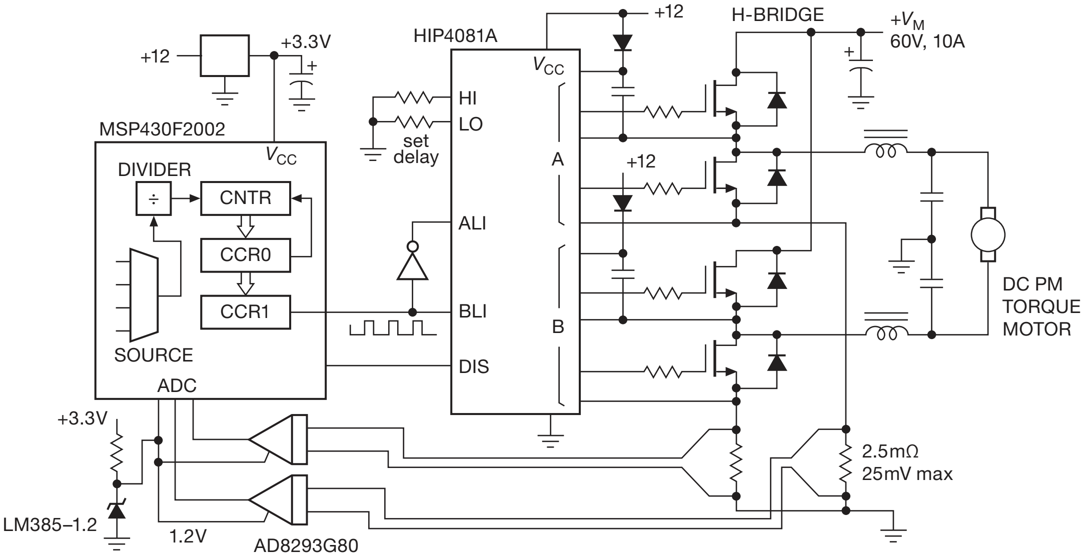

Figure 13.12. Controlling a torque motor with pulse-width modulation.

13.2.9 Frequency-to-voltage converters

In conversion applications the "digital" input may be a train of pulses or other waveform of some frequency; in that case, direct conversion to a voltage is sometimes more convenient than the alternative of counting for predetermined time, and then converting the binary count as in the preceding methods. In direct F/V conversion, a standard pulse is generated for each input cycle; it may be a voltage pulse or a pulse of current (i.e., a fixed amount of charge).

An *RC* lowpass filter or integrator then averages the pulse train, giving an output voltage proportional to the average input frequency. Of course, some output ripple results, and the lowpass filter necessary to keep this ripple less than the D/A precision (e.g., $\frac{1}{2}$LSB) will, in general, cause a slow output response. To ensure less than $\frac{1}{2}$LSB output ripple, the time constant τ of a simple *RC* lowpass filter must be at least $\tau \geq 0.69(n+1)T_0$, where T_0 is the output period of the *n*-bit F/V converter corresponding to maximum input frequency. The output of this *RC* network will settle to $\frac{1}{2}$LSB, following a full scale change at the input, in $0.69\,(n+1)$ filter time constants. In other words, the output settling time to $\frac{1}{2}$LSB will be approximately $t = 0.5\,(n+1)^2\,T_0$. A 10-bit F/V converter with 100 kHz maximum input frequency, smoothed with an *RC* filter, will have an output-voltage settling time of 0.6 ms. With more complicated lowpass filters (sharp cutoff) you can get improved performance. Before you get carried away with fancy filter design, however, you should remember that F/V techniques are most often used when a voltage output is not what's needed. For some perspective, see the previous discussion about intrinsically slow loads in connection with pulse-width modulation (§13.2.8).

13.2.10 Rate multiplier

This is a somewhat rarified method, of occasional (*very* occasional!) utility. A "rate multiplier" is a bit of clocked synchronous logic that accepts a multibit digital input quantity (binary or BCD), and that passes (or blocks) clock pulses to its single output line with an *average* rate proportional to that digital quantity. You can get these as standard logic (CD4089, CD4527, or SN7497), or you can make your own. Then simple averaging, as in the preceding F/V converter, can be used to generate a dc output proportional to the digital input code, although in this case the resulting output time constant may be intolerably long, because the rate-multiplier output will have to be averaged for a time equal to the longest output period it can generate (i.e., $2^n/f_{\text{clk}}$ for a rate multiplier with an *n*-bit rate-setting input). As with PWM, rate multipliers are most useful when the output is intrinsically averaged by the slowly responding characteristics of the load itself.

An application for which this is suited is in digital temperature control, where complete cycles of ac power are switched across the heater for each rate-multiplier output pulse. In this application the rate multiplier is arranged so that its lowest output frequency is an integral submultiple of 120 Hz, and a solid-state relay (or triac) is used to switch the ac power (at zero crossings of its waveform) from logic signals.

Note that the last four conversion techniques involve some time averaging, whereas the resistor-ladder and current-source methods are "instantaneous," a distinction that also exists in the various methods of analog-to-digital conversion. Whether a converter averages the input signal or converts an instantaneous sample of it can make an important difference, as we will see shortly in some examples.

13.2.11 Choosing a DAC

To guide you in choosing a DAC for a particular application, we've assembled in Tables 13.2 and 13.3 a representative selection of DACs of various precisions and speeds. This listing is by no means exhaustive, but it does include many of the more popular converters and some more recent entries that were intended as improved replacements.

When looking for a DAC for some application, here are some issues to keep in mind:

1. resolution;
2. speed (settling time, update rate);
3. accuracy (linearity, monotonicity; external trimming required?);
4. input structure (parallel or serial? latched? CMOS/TTL/ECL-compatible?);
5. reference (internal, or externally supplied? if external, MDAC?);
6. output structure (current output? compliance? voltage output? range?);
7. required supply voltages and power dissipation;
8. single or multiple DACs per package;
9. package style;
10. price.

13.3 Some DAC application examples

It's always helpful to get a guided tour of a real-world application example, to get a sense of the details wherein the devil resides. It's remarkably easy to put together a circuit that delivers nowhere near the performance that its converter is capable of. The four examples in this section illustrate some of the things you've got to worry about when using a DAC.

13.3.1 General-purpose laboratory source

In our research laboratories it's common to control experimental parameters with low-noise analog voltages, which need to be highly stable over temperature and time. For example, electromagnetic traps for ions and molecules require precise voltages applied to pairs of electrostatic plates and precise currents through coils. Given the diversity of applications, the output range should be selectable in both polarity and span.

Figure 13.13 shows the business end of a popular product (the "BabyDAC"[18]) from our university's Electronic Instrument Design Laboratory. The core is the AD5544, a quad 16-channel current-output multiplying DAC that accepts an external reference voltage and outputs a set of four currents into an external node held at ground. You generate a voltage output with an external op-amp, using the matched internal feedback resistor. The internal structure for each channel is an R–$2R$ ladder driven by V_{ref}, and a set of switches that connect each $2R$ leg either to the I_{o} output or to ground. The external reference voltage can be of either polarity, in the range ± 10 V. In fact, it can be a *signal* whose instantaneous voltage is multiplied by the digital input code to produce an output signal (hence a "multiplying DAC"); in such an application it has a signal bandwidth to audio frequencies and beyond.[19]

For this application the designer used a static V_{ref}, derived from the low-noise ADR440-series of voltage references (§9.10.3) based on a JFET analog of the standard BJT bandgap reference. The outboard circuitry is rigged up to provide jumper-selectable output-voltage ranges, both unipolarity and bipolarity; so J_1 selects a reference voltage of +5 V or +10 V. Jumper J_3 selects a gain of -2 for the output amplifier, doubling the span of U_{1a}'s output; and jumper J_2 offsets the output by the selected value of V_{ref}. With these three jumpers you can select any of the six V_{out} ranges listed in the figure.

That's the basic circuit. With ideal components the output would be precise, noiseless, and drift-free. We live in a real world, though, in which we have to choose among available components to provide the best balance of necessary compromises. For the kind of laboratory applications we have in mind, stability and low noise are paramount. In the noise department the voltage reference is usually the biggest troublemaker, thus the choice of the

[18] One of hundreds of elegant circuits and instruments from the ever-prolific Jim Macarthur, EIDL's design guru.

[19] Caution, here: the datasheet lists a "reference multiplying bandwidth" of 2 MHz, but that's measured at full-scale digital code. The bandwidth is more like 20 kHz if you want 0 to -50 dB digital control. See §13.2.4.

C_C: 10nF (~1kHz); R_1, R_2: precision 10.0k arrays, e.g. Vishay type PRA100I4

Figure 13.13. General-purpose programmable laboratory source, designed with the four-channel DAC5544 for low noise and good stability. Use an isolator for the SPI digital link signals to minimize coupled digital noise.

"ultra-low-noise" ADR445, among the quietest with its ~2 μVpp typical low-frequency (0.1–10 Hz) noise. Its drift spec is also quite good (1 ppm/°C typ, 3 ppm/°C max).[20] Reference noise can be reduced by *RC* filtering (see Figure 13.19 on page 898 for an example), or, if you're desperate, by paralleling the outputs of several references (with small ballasting resistors to ensure current sharing). The op-amps are quiet by comparison: 0.1 μVpp (max) low-frequency noise; similarly, the noise contributed by the DAC is negligible.

In this circuit the op-amp gains are rolled off around 1 kHz to minimize high-frequency noise at the output (originating in the reference, and in the DAC's code-change glitches). This bandwidth was chosen somewhat arbitrarily, on the assumption that the outputs are not going to be changing rapidly. The output bandwidth could be extended by a decade if the DAC were being programmed near its maximum rate. Or, for an application that is basically quasi-static, you could limit the bandwidth still further.

For the output *stability* it's common to look for specifications of drift with temperature and with time. The typical voltage tempcos here are 1 ppm/°C for the reference and for the DAC (thus the gain: the corresponding full-scale tempco is 5 μV/°C or 10 μV/°C), and 0.3 μV/°C for the op-amps (which scales according to the gain jumper, either ×1 or ×2). With BJT-input op-amps you have to worry about input bias current and its tempco. For these op-amps the bias current is 3 nA (typ), with no tabulated tempco; however, there's an unsatisfying graph of I_B versus temperature that suggests a tempco in the range of 5 pA/°C. With the circuit's 5k (or less) impedance seen at the op-amp inputs, this amounts to a 25 nV/°C drift, entirely negligible in comparison with everything else that's going on.

Manufacturers tend to be shy about specifying drift over *time*. For the components here there's no long-term drift spec for the DAC or op-amps. The ADR445 voltage reference specifies 50 ppm typical drift over 1000 hours, but with an interesting footnote that reads "The long-term stability specification is noncumulative. The drift in the subsequent 1000-hour period is significantly lower than in the first 1000-hour period."[21]

[20] You'd get lower drift with the best-in-class MAX6350, at 1 ppm/°C max, but with somewhat greater noise: 3 μVpp.

[21] Curiously, some manufacturers prefer to specify the long-term drift per *square root* of time, suggestive either of a decreasing drift as the part ages, or perhaps a random walk. An example is the astonishing LTZ1000 ovenized zener, with a specified long-term drift of $2\,\mu\mathrm{V}/\sqrt{\mathrm{kHr}}$ (typ), and a claimed typical tempco of 0.05 ppm/°C.

As we remarked at the outset, for the intended application it is noise and drift that are most important. By contrast, the absolute accuracy is not particularly impressive: the worst-case specs are ±200 ppm for the voltage reference, ±75 μV for the op-amps, and ±3 mV full-scale gain error for the DAC. Translated to units of 16-bit LSB steps, and taking the output range to be ±10 V (for which an LSB is 0.3 mV), these correspond to ±13 LSB, ±0.5 LSB, and ±10 LSB.

13.3.2 Eight-channel source

If your application does not need the flexibility of output polarities and scale factors of the last example, and if you can tolerate a bit more noise and drift, you can do pretty well with a fully integrated multiple-section voltage-output DAC, for example the LTC2656 in Figure 13.14. This particular IC includes an internal voltage reference of good stability (±2 ppm/°C typ, ±10 ppm/°C max), with a 1 ppm/°C typical full-scale tempco for the DAC

outputs. The DAC's low-frequency (0.1–10 Hz) output noise is 8 μVpp, typical. This is four times the noise voltage of the previous example; taking into account the more limited output span (0–2.5 V), it represents a larger relative noise contribution still. The good news is the relative simplicity of this part: no external reference or amplifiers, and operation from a single positive supply.

The SPI digital interface is simple and clean: every transfer is 24 bits, with 4 bits to specify the channel number (with an option to load all channels with the same value), 4 bits to specify the operation, and 16 bits to carry the digital value. Each channel is double buffered, so you can load the next value into each channel's input buffer, then transfer them simultaneously to the DAC's register so that all outputs change to their new values at the same time.

13.3.3 Nanoamp wide-compliance bipolarity current source

Here's an unusual application, and a circuit implementation of considerable subtlety, using a dual-supply current-output DAC: suppose you need a programmable current source that can operate over a wide voltage range (say ±10 V) while sourcing (or sinking) very small currents (in the nanoamp range, say). You might need this to measure the V–I characteristics of a semiconductor at the low end of its current range, or perhaps for a research application such as the electrical properties of nanofibers. Another application might be to cancel the input leakage current of a high-impedance measuring device, for example an 8-digit digital multimeter with a JFET frontend (a discrete matched JFET pair or a precision JFET-input op-amp), in which the leakage current rises rapidly (but predictably) with temperature.[22] Such an instrument could store a table of leakage versus temperature, measured during initial calibration, to be used in conjunction with a temperature sensor to program the cancellation current during normal operation. Current-output DACs don't operate successfully down at these currents, and furthermore they don't generally provide outputs that can both source and sink current under control of a digital input code.

This circuit (Figure 13.15) is tricky, and seriously confusing at first. Work with us, here, and you'll get it (eventually). An essential component is the simple floating current source circuit (Figure 13.16), in which an op-amp follower with an added voltage V_0 at the output bootstraps a feedback resistor R to create a current V_0/R. That voltage can be created by biasing a zener-type reference, as shown; or

[22] It was an analogous circuit in Agilent's 34420A multimeter (see §5.12.5) that inspired this example. (Their circuit used a voltage reference in place of R_3, allowing the use of a single DAC output. They also used a smaller R_s, so that the output range was ±2 nA.)

Figure 13.14. Eight-channel voltage-output DAC.

it can arise from a current flowing through a resistor that returns to the op-amp's output.

Now for the complete circuit of Figure 13.15. The DAC08 is an oldie (circa 1984), with a pair of opposite-ramping current-sinking outputs that sum to a constant current $I_{\rm ref}$ (set by the current sourced through R_1, here equal to 5 V/39.2 kΩ). An 8-bit offset-binary input code sets the individual output currents. For example, the minimum code (00h) causes $I_{\rm o}'$ to sink 128 μA and $I_{\rm o}$ to sink 0; for a quarter-scale code (20h, or 32 decimal) the corresponding currents are 96 μA and 32 μA; and so on. With +18 and −15 V supplies, the output compliance extends from −12 V to +18 V.

The external circuitry works the real magic, by (a) converting this unipolar current-sinking pair into a bipolarity (sourcing or sinking) output current, and (b) simultaneously scaling down the current by a factor of 10,000, to generate an output terminal that programmably sources or sinks currents with a full-scale range of ±12.8 nA, in LSB steps of 0.1 nA.

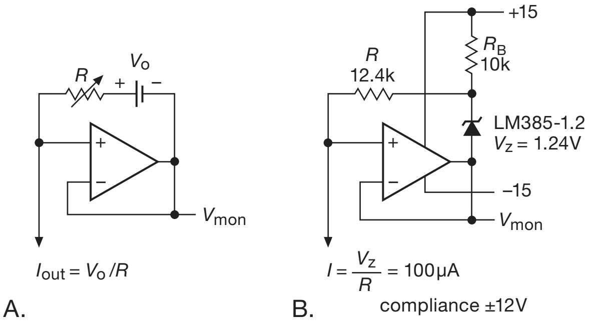

Figure 13.16. A follower with a voltage applied in series with a resistor creates a simple floating current source, and the op-amp's output pin provides a "voltage monitor." A. The basic scheme. B. Implementation with a bandgap voltage reference.

To understand first the current scaling, disconnect U_{2b} and look at the upper op-amp alone: the current sunk by the DAC generates a small voltage across $R_{\rm s}$, approximately $I_{\rm o}R_{\rm s}$ (for $R_{\rm o} \gg R_{\rm s}$). That's the $V_{\rm o}$ of the floating current

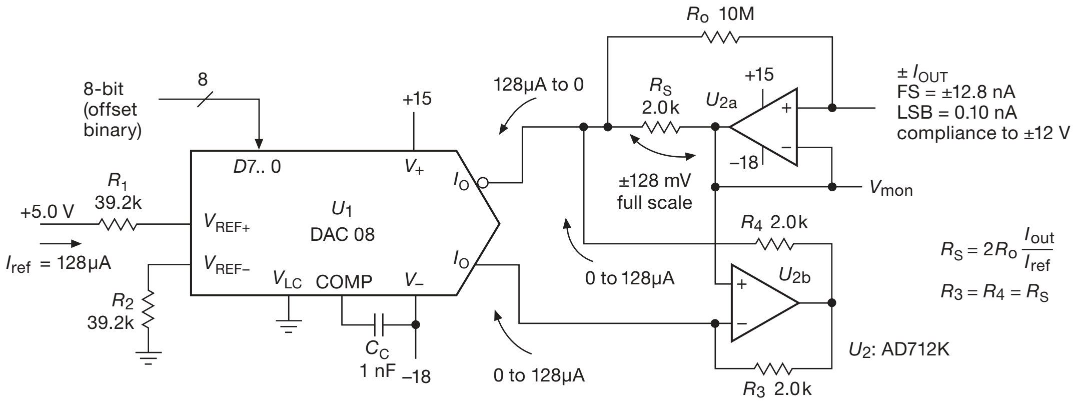

Figure 13.15. Wide-compliance programmable nanoamp current source/sink. The output voltage is buffered at U_{2a}'s output, for "source-measure" applications (i.e., source a current, measure the corresponding voltage). For a 2 nA range, set R_s=R_3=R_4=316Ω (or increase R_o).

source of Figure 13.16, here sinking a current I_oR_s/R_o from the load; that is, the current is scaled down by a factor of 5000. This is really just a "current divider" in fancy clothing. (For the complete circuit the ratio is 10,000:1, because R_4 is in parallel with R_s.)

Now reconnect the lower op-amp, and for the moment ignore the DAC's upper output, I'_o. The current sunk by the DAC puts U_{2b}'s output above its inputs by I_oR_3, which *sources* a current through the series pair R_4 and R_s.[23] So, with everything reconnected, the net current sourced into the left-hand side of R_s is the (positive) current equal to the magnitude of the DAC's I_o output, minus the (negative) current equal to the magnitude of the DAC's I'_o output. So the net current goes from $-128\,\mu$A (at minimum input code, 00h) to $+128\,\mu$A (at maximum input code, FFh). That current is divided by a factor of 10,000 ($R_o/[R_s\|R_4]$) to generate the net output current, with its full-scale range of ±12.8 nA.

If you need more precision, substitute the similar 10-bit DAC10. It differs in having somewhat less negative compliance, and in providing a full-scale output sink current equal to *twice* the reference current.

And a final comment: there are other ways to make a wide-compliance nanoamp current source; see, for example, the relatively simple design of Figure 5.69A.

A. Variations on the floating current source

Going back to the simple floating current source circuit of Figure 13.16, there are several useful variations that permit control via a dc input voltage (with respect to ground), or by a digital code. Figure 13.17 shows how to substitute the floating output of a difference amplifier (§5.14) in place of the biased zener of Figure 13.16B. Here the G=0.1 difference amplifier converts the programming voltage, in the range ±10 V with respect to ground, to a ±1 V output referenced to the op-amp's output, thus an output current of $I = V_{\rm prog}/10R$.

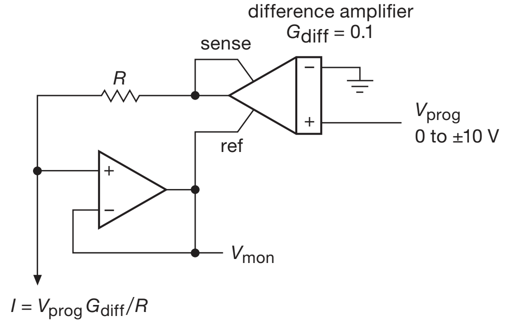

Figure 13.17. Floating current source analogous to Figure 13.16, programmed with a difference amplifier. See also Figure 5.69.

Some commercial instruments are capable of providing programmable currents over a very wide voltage range (say ±200 V). This they do (Figure 13.18) by powering the op-amp with a floating dc supply (say ±5 V), with a DAC (powered from the same supply) substituting for the difference amplifier in Figure 13.17. Both the op-amp and the DAC fly over the wide compliance range, with the DAC's digital input data fed via opto-isolators. In this scheme the op-amp's output is buffered and used to bootstrap the dc supply common, thus keeping the op-amp's

[23] This op-amp configuration is in fact a current mirror, sourcing into the node at its noninverting input a current proportional to the current sunk from its inverting input, in the ratio of the output resistor to R_3.

inputs and outputs near mid-supply; the bootstrap acts also to prevent dynamic currents caused by the supply's capacitance to its primary power source. These programmable current sources with voltage-monitor outputs are examples of what's called a "source-measure unit" (SMU), typified by units from Keithley (their 2400 series) or Keysight (their B2900 series).

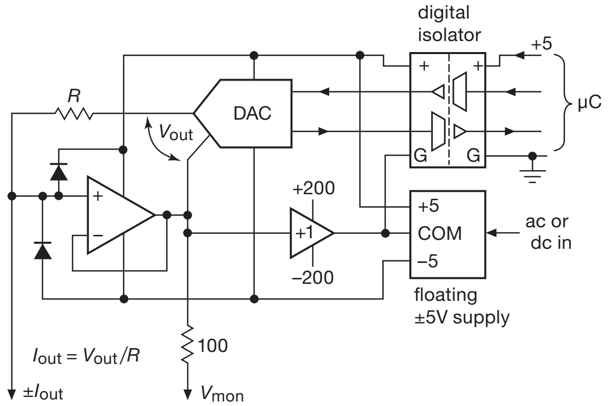

Figure 13.18. High-voltage floating current source scheme used in "source-measure" instruments. The unity-gain high-voltage buffer can be a simple push–pull follower, as its job is only to bootstrap the ±5 V floating supply. Adding a divider and buffer to the V_{mon} output produces a low-voltage replica.

13.3.4 Precision coil driver

Here's an application that pushes the limits of DAC resolution and stability: a current-source driver to provide a settable and stable current (of either polarity) through a pair of coils that trim the magnetic field in a magnetic resonance apparatus. This kind of application can require parts-per-million (ppm) resolution and stability. It's an instructional example worthy of some detailed discussion.

A. DAC and voltage reference

Figure 13.19 shows an implementation, with the remarkable AD5791 20-bit DAC at its core. Looking first at the circuitry surrounding the DAC, we've again chosen the ADR445 reference (in the best-performing B-grade) for its low noise and excellent stability (an alternative is the MAX6350, with the recommended capacitor from its noise reduction pin to ground). We added a 10 Hz *RC* lowpass filter to suppress wideband noise: according to the datasheet the ADR445's noise in the band from 0.1–10 Hz is about 2.3 μVpp, increasing to 66 μV when that band is extended to 10 kHz.

When you're working at ppm error levels, you have to worry about everything! For example, just 1.5 nA of leakage current in the 10 μF filter capacitor (C_3) would cause nearly 1 ppm error in the +5.0 V reference driving the DAC (from the IR drop across R_{10}). The noise filter shown exploits a nice trick[24] to eliminate that error: the lower leg ($R_{11}C_4$) bootstraps the bottom of C_3 so that there's essentially no dc voltage across it, hence no leakage current; this is analogous to the technique of a *guard* electrode, which is used to eliminate leakage currents in sensitive low-current measurements (or to eliminate the effects of shunt capacitance where signals are present).

The AD5791 can operate with a single positive reference, or with both positive and negative references. For our application we want an output range of ±5 V, but we can exploit the DAC's internal precision matched resistor pair (which returns to the positive reference) so that only a positive reference is needed. The DAC provides a "sense" output from both internal reference nodes, used with feedback as shown to eliminate IR errors. Note the matched input resistances at U_2's inputs, to take advantage of input current matching ($\Delta I_B < 1$ nA); the input-current tempco, estimated from graphs in the datasheet, is less than 10 pA/°C. The op-amp's offset voltage is 12 μV typ (50 μV max), and the offset voltage tempco is 0.6 μV/°C max (0.2 μV/°C typ).

On the scale of the +5.0 V reference that the op-amp is buffering, these figures translate into 0.7 ppm, 0.007 ppm/°C, 2.4 ppm, and 0.12 ppm/°C, respectively. In other words, the bias current and offset voltage errors add up to about 3 ppm, or 3 LSBs; but the drifts are just 0.13 ppm/°C (max), or an LSB for an 8°C change in temperature. We're happy with that stability, which is what we really care about for this application. The ~3 ppm scale error is unimportant, because in practice the current will be adjusted until the coil current is doing the right thing. Finally, we've got to consider the error and drift contributed by the DAC itself, which are comparable: its full-scale and zero-scale errors are each ±2 ppm (2 LSB) max, and its output tempco (at zero, midscale, or full-scale) is ±0.05 ppm/°C typ, ±0.5 ppm/°C max. Its typical low-frequency output noise is 0.6 μVpp at mid-scale, roughly half as much as that contributed by the reference.

B. Amplifier loop

The job here is to use the DAC's stable output voltage to control the coil current[25] over a range of ±0.1 A while

[24] Originated by Walter Jung, as far as we know.

[25] We took as a reference design a pair of coils, each 30 cm in diameter with 500 turns, spaced axially by 15 cm in the so-called "Helmholtz"

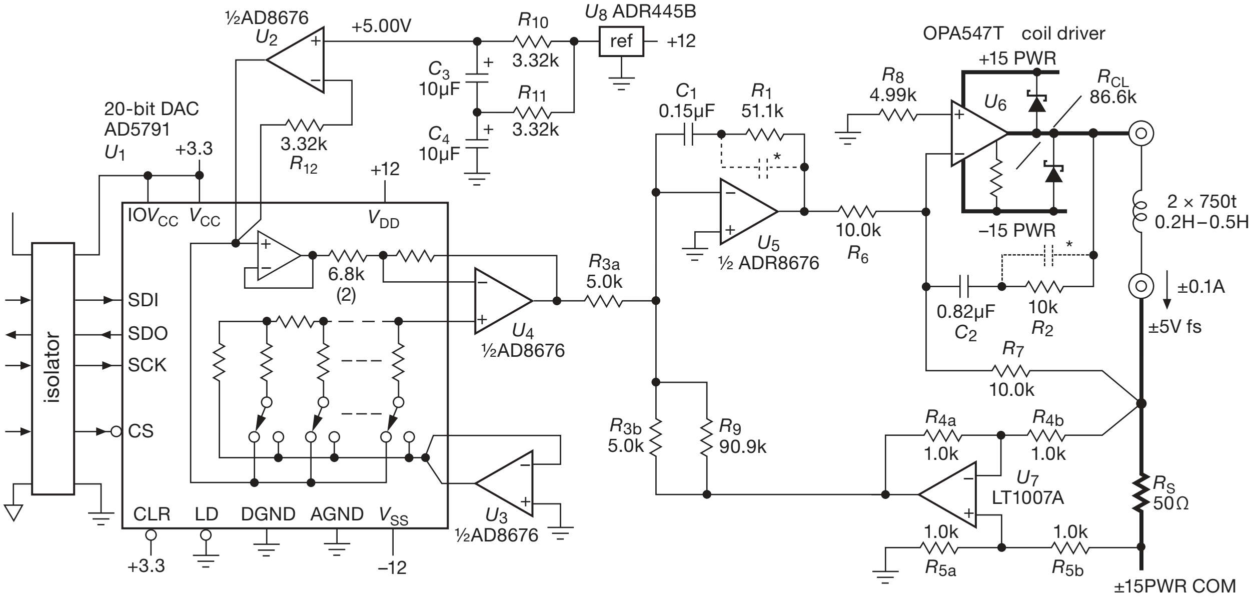

Figure 13.19. Precision programmable Helmholtz coil driver featuring the AD5791 20-bit DAC. The high current path is indicated with heavy lines. Resistors R_3–R_5 are Vishay MPM matched pairs (2 ppm/°C tracking), and R_s is a Vishay VPR221 (Y0926) bulk foil power resistor (2 ppm/°C tempco) with heat-sinking.

preserving part-per-million dc stability and noise. There's also the *other* kind of stability – freedom from oscillation.

Ignoring the latter for the moment (i.e., neglecting all of the capacitors in the circuit), at the top level the amplifier loop works like this: a temperature-stable current-sensing resistor $R_s = 50\,\Omega$ generates a full-scale voltage of ± 5 V, a replica of which is subtracted from the DAC's output by the matched resistor pair R_{3ab}. Error amplifier U_5 supplies the loop gain, applying the amplified error to the coil driver U_6, which operates as a unity-gain inverter. The phases are correct: too much current through R_s drives the output of U_7 down, U_5 up, and U_6 down.

At the next level there's the dc accuracy and drift to worry about. Once again we've chosen precision BJT op-amps, the now-familiar AD8676 for the error amplifier, and the vintage LT1007A for the unity-gain difference amplifier. The latter has the lower noise and offset voltage, at the expense of a higher input current; we circumvent the latter problem by reducing the resistance seen at the inputs, which is possible because of the low (50 Ω) source impedance. The power op-amp U_6 need not be accurate, because it is within an overall feedback loop whose gain rises at low frequencies as $1/f$.

The sense resistor R_s is a Vishay "bulk metal foil" 4-wire (Kelvin connection) precision power resistor in a TO-220 package, rated at 8 W dissipation; the best grade is accurate to $\pm 0.01\%$, with a typical tempco of 2 ppm/°C. The resistor pairs R_3–R_5 are each precision matched duals in convenient SOT23 packages, with 0.05% matching, and 2 ppm/°C (typ) tracking. The resistor shunting R_{3b} compensates for the reduction of R_s's effective resistance that is due to loading by R_7 and R_{4b}.

Assuming there's plenty of loop gain (and there is, see next paragraph), the ppm-scale dc stability of the DAC output is reasonably well preserved with these op-amps, assisted by resistors of this stability and tracking.

Finally, there's the serious business of stability against oscillations, which is complicated here by the inductive load. The latter alone causes a 6 dB/octave rolloff beginning at the frequency at which the inductive reactance equals the sense resistance, about 20 Hz for the nominal 400 mH coil pair. We've addressed it by making the error amplifier an integrator at lower frequencies (for plenty of dc gain), flattening to a gain of ×10 at 20 Hz.[26] That prevents the curve of overall loop gain versus frequency from dropping at more than 6 dB/octave, at least until well beyond the unity-gain frequency. The output amplifier U_6

configuration. With #20 gauge wire, the total dc resistance is 30Ω, the inductance is about 400 mH, and a current of 0.1 A produces a central field of 3 gauss (about six times Earth's field).

[26] In fancy language, a pole at dc and a zero at 20 Hz.

gets the same treatment. An additional small capacitor across R_1 (and similarly across R_2) rolls off the local gain at higher frequencies still, to stabilize against high-frequency oscillations. Suitable values are 150 pF and 4.7 nF (rolling off at 20 kHz and 3 kHz, respectively).

Rather than prattle on about this, we present the self-explanatory Bode plots of Figure 13.20. Readers who are likely to encounter situations like this can benefit from the thinking presented there.

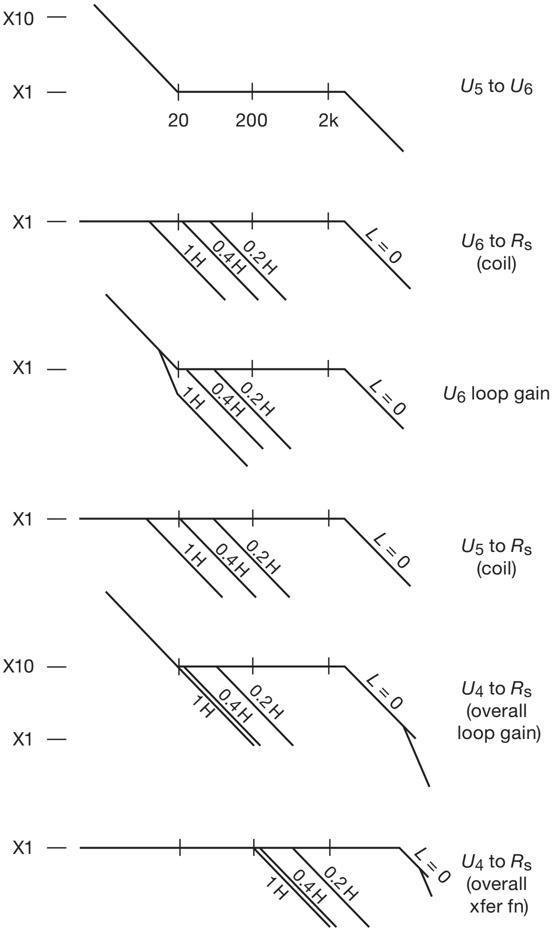

Figure 13.20. Bode plots for the coil driver amplifier in Figure 13.19, shown with several values of load inductance.

13.4 Converter linearity – a closer look

In §13.1.3 we mentioned, briefly, the sorts of errors that afflict DACs (and ADCs as well). The business of *linearity errors* deserves some more discussion.

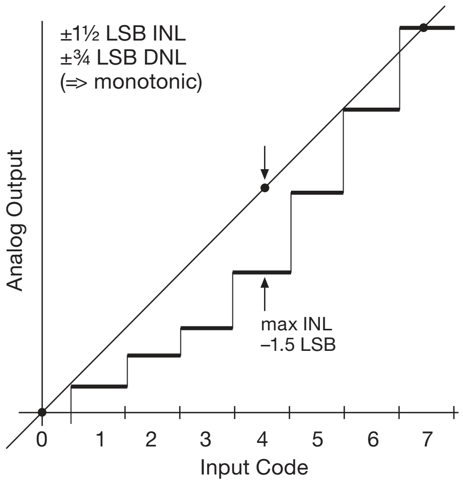

Figure 13.21. A DAC can exhibit both monotonicity (DNL<1 LSB) and relatively large integral nonlinearity (here INL=1.5 LSB).

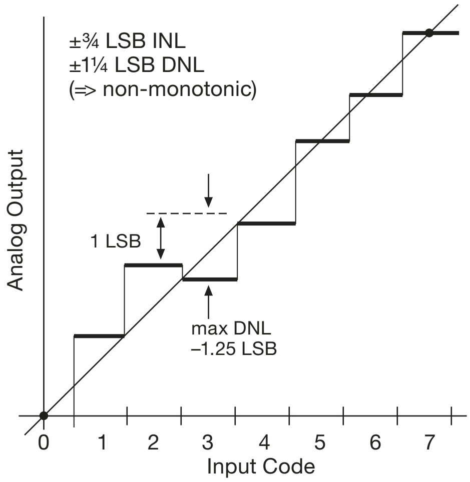

Figure 13.22. This converter has less INL (0.75 LSB) than in Figure 13.21, but its larger DNL (1.25 LSB) permits non-monotonicity. Which matters more depends on the application.

Take a look at Figures 13.21 and 13.22. Both 3-bit DACs suffer from linearity errors. But there's some subtlety here. We need a couple of definitions: *integral* nonlinearity (INL) is the maximum deviation from the ideal straight line of analog output versus digital input, over the full conversion range;[27] whereas *differential* nonlinearity (DNL) is the maximum error in any single digital step (i.e., from n=2 to n=3 in this example) from its proper step size of 1 LSB.

When do you care about INL versus DNL? If you need

[27] There's a bit of wiggle room here, because you can define the line as passing though the endpoints ("endpoint linearity," as used here), or you can make things look a bit better by using the best-fit straight line.

a DAC to hit a desired voltage with minimal error, the INL and gain-error terms will dominate, and you don't care about monotonicity. If, however, you're closing a control loop, it's the exact opposite: the servoing action of the loop will remove the INL, but large DNL could cause hidden zones of instability, which are particularly hard to debug.

A DAC's architecture influences the mix of INL/DNL. Consider two good 16-bit DACs, the DAC8564 and the AD5544. The first uses a string of resistors, so you have to work pretty hard to end up with a DNL greater than 1 LSB. And you are *guaranteed* monotonicity. However, nothing is controlling the INL except the statistical distribution of the resistor values, so it's not surprising that the INL is ±8 LSBs, and that's for the expensive part. It's 12 LSBs in the bleachers.

In contrast, in the R–$2R$ architecture a large INL will often translate to a large DNL; the same process that keeps the DNL under control also keeps the INL down, to some extent, so the INL spec of the AD5544 is ±4 LSBs, with a DNL of 1.5 LSBs. So all other specs being equal (which they aren't), one would choose the AD5544 for precisely setting voltages, and the DAC8564 for use in a control loop.

And, while we're issuing warnings, beware, Beware, *BEWARE* using audio DACs in non-audio applications. If a DAC doesn't provide a DNL spec, it's because it's embarrassingly large. This is often acceptable in audio, but not for either control loop use or voltage setting. Likewise, gain-drift specs for audio DACs are often too large for use in voltage-setting applications.

13.5 Analog-to-digital converters

Look back at the earlier section on "Preliminaries" (§13.1) to remind yourself of some of the things to think about when choosing a converter (whether DAC or ADC). At the top level you're concerned much less with the details of how the thing actually does its conversion, and much more with the major questions of (a) performance (speed, accuracy, etc.), (b) digital interface (parallel or serial; single-ended or LVDS; etc) and (c) integration (single or multiple units; stand-alone, or integrated into a microcontroller or other complex function). In most cases you'll use a commercial ADC chip or module rather than building your own. But it's important to know about the inner workings of the various A/D conversion methods, in order not to be caught unaware by their idiosyncrasies.

13.5.1 Digitizing: aliasing, sampling rate, and sampling depth

We'll get into the nitty-gritty of analog-to-digital conversion soon enough, but first a short riff on the business of *sampling*, which will come up again and again as we visit various ADC methods.

When you convert an analog signal (e.g., an audio waveform) to a series of digital quantities (i.e., numbers corresponding to the instantaneous voltage at successive moments in time), you need to choose both the precision of the voltage measurements (the sampling *depth*) and the rate at which such samples are taken (the sampling *rate*). We saw this briefly in Chapter 6, in connection with anti-alias lowpass filters (§6.3.7A); let's look a bit more deeply here, in the context of ADC sampling of analog waveforms.

A. Sampling depth

Let's look first at the effects of bit depth (because they are the more easily understood): sampling to n equally spaced bits quantizes the waveform samples to 2^n levels, effectively limiting the dynamic range to $6n$ dB. A waveform so sampled, when properly scaled to exploit the full conversion range, will also exhibit quantization distortion, to the tune of 2^{-n} (i.e., $100/2^n$ percent).

As an example, 16-bit quantization of audio (the standard used in CD audio) has a dynamic range limited to 96 dB, and minimum distortion of 0.0015%. Of course, the signal itself is typically limited in both dynamic range and distortion; a well designed digitizing system should have sufficient bit depth (and sampling rate) so that it does not degrade the signal's quality.

At a deeper level there is more to the story than mere bit depth: nonlinearity (even nonmonotonicity!), noise, spurs, etc., all contribute to the fidelity of the digitized signal. A common metric that captures much of this is "ENOB" (effective number of bits); we'll see more of this later (see for example Figure 13.56).

B. Sampling rate and filtering

The story here is more subtle (and more interesting). Contrary to intuition, a waveform that is perfectly sampled at a rate at least twice that of the highest frequency component present suffers *no loss of information whatsoever*. Nothing is lost in the unsampled portion of the waveform in between the samples; this is the Nyquist sampling theorem (which has its cadre of unbelievers, who swear that digital audio removes the very soul of music).[28]

[28] It can be shown mathematically that the original signal (excluding a set of pathological waveforms) is perfectly recovered:

Readers harboring contempt for authority may wonder what happens if one violates statute by *under*sampling. Easy enough to try: look at Figure 13.23, where we've sampled a 100 Hz sinewave (requiring $f_{\text{samp}} \geq 200$ sps) at 90 sps, in serious violation of Nyquist's prescription. The sampled points trace out a false signal, in this case 10 Hz. This is called an "alias," and most of the time it's something you don't want.[29] Put simply, for a given sampling rate f_{samp}, the analog input signal must be lowpass filtered (with an "anti-alias filter") such that no significant signal remains above $f_{\text{samp}}/2$. Conversely, for an analog signal that extends to some maximum frequency $f_{\max}$, the minimum sampling rate is $2f_{\max}$. (You can, of course, sample more rapidly than the Nyquist limit $f_{\text{samp}}{>}2f_{\max}$, and in fact it's wise to do a modest degree of "oversampling" because that permits more relaxed lowpass filtering of the analog signal, as we'll see presently.)

It's helpful to look at the business of aliasing in the *frequency* domain. In Figure 13.24A we've attached a wimpy 2-section *RC* filter to a broadband signal, putting the -3 dB point of each section at the Nyquist limit ($f_{\text{samp}}/2$). Frequency components in the forbidden region get falsely digitized as shown,[30] contaminating the intended signal band; they cannot be removed later by filtering – in the digitized output they are now "in-band."

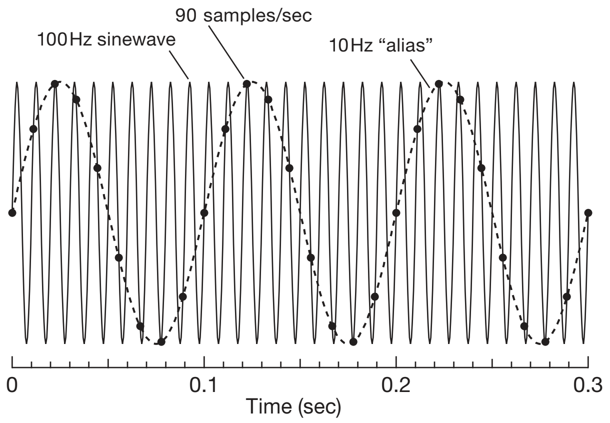

Figure 13.23. Digitizing at less than the Nyquist rate produces "aliases." A 100 Hz sinewave (solid line) sampled at 90 sps (far below the 200 sps Nyquist rate) produces a 10 Hz alias (dots, connected by a dashed line).

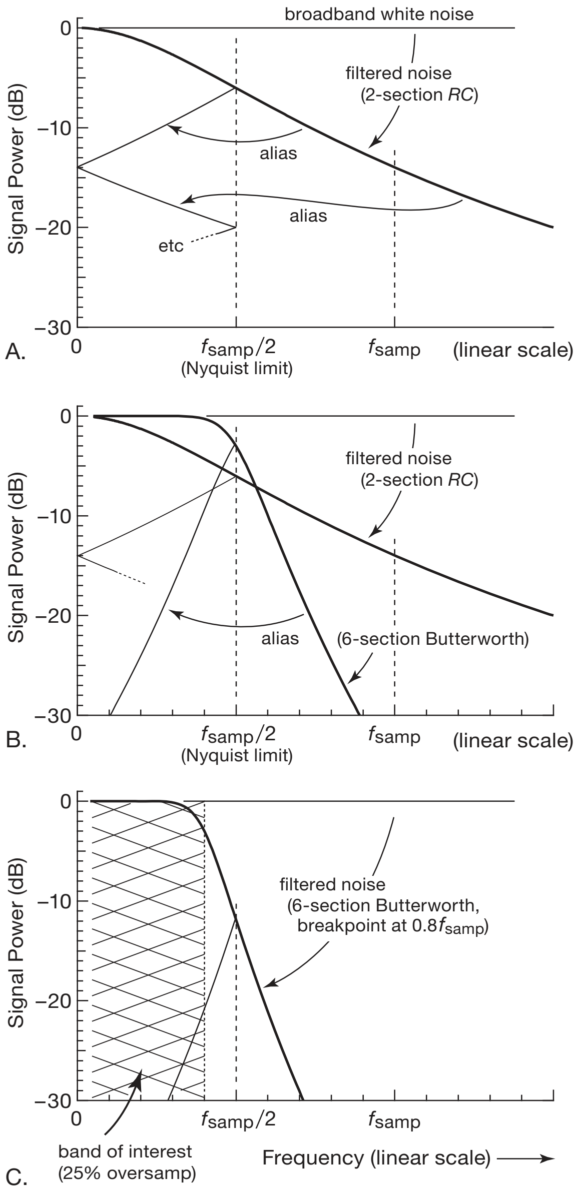

Figure 13.24. Undersampling, oversampling, and aliasing. A. Sampling a signal with frequency components above the Nyquist limit ($f_{\text{samp}}/2$) produces aliased digitized versions that fall within the properly-sampled signal; here a gentle 2-section *RC* rolloff allows significant aliased out-of-band signal energy to contaminate the intended signal. B. A steeper filter is more effective; but aliasing still contaminates the Nyquist band edge. C. Oversampling (setting the Nyquist frequency above the band of interest, here by 25%) gives the anti-alias filter a guard band in which to roll off, greatly reducing aliasing.

$v(t){=}\sum v_i \operatorname{sinc} \pi(f_s t - i)$, where f_s is the sampling rate and v_i is the amplitude of the ith sample.

[29] See §13.6.3 for an important exception.

[30] To draw these "elevation sketches," just mirror the contours seen past the multiples of the Nyquist frequency.

A steeper anti-alias filter does a better job, as seen in Figure 13.24B, where we've included a 6-pole Butterworth whose $-3\,\text{dB}$ point is set at $f_{\text{samp}}/2$. But the situation is still far from ideal, with plenty of aliased signal present, especially at the high frequency end.

What you do, then, is to run the sample clock somewhat faster than the Nyquist minimum, as seen in Figure 13.24C, illustrating 25% oversampling relative to the signal band we care about. That gives the anti-alias filter a guard band in which to transition from passband to stopband. Note that we've set the filter's $-3\,\text{dB}$ point at the band edge, not at the Nyquist frequency.

This is how it's done, in applications where signal purity is important. Using again the example of CD audio, the 20 kHz audio band, if limited by a perfect brickwall lowpass filter at 20 kHz, could be sampled at the Nyquist limit of f_{samp}=40 ksps; but the CD standard sets the rate at 44.1 ksps (10% oversampling), allowing for a 20% filter guard band.[31] Later, in Figure 13.60, we'll use a frequency-domain view of aliasing to understand some benefits of delta–sigma conversion.

Note that there are compromises involved in anti-alias filter design. For example, an analog multi-section filter with steeper transition to cutoff (e.g., a Chebyshev filter) exhibits poorer performance in the time domain (overshoot and ringing, poor phase characteristics, sensitivity to component values, etc.) – see Figures 6.25 and 6.26. For much more on filter types and characteristics see the extensive discussion in Chapter 6 (particularly §6.2.5). And, while you're paging through earlier chapters in search of wisdom, be mindful always of the degrading effects of noise (Chapter 8).

13.5.2 ADC Technologies

There are half a dozen basic techniques of A/D conversion, each with its peculiar advantages and limitations. In the following subsections we'll take each in turn, along with some application examples. Here, in outline form, is a compact summary of these techniques.

Flash, or "parallel" (§13.6) The analog input voltage is compared with a set of fixed reference voltages, most simply by driving an array of 2^n analog comparators to generate an n-bit result. Variations on this theme include pipelined or folded architectures, in which the conversion is done in several steps, each of which converts the "residue" of the previous low-resolution conversion.

Successive approximation (§13.7) Internal logic generates successive trial codes, which are converted to voltages by an internal DAC and compared with the analog input voltage. It requires just n such steps to do an n-bit conversion. The internal DAC can be implemented as a conventional n-stage R–$2R$ resistor ladder or, interestingly, as a set of 2^n binary-scaled capacitors; the latter method is known as a *charge-redistribution* DAC.

Voltage-to-frequency (§13.8.1) The output is a pulse train (or other waveform) whose frequency is accurately proportional to the analog input voltage. In an *asynchronous* V/F the oscillator is internal and free running. By contrast, a *synchronous* V/F requires an external source of clock pulses, gating a fraction of them through such that the *average* output frequency is proportional to the analog input.

Single-slope integration (§13.8.2) The time required for an internally generated analog ramp (capacitor charged by a current source) to go from zero volts to the analog input voltage is proportional to the value of the analog input. That time is converted to an output number by gating a fast fixed-frequency clock, and counting the number of clock pulses. Note that pulse-width modulation employs the same ramp-comparator scheme as single-slope integration to generate the ON time of each cycle.

Dual-slope and multislope integration (§§13.8.3–13.8.4, 13.8.6) These are variations on single-slope integration, effectively eliminating errors from comparator offsets and component stability. In *dual-slope integration* the capacitor is ramped up for a fixed time with a current proportional to the input signal, and ramped back down with a fixed current; the latter time interval is proportional to the analog input. In *quad-slope integration* the input is held at zero while a second such "auto-zero" cycle is done. The so-called *multislope* technique is somewhat different, with a single conversion consisting of a succession of fast dual-slope cycles (in which the input is integrated continuously, combined with subtractive fixed-current cycles), and with a correction based upon the partial-cycle residue at both ends. In some aspects it's a close cousin of the delta–sigma method.

Delta–sigma (§13.9) There are two parts: a *modulator* converts the analog input voltage to a serial *bitstream*; then a digital lowpass filter accepts that bitstream as input, producing the final n-bit digital output. Most simply (and it's never very simple!), the modulator consists of an integrator acting on the difference between the

[31] Much higher oversampling – at *many* times Nyquist rate – is exploited in the technique of delta–sigma conversion, see §13.9.

analog input voltage and the value of the 1-bit output serial bitstream to determine the next output bit. Variations include higher-order modulators (a succession of weighted integrators), or bitstreams that are several bits wide (a "wordstream"?), or both. Delta–sigma converters are both popular and confusing, and they deserve the extensive section later in the chapter.

13.6 ADCs I: Parallel ("flash") encoder

This is probably the simplest ADC concept; it's also the fastest (see Table 13.4). In this method the input signal voltage is fed simultaneously to one input of each of n comparators, the other inputs of which are connected to n equally spaced reference voltages. The output levels of the n comparators form a "thermometer code," which is converted (in a *priority encoder*) to a $(\log_2 n)$-bit binary output corresponding to the highest comparator activated by the input voltage. Figure 13.25 shows the idea *notionally* – here clumsily implemented with discrete comparators and standard logic. You wouldn't do that, of course; much better to let the silicon wizards do their integrated magic. In this simple (single-stage) scheme the delay time from input to output is the sum of comparator, encoder, and output latch (if provided) delays. An example of a commercial flash encoder using this scheme is the MAX1003: it does 6-bit conversions on each of two input channels, at sampling rates to 90 Msps, with the digitized and latched result available one clock cycle after sampling.

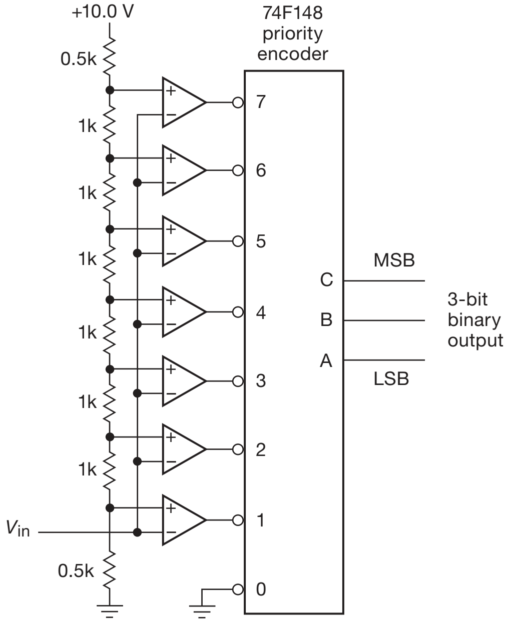

Figure 13.25. Parallel-encoded ("flash") ADC.

13.6.1 Modified flash encoders

In practice, the simple flash scheme has been largely supplanted by modified flash variants, with names like "half flash," "subranging flash," "folding/interpolating architecture," or "pipelined flash." These generally involve successive stages of partial conversion, so there is some amount of delay (or *latency*) from the moment of input sampling to valid digital output. This does not necessarily reduce the maximum sampling rate. In fact, quite the contrary: by subdividing the conversion into a succession of coarser quantizations, these converters can achieve very high sampling rates, with the partially quantized analog "residues" propagating along in a capacitor-based pipeline as newer samples begin their conversion. In such a converter an initial coarse conversion (say to 2-bit resolution) is followed by successive stages that operate on the residue (the difference between the analog input and that coarse estimate). An example is the ADC10D1500, a dual 10-bit 1.5 Gsps ADC (the two sections can be interleaved, to achieve 3 Gsps); it has a latency of 35 clock cycles.

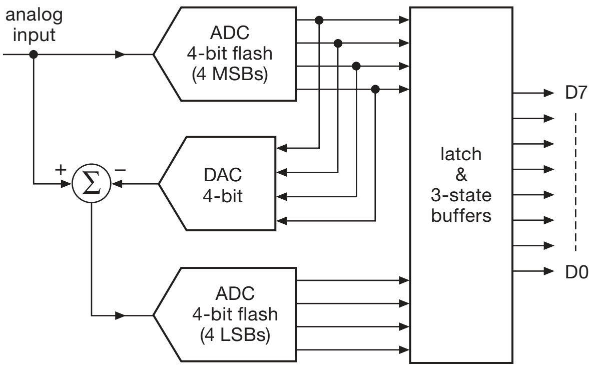

Figure 13.26. Half-flash ADC.

Perhaps the simplest of these converter architectures is the *half-flash*, a two-step process in which the input is flash-converted to half the final precision; an internal DAC converts this digital approximation back to analog, where the difference "error" between it and the input is flash-converted to obtain the least significant bits (Figure 13.26). This technique yields low-cost converters that operate at relatively low power. Examples are TI's TLC0820, ADI's AD7820, and TI's TLC5540, inexpensive 8-bit ADCs with latencies of two or three clock cycles, and modest conversion speeds (40 Msps for the latter).

As remarked above, more sophisticated ADC architectures perform the conversion with various pipeline schemes, in which the analog residues are carried along through a succession of relatively coarse quantizers. An example is ADI's AD9244, which uses a 10-stage pipeline to achieve 14-bit conversions at 65 Msps, with a latency of eight clock cycles. Their AD9626 trades some accuracy for speed: 12 bits and 250 Msps, with six clocks of latency. Its datasheet says it all:

> The pipelined architecture permits the first stage to operate on a new input sample, while the remaining stages operate on preceding samples. Each stage of the pipeline, excluding the last, consists of a low resolution flash ADC connected to a switched capacitor DAC and interstage residue amplifier (MDAC). The residue amplifier magnifies the difference between the reconstructed DAC output and the flash input for the next stage of the pipeline.... The last stage simply consists of a flash ADC.

Similar technology is offered by TI's ADS5547, a 14-stage pipelined ADC that achieves 14-bit conversions at 210 Msps, with a latency of 14 clocks (these guys like the number fourteen). Their fastest high-resolution ADCs at the time of writing are 14-bit 400 Msps (ADS5474) and 16-bit 370 Msps (ADC16DX370).

The "folding" architecture (usually implemented as a combined folding/interpolating scheme) achieves a similar goal (creating the final conversion via coarse and fine quantizations), but by a clever method that does not involve a pipeline of successive steps. Rather, the analog input passes through an analog folding circuit (made from a string of cross-connected differential pairs) that maps the full input-voltage range to an output consisting of a set of repeating folds. That output is flash-converted to produce the lower-order bits, while a coarse flash conversion of the full-range input signal simultaneously determines in which fold the signal lies (i.e., the higher-order bits); see Figure 13.27. The "Ultra High Speed ADC" family from National Semiconductor uses these techniques, with current offerings going to speeds of 3.6 Gsps at 12-bit resolution (ADC12D1800). There are lots of tricks involved in making this work well; as the saying goes, they are "well beyond the scope of this book."

Flash encoders are worth considering in waveform digitizing applications even when the conversion rate is relatively slow, because their high speed (or, more precisely, their short *aperture* sampling interval) ensures that the input signal is effectively not changing during the conversion. The alternative – the slower converters we describe next – usually requires an analog sample-and-hold circuit to freeze the input waveform while conversion is going on. Note that a converter's latency may or may not matter, depending on the application: latency would not be of concern in an oscilloscope frontend, or in a "software radio"; but it would be a disaster in a fast digital control loop.

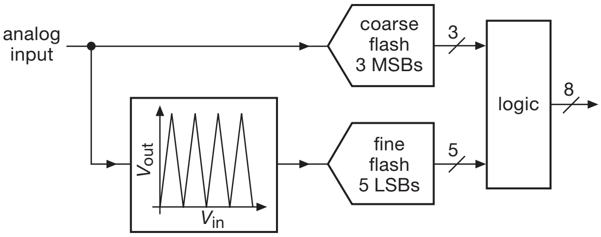

Figure 13.27. Flash ADC with "folding" architecture.

13.6.2 Driving flash, folding, and RF ADCs

Today's ADCs are not your father's simple converters. It's true they're much more capable than converters of previous generations, but they're cantankerous, they no longer observe the rule of speaking only when spoken to, and they may be very demanding of resources, especially power and digital assets. This is especially true for high-speed low-voltage converters with differential inputs. No longer can you count on simply taking an op-amp and connecting it to your ADC.

To illustrate with an example, Figure 13.28 shows a dual-channel 16-bit flash ADC capable of working up to low RF frequencies, ideal for digitizing I, Q signals for software radios. It employs a differential amplifier IC discussed in §5.17, performing the tasks shown in Figures 5.102 and 5.103. As we draw these circuits, at first glance they may look alike, but we find ourselves spending time on the details, looking up datasheet rules and suggestions, considering alternative parts with new rules, and honing the design.

The AD9269 converter[32] is a flash type, but later in the chapter we'll encounter the same issues with the other primary ADC types. For example, some successive-approximation register (SAR) converters (and many of the delta–sigma converters as well) will require the distinctive two-resistor plus capacitor configuration at their inputs. Many SAR types go further, being quite picky about

[32] The AD9269 (listed in Table 13.4) is a dual ADC with conventional CMOS logic outputs, but ADCs with slightly faster data rates generally upgrade to differential LVDS outputs, or 32 lines per 16-bit ADC channel.

Notes: (a) listed in order of increasing sample rate, for the fastest member of a family; unless noted otherwise, inputs are differential, with sampling capacitors at the inputs introducing switching transients that require low drive impedance and RC input networks; all guarantee no missing codes. (m) min or max. (t) typical. (y) includes int ref.

Comments: A: input buffer, isolates sampling transients. **B:** both. **C:** *n*-line parallel CMOS. **D:** n/2-lane DDR LVDS/ch. **F:** 1024-lane LVDS at 440MHz/ch. **G:** 1, 2, or 4 LVDS lanes/ch. **I:** interleave for 2x sampling rate. **J:** non-interleaved. **K:** fastest ADC; 320 interleaved 175Msps SARs. **L:** *n*-lane LVDS/ch. **N:** negative only. **O:** one LVDS lane. **P:** programmable operating parameters, usually via SPI. **R:** resistor ladder and comparators. **S:** single-ended input. **V1:** 3.3V and 5V. **V2:** 1.8V and 3.3V.

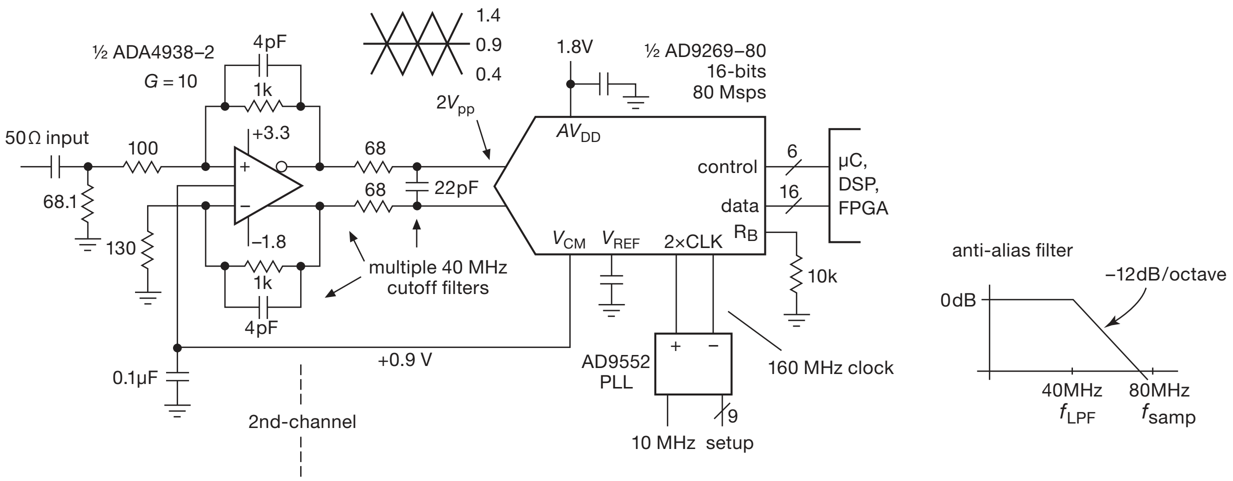

Figure 13.28. Fast ADCs are usually driven differentially, as in the two-channel 16-bit 80 Msps (40 MHz) RF digitizer. Radiofrequency applications like this require an accurate and stable clock source at some multiple of the conversion rate, here provided by a phase-locked-loop (§13.13).

what R and C values are allowed to achieve specified performance.

An 80 Msps converter has a 40 MHz Nyquist limit, set approximately with our $2R+C$ differential lowpass input filter. The filter R,C parts play two other roles: the ADC responds to noise (white and other) all the way up to its 700 MHz input bandwidth, so we need to quiet the output of the amplifier aggressively above 40 MHz; and the ADC's input switched-capacitor S/H needs to grab some charge from an input capacitor to work properly. The two R's also serve to isolate the capacitor from the op-amp, important because 1000 MHz op-amps don't kindly tolerate direct capacitive loads. So we have three motivations for these new parts, not seen in the good old days.

Why do we use a differential-*output* amplifier? Generally, when driving a device that presents a differential input, we have the option of grounding one side and feeding the other. But doing this with today's ADCs will cost us a substantial distortion penalty, and half the full-scale input range as well. But in choosing the differential amplifier IC we were boxed into a corner: looking in the 500–1500 MHz region of Table 5.10 on page 375, we couldn't find a part with high "$Z_{\text{in(diff)}}$." We wanted additional 40 MHz anti-alias filtering, which ruled out attractive parts with internal gain-setting resistors because the summing junctions aren't exposed. And we wanted a gain of at least 10, or 20 dB. So we chose, finally, an Analog Devices ADA4938 with a 1000 MHz rated bandwidth.[33] Looking at its frequency-response plots, we see its GBW=800 MHz, thus an $f_{-3\text{dB}}$=GBW/G=80 MHz for G=10, so we have some loop gain left at 40 MHz.

Configuration-D amplifiers like this (Figure 5.96) have rather low input impedances, especially at high gains, because Z_{in}=2R_{g}, and $R_{\text{g}} = R_{\text{f}}/G$. Having thrown in the towel on high input impedances, we opt for matching the ubiquitous 50 Ω source impedance of wideband signals. If we choose R_{g}=100 Ω, the Johnson noise[34] of two of these will be 1.8 nV/$\sqrt{\text{Hz}}$, or nicely below the amplifier's rated e_{n}=2.6 nV/$\sqrt{\text{Hz}}$.

We have to provide a 50 Ω load for the input, and recognizing that Z_{in} isn't exactly R_{g},[35] we turn to the formula provided in the datasheet, $Z_{\text{in}} = R_{\text{g}}/(1 - R_{\text{f}}/2[R_{\text{g}} + R_{\text{f}}])$, to determine that we need a 68 Ω load resistor; then we match the impedance seen driving the noninverting input by using a 130 Ω resistor to ground at the inverting input. This added resistance disturbs the usual $R_{\text{f}} = GR_{\text{g}}$ relationship, and we are forced to increase R_{f} by 11% to maintain $G = 10$, as detailed in §5.17.4. Finally we evaluate the single-ended to differential conversion by examining the datasheet's V_{ocm} specifications. The V_{ocm} −3dB spec is 230 MHz, which means that with our feedback attenuation the full-differential ADC drive will be down by 3 dB at 24 MHz.[36]

[33] We could also have chosen a TI LMH6552 or LMH6553.

[34] See §§8.1 and 8.2.

[35] A fraction of the differential-output voltage appears at the inputs as a common-mode signal, partially bootstrapping the voltage across the input resistor R_{g}.

[36] If this is not acceptable, we need to reduce our amplifier gain by half or

Our AD9269 ADC needs a sampling clock, for which we choose the capable AD9552 PLL upconverter (see §13.13.6H and Table 13.13). It seemed a good idea to take advantage of the ADC's internal divide-by-two option, to help ensure an internal 50% duty cycle, so we'll need a 160 MHz clock for 80 Msps sampling; thus, if we use a 10 MHz reference, we set the PLL multiplication to 16. If we want other sampling rates we can employ the AD9552's powerful delta–sigma modulator fractional-frequency synthesis capabilities, and we can also choose other ADC division ratios.

A final worry (if you haven't had enough already) is *clock jitter*. The AD9269 datasheet's graphs show that, to obtain the desirable best-available 75–78 dB signal-to-noise ratio (SNR), the clock jitter should be (gasp!) no more than 0.2 ps (about 15 ppm of the sampling period). Our AD9552 PLL datasheet specifies the jitter (for a 4–80 MHz reference input to be 0.11 ps, so we slip under the wire on that one (but without much to spare).

13.6.3 Undersampling flash-converter example

Figure 13.29 shows, in somewhat simplified form, an "undersampling converter" application, in which an input signal centered at some rather high frequency (say 500 MHz) is digitized at a rate far less (say 200 Msps) than would appear necessary from the Nyquist criterion. This works successfully if two conditions are satisfied: (a) the signal's *bandwidth* must satisfy the Nyquist sampling criterion, i.e., the sampling rate must be at least twice the bandwidth occupied by the signal; and (b) the signal's full spectrum (including the high carrier frequency) must fall within the ADC's analog input bandwidth.

The first condition requires that the input signal be strictly limited in bandwidth, usually with a bandpass filter. The second condition implies that the ADC has been designed for an undersampling application. The ADC08200 in the figure, for example, specifies a full-power bandwidth of 500 MHz, even though its maximum sampling rate is 200 Msps (which would normally be appropriate for signals only to 100 MHz). You can think of this as exploiting the aliased spectrum produced by undersampling; that's OK, as long as there are no other spectral components competing for that "baseband" piece of spectrum (see Figure 13.30).[37]

In the example circuit we've used a relatively slow member from National Semiconductor's family of flash converters. This puppy runs from a single +3 V supply, converts at rates to 200 Msps with byte-wide output through a simple parallel output port, and costs under $15 in single quantities.[38] You get to supply the top and bottom of the conversion range (here ground and +1.25 V), and the datasheet sternly advises you to bypass the midpoint of the 256-tap resistor string. The 100 μH choke decouples the analog pin from the noisy V_D digital supply pin. With the positive-only conversion range it's necessary to bias the input signal to half the conversion range, as shown; the pair

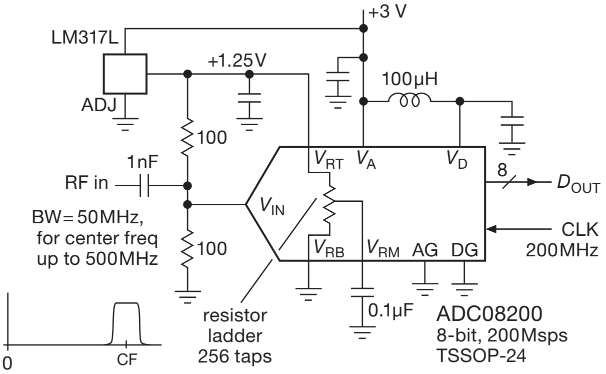

Figure 13.29. An inexpensive flash ADC digitizes a band-limited signal well above the Nyquist cutoff frequency, a job that traditionally calls for frequency downconversion with a local oscillator ("LO") and mixer.

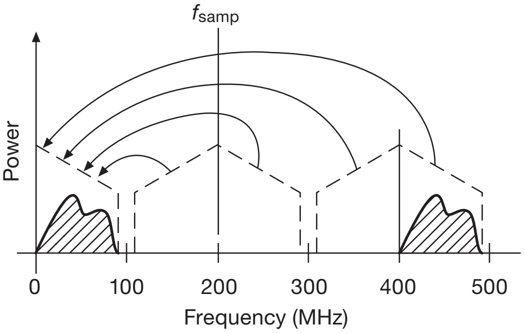

Figure 13.30. Putting the alias to work: a sampling rate of 200 Msps properly samples signals in the "baseband" extending to 100 MHz; but it creates aliases of successive 100 MHz bands. You can use this to your advantage by filtering out all input signals except those in the 400–500 MHz band (for example); that band is then properly digitized, and appears as a 0–100 MHz signal stream.

seek out a faster amplifier IC, such as an ADA4937, with a 440 MHz V_{ocm} spec.

[37] Sometimes called "super-Nyquist operation." See, for example, Application Note AN-939 from Analog Devices.

[38] A related part, the ADC08B200, includes a 1024-byte output buffer, a handy thing if you want to sample in bursts and need to read the output stream at less than full speed.

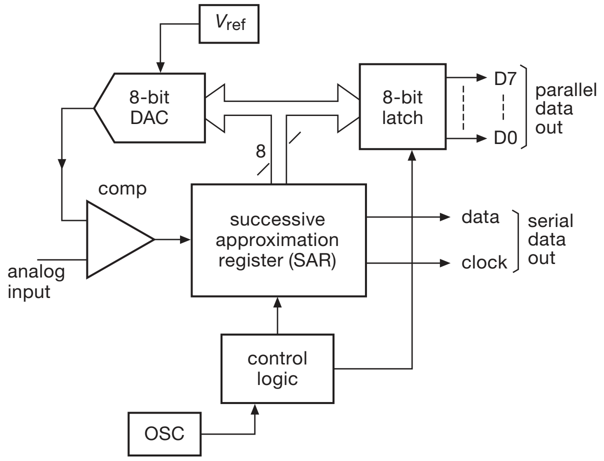

Figure 13.31. Successive-approximation ADC.

of 100 Ω resistors terminates the signal input with the usual 50 Ω expected by RF signals.

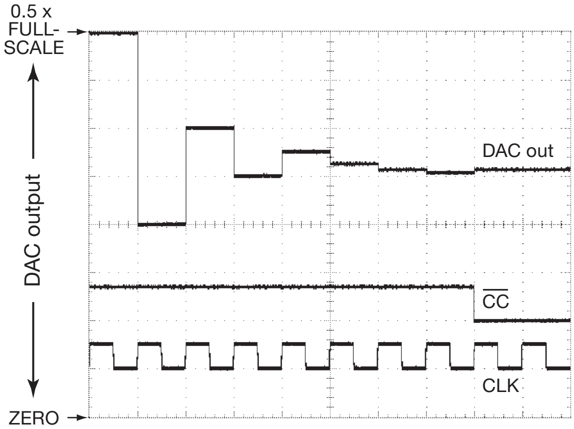

Figure 13.32. ’Scope trace of an 8-bit successive-approximation DAC’s analog output converging to the final value. It’s a binary search, with first guess equal to half of full scale. Note clock waveform and conversion-complete flag.

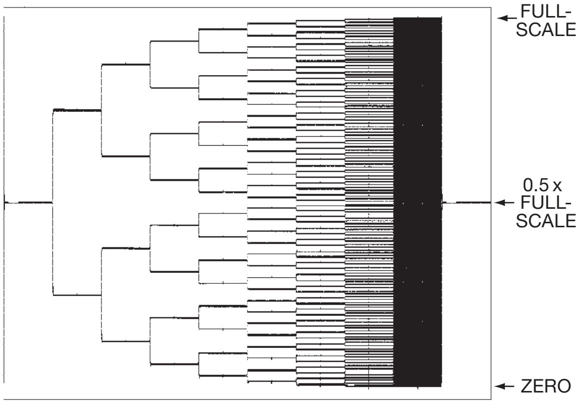

Figure 13.33. Accumulated ’scope trace of the 8-bit SAR’s full “tree.”

13.7 ADCs II: Successive approximation

In the classic successive-approximation technique (sometimes called “SAR”) you try various output codes by feeding them into a DAC and comparing the result with the analog input present at an input comparator (Figure 13.31). The way it’s usually done is to set all bits initially to 0. Then, beginning with the most significant bit, each bit in turn is set provisionally to 1. If the D/A output does not exceed the input signal voltage, the bit is left as a 1; otherwise it is set back to 0. For an *n*-bit ADC, *n* such steps are required. What you’re doing is called a *binary search*, in the language of computer science.[39] A successive-approximation ADC has a BEGIN CONVERSION input and a CONVERSION DONE output. The digital output may be provided in parallel format (all bits at once, on *n* separate output lines), in serial format (*n* successive output bits, MSB first, on a single output line), or both.

In our electronics course the students construct a successive-approximation ADC, complete with DAC, comparator, and control logic. Figure 13.32 shows the successive outputs from the DAC, along with the eight clock pulses, as the trial analog output converges to the input voltage. And Figure 13.33 shows the full 8-bit “tree,” a pretty picture you can generate by watching the DAC output while driving the input with a slow ramp that runs over the full analog input range.

Successive-approximation ADCs are intermediate in speed and accuracy (compared with the faster flash converters, or the more accurate but slower techniques used in “delta–sigma” converters, and multislope integrating converters); see Tables 13.5 and 13.6. They require *n* settling times of the DAC for *n*-bit precision. Typical conversion times are in the vicinity of 1 μs, with accuracies of 8 to 18 bits commonly available. This type of converter operates on a brief sample of the input voltage, and if the input is changing during the conversion, the error is no greater than the change during that time; however, spikes on the input are disastrous. Although generally quite accurate,

[39] Historically this goes *way* back: in 1556 a mathematician by the name of Tartaglia proposed using a set of weights (1 lb, 2 lb, 4 lb. . . 32 lb) in just such a manner to determine the weight of an object in the minimum number of trials on a balance.

these converters require accurately trimmed resistor networks, and they can have strange nonlinearities and "missing codes." One way to prevent missing codes is to use a chain of 2^n resistors and analog switches to generate the trial analog voltages, in the manner of the resistor-string DACs of §13.2.1; this technique was used in NSC's ADC0800-series 8-bit ADCs.

In contemporary successive-approximation ADCs, the conventional resistive DAC (R–$2R$ or resistor string, used internally to generate the analog voltages for the trial codes) is usually replaced with a *charge-redistribution* DAC architecture (Figure 13.34).[40] This scheme requires a set of binary-weighted *capacitors*, which nowadays is easy enough to fabricate and trim on-chip. (So an 18-bit converter like the AD7641 contains, remarkably enough, a set[41] of 18 binary-scaled capacitors going from some C_0, $2C_0$, …, to a final $131{,}072C_0$; these capacitors are really small, with the capacitance of C_0 measured in the *femto*farads – f F, or 0.001 pF.)

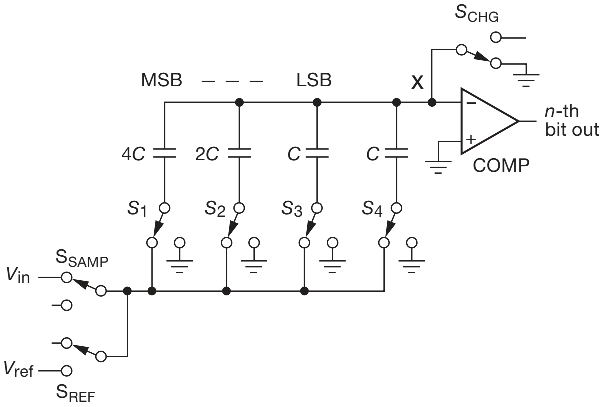

Figure 13.34. A capacitor-based "charge-redistribution" scheme replaces the R–$2R$ resistor ladder in many successive-approximation ADCs. The capacitor beyond the LSB is not used in the bit testing, but is needed to preserve the exact fractional ratios.

To understand how it works, look at the operation of the simplified 3-bit converter in the figure.

1. The switches are shown in the *sample* part of the cycle, during which the voltage across each of the capacitors follows (or *tracks*) the input signal.
2. Switch $S_{\rm SAMP}$ is opened, leaving the capacitors all holding the sampled input voltage.
3. Switch $S_{\rm CHG}$ is then opened, so the input to the comparator can move around as trial codes are applied to the bit switches S_1–S_3; for example, if the bit switches are all set to ground, the comparator input X would be at a voltage $-V_{\rm in}$.
4. Now, to measure the held value of $V_{\rm in}$, the bit switches are operated in turn: first the MSB switch S_1 is switched to $+V_{\rm ref}$ (the full-scale range of the ADC), while S_2, S_3, and S_4 are switched to ground; this adds an offset of $V_{\rm ref}/2$ to that $-V_{\rm in}$ (it's a capacitive voltage divider: call it "charge redistribution" if you prefer).
5. The comparator's output now indicates the MSB: HIGH if $V_{\rm in}>V_{\rm ref}/2$, LOW otherwise.
6. As with the classic successive-approximation procedure, that switch is either returned to ground or left at $V_{\rm ref}$, accordingly; the next-lower bit value is then tested similarly, with the process continuing in n steps (here n=3) to determine the full n-bit converted value.

13.7.1 A simple SAR example

Successive-approximation ADCs can be extremely easy to use, as illustrated by the circuit in Figure 13.35. The SPI serial interface is simplicity itself: assertion of CS′ starts conversion, with successive bits clocked out by SCK (as each clock pulse triggers the SAR conversion of a new bit). The timing allows you to keep both serial lines quiet before assertion of CS′, as shown, to minimize coupled digital noise. This family of relatively low-speed converters integrates on-chip track-and-hold, and includes three speed grades, three resolutions (8, 10, and 12 bits), and four packaging options (single, dual, quad, and octal): 36 choices! (The figure shows how to construct the part numbers.) The single units, like the 12-bit 1 Msps specimen in the figure, come in tiny SOT23-6 packages, with prices (in single quantities) ranging from about \$2 (8 bit, 200 ksps) to \$4.50 (12 bit, 1 Msps).

The input of an ADC is often less benign than something like an op-amp, where we've come to expect a high impedance (very low input current), and low capacitance. Figure 13.36 shows the equivalent input circuit of this converter, with its 26 pF sampling capacitor that the input signal must drive. This is not much of a burden at the relatively low frequencies here; but it's something to keep in mind, for example in the circuit of Figure 13.37 with its much higher resolution (18 bits) and somewhat higher speeds.

13.7.2 Variations on successive approximation

A variation known as a "tracking ADC" uses an up–down counter to generate successive trial codes; it is slow in responding to jumps in the input signal, but it follows

[40] There are also hybrid designs, in which a charge redistribution DAC is used to subdivide the steps of a coarse resistor-string DAC.

[41] Actually, *two* such sets, because its input is differential.

Table 13.5 Selected Successive-approximation A-to-D Converters[a]

Part #	ADCs per pkg	Bits	Conv Rate	Analog BW	Channels/ADC	Single-ended	Differential	Internal Ref	Interface[k]	Power		Analog Input			Supply			Pkgs, Pins				Cost	Comments

smooth changes somewhat more rapidly than a successive-approximation converter. For large changes its slew rate is proportional to its internal clocking rate. The succession of up–down bits is itself serial, a simple form of *delta modulation*.

Another variation is *CVSD* (continuously variable-slope delta modulation), a simple scheme that is sometimes used for 1-bit serial encoding of speech, for example in wireless phones. With CVSD modulation the 1s and 0s represent steps (up or down) of the input waveform, but with the step size adaptively changing according to the past history of the wave. For example, the step size corresponding to a 1 increases if the last few bits have all been 1s, according to a preset rule. The decoder knows the rule, so it can recreate an approximate replica of the (quantized) original analog input. In the past you could get CVSD chips, but in contemporary practice this is implemented in software in a microcontroller or DSP chip.

13.7.3 An A/D conversion example

Before continuing on to the important "integrating" conversion techniques (V-to-F, multislope, and *delta–sigma*), let's look at a demanding application example using a successive-approximation ADC: a low-noise, high-stability 18-bit converter with 2 Msps conversion rate.

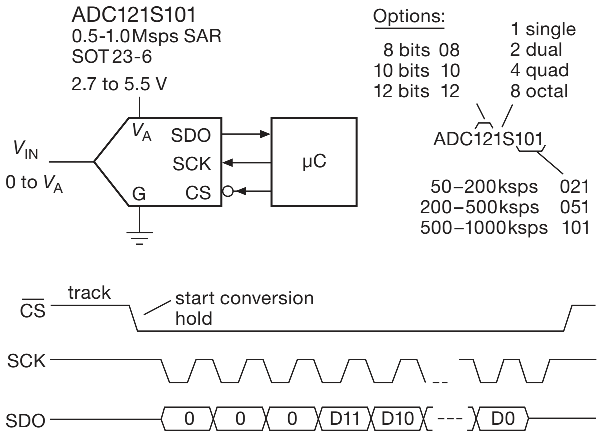

Figure 13.35. National Semiconductor's ADC08/10/12S family of simple-to-use successive-approximation ADC with SPI serial output.

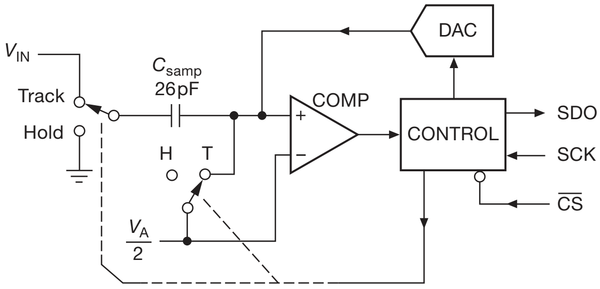

Figure 13.36. Block diagram of the ADC in Figure 13.35. The input signal drives the track-and-hold capacitor C_{samp} during acquisition.

Figure 13.37 shows a typical high-performance ADC, in this case Analog Devices' 18-bit 2 Msps PulSAR-series AD7641 converter. The AD7641 uses three positive power supplies,[42] with the nice characteristic that they may be turned on and off in any sequence.

The AD7641 has a full scale range of $\pm V_{\text{ref}}$, as is common with low-voltage ADCs. To maintain quiet conversions it's desirable to use a large voltage reference and signal voltage ranges. The AV_{DD} supply is 2.5 V, so the (differential) analog inputs are limited to 0 V to +2.5 V. If we use the maximum allowed +2.5 V reference, we get up to ±2.5 V (differential) full scale: as +IN goes from 0 V to +2.5 V, −IN will have to go from +2.5 V to 0 V (otherwise we'd have only a 17-bit converter). For an 18-bit converter this corresponds to a differential LSB step of just 19 μV. You have to take great care with such small signals, especially when the converter's sample rate is 2 MHz, and the −3dB bandwidth corresponding to its aperture time is 50 MHz – there's plenty of analog noise in these bandwidths,[43] aided and abetted by coupled digital noise from the happenings at the output end.

Both the signal and voltage reference inputs experience charge-injection pulses from the charge-redistribution conversion process, so we use sizable capacitors (the datasheet's recommended 2.7 nF) on these pins to maintain a quiet voltage.[44] Op-amps don't like direct capacitive loads, because they cause ringing in combination with the inductive closed-loop output impedance (see §4.6.2 and the section on capacitive loads in Chapter *4x*), hence the 15 Ω series resistors. This *RC* also acts as a 4 MHz low-pass filter to reduce out-of-band noise; in this bandwidth an LSB corresponds to a more relaxed noise density of 9.6 nV/$\sqrt{\text{Hz}}$. Note that the series resistor in the V_{ref} path is larger (120 Ω) because we need to limit the peak current during power-supply startup, and the dc reference does not need the bandwidth of the signal paths.

The circuit shows an amplifier setup optimized for wideband operation with a single-ended input in the range 0 V to +1.25 V. The AD8021 is a wideband low-noise op-amp that is suggested in the ADC's datasheet. This may not be the best part to use,[45] but we'll continue our narrative with the manufacturer's suggested op-amp. The amplifier pair generates an accurate unipolarity differential output from the unipolarity single-ended input: the top stage has a noninverting voltage gain of +2, and the bottom inverting stage a gain of −2. Note the low resistor values, to maintain bandwidth and also reduce Johnson noise. To help ensure equal time delays, separate signal paths are used, instead of the alternative of cascaded amplifiers. Note how the inverting op-amp is biased at $V_{\text{ref}}/3$ to create the desired +2.5 V to 0 V signal. The two op-amp pathways have different noise gains, but the AD8021 lets us add a 10 pF capacitor to its compensation node to rolloff the response to achieve approximately equal bandwidths. To deal with the op-amp's high 7.5 μA input bias current, we've rigged

[42] Separate +2.5 V pins for the analog and digital sections, and a digital I/O pin that accepts +2.3 V to +3.6 V. Low-voltage ICs often need several supply voltages, requiring separate regulators.

[43] In a 50 MHz bandwidth, 19 μV rms noise corresponds to a noise density e_n of just 2.7 nV/$\sqrt{\text{Hz}}$.

[44] Consider what's going on inside this successive-approximation ADC when operating at its full "warp-mode" speed of 2 Msps: its comparator has to make a new 19 μV decision every ~20 ns. Hectic!

[45] The choice is a bit curious, because this op-amp is not "precision" – its maximum offset voltage is an unimpressive 1 mV, and its input bias current is a rather high 7.5 μA – evidently design tradeoffs needed to achieve far more speed than is needed here (100 MHz bandwidth, 20 ns settling time).

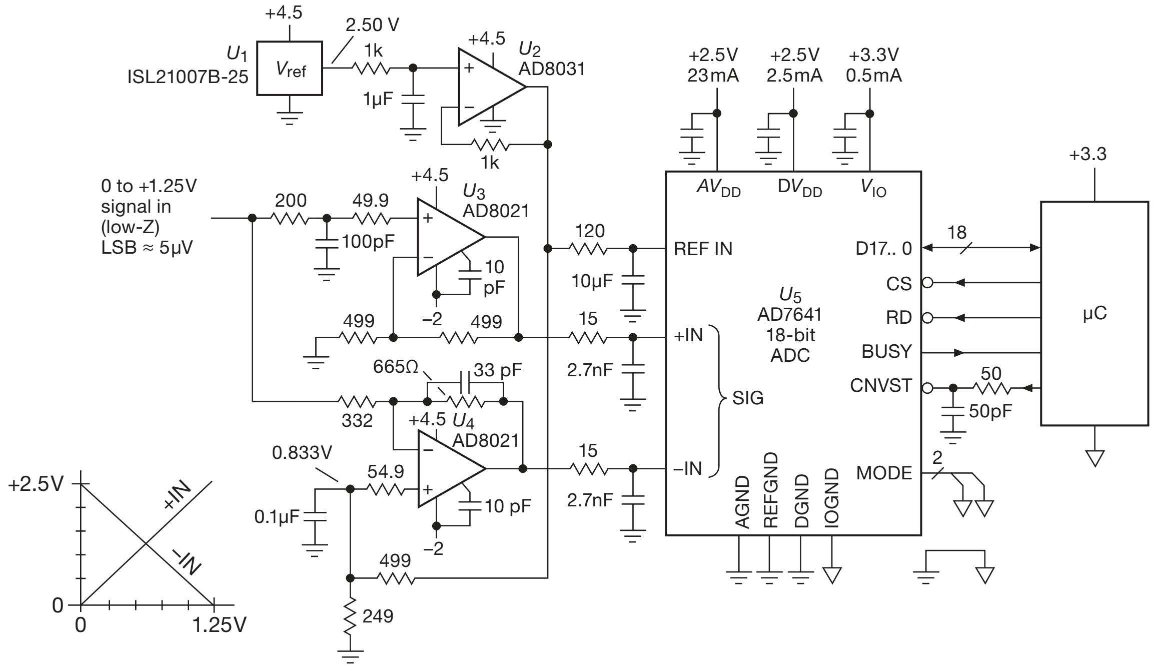

Figure 13.37. The AD7641 18-bit successive-approximation ADC, configured with fast op-amps for 2 Msps conversions.

up equal dc resistances seen at the inverting and noninverting inputs: this is effective here, because the typical offset current (0.1 μA) is 75 times smaller than the bias current itself.

The Intersil ISL21007/9BFB825 voltage reference (Table 9.8 on page 678) exploits floating-gate technology (i.e., a buried charged capacitor, §9.10.4) to achieve remarkably low drift over time ($<10\,\text{ppm}/\sqrt{\text{kHr}}$). It has excellent initial accuracy (0.02%), and low tempco (3 ppm/°C). We've added a noise-quieting filter, and an op-amp is used to buffer the 3.3 mA load current to minimize power dissipation in the reference IC. The op-amps are powered from +4.5 V and −2.0 V, derived from the same ±5 V power that provides the regulated dc for the ADC (Figure 13.38), so that the op-amps are powered up at the same time as the ADC, thus minimizing clamp currents in the converter's input diodes at startup. Another way to prevent ADC input overdrive is to use a clamping op-amp like the AD8036, but this part has even larger dc errors than the AD8021. But there's a nice solution here, namely to clamp the C_{COMP} pin of the AD8021 op-amp with a pair of low-capacitance (2 pF) SD101 Schottky diodes, one to ground and the other to the ADC's +2.5 V supply, as shown in Figure 13.39.[46]

The AD7641 converter is shown in its 18-bit parallel data mode, selecting by grounding both MODE pins.[47] The CNVST′ start-conversion signal is *RC* filtered (2.5 ns) to slow its fall-time and help prevent undershoot, etc., as suggested by Analog Devices. The CNVST′ signal should not return to the HIGH state until conversion is finished, about 400 ns in its high-speed "warp" mode.

13.8 ADCs III: integrating

13.8.1 Voltage-to-frequency conversion

We continue our tour of A/D conversion techniques with the V-to-F (or V/F) converter. In this method an analog input voltage is converted to an output pulse train whose frequency is proportional to the input level. This can be done simply by charging a capacitor with a current proportional to the input level and discharging it when the ramp reaches a preset threshold. For greater accuracy, a feedback method is generally used. In one technique you compare

[46] The AD8021 datasheet does not tell you about this trick. But it does show a simplified schematic, from which you can see that the signal at the C_{COMP} pin is the (high-impedance) output of the gain stages, on its way to the zero-offset complementary emitter followers that form the output stage (Figure 13.39); i.e., it is a clampable high-*Z* replica of the output signal.

[47] The other choices are 16-bit parallel (two READ cycles), 8-bit parallel (three READ cycles), or SPI (clocked out over 18 clock cycles).

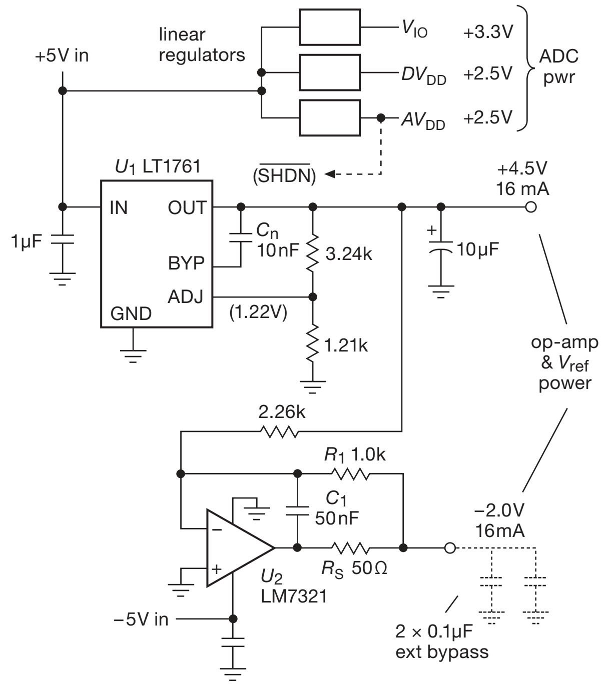

Figure 13.38. Linear regulators provide low-noise dc for the op-amps and ADC. The LM7321 is a high-current op-amp, good for 50 mA of output current. The split-feedback path (crossover at ~3 kHz) keeps it stable into the capacitive load of the op-amps' bypass capacitors while maintaining dc accuracy.

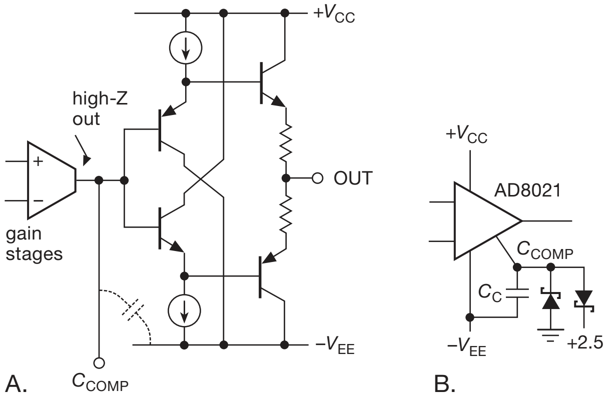

Figure 13.39. The compensation pin of some op-amps can be used to clamp the output signal. A. The AD8021's output stage is a push–pull arrangement of "zero-offset" complementary followers, with the C_{COMP} pin connected at the high-impedance output of the high-gain transconductance stages. B. Clamping that node with Schottky diodes limits the output swing to the reference voltages, here set to the ADC's conversion range.

the output of an F/V circuit with the analog input level and generate pulses at a rate sufficient to bring the comparator inputs to the same level. In the more popular methods, a "charge-balancing" technique is used, as will be described in greater detail later (in particular, the "capacitor-stored charge-dispensing" method).

Typical V/F output frequencies are in the range 10 kHz to 1 MHz for full-scale input voltage. Commercial V/F converters are available with the equivalent of 13-bit resolution (0.01% accuracy); they are examples of high-quality voltage-controlled oscillators (§7.1.4D). For example, the excellent AD650 from Analog Devices has a typical nonlinearity of 0.002% when operating from 0 to 10 kHz. They are inexpensive, and they are handy when the output is to be transmitted digitally over cables or when an output frequency (rather than digital code) is desired. If speed isn't important, you can get a digital count proportional to the average input level by counting the output frequency for a fixed time interval. This technique is popular in moderate-accuracy (3-digit) digital panel meters.

A VCO like the AD650 is an *asynchronous* V-to-F converter: Its oscillation is free running and internally generated, and it has no clocking input. But you can do things differently, namely by having a clock input and gating through clocking pulses such that the *average rate* coming out is proportional to an analog input voltage. For such a *synchronous* V/F converter, the output pulses, when present, occur coincident with the input clock; but the pulses are present or absent, as needed to keep their average rate proportional to V_{in}. In general the pulses are not equally spaced (though their spacings are exact multiples of the input clock period); that is, you don't get a single frequency out. The pulse train has "jitter." That's fine for some applications, particularly those that inherently average the output; an example is a resistive heater element, perhaps within a temperature controlled loop with an analog temperature sensor.

We rigged up an AD7741 synchronous V/F converter, clocked at 5 MHz, and measured its output frequency (averaged over several seconds) versus input voltage. It's pretty good (Figure 13.40).

The synchronous V/F converter is a simple example of a "1-bit" ADC. There are better ways to generate a bitstream whose average value represents the conversion of an analog input signal. In particular, the so-called *delta–sigma* converters do a far better job. Better job, but quite a bit harder to wrap your brain around. We'll get to these shortly, in §13.9, where we'll try valiantly (but perhaps unsuccessfully) to deconfuse the situation.

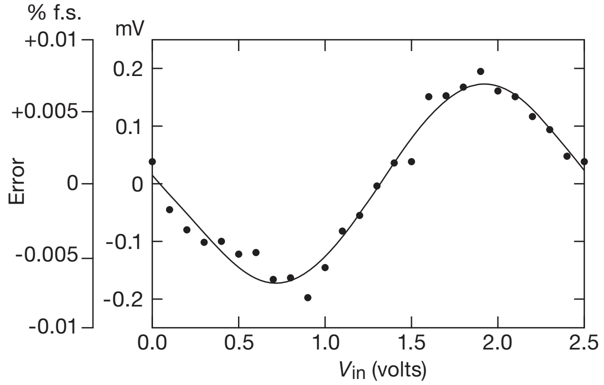

Figure 13.40. Measured nonlinearity of an AD7741 synchronous V/F converter as a function of input voltage. The specified linearity is ±0.015%.

13.8.2 Single-slope integration

In this technique an internal ramp generator (current source + capacitor) is started to begin conversion, and at the same time a counter is enabled to count pulses from a stable clock. When the ramp voltage equals the input level, a comparator stops the counter; the count is proportional to the input level, i.e., it's the digital output. Figure 13.41 shows the idea.

At the end of the conversion the circuit discharges the capacitor and resets the counter, and the converter is ready for another cycle. Single-slope integration is simple, but it is not used where high accuracy is required because it puts severe requirements on the stability and accuracy of the capacitor and comparator. The method of "dual-slope integration" eliminates that problem (and several others as well) and is now generally used where precision is required.

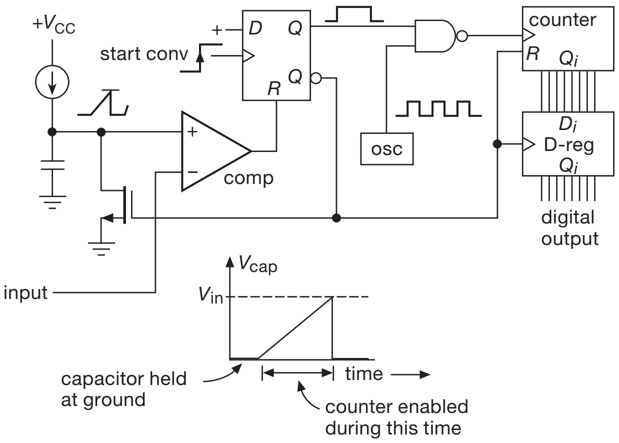

Figure 13.41. Single-slope ADC.

Single-slope integration is still alive and well, particularly in applications that don't require absolute accuracy, but rather need conversion with good resolution and uniform spacing of adjacent levels. A good example is pulse-height analysis, where the amplitude of a pulse is held (peak detector) and converted to an address. Channel-width equality is essential for this application, for which a successive-approximation converter would be totally unsuitable. The technique of single-slope integration is also used in time-to-amplitude conversion (TAC).

13.8.3 Integrating converters

There are several techniques that have in common the use of a capacitor to keep track of the ratio of an input signal level to a reference. These methods all average (integrate) the input signal for a fixed time interval for a single measurement. There are two important advantages.

1. Because these methods use the same capacitor for the signal and reference, they are relatively forgiving of capacitor stability and accuracy. These methods also make fewer demands on the comparator. The result is better accuracy for equivalent-quality components, or equivalent accuracy at reduced cost.
2. The output is proportional to the *average* input voltage over the (fixed) integration time. By choosing that time interval to be a multiple of the powerline period, the converter becomes insensitive to 60 Hz powerline "hum" (and its harmonics) on the input signal (Figure 13.42).

This nulling of 60 Hz interference requires accurate control of the integration time, since an error of even a fraction of a percent in the clock timing will result in incomplete cancellation of hum. One possibility is to use a crystal oscillator. An elegant alternative is the use of a *phase-locked loop* (§13.13) to synchronize the workings of an integrating converter to a multiple of the powerline frequency, making the rejection perfect.

These integrating techniques have the disadvantage of slow speed, as compared with successive approximation; but they excel in precision, particularly in dual-slope or multislope incarnations, or as sophisticated delta–sigma converters (§13.9).

13.8.4 Dual-slope integration

This elegant and very popular technique eliminates most of the capacitor and comparator problems inherent in single-slope integration. Figure 13.43 shows the idea. First, a current accurately proportional to the input level charges a

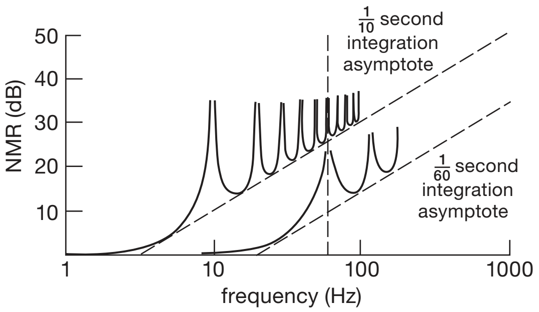

Figure 13.42. Normal-mode rejection with integrating A/D converters.

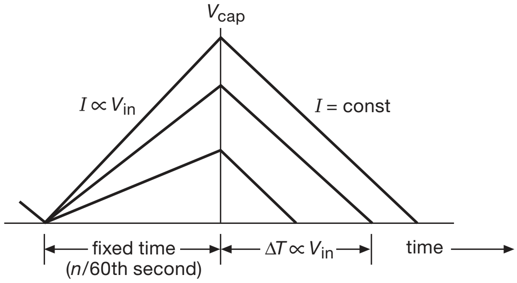

Figure 13.43. Dual-slope conversion cycle.

capacitor for a fixed time interval; then the capacitor is discharged by a constant current until the voltage again reaches zero. The time to discharge the capacitor is proportional to the input level and is used to enable a counter driven from a clock running at a fixed frequency. The final count is proportional to the input level, i.e., it's the digital output.

Dual-slope integration achieves very good accuracy without putting extreme requirements on component stability. In particular, the capacitor value doesn't have to be particularly stable, because the charge cycle and the discharge cycle both go at a rate inversely proportional to C. Likewise, drifts or scale errors in the comparator are cancelled out by beginning and ending each conversion cycle at the same voltage and, in some cases, at the same slope. In the most accurate converters, the conversion cycle is preceded by an auto-zeroing cycle in which the input is held at zero. Because the same integrator and comparator are used during this phase, subtracting the resulting "zero-error" output from the subsequent measurement results in effective cancellation of errors associated with measurements near zero; however, it does not correct for errors in overall scale.

Note that even the clock frequency does not have to be of high stability in dual-slope conversion, because the fixed integration time during the first phase of the measurement is generated by subdivision from the same clock used to increment the counter. If the clock slows down by 10%, the initial ramp will go 10% higher than normal, requiring 10% longer ramp-down time. Since that's measured in clock ticks that are 10% slower than normal, the final count will be the same! Only the discharge current has to be of high stability in a dual-slope converter with internal auto-zeroing. Precision voltage and current references are relatively easy to produce, and the (adjustable) reference current sets the scale factor in this type of converter.

When choosing components for dual-slope conversion, be sure to use a high-quality capacitor with minimum dielectric absorption ("memory" effect; see §5.6.2 and the expanded discussion in §*1x.3*) – polypropylene, polystyrene, or Teflon capacitors work best. Although these capacitors are not polarized, you should connect the outside foil (indicated with a band) to the low-impedance point (the output of the integrator op-amp). To minimize errors, choose integrator R and C values to use nearly the full analog range of the integrator. A high clock frequency improves resolution, although you gain little once the clock period becomes shorter than the comparator response time.

When using precision dual-slope converters (and, indeed, any kind of precision converter) it is essential to keep digital noise out of the analog signal path. Converters usually provide separate "analog ground" and "digital ground" pins for this purpose. It is often wise to buffer the digital outputs (say with a '541 three-state octal driver, asserted only when reading the output) to decouple the converter from the digital roar of a microprocessor bus (see Chapters 14 and 15). In extreme cases you might use opto-couplers (§12.7) to quarantine the noise of a particularly dirty bus. Be sure to use liberal power-supply bypassing right at the converter chip. And be careful not to introduce noise during the critical endpoint of the integration, as the ramp reaches the comparator trip point. For example, some converters let you check for end-of-conversion by reading the output word: *don't do it!*[48] Instead, use the separate BUSY line, suitably isolated.

Dual-slope integration is used extensively in precision digital multimeters. It offers good accuracy and high stability at low cost, combined with excellent rejection of powerline (and other) interference, for applications where speed is not important. The digital-output codes are strictly monotonic with increasing input.

The alternative, for highest precision, is the delta–sigma

[48] OK, if you insist, go ahead and check it – but only after you're sure it's done.

converter. There's a lot of confusion surrounding this elegant technique. In a subsequent section (§13.9) we aim to blow away the smoke and provide some intuition into the workings of these things. First, though, a look at the ultimate in integrating converters – the so-called "multislope" technique devised by Hewlett–Packard (subsequently Agilent, now Keysight), and commercialized in their world-class $8\frac{1}{2}$-digit multimeters – preceded by a relevant detour into the use of analog switches in conversion applications.

13.8.5 Analog switches in conversion applications (a detour)

Analog switches, first seen in §3.4.1, figure importantly in conversion applications, both as components of the converter itself (see, e.g., Figures 13.2, 13.9,, 13.34, and 13.36), and as external helpers. In their former role they are an essential part of the precision multislope converter (§13.8.6), and of the delta–sigma converter (§13.9). Here we explore briefly some converter applications in which a discrete logic-family CMOS analog switch is particularly useful.

A. Logic-family analog switches

The widely available '4051 to '4053 family of CMOS switches is particularly useful for analog applications, because these parts have a negative V_{EE} supply line for the switches, along with internal logic-level shifters; so the switches work over an analog range of $-V_{EE}$ to $+V_{DD}$, and in fact an additional 0.25 V or so beyond these supply rails. Table 13.7 shows the logic families in which these switches are available. There are three parts in the family: the '4053 is especially attractive, with its three independently controlled SPDT switches; there's also the '4052 with a pair of 4-to-1-line switches, and the 4051 with a single 8-to-1 switch. Although these switches are attractive because they are inexpensive (less than $0.50) and available from a half-dozen companies, they're even more attractive to designers because they're very fast, and have low capacitance.

For example, the 74HC4053 typically has 40 Ω of ON resistance, switches in 20 ns, and has 8 pF of capacitance to ground. Compared with ICs officially intended for analog switching and multiplexing, a '4053 has a more limited voltage swing, and no electrostatic discharge (ESD) protection. When compared with CMOS power switches, it has higher ON resistance, but it doesn't suffer from their high capacitance. It's in a sweet spot that's ideally suited for switching signals between the circuits on the same circuit board.

Single SPDT versions are available in space-saving SOT23 and other SMT packages. These parts, for example the '1G3157 types (the 1G means single gate), do not

include the negative supply feature, so they do not use “4053” in their name.

Let’s look at two examples in which ’4053-style switches form a nice bridge between the analog and digital worlds. The second example (sawtooth generation with current-steering switches) will take us directly to the multislope and delta–sigma converters.

B. Programmable high-voltage pulse generator

It’s nice to be able to generate a pulse that is gated by a logic signal, but whose amplitude is set separately. For the latter you might use a DAC under computer control, or maybe just a panel knob.[49] The simple circuit in Figure 13.44 does the job, in this case allowing output amplitudes up to +100 V.

The ’4053-style analog switch applies the level selected by panel switch S_1 to the OPA454 high-voltage op-amp, here configured for a noninverting gain of 20. This op-amp is not terribly fast ($\sim 10\,\mu$s switching times), but it’s quite inexpensive ($5), and it can supply 100 mA pulsed outputs to charge capacitive loads. You could substitute a faster op-amp to exploit the fast switching capability (~ 20 ns) of the analog switch.[50] Center-off panel toggle switch S_2 lets you turn pulses on or off, or enable continuous switch conduction for reading and setting the high-voltage (HV) level with a DMM, etc. We are fond of easy-to-use instruments that combine panel controls with CMOS signal switching.

C. Current-steering sawtooth generator

Here’s a circuit (Figure 13.45) that exploits the nice switching characteristics of ’4053-style analog switches, in the

[49] Back in Chapter 5 we showed a way to generate programmable high-voltage waveforms (Figure 5.47), however without the gating feature.

[50] For example, the Cirrus/Apex PA85 slews at 1000 V/μs (with closed-loop gain of 100), and can run from 450 V total supply. Here you could power it from +400 V and −15 V rails. Be prepared to shell out some serious cash, though: this puppy costs about $300. (See the selection of high-voltage op-amps in Table 4.2b.) A more economical solution is to build your own high-voltage amplifier, along the lines of Figure 3.111; see also the section on a precision high-voltage amplifier in Chapter *4x*.

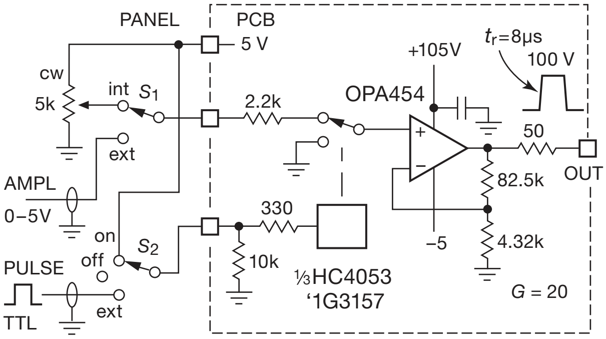

Figure 13.44. Simple high-voltage pulse generator, with programmable pulse amplitude and waveform. The ’4053 switch includes a $-V_{\mathrm{EE}}$ pin for bipolarity signal switching (to ±5 V), whereas the single-section ’3157 operates with positive polarities only.

same current-steering arrangement that’s used in the remarkable multislope converter we’ll see in the next subsection. Op-amp U_1 is an integrator, with its summing junction biased at half the supply voltage (for single +5 V supply operation). Switches S_1 and S_2 are sections of an ’HC4053, running at the same +5 V; they individually program the rising and falling ramp rates, set by resistors R_1 and R_2. Closing S_1 sources a current $V_{\mathrm{cc}}/2R_1$, causing the integrator to ramp down according to $dV_{\mathrm{ramp}}/dt = I/C$; S_2 causes an analogous upward ramp. The comparator has thresholds at 1/3 and 2/3 of V_{cc}, turning the ramp around after it goes through $\Delta V = V_{\mathrm{cc}}/3$. It’s easy to show that the resulting ramp intervals are given by $t_{\mathrm{rise}} = \frac{2}{3}R_2C$ and $t_{\mathrm{fall}} = \frac{2}{3}R_1C$, and $f = 1.5/C(R_1 + R_2)$.

Exercise 13.4. Go ahead, show it!

Both the switches and the comparator are fast, permitting operation to at least a few megahertz, for which suitable values might be resistors of a few thousand ohms, and C in the range of 100–500 pF. With such a small integrator capacitor, you have to worry about the effects of the switch capacitance C_{sw}, typically in the range of 5–10 pF. Consider for example switch S_1, in the position shown in the figure: its capacitance is charged to +5 V, and so it transfers a slug of charge $\Delta Q = C_{\mathrm{sw}}\Delta V$ (where $\Delta V = V_{\mathrm{cc}}/2$) to the summing junction when the switch moves to the lower terminal. That charge transfer causes a step in the integrator’s output, as in Figure 13.46. The cure here (and in the multislope ADC we’ll see next) is to hold the other switch terminal at the same voltage as the summing junction (the dotted circuit).

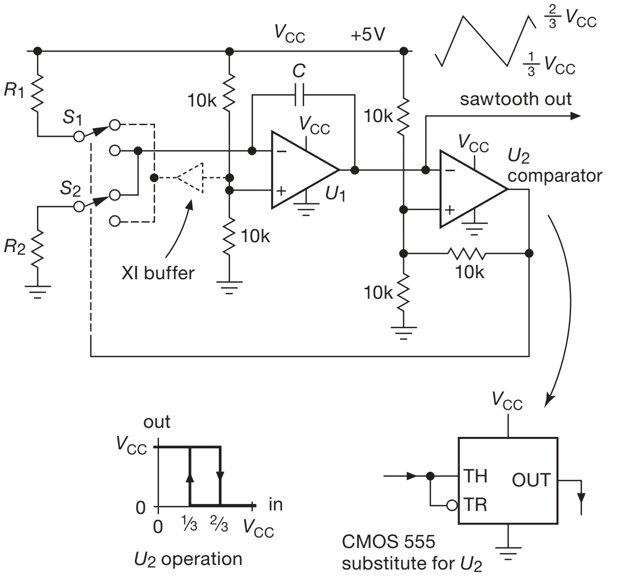

Figure 13.45. Sawtooth generation with current-steering switches. Comparator U_2 is configured as a Schmitt trigger with thresholds at $V_{\mathrm{cc}}/3$ and $2V_{\mathrm{cc}}/3$, for which a suitable part (with active rail-to-rail outputs) is the fast TLV3501 (t_{p}=4.5 ns); a CMOS 555 could be substituted, though it’s not nearly as fast (t_{p}=100 ns).

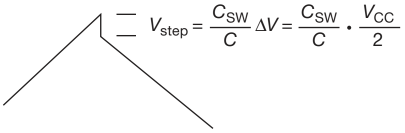

$V_{\mathrm{step}} = \frac{C_{\mathrm{SW}}}{C}\Delta V = \frac{C_{\mathrm{SW}}}{C} \cdot \frac{V_{\mathrm{CC}}}{2}$

Figure 13.46. Charge injection produces a step change in integrator output, when a circuit node (of capacitance C_{sw}) at a different voltage is switched on.

13.8.6 Designs by the masters: Agilent’s world-class “multislope” converters

With these analog-switch applications in mind, we’re in good shape to understand the “multislope” techniques used in instruments like the Keysight[51] 34420 $7\frac{1}{2}$-digit and 3458A $8\frac{1}{2}$-digit multimeters.[52] This has been Agilent’s top-of-the-line instrument for more than twenty years, with a current price (year 2015) of $9.5k. A simplified variant (“Multislope III”) is used in Keysight’s contemporary high-performance DMM series of instruments (the 34420A 7.5-digit nanovolt and micro-ohm meter, the 34401A 6.5-digit

[51] Formerly Agilent, 1999–2014, and prior to that Hewlett–Packard or “HP,” 1939–1999.

[52] The latter described on their website as “Recognized the world over as the standard in high performance DMMs.”

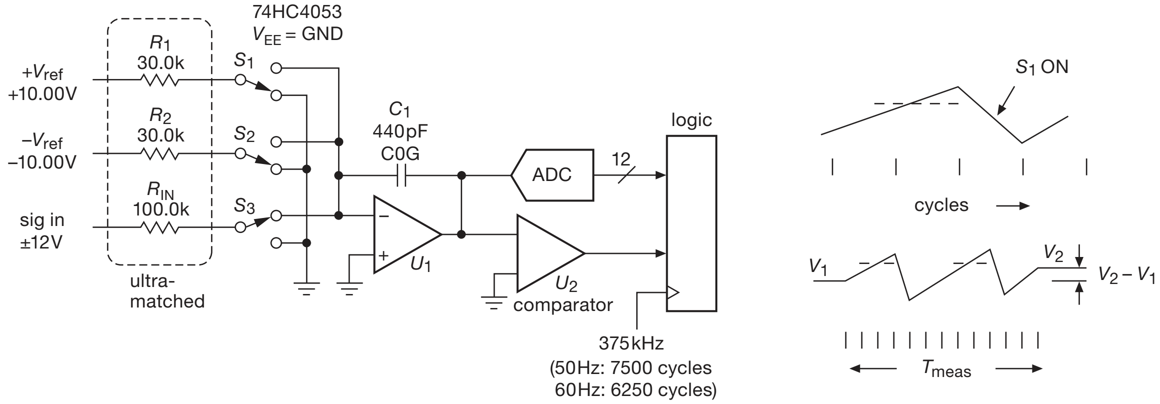

Figure 13.47. Keysight's "Multislope III" converter, a clocked charge-balancing integrator with endpoint correction via a low-precision ADC.

industry-standard bench DMM, and the 34970A 6.5-digit data-acquisition system). We'll see in detail how Multislope III works, and reveal a bit of the operation of next-generation Multislope IV (introduced in 2006).

A. The basic technique

To put it in perspective, the multislope technique is an evolution of the dual-slope integrator, exploiting a multicycle charge-balancing integration scheme that is both more forgiving of capacitor imperfections, and that takes account of the residue remaining after the final cycle of integration. It blends aspects of dual-slope and delta–sigma conversion, and it is a natural stepping-stone to the latter.

The basic circuit is extremely simple (Figure 13.47) and uses mostly low-cost parts (except for the voltage references and precision resistors). There's an integrator U_1, a "logic engine" that keeps track of the integrator output (via comparator U_2) at each 375 kHz clock tick, and a pair of switches (S_1 and S_2) that are operated synchronously by the logic to keep the integrator approximately balanced (by sinking or sourcing an accurate current into the integrator). There's also an ADC of only modest precision (12 bits) that is used to read the integrator's output voltage at the beginning and end of a multicycle measurement.

Here's how it works, at a basic level: to begin a measurement, switch S_3 is closed,[53] causing the integrator to ramp up or down (according to $dV/dt = -I_{\text{in}}/C_1 = -V_{\text{in}}/R_{\text{in}}C_1$). At each successive clock the logic engine causes either switch S_1 or S_2 to close (depending on the polarity of the integrator's output), thus adding or subtracting the corresponding reference current ($\pm 10\,\text{V}/30\,\text{k}\Omega$) to force the integrator to come back toward ground. This goes on for many clock cycles (for maximum rejection of powerline pickup it's desirable to use a measurement time corresponding to an integral number of powerline cycles; e.g., 6250 clock ticks equals 1/60 of a second), after which the logic tallies up the number of positive (n_+) and negative (n_-) cycles. This gives a *first-order* estimate of the average input voltage during the measurement time:

$$V_{\text{sig}}(1) \approx V_{\text{ref}} \frac{n_- - n_+}{N_{\text{cycles}}} \frac{R_{\text{in}}}{R_1} = V_{\text{ref}} \frac{n_- - n_+}{6250} \frac{100\text{k}}{30\text{k}}.$$

This is not terribly accurate: a full-scale input of ±12 V produces a net count ($n_- - n_+$) of ±2250 (figure out why), so the resolution is approximately 12 bits. Now for a nice trick: because the measurement is timed by an integral number of clock cycles (rather than by a zero crossing, as in the dual-slope method), the residual integrator level contains additional information. It allows us effectively to perform a vernier-like subdivision of a clock cycle. That's the reason for the ADC in Figure 13.47, which is used to measure the integrator voltage at the beginning and end of the measurement cycle. For the 12-bit ADC in the figure, this provides some 512 levels of subdivision of the first-order LSB, adding 9 bits to the ~12-bit first-order estimate, for a final result of ~21 bit resolution.[54]

More precisely, the second-order (and final!) answer is given by

$$V_{\text{sig}}(2) = V_{\text{sig}}(1) + \frac{R_{\text{in}}C_1}{T_{\text{meas}}}(V_{\text{f}} - V_{\text{i}}) = V_{\text{sig}}(1) + 0.00264(V_{\text{f}} - V_{\text{i}}),$$

[53] We use the term "closed" to mean that a given switch is connected to the summing junction.

[54] The ADC's conversion range matches that of the integrator, but both are ~8× larger than the integrator's ramp over a clock tick when the input signal is at ±full scale. That is why the ADC effectively loses 3 bits of resolution when digitizing the residue ($V_{\text{f}} - V_{\text{i}}$).

where the coefficient of the ΔV "vernier" term represents the decreasing contribution of the endpoint correction with increasing measurement time. More specifically, it's easy to show that the ΔV term by itself yields the correct input voltage for a measurement whose duration equals a single clock cycle (i.e., $T_{\text{meas}} = 1/f_{\text{clk}}$).

Exercise 13.5. Take the challenge: show that this is correct.

B. Details, details...

That's the top-level view of the multislope conversion technique. There is much more to say – there's the usual devil in the details; and there are many possible refinements, to squeeze the most performance from this core idea. Here we restrain ourselves, restricting our commentary to a terse summary of the more interesting and instructive aspects.

Noncritical components For S_1–S_3, Agilent uses a standard 74HC4053 switch array (from NXP), and for C_1 a commodity ceramic chip capacitor of the stable NP0/C0G variety (from AVX). This type of capacitor, which is stunningly inexpensive,[55] exhibits a low temperature coefficient (±30 ppm/°C) and negligible dielectric absorption ("memory," see Figure 5.4 in §5.6.2 and the more extensive figures in §*1x.3*), unmeasurable on the switching time scales here. Likewise, no great accuracy or stability is needed for the comparator or endpoint-quantizing ADC.

Critical components The voltage references set the scale of the measurement, and must be highly stable. In practice these instruments use a single 7.0 V zener-type reference and a pair of precision op-amps to produce the ±10.0 V reference voltages.[56] The "10.0 V" voltage does not need to be precise to the ultimate accuracy of the instrument, which undergoes a factory calibration; it does need to be *stable*, of course, to maintain that calibrated accuracy.[57]

Two other critical components are the matched resistor arrays (R_1–R_3, and the gain-setting resistors in the voltage references) and the integrator op-amp. The latter is in fact a composite amplifier (an OP27+AD711), achieving high slew rate and high loop gain along with very low offset voltage (Figure 13.48). The resistors are specially packaged arrays for close matching and tracking. What matters here is the drift (over time and temperature) of the resistor ratios, because minor mismatches in the initial resistor ratios are handled in the factory calibration.

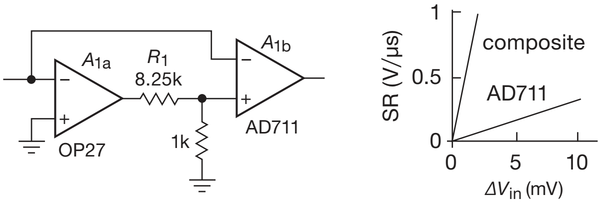

Figure 13.48. A "composite amplifier" greatly increases slew rate. The interstage attenuator's 8.25k (nominal) value is chosen large enough to ensure U_1's stability

Not shown, but just as critical, is the selectable-gain input amplifier. It must have precise and stable gains, and means to carry out calibrations and corrections; see §5.12.

The switches The 74HC4053 switch is used in a current-steering scheme like that in Figure 13.45, arranged so that the voltages on all of the '4053 switch pins remain always close to zero volts. The switches serve only to steer the currents, adding or subtracting a slew rate to the integrator output that is in a precise ratio to the slew rate produced by an input voltage. The on-resistance of the switches does, of course, figure into the value of these currents. But as long as the R_{on} of the switches is well matched, stable, and small compared with R_1–R_3, the effect is corrected by the calibration cycle that the instrument performs automatically before each measurement (see next paragraph). For the NXP 'HC4053 used in the Keysight instruments, for example, R_{on} is typically 85 Ω, matched to 8 Ω. It's important that these switches operate as "break-before-make," so that their output terminal pairs are not momentarily shorted (which would connect the integrator summing junction to ground, acting like a differential input signal equal to the op-amp's offset voltage). Some manufacturers include such a specification, others don't. For example, the same NXP datasheet specifies turn-ON and turn-OFF times, whose difference represents a break-before-make interval of 4 ns; but it does not specify that interval directly, whereas the DG4053 datasheet from Siliconix lists a "Break-Before-Make Time Delay" t_{D} of 6 ns typ (2 ns min).

Calibration The simple current-switched input topology is well suited to calibrating, and eliminating, the effects of resistor ratio mismatches, voltage reference

[55] $0.06 in 100-piece quantities, some 50,000 in stock at DigiKey this morning.

[56] We are told by reliable sources that Keysight uses the spectacular LTZ1000, see §9.10.1B.

[57] For the 34401A standard bench DMM, for example, the initial factory-calibrated dc accuracy is within ∼2 ppm; it is specified to drift no more than ±0.0015% over 24 hours, but ±0.0035% after one year.

mismatches, op-amp offsets, switch delays, and the like. For example, when S_3 is turned off (i.e., no input signal) and S_1 and S_2 are alternated for some number of successive cycles, the endpoint ΔV is a measure of the mismatch of positive and negative reference currents. Likewise, by routing V_{ref} to the signal input and performing a voltage measurement, you get a measure of the mismatch of signal and reference currents. The Keysight instruments perform a suite of such calibrations before each measurement on its higher-resolution settings (where it makes a difference). Of course, there's no way it can determine the drift of its primary voltage reference; for that you need an external source of known voltage. This is the business model of calibration laboratories.

Measurement interval We used the example of a measurement time T_{meas} equal to the period of one powerline cycle (PLC), in this case 6250 cycles of 375 kHz, or 1/60 of a second. A measurement time that is an integral number of PLCs ("NPLCs") powerfully rejects coupled interference, and the longer measurement times improve the ultimate accuracy; see Table 13.8. But, as the table shows, you can make more rapid measurements, at the expense of powerline rejection and of accuracy.[58] It's also possible to make *continuous* measurements, in which signal switch S_3 is always on (in this mode the endpoint ADC must take accurately timed samples).

"*Multi*multislope" Circling back to the original game-changing HP3458A 8.5-digit DMM, it uses an amusing bit of trickery: it has four sets of input resistors and switches, such that it can reduce the integrator slew rate dramatically (by a factor of ~600) as it nears the endpoint.[59] Oddly, it does not measure the endpoint residue; it ramps down to 0 V instead, missing out on a very powerful trick.

Miscellany There's a lot of detail in the final implementation of this conversion technique, as described in the service manuals and *HP Journal* articles, as well as the relevant patents.[60] For example, it's necessary only to prevent integrator saturation; so you can use more than one comparator, and turn on the reference current switches (S_1 and S_2) only as needed to keep the integrator in range. This minimizes the number of switching cycles and the errors that go with it. There are also some curious circuit quirks; for example, there are lossy ferrite beads on the '4053 analog outputs, and there's a capacitor from the integrator summing junction to ground. Go figure. . . .

Evolution of the technique In 2006 Agilent introduced faster "Multislope IV" versions,[61] the 34410A, 34411A, and the 34972A, all with USB and Ethernet data links; they cost more, and the classic 34401A and 34970A were reduced in price. They subsequently introduced the 34460A and 34461A models, with additional features such as display-panel signal processing and sensor interfaces (the 34461A has the same measurement speeds and capabilities as the 34401A, listed in Table 13.8). The 34420A remained the only 7.5-digit (20 ppm) meter in the lineup, and was not upgraded.

Table 13.8 Keysight's Multislope-III ADCs[a]

measurement duration			digits[d]	rdgs per sec[c]	50/60Hz reject[e]
(PLC[b])	(ms[c])	(clocks[c])			(dB)
0.024	0.4	150	4.5	1000	–
0.2	3	1500	5.5	300	–
1	16.7	6250	5.5	60	60
10	167	62.5k	6.5	6	95
100	1.67s	625k	6.5[f]	0.6	105
200[g]	3.33s	1.25M	7.5	0.3	110

Notes: (a) 34401A DMM, 34420A MicroVolt, 34970A DAQ. (b) powerline cycles; selectable 50/60Hz via setup menu. (c) when set for 60Hz; clock rate is 375kHz. (d) reported. (e) normal-mode rejection, at selected powerline freq. (f) 7.5 digits for the 34420A. (g) 34420A only.

C. From multislope to delta–sigma

The multislope converter takes us naturally to the wildly popular delta–sigma conversion technique, with which it has much in common. At the most basic level, both are

[58] Improving on the basic multislope technique, the recent Keysight 34411A bench DMMs do better: 1000 readings/s at 6.5-digit resolution, and 50,000 readings/s at 4.5-digit resolution.

[59] This suite of slopes may be the origin of the "multi" in multislope. They created the name "Multislope III" for the subsequent (and simpler) scheme outlined earlier.

[60] *HP Journal*, April 1989; US patents 4,357,600 and 4,559,521.

[61] Looking at Multislope IV waveforms with a scope, you see a much different beast. A_{1b} has been replaced with a faster AD829 op-amp (120 MHz, 230 V/μs), with the integrating capacitor C_1 reduced by 5×. A hardware engine forces the error integrator to produce consistent 10 Vpp ramps with a 2 μs period, using coarse data from an 80 MHz AD9283 converter digitizing the 10 V ramp at 14 ns intervals, and fine data from an AD9200 10-bit converter with a limited 2 V range, clocked at 75 ns intervals near zero volts. Slope changes and the counter record are made at 75 ns intervals, and the AD9200 makes starting and ending readouts with 0.02% resolution. As a result, a Multislope IV converter can measure 4.5 digits in 20 μs (0.001 PLC), or 20× faster than Multislope III.

integrating methods in which a discrete offset is applied to the input at periodic intervals, based on the integrator's output level. As we'll see, however, the delta–sigma technique has several subtle tricks up its sleeve, enabling it to deliver astonishing performance.

13.9 ADCs IV: delta–sigma

Now, finally, an extended section on what has become a favorite A/D (and sometimes D/A) conversion technique: the "delta–sigma" converter. These things are confusing, but they're worth some serious effort to understand, because they deliver top-notch performance in resolution and accuracy (e.g., monotonic to 31 bits or more) from "voltmeter" through audio speeds and beyond. Their "oversampling" architecture greatly simplifies the input anti-alias lowpass filter, and performs some magic in shifting the noise spectrum out of the passband. And they provide this performance at surprisingly low cost. In the coming subsections we introduce the basic idea; then we take a serious look at how these converters deliver performance far better than would appear possible. We conclude with some application examples.

13.9.1 A simple delta–sigma for our suntan monitor

To get started, let's revisit the saga of our suntan monitor (see §§4.8.4; to be revisited yet once again, and finally set to rest, in §15.2), this time implemented with the simplest delta–sigma digital integrator. Figure 13.49 shows the implementation, using a clocked charge-dispensing integrator that operates in the same way as the multislope integrator. In fact, it is simpler, because it does not bother with the fractional-cycle endpoint correction: it simply accumulates the integrated sunlight dose, by counting the number of clock cycles during which it is obliged to inject a reference current (here V_{cc}/R) to balance the outgoing photodiode current $I_{\rm PD}$. Not shown here is the circuitry to sound an alarm when the preset count is reached: the reader who has come this far knows well how to do that!

This is the simplest delta–sigma integrator: it accumulates (sigma) the difference (delta) between the analog input and the measured current that is combined at the summing junction. It *could* become a complete analog-to-digital *converter* (rather than a mere *integrator*), if some circuitry were added to (a) clear the counter to begin a conversion, and (b) read the counter's value after a fixed time interval that is much longer than the clock period. Indeed, that scheme would work as an ADC. But in practice you get far better performance by replacing the counter with a digital filter; and you improve things still further by cascading several stages of difference amplifier plus integrator.

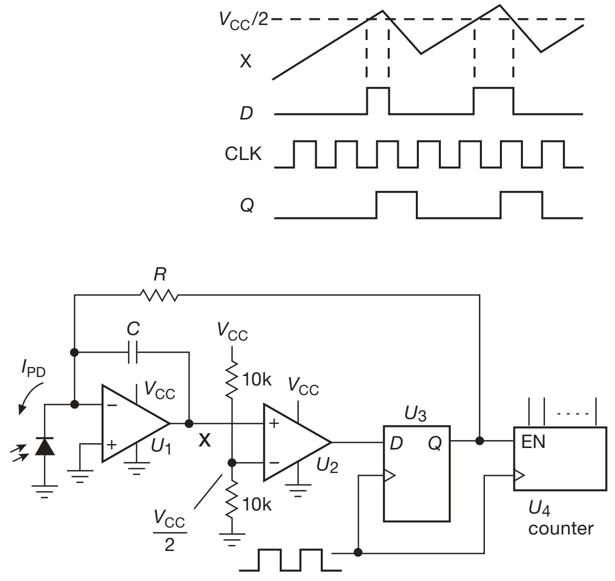

Figure 13.49. Discrete delta–sigma photocurrent-integrating suntan monitor.

We'll get to all of that, soon enough. First, though, let's take the time to understand this simplest example.

In this circuit U_1 is a single-supply op-amp that operates with inputs to (and slightly beyond) the negative rail, and U_2 is a comparator with active pullup. For a low-speed application like this you could use a dual RRIO op-amp like our favorite LMC6482, running on the same +3.3 V or +5 V supply as the digital logic. The integrator ramps up (with slope proportional to the photodiode current $I_{\rm PD}$) until the next clock rising edge at which its output is greater than $V_{\rm CC}/2$, at which point it ramps down with slope proportional to the net current at the summing junction, $V_{\rm CC}/R - I_{\rm PD}$. The result is that the duty cycle D (fraction of time that the Q output of U_3 is HIGH), averaged over many cycles, is $D{=}I_{\rm PD}R/V_{\rm CC}$, thus $I_{\rm PD}{=}DV_{\rm CC}/R$. The duty cycle D is gotten from the count N in U_4 during time interval T by $D{=}N/f_{\rm clk}T$; note that this result does not depend on the comparison voltage $V_{\rm CC}/2$ (or the voltage at point X).

The design goes like this.

(a) Choose a clock period that is much shorter than the expected baking time, for example $f_{\rm clk}$=10 Hz; faster is OK, but then you need a larger counter.

(b) Choose R to source more current than the anticipated full-scale input current; for $I_{\rm FS}$=1 μA and $V_{\rm CC}$=5 V, R must be less than 5 MΩ.

(c) Choose C to keep the maximum integrator excursion safely less than $V_{CC}/2$ during one clock cycle.

Here we might choose f_{clk}=10 Hz, R=3.3 MΩ, and C=100 nF. The integrator ramps through at most 1.5 V per clock period (at minimum I_{PD}), so it cannot saturate. The peak count rate equals the clock frequency (and the average count rate is somewhat less, in this case $0.6f_{\text{clk}}$), so a 16-bit counter is conservatively adequate for bake settings up to 2 hours full-sunlight equivalent.

Some important points.

(a) The overall calibration depends on the supply voltage V_{CC}, which we've assumed is a stable +5 V; and we've taken advantage of CMOS logic's clean saturation to the rails.

(b) Note that the integrator waveform is not accurately periodic; its excursions above and below the threshold at $V_{CC}/2$ wander somewhat, the guarantee being only that it will be turned around at the next clock following a threshold crossing. This does not, however, degrade its overall accuracy, averaged over many cycles: the integrating nature of the delta–sigma system properly keeps track of the deficits and surpluses; the integrator gets credit for its extra mileage.

(c) The dynamic range of the converter is limited by the op-amp's offset voltage, which causes an equivalent input-current error of V_{os}/R; for this design that is about 0.2 nA (worst case) for the -A grade, thus a dynamic range of 5×10^3. The op-amp's bias current is negligible by comparison (4 pA, max, over temperature).

(d) The dynamic range would be greatly extended if R were replaced with a switched current source, assuming of course that the input signal remains in the form of a current.

(e) In this circuit the comparator U_2 need not be accurate; in fact, it could be omitted altogether, with the flip-flop's logic threshold taking its place. Similarly, the operation does not require an accurate comparison threshold voltage; we chose $V_{CC}/2$ for convenience.

We'll see some additional examples of delta–sigma conversion in §13.9.11. The impatient reader may wish to skip over the following subsections, in which we explore more deeply the operation and performance of the often-confusing delta–sigma technique.

13.9.2 Demystifying the delta–sigma converter

As we noted, the delta–sigma integrator becomes a *converter* of the average analog input voltage, if you capture the count accumulated over a fixed measurement time T_{meas}. The measurement time must be much longer than the clock period, of course, to achieve decent resolution, because the maximum count is just $T_{\text{meas}}/T_{\text{clk}}$. So, for example, if you were to design an ADC to convert at 100 ksps, you might use a 10 MHz clock, cleared at the beginning of each conversion, and read out 10 μs later. The full-scale count would be 100, which you could describe as a (nearly) 7-bit conversion. To achieve 16 bits, you'd need to run the clock at $2^{16}\times100$ kHz, or 6.5536 GHz!

This does not sound promising. It just seems like a bad idea to design a "1-bit" converter – which is what you have in the stream of bits that is driving the counter in this design. So it will come as a surprise that the impossible *can* be done: there are plenty of 16-bit delta–sigma ADCs that convert at audio rates (e.g., 96 ksps), and in fact there are some that achieve 20 bits or more of resolution at that speed (see §13.10.1, and Tables 13.9 and 13.10). How can this be?! Read on. . . .

Sometime in the 1990s the promotional materials for consumer-grade CD audio players began to trumpet their use of "1-bit digital-to-analog converters," as if there was something good about *reducing* the resolution from the previously trumpeted 16 bits.[62] This seemed puzzling to many of us; but we didn't complain because, well, the players sounded pretty good.

As Bob Pease would say, what's all this 1-bit converter stuff, anyhow?

13.9.3 ΔΣ ADC and DAC

As we'll see, ΔΣ (also known as ΣΔ) conversion can go either way – D/A, or A/D. In contemporary practice ΔΣ *DAC*s are used primarily for audio applications, where they excel in linearity, monotonicity, and low cost. A typical audio ΔΣ DAC might integrate six 24-bit 192 ksps converters, with 114 dB effective dynamic range, for about \$10.[63] By contrast, ΔΣ *ADC*s cover a broad range of applications, ranging from precision (24-bit) dc-accurate slow converters, to audio-rate converters of high resolution (e.g., 24-bit, 96 ksps), and up to speedy ADCs with more accuracy than you would imagine (e.g., 16-bit, 20 Msps).

[62] Trumpet blasts are still echoing. Here's a contemporary example: "There is virtually no noise or sound degradation during the signal transmission and amplification process as 1-bit signals are digital." As if n-bit signals are *not* digital?!

[63] For audio applications the dc performance is irrelevant, and in general is not even specified. An exception is the excellent DAC1220 20-bit ΔΣ DAC from Texas Instruments.

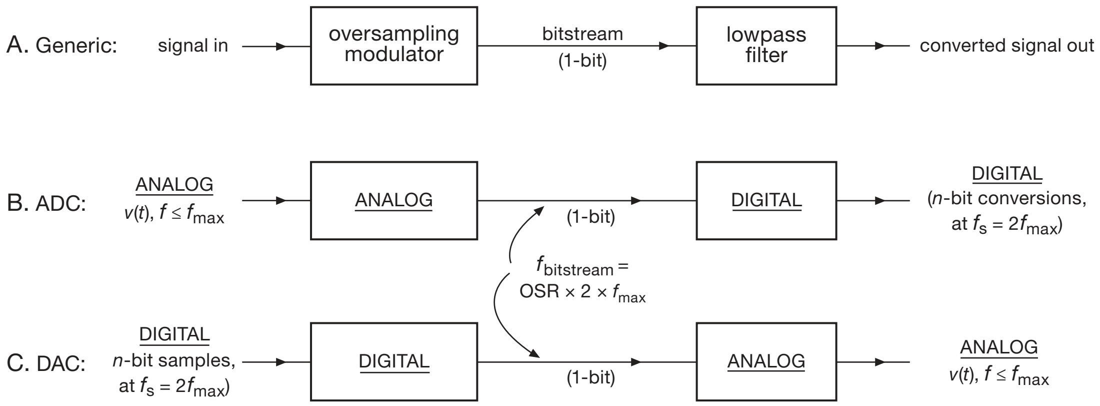

Figure 13.50. A delta–sigma converter, whether A/D or D/A, consists of two parts: an oversampling *modulator* that produces an intermediate *bitstream*, followed by a lowpass filter that recovers the converted output.

In the discussion that follows, we talk primarily about ΔΣ ADCs, both because of their importance and also because their architecture exploits the ideal characteristics of digital filtering.

Along the way, we will try to get to the bottom of what, to us, had seemed like a *big mystery*, namely: *How can it be that 1-bit conversions, at some modest "oversampling" rate (say 64 times the usual Nyquist rate of* $2f_{\max}$*), can produce digitized output samples of great accuracy (say 16 bits)?* To rephrase the mystery: naively one might expect that 1-bit conversions at a 64-fold oversampling rate might allow us to recover a final digital output with 6-bit resolution (because 2^6=64), but no better.[64] We'll see, though, that it's possible (and mandatory, for audio applications!) to do considerably better.[65]

13.9.4 The ΔΣ process

Figure 13.50 shows the basic ΔΣ process. An incoming signal, bandwidth limited to some maximum frequency $f_{\max}$ (usually by an anti-alias filter[66]), is converted to a bitstream[67] by a *modulator*. The latter is clocked at some multiple of the minimum Nyquist sampling rate $2f_{\max}$, generating an output bitstream of rate f_{bit}=OSR×$2f_{\max}$, where OSR is called the *oversampling ratio*. This bitstream is the intermediate step in the overall converter: to get the converted output, the bitstream must be lowpass filtered.

Note that both the modulator and the lowpass filter may each be analog or digital, depending on the type of converter: a delta–sigma ADC consists of an analog modulator followed by a digital filter, whereas a delta–sigma DAC consists of a digital modulator followed by an analog filter.[68] In what follows we will deal primarily with the modulator portion of the overall converter.

A. The modulator

In either case, the lowpass filter is "just a filter," which simply bandwidth limits the incoming bitstream.[69] The

[64] That is, in fact, the case with filtered PWM, as used, for example, for motor control or LED dimming: there one might divide the Nyquist period into 64 time slots, setting the first few as 1s and the rest 0s. Delta–sigma is more subtle, and better, with 0s and 1s sprinkled through the Nyquist period in such a way as to produce a filtered output of high accuracy.

[65] Plot spoiler, for the impatient: thinking in the time domain, it's a willing conspiracy between an output lowpass filter that views a long stretch of the bitstream, and a very clever bitstream-building modulator whose filtered output represents an accurate conversion. A better (and quantitative) understanding comes in the frequency domain, where the oversampling modulator acts to reduce in-band quantization noise, "shaping" it to higher (out-of-band) frequencies.

[66] Which, as we'll see later, need not cut off sharply, thanks to the beneficial effects of oversampling; see Figure 13.60.

[67] Here shown as 1 bit wide, for simplicity, though in practice it may be several bits wide (i.e., more than 2 levels).

[68] An interesting third possibility (analog/analog) is exemplified by the Avago HCPL-7800A analog opto-isolator: an internal input modulator creates a bitstream that is optically coupled to an internal analog output demodulator, to deliver an accurate analog replica (0.004% nonlinearity, typical) of high stability (3 ppm/°C gain change, typ), kilovolt-level isolation, and 100 kHz bandwidth. Another example of delta–sigma "A-to-A" is the Super Audio CD (SACD), a CD-like audio storage format in which the 2.8 Mbps intermediate (encrypted) bitstream itself is recorded and distributed to the user, with lowpass filtering applied at playback.

[69] The bitstream can be thought of either as *digital* (1s and 0s), which is then filtered by a digital filter (if this is an ADC), or as an *analog wave-*

interesting action (and the *magic*) takes place in the modulator. Figure 13.51 shows a block diagram of a "first-order" oversampled modulator, which accepts analog input voltages between −1 V and +1 V, bandlimited to a maximum frequency of $f_{\max}$, and produces a 1-bit output bitstream at a rate OSR time higher than the critical Nyquist sampling rate $2f_{\max}$.

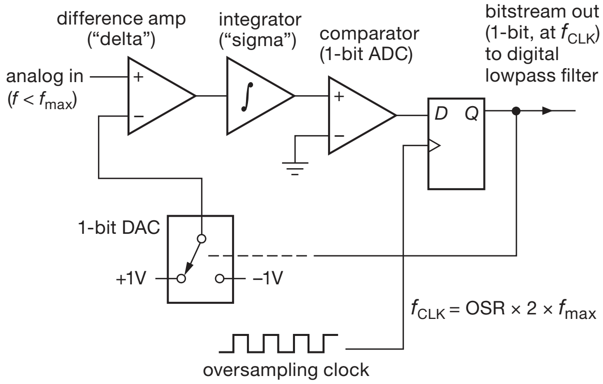

Figure 13.51. A first-order delta–sigma analog modulator.

At each clock cycle the current bitstream value, converted to an analog voltage (in this case ±1 V), is subtracted from the analog input, the difference signal being integrated (in a standard op-amp analog integrator, here assumed to be noninverting) and presented to a latched comparator. The integrator gain is such that a full-scale analog input to the integrator (i.e., +1 V) produces a full-scale (+1 V) change in the integrator's output after one clock period. That is, you can think of the integrator as an "analog accumulator": for a (fixed) input voltage V, its output voltage increases by V during one clock period.

The result is a rapid stream of 1s and 0s (at, say, 64 times the usual $2f_{\max}$ sampling rate), responding to the relatively slow (64 times slower, say) changes in the input signal. Thinking of these bits as ±1 V, the modulator produces a stream whose *average value* matches the input signal. We can understand this by thinking of the modulator circuit as a negative-feedback loop that strives to minimize the averaged (i.e., integrated) error between the input signal and the output stream (which has been converted back to analog by a "1-bit DAC"). Looking more closely, though, we can see that it is doing a *terrible job*: sample by sample, its output bitstream simply bounces between extremes. As Bob Adams has written,[70] pithily, "Oversampling converters achieve increased resolution not by decreasing the error between analog input and digital output, but by making the error occur more often."

B. The ADC's dynamic range (resolution)

The output lowpass digital filter (typically an FIR digital filter – see Figure 13.52 – in this case a 1-bit shift register with the marching 1- and 0-bit values turning on or off a set of fixed digital coefficients[71] that are added digitally to create the multibit output samples) creates the digital n-bit numbers that are the converter's output. Because they emerge from the filter at the full oversampling rate, they are subjected to a "decimation" operation, most simply by discarding superfluous outputs and outputting only one converted output for every OSR clock cycles.[72]

Naively, then, we achieve increased resolution by having plenty of 1-bit samples to average over, for each half-cycle of the highest frequency in the incoming waveform. Because the average value of the bitstream tracks the input signal, we understand Bob Adams' statement, and all is well.

Or is it? Consider an example: suppose we are digitizing audio, with an $f_{\max}$ of 20 kHz. A conventional ADC (say a successive approximation converter) might sample at 48 ksps, comfortably above the critical minimum of 40 kHz. Imagine instead that we rig up a ΔΣ ADC, with a typical oversampling ratio of 64; that is, we run the modulator at 3.072 Msps (64×48 kHz), creating the (1-bit) bitstream at that rate. Now we filter that bitstream, for example by taking a running average,[73] digitally, that captures 64 successive bits at a time. What does the output look like? Well, when you take the average value of 64 bits, there are only 64 possible values. So we've invented a paltry 6-bit ADC.

Following this logic, we'd need to oversample by 2^{16} (i.e., 64K) to achieve 16-bit conversion. That would require a sampling rate of roughly 3 *giga*hertz! Delta–sigma conversion is not looking good.

form that switches between two fixed voltage levels (if this is a DAC). Note also that the phrase "just a filter" does not mean that the filter design is simple, or trivial. In particular, *digital* filter design is a sophisticated art, with issues of window functions, nulls in the response, and so on. See §6.3.7.

[70] "Design and implementation of an audio 18-bit analog-to-digital converter using oversampling techniques," *J. Audio Eng. Soc.* **34**, 153–166 (1986).

[71] To a first approximation the time-series coefficients are a (signed) sinc function, the Fourier transform of a "brickwall" lowpass function. See §6.3.7, on digital filters.

[72] In practical implementations the filtering and decimation are combined, using a "multirate decimation filter."

[73] Rather than the more complicated sinc-function weighted average that's required for implementing an ideal "brick-wall" lowpass; see §6.3.7.

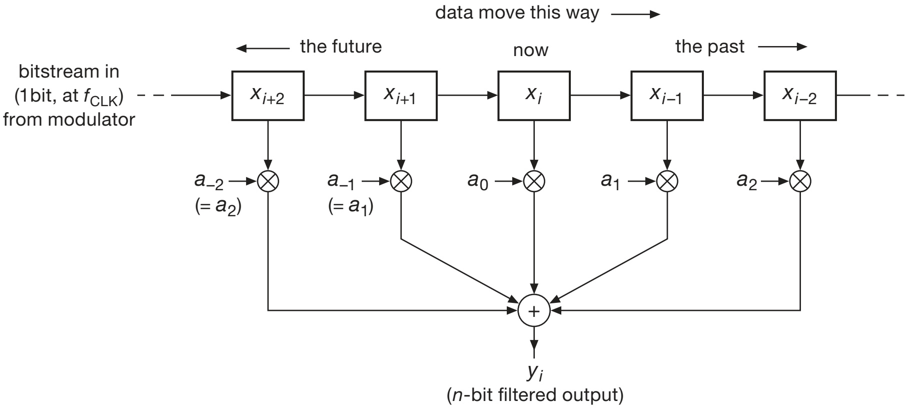

Figure 13.52. A digital filter uses digital memory and arithmetic elements to generate a digital-output sequence that represents a filtered version of a digital input sequence (see §6.3.7). Here a shift register, digital multipliers, and an adder form a symmetric nonrecursive (finite impulse response, FIR) filter, suitable as the output lowpass filter in a 1-bit delta–sigma ADC.

C. So, what's going on? (time-domain intuition)

The answer to this paradox can be stated in different ways. In the literature the usual approach is to say that the operation of the 1-bit digitizer consists of a perfect conversion, but with added broadband "noise" (consisting of the difference between the actual analog waveform and the 1-bit quantized samples). This "injected quantization noise" has a broad spectrum (because of the oversampled clocking frequency), extending to the clock frequency and beyond. Of greater importance, the resulting "output quantization noise" (what remains at the output) is lowest at low frequencies, being "shaped" by the modulation process such that most of the output quantization noise is well above $f_{\max}$. Because of this so-called "noise shaping," the final lowpass filter acts to selectively eliminate most of the quantization noise from the bitstream, while preserving the converted signal. Voilà: resolution and dynamic range far better than our naive estimate above.

This is all quite correct, but, to us, unsatisfying (though we'll take a brief look at that approach in §13.9.5). We wanted to understand the secret of ADC dynamic range *in the time domain*, without recourse to the frequency domain. We struggled with this, reading exposés with titles like "Demystifying Sigma–Delta ADCs" and "Delta–Sigma ADCs in a Nutshell." Not much help – they all get to the critical step, then punt ("…sigma–delta converters overcome this limitation with the technique of noise shaping…" and "…you can see how the modulator shapes the noise to higher frequencies, facilitating the production of a higher resolution result," excerpts from those two articles, respectively).

Here's how to think of this in the time domain:[74] First, the lowpass filter does not simply take a running ("boxcar") average of the bitstream. Rather, it weights the individual 1-bit samples with carefully tailored coefficients to produce a better lowpass filter characteristic (see §6.3.7D). Because the individual bits are weighted differently, there are many more than 64 possible results (taking the example above). Furthermore, a typical FIR digital filter will weight and sum many more bits, and over a spread of time (samples) much longer than the oversampling rate (i.e., extending beyond what we might call a single "Nyquist interval," by which we mean the time interval equal to a half-period of $f_{\max}$). For a 64× oversampling ADC, the digital lowpass filter might use of order a thousand "taps" (samples along the bitstream), each with its multiplying coefficient, and spanning perhaps ten to twenty Nyquist intervals, to generate each final (decimated) output number. So it is at least *plausible* that you could achieve resolution far greater than possible with simple averaging.

Continuing in this vein, it's worth noting that each bit in the bitstream contributes to many final n-bit output numbers (after decimation). So, in a conspiratorial vein, it's plausible that a cleverly contrived modulator could generate a bitstream that, after lowpass filtering, could produce an n-bit digitized output with quite considerably improved dynamic range. Thinking this way, we would not be wrong[75] in concluding that "the magic is in the modulator."

[74] We are indebted to Bob Adams of Analog Devices for helpful discussions, and the extermination of mental cobwebs. He is not responsible, however, for any errors (egregious or otherwise) here committed.

[75] "You're not *wrong*, Walter; you're just …."

So the question becomes “How does such a simple device (Figure 13.51) behave so cleverly?”

13.9.5 An aside: “noise shaping”

As we remarked, the usual description of delta–sigma converters talks about *noise shaping* in the frequency domain: the flat-spectrum “quantization noise” introduced in the quantizer (the comparator of Figure 13.51) gets “pushed up” to high frequencies, mostly above the output sampling rate. And less in-band noise equates to higher accuracy – end of argument.

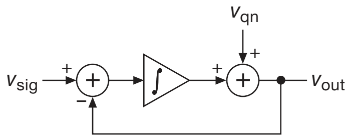

Figure 13.53. Noise shaping in a first-order delta–sigma ADC: an all-analog model, with quantizer replaced by an additive quantization noise source.

To many engineers this is a satisfactory explanation. But even if you aren’t particularly convinced by this argument, it’s worth understanding it. To see most simply how this works, look at Figure 13.53, in which the modulator is constructed with an *analog* integrator, and converts the (continuous) analog input to a 2-state analog (±1 V) output. In this equivalent analog model we’ve replaced the 1-bit quantizer (comparator) with an additive quantization noise voltage v_{qn}, whose flat spectrum extends to the oversampling clock frequency (and beyond).[76] You can think of the integrator as being in the forward path of the loop for the signal input (thus lowpass), but in the feedback path for the noise input (thus highpass).[77] From this simple analog loop we can easily figure the frequency responses to both the input signal and to the quantization noise signal. There’s only one gain parameter, namely that of the integrator, whose gain we write as $\mathbf{G} = \omega_0/j\omega$; that is, the integrator’s gain (proportional to $1/\omega$) is such that its magnitude is unity at ω_0. From our earlier discussion, $\omega_0 \approx 1/2\pi f_{\text{overclock}}$, the frequency of the converter’s oversampling input clock.

Let’s figure the gains, for which we properly have to do the full complex-number business. To get the input signal gain $\mathbf{G}_{\text{sig}}$ we set v_{qn}=0; then

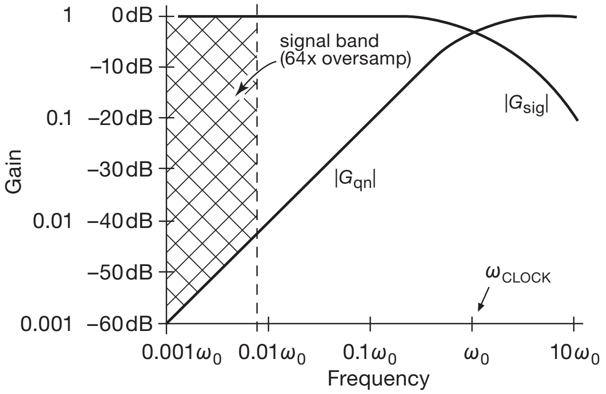

Figure 13.54. Signal gain and quantization noise gain versus frequency for a first-order delta–sigma ADC. The clock frequency $\omega_{\text{clk}} = \omega_0 = 2 \cdot \text{OSR} \cdot \omega_{\text{max}}$ here equals 128 times ω_{max}.

$$v_{\text{out}} = \frac{\omega_0}{j\omega}(v_{\text{sig}} - v_{\text{out}}),$$

$$\text{so} \quad \frac{v_{\text{out}}}{v_{\text{sig}}} = \frac{\omega_0/j\omega}{1+\omega_0/j\omega},$$

$$\text{and} \quad \left|\mathbf{G}_{\text{sig}}\right| \equiv \left|\frac{v_{\text{out}}}{v_{\text{sig}}}\right| = \frac{1}{\sqrt{1+(\omega/\omega_0)^2}}.$$

That’s a lowpass filter, with breakpoint at $\omega = 2\pi f = \omega_0$ (Figure 13.54).[78]

Similarly, for the quantization noise gain $\mathbf{G}_{\text{qn}}$ we set v_{sig}=0; then

$$v_{\text{out}} = v_{\text{qn}} - \frac{\omega_0}{j\omega}v_{\text{out}}$$

$$\text{so} \quad \frac{v_{\text{out}}}{v_{\text{qn}}} = \frac{1}{1+\omega_0/j\omega}$$

$$\text{and} \quad \left|\mathbf{G}_{\text{qn}}\right| \equiv \left|\frac{v_{\text{out}}}{v_{\text{qn}}}\right| = \frac{\omega/\omega_0}{\sqrt{1+(\omega/\omega_0)^2}}.$$

And that’s a highpass filter, with the same breakpoint.[79]

So, in this lowest-order delta–sigma ADC the quantization noise is attenuated at low frequencies, its spectrum

[76] You usually think of additive “noise” as being small compared with the signal that it is guilty of degrading. Here the quantization noise (the difference between the analog signal and the 2-level output voltage v_{out}) is actually larger than the signal itself.

[77] Explained nicely by Ewe Beis, on his website at `http://www.beis.de/Elektronik/Electronics.html`.

[78] A bit of intuition may be helpful here: at *low* frequencies (well below ω_0) the integrator has lots of gain, so the loop is closed with plenty of loop gain, creating a unity-gain output (in spite of the integrator within). In fact, the combination of input adder and integrator is not unlike a standard op-amp with its $1/f$ (compensation) rolloff. But at high frequencies there’s no loop gain, so you get the $\sim 1/f$ integrator rolloff.

[79] Intuition, again: this time the “signal” (i.e., the quantization noise v_{qn}) acts like an additive output disturbance to the closed-loop unity-gain amplifier. So it is *removed* by the loop gain, which is high at low frequencies (its magnitude is ω_0/ω), but ineffective above ω_0.

sloping linearly up to the oversampling clock frequency. But this is an *over*clocked ADC, so the input signal frequency range of interest sits down at the low end of that spectrum (by the ratio of oversampling). In other words, the quantization noise is mostly out of the signal band. And, for higher-order modulators, the effect is more pronounced: the noise curve is quadratic for a second-order modulator, cubic for third-order, and so on. Thus the conclusion you usually see: a delta–sigma converter achieves its accuracy by "shaping the noise to higher frequencies."[80] You may not be particularly impressed by this little bit of arithmetic. But, hey, at least you've seen it done, simply and explicitly.

13.9.6 The bottom line

Both from plausibility arguments in the time domain, and from explicit calculation in the frequency domain, it appears that the modulator circuit holds the key to the sigma–delta ADC's performance; that is, its ability to quantize an analog input signal with a resolution considerably greater than the oversampling ratio. Furthermore, that figure of merit ($N_{\text{eff}}/\log_2\text{OSR}$, where N_{eff} is the effective number of bits in the quantized digital output) grows with modulator complexity: contemporary ADCs employ "higher-order" modulators, meaning that the single difference amplifier and integrator is replaced with several cascaded stages of difference amplifier plus integrator, each driven from the common bitstream (see Figure 13.55).[81] Higher-order modulators are widely used, because they extend the dynamic range without having to increase the oversampling ratio (see below); they also suppress to a large extent the *idle tones* (see §§13.9.9 and 13.9.10) that afflict first-order modulators.

Although our time-domain musings above may be helpful (if only to make plausible the excellent dynamic ranges that are claimed), any serious analysis must use the frequency-domain approach. The latter shows that a higher-order modulator (constructed with m integrators) modifies the noise shaping such that the in-band quantization noise (i.e., dc to f_{max}) is suppressed as $\text{OSR}^{m+0.5}$, where m is the modulator order (m=1 for Figure 13.51). Put another way, each doubling of the oversampling ratio suppresses quantization noise so as to increase the dynamic range by $m+\frac{1}{2}$ bits; or, to state it in terms of modulator order, the effective number of bits (ENOB) is the $\log_2$ of the oversampling ratio (e.g., 6 for OSR=64) multiplied by $m+\frac{1}{2}$ (thus, for example, ENOB≈15 for a second-order modulator with oversampling ratio of 64). The graph in Figure 13.56 shows the theoretical maximum dynamic range of a delta–sigma ADC as a function of oversampling ratio and modulator order.[82]

Another technique for extending dynamic range, speed or both, is to design a modulator that generates a modulated "wordstream" that is more than one bit wide. In Figure 13.51, for example, the 1-bit ADC, 1-bit DAC, and 1-bit register would be replaced with analogous 2-bit (4-level) components. There are lots of clever tricks to address imperfections in the multibit converters within the modulator (for example, cyclically exchanging bit positions to average out nonlinearities caused by offsets); they are well beyond the scope of this book.

13.9.7 A simulation

We wanted to see for ourselves just how the signals move through a delta–sigma ADC – particularly the bitstream produced by some random-looking analog input signal, and of course the resultant output numbers (plotted as discrete points alongside the analog input waveform). We also wanted to see what things look like in the frequency domain, where the noise shaping should be evident.

The simulation was coded[83] in Mathematica®, with the following recipe:

(a) a spectrally-flat pseudorandom waveform with Gaussian amplitude distribution was generated, evaluated at 8192 successive time steps;

(b) this waveform was filtered with an approximate ideal brick-wall lowpass, with cutoff at 1/8 of the maximum frequency; it was then normalized so that its amplitude was bounded by ±1, generating the "analog input

[80] Sometimes stated as "pushing the noise upward to higher frequencies." In our *linear* model here, nothing gets *pushed*; it just gets attenuated at the low-frequency end, and passes unattenuated at the high end. However, a fully accurate quantization noise model must properly take account of the fact that the 2-state bitstream has unit amplitude (always ±1), with the result that reducing the quantization noise power at the low-frequency end causes it to rise at the high end.

[81] A simple cascade of integrators can be used up to second order, but not beyond (because their accumulated phase shift produces instability); a weighted sum of cascaded integrator outputs is used instead, in a higher-order modulator. Contemporary audio ΔΣ ADCs typically use fifth-order modulators and 64× oversampling to achieve 20-bit effective dynamic range.

[82] Note, however, that practical modulators of order greater than 2 use a modified structure (weighted sum of integrator outputs), for which the formula is not strictly correct.

[83] By the ever-talented Jason Gallicchio, to whom we are indebted.

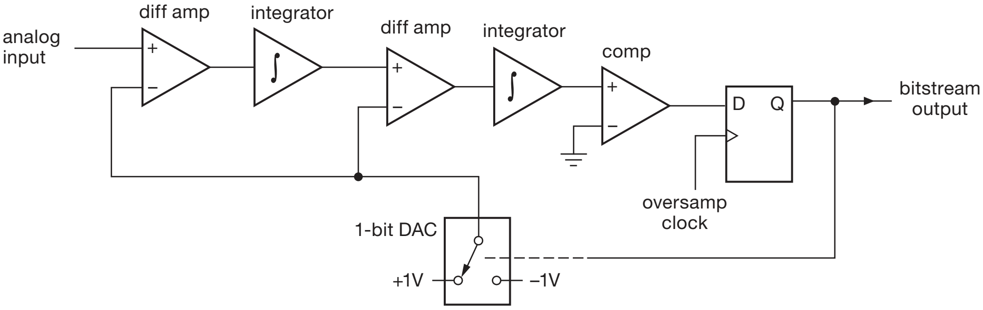

Figure 13.55. A second-order delta–sigma analog modulator. Lowpass filters can be substituted for one or more of the integrators.

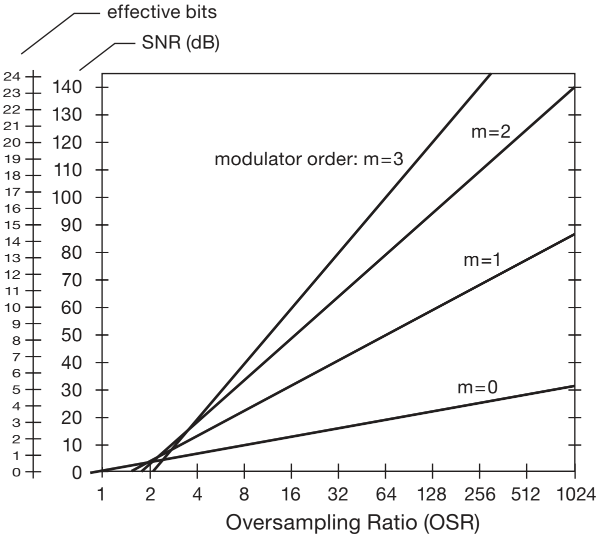

Figure 13.56. Dynamic range (SNR) and effective number of bits (ENOB), as functions of oversampling ratio (OSR) and modulator order (*m*), for a 1-bit oversampling ADC. (For a 2-bit modulator the slopes are doubled.)

signal"; the maximum frequency present in this signal was defined as the Nyquist frequency, f_{nyq};

(c) this signal is used to generate a bitstream with values of ±1, by numerically simulating a first-order oversampling delta–sigma modulator (in which the integrator is realized as a discrete digital accumulator); the oversampling ratio is 8×, and thus the clock frequency f_{clk}=16f_{nyq} (recall that critical "1×" sampling requires f_{clk}=2f_{nyq}); finally,

(d) the bitstream, considered as an analog waveform itself, was lowpass filtered with the same filter function as in step (b), to produce the output samples; these emerge at the full 8× oversampled rate, and would normally be decimated (e.g., by preserving only every eighth point) to produce the ADC's digitized output at the "1×" rate (twice the highest frequency present in the input waveform).

Figure 13.57 plots a typical portion of the (longer) simulation, showing what's happening in the time domain. The tick marks on the time axis correspond to 1× (critical Nyquist) sampling, with individual dots plotted at the 8× oversampling rate. The input signal is the wiggly solid line, closely approximated by the discrete dots that are the digitized output numbers (plotted at their full 8× rate). You can see the bitstream waveform, on the same amplitude scale, as dots at ±1. Finally, the error (i.e., digitized output minus analog input, at each oversampling point) is the dotted waveform of small amplitude. From these plots you can do an eyeball estimate of the converter's accuracy; to us it appears to exhibit something like ±6% peak-to-peak amplitude error, which translates to an amplitude SNR of 16:1 (24 dB), in good agreement with the graph of Figure 13.56.

From this same simulation we plotted also the frequency spectra of the input signal, the output digitized "waveform," and the difference (an "error signal"); see

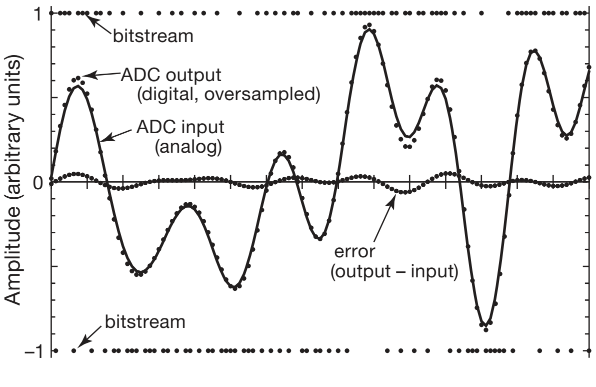

Figure 13.57. Numerical simulation of an 8× oversampling first-order delta–sigma DAC.

Figure 13.58. The spectra[84] extend to half the oversampling clock frequency, which corresponds to 8 times the highest input frequency. The top graph shows the flat input spectrum, cutting off sharply (nearly "brick wall") at unit frequency. The middle graph shows the spectrum of the raw bitstream itself, considered as a "waveform," where we would expect an approximate replica of the input, plus additional "noise" extending up to the oversampling clock frequency. In fact, we see just that – almost the same input spectrum up to unit frequency, with an additional quantization noise that increases roughly proportional to frequency. By taking the difference of these two spectra you can extract approximately the spectrum of the added noise introduced by quantizing (bottom graph), showing an approximately linear growth from zero up to at least half the oversampling clock frequency. The quantization noise above unit frequency is, of course, removed by the digital lowpass filter that accepts the bitstream as input and that completes the converter circuit (Figure 13.50).

The linear shape of the quantization noise spectrum, for this first-order modulator, would be replaced with a quadratic shape for a second-order modulator, and so on for higher orders. That higher-order noise shaping corresponds to improved accuracy (or SNR, or effective number of bits), as shown graphically in Figure 13.56.

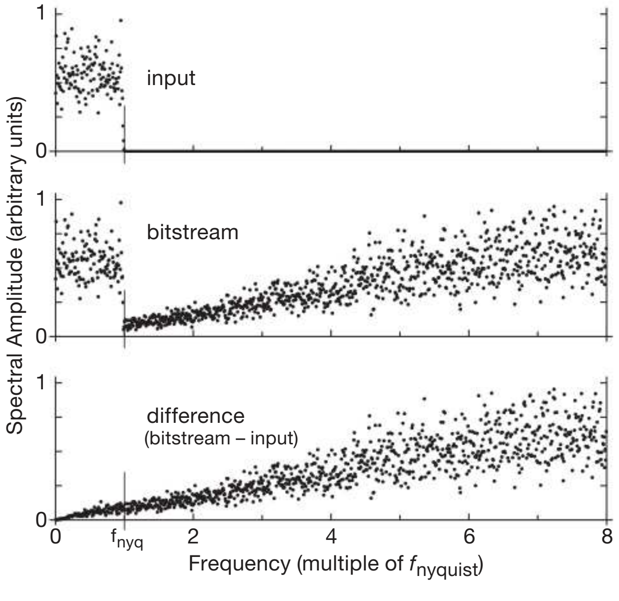

Figure 13.58. Frequency spectra of simulated 8× oversampling first-order delta–sigma ADC.

13.9.8 What about DACs?

As we indicated at the outset, the same scheme of lowpass filtering a bitstream produced by an upstream modulator is used also to make ΔΣ *digital-to-analog* converters. Look at Figure 13.59. Playing this role, the modulator accepts *n*-bit digital input samples representing the input signal. Comparing it with the modulator used for the ADC (Figure 13.51), the difference amplifier is replaced with a digital subtractor, and the integrator is replaced with a clocked digital accumulator. (At each clock the accumulator replaces its current latched value by the sum of that value and the input value.) The analog comparator is replaced with a digital comparator, most simply by just forwarding the sign bit (or the MSB, for unsigned offset binary) to create the 1-bit bitstream according to whether the accumulator's value is above or below the midpoint. And, finally, the 1-bit DAC is replaced with an "*n*-bit ADC" that simply generates one or the other of the full-scale *n*-bit quantities, in response to the 1-bit bitstream output. For 16-bit unsigned (offset) binary, for example, those values would be 0000h and FFFFh (all bits LOW or all bits HIGH).[85]

As with the analog modulator used in ΔΣ ADCs, the digital modulator for a DAC can be of higher order, with several stages of subtractor and accumulator (or digital lowpass filter); likewise, the digital modulator is not restricted to a 1-bit output stream. It could (and often does) generate a several-bit wordstream, in which case the several most significant bits form both the output wordstream and the digital feedback. Taking the example of a 2-bit (4-level) modulator, the 2-bit output stream would be both (a) converted to a 4-level analog voltage with a resistor ladder, then analog lowpass filtered to form the (analog) output signal, and (b) simultaneously mapped to one of four *n*-bit codes spanning the full input range (e.g., 0000h, 5555h, AAAAh, and FFFFh), then used as input to the *n*-bit digital subtractor at the input.

The output stage of a ΔΣ DAC is, as with the ADC, a lowpass filter. Here, however, it is an *analog* filter, which denies you the benefits of sophisticated digital filtering. The result is some compromise in filter characteristics, including clock feedthrough, and (with an analog, or "continuous-time" filter) sensitivity to clock timing jitter.[86]

[84] The spectral amplitudes were binned in groups of four to generate a sparser, and therefore more easily plotted, figure.

[85] For 2's complement 16-bit quantities, the corresponding values are 8000h and 7FFFh (corresponding to −32768 and +32767, the lowest and highest values).

[86] The lowpass filter can alternatively be implemented as a switched-capacitor (or "discrete-time") filter, which, sharing the same clock signal, effectively suppresses clock jitter.

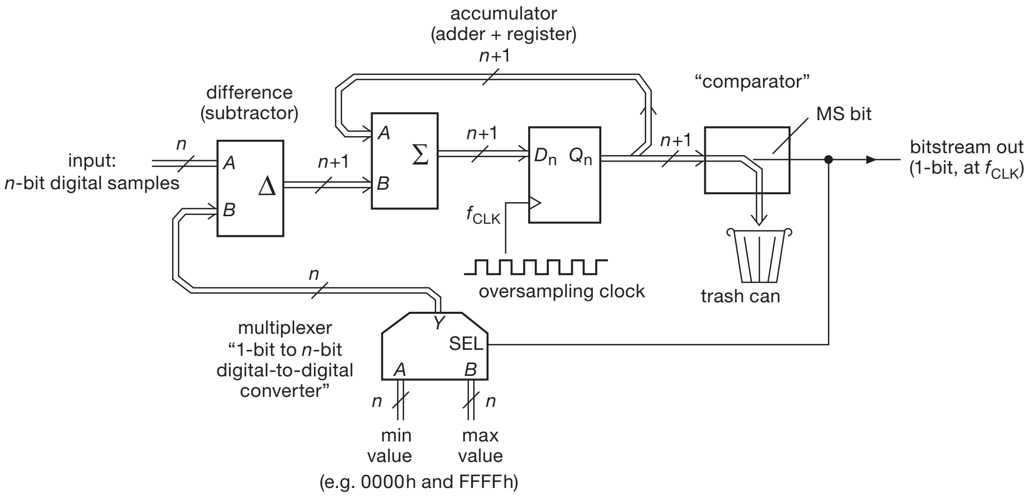

Figure 13.59. A first-order digital modulator in a delta–sigma DAC. The adder output is shifted one bit to prevent word growth.

13.9.9 Pros and Cons of ΔΣ oversampling converters

A. Advantages

Linear, monotonic, accurate Delta–sigma 1-bit converters are guaranteed monotonic; they are inherently linear, and can achieve 24-bit resolution at audio rates and below.

Inexpensive Delta–sigma ADCs use inexpensive (and accurate) *digital* lowpass filtering, and (because of oversampling) require only a low-order analog anti-alias filter at the input (see Figure 13.60)

B. Disadvantages

Limited bandwidth To ∼10–100 Msps at most (limited by gigahertz-scale oversampling clock).

Time delay The built-in ADC post-conversion digital filter achieves nearly ideal "brick wall" cutoff by using many taps, resulting in significant delay (or "latency," typically tens of output sample times, thus ∼millisecond for audio ADCs).[87]

DAC noise Delta–sigma DACs use an *analog* post-conversion lowpass filter, which permits some digital-switching feedthrough (by contrast, an *R*–2*R* DAC is completely "quiet").

Idle tones An ADC with first-order modulator can produce "idle tones" (see below) when presented with a static input that causes the integrator output to cycle with a sufficiently long period to be in-band (and causing apoplexy among audio aficionados); higher-order modulators suppress this artifact, even if present in the quantizer, owing to the higher in-band loop gain.

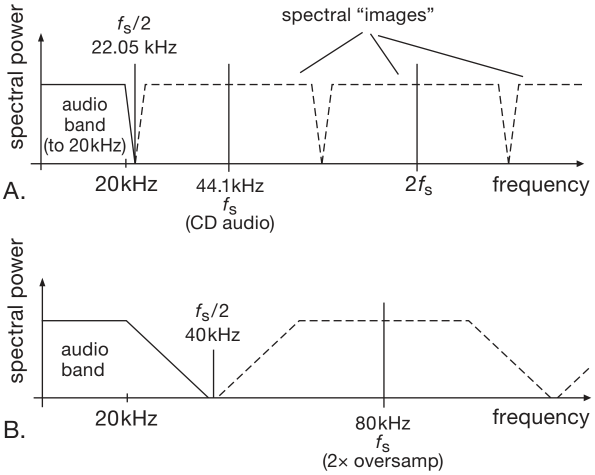

Figure 13.60. The spectrum of an analog signal that has been digitized ("sampled") periodically at a sampling frequency f_s includes mirrored copies ("images") centered at multiples of f_s. The analog signal must be lowpass filtered, before sampling, to eliminate components above $f_s/2$ (the "Nyquist frequency"); otherwise the mirrored bands create in-band "aliases" that cannot be subsequently removed. Oversampling relaxes the required steepness of such an "anti-alias LPF," as seen here for conventional CD-audio sampling (*A*, ≈10% oversampling) compared with 2× oversampling (B).

[87] However, note that the time delay is the same as would be produced by a sharp input anti-alias filter (of similar cutoff characteristics to that of the delta–sigma's post-conversion digital filter) followed by a conventional (zero-latency) ADC.

13.9.10 Idle tones

A distinguishing idiosyncracy of delta–sigma converters is the possibility of producing an "idle tone" – an unprovoked in-band periodic low-level (you hope) output signal. This undesirable characteristic afflicts particularly first-order modulators, which for this reason are never used for serious audio applications. You can get in-band idle tones (i.e., in the passband of the output lowpass filter) for particular values of static (dc) input; these are generally suppressed when there's signal activity at the input, hence the term "idle."

To see how this goes, consider the first-order modulator of Figure 13.51, which has a full-scale input range of ±1 V. If you apply a fixed dc input of value 0.625 V, and watch what happens with successive clock cycles, you get the states shown in Figure 13.61. The modulator (and therefore the output bitstream) goes periodically through a cycle of length 16 clocks. Such a repeating pattern can be of long enough period to produce a signal in the final lowpass-filtered output: if, in this example, the oversampling ratio were 4×, the idle tone would fall at the midpoint frequency of the output band.

This can be seen in Figure 13.62, where we've[88] calculated and plotted two complete cycles of this idle tone. Note particularly the brick-wall lowpass filtered output, where the sinusoidal idle tone can be clearly seen. Its amplitude (118 mV pp) is about 6% of full scale; that's a meager suppression of just 25 dB, totally unacceptable even for inexpensive consumer audio devices.

Delta–sigma converters intended for audio applications typically use third-order (or higher) modulators, both to suppress[89] idle tones and to increase the dynamic range (effective number of conversion bits, ENOB).

13.9.11 Some delta–sigma application examples

Enough theory! Let's look at a few simple delta–sigma application examples (with some of greater complexity in §§13.11 and 13.12). We urge the reader to have copies of the relevant datasheets in hand while reading through these examples (get them from the manufacturers' websites or, often more quickly, linked through a distributor like DigiKey, Mouser, or Newark).

Input	Delta	Sigma	Bit	Feedbk
5/8	0	0	0	-1

cycle of 16

Figure 13.61. Sequence of states of the first-order delta–sigma modulator (Figure 13.51), with a fixed dc input of 625 mV. "Delta" and "Sigma" are the input and output, respectively, of the integrator, "Bit" is the bitstream output, and "Feedbk" is the feedback DAC's output voltage.

A. An even-simpler delta–sigma ADC

In §13.9.1 we presented "the simplest delta–sigma" in the form of the integrating charge-dispensing suntan monitor. With the sophistication of the preceding sections, we can now recast that example as a first-order delta–sigma modulator with simple accumulation of the 1-bit bitstream. If that's what you need, you can implement it even more simply, with a microcontroller.

These devices (Chapter 15) are the flexible putty of electronics, and one of them can easily replace the logic portion of the previous example, as in Figure 13.63. Here the pin labeled Q is an output-port bit that swings cleanly rail-to-rail, and A_{in} is an input that sets the threshold, analogous to U_2 in Figure 13.49. It could be an internal comparator, provided in many microcontrollers (see, e.g., Figure 13.64); or it could be a low-resolution ADC internal to the microcontroller (also quite common); or, at the crudest level, it could be a logic input, whose (inaccurate) threshold voltage replaces an honest comparator.

A microcontroller implementation like this lets you do

[88] Jason, again.

[89] Higher-order modulators do not *eliminate* idle tones, they merely suppress them enough to render them almost harmless. As delta–sigma guru Bob Adams puts it, "Higher order modulators are less likely to fall into a simple repeating pattern, but it is still possible. The real benefit of higher-order modulators is that they have excellent suppression of quantization noise (because the loop gain at low frequencies is extremely high), so that, even if the quantizer decides to fall into an idle-tone-producing pattern, it will be suppressed by such a large amount that it will be buried in thermal noise."

more: at the simplest level you could write software that implements the counter and other logic needed to complete the suntan monitor (including features such as a display of progress of baking, time remaining, clock time and date, your next appointment, and so on...). At a more sophisticated level you could implement a digital filter to create a sequence of converted values, in the manner of a fully integrated delta–sigma ADC. You could, but you probably shouldn't, because many highly skilled designers are turning out excellent delta–sigma ADCs, a sampling of which we'll visit soon enough. And there is a danger in hijacking a microcontroller to control the integrator charge cycles, namely that the accuracy of sigma-delta integration depends upon a stable switch ON-time; and the stability of a converter depends also upon a stable sampling clock frequency. You must ensure that the controller gives you control over that timing; and, even so, you may find that the firmware coding becomes inconveniently constrained. These examples are intended merely to illustrate the simplest kind of delta–sigma circuit. If what you want is a high-quality converter, you should choose one from the many hundreds that are available, that are easy to use, and that are remarkably inexpensive; several of these are illustrated below.

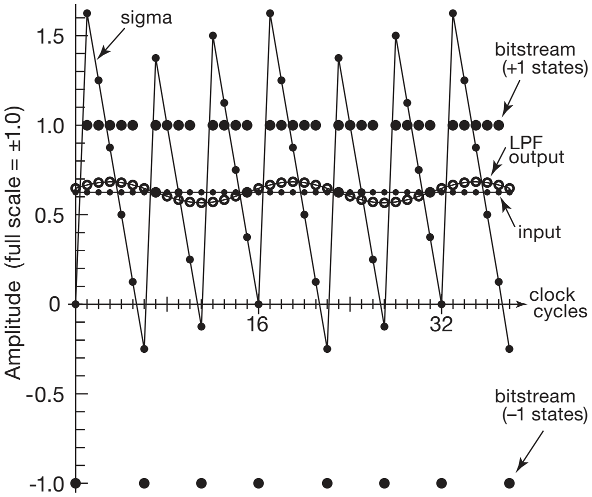

Figure 13.62. Modulator signals, along with time-aligned filtered-output waveform, for the idle-tone example of Figure 13.61. The tone is down ~25 dB, relative to full scale, and would fall at midband (half of Nyquist frequency) for 4× oversampling.

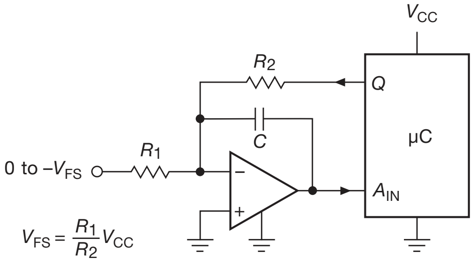

Figure 13.63. A microcontroller can replace the logic portion of a discrete delta–sigma ADC.

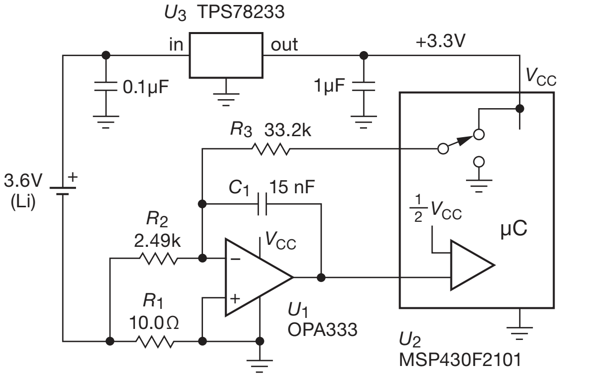

Figure 13.64. Keeping track of battery capacity with a discrete delta–sigma charge integrator.

B. Coulomb counter

Here's an example of a microcontroller-assisted converter with low quiescent current and a wide dynamic range. In all candor, an admission: we designed the converter first, then we looked for a plausible application. Figure 13.64 shows what we came up with – a low-side sensing battery "gas gauge" to keep track of the state of discharge of a lithium cell that powers a portable instrument.

Here's how it works: we used a small (10 Ω) current-sensing resistor, to limit the voltage burden to 0.25 V at the maximum anticipated load current of 25 mA (caused, for example, by switched loads such as a 350 Ω strain gauge). Then we chose a single-supply chopper op-amp (maximum offset voltage of 10 μV) to minimize the error at low currents; here the offset voltage corresponds to a sensed current error of 1 μA (max), or a dynamic range of 25,000:1. The voltage developed across the sense resistor drives the integrator through R_2, with a full-scale input current of 100 μA. (You can think of R_1R_2 as a "current divider," if you like that concept.)

Next we chose R_3 to set the converter's full-scale input current ($I_{FS} = V_{CC}/R_3$), i.e., to source the full-scale current into the summing junction when the switch is on. Finally, taking a clock frequency of 10 kHz, we chose the value of the integrating capacitor C_1 such that the integrator would ramp no more than $V_{CC}/5$ in one clock cycle. It's easy to figure out that this condition makes $C = 5/fR_3$, or 15 nF.

Exercise 13.6. Make sure you understand this design, by running through the calculations of maximum load current and dynamic range, and the design of the integrator components R_2, R_3, and C_1.

The MSP430 is a low-power microcontroller series from TI. This particular variant conveniently includes a comparator whose reference input can be biased at $V_{CC}/2$, which we use in conjunction with a digital output bit that we switch between ground and V_{CC}.[90] With a clock frequency of 1 MHz the microcontroller draws 0.3 mA when active, and 25 μA when running in "low-power mode 2"; think of the latter as a "sleep" mode, during which an internal timer continues to run, and from which the processor can wake up to full alertness in one clock cycle. This is important, because it's common to put portable equipment into a low-power mode to conserve battery charge.

Note that this "Coulomb meter" keeps track of *all* loads, including the regulator's quiescent current, the microcontroller's operating current, additional loads powered from the regulated V_{CC} line, and even the current needed to run the delta–sigma's integrator op-amp itself. Exclusive of additional loads, the power budget is dominated by the processor, followed by the chopper op-amp (17 μA, typ) and the regulator (1.3 μA, max); that equates to a battery life of several months (with processor active) for a typical 1 Ah rechargeable Li-ion cell. The peripheral loads would likely reduce battery life considerably, and would typically be power switched by the processor.[91]

Note that the zero error of 1 μA (from the op-amp's worst-case offset) is completely negligible in comparison with the system current, even in sleep mode. The 25,000:1 dynamic range is extravagant for this application.

C. Three fully integrated delta–sigma ADCs

We conclude these delta–sigma examples with three elegant integrated ADCs from three different manufacturers. For more parts to consider, see Table 13.9.

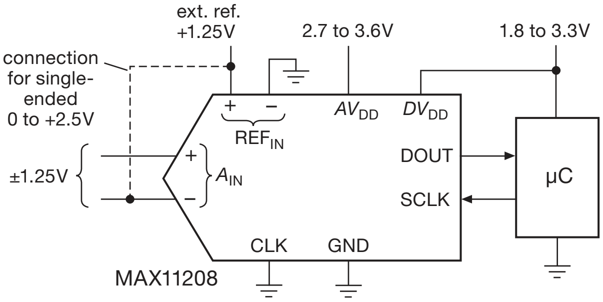

Figure 13.65. Maxim's MAX11208B 20-bit low-noise ADC with internal clock. The differential input can be reconfigured for single-ended 0 to $+2V_{ref}$ by connecting the A_{IN} input to the reference, as shown.

Maxim MAX11208B: inexpensive 20-bit ADC

From Maxim comes this compact (10-pin) converter (Figure 13.65), both inexpensive ($3.75 in single quantities) and quiet (0.7 μVrms noise). It delivers true 20-bit resolution at a leisurely 13.75 sps, and it has 80 dB rejection of both 50 Hz and 60 Hz powerline frequencies with its accurate internal system clock (enabled by grounding the CLK pin).[92] The full-scale conversion range of the differential input is $\pm V_{ref}$, over the common-mode range of 0 to $+AV_{DD}$. It performs a gain and offset calibration at power-on, and also on request via an amusing digital command (two extra SCLKs tacked onto the end of the normal serial readout). In common with most converters, it has a separate digital supply pin for compatibility with low-voltage digital logic.

Analog Devices AD7734: versatile 24-bit ADC

From Analog Devices comes this 4-channel multiplexed 24-bit converter (Figure 13.66), with an unusual input structure of trimmed resistors that provides a full ±10 V input range (while operating from a single +5 V supply), and in fact with an over-range bit that extends the conversion range to 11.6 V, thus permitting accurate gain calibration at full-scale input. It is extremely tolerant of input overdrive: to ±16.5 V without affecting the accuracy of the other inputs, and to ±50 V without damage.

There's lots of flexibility in the conversion process, with programmable selection of parameters like filter length, auto-zero, and "chopping" mode. The latter consists of differential-input reversal on successive conversions, with the outputs averaged to cancel offsets in the buffer and delta–sigma modulator. With chopping mode enabled and with the longest filter setting, the converter delivers an

[90] This processor provides several "capture control registers" by which we can ensure that those pulses are of accurate and stable duration, a necessary condition for delta–sigma integration.

[91] With a much smaller battery, one could put the processor into sleep mode as well, waking up only often enough to ensure that the system current during sleep does not cause the integrator ramp to saturate between naps. For this system the ~ 45 μA total sleeping quiescent current would require measurements every 80 ms to limit the unobserved ramp amplitude to 1 V. This microcontroller can do that easily, because it has the nice property of waking up in a single 1 μs clock cycle.

[92] The –A suffix version runs at 120 sps, with poor rejection of powerline frequencies, but deep rejection at 120 Hz and its harmonics.

Notes: (a) sorted by precision and speed; all except AD7734 have differential inputs; all have no missing codes except as noted. (b) at minimum PGA gain. (c) after calibration. (d) unused input biased at mid-supply. (e) at V_S=3.3V. (f) pseudo-diff'l. (g) external bare xtal. (h) opt ext osc input. (k) in chopper mode. (m) min or max. (n) 0.1 to V_-0.1 with buffers enabled. (o1) has neg supply, 0 to –2.6V, with 5.25V max total supply. (o2) has neg supply, 0 to –3.5V, with 5.5V max total supply. (o3) has neg supply, 0 to –6V, with 6V max total supply. (p) 2 differential, 4 pseudo-diff'l with single common return. (q) S=SPI, P=parallel, LC=LVDS or CMOS serial. (r) five supplies: +5 ±5%, +2.5 ±5%, +3.15 to +5.25 (2x), and +1.67 to +2.7. (s) at max decimation. (u) four supplies: +5 ±5% (3x), +2.5 ±5%. (v) 4.75-5.25V and 1.65-2.2V. (w) 8 diff'l, 16 single-ended (pseudo-diff'l); (x) before cal. (y) 2ppm after cal. (z) 0.4mW unbuffered.

Comments: A: 16 single-ended (pseudo-diff'l) or 8 diff'l; MUX output and ADC input pins. **B:** internal clk; self-cal. **C:** 4 single-ended (not pseudo-diff'l) or 2 diff'l; auto-shutdown in single-shot mode. **D:** CS5512 has ext osc; CS5510/11 = 16-bit. **E:** low-noise, 2.5µVrms; auto-shutdown in single-conv mode. **F:** no latency; 0.8µVrms noise; a favorite. **G:** bridge subsystem with offset DAC and ac excitation output. **H:** low-noise; opt input buffer for hi-Z; INA PGA; includes 2 curr srcs; chopper mode; auto-shutdown in single-conv mode; int ref 4ppm/°C typ; AD7793 has fewer channels; a favorite. **J:** opt input buffer for hi-Z. **K:** low noise; 20-pin ADS1247 has 2 channels, 28-pin ADS1248 has 4 channels, both have int 10ppm/°C ref. **L:** CS5534 4-ch diffl; industrial workhorse; 6nV/√Hz. **M:** low noise. **N:** off-scale detectors. **O:** has chopper mode; AD7732 has two diff inputs. **P:** ADS1211 has 4 ch diff'l MUX; sample-rate boost to 312kSps; no missing codes to 22 bits. **Q:** low noise; pins for MUX diff'l output and ADC input. **R:** biopotential measurements (EKG, EEG, etc); ADS1294=quad. **S:** ADS1274 = quad. **T:** diff'l input buffer; AD7765 to 156kSps. **U:** diff'l input buffer. **V:** pin-programmed (no registers); LVDS or CMOS serial output. **W:** no missing codes to 31 bits.

effective 21-bit conversion at 372 sps for input signals of ±10 V full scale; this figure comes from a consideration of the converter's noise level, which is 9.6 μVrms under these conditions (21 bits is the ratio of a ±10 V span to ~ 10 μV). The datasheet specifies resolution alternatively as "peak-to-peak resolution in bits," which for these same conditions is listed as 18.1 bits. This turns out to be the more conservative specification, which is explained as "representing [bit] values for which there will be no code flicker within a 6-sigma limit." In other words, you can rely on any single conversion to be accurate to 18 bits, taking into account the fact that the occasional peak excursions of a signal of given rms noise voltage are substantially larger than V_{rms}.[93] If you know the rms noise voltage V_{rms},

[93] The datasheet for Cirrus' CS5532 explains it this way: " 'Noise-free resolution' is not the same as 'effective resolution.' Effective resolution is based on the RMS noise value, while noise-free resolution is based on a peak-to-peak noise value specified as 6.6 times the RMS noise value."

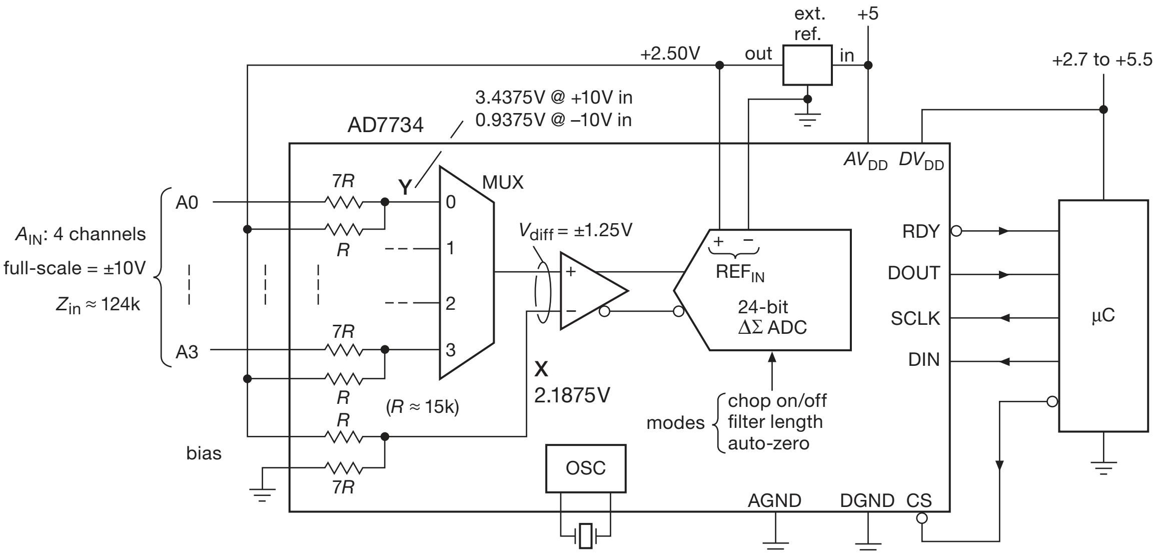

Figure 13.66. Analog Devices AD7734 multiplexed 4-channel 24-bit converter (21-bit ENOB) with wide input-voltage range and robust overdrive tolerance, courtesy of Analog Devices, Inc.

you can calculate the noise-limited effective resolution as ENOB $= \log_2(V_{\text{span}}/V_{\text{rms}}) = 1.44\log_e(V_{\text{span}}/V_{\text{rms}})$; from that you get the peak-to-peak resolution by subtracting 2.7 bits.

This converter can be operated at conversion rates to 12 ksps, with correspondingly degraded resolution. It has maximum offset and gain drifts of ±2.5 μV/°C and ±3.2 ppm/°C, respectively. It comes in a 28-pin package and is currently priced at about $15 in single quantities.

Cirrus CS5532 high-performance "industrial" ADC

From Cirrus Logic (formerly Crystal Semiconductor) comes the long-lived (circa 1999) CS5532-BS 24-bit delta–sigma converter (see Figure 13.67), with a chopper-stabilized PGA (gains of 2, 4, 8, 16, 32, and 64) and with particularly good noise, drift, and linearity characteristics: $e_n = 6.4\,\text{nV}/\sqrt{\text{Hz}}$ (typ) at 0.1 Hz with $G = 64$,[94] $i_n = 1\,\text{pA}/\sqrt{\text{Hz}}$ (typ), $\Delta V_{\text{os}} = 15\,\text{nV/°C}$ (typ) with $G = 64$, full-scale drift of 2 ppm/°C (typ), and ±0.0015% (max) nonlinearity. It can convert at rates from 6.25 sps to 3.8 ksps. At the slowest rates it delivers noise-free resolution ranging from 20 bits (for $G = 64$) to 23 bits ($G \leq 8$); or, if you prefer, corresponding "effective resolutions" (ENOBs) of 23 and 24 bits, respectively.

With its low-noise, high-gain PGA and ability to run from split ±3 V supplies,[95] this converter has what it takes to process the low-level signals from a thermocouple (∼40 μV/°C) or a strain gauge (full scale $\Delta V \approx \pm 2$ mV per volt of bridge excitation). With a PGA gain of 64, the full-scale span is ±2.5 V/64, or ±40 mV, and an LSB (at 20-bit resolution) corresponds to 80 nV which is 500× less than the thermal-voltage change corresponding to a temperature change of 1°C. Likewise, at this gain a 20-bit LSB corresponds to 0.0008% of the strain gauge's full scale. At this gain, full-scale inputs from these sensors stay within the conversion range. Evidently there's no need for external front-end gain stages or the like. This converter costs about $16 in unit quantities.

In our circuit we balanced the thermocouple signals about ground to minimize the effects of common-mode pickup in the lead wires, which are often unshielded. And for both sensors we added a simple *RC* filter (time constant 0.1 ms) to suppress spikes and protect the inputs. We chose the ADR441 because we needed a low-dropout voltage reference that would operate with 500 mV of headroom.

D. Pro-audio ADCs

Delta–sigma converters are adored by the professional audio community, owing to their combination of resolution,

[94] Analog Devices' AD7190 comes close, at $8.5\,\text{nV}/\sqrt{\text{Hz}}$

[95] Other high-resolution delta–sigma converters that allow bipolar input supplies and signals include (a) the 32-bit ADS1281, with ±2.5 V analog supplies and input signals to those same limits (but sadly not to ±3 V, with their total supply limit of 5.25 V), and (b) three 24-bit converters: the 16-channel ADS1258, the ADS1259 with its 2 ppm voltage reference, and the ADS1246 family with internal PGA.

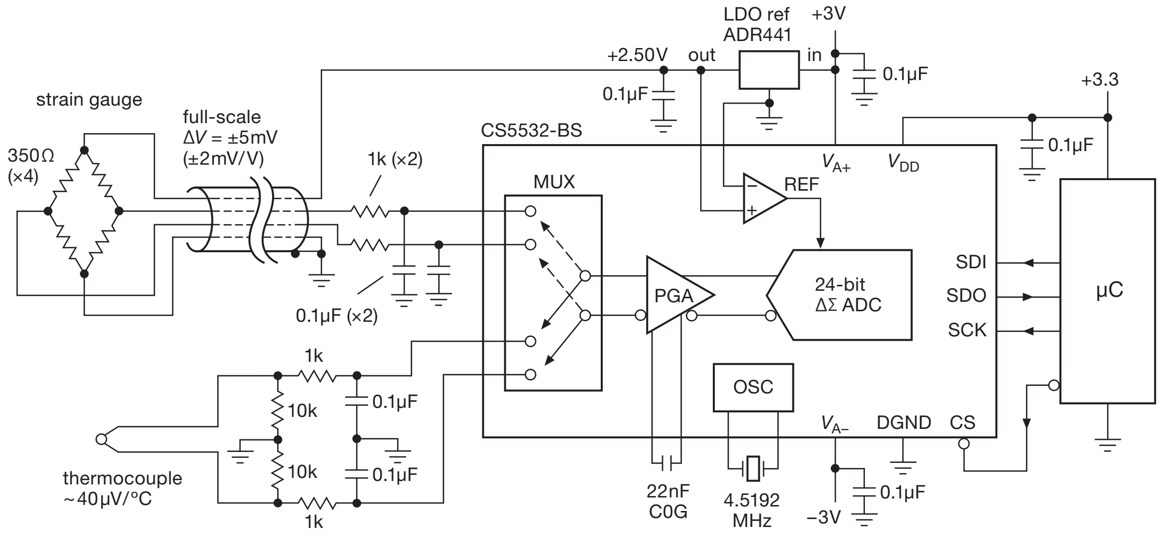

Figure 13.67. Cirrus' CS5532-BS precision low-noise 24-bit converter. The PGA permits gains of 1, 2, 4, . . . , 64. This circuit omits the cold-junction compensation. The Maxim MAX31855 includes this important compensation for seven thermocouple types; see item 44 in §15.8.2 and accompanying figure.

Table 13.10 Selected Audio Delta-Sigma ADCs

	Channels	Bits	f_{samp} max (kHz)	SNR[k] (dB[a])	THD+N[k] (dB[b])	Supply V_{CC} (V)	P_{diss} (mW)	inputs, other

Notes: (a) A-weighted filter. (b) at max sample rate. (c) codec: 4 in + 6out. (d) codec: 2 in + 6 out. (e) at 48kHz. (f) -110dB at 96kHz. (g) consider also the PCM4420. (h) stereo codec (ADC + DAC) with S/PDIF to USB in/out. (k) SNR and THD+N is with respect to full-scale; SNR is typically measured with a -60dB input signal, processed with an A-weighted filter; THD is typically measured at 1kHz, with a -1dB signal.

inherent anti-aliasing, noise shaping, and monotonicity. (See Table 13.10.) If you open up pretty much anyone's high-quality audio gear, you'll probably find a circuit based around a 24-bit, 192 ksps 128× oversampling delta–sigma ADC; and chances are it will be a part from Cirrus (e.g., the CS5381) or AKM (e.g., the AK5394A). These parts seem to have "long legs" – they have been around for many years and represent good value in terms of price and performance.

Audio ADCs universally use delta–sigma technology, but they differ greatly from their industrial ADC counterparts in the delta–sigma table. They generally have poor gain accuracy (5% to 10%) and dc offset (∼25 mV), in part because these don't matter in the audio field. On the other hand, they do offer 0.1 dB or 1% stereo-channel gain *matching*. They're usually wired with ac-coupling, and they also have an internal digital highpass filter (typically ∼1 Hz).[96] They are meant to operate at specific audio data rates, and they employ specialized audio PCM data-output interfaces (I^2S, TDM, etc.). Compared with industrial ADCs they have high latencies (data-output delays) of 12 to 63 sample intervals, even though they may advertise "low latency" (by which they mean small compared with, say, one millisecond of time delay). They have unique audio specifications, like A-weighted SNR, and spectral-analysis-derived THD+N distortion specs.

Figure 13.68 shows a straightforward signal-conditioning circuit, adapted from AKM's evaluation board, not unlike the innards of many commercial audio digitizers. The 5534 op-amp seems to be the perennial

[96] You'll discover this if you bypass the coupling capacitors. However, many of these converters offer a dc mode, and some (like the CS5381 and AK5394A) provide a logic-triggered dc-auto-zero function, which is convenient for very slow or dc applications.

favorite (it's been around for at least three decades), inexpensive and "good enough." Although you can do better in terms of distortion, what seems to matter most to audiophiles is dynamic range (set by the ADC resolution and the noise level); harmonic distortion at 0.001% is inaudible. However, we prefer full differential signal-conditioning circuits for high-performance audio ADCs, as described expansively in Chapter 5 (see Figures 5.70 and 5.102).[97] See §5.14.2E for more about pro-audio signal levels.

13.10 ADCs: choices and tradeoffs

The good news is that world of ADCs is a world of richness, with many choices. The bad news is, well, that the world of ADCs is a world of richness, with many choices. In the following sections we offer some guidance, to help navigate the welter[98] of choices.

13.10.1 Delta–sigma and the competition

A. Analog-to-digital converters

Delta–sigma converters are one of several ADC conversion technologies, which (as we've seen) include also (a) dual-slope and quad-slope integrating converters, (b) successive-approximation converters, (c) flash converters, and (d) pipelined flash converters.

Low speed For "voltmeter-speed" conversion (e.g., 10/sec), multislope integrating converters have been the perennial favorite, but their dominance is being challenged by excellent ΔΣ's from LTC (e.g., the LTC2412: 24 bit) and ADI (e.g., the AD7732: 24 bit, ±10 V range), among others.

Medium speed (to ~100s of ksps) Delta–sigma converter ICs dominate at resolutions above 16 bits, with nice products from companies like Cirrus and AKM (e.g., the AK5384: 24 bit, 96 ksps, 4 channels, or the converters in Figure 13.68). There are many good delta–sigma audio ADCs, but their dc specs tend to be poor (several percent) or nonexistent. For resolutions of 16 bits or less, consider the highly usable successive approximation converters.

Medium-high speed (to a few Msps) Here there is a fierce battle between ΔΣ's and successive-approximation ADCs using a switch-capacitor charge-redistribution ADC: comparable accuracy, but the SARs are faster (e.g., the ADI AD7690: 18 bit, 400ksps; a member of the AD76xx/79xx PulSAR™series). See the "shootout" below.

High speed (to 100s of Msps) For these speeds you choose a pipelined flash converter (previously known as "half-flash"), with successive stages of low-resolution flash conversion operating on the analog residue of the previous stages, or with the "folding-amplifier" architecture (Figure 13.27). Pipelining results in high throughput, but with the latency of typically 10 sample intervals. Examples are the ADI AD9626 (12 bit, 250 Msps) and the TI ADS6149 (14 bit, 250 Msps).

Breakneck speed (>250 Msps) Variants on the basic flash (such as folding/interpolating) rule the roost here, but the tradeoff is modest resolution (6–10 bits). National has some nice ones, for example the ADC08D1520 (8 bits, 3000 Msps), ADC10D1500 (ditto, 10 bits), and ADC12D1800 (12 bits, 3600 Msps). These kinds of converters are used widely in 'scope front-ends,[99] and in digital radio. At the extreme (and we're not sure how they do it), Fujitsu is featuring a 56,000 Mbps (!) 8-bit converter.[100]

B. Digital-to-analog converters

Competing DAC technologies are (a) *R*–2*R* ladder, (b) linear resistor ladder with switch array, and (c) current-steering switch array.

Highest linearity Delta–sigma DACs are best, with accuracy and linearity to 20 bits at audio speeds, and sometimes with excellent dc specs as well (e.g., the millisecond-speed 20-bit TI DAC1220); however, watch out for broadband and clock noise (the DAC1220 has ~1000 nV/$\sqrt{\text{Hz}}$ at 1 kHz compared with ~10 nV/$\sqrt{\text{Hz}}$ for resistor ladder converters).

Medium speed, high accuracy Many excellent *R*–2*R* and linear ladder DACs compete, for example:

- TI DAC8552 (dual 16 bit, serial in, voltage out, ext

[97] Interestingly, both AKM and Cirrus use this simple scheme, and inexpensive '5534 amplifiers, in their ADC evaluation kits. However, the Cirrus "reference design" kit substitutes the lower-noise LT1128 op-amp. By contrast, TI uses a true differential amplifier (the OPA1632) in the evaluation kit for their comparable PCM4222 audio delta–sigma converter.

[98] Merriam–Webster: "A large number of items in no order; a confused mass. *Synonyms:* confusion, jumble, tangle, mess, hodgepodge, mishmash, mass; *informal* rat's nest.

[99] Currently available digital 'scopes achieve analog bandwidths of 32 GHz with sampling rates of 80 Gsps (e.g., Agilent 90000X series), figures sure to increase with time.

[100] Evidently they're so excited about it that they have neglected, thus far, to assign a part number.

Comments: **A:** low power. **B:** 8-pin, "entry level"; choose p/n for data format. **C:** PCM1754=H/W interface. **D:** stereo headphone drivers, and class-D mono spkr amp, 2.7-5.5V. **E:** high performance consumer audio/video. **F:** portable consumer audio; 100dB SNR at headphone output. **G:** octal, multichannel consumer audio/video. **H:** quad, professional and high-end audio, high performance. **J:** low jitter. **L:** premium; DSD1794A=IIC/SPI. **M:** 16 channels; automotive, etc. **N:** supports SACD output. **P:** premium. **Q:** legendary, the best of the legacy R-2R audio DACs; needs external filter.

ref, very low glitch, 10 μs settle; DAC8560/4/5 similar, with int ref)

- ADI AD5544 or TI DAC8814 (quad 16 bit MDAC, serial in, current out, 0.5–2 μs settle with external *I*-to-*V* op-amp)
- LTC1668 (16 bit, parallel in, differential current out, 20 ns settle into 50 Ω as "voltage out")
- TI DAC9881 (18 bit serial in, rail-to-rail voltage out, ext ref, low-noise, 5 μs settle)

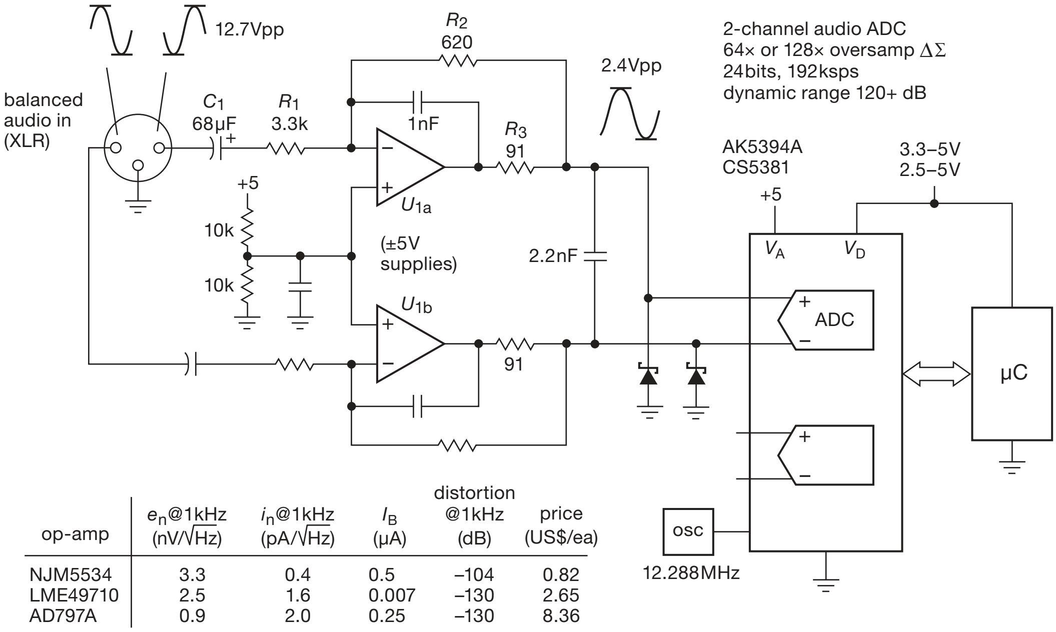
Highest speed Here you can't beat current-steering converters, for example the TI DAC5681/2 (16 bit, 1 Gsps) or the ADI AD9739 (14 bit, 2.5 Gsps).

C. Interlude: shootout at the ADC corral

To illustrate the important performance differences between delta–sigma and successive-approximation ADCs, we invited two able and well-matched contenders from the same training camp (Analog Devices) to slug it out. They came forward with their respective (and respectable) specifications, which look like this:

	SAR AD7641	ΔΣ AD7760	units
Introduced	2006	2006	year CE
Price	$47	$53	US dollars
Conv rate	2.0	2.5	Msps
Samp freq	2	40	MHz
Alias above	1	20	MHz
Resolution	18	24	bits
Zero error	60	200	ppm max
" tempco	0.5	0.1	ppm/°C typ
Gain error	0.25%	0.016%	max/typ
" tempco	1	2	ppm/°C typ
SNR	93	100	dB typ
THD	−101	−103	dB typ
INL	±7.6	±7.6	ppm typ
Data delay	0.5	12	μs
Reference	int	ext	
Supplies	1	3	
Power	75	960	mW

The delta–sigma contender put in a few good jabs, with its superior resolution and the ease with which the user could



op-amp	e_n@1kHz (nV/√Hz)	i_n@1kHz (pA/√Hz)	I_B (μA)	distortion @1kHz (dB)	price (US$/ea)
NJM5534	3.3	0.4	0.5	–104	0.82
LME49710	2.5	1.6	0.007	–130	2.65
AD797A	0.9	2.0	0.25	–130	8.36

Figure 13.68. The AKM and Cirrus delta–sigma ADCs are ubiquitous in professional audio digitizers. They are often implemented with a simple analog frontend like this, though a better approach would exploit a true differential amplifier (§5.17). Reproduced with permission of Asahi Kasei Microdevices, Tokyo, Japan.

design an input bandwidth-limiting (anti-aliasing) lowpass filter (owing to its 8× oversampling ratio). The SAR responded that the number of bits isn't a big deal, it's really *linearity* (for which both are equal) that counts. And, by the way, the SAR produces output bits 25 times faster, with its superior low latency. The sigma–delta counterpunched with its claim to superior SNR, to which the SAR parried with disapproval at the ΔΣ's need for at least two power supplies and an external reference, and its profligate waste of 13× as much power. The sigma–delta, though somewhat chastened, bounced back with a claim of 15-fold smaller gain error, to which the SAR replied that the delta–sigma was cheating because it relied on a gain-correction register to do "smart" calibration. This set up the delta–sigma to deliver the ultimate insult, namely that the SAR wasn't even smart enough to cheat. Both contenders claimed victory (as they staggered back to their respective corners), but onlookers judged it a close match, with good punches on each side.

13.10.2 Sampling versus averaging ADCs: noise

Delta–sigma converters are inherently *integrating*; that is, a measurement takes account of the varying signal throughout the conversion time; you can think of this as simple *averaging*. With a SAR converter, by contrast, the instantaneous voltage of the input signal is captured in a track-and-hold (during the so-called *aperture* time) when the converter is triggered. This distinction has some important consequences, among them the ability of SAR converters to operate at exceptionally low average power consumption when sampling at a leisurely rate (see next section).

Another consequence of importance is the effective bandwidth at which the input signal is sampled. A short aperture corresponds to a wide bandwidth, and vice versa. Intuition serves well, here: high frequencies are washed out during a long averaging interval, whereas a quick sample can record the signal's amplitude as it gyrates rapidly. Put another way, averaging a signal over some time interval τ acts like a lowpass filter, whose bandwidth is very roughly of order $1/\tau$; mathematically speaking, they are related by the Fourier transform.[101]

To make these statements quantitative, look at Figure 13.69, which illustrates the lowpass filter function of an averaging window of time duration T. Low frequencies pass through, but higher frequencies suffer from averaging;

[101] And particularly by the convolution theorem, where the sampling interval is represented by a unit-amplitude rectangular window in time. Its Fourier transform is the sinc function, $(\sin t)/t$, with a first zero at $f{=}1/\tau$.

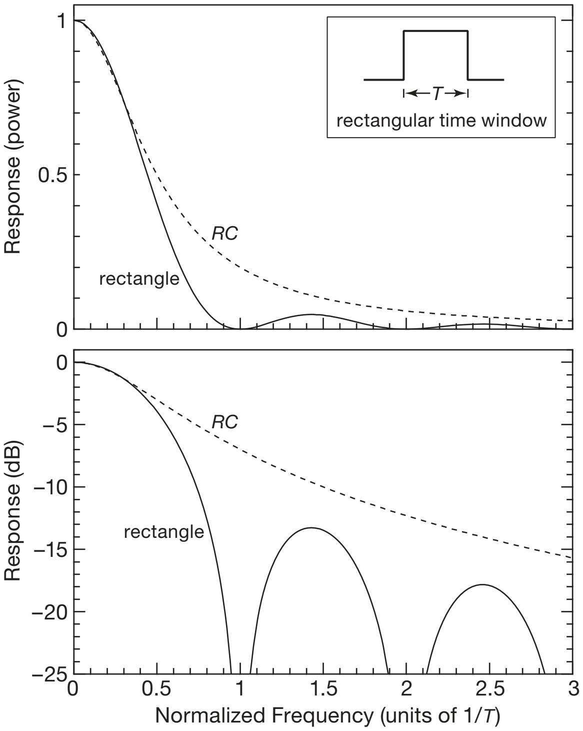


Figure 13.69. Spectrum of a rectangular pulse $\Pi(t)$ of length T. An input signal, gated (windowed, or multiplied) by $\Pi(t)$, is effectively lowpass filtered by the indicated power spectrum. An *RC* lowpass filter with 3 dB rolloff at $f{=}1/2T$ is shown for comparison.

a signal of frequency $f{=}1/T$ completes one full cycle during the window's time duration T, thus averages to zero. Additional zeros occur at multiples of $1/T$, where a signal of the corresponding frequency completes an integral number of cycles.[102]

So a short window admits wideband noise that may be present, degrading the accuracy of an intrinsically slow signal that would benefit from averaging. Keep this in mind when designing a conversion circuit, particularly one that operates on intermittent samples of a slowly varying signal (for example, a temperature sensor or strain gauge). It's OK to use a fast-sampling successive-approximation ADC, as long as you are willing to add a lowpass filter at the input. With an averaging converter (delta–sigma, dual-slope, or multislope) you get that benefit for free.

13.10.3 Micropower A/D converters

Small battery-powered devices often need some information about the real world, which they can get from a sensor signal and a low-power ADC. Frequently a simple 8- or 10-bit ADC included in the microcontroller IC will do, but for those who need better performance we offer a selection of micropower ADCs in Table 13.6 on page 916. The table lists both SAR and ΔΣ converters, with most of the entries appearing also in either Tables 13.5 or 13.9. Let's take a look at a comparison of these converter types for a typical micropower application.

SAR types are known for fast conversion speeds, but this comes at the expense of higher power consumption. SAR ADCs capture a sample of the signal when they are triggered, allowing you to turn the sensor off immediately; this saves power with something like a hungry strain-gauge bridge. Fast SAR converters draw more current, but they also finish faster and go to sleep. For example the AD7685 consumes 2.7 mW during continuous 16-bit conversions at 200 ksps (its maximum, when running on 3 V); but for a sensor application we can make measurements far less frequently, say at 100 samples per second where the average power dissipation is just 1.4 μW (2000× less). As noted in the table, for most SAR types the power dissipation is proportional to the sample rate, so there are plenty of other low-power candidates to be found in Table 13.5.

As remarked above, delta–sigma converters are integrating by nature, and they take longer to perform a conversion. Furthermore, a 16-bit conversion can take 16 times longer than a 12-bit conversion. But ΔΣ ADCs generally consume less operating power than comparable SARs. The delta–sigma MCP3425 dissipates 0.44 mW when operating continuously at its maximum 15 samples/second (for 16-bit conversions), six times less than the SAR above running at its maximum 200 ksps. At this stage you may conclude that the delta–sigma is the low-power winner. But the comparison is lopsided, because the sampling rates differ by a factor of more than 10,000. Note, by the way, that these power requirements are much larger than the promising figures you may find on the datasheet, where for example the MCP3425 claims the ability to operate at power levels as low as 1.8 μW average; but there's a gotcha, because that rosy figure applies to operation in 12-bit mode, and at just one sample per second.

Low-power ADC shootout. To compare these two converters fairly, then, let's assume we want to make ten measurements per second at 16-bit resolution, and we want to choose the converter that minimizes the power dissipation. At that rate the delta–sigma converter requires 290μW

[102] It is this complete rejection of signal frequencies at $1/T$ and all its harmonics that lets you make benchtop DMM measurements without worrying about powerline pickup: the DMM's integrating interval is chosen to be an integral number of powerline cycles (PLCs), recall §13.8.3, and particularly Figure 13.42.

average power, to be compared with the SAR's required 0.14μW. The SAR beats the pants off the $\Delta\Sigma$ – it's using just 1/2000 of the power! On this figure of merit alone, it's a slam-dunk.[103] But there's more to consider. The delta–sigma integrating conversion takes 66 ms, which yields a quieter measurement than a SAR ADC sampling the signal in a fraction of a microsecond, as described in §13.10.2.[104] By comparison, the AD7685 SAR mentioned above can perform 2000 measurements for the same total energy as one $\Delta\Sigma$ measurement – but you may need to take and average all of them to reduce the noise.

We always suggest a careful study of any candidate part's datasheet. When evaluating micropower ADCs, consider also whether they include an on-chip input amplifier, internal voltage reference, and conversion oscillator. If not, these functions may require additional external power. Some ADCs use the supply as the voltage reference, which is well suited for a ratiometric sensor like a thermistor or strain gauge. For other sensors you may have to operate the entire ADC from an external voltage reference. Some ADCs use the interface data shifting as the conversion clock, which may force the controller to waste time and power creating a slow data-clock rate. Note also that some external-clock converters require quite high frequencies, for example the AD7091R SAR ADC needs a 50 MHz clock to run at its 1 Msps maximum speed; requirements like this can have a severe impact on power consumption.[105] When considering converters for applications where you are planning to power them intermittently, keep in mind also that some converters have a non-trivial startup delay time from sleep mode.

One last consideration is the supply voltage. Most of the parts in Table 13.6 require a moderately high minimum supply voltage, such as 2.7 V. But ADCs capable of operating at lower voltages can save considerable power. For example, the AD7466 consumes 620 μW at 100 ksps when running with a 3.0 V supply, but it uses only 120 μW at 1.6 V.[106] This ADC suffers modest performance penalties at 1.6 V, but the bigger problem may be designing analog circuitry to operate on such a low voltage. Looking at the bright side, you may be rewarded with a simplified battery arrangement.

13.11 Some unusual A/D and D/A converters

Here are some interesting converter ICs, both instructive and useful, that we cannot resist displaying. These all come from Analog Devices, a traditional leader in conversion ICs and other high performance analog products. (See also the low-power ADCs in Table 13.6, and the unusual "specialty converters" in Table 13.12.)

Table 13.12 Specialty A-to-D Converters[a]

Part #	Bits	Conv Rate max (ksps)	Channels	ADCs	SAR	Integrating	Comments
AMC1203	1	10M	1	1	-	•	$\Delta\Sigma$ modulator, AC motor curr
AD7873	12	125	6	1	•	-	resistive X,Y touch screen

AD7609	18	200[f]	8[f]	1	•	-	simultaneous-sampling, diff'l
DDC232	20	6	32	32	-	•	32 current inputs, 3 to 12pC
78M6631	22	2.5	6	1	-	•	3-phase power, w/ 8051 CPU
AD7746	24	0.09	2	1	-	•	precise capacitance, ±4pF FS
ISL26102	24	4	2	1	-	•	quiet, 7nV/√Hz, 2ppm linearity
LDC1000	24[b]	d	2	2	•	•	inductance, loss resistance
ADS1298	24	32	8	8	-	•	standard 12-lead ECG
TPA5050	24	192	2	2	-	•	audio, lip-sync delay to 120ms

Notes: (a) wherein we find inductance, capacitance, ultrasound, ECG, powerful sensor analog front ends, and RF communication, etc. (b) 24 bits for L(inductance), 16 bits for R_P (equiv parallel resistance). (c) 14kHz RMS bandwidth. (d) fastest response = 192 LC cycles, for example 10 ksps for 2MHz. (e) sensor analog front end. (f) simultaneous sampling, 200kHz all channels.

[103] And, of course, there's also the power saved if the external sensor is power-switched.

[104] Recall that bandwidth is related inversely to pulse width, as BW≈ $1/\tau$, and that noise power grows with bandwidth (P_n=e_n·BW for white noise). So a slower measurement corresponds to reduced bandwidth; it averages out the high-frequency noise.

[105] Taking the AD7091R as an example, the SCLK driver consumes P=CV^2f; taking C=5 pF, that amounts to 2.25 mW for a 3 V logic swing at 50 MHz, which is significantly greater than the converter's own specified power dissipation of 1 mW. Happily, the 50 MHz clocking on the SCLK pin is needed only during the 12 or 13 shifts of output data, thus reducing the average SCLK power to 0.6 mW (i.e., a factor of 13/50); much better, but still a significant contributor to the total power.

[106] The 5.2× power ratio is more than the square of the 1.9× supply-voltage ratio, revealing that the operating current drops faster than linearly versus supply voltage. This should not be a surprise, considering the effect of class-A "shoot-through" current in CMOS logic, see Figure 10.101.

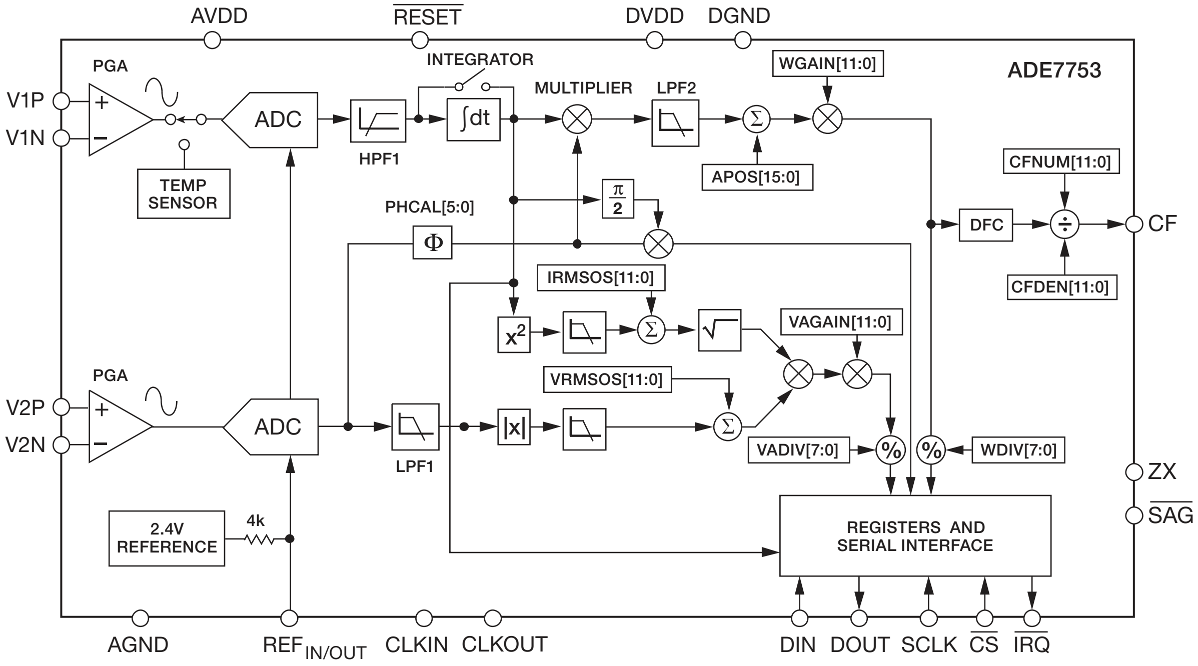

Figure 13.70. The Analog Devices ADE7753: an elegant ac power-monitor IC, courtesy of Analog Devices, Inc.

13.11.1 ADE7753 multifunction ac power metering IC

In industrial settings (and, increasingly, in the energy-aware residential context as well) it's important to keep track of electrical energy usage, in the manner of the traditional power meter with the rotating disk and the accumulated watt-hour dials. As important, or more so, is the need to monitor and minimize *reactive* power; that is, to compensate for reactive loads (such a motors) in order to keep the power factor (§1.7.6) close to unity. The power company cares about reactive power, and indeed conveys that care in the form of surcharges to industrial users, because it produces I^2R heating losses in their lines and transformers, even though it delivers no useful power to the load. It's nice also to be able to monitor the instantaneous power (both real and reactive), and, while we're at it, the presence of voltage dips (brownouts) or peaks (surges).

The elegant ADE7753 from Analog Devices[107] (Figure 13.70) is a fine example of A/D conversion, tailored specifically to this application. It normally would be paired with a microcontroller, as shown in Figure 13.71 (and in Figure 15.21). Here we'll simply admire its many thoughtful design features.

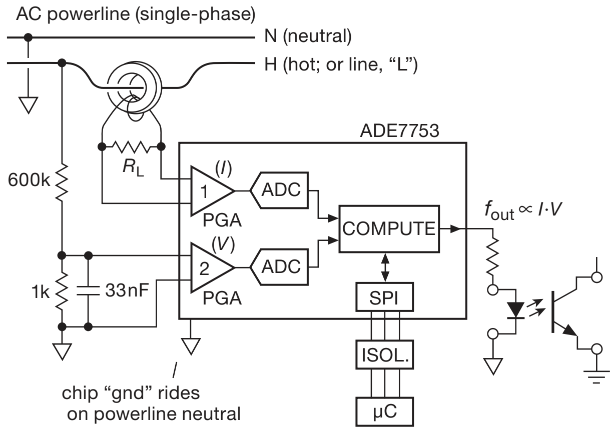

Figure 13.71. Basic powerline connection, with current transformer sensing of ac line current. The f_{out} pulse train provides a running count of energy usage, in the manner of the traditional rotating-disk power meters.

Overview From an analog input signal pair that provides a sample of line voltage and line current, this chip uses purely digital techniques (after the front-end amplifiers) to calculate continually the values of real ("active") power, reactive power, and the volt–amp product ("apparent power"). It also accumulates active and apparent power, and detects voltage sags and peaks. It is highly configurable

[107] We've chosen the single-phase part, for simplicity; the similar ADE7758 handles 3-phase power.

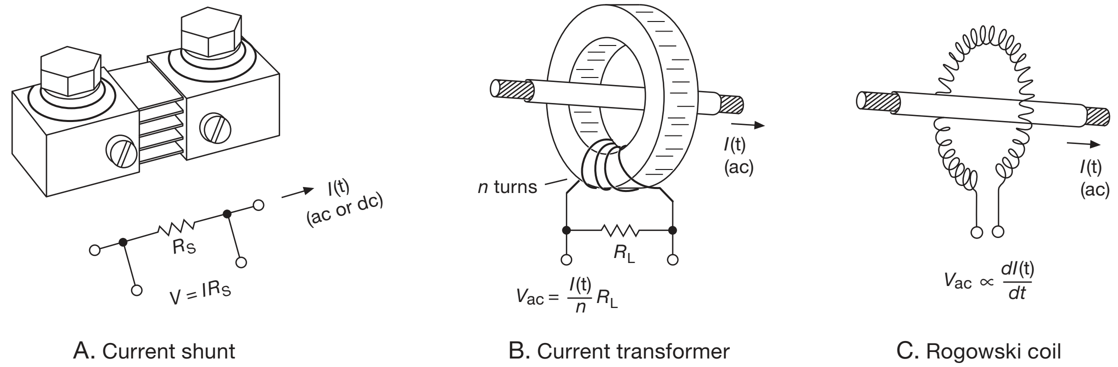

Figure 13.72. Current-sensing techniques. The 4-wire resistive shunt (A) works with ac or dc, but provides no isolation. The current-transformer (B) and Rogowski coil (C) methods work only with ac.

by way of the simple 3-wire SPI bus (§14.7); that's how an embedded microcontroller communicates with the chip's 64 internal registers, which are used both to set up operating modes and to report measured values. It also provides a pulse-train output whose rate is proportional to active power (the rotating disk in a mechanical power meter); so, once calibrated, it can be used in stand-alone mode (no microcontroller) if all you want is a running count of accumulated energy usage.

Details, details A pair of programmable gain difference amplifiers accept the low-level (± 0.5 V) signal inputs from the line voltage and current samples. There are three ways to derive the latter (Figure 13.72): (a) a small-value calibrated 4-wire in-line series resistor (a "shunt"); (b) a toroidal current transformer (as in Figure 13.71) with resistive load; or (c) a "Rogowski coil." The latter produces a voltage signal proportional to dI/dt, compared with $\propto I$ for the other two, thus requiring an additional integration. In exchange for that hassle it has the advantages of linearity (no magnetic core) and easy installation[108] (no need to disrupt power). The amplifiers have digitally trimmable offsets; their outputs are digitized with a pair of second-order 16-bit $\Delta\Sigma$ ADCs, producing the $\sim$28 ksps digitized stream of V and I samples.

Now comes the fun. The top path through the block diagram of Figure 13.70 is the active (real) power computation: channel 1 is the line current signal, with dc removed, feeding an optional integrator (for Rogowski); that is multiplied by the channel 2 voltage waveform, with a 0.05° phase trim (PHCAL) to ensure accurate in-phase multiplication. The result – instantaneous active power – has offset and gain trims, and then generates a proportional output frequency (at the CF pin) by way of a digital frequency converter (DFC); it also goes to the register bank, where it (and its accumulated value) can be read out.

The middle path is the reactive power computation: it's similar, but with a 90° phase shift in the current path. Finally, the bottom path is the volt–amp product (apparent power) computation, done as the product of the magnitude of voltage times the rms current, with the usual trimmable offsets and settable gain.

The block labeled "registers and serial interface" shyly conceals its considerable intelligence. It's really in charge here, with all those trims and gain settings, mode settings for things like the sag and peak detectors, the optional integrator, and the frequency scaling of the CF output. It also houses the 49-bit energy (power × time) accumulators (both real and apparent), and registers that hold data about sags and peaks. It can be configured to make an *interrupt* (§14.3.7) to the processor when bad things happen.

Overall, a pretty impressive performance for a part that costs about $4 in small quantities.

13.11.2 AD7873 touchscreen digitizer

A "touchscreen" is the familiar combination of a display device (usually a backlit color LCD), on top of which is an overlay that is sensitive to contact pressure (by fingertip or stylus). These things are used in smartphones, PDAs, tablet PCs, teller machines, point-of-sale terminals, and the like, to allow simple digital (that's a pun, get it?) manipulation of displayed objects. A simple and effective type, called a *resistive touchscreen*, consists of two thin sheets of

[108] It's even better than the figure suggests, because in practice one lead snakes back through the coil so that both leads come out at the same end. See datasheets for the RoCoil from DENT Instruments or the RopeCT from Magnelab.

transparent material, each with a conductive coating, which are pressed together by the finger's contact force.

How can you figure out where that happens? Easy: there is a metal-strip electrode along two opposing edges of each sheet; so if you apply a dc voltage across one such sheet, it acts like a resistive voltage divider, with a linear increase of voltage from one edge to the other. The touchscreen sandwich is a stacked pair, one oriented in the *x* direction, the other in the *y* direction. To read out the contact position, you first energize one sheet (say the *x* sheet) with a dc voltage, and read the voltage that the contacting point transfers to the other (*y*) undriven sheet; that gives you the *x* coordinate of the pressed location. Then you reverse the roles, energizing the *y* sheet and reading the voltage transferred to the *x* sheet.

The AD7873 (Figure 13.73) does everything you need, and more. It talks to the usual embedded processor (Chapter 15) via a 3-wire SPI serial port (§14.7 and §15.8.2), for both setup and readout. It includes internal MOSFET switches for energizing alternately the *x* and *y* sheets; an internal voltage reference; an internal temperature sensor; and a 12-bit SAR ADC with input multiplexer to select and digitize among (a) the undriven sheet, (b) the driving voltage, to make the measurement ratiometric, (c) the battery voltage, (d) the temperature, and (e) an uncommitted analog input of your choosing. This thing runs on a single supply (+2.2 V to +5.25 V), with power consumption of a few milliwatts and a price tag of about $2 in modest manufacturing quantities (1000 pcs).

An alternative touchscreen technique substitutes *capacitance* for resistance, with various schemes for determining the point of proximity. You can get complete capacitance converters, with on-chip reference, excitation, delta–sigma converter, and serial interface, for example the AD7140/50 and AD7740-series from Analog Devices. These come in single- and multiple-channel varieties, with resolutions from 16 to 24 bits. They're not fast (∼100 sps), but they're quite inexpensive (a dual 12-bit 200 sps or an 8-channel 16-bit 45 sps converter costs about $2 in quantities of 25).

13.11.3 AD7927 ADC with sequencer

Many ADCs include an on-chip analog multiplexer, so you can sample and convert a succession of analog inputs. The AD7927 (Figure 13.74) lets you do this; but it adds a programmable sequencer mode, so that you can designate a subset (actually, two subsets) of input channels to be converted in sequence, over and over. Sampling and conversion are triggered by the chip select pin, without the pipeline delays characteristic of delta–sigma converters. It uses an SPI serial port for both control/programming and for data readout; it's described in this context in §14.7.1.

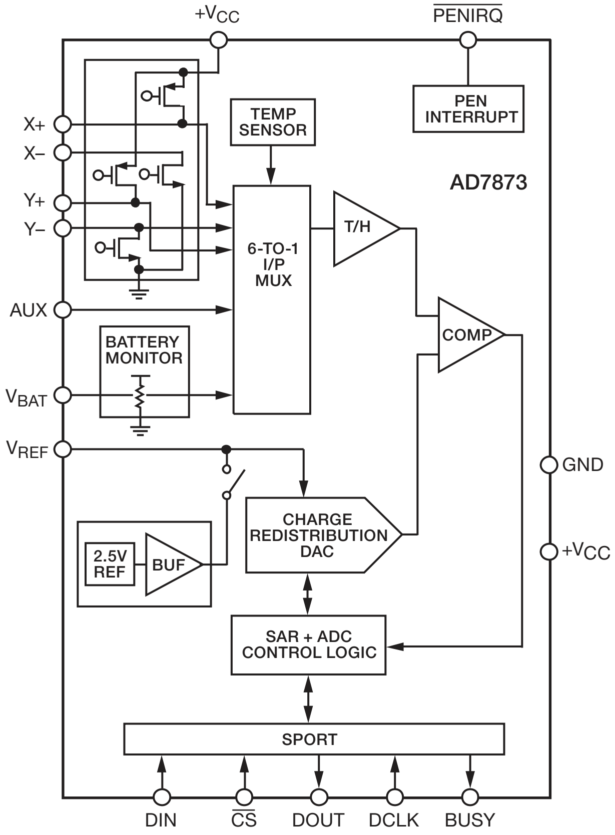

Figure 13.73. The AD7873 Resistive touchscreen digitizer. The fingertip's *x* and *y* position is determined in two phases, by energizing each plane in succession and reading the voltage-divided output from the other, courtesy of Analog Devices, Inc.

13.11.4 AD7730 precision bridge-measurement subsystem

Here's a nice chip (Figure 13.75), which takes aim at the weigh-scale market where resistive bridge transducers (strain gauges) are used. Its nicely organized datasheet makes it easy to navigate its host of clever features. It has programmable gain frontend differential amplifiers with adequate gain for 10 mV full-scale inputs, and a differential reference input for fully ratiometric measurements. It can be operated in a chopping mode, to minimize offset voltage errors and drift; and it has internal calibration modes to correct for scale errors. So you can connect the strain-gauge terminals directly to this chip, without any external preamps.

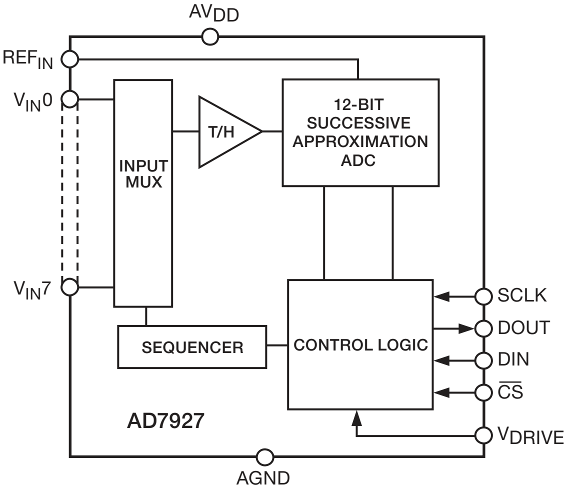

Figure 13.74. The AD7927 multiplexed successive-approximation ADC with flexibly programmed "sequencer" modes, courtesy of Analog Devices, Inc.

Of particular note is the built-in "ac excitation" signal, which you can use to reverse the polarity of bridge drive on successive measurements, thus cancelling residual offsets – including *external* offsets caused, for example, by thermoelectric voltages at the junctions of dissimilar metals. The front-page banner proclaims "Offset Drift: 5 nV/°C, Gain Drift: 2 ppm/°C." On the digital side of the fence, there's lots of programming flexibility in the control of its 24-bit delta–sigma converter and digital filter, by way of the SPI serial port (§14.7). This puppy runs on a single +5 V supply; it's available in both DIP and SMT package styles, and it costs about $15 in small quantities.

13.12 Some A/D conversion system examples

In this section we look at a few examples of complete conversion *systems*. These illustrate the kinds of design tradeoffs and subcircuit interplay that you've got to worry about when you incorporate a converter within a larger system, one that includes front-end amplifiers, voltage references, and digital interfaces.

13.12.1 Multiplexed 16-channel data-acquisition system

This application example uses a successive-approximation ADC to create a 16-channel multiplexed A/D data-acquisition system (DAQ). Figure 13.76 shows the circuit configuration, which lets you digitize any combination of 16 differential analog inputs (or 32 single-ended inputs), under flexible control of an embedded microcontroller (the latter is the subject of Chapter 15). For example, the various input channels can be configured on-the-fly as single ended or differential and with different front-end gains (set by the PGA programmable-gain amplifier), along with timestamps for each measurement; and the channels can be sampled (or skipped over) in any order, with programmable sampling intervals. A subsystem like this could form the "front end" of a microprocessor-controlled data-taking experiment, in which a quick scan of a dozen voltages is programmed to occur, with successive scans taken at intervals of 100 ms or so.

Although it looks pretty straightforward on its face, a finished circuit like this is usually the result of lots of juggling of features and compromises, as you struggle to find components with the right properties. This example was no exception. Let's take a "design walkthrough" to visit the various choices we made, and the resulting performance.

Input multiplexer Analog multiplexers are plentiful (DigiKey lists nearly a thousand); but less so in varieties that will handle a full ±10 V analog input range. And even less so in devices that permit swings beyond the ±15 V supply rails, or that do not clamp the input when unpowered. The long-lived MPC506[109] from TI (originally Burr–Brown, a leader in analog ICs) is outstanding in this regard, though at the expense of relatively high on-resistance (1.5 kΩ). Its dielectrically isolated CMOS process permits input swings 20 V beyond the rails, without "SCR latchup" or crosstalk between inputs; and its switches are "break-before-make," which means that the various input channels don't find themselves shorted together during address changes in the MUX. Watch out for considerations of this type when shopping for linear switches. They sometimes involve a compromise. For example, "break-before-make" results in a slower switching-time specification (here 0.3μs typ) because the "make" must be delayed (by 80 ns here) to allow the switch to open.

A side note: what happens if an analog input swings more than 20 V beyond the MUX's supply rails? There will be some input current, beginning at about 15 V beyond the rails, and increasing to about 20 mA when you are 40 V beyond the rails. Beyond that you risk damaging the part. If you are expecting serious input overvoltages and want *real* protection, you can include an

[109] Or Intersil's original HI-506A, which is often listed with a break-the-search-engine part number like HI3-0506A-5Z. Ordinary ±15 V switches without beyond-the-rail capability have part numbers like DG506, HI-506, or ADG1206.

Figure 13.75. Frontend analog subsystem tailored for bridge-type transducers such as strain gauges, weigh scales, and pressure transducers. The AD7730 datasheet, from which this figure is taken, is a model of clarity, and a delight to read, courtesy of Analog Devices, Inc.

input current-limit circuit like the one in Figure 13.77: the back-to-back depletion-mode MOSFETs, in convenient TO-92 or SOT-23 packages, can hold off 500 V, and limit the current to ∼1 mA.[110] See §5.15.5 and Figure 5.81 and associated discussion for more detail.

Differential/single-ended selector switches Dual SPDT analog switches, under digital control, route the multiplexers' outputs: in 16-channel differential mode, S_1 and S_2 always look at U_1 and U_2; in 32-channel single-ended (SE) mode S_2 looks at signal common, while S_1 looks at U_1 or U_2 for channels 1–16 or 17–32, respectively. (This is often called a *pseudo-differential* input, because the common terminal is shared by all the SE channels.) Mode and channel switching can be done on a channel-by-channel basis (explained below). Note the absence of an anti-alias filter, which would limit the multiplexing speed: we assume the input signals are appropriately band limited upstream of the multiplexers.

The IH5043[111] SPDT analog switches S_1 and S_2 were chosen for their low leakage, low capacitance, and low charge injection. These come at the expense of relatively high R_{on} (80 Ω max). (You can get plenty of analog

[110] Under normal conditions the series resistance is $2R_{\text{on}}+R_{\text{s}}$, or about 2.7kΩ. The added 1 kΩ of series resistance is not much of a compromise; you could omit the resistor, and the saturation $I_{\text{DSS}} \approx 2$ mA would still protect the MUX, but then the transistors' dissipation limit means that you'd need to limit sustained input overvoltages to 100 V or so.

[111] Alternative part numbers are HI5043 and DG403.

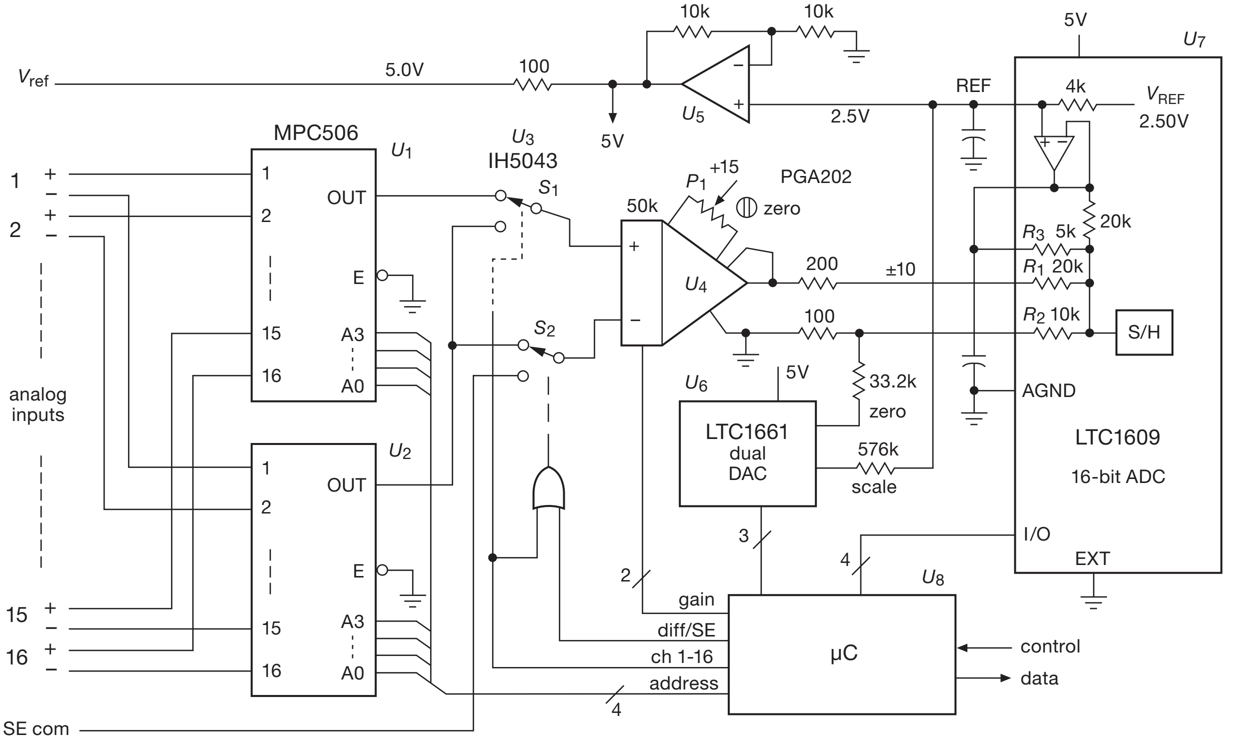

Figure 13.76. A 16-bit 16-channel (differential) or 32-channel (SE) successive-approximation ADC system. The analog ICs in the signal path (U_1–U_5) are powered from ±15 V; the other ICs run from a single +5 V supply.

switches with very low R_{on}, down to 0.5 Ω or less; but you don't need that here, and you'd pay the price in leakage, capacitance, and charge injection.[112])

Instrumentation amplifier Ideally we want an instrumentation amplifier (see §5.15 and Table 5.9) with digitally programmable gain (a PGA), that can accommodate the full ±10 V analog signal range, and that has fast settling time, stable gain, low offset voltage, low noise, and low bias current. It's fine to tick off a laundry list of desirable characteristics – but just how good does each of these need to be? What matters, ultimately, is that the amplifier's limitations do not degrade the overall system's performance.

Given the surrounding system, the PGA202 from TI (Burr–Brown) is a good choice here: it has programmable gains of 1, 10, 100, and 1000 (set by a pair of logic-level input pins), with a settling time (to 0.01%) of 2 *μ*s (for all but G_V=1000), adequate for the downstream ADC's 200 ksps conversion rate. The three lowest gain settings correspond to full-scale input ranges of ±10 V, ±1 V, and ±0.1 V. Its high input impedance and low input current (10 GΩ, 50 pA) do not degrade the combined characteristics of the upstream multiplexer and switch (the MUX specifies a typical leakage current of 2 nA).

Finally, what about amplifier offset voltage and noise? We chose a JFET-input instrumentation amplifier for its high-*Z* input; but, looking at comparable amplifiers in Table 5.9, we see that we've paid a price, in terms of offset voltage and noise, compared with the bipolar-input PGA204. We need to compare these effects with the resolution (LSB step size) of the downstream ADC, which looks at the amplifier's output. But amplifier offset and noise is always specified at the *input* ("RTI," referred to the input); so we need to figure out the converter's RTI step size, which depends on the amplifier's gain. That's easy enough: the ±10 V converter input range, divided by its 2^{16} steps, amounts to an LSB

[112] For example, the ADG884 analog switch has a very low $R_{\text{on}} = 0.4\,\Omega$ (max); but its shunt capacitance C_S(on) is 295 pF, compared with 22 pF for our chosen IH5043. It's also a low-voltage part, with a maximum analog swing of 5 Vpp. The ADG1413 operates over the full ±15 V range, with a low R_{on} of just 1.5 Ω, but its charge injection (±300 pC) is five to ten times greater than that of the '5043/DG403.

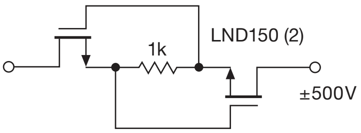

Figure 13.77. Input current-limiter circuit, good to ±500 V overdrive.

step size of 0.3 mV. So the step size, referred to the amplifier's input, is 300 μV, 30 μV, and 3 μV, for gains of 1, 10, and 100, respectively.

We're seriously challenged here, because the amplifier specifies a typical RTI offset voltage of (0.5+5/G) mV; that is, 0.5 mV in its frontend amplifier, combined with 5 mV in its internal output stage. Without some additional tricks we're facing typical offset errors of 5.5 mV, 1 mV, and 0.55 mV at gains of 1, 10, and 100; that's 18, 33, and 180 times the converter's RTI step sizes, respectively. Clearly we need to manually trim its offset, and also include some electronic nulling circuitry;[113] and, even with that, we'll be limited ultimately by the amplifier's tempco and drift.

In our design we've got the recommended manual trim (set once, at maximum gain), and a 10-bit DAC to zero the offset; the latter has a 0–5 V output, for a trim range of ±7.5 mV at the amplifier's output ("RTO"). Its 10-bit resolution gives a 15 μV step size, far better than needed, given the converter's 300 μV LSB step size.

So, to use this thing for full-accuracy measurements, we zero the offset error (via the ADC) at the beginning of a suite of measurements, and we hope that short-term offset drifts are small. Are we on solid ground? Well, the amplifier's specified typical offset drift is (3+50/G) μV/°C, 50 μV/month, and (10+250/G) μV/V(supply). We use regulated supplies, and we are concerned with short-term drifts only; so we're generally OK, with thermal drifts a potential problem only at the highest gain (G=100), where a 1°C change causes a 1-LSB error. There's also drift of amplifier *gain* with temperature to worry about. Here that's 3 ppm/°C (typ) for G=1 or 10, and 40 ppm/°C for G=100. An LSB corresponds to 30 ppm at ±full scale, so once again we're in good shape except at the highest gain (G=100), where the amplifier's gain tempco causes a 1-LSB error for a 1°C temperature change.

Finally, what about the amplifier's voltage noise? The RTI specified values are 1.7 μVpp (typ) for the $1/f$-plagued low-end band of 0.1–10 Hz, and a density e_n=12 nV/$\sqrt{\text{Hz}}$ (typ) at 10 kHz (the $1/f$ corner is roughly 100 Hz). So a band extending from 0.1 Hz to ~10 kHz has an RTI noise voltage of about 3 μV, comparable to the RTI step size at G=100; it's negligible at lower gains.

Analog-to-digital converter We need a converter to handle the full ±10 V signal range, with enough speed for scanning at rates of 100 kHz or more. (There are scanning ADCs, with input multiplexers and sequencer logic, such as the 8-channel 16-bit 500 ksps AD7699, but they force you to live with their limited input range, e.g., 0–5 V or ±2.5 V, rather than the ±10 V as we have here.) The LTC1609 does the job, and runs on a single +5 V supply, which we can regulate and filter individually to keep it quiet. It converts up to 200 ksps, with 2 μs acquisition (input-settling) time, and a serial interface with multiple modes (internally or externally clocked serial data, etc.; see §15.9.2 for interfacing and programming details). Its worst-case zero-offset (±10 mV) and gain (±1.5%) errors have to be calibrated out (done here with the dual DAC, U_6), after which it has acceptably low offset and gain drifts of ±2 ppm/°C and ±7 ppm/°C, typ, respectively. (Recall that an LSB at full-scale is 30 ppm.)

Voltage reference Much of the gain error and drift is due to the internal +2.5 V reference, with its ±1% (worst case) accuracy and ±5 ppm/°C typical tempco. This is in fact a very good drift specification for an internal-reference ADC. But if you want better performance, use a precision external reference (see Tables 9.7 and 9.8), the best of which have ±0.02% (worst case) accuracy and ±1 ppm/°C or better typical tempcos. The LTC1609's REF pin invites an external reference, which simply overdrives the 4 kΩ internal source. With such an external voltage reference the untrimmed gain error is reduced to ±0.5% (which we can trim out with the DAC), and the gain drift is reduced to ±2 ppm/°C (typ). These gain drifts are comparable to those of the upstream amplifier, except at the latter's highest gain (G=100), where the amplifier's drift is an order of magnitude larger and becomes problematical.

Programming and operation With systems that include microcontrollers, there's still plenty of work to do! Here you'd run a calibration setup, storing the ADC trims in non-volatile microcontroller memory. Then at startup you would program the DAC as well as ADC ranges and communication modes. Look first at §15.9.2 and the

[113] Or software offset subtraction: we could devote one (shorted) channel to zero-error measurement. And we could use another to measure the voltage reference for full-scale calibration. Zero-offset error corrections are often stored as parameters that have been measured during calibration.

timing diagram in Figure 15.23 to see how a single ADC conversion is handled. But there's much more involved in controlling a full data-acquisition system like this: you need to set up in advance details such as the active input channels and their sequence, and for each channel whether it's single ended or differential, its gain, etc. This would typically be done with a lookup table, accessed at run time. You also need to specify scan rate, interrupt modes, what data are to be stored at run time (channel number, mode, gain, time stamp, and so on), along with header information that goes into the data file (such as machine ID, experiment type, date, operator, sensor configuration, and so on). We could ramble… but you get the picture: there's plenty of follow-on organization and programming to make it all fly. For these tasks we've found that it's nice to have dedicated graduate students, who have lots of time, lots of skills, and whose degree depends on making it all work.

13.12.2 Parallel multichannel successive-approximation data-acquisition system

The previous example is *multiplexed*, with a single ADC digitizing the input channels successively in some programmed sequence. That's OK in many applications; but sometimes it's important to capture *simultaneously* the input levels on multiple analog inputs. One way to do this is to capture each analog input on its own sample-and-hold (or track-and-hold), then multiplex these stable analog voltages into a single ADC. But ADCs are inexpensive, so it's often better (and always faster) to use a set of them to digitize the inputs simultaneously. In this example we illustrate this with successive approximation ADCs, and in §13.12.3 we'll do it with delta–sigma converters.

Figure 13.78 shows one implementation, using a set of chips from Analog Devices that play well together in this application. Let's walk through it.

Input amplifier Problem: you want to accept bipolarity input signals, say over a ±10 V range – but you've got an ADC running from a single positive supply, which accepts positive signals only. Solution: use an op-amp input stage to offset the signal and reduce its swing. You can do this, but you'll need matched resistors of high precision in order not to compromise the accuracy of the ADCs.

Here we've taken advantage of the elegant AD8275 level-translating ADC driver, which does what you want: it's basically a single-supply difference amplifier with $G = 0.2$ and with an input offset terminal. As here configured it converts a bipolarity input range (±10.24 V) to a positive-only output centered on half the reference voltage, i.e., 0–4.096 V. It's got plenty of bandwidth (0.45 μs settling to 0.001%, which is less than an LSB), rail-to-rail output (so it can run from the same +5 V as the converter, protecting against ADC overdrive), accurate and stable gain ($G = 0.2 \pm 0.024\%$, tempco 1 ppm/°C max), and acceptably low offset and drift ($V_{\text{os}} < 0.5$ mV max, tempco 7 μV/°C max).

Two important points. (a) The offset and drift specifications are *referred to the output* (RTO), not to the input. In other words, the input offset is five times larger, or ±2.5 mV (max), and likewise for the drift. This amount of offset is not insignificant: the 16-bit converter's LSB, referred to the amplifier's input (RTI), corresponds to $2\times10.24\,\text{V}/2^{16}$, or 0.31 mV; so the amplifier's worst-case offset is about 8 LSBs. The drift, by comparison, *is* insignificant: it would take a 45°C change of temperature to move by 1 LSB. So the channels should be calibrated at zero input (and also at full-scale input). (b) The unround reference voltage (4.096 V) is popular because it produces a round-number conversion gain, namely precise 10.0 mV steps at the 11-bit level (which you can think of as further subdivided by 2^5 at the full 16-bit resolution). Also, because the full-scale range extends to ±10.24 V, you can calibrate the system using a 10.0 V reference without driving it over-range.

ADC The AD7685 is a single-supply 16-bit successive-approximation converter with an SPI serial output fast enough to handle its maximum 250 ksps conversion rate. The SPI interface permits daisy chaining with additional converters, as shown; and the serial interface allows packaging in a small 10-pin package. It has good linearity and accuracy properties: no missing codes, ±3 LSB (max) integral nonlinearity, ±0.3 ppm/°C (typ) gain drift.[114]

Reference The ADC requires an external reference, which sets the positive full-scale range. The ADR440 series of "XFET" voltage references (§9.10.3) exploit the pinch-off voltage of a pair of JFETs, in a clever configuration that achieves low noise and low drift: 1.8 μVpp (typ) and 3 ppm/°C (max).

Serial port isolator Quiet systems get noisy if you allow digital hash and ground currents into the analog

[114] This is a charge-redistribution ADC, for which it is sometimes advisable to put a capacitor across the analog input, isolated from the driving amplifier with a small resistor, as in Figure 13.37; a suitable choice here would be 2.7 nF and 33 Ω.

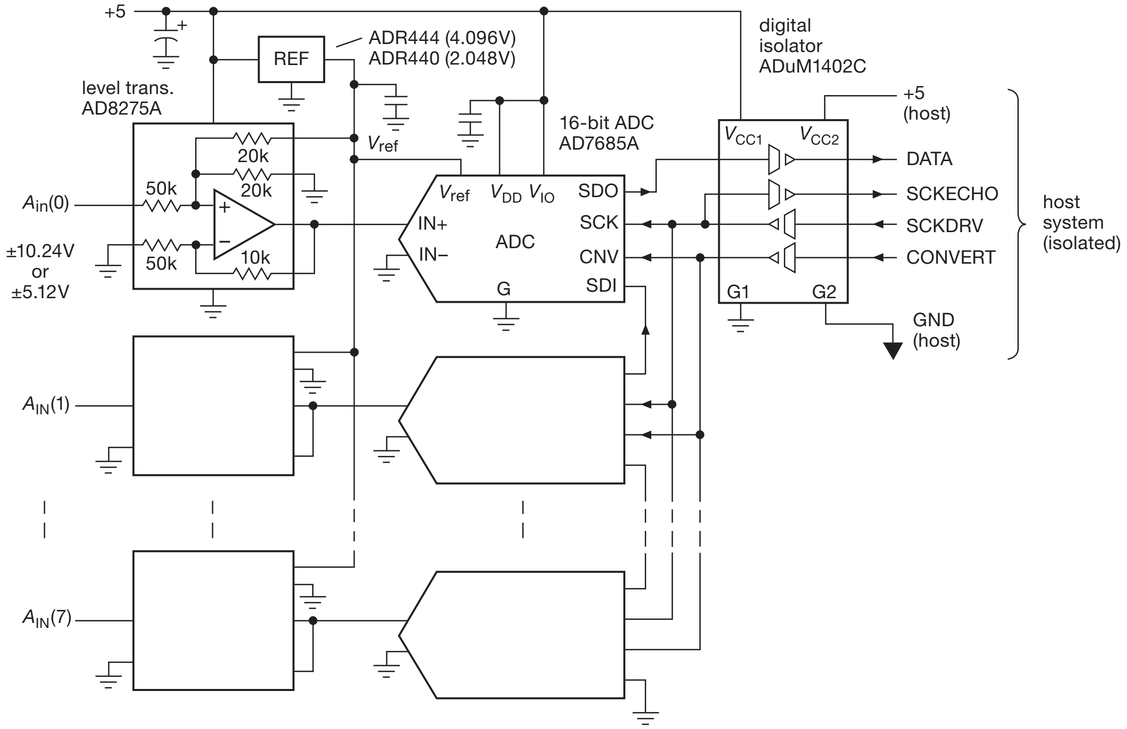

Figure 13.78. Multichannel parallel successive-approximation ADC with isolated SPI serial output port.

portion. With a 3-wire interface it's easy to add full galvanic isolation, in this case with the ADuM1402C 4-channel isolator. This puppy uses on-chip transformer coupling, and is good to 90 Mbps. Note the readback of the SPI clocking signal: that's needed because the signal delay through the isolator (27 ns typ) is comparable to the period of the maximum readout clock rate (∼50 Mbps); by echoing back the SCK received by the ADC, the host system sees the output data accurately synchronized to that echoed clock. This is inaccurate only to the extent that the isolator delay time varies between channels (skew), which for this isolator is an impressive 2 ns (max).

Component cost The amplifier and ADC blocks, which are replicated for each channel, are not expensive: about $3 and $10, respectively (in quantities of 25). Adding $5 for the reference and $9 for the isolator, we have about $118 for an 8-channel system.

A. An integrated parallel multichannel SAR solution

Why build it, when you can buy it? As it happens, the clever folks at Maxim have integrated a simultaneous 8-channel 16-bit successive-approximation ADC system on a chip, with performance comparable to that in the previous section: 250 ksps, single +5 V supply, bipolarity conversion range (±5 V), and good accuracy and linearity (±0.01% maximum offset, ±2.4 μV/°C typical offset tempco, no missing codes, ±2 LSB maximum integral nonlinearity). The MAX11046 uses a parallel data interface, with a separate digital supply pin for compatibility with a low-voltage microcontroller. Figure 13.79 shows the scheme.

This part is unusual in accommodating a bipolarity input voltage range while running from a single positive supply.[115] A single CONV pulse starts the conversion, simultaneous on all channels; the signals are sampled at the rising edge of CONV, with a typical timing skew of 0.1 ns (!). The conversions are complete 3 μs later, and are read out as 16-bit parallel words, one channel per RD′ pulse, as shown.

Figure 13.80 shows in more detail what's included on-chip. The analog inputs are clamped at about 0.3 V beyond the conversion range (i.e., ±5.3 V), but you have to include current-limiting series resistors to limit the clamp current to 20 mA. A set of fast (BW=4 MHz) track-and-hold

[115] The datasheet does not say how this is done, but it's most likely an on-chip charge-pump negative supply generator. The very high input impedance rules out something like the previous voltage-translation scheme.

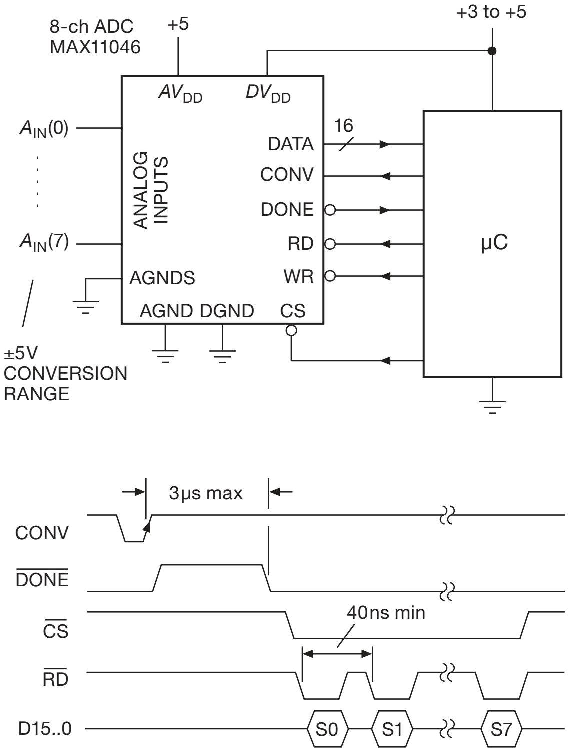

Figure 13.79. The MAX11046 integrates an 8-channel parallel successive-approximation ADC onto a single chip.

circuits capture the input signals, followed by the array of latched ADCs and the output multiplexer. The digital port allows some configuration, via the four low-order bidirectional data lines: internal or external reference, offset binary or 2's complement, and single or continuous conversion mode. You could think about adding galvanic isolation to the digital lines – but you'd have to use 21 channels of isolation, and you'd have to arrange for bidirectional signaling on the four low-order data lines D3..D0 (with the direction set by WR′). Ah, the elegance of serial communication!

Compared with our à la carte design of the previous section, this system is a bargain: about $42 (single-piece price) for the complete 8-channel converter system. As one might expect in the competitive world of silicon, Maxim is not alone in integrating a simultaneous-sampling multichannel ADC. The AD7608 from Analog Devices provides eight channels of T/H (spanning a full ±10 V range) multiplexed into an 18-bit ADC capable of 200 ksps on all channels, with an on-chip digital filter and both parallel and serial output formats. Note the different approach: this latter part uses a single fast ADC to convert the levels captured on the eight T/Hs, whereas the Maxim part uses eight ADCs.

13.12.3 Parallel multichannel delta–sigma data-acquisition system

Here's another example of a multichannel simultaneous-sampling system, this time exploiting the advantages of delta–sigma conversion: high accuracy, low cost, and greatly relaxed requirements for the anti-alias filter (whose rolloff is set by the much higher *over*sampling frequency). Delta–sigma ADCs with integral PGA and serial output (I^2C or SPI) are available in low-pincount packages like the SOT23-6, with prices of just a few dollars, and with conversion resolutions of 16 to 22 bits. A non-multiplexed multichannel data acquisition system is easily assembled by corralling a bunch of these elegant ICs (Figures 13.81 and 13.82), in this case taking aim at a relatively slow but accurate "voltmeter"-like system.

Circuit design involves the fine art of compromise, trading off the various benefits and drawbacks involved in component selection, in the choice of circuit topology and complexity, and in their impact on system cost. The choices we faced, as we worked out this example, illustrate the process nicely. Let's take it in stages.

A. First try

We began with the notion of a bused I^2C array of ADCs (Figure 13.81), which minimizes the number of microcontroller pins needed (compared with an SPI interface), because there is no need for individual chip-select (CS′) lines. TI's ADS1100 converter ($4.50 in unit quantity) looked good: it describes itself as a "self-calibrating, 16-bit ADC" that is a "complete data acquisition system in a tiny SOT23-6 package." It contains a differential input PGA (gains of 1, 2, 4, or 8), runs on a single supply from +2.7 V to +5.5 V (at 90 μA), includes an internal clock, and guarantees 16-bit conversions with no missing codes at its lowest conversion rate of 8 samples/s. It has a maximum integral nonlinearity (INL) of 0.013%, and a typical gain error of 0.01% (the positive supply V_{DD} is the reference, with full scale of $\pm V_{DD}/G$).

That's the good news. Here's the bad news: the I^2C protocol (§14.7.2) requires each bused device to have a unique address (of 128 possible); that's the price you pay for a 2-wire bus with no individual chip-select lines. This is usually accomplished by dedicating a few device pins to set the address (e.g., three pins to select 1 of 8 addresses within a subset of the full 128 possible addresses). But a part with only six pins cannot afford this luxury: count them – differential input (2 pins), power and ground (2 pins), I^2C bus (2 pins) – there are no pins left!

The ADS1100 solves this problem by pre-assigning the addresses, with a different part number for each of eight

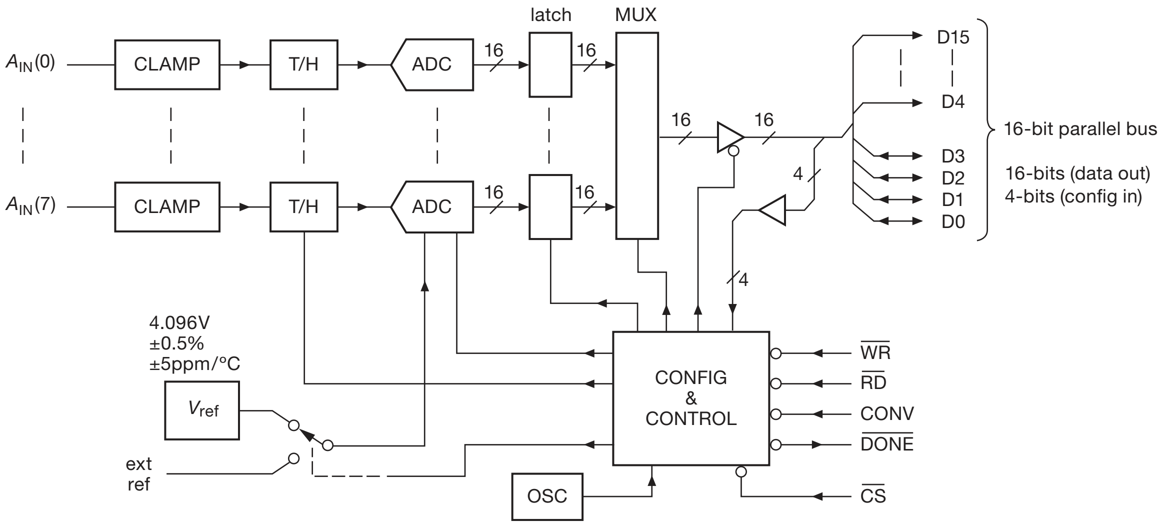

Figure 13.80. Block diagram of the MAX11046 innards.

possible addresses (decimal 72 through 79). For an eight-channel system, then, you've got to order eight different parts (if you can find them in stock: at the moment of writing, DigiKey has addresses 72 and 74; Mouser has addresses 75 through 79; and Newark has addresses 72 through 74), and with less opportunity for quantity pricing.

There's one more piece of bad news: the ADS1100 has an internal clock of coarse accuracy (±20%), with no option for an external clock (no pins remaining!). So you cannot achieve the high rejection of powerline frequencies (60 Hz or 50 Hz) that comes with a sampling rate that is an integral number of powerline cycles (e.g., exactly 10 conversions/s). You wind up with a mediocre ∼30 dB rejection of normal-mode signal at 50 Hz or 60 Hz.

B. Second try

The ADS1115 is a related part from the same manufacturer, priced around $5 (in quantities of 25), this time housed in a 10-pin package, with one of the additional pins allowing some degree of address selection. This is done cleverly: a single pin sets one of *four* addresses (decimal 72–75), according to whether it is tied HIGH, tied LOW, or connected to one of the two I^{2}C serial-interface lines (Figure 13.81). This is an improvement over the 6-pin ADS1100, but with only four possible I^{2}C addresses you'd have to use a second I^{2}C channel to get eight input channels.

There's a second input channel, which could be used for multiplexed conversion. But we want simultaneous conversions on all channels, so we've used the second channel for zero calibration, as shown, which you'd do between active conversions. Some other nice features of this chip are its operation from +2.0–5.5 V, a wide range of PGA gains (0.66×, and 1× to 16×, by factors of two), a wide range of conversion rates (8–860 sps at full 16-bit resolution), and an internal clock and voltage reference.

So far, so good. But there's trouble still in paradise. As with the ADS1100, the internal clock is of only coarse accuracy (±10%), so you get only some 30 dB of powerline rejection.[116] Likewise, the internal voltage reference is not of great precision, and there is no option for an external reference: this is specified as *gain error*, which for this part is 0.01% (typ), 0.15% (max). To give it perspective, an LSB (at 16-bit resolution) is 0.0015% (15ppm); so the worst-case full-scale error corresponds to 100 LSB steps. Furthermore the gain drift (tempco) is specified as 40 ppm/°C (max), which corresponds to 3LSBs/°C.

C. Third try

Not satisfied with these choices, we next explored converters with an SPI digital interface. Instead of I^{2}C's bus addresses, you need to provide a separate chip-select line to each converter (Figure 13.82). That's the bad news. The good news is that there are some terrific converters out there.

We looked at many candidates; the first to pass muster

[116] You need to read the datasheet carefully, here: it lists 105 dB typical *common-mode* rejection at 50 Hz and 60 Hz, but no listed value for *normal-mode* (i.e., differential) powerline signals. Later there's a graph that shows the ∼30 dB value.

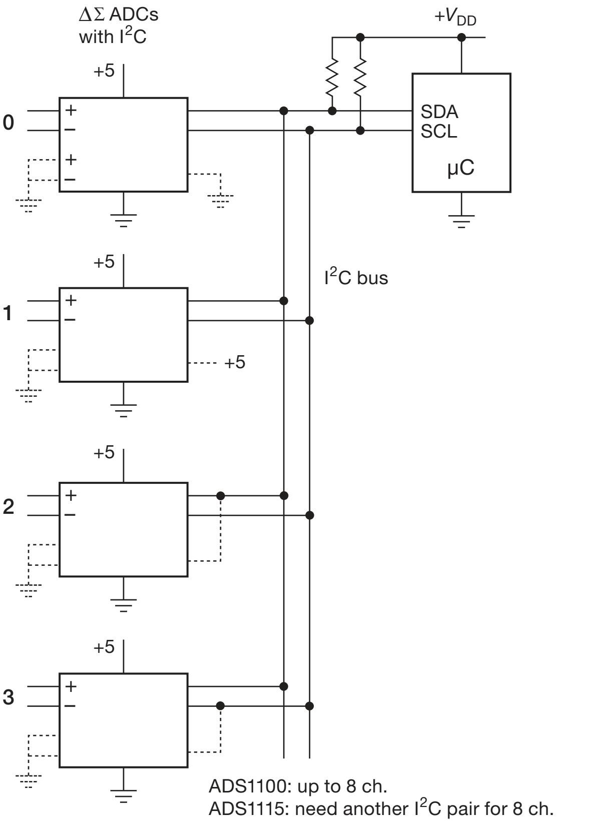

Figure 13.81. Multichannel parallel ΔΣ ADC with I²C output port. The dashed lines show connections for the ADS1115 converter only.

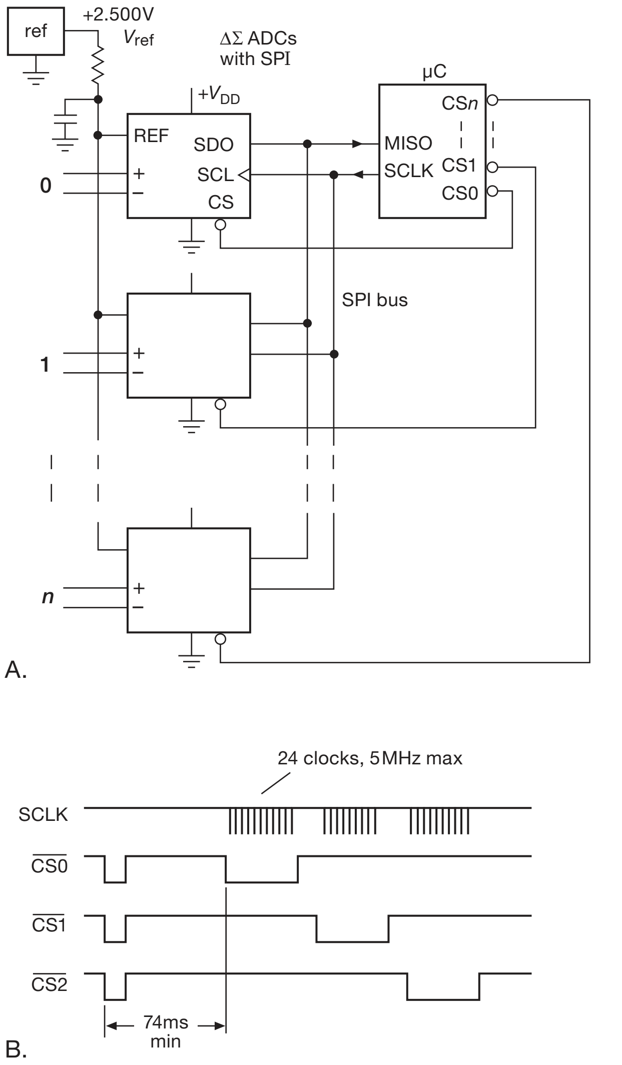

Figure 13.82. Multichannel parallel ΔΣ ADC with SPI output port (e.g., a CS5512 or an MPC3551). The timing diagram applies to the MCP3551 family, for which the first assertion of CS′ initiates conversion (simultaneous across all channels), with subsequent serial data readout (of the individual channels) clocked by SCLK during reassertion of CS′.

was the CS5512 from Cirrus Logic. This is a single-supply (+5 V) 20-bit delta–sigma converter in an 8-pin SOIC, priced around $4.25 (in quantities of 25). An external clock source (32.768 kHz nominal) times the conversions, and also the SPI clocking. The accurate clock frequency is exploited for true *normal-mode* powerline rejection: the chip's digital filter is configured with a broad 80 dB (minimum) notch extending from 47 Hz to 63 Hz, with ∼90 dB simultaneous rejection at both 50 Hz and 60 Hz.

This chip also excels in linearity (±0.0015% of full scale, maximum), and delivers 20-bit resolution with no missing codes. And its typical offset voltage and gain drifts are 0.06 μV/°C and 1 ppm/°C, respectively. This is one classy converter chip!

Now for the thunderclap: this chip requires an external voltage reference, which is normally a good feature (because you can use a high-quality reference, whose voltage also sets the analog scale). Imagine our surprise, then, when we read the datasheet's specification of the full-scale analog input range: $V_{FS}=0.8V_{REF}$, ±10%. In other words, this is a highly linear and stable converter, but with a conversion gain that is uncertain to ±10%.

D. Fourth try

From Microchip (a company traditionally known for its microcontrollers) comes the winning candidate. Their MCP3551 is a 22-bit delta–sigma converter in an 8-pin SOIC (or smaller MSOP), priced around $3.25 (in quantities of 25), with an accurate (±0.5%) internal clock that delivers excellent powerline rejection. It runs from a single +2.7 V to +5.5 V supply, drawing about 0.1 mA. It requires an external voltage reference, which (unlike the previous converter) accurately sets the analog scale factor; and it allows 12% over- and under-range inputs, signaled with two additional data bits. And it performs single-cycle conversions with no digital-filter settling time, during which it also carries out an offset and gain calibration.[117] Figure 13.82's timing diagram shows the scheme for simultaneous multichannel conversion, followed by sequential data readout.

The specifications are impressive: 22-bit resolution with no missing codes; V_{os} of $\pm 12\,\mu$V (max), full-scale error of ±10 ppm (max), INL of 6 ppm (max), and normal-mode powerline rejection of 85 dB (typ) at both 50 Hz and 60 Hz (Figure 13.83).[118] The typical offset and gain drifts are 0.04 ppm/°C and 0.028 ppm/°C, respectively. What's not to like in this converter? The only thing we can really complain about is the absence of a PGA: lacking that, it takes the converter's full 22-bit capability to achieve $1.2\,\mu$V resolution, the same that you would get with a 16-bit converter having a built-in PGA with 64× gain.

Totaling up the cost for an 8-channel delta–sigma simultaneous-conversion system, we have $34 for the ADCs and about $4 for an ADR441A reference, or a very economical $38.

E. An integrated parallel multichannel ΔΣ solution

Never underestimate what can be done on a single piece of silicon. Here again the wizards of Silicon Valley have come through, with several interesting multichannel ADCs featuring simultaneous conversion on all channels.

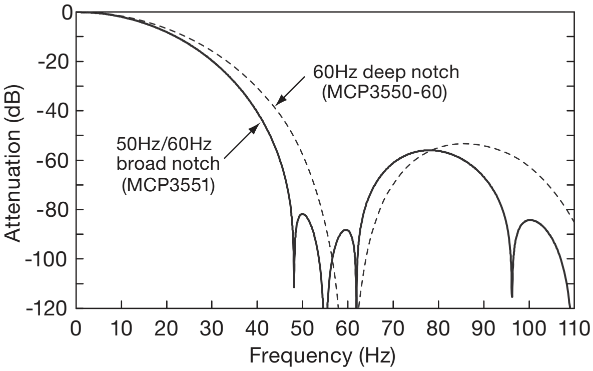

Figure 13.83. The MCP3551's digital filter is configured to create a broad notch covering 50 Hz and 60 Hz powerline frequencies, and a bit more. By contrast, the MCP3550-60 (or -50) is configured for a single deep notch.

For relatively low-speed conversion there's the AD73360, which houses six 16-bit 64 ksps delta–sigma converters, each with its own programmable-gain amplifier (0–38 dB). It comes in a convenient 28-pin SOIC and costs about $8 (in quantities of 25). It has a programmable sampling clock and a serial-output port optimized for transferring data automatically into a downstream DSP chip (from as many as eight cascaded converters). Its six channels are ideal for voltage and current measurements in a 3-phase motor drive, or for industrial power monitoring. It requires in-system calibration (±10% gain accuracy), and is usually used with ac coupling (worst-case dc offset ∼10% of full scale).

What about *really* fast multichannel delta–sigma conversion? Our design runs at a leisurely conversion rate of just 15 samples per second (the AD73360 betters that by three orders of magnitude, but with lower resolution and degraded accuracy). The analogous task becomes extraordinarily difficult if you were to increase this by a factor of a million or so. Difficult, but evidently not impossible: the impressive ADC12EU050 from National Semiconductor (Figure 13.84) packs eight simultaneous 12-bit differential-input delta–sigma ADCs that run at 50 Msps (!). That creates a firehose of digital output, for which it devotes an LVDS pair to each output channel; it consumes about 0.4 W at full tilt, and costs about $100.

13.13 Phase-locked loops

13.13.1 Introduction to phase-locked loops

The phase-locked loop (PLL) is an interesting and useful building block, available both as a single stand-alone

[117] In the words of the datasheet, "A self-calibration of offset and gain occurs at the onset of every conversion. The conversion data available at the output of the device is always calibrated for offset and gain through this process. This offset and gain auto-calibration is performed internally and has no impact on the speed of the converter since the offset and gain errors are calibrated in real-time during the conversion. The real-time offset and gain calibration schemes do not affect the conversion process."

[118] How do they achieve simultaneous rejection at both frequencies? According to the datasheet, "The digital decimation SINC filter has been modified in order to offer staggered zeros in its transfer function. This modification is intended to widen the main notch in order to be less sensitive to oscillator deviation or line frequency drift. The MCP3551 filter has staggered zeros spread in order to reject both 50 Hz and 60 Hz line frequencies simultaneously." For maximum rejection at a *single* powerline frequency, use the MCP3550-50 or -60, which offer 120 dB (typ) normal-mode rejection at the corresponding frequency, once again with the internal clock.

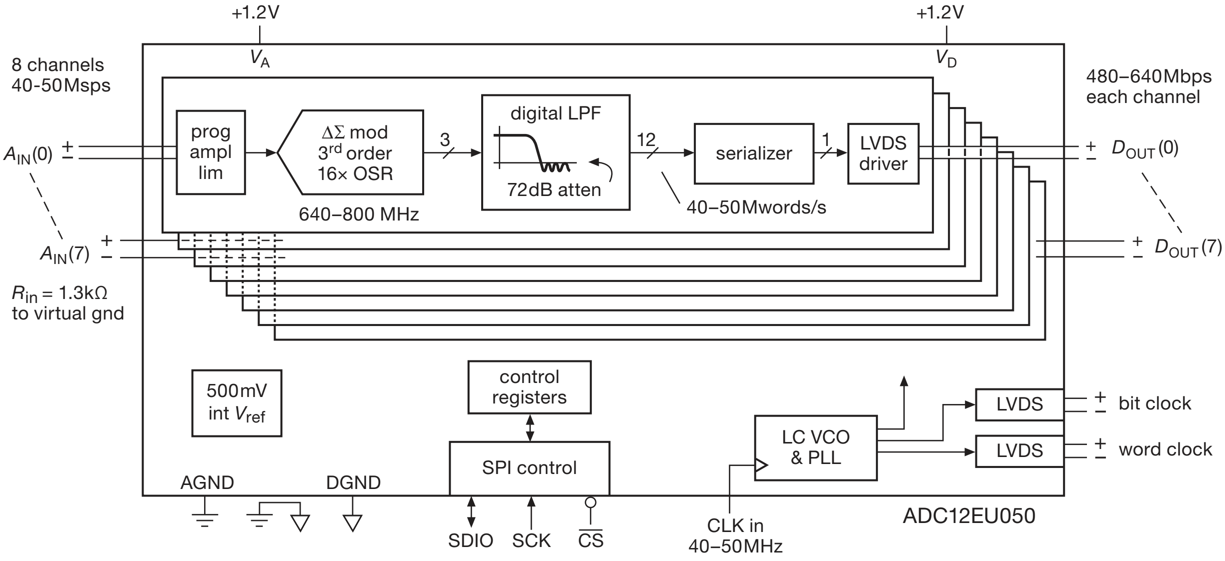

Figure 13.84. The ADC12EU050 is a fast 8-channel delta–sigma converter with 3-bit wordstreams generated by third-order modulators. Its PLL includes an on-chip *LC* VCO to generate the 16× oversampling clock from the 40–50 MHz sample-rate clock input.

integrated circuit, and also often incorporated within more complex ICs. A PLL contains a phase detector, amplifier, and voltage-controlled oscillator (VCO), and represents a blend (sometimes called "mixed signal") of digital and analog techniques. A few of its applications, which we will discuss shortly, are frequency multiplication and frequency synthesis, clock generation and clock recovery, tone decoding, and demodulation of AM, FM, and digitally modulated signals.

In the past there had been some reluctance to use PLLs, partly because of the complexity of discrete PLL circuits and partly because of a feeling that they cannot be counted on to work reliably. With inexpensive and easy-to-use PLLs now widely available, the first barrier to their acceptance has vanished. And with proper design and conservative application, the PLL is as reliable a circuit element as an op-amp or flip-flop.

Figure 13.85 shows the classic PLL configuration. The phase detector is a device that compares two input frequencies, generating an output that is a measure of their phase difference (if, for example, they differ in frequency, it gives a periodic output at the difference frequency). If $f_{\rm in}$ doesn't equal $f_{\rm VCO}$, the phase-error signal, after being filtered and amplified, causes the VCO frequency to deviate in the direction of $f_{\rm in}$. If conditions are right (lots more on that soon), the VCO will quickly "lock" to $f_{\rm in}$, maintaining a fixed phase relationship with the input signal.

At that point the filtered output of the phase detector is a dc signal, and the control input to the VCO is a measure of the input frequency, with obvious applications to tone decoding (sometimes used over telephone lines) and FM demodulation. The VCO output is a locally generated frequency equal to $f_{\rm in}$, thus providing a clean replica of $f_{\rm in}$, which may itself be noisy. Since the VCO output can be a triangle wave, sinewave, or whatever, this provides a nice method of generating a sinewave, say, locked to a train of input pulses.

In one of the most common applications of PLLs, a modulo-*n* counter is hooked between the VCO output and the phase detector, thus generating a multiple of the input reference frequency $f_{\rm in}$. This is an ideal method for generating clocking pulses at a multiple of the powerline frequency for integrating ADCs (dual-slope, charge-balancing) in order to have infinite rejection of interference at the powerline frequency and its harmonics. It also provides the basic technique of frequency synthesizers.

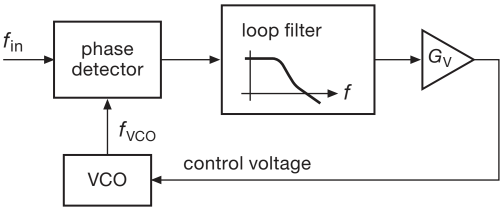

Figure 13.85. Phase-locked loop.

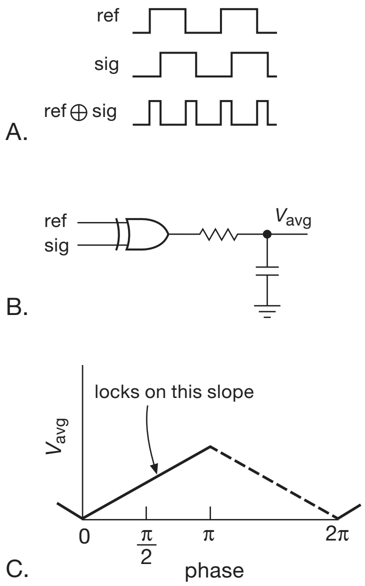

Figure 13.86. Exclusive-OR-gate phase detector (type I).

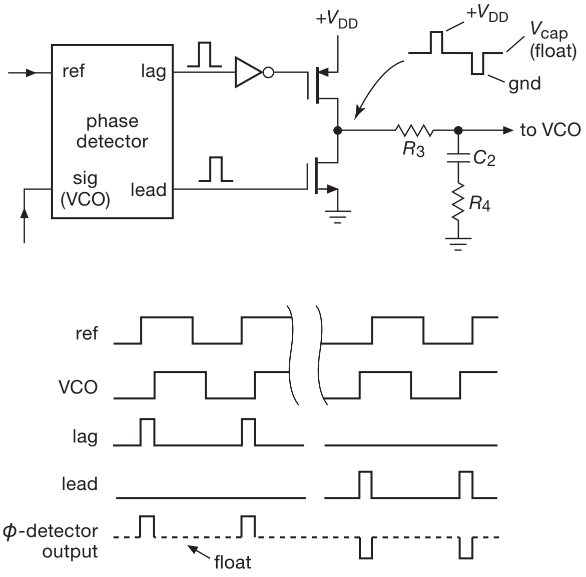

Figure 13.87. Edge-sensitive lead–lag phase detector (type II).

13.13.2 PLL components

A. The phase detector

Let's begin with a look at the phase detector (PD). There are two basic types, sometimes referred to as type I and type II.

The **type I phase detector** is applicable to either analog- or digital-input signals, and performs a simple multiplication of the inputs. For *digital* signals this is just an exclusive-OR gate (Figure 13.86). With lowpass filtering, the graph of the output voltage versus phase difference is a ramp, as shown, for input square waves of 50% duty cycle. For *analog* signals the type I "linear" phase detector is a true analog multiplier (called a "four-quadrant multiplier" or a "balanced mixer"), with similar output-voltage-versus-phase characteristics as with the digital XOR phase detector. Highly linear phase detectors of this type are essential for synchronous detection (also known as *lock-in detection*).

The **type II phase detector**, on the other hand, is a purely digital beast, driven by digital transitions (edges). It is sensitive only to the relative timing of *edges* between the signal and VCO input, as shown in Figure 13.87. The phase-comparator circuitry generates either *lead* or *lag* output pulses, depending on whether the transitions of the VCO output occur before or after the transitions of the reference signal, respectively. The width of these pulses is equal to the time between the respective edges, as shown. The output circuitry then either sinks or sources current (respectively) during those pulses and is otherwise open-circuited, generating an average output-voltage-versus-phase difference like that in Figure 13.88. This is completely independent of the duty cycle of the input signals, unlike the situation with the type I phase detector.

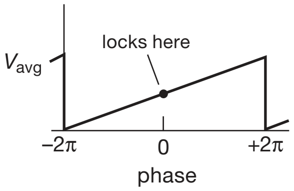

Figure 13.88. Type II phase detector output.

Another nice feature of this phase detector is the fact that the output pulses disappear entirely when the two signals are in lock. This means that there is no "ripple" present at the output to generate periodic phase modulation in the loop, as there is with the type I phase detector. And while we're lavishing praise on the type II, let's point out that it has the pleasant property of producing an average dc output that is indicative of the *sign* of the frequency error (Figures 13.89–13.91). For this reason it's sometimes called a "phase-frequency detector" (PFD). We'll see how that ensures prompt lockup in a PLL.

The classic 74HC4046 PLL (which includes both oscillator and phase detector) gives you a choice (it contains both types of phase detector). Here is a comparison of the properties of the two basic types of phase detector:

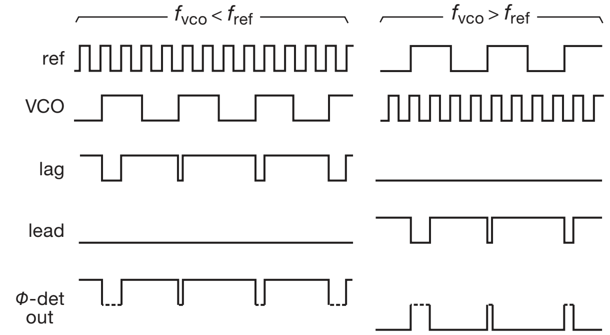

Figure 13.89. The type II phase-detector produces an average dc output that indicates the *sign* of the frequency error.

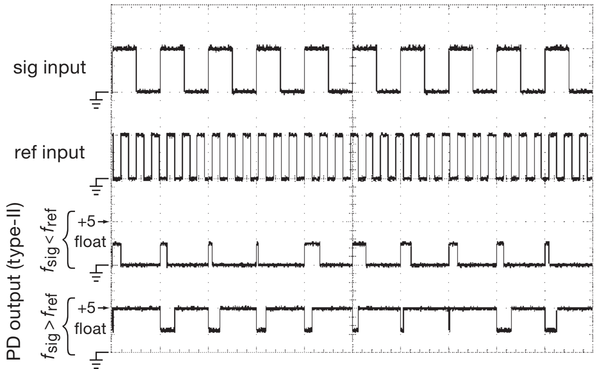

Figure 13.90. Measured waveforms from a type II phase detector driven with greatly mismatched frequencies. The 1 kHz signal and π-kHz reference inputs shown produce the phase-detector output shown in the third trace when driving a 10k–10k resistive divider that floats to +2.5 V. The bottom trace shows what happens when the inputs are interchanged. Horizontal: 1 ms/div.

Parameter	*Type I* *exclusive*-OR	*Type II* *edge triggered* *("charge pump")*
Input duty cycle	50% optimum	Irrelevant
Lock on harmonic?	Yes	No
Rejection of noise	Good	Poor
Residual ripple at $2f_{\text{IN}}$	High	Low
Lock range (L)	Full VCO range	Full VCO range
Capture range	$fL(f<1)$	L
Output frequency when out of lock	f_{center}	f_{min}

There is one additional point of difference between the two kinds of phase detectors. The type I detector is always generating an output wave, which must then be filtered by the loop filter (much more on this later). Thus, in a PLL with type I phase detector, the loop filter acts as a lowpass filter, smoothing this full-swing logic-output signal. There will always be residual ripple, and consequent periodic phase variations, in such a loop. In circuits where PLLs are used for frequency multiplication or synthesis, this adds "phase-modulation sidebands" to the output signal.

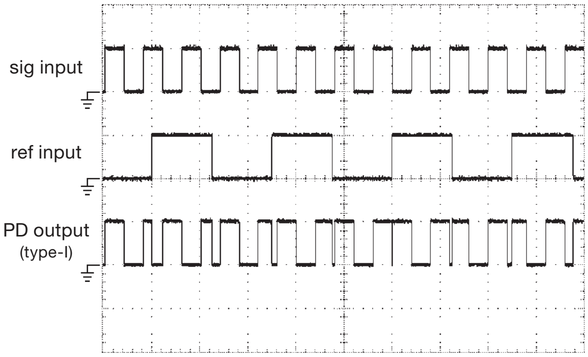

Figure 13.91. By contrast, the type I (XOR) phase detector, presented with the signal and reference frequencies of Figure 13.90, produces a frenetic rail-to-rail output whose dc average is $V_{\text{DD}}/2$. Horizontal: 0.4 ms/div.

By contrast, the type II phase detector generates output pulses only when there is a phase error between the reference and the VCO signal. Since the phase-detector output otherwise looks like an open circuit, the loop filter capacitor then acts as a voltage-storage device, holding the voltage that gives the right VCO frequency. If the reference signal moves away in frequency, the phase detector generates a train of short pulses, charging (or discharging) the capacitor to the new voltage needed to put the VCO back into lock. It is a phase-error integrator.

"Dead zone" and "backlash"

A persistent problem with early PLLs using type II phase detectors was the presence of a *dead zone*: the phase pulses became vanishingly small at nearly zero phase error, so the loop tended to "hunt" (bounce back and forth), producing phase modulation and jitter. And this was exacerbated by the effects of capacitive loading at the phase-detector output. For applications that need a clean signal (for example, the synthesized oscillator in a cellphone, communications receiver, or RF frequency synthesizer) this was (and is) a serious problem. The solution, now nearly universally adopted, is to introduce some intentional overlap of the sourcing and sinking output pulses; to make this work you need to reconfigure the phase detector to produce *current* pulses (rather than voltage pulses).

Figure 13.92 shows how this is done: the current source or sink is activated by the first rising edge of the signals being compared (reference or signal, respectively), but it is not turned off until a short interval after the complementary

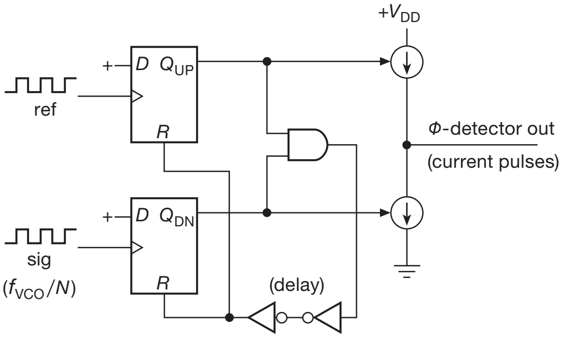

Figure 13.92. Improved type II phase detector (the '9046 version is shown here) replaces the switches with current sources and prevents a dead zone and backlash by creating intentional overlap of phase pulses.

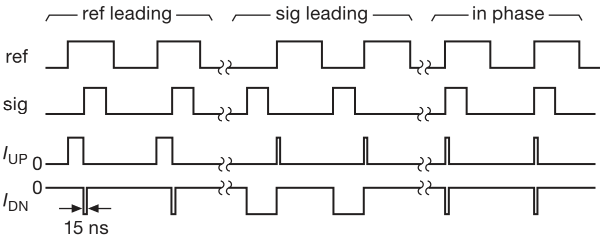

Figure 13.93. Current pulses (both sourcing and sinking) for the phase detector of Figure 13.92. The 15 ns pulses are created by the anti-backlash circuit.

current source is switched on. This "anti-backlash" circuit guarantees that the output pulses never vanish. When the two signals are exactly in phase (the loop is *locked*), the current pulses are short (~15 ns for the 74HCT9046, an improved version of the classic '4046) and of opposite sign, thus cancelling (Figure 13.93). Moving away from lock, a small phase difference produces an unbalanced pair of current pulses. This linear behavior around zero phase solves the problem; and capacitive loading does not cause trouble, because it behaves like a perfect integrator.

A cheap cure for backlash, if you need it, is to put a large resistor across the loop filter capacitor (C_2 in Figure 13.87), which biases the loop away from the dead zone. The tradeoff is that you introduce a nonzero phase shift, which is not well defined; but at least you've gotten rid of the jitter.

B. The VCO

An essential component of a PLL is an oscillator whose frequency can be controlled by the phase-detector output. We discussed VCOs back in Chapter 7 (§§7.1.4D and 7.1.5D), and we'll see them again presently, in a PLL design example. For now, let's just look at the simple *RC* voltage-controlled oscillator used in the '4046 and its successors (Figure 13.94).

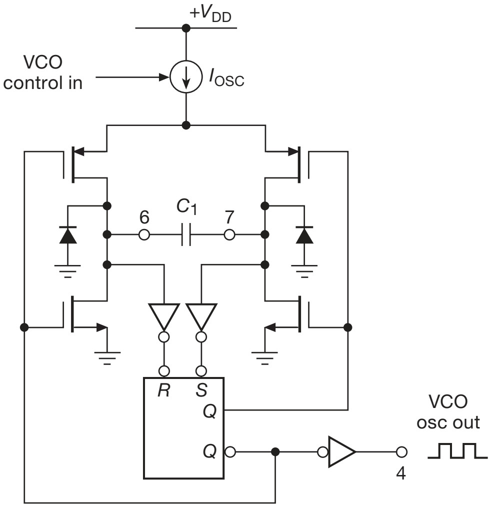

Figure 13.94. Voltage-controlled *RC* oscillator used in the classic '4046 PLL. Output frequency is approximately proportional to controlled current I_{osc}, which charges external capacitor C_1 alternately through the pMOS switches.

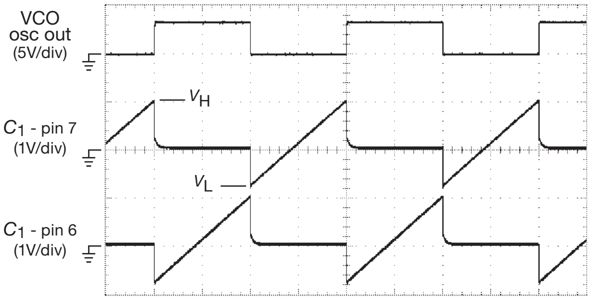

Figure 13.95. Observed waveforms of a 74HC4046 oscillator, with V_{CC}=3.3 V; with a 5 V supply the ramp starts at the same voltage but ends 0.2 V higher. Horizontal: 10μs/div.

The operation is simple: the flip-flop's output holds one side of the external timing capacitor C_1 at ground (via an nMOS switch) while coupling charging current I_{osc} to the other side (via a pMOS switch). The cycle reverses when the rising voltage reaches the inverter's threshold, approximately +1.1 V. Figure 13.95 shows measured waveforms for an 'HC4046 powered from +3.3 V, with C_1=10 nF and I_{osc}=0.85 mA. Note that each cycle begins at approximately −0.7 V, clamped at a diode drop below ground when the high side is switched to ground.

In a PLL you often want to restrict the oscillator's tuning range, to span a modest range of frequency centered on the

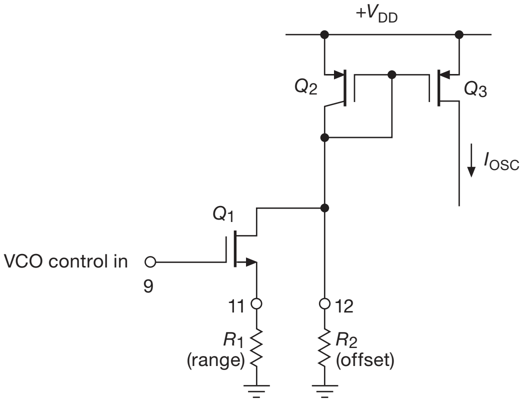

Figure 13.96. External resistors set the range and offset of the ground-referenced programming voltage in the classic high-voltage CD4046 VCO. The 74HC4046 types use op-amps to more tightly control the R_1 and R_2 currents.

desired output frequency. For example, the PLL in an FM radio needs to span ±10 MHz about a central frequency of ∼100 MHz; and we'll see examples later in which this range can be as narrow as ±0.01% (a "voltage-controlled crystal oscillator," VCXO). The oscillator in the '4046 accommodates this rather simply (Figure 13.96), by letting you use a pair of resistors: R_1 sets the span ($f_{\max}$–$f_{\min}$), and R_2 sets the minimum frequency. In this circuit Q_1 is a programmable current sink, bounced off a pMOS current mirror to create the charging current I_{osc}.

Soon enough we'll see other PLLs, both with and without integrated on-chip oscillators. First, though, we want to have some fun with a PLL design, using our new friend the '4046. Keep in mind, though, that PLLs (and their VCOs) don't have to be restricted to maximum speeds in the tens of megahertz. In fact, it's probably accurate to say that most PLLs in the world earn their livings at frequencies in the hundreds to thousands of megahertz. At those frequencies you don't use *RC* timing – instead you use *LC* circuits (tuned with a voltage-variable capacitor, known as a *varactor*), or a *ring oscillator* (a chain of inverters) tuned by adjusting the operating current (a "starved inverter chain"), or more exotic techniques such as a surface acoustic wave (SAW) delay-line oscillator or a resonator made from a silicon microelectromechanical system (MEMS). A VCO for use in a phase-locked loop doesn't have to be particularly linear in its frequency-versus-control-voltage characteristic, but if it is highly nonlinear, the loop gain (see below) will vary according to the signal frequency, compromising loop stability.

13.13.3 PLL design

A. Closing the loop

The phase detector gives us an error signal related to the phase difference between the signal and reference inputs. The VCO allows us to control its frequency with a voltage input. It would seem straightforward to treat this like any other feedback amplifier, closing the loop with some gain, just as we did with op-amp circuits.

However, there is one essential difference. Previously, the quantity adjusted by feedback was the same quantity measured to generate the error signal, or at least a proportional quantity. For example, in a voltage amplifier we measured output voltage and adjusted input voltage accordingly. But in a PLL there's an integration; we measure *phase*, but adjust *frequency*, and phase is the integral of frequency. This introduces a 90° lagging phase shift in the loop.

This integrator included within the feedback loop has important consequences, since an additional 90° of lagging phase shift at a frequency where the loop gain is unity can produce oscillations. A simple solution is to avoid any further lagging components within the loop, at least at frequencies where the loop gain is close to unity. After all, op-amps have a 90° lagging phase shift over most of their frequency range, and they work quite nicely. This is one approach, and it produces what is known as a "first-order loop." It looks just like the PLL block diagram shown earlier, with the lowpass filter omitted.

Although they are useful in many circumstances, first-order loops don't have the desirable property of acting as a "flywheel," allowing the VCO to smooth out noise or fluctuations in the input signal. Furthermore, a first-order loop will not maintain a fixed phase relationship between the reference and VCO signals, because the phase detector output drives the VCO directly. A "second-order loop" has additional lowpass filtering within the feedback loop (as drawn earlier), carefully designed to prevent instabilities. This provides flywheel action and also reduces the "capture range" and increases the capture time. Furthermore, with type II phase detectors, a second-order loop guarantees phase lock with zero phase difference between reference and VCO, as will be explained soon. Second-order loops are used almost universally, because the applications of PLLs usually demand an output frequency with low phase noise and some "memory," or flywheel action. Second-order loops permit high loop gain at low frequencies, resulting in high stability (in analogy with the virtues of high loop gain in feedback amplifiers). Let's get right down to business, illustrating the use of phase-locked loops with a design example.

13.13.4 Design example: frequency multiplier

Generating a fixed multiple of an input frequency is one of the most common applications of PLLs. This is done in frequency synthesizers, in which an integer multiple *n* of a stable low-frequency reference signal (1 Hz, say) is generated as an output; *n* is settable digitally, giving you a flexible signal source, easily controlled through a digital interface. In more mundane applications, you might use a PLL to generate a clock frequency locked to some other reference frequency already available in the instrument. For example, suppose we want to generate a 61.440 kHz clock signal for a dual-slope ADC. That particular choice of frequency permits 7.5 measurement cycles per second, allowing 4096 clock periods for the ramp-up (remember that dual-slope conversion uses a constant time interval) and 4096 counts full scale for the constant-current ramp-down. The unique virtue of a PLL scheme is that the 61.440 kHz clock can be locked to the 60 Hz powerline (61,440=60×1024), giving infinite rejection of 60 Hz pickup present on any signal input to the converter, as we discussed in §13.8.4.

We begin with the standard PLL scheme, with a divide-by-*n* counter added between the VCO output and the phase detector (Figure 13.97). In this diagram we indicate the units of gain for each function in the loop. That will be important in our stability calculations. Note particularly that the phase detector converts phase to voltage and that the VCO converts voltage to the time derivative of phase (i.e., frequency). This has the important consequence that the VCO is actually an integrator, with phase representing the variable in the lower part of the diagram; a fixed input-voltage error produces a linearly rising phase error at the VCO output. The lowpass filter and the divide-by-*n* counter both have unitless gain.

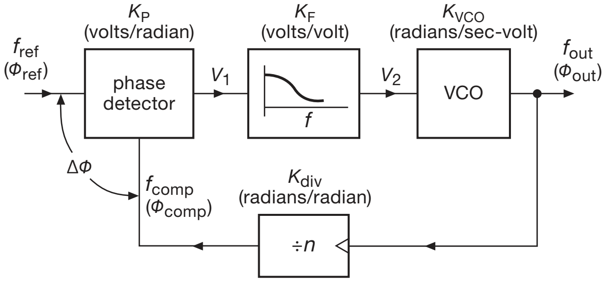

Figure 13.97. Frequency-multiplier block diagram.

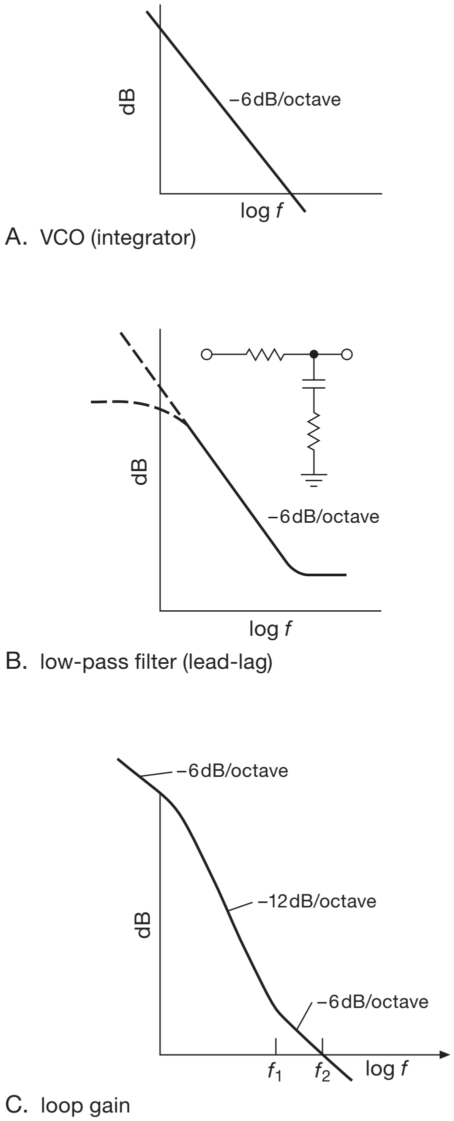

Figure 13.98. PLL Bode plots.

A. Stability and phase shifts

The trick to a stable second-order PLL is shown in the Bode plots of loop gain in Figure 13.98. The VCO acts as an integrator, with $1/f$ response and 90° lagging phase shift (i.e., its response is proportional to $1/j\omega$, a current source driving a capacitor). In order to have a respectable phase margin (the difference between 180° and the phase shift around the loop at the frequency of unity loop gain), the lowpass filter has an additional resistor in series with the capacitor to stop the rolloff at some frequency (fancy name: a "zero"). The combination of these two responses produces the loop gain shown. As long as the loop gain

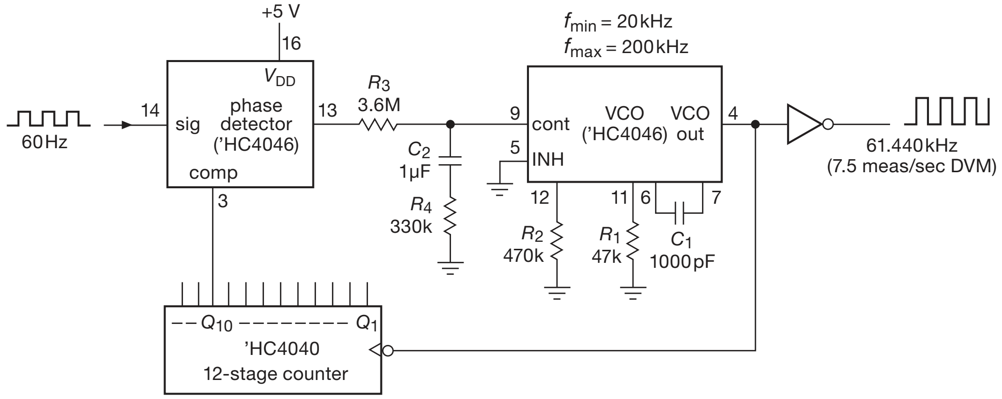

Figure 13.99. Using a PLL multiplier to generate a clock locked to the 60 Hz ac line. Parts values are for TI's CD74HC4046A.

rolls off at 6 dB/octave in the neighborhood of unity loop gain, the loop will be stable. The "lead–lag" lowpass filter does the trick, if you choose its properties correctly (this is the same as lead–lag compensation in op-amps). Next we'll see how it is done.

B. Loop-gain calculations

Figure 13.99 shows the schematic of the 61.440 kHz PLL synthesizer. Both the phase detector and the VCO are parts of an 'HC4046 CMOS PLL. We used the edge-triggered (type II) phase detector in this circuit (recall the 4046 contains both kinds). Its output comes from a pair of CMOS transistors generating saturated pulses to V_{DD} or ground. It is really a three-state output, as explained earlier, since it is in the high-impedance state except during actual phase-error pulses.

The VCO allows you to set the minimum and maximum frequencies corresponding to control voltages of zero and V_{DD}, respectively, by choosing R_1, R_2, and C_1 according to some design graphs. We have made the choices shown, based upon an initial design from the datasheet, validated (and adjusted!) by some bench measurements – see the "real-world" commentary that follows, in §13.13.4E. *Note*: the 4046 has chronic severe supply-sensitivity disease; check the graphs on the datasheet. The rest of the loop is standard PLL procedure.

Having rigged up the VCO range, the remaining task is the lowpass-filter design. This part is crucial. We begin by writing down the loop gain, as in the "PLL gain calculation" box, considering each component (refer to Figure 13.97). Take special pains here to keep your units consistent; don't switch from f to ω or (worse) from hertz to kilohertz. Having chosen the oscillator components, divider ratio, and supply voltages, we need to determine the one remaining gain term (that of the loop filter), K_F. We do this by writing down the overall loop gain, remembering that the VCO is an integrator:

$$\phi_{\text{out}} = \int V_2 K_{\text{VCO}} dt.$$

The loop gain is therefore given by

$$\begin{aligned}\text{Loop gain} &= K_P K_F \frac{K_{\text{VCO}}}{j\omega} K_{\text{div}} \\ &= 0.40 \times \frac{1 + j\omega R_4 C_2}{1 + j\omega(R_3 C_2 + R_4 C_2)} \times \frac{3.77 \times 10^5}{j\omega} \times \frac{1}{1024}.\end{aligned}$$

Now comes the choice of frequency at which the loop gain should pass through unity. The idea is to pick a unity-gain frequency high enough so that the loop can follow input-frequency variations you want to follow, but low enough to provide flywheel action to smooth over noise and jumps in the input frequency. For example, a PLL designed to demodulate an FM input signal, or to decode a rapid sequence of input tones, needs to have rapid response (for the FM input signal, the loop should have as much bandwidth as the input signal, i.e., response up to the maximum modulating frequency; while to decode input tones, its response time must be short compared with the time duration of the tones). On the other hand, a loop such as this one, designed to generate a fixed multiple of a stable and slowly varying input frequency, should have a low unity-gain frequency. That will reduce phase noise at the output and make the PLL insensitive to noise and glitches on the input. It will hardly even notice a short dropout of input signal, because the voltage held on the filter capacitor will instruct the VCO to continue producing the same output frequency.

In this case, we choose the unity-gain frequency f_2 to be 2 Hz, or 12.6 radians per second. This is well below

PLL GAIN CALCULATION

Component	*Function*	*Gain*	*Gain calculation* $(V_{\rm DD}=+10{\rm V})$
Phase detector	$V_i = K_{\rm P}\Delta\phi$	$K_{\rm P}$	$K_{\rm P}=\dfrac{V_{\rm DD}}{4\pi}$ (0 to $V_{\rm DD} \leftrightarrow -360°$ to $+360°$)
Lowpass filter	$V_2 = K_{\rm F}V_1$	$K_{\rm F}$	$K_{\rm F}=\dfrac{1+j\omega R_4C_2}{1+j\omega(R_3C_2+R_4C_2)}$ volts/volt
VCO	$\dfrac{d\phi_{\rm out}}{dt}=K_{\rm VCO}V_2$	$K_{\rm VCO}$	$20{\rm kHz}\ (V_2=1{\rm V})$ to $200{\rm kHz}\ (V_2=4{\rm V})$ $\rightarrow K_{\rm VCO}=60{\rm kHz/volt}$ $=3.77\times10^5$ radians/second-volt
Divide-by-n	$\phi_{\rm comp}=\dfrac{1}{n}\phi_{\rm out}$	$K_{\rm div}$	$K_{\rm div}=\dfrac{1}{n}=\dfrac{1}{1024}$

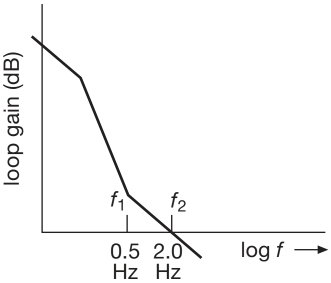

Figure 13.100. Stabilizing a second-order PLL: -6 dB/octave rolloff of loop gain around the frequency of unity gain.

the reference frequency, and you wouldn't expect genuine powerline frequency variations on a scale shorter than this (remember that the 60 Hz power is generated by enormous generators with lots of mechanical inertia). As a rule of thumb, the breakpoint of the lowpass filter (its "zero") should be lower by a factor of at least 3 to 5 for a comfortable phase margin. Remember that the phase shift of a simple RC goes from 0° to 90° over a frequency range of roughly 0.1 to 10 times the -3 dB frequency (its "pole"), with a 45° phase shift at the -3 dB frequency. In this case we put the frequency of the zero, f_1, at 0.5 Hz, or 3.1 radians per second (Figure 13.100). The breakpoint f_1 determines the R_4C_2 time constant: $R_4C_2 = 1/2\pi f_1$. Tentatively, take $C_2 = 1\mu$F and $R_4 = 330$k. Now all we do is choose R_3 so that the magnitude of the loop gain equals 1 at f_2. In this case, that works out to $R_3 = 3.6\,{\rm M}\Omega$.

Exercise 13.7. Show that these choices of filter components actually give a loop gain of magnitude 1.0 at f_2=2.0 Hz.

Sometimes the filter values are inconvenient, so you have to readjust them, or move the unity-gain frequency somewhat. With a CMOS phase-locked loop these values are acceptable (the VCO input terminal has a typical input impedance of $10^{12}\,\Omega$). For VCOs with a low input impedance you might want to use an external op-amp buffer.

We used an edge-triggered (type II) phase detector in this circuit example because of its simplified loop filter. In practice, that might not be the best choice for a PLL locked to the 60 Hz powerline because of the relatively high noise level present on the 60 Hz signal: many engineers have stumbled on this point, with a noisy reference signal causing false type-II triggering. With careful design of the analog input circuit (e.g., a lowpass filter followed by a Schmitt trigger) the type-II phase detector would likely perform satisfactorily; otherwise an exclusive-OR (type I) phase detector should be used.

C. "Cut and try"

For some people, the art of electronics consists of fiddling with filter component values until the loop "works." If you are one of those,[119] we will oblige you by looking the other way. We presented these loop calculations in detail because we suspect that much of the PLL's bad reputation is the result of too many people "looking the other way." Nevertheless, we can't resist supplying a hot tip for cut-and-try addicts: R_3C_2 sets the smoothing (response) time of the loop,

[119] You can derive some comfort (and perhaps even hold your head high) from some remarks in the TI app note (referring to the loop-filter design) "Optimizing by trial and error should be considered in all cases."

and R_4/R_3 determines the damping, i.e., absence of overshoot for step changes in frequency. You might begin with a value of R_4 somewhere in the range of 10% to 20% of R_3.

D. Loop damping and jitter

A side effect of the nonzero "damping" resistor R_4 is the creation of some jitter in the PLL output. An easy way to see this is to realize that even at high frequencies the loop filter permits a fraction $R_4/(R_3+R_4)$ of the raw phase-detector output to reach the VCO. For typical ratios, $R_3 \approx 10R_4$, this can add substantial jitter to the VCO output. The usual solution is to add a small capacitor ($\sim C_2/20$) from the VCO control input to ground, preferably close to the VCO pin to filter any other high-frequency noise as well.

E. PLL real-world design

We sailed through this design example, having faith that the information in the datasheets for the IC we chose (the popular 'HC4046) was reliable. That faith was, perhaps, a bit misplaced. To give this cautionary section some context, here's the story (the short version) of our oscillator component choices in Figure 13.99:

We wanted a 3× safety margin for our 61 kHz center frequency, so we set $f_{\min}$=20 kHz and $f_{\max}$=200 kHz. We chose TI's CD74HC4046A because it was RCA's original time-proven design. Based on the datasheet's graphs, a good value for the timing capacitor C_1 was 1000 pF. For the timing resistors one of us started with the R_1 plots and came up with 30k and 300k for R_1 and R_2, and we edited the figure accordingly. The other author started with the R_2 plot (as suggested by two manufacturers, but it should not have mattered) and came up with 40 k and 410 k. Worried about these and other inconsistencies (e.g., one spec in the TI datasheet gives f_{osc}=400 kHz, typ, for C_1=1 nF and R_2=220k, while their Figure 27 suggests it should be more like 33 kHz), we went to the bench and found actual values of 45k and 482k for the desired frequency range. The values we chose initially would have worked, despite the factor of 1.5 deviation from reality, but they would have used up half of our 3× safety margin.[120]

So, what's going on here? Each of the 'HC4046 manufacturers uses a different circuit for their VCO design.[121] Although intended to be predictable and linear, in practice the VCO control is nonlinear, and its parameters vary with control current, supply voltage, and operating frequency, especially above 10 MHz. Although you can find analytical expressions for the VCO's frequency (ON Semi app note AN1410), the recommended method is still to start with the timing component values (R_1, R_2, and C_1) from datasheet graphs; then the designer is sternly admonished to adjust and validate those values with careful bench measurements before committing to manufacturing.

This sort of variability and lack of confident predictability leads us to render this advice:

(1) choose one manufacturer for your production design, and do not allow substitutes;
(2) choose a wide safety margin for $f_{\min}$ and $f_{\max}$, such as the 3× factor in our Figure 13.99;
(3) replace your initial paper calculations with measured bench values for production.

Rule (1) applies to any linear functionality in a logic IC, e.g., mixed-signal functions such as phase comparators, oscillators, VCOs, mixers, Schmitt triggers, monostables, or comparators.

13.13.5 PLL capture and lock

Once locked, it is clear that a PLL will stay locked as long as the input frequency doesn't wander outside the range of the feedback signal and doesn't change more rapidly than the loop's bandwidth can track. An interesting question to ask is how PLLs get locked in the first place. After all, an initial frequency error results in a periodic output from the phase detector at the difference frequency. After filtering by the lowpass filter, it is reduced to small-amplitude wiggles rather than to a nice clean dc error signal.

A. Capture transient

The answer is a little complicated. First-order loops will always lock, because there is no lowpass attenuation of the error signal. Second-order loops may or may not lock, depending on the type of phase detector and the bandpass of the lowpass filter. In addition, the exclusive-OR (type I) phase detector has a limited *capture* range that depends on the filter time constant (this fact can be used to advantage

[120] We made additional bench measurements on both old and new 74HC4046A parts from TI, NXP, ON Semi, and Fairchild. We found good self-consistency within any single manufacturers parts; the variations in span and zero frequency within a batch and over a 15-year period were generally under 5%. Measured frequencies for the NXP, ON Semi, and Fairchild parts deviated by +5%, +160%, and −60%, respectively, from that of the TI parts, when configured with the timing component values shown in Figure 13.99.

[121] For example, TI biases R_2 from $V_{\text{DD}}-0.7$ V, whereas ON Semi biases it from $V_{\text{DD}}/3$. Their current mirrors have nominal gains of 7.5 and 25 respectively. We think NXP's 74HCT9046 is arguably the best mannered '4046 part available, and the NXP datasheets have better graphs.

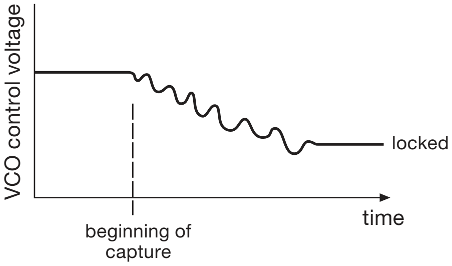

Figure 13.101. PLL capture transient.

if you want a PLL that will lock to signals only within a certain frequency range).

For a type I phase detector you might wonder how the loop can lock up at all, because, with the phase detector's output being periodic at the difference frequency, the VCO's frequency should just wiggle back and forth forever. But looking more closely, the capture transient goes like this: as the (phase) error signal brings the VCO frequency closer to the reference frequency, the error-signal waveform varies more slowly, and vice versa. So the error signal is asymmetric, varying more slowly over that part of the cycle during which f_{VCO} is closer to f_{ref}. The net result is a nonzero average, i.e., a dc component that brings the PLL into lock.[122] If you look carefully at the VCO control voltage during this *capture transient*, you'll see something like what is shown in Figure 13.101. That final overshoot has an interesting cause. Even when the VCO *frequency* reaches its correct value (as indicated by correct VCO control voltage), the loop isn't necessarily in lock, because the *phase* may be wrong. So it may overshoot. As with snowflakes, each capture transient is an individual – it looks a bit different each time.

For a PLL with a type II phase detector, the situation is considerably simpler: because this kind of detector produces a dc component indicating the direction of frequency error (recall it's a "phase-frequency detector"), the VCO's frequency is steered rapidly in the right direction.

B. Capture and lock range

For the exclusive-OR (type I) phase detector, the capture range is limited by the lowpass-filter time constant. This makes sense, because if you begin sufficiently far away in frequency, the error signal will be attenuated so much by the filter that the loop will never lock. It should be evident that a longer filter time constant results in narrower capture range, as does reduced loop gain. The edge-triggered phase detector does not have this limitation, because it acts like a true integrator of the phase-error charge pulses. Both types have a lock range extending to the limits of the VCO, given the available control input voltage.

C. Capture time

PLLs with type II (integrating) phase detectors will always lock (assuming the VCO has sufficient tuning range, of course), with a time constant characteristic of the loop bandwidth.

A type I (multiplier or mixer) phase detector, if followed by an integrating loop filter, will also lock – but it can take a very long time if the loop bandwidth is narrow. It can be shown that the lockup time is roughly $(\Delta f)^2/\text{BW}^3$, where Δf is the initial frequency error and BW is the loop bandwidth. So a PLL with 100 Hz loop bandwidth and 100 kHz comparison frequency might take a minute to lock up if the VCO's initial frequency is 10% away from lock.

In such cases you sometimes see a cute trick: a slow full-range sawtooth is applied to the VCO control voltage of the unlocked loop, until lock takes place. For example, I have in my hand (I'm typing one-handed) an Efratom model FRS rubidium frequency standard, which uses the weak but extremely stable atomic resonance in an optically pumped vapor cell as a reference to which a high-quality crystal oscillator is phase locked. The 20 MHz ovenized crystal oscillator (XO) is voltage controlled (a VCXO), with a narrow tuning range (of order ±1 kHz); it is the flywheel in a low-bandwidth PLL (the loop integrator has R=2M, C=1μF).

Without some help, this thing would take forever to lock. The helpful "Operation Manual" explains how they do it: "When no 'lock' signal is present… [there is] a slow down sweep of the crystal control voltage of about 250 mV per second. Sweeping continues until 'Lock' occurs. 'Lock' then disables the sweep circuit by disconnecting [analog switch] U3 pins 13 and 14, and connecting U3 pins 12 and 14. This switching places the integrator under fundamental loop control."

Such gimmicks aren't necessary with type II phase detectors, as we remarked above, thanks to their indication of both phase and (sign of) frequency difference. But passive mixer-type phase detectors (therefore type I) are prevalent in communications systems at very high radio frequencies, where the digital phase-frequency detector is impractical.

[122] Another way of looking at it is to realize that the error signal weakly modulates the VCO at the difference frequency $\Delta f = |f_{\text{ref}} - f_{\text{VCO}}|$. That frequency modulation puts weak symmetrical sidebands onto f_{VCO}, spaced apart by Δf. One of these is exactly at f_{VCO}, producing an average dc output component from the phase detector, which the loop filter integrates (type II) to bring the system into lock.

13.13.6 Some PLL applications

We have spoken already of the common use of phase-locked loops in frequency multiplication. The latter application, as in the preceding example, is so straightforward that there should be no hesitation about using these mysterious PLLs. In simple frequency-multiplication applications (e.g., the generation of higher clock frequencies in a digital system) there isn't even any problem of noise on the reference signal, and a first-order loop may suffice.

As will become evident, what you care about in a PLL depends on the application: there's a tradeoff among wide tuning range versus high quality (low phase noise, low jitter, low spurious frequency components) versus frequency step size versus loop bandwidth (and switching speed) versus low external component count. For example, for a microprocessor or memory clocking application you don't need high-quality waveforms, and you need only coarse tuning steps; for a cellphone synthesizer you want low phase noise and spurs, with tuning range and step size matched to the cell band and channelization; for a general-purpose sinewave synthesizer you want low phase noise and spurs, small tuning steps, and wide tuning range; for high-speed serial links you care about jitter, as you do when clocking high-quality ADCs (where jitter translates to distortion); and for a motherboard clock generator you'd like a single-chip solution that generates a suite of standard clocks (for the processor, memory, video, internal buses like PCIe and SATA, external serial ports like USB and Ethernet, and so on) without great concern about signal quality.

We would like now to describe two important variations (known as "n/m" and "fractional-n" synthesis) on this basic frequency-multiplication scheme; we'll continue with some other interesting applications of phase-locked techniques, to give an idea of the diversity of PLL uses. Finally, we'll conclude the discussion of phase-locked loops with examples of contemporary PLL ICs, which use a variety of clever tricks to create on-chip oscillators with admirable performance.

A. Fractional-*n* synthesis

The frequency multiplication scheme of Figure 13.97 generates an output frequency that is restricted to an integral multiple of the reference input: $f_{\mathrm{out}}=nf_{\mathrm{ref}}$. That's fine for an application like that of Figure 13.99, but it's not of much use for something like a general-purpose sinewave synthesizer, where you want to generate any old output frequency, perhaps settable down to 1 Hz, or even 0.001 Hz.

D.

Figure 13.102. Getting to fractional-*n*. A–C. Integer-*n* with input prescaler, output scaler, and both. D. "Fractional-*n*" allows the feedback divider to effectively take on non-integer values. For simplicity the loop filter between phase detector and VCO has been omitted.

Input prescaler

Taking it in several steps (see Figure 13.102A), the first thing you might do is to reduce the reference frequency to the resolution step size, say 1 Hz. This can be done by "prescaling" the reference input frequency with a modulo-r counter: r is an integer, chosen so that $f_{\mathrm{comp}}=f_{\mathrm{ref}}/r$ equals the desired step size; for example, if we have a 10 MHz input reference (a common standard) and we want 1 Hz settability, we would choose $r=10^7$. The output frequency is then $f_{\mathrm{out}}=n \cdot f_{\mathrm{ref}}/r$.

OK, that would work. But the phase detector is now working on a pair of 1 Hz signals, which requires a very long loop time constant (many seconds). That's not good: it takes a long time to lock to a new frequency setting; and there's more phase noise, because the VCO's intrinsic instabilities are not corrected on short time scales (no loop gain at those frequencies). And (if you need more convincing), the phase detector's correction pulses to the VCO are at low frequency, producing spurious modulation sidebands ("spurs") that are close in frequency to the desired output frequency (to be precise, they are spaced apart by f_{comp}, going both up and down from f_{out}).

Output scaler

The next thing you might try is to keep a high reference frequency, but divide the *output* frequency instead (Figure 13.102B). The output frequency is now $f_{\text{out}}=f_{\text{ref}}\cdot n/m$. This looks pretty good: we can keep plenty of loop bandwidth (because the phase detector is operating at the high-frequency f_{ref}), and we get as small a step size as we want by choosing a large output divider modulus m.

And this works fine, as long as you're happy with low output frequencies. The problem is that the VCO now has to run at m times higher frequency to generate a given f_{out}. For example, with a 10 MHz reference input and with $m=10^7$ (for 1 Hz step size), the VCO would have to run at 1 GHz just to generate a 100 Hz output frequency (n=100). This is clearly a loser.

Input and output scalers

A compromise is in order: use integer frequency dividers at both input *and* output (Figure 13.102C). This way we can set the phase detector's comparison frequency somewhere between the (too small) output step size and the (larger than necessary) input reference frequency. The output frequency is now $f_{\text{out}}=(f_{\text{ref}}/r)\cdot(n/m)$. This is the standard configuration of an "integer-n" phase locked loop (because all three frequency dividers operate with an integer division ratio).

Taking our standard example with 10 MHz reference, we might choose $r=10^4$ (so f_{comp}=1 kHz) and $m=10^3$. The output step size is 1 Hz, the output frequency is n Hz, and we can generate output frequencies to 100 kHz (with 1 Hz resolution) with a VCO that goes to 100 MHz.

The whole enchilada: "fractional-*n*"

We've got a compromise among competing factors of step size, loop bandwidth, maximum output frequency, and maximum VCO frequency. In the example above we can get to a higher output frequency with the same 1 Hz step size and 10 MHz input frequency, (i.e., keeping the product $m\cdot r$ constant), but only at the expense of either smaller loop bandwidth (smaller m, larger r) or reduced maximum output frequency (larger m, smaller r).

Can we do better? The answer is yes, if we can somehow trick one of the dividers (say the n divider) into a non-integer "in-between" division ratio. We can do that *on the average* with an integer-n divider, if we arrange things to change the modulus so that it spends some of its time as n, and the rest of its time as n+1.[123] This is *fractional-n* synthesis (Figure 13.102D). The output frequency is still $f_{\text{out}}=(f_{\text{ref}}/r)\cdot(n/m)$, but with n now permitted to take on a fractional value. With fractional-n synthesis you have (mostly) the best of both worlds: wide output-frequency range with high resolution (small step size), while retaining high f_{comp} (which permits plenty of loop bandwidth, and therefore fast lock and fast tracking, along with spurs widely offset from the synthesized frequency).

Fractional-n requires some additional counters and logic, to figure out how often to alternate between n and n+1. There's an analogous everyday situation: it's beneficial to keep the annual calendar (the kind you hang on a wall) synchronized to Earth's motion around the sun. Trouble is, there are not an integral number of days in a year. The Gregorian calendar's solution (leap years) is fractional-n: alternate the modulus between 365 and 366, with a 3:1 ratio, to achieve the (approximately) correct value of 365.25.[124,125]

Details, details...

Fractional-n synthesis[126] is a nice technique, but it's not without its own problems. For example, the phase detector is periodically presented with a phase discontinuity (i.e., each time the modulus is alternated), which creates periodic phase modulation at the output if not corrected or otherwise filtered. There are several tricks to fix this problem, involving either injecting compensating charge pulses at the phase detector's charge-pump output, or (probably better) a precomputed correction to the output waveform to create equally spaced output cycles (see later). Perhaps the best technique, though, is the use of delta–sigma

[123] You sometimes hear the visually graphic term "pulse-swallowing" used for this subcircuit.

[124] Astronomers, and other fussy readers, will complain that the number of Earth rotations in a year is actually one greater (366.25), and that Earth rotates once *not* in 24 hours, but in 23h 56m 4s (approximately). Of course they are right. But everyone hates a smarty-pants.

[125] That gets the calendar close, but not perfect: there are 365.242374 solar days in a year. Hence the next-order fix: leap-years are *omitted* in years that are divisible by 100 (i.e., the turn of each century, which, being divisible by 4, would ordinarily be a leap year) unless they are also divisible by 400; we had a leap year in 2000, but we (more properly, our descendants; by then this book, and its authors, will be out of print) will not enjoy one in 2100, or 2200, or 2300. This will keep the calendar on track for about 8000 years.

[126] Some PLLs do the fractional-*n* business on the input reference (r) divider; they're still called "fractional-*n*."

Figure 13.103. By making small frequency adjustments to its clean crystal-oscillator reference clock, the method of "rational approximation frequency synthesis" used in the SRS synthesizers achieves microhertz resolution while operating its PLL phase-detector at megahertz frequencies. The resulting output has excellent purity, with very low phase noise and absence of spectral "spurs."

modulation of the modulus: instead of simply alternating between the two moduli that surround the (fractional) desired modulus, the divider's modulus is distributed among a larger set, in such a way that the production of modulation sidebands is shaped to higher frequencies, and the production of discrete spurs is minimized. As with the delta–sigma modulators we saw earlier in the chapter, higher-order loops along with some randomization ("dithering") can be employed to reduce close-in spurs (analogous to its use there to suppress idle tones). This is a complicated business, and best left to the real professionals.[127] Bottom line: leave the converter design to others; but be aware of both the benefits and pitfalls, and examine the datasheets closely for the things you care about in your application.

B. Rational approximation synthesis

With an ingenious variation on integer-*n* synthesis, the ever-creative John Willison at Stanford Research Systems has devised a synthesizer that combines the best of both worlds: it operates with a small integer *r* value (thus a relatively high reference frequency input to the phase detector, for wide VCO loop bandwidth and thus low noise and jitter sidebands), along with integer *n* (avoiding VCO phase modulation); but, with a bit of magic, it permits essentially infinite frequency resolution (*micro*hertz frequency setting) even though the phase detector's reference input is typically in the megahertz region.

How can this be? The trick is to choose a small integer *r* (and corresponding *n*) such that the synthesized frequency is *close to* (say within ±100 ppm of) the target frequency; you then adjust the master reference oscillator correspondingly, to bring the integer-synthesized output frequency on target. This technique, which they call "rational approximation frequency synthesis" (RAFS), was introduced in SRS's SG380 series of RF signal generators, which currently include models that provide outputs from dc to 6 GHz, settable with microhertz resolution. The use of integer PLL synthesis with a wide-bandwidth loop produces excellent output purity, seen for example in the phase noise specification of −116 dBc (relative to the "carrier," i.e., the signal amplitude) at an offset of 20 kHz from a 1 GHz output signal; and the use of a low-noise reference oscillator (the OCXO) keeps the close-in phase noise down to an impressive −80 dBc at an offset of just 10 Hz from a 1 GHz output.

Figure 13.103 shows the scheme, stripped down to its

[127] Take a look at National Semiconductor's App Note 1879, if you want to dip your toe into the turbulent waters.

basics. A microcontroller rides herd over the system, beginning with the choice[128] of r and n to get close to the desired f_{out}. The microcontroller also tunes the loop filter according to the resulting phase detector input frequency (here called f_ϕ). Finally, it fine-tunes the master clock, over the needed ±100 ppm range, by way of a 64-bit (thus effectively infinite resolution) direct digital synthesizer running from the clean fixed-frequency input clock. The DDS output is not as pure as its reference input (owing to irregular phase jumps inherent in the DDS process), so its output is cleaned up by phase locking a high quality crystal oscillator, whose frequency can be electrically "pulled" over a ±100 ppm range via a varactor (thus a "VCXO" – voltage-controlled crystal oscillator). With hindsight we can see that it's the VCXO's tuning range that constrains the initial selection of r and n.

To illustrate with an example, suppose we wish to synthesize an output at 1234.56789 MHz. You can bang away on a pocket calculator (does anyone under 50 still use those?), working your way up successive integer r values, until you find that r=26 gives you a "fractional-n" (320.9876514) that is within 100 ppm of an integer (n=321). So we go with the choice $[r, n]$=[26, 321], and we offset the master clock by −38.469 ppm (to 99.9961531 MHz) to get what we want. With this choice the phase detector's reference frequency f_ϕ is pleasantly high (∼3.85 MHz), allowing plenty of loop bandwidth (thus low sideband noise, and absence of close-in spurs that would be caused by a low f_ϕ) in the synthesizing PLL.

In practice there are a host of details (as with any sophisticated and well engineered system) not seen in this simplified description. For example, (a) the output synthesizer tunes only over an octave (2:1 frequency range), driving a set of binary dividers and lowpass filters to generate the final output; (b) the actual production instruments use several staggered fine-tuned VCXOs, greatly relaxing the constraints on r and n (and resulting in values of f_ϕ typically greater than 10 MHz, with a worst case of 2.4 MHz); (c) there are additional DDSs and PLLs in the system, used among other things to create favorable clocking frequencies (which generally are chosen not to be the kind of "round-number" frequencies shown here, to prevent clock-collision artifacts); (d) the 64-bit DDS is dithered to reduce fixed-frequency spurious sidebands ("spurs"); and (e) there are additional subcircuits to provide for modulation, amplitude control, and the like. These are the sort of real-world issues that challenge the instrument designer, to whom great satisfaction can come when a nice solution is found.

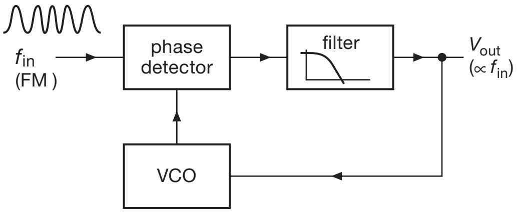

Figure 13.104. PLL FM discriminator.

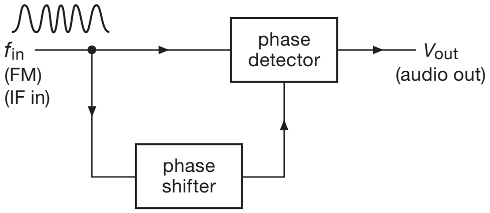

Figure 13.105. Quadrature FM detection.

C. FM detection

In frequency modulation, information is encoded onto a "carrier" signal by varying its frequency proportional to the information waveform. There are two methods of recovering the modulating information with phase detectors or PLLs. The word *detection* is used to mean a technique of demodulation.

In the simplest method, a PLL is locked to the incoming signal. The voltage controlling the VCO frequency is proportional to the input frequency and is therefore the desired modulating signal (Figure 13.104). In such a system you would choose the filter bandwidth to be wide enough to pass the modulating signal, i.e., the response time of the PLL must be short compared with the time scale of variations in the signal being recovered.[129] A high degree of linearity in the VCO is desirable in this method of FM detection, to minimize distortion in the audio output.

The second method of FM detection involves a phase detector, although not in a phase-locked loop. Figure 13.105 shows the idea. Both the input signal and a phase-shifted version of the signal are applied to a

[128] SRS uses an iterative approach for calculating r and n: the microcontroller chunks along, trying successive small-integer pairs until it's happy. This takes about a millisecond.

[129] The signal applied to the PLL does not have to be at the radiofrequency sent by the distant transmitter; it can be an "intermediate frequency" (IF) generated in the receiving system by the process of *mixing*. This *superheterodyne* technique was invented by Edwin H. Armstrong, who also invented FM. The big guys moved in, claimed his inventions, beat him up in court, and drove him to suicide.

phase detector, generating some output voltage. The phase-shifting network is diabolically arranged to have a phase shift varying linearly with frequency in the region of the input frequency (this is usually done with resonant *LC* networks), thus generating an output voltage with linear dependence on input frequency. That is the demodulated output. This method is called doubly balanced quadrature FM detection, and it is used in some IF amplifier/detector ICs.

Lest we leave the wrong impression, we hasten to add that you can demodulate FM without the help of phase locked loops. The classic techniques exploit the steep amplitude versus frequency characteristic of *LC* tuned circuits. In its simplest form (a "slope detector"), the FM signal is applied to an *LC* resonant circuit tuned off to one side, so it has a rising curve of response versus frequency; the output amplitude then varies approximately linearly with frequency, turning FM into FM+AM. An AM envelope detector completes the job of converting the AM to audio. In practice, a slightly more complicated arrangement (called a ratio detector, or Foster–Seeley detector) is used. Another (and simpler) technique uses averaging of a train of identical pulses at the intermediate frequency.

D. AM detection

Wanted: a technique to give an output signal proportional to the instantaneous *amplitude* of a high-frequency signal. The usual method involves rectification (Figure 13.106). Figure 13.107 shows a fancy method ("homodyne detection," or "synchronous detection") using PLLs. The PLL generates a square wave at the same frequency as the modulated carrier. Multiplying the input signal by this square wave generates a full-wave-rectified signal that only needs some lowpass filtering to remove the remnants of the carrier frequency, leaving the modulation *envelope*. If you use the exclusive-OR type of phase detector in the PLL, the output is shifted 90° relative to the reference signal, so a 90° phase shift would have to be inserted in the signal path to the multiplier.

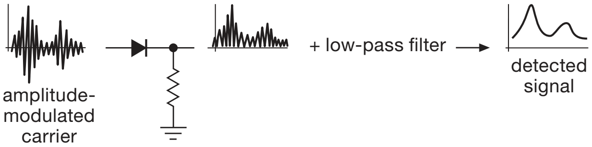

Figure 13.106. AM detection.

E. Digital demodulation

A phase locked loop is an essential component in recovering ("demodulating") data from a carrier that has been modulated with a *digital* signal. In a simple form of digital modulation ("binary phase-shift keying," or BPSK), each bit to be transmitted either inverts, or not, the phase of a constant-amplitude carrier (Figure 13.108). These encoded bits are recovered at the receiving end by multiplying the received BPSK-modulated carrier by a signal at the same carrier frequency. Your first thought might be to use a PLL to recover a carrier replica. But that doesn't work, because the BPSK-modulated spectrum has no component at the carrier frequency.

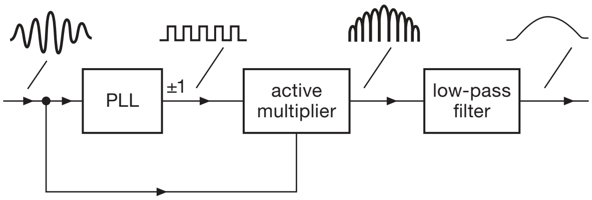

Figure 13.107. Homodyne detection.

One cute solution[130] is to notice that the *square* of the transmitted signal ignores the phase reversals, generating a signal at twice the carrier frequency. Pursuing that idea, you get the "squaring-loop" method of Figure 13.108. The first mixer M1 (a mixer is a multiplier) generates the doubled carrier frequency $2f_c$, which is cleaned up with a bandpass filter and used to lock a PLL, with the VCO acting as a flywheel (low loop bandwidth); a divide-by-2 then creates the carrier replica at f_c, with a phase trim to bring it into alignment with the (suppressed) underlying received carrier. Finally, multiplier M3 synchronously recovers the modulating bits, with a final lowpass filter to remove the $2f_c$ ripple.

If the phased bursts of cycles are thought of as *symbols*, BPSK encodes one bit per symbol. Commonly used digital-modulation schemes typically encode several bits per symbol. For example, you could encode symbols of 2 bits each by sending bursts of carrier cycles, each phased 0°, 90°, 180°, or 270°, according to the 2-bit symbol. This is called quadrature phase-shift keying (QPSK), also known as 4-QAM ("quadrature amplitude modulation," pronounced "quam"). More generally, you can create a "constellation" of symbols, each a (tapered) burst with some amplitude and phase. For example, cable television is commonly delivered as 256-QAM, each symbol carrying 8 bits of information. For all these modulation schemes you still need to recover a signal at the carrier frequency (or

[130] There's a more subtle method of BPSK demodulation, again using a PLL, known as a "Costas Loop." Its performance is comparable, but it's harder to understand what's going on. We like simplicity.

its frequency-shifted replica, an “intermediate frequency”), for which a PLL is essential. A trick that is sometimes used is to transmit a weak “pilot” signal at the carrier frequency, so that schemes like the squaring loop aren’t needed. This is used, for example, in digital television broadcasting in the United States, where 3-bit symbols are encoded as amplitude modulation (four amplitude levels, at 0° or 180°), with a slight dc offset to create the pilot to which the receiver’s PLL can lock.

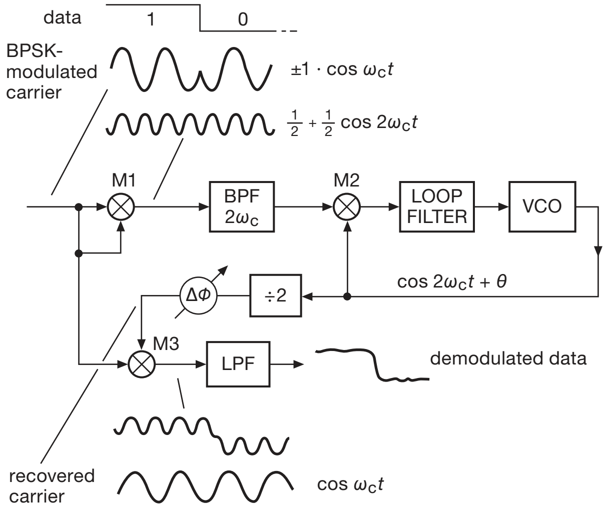

Figure 13.108. Squaring-loop demodulation of BPSK digital signal.

F. Other communications applications

As we suggested earlier, PLLs play an essential role in many aspects of communications. Channelized transmitters (think cellphones) must keep their signals at defined frequencies, with sufficient signal purity to prevent out-of-channel interference. And receivers (cellphones again; or FM radios, televisions, satellite receivers) use a *local oscillator* (LO) to determine their receiving frequency (that’s Armstrong’s superheterodyne technique, nearly a century old). Signal impurity (jitter, spurs) in the LO cause degradation of the received signal, in just the way that it would if it were the transmitter. For applications like these, signal quality is paramount and requires better VCOs than you get with simple capacitive charging circuits like those in the ’4046.

For this kind of application you can get PLL chips that are intended for use with external VCOs and do not include an on-chip oscillator; examples are the NSC LMX2300-series, or the compatible ADI ADF4116–18. These families include members with phase detectors that can run to 6 GHz and beyond. With such PLL chips you can use any commercial VCO; or you can make your own (e.g., a JFET *LC* oscillator, electrically tuned with a varactor, §1.9.5B). An example of the latter is the PLL-disciplined JFET oscillator of Figure 7.29, with a noise spectrum as shown in Figure 7.30.

There’s been considerable effort recently aimed at integrating high-quality VCOs directly onto the PLL chip, so you don’t have to rig up a separate oscillator. Some of these need an external inductor (the hardest part to integrate with the required inductance, and with sufficient quality factor *Q*), for example the ADF4360-8. Others include all components on-chip, for example the LMX2531 or ADF4360-3; these latter are intended for cellphone use and have relatively narrow VCO oscillator tuning ranges, of order 5%. Other technologies used for on-chip oscillators include silicon micromachined (MEMS) resonators (e.g., the SiTime SiT3700-, 8100-, 9100-series), and surface acoustic wave (SAW) resonators (e.g., the IDT M680-series). These have very narrow VCO tuning ranges (∼100 ppm), but you get very low phase noise and jitter, as you do with the competitive technology of crystal oscillators with a similar narrow range of voltage tuning (a VCXO; used, for example, within the IDT 810252 PLL).

G. Pulse synchronization and clean-signal regeneration

In digital signal transmission, a string of bits containing the information is sent over a communications channel. The information may be intrinsically digital or it may be digitized analog signals, as in “pulse-code modulation” (PCM). A closely related situation is the decoding of digital information from magnetic tape or disk, or optical disk storage. In such cases there may be noise or variations in pulse rate (e.g., from tape stretch), and it is desirable to have a clean clock signal at the same rate as the bits you are trying to read. PLLs work very nicely here. The PLL lowpass filter would be designed to follow rate variations inherent in the data stream (e.g., variations in tape or disk speed), while eliminating cycle-to-cycle jitter and noise that come from less-than-ideal received clock signal quality. This widespread application is often called “clock and data recovery” (CDR). An example in the audio world is the Burr–Brown (TI) DIR9001 Digital Audio Interface Receiver, which includes a low-jitter on-chip PLL/VCO clock-recovery subsystem, along with data demodulation. It is flexibly programmable to handle a wide range of data rates (28–108 ksps) and digital formats (with names like S/PDIF, AES3, IEC60958, and CPR-1205).

Notes: (a) sorted approximately by increasing VCO f_{max}. (b) eV - external VCO; eVX - external VCO or VCXO; int/eV - int or eV; iL - internal VCO with external inductor; int - internal VCO, no external components; iR - internal VCO with external resistor; iRC - internal VCO with external R and C; iX - internal VCO with external bare xtal. (d) 25, 125, 156.25, and 312.5MHz only. (f) FM and FSK demod, audio bandwidth. (g) at 10kHz and 10V. (m) min or max. (o) phase detector muxed to output. (p) PLCC. (q) no power-down mode, but quiescent current <1μA.

Comments: A: FM and FSK demod applications. **B:** classic 4000B ("HV") CMOS. **C:** classic HCMOS. **D:** improved 4046, no dead zone. **E:** LVCMOS. **F:** 74HCT also available. **G:** digital 1st-order PLL. **H:** can run at 3V, 14-21MHz. **I:** internal ring oscillator. **J:** f_{ref}=8-30MHz with bare xtal; ref can be VCXO; can generate spread spectrum. **K:** can run at 3V, 38-55MHz. **L:** can run at 3.3V, 0.25-100MHz; ICS663 (SOIC-8) lacks power-down and output enable. **M:** wireless local-osc with PLL synth; versions with other freq ranges. **N:** wireless local-osc with integer-*n* PLL synth; 1.2GHz, 3GHz, and 4GHz versions. **O:** 2-stage PLL (VCXO PLL drives PLL multiplier, with input and output dividers, for Gigabit and 10-Gig Ethernet. **P:** can run at 3.3V; complementary PECL outputs; ext osc to 2GHz. **Q:** wireless local-osc with PLL synth; 0.55GHz and 2.8GHz versions. **R:** eight individual dividers, output clock distribution, multiple refs, highly complex. **S:** SPI interface. **T:** eight LVDS outputs, 0.2ps jitter, adjustable delay. **U:** wireless local-osc with PLL synth; diff'l PECL; parallel and SPI interfaces; replaces MC12430. **V:** Ethernet clock generator, etc.; four outputs; <1ps jitter. **W:** wireless local-osc with PLL synth; stable low-noise; p/n selects ±5% freq band. **X:** delta-sigma fractional-*n*; 0.5ps jitter; includes xtal osc. **Y:** wireless local-osc with PLL synth; 0.5ps jitter. **Z:** ADF4107=7GHz, ADF4108=8GHz.

H. Clock generators

As we remarked earlier, there are plenty of applications crying out for a suite of standard clock frequencies, synthesized from a single oscillator input, in which the niceties of low phase noise and spurs, etc., are of less concern than minimum parts count and the ability to program among a few standard frequencies. See Table 13.13. An example is the IDT 8430S010i: it's a single chip PLL with multiple synthesized outputs intended for embedded processor applications. You connect a single 25 MHz crystal, and out comes (a) choice of two processor clock frequencies, (b) choice of four PCI or PCIe clock frequencies, (c) choice of four DDR DRAM clock frequencies, (d) gigabit Ethernet MAC clock and PHY clocks, and (e) choice of three SP14.2 link frequencies.

Parts like this may use a simple interchip SPI-like serial programming protocol, or they may be pin-strappable (as this one is). Or they may allow both, as for example

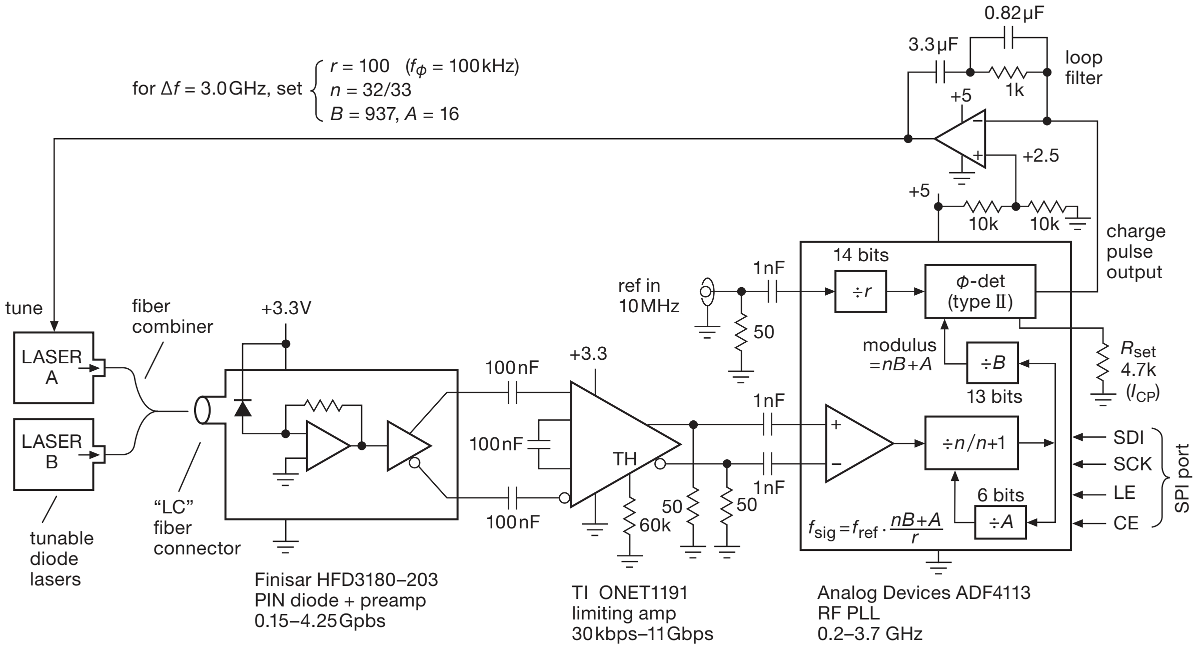

Figure 13.109. Controlling a diode laser to maintain a desired optical frequency difference relative to a reference laser. The components in this circuit cost less than $40, exclusive of the lasers; the latter are in a completely different ballpark, roughly "40 dB$."

the venerable NBC/MC12430 (or equivalent MPC9230), a simple integer-*n* PLL with a 9-bit *n*-counter and a 3-bit *m*-counter, programmable from 50–800 MHz. The on-chip VCO tunes from 400–800 MHz, and likely uses a starved inverter chain ring oscillator (the datasheet isn't talking). We used these as a clocking source in a quirky terasample/second data-acquisition instrument we built to detect intentional pulsed laser signals from possible extraterrestrial civilizations (no kidding).

I. Laser offset locking

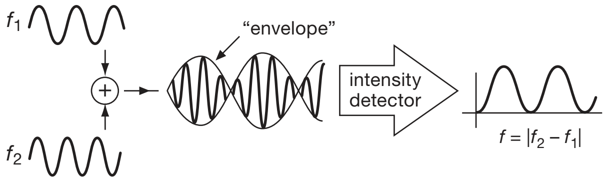
In some scientific applications it's useful to be able to control a tunable laser, such that the frequency of its optical emission is offset by a specific frequency difference from that of a "reference" laser. As a specific example, a favorite technique in the business of "laser cooling" is to subject a beam of atoms to converging beams of laser light at a frequency slightly below that of a natural resonance of the atom. The Doppler effect causes an atom moving toward one of these lasers to see the light shifted upward in frequency, therefore more strongly absorbed by the atom, which is slowed by the transferred momentum.[131]

A phase-locked loop is perfect for this *offset locking*. Figure 13.109 shows how this goes, as implemented in a colleague's laboratory.[132] A portion of the light from the pair of tunable diode lasers is combined and sent to a wideband PIN-diode detector/amplifier module. What happens there is interesting; let's take it in two steps. (a) In a completely linear process, the two combined laser beams create a waveform consisting of a sinewave at the average laser frequency, modulated (multiplied) by a sinewave at half the difference frequency (Figure 13.110). (b) The detector cannot follow the *optical* waves, whose frequency is $\sim 10^{14}$ Hz. It responds only to the *intensity* of the light, proportional to the square of the "envelope" shown in Figure 13.110. And the square of a sinewave is just a sinewave at twice the frequency, plus a dc offset so that it sits atop the horizontal axis as shown.

In other words, at the output of the detector module you get a signal at the lasers' difference frequency (also called the *beat frequency*): $f_{\text{PDout}} = |f_2 - f_1| \equiv \Delta f$. The function of the rest of the circuit is simply to feed back a control signal to laser A so that the difference frequency Δf equals the desired offset. That's done with a fractional-*n* PLL, here preceded by a limiting amplifier that creates a clean

[131] This is known by the colorful term "optical molasses." Add some magnetic fields, and a few more tricks, and you've got a magneto-optical trap.

[132] The ever-capable Dr. Andrew Speck, to whom we are grateful for this and other excellent suggestions.



$$\cos \omega_1 t + \cos \omega_2 t = 2 \cos\left(\frac{\omega_1 - \omega_2}{2}\, t\right) \cos\left(\frac{\omega_1 + \omega_2}{2}\, t\right)$$

Figure 13.110. A linear combination of two sinewaves produces a wave at the midfrequency with a sinusoidal amplitude "envelope." A photodetector cannot capture the optical frequencies themselves ($\sim 10^{14}$ Hz); it responds to the intensity (the square of the envelope), producing an output "beat frequency" equal to the lasers' difference frequency.

saturated 0.6 Vpp signal from a detector output anywhere between 10 mV and 1 V.

For the laser cooling/trapping application, the frequency offset Δf is in the range of 10 MHz or so, relative to the much higher optical resonance frequency; for rubidium atoms the latter is 3.85×10^{14}Hz, corresponding to a wavelength of 780.24 nm.[133] As is often the case, there's much more to love (and hate) in this business: it turns out that there's a "hyperfine splitting" of the ground state of ^{85}Rb, so you need to kick out (the polite term is "optically pump") the atoms that happen to fall all the way to the bottom with some laser light that is offset by that energy difference. That's about 3 GHz,[134] which is why this circuit was designed for offsets in the gigahertz range, as indicated by the notations in the figure.

13.13.7 Wrapup: noise and jitter rejection in PLLs

We've seen applications where the reference is the higher-quality signal (e.g., multiple clocking signals derived from a single stable crystal reference), and applications where the opposite is true, namely that the PLL-generated signal is cleaner than the reference (e.g., clock recovery in a noisy channel, where the "flywheel" action of the VCO cleans up the output).

It's helpful, when thinking about these kinds of issues while setting loop bandwidths and the like, to understand how noise or jitter that originates in different places (reference input, phase detector, or VCO) is filtered by the action of the PLL. You can write lots of equations at this point. But it's not hard to get an intuitive understanding by simply looking at the loop diagram (Figure 13.85): (a) jitter at the reference input is *lowpass* filtered, because variations within the PLL loop bandwidth are tracked by the VCO, whereas fast variations are ignored by the VCO flywheel; (b) intrinsic jitter in the VCO itself is *highpass* filtered, because variations within the loop bandwidth are detected and removed by the loop; and (c) jitter that is introduced by the phase detector is *bandpass* filtered, because slow variations (within the loop bandwidth) are detected and removed, and fast variations are suppressed by the (lowpass) loop filter and the integrating action ($f \rightarrow \phi$) of the VCO.

So, for example, a PLL with clean reference input benefits from a wide loop bandwidth, whereas a PLL presented with an intrinsically stable reference that has acquired additive noise in transmission will benefit from a narrow loop bandwidth (and an intrinsically clean VCO). And the "noise" can be more subtle: the divided VCO signal seen by the phase detector in a fractional-*n* PLL has jitter (introduced by the deliberate changes of modulus); a narrow loop bandwidth smooths this jitter source as well.

Of course, if the PLL output needs agility (as with tone decoding, or FM demodulation) then the loop bandwidth must be tailored accordingly, quite independent of noise and jitter tradeoffs.

13.14 Pseudorandom bit sequences and noise generation

13.14.1 Digital-noise generation

An interesting blend of digital and analog techniques is embodied in the subject of pseudorandom bit sequences (PRBSs).[135] It turns out to be remarkably easy to generate sequences of bits (or words) that have good randomness properties, i.e., a sequence that has the same sort of probability and correlation properties as an ideal coin-flipping machine. Because these sequences are generated by standard deterministic logic elements (shift registers, to be exact), the bit sequences generated are in fact predictable and repeatable, although any portion of such a sequence looks for all the world just like a random string of 0s and 1s.

[133] This happens to be the wavelength used in compact disc recorders; so the system of Figure 13.109 was implemented economically by using a pair of these ubiquitous laser diodes, which can put out 100 mW (caution, definitely *not* eye-safe!). To tune these things, you attach a piezo-tiltable external grating, adjusting the diode current in tandem to keep its wavelength tracking that of the external cavity. Less inventive souls can throw money at the problem: you can buy tunable diode lasers from companies like New Focus, ThorLabs, and Toptica.

[134] Actually, 3.035732439 GHz, if you really need to know.

[135] This is the example we used in Chapter 11 to illustrate programmable logic, where we contrasted PRBS implementations in discrete logic, in programmable logic, and in a microcontroller. See also its use as an analog noise generator in §8.12.4A.

With just a few chips you can generate sequences that literally go on for centuries without repeating, making this a very accessible and attractive technique for the generation of digital bit sequences or analog noise waveforms. When generating eye diagrams (e.g., Figures 12.132 and 14.33), or testing serial links for bit error rates (BERs), it is common to use a PRBS source. PRBSs are used also to "scramble" (deterministically) the serial data in gigabit Ethernet communications, in order to generate a lively bit pattern for the ac-coupled (transformer) physical link; the scrambling is reversed at the receive end, by XOR-ing with a synchronized PRBS running the same sequence.

A. Analog noise

Simple lowpass filtering of the output bit pattern of a PRBS generates bandlimited white Gaussian noise, i.e., a noise voltage with a flat power spectrum up to some cutoff frequency (see Chapter 8 for more on noise). Alternatively, a weighted sum of the shift-register contents (via a set of resistors) performs *digital filtering*, with the same result. Flat noise spectra out to several megahertz can easily be made this way. As you will see later, such digitally synthesized analog noise sources have many advantages over purely analog techniques such as noise diodes or resistors.

B. Other applications

Besides their obvious applications as analog or digital noise sources, pseudorandom bit sequences are useful in a number of applications that have nothing to do with noise. As just mentioned, they are used for pattern generation in serial link testing (eye diagrams, bit error rate), and for bit scrambling (as opposed to real encryption) in serial network protocols like Ethernet. They are used in "direct-sequence" spread-spectrum digital communications (in which each bit to be transmitted is sent as a predetermined sequence of shorter "chips"); such a technique is used, for example, in CDMA (code-division multiple-access) cellular phone systems, and in the airlink privacy cipher of the GSM cellular standard. They're also used in digital TV broadcasting. These sequences are used extensively in error-detecting and error-correcting codes, because they allow the transcription of blocks of data in such a way that valid messages are separated by the greatest "Hamming distance" (measured by the number of bit errors). Their good autocorrelation properties make them ideal for radar-ranging codes, in which the returned echo is compared (cross-correlated, to be exact) with the transmitted bit string. They can even be used as compact modulo-n dividers.

13.14.2 Feedback shift register sequences

The most popular (and the simplest) PRBS generator is the linear feedback shift register (LFSR, Figure 13.111). A shift register of length m bits is clocked at some fixed rate, f_0. An exclusive-OR gate generates the serial input signal from the exclusive-OR combination of the nth bit and the last (mth) bit of the shift register. Such a circuit goes through a set of states (defined by the set of bits in the register after each clock pulse), eventually repeating itself after K clock pulses; i.e., it is cyclic with period K.

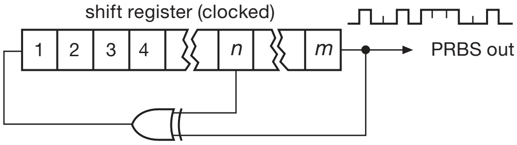


Figure 13.111. Pseudorandom bit sequence generator.

The maximum number of conceivable states of an m-bit register is $K = 2^m$, i.e., the number of binary combinations of m bits. However, the state of all 0s would get "stuck" in this circuit, because the exclusive-OR would regenerate a 0 at the input. Thus the maximum-length sequence you can possibly generate with this scheme is $2^m - 1$. It turns out that you can make such "maximal-length shift-register sequences" if m and n are chosen correctly, and the resultant bit sequence is pseudorandom.[136] As an example, consider the 4-bit feedback shift register in Figure 13.112. Beginning with the state 1111 (we could start anywhere except 0000), we can write down the states it goes through:

1111
0111
0011
0001
1000
0100
0010
1001
1100
0110
1011
0101
1010
1101
1110

We have written down the states as 4-bit numbers

[136] The criterion for maximal length is that the polynomial $1+x^n+x^m$ be irreducible and prime over the Galois field GF(2).

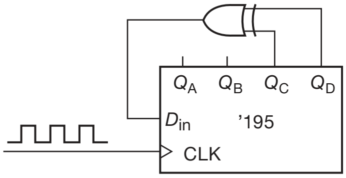

Figure 13.112. 4-bit linear feedback shift register (m=4, n=3; 15 states).

$Q_AQ_BQ_CQ_D$. There are 15 distinct states (2^4-1), after which it begins again; therefore it is a maximal-length register.

Exercise 13.8. Demonstrate that a 4-bit register with feedback taps at the second and fourth bits is not maximal length. How many distinct sequences are there? How many states within each sequence?

A. Feedback taps

Maximal-length shift registers can be made with exclusive-OR feedback from more than two taps (in these cases you use several exclusive-OR gates in the standard parity-tree configuration, i.e., modulo-2 addition of several bits). In fact, for some values of m, a maximal-length register can be made only with more than two taps. Table 13.14 is a listing of all values of m up to 167 for which maximal-length registers can be made with just two taps, i.e., feedback from the nth bit and the mth (last) bit, as previously. A value is given for n and for the cycle length K, in clock cycles. In some cases there is more than one possibility for n, and in every case the value $m-n$ can be used instead of n; thus the earlier 4-bit example could have used taps at n=1 and m=4. Since shift-register lengths in multiples of 8 are common, you may want to use one of those lengths. In that case, more than two taps are necessary. Table 13.15 gives the magic numbers.

It's rarely necessary to use a register much longer than 32 bits: when clocked at 1 MHz the repeat time is about an hour. Go to 64 bits and you can clock at 1 GHz for six centuries before it comes around again.

Table 13.14 Single-tap LFSRs

B. Properties of maximal-length shift-register sequences

We generate a string of pseudorandom bits from one of these registers by clocking it and looking at successive output bits. The output can be taken from any position of the register; it is conventional to use the last (mth) bit as the output. Maximal-length shift-register sequences have the following properties:

1. In one full cycle (K clock cycles), the number of 1s is one greater than the number of 0s. The extra 1 comes about because of the excluded state of all 0s. This says that heads and tails are equally likely (the extra 1 is totally insignificant for any reasonable-length register; a 17-bit register will produce 65,536 1s and 65,535 0s in one of its cycles).
2. In one full cycle (K clock cycles), half the runs of

consecutive 1s have length 1, one-fourth the runs have length 2, one-eighth have length 3, etc. There are the same numbers of runs of 0s as of 1s, again with the exception of a missing 0. This says that the probability of heads and tails does not depend on the outcome of past flips, and therefore the chance of terminating a run of successive 1s or 0s on the next flip is 1/2 (contrary to the person-in-the-street's understanding of the "law of averages").

3. If one full cycle (K clock cycles) of 1s and 0s is compared with the same sequence shifted cyclically by any number of bits n (where n is not 0 or a multiple of K), the number of disagreements will be one greater than the number of agreements. In fancy language, the autocorrelation function is a Kronecker delta at zero delay, and $-1/K$ everywhere else. This absence of "sidelobes" in the autocorrelation function is what makes PRBSs so useful for radar ranging.

Exercise 13.9. Show that the 4-bit shift-register sequence listed earlier (taps at $n=3, m=4$) satisfies these properties, considering the Q_A bit as the "output": 100010011010111.

13.14.3 Analog noise generation from maximal-length sequences

A. Advantages of digitally generated noise

As we remarked earlier, the digital output of a maximal-length feedback shift register can be converted to band-limited white noise with a lowpass filter whose cutoff frequency is well below the clock frequency of the register. Before getting into the details, we point out some of the advantages of digitally generated analog noise. Among other things, it allows you to generate noise of known spectrum and amplitude (see the circuit example in §8.12.4A), with adjustable bandwidth (via clock-frequency adjustment), using reliable and easily maintained digital circuitry. There is none of the variability of diode noise generators, nor are there interference and pickup problems that plague the sensitive low-level analog circuitry used with diode or resistor noise generators. Finally, it generates repeatable "noise" and, when filtered with a weighted digital filter (more about this later), repeatable noise waveforms independent of clocking rate (output noise bandwidth).

13.14.4 Power spectrum of shift-register sequences

The output spectrum generated by maximal-length shift registers consists of noise extending from the repeat frequency of the entire sequence, f_{clock}/K, up to the clock frequency and beyond. It is flat within ±0.1dB up to 12% of the clock frequency (f_{clock}), dropping rather rapidly beyond its -3 dB point of 44% f_{clock}. Thus a lowpass filter with a high-frequency cutoff of 5%–10% of the clock frequency will convert the unfiltered shift register output to a band-limited analog noise voltage. Even a simple *RC* filter will suffice, although it may be desirable to use active filters with sharp cutoff characteristics (see Chapter 6) if a precise frequency band of noise is needed.

To make these statements more precise, let's look at the shift-register output and its power spectrum. It is usually desirable to eliminate the dc offset characteristic of digital logic levels, generating a bipolarity output with 1 corresponding to $+a$ volts and 0 corresponding to $-a$ volts (Figure 13.113). This can be done in various ways, for example, referring to Figure 13.114, (A) with an 'HC4053 linear CMOS switch, operating from dual supplies and with a pair of inputs tied to $\pm a$ volts; (B) with a fast op-amp with dc offset current into a summing junction; (C) with a fast rail-to-rail comparator running between $\pm a$-volt split supplies; (D) with a CMOS logic gate, powered from $\pm a$-volt supplies, driven by a properly shifted and scaled logic swing; or (E) with the same logic gate, driven with a diode-clamped (and current-limited) logic swing. This last method is a bit weird, and works only if the total supply voltage ($V_{\text{total}}=2a$) is in the range of a standard logic family (say 1–5 V); but it excels in speed. It's not dc-coupled, so it requires a logic input that's busy; that's OK here – a PRBS is peripatetic, and cannot rest for longer than m clock periods.[137]

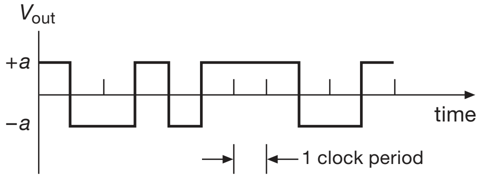

Figure 13.113. A symmetrical PRBS waveform eliminates the dc component.

As we remarked earlier, the string of output bits has a single peak in its autocorrelation. If the output states represent +1 and −1, the digital autocorrelation (the sum of the product of corresponding bits, when the bit string is compared with a shifted version of itself) is as shown in Figure 13.115.

[137] To paraphrase Woody Allen, "A clamped ac-coupled logic input is like a shark; it has to keep moving, or it dies."

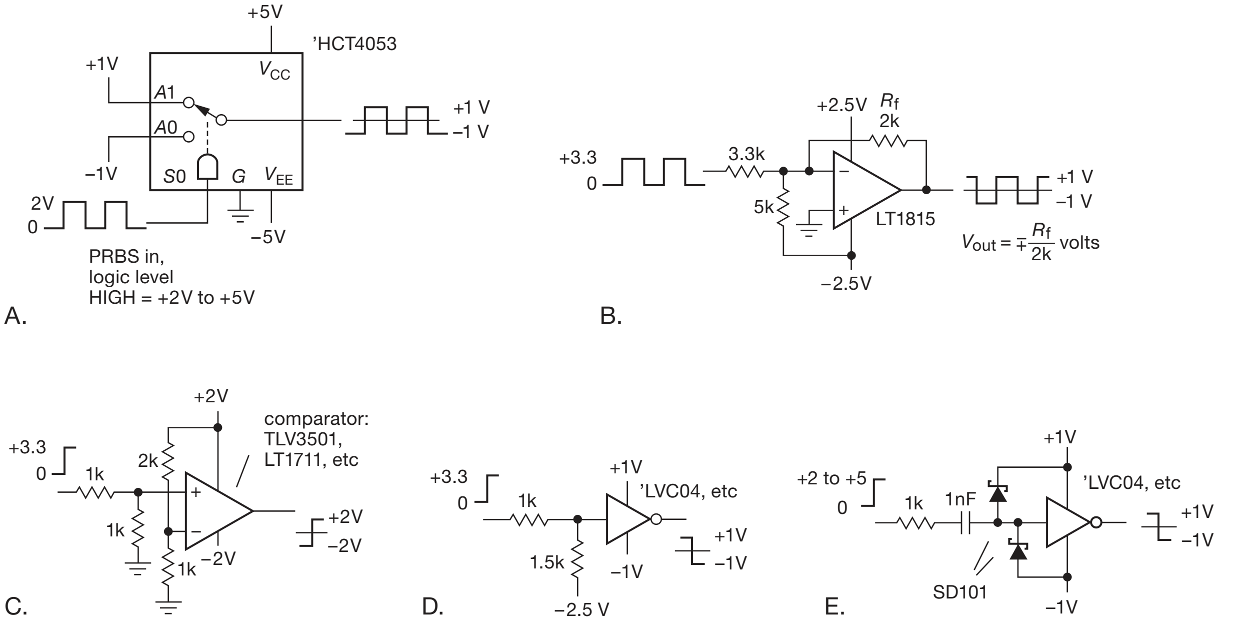

Figure 13.114. Converting a positive-only logic swing to a symmetrical voltage waveform.

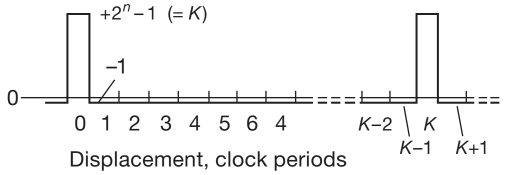

Figure 13.115. Full-cycle discrete autocorrelation for a maximal-length shift-register sequence.

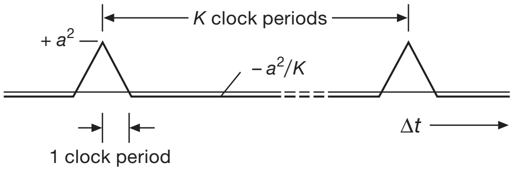

Figure 13.116. Full-cycle continuous autocorrelation for a maximal-length shift-register sequence.

Don't confuse this with a *continuous* autocorrelation function, which we consider later. This graph is defined only for shifts corresponding to a whole number of clock cycles. For all shifts that aren't zero or a multiple of the overall period K, the autocorrelation function has a constant -1 value (because there is an extra 1 in the sequence), negligible when compared with the zero-offset autocorrelation value of K. Likewise, if we consider the unfiltered shift-register output as an *analog* signal (whose waveform happens to take on values of $+a$ and $-a$ volts only), the normalized autocorrelation becomes a continuous function, as shown in Figure 13.116. In other words, the waveform is totally uncorrelated with itself when shifted more than one clock period forward or backward.

The power spectrum of the unfiltered digital output can be obtained from the autocorrelation by standard mathematical techniques. The result is a set of equally spaced series of spikes (delta functions), beginning at the frequency at which the whole sequence repeats, f_{clock}/K, and going up in frequency by equal intervals f_{clock}/K. The fact that the spectrum consists of a set of discrete spectral lines reflects the fact that the shift-register sequence eventually (and periodically) repeats itself. Don't be alarmed by this funny spectrum; it will look continuous for any measurement or application that takes less time than the cycle time of the register. The envelope of the spectrum of the unfiltered output is shown in Figure 13.117. The envelope is proportional to the square of $(\sin x)/x$. Note the peculiar property that there is *no* noise power at the clock frequency or its harmonics.

A. Noise voltage

Of course, for analog noise generation you use only a portion of the low-frequency end of the spectrum. It turns out to be easy to calculate the noise power per hertz in terms of the half-amplitude (a volts) and the clock frequency

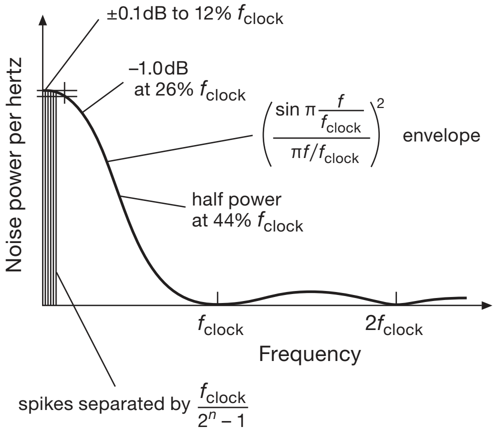

Figure 13.117. Power spectrum of unfiltered digital shift-register output signal.

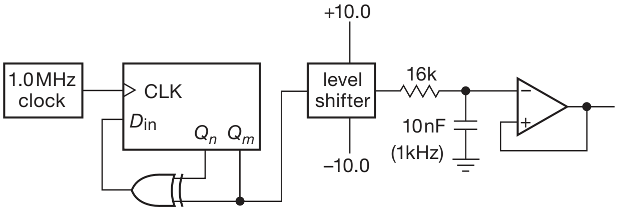

Figure 13.118. Simple pseudorandom noise source.

(f_{clock}). Expressed as an rms noise *voltage*, the answer is

$$v_{\text{rms}} = a\left(\frac{2}{f_{\text{clock}}}\right)^{1/2} \quad \text{V}/\sqrt{\text{Hz}}, \qquad (f \leq 0.2 f_{\text{clock}}).$$

This is for the bottom end of the spectrum, the part you usually use (you can use the envelope function to find the power density elsewhere).

For example, suppose we run a maximal-length shift register at 1.0 MHz and arrange it so that the output voltage swings between +10.0 and −10.0 volts. The output is passed through a simple *RC* lowpass filter with 3 dB point at 1 kHz (Figure 13.118). We can calculate the rms noise voltage at the output exactly. We know from the preceding equation that the output from the level shifter has an rms noise voltage of 14.14 mV per root hertz. From §8.13 we know that the noise bandwidth of the lowpass filter is (π/2)(1.0 kHz), or 1.57 kHz. So the output noise voltage is

$$V_{\text{rms}} = 0.01414 \cdot (1570)^{1/2} = 560\,\text{mV}$$

with the spectrum of a single-section *RC* lowpass filter.

13.14.5 Low-pass filtering

A. Analog filtering

The spectrum of useful noise from a pseudorandom sequence generator extends from a low-frequency limit of the reciprocal repeat period (f_{clock}/K) up to a high-frequency limit of perhaps 20% of the clock frequency (at that frequency the noise power per hertz is down by 0.6 dB). Simple lowpass filtering with *RC* sections, as illustrated in the earlier example, is adequate provided that its 3 dB point is set far below the clock frequency (e.g., less than 1% of f_{clock}). To use the spectrum closer to the clock frequency, it is advisable to use a filter with sharper cutoff, e.g., a Butterworth or Chebyshev. In that case the flatness of the resultant spectrum depends on the filter characteristics, which should be measured, since component variations can produce ripples in the passband gain. Likewise, the filter's actual voltage gain should be measured if the precise value of noise voltage per root hertz is important.

B. Digital filtering

A disadvantage of analog filtering is the need to readjust the filter cutoff if the clock frequency is changed by large factors. In situations where you want to change the clocking frequency, an elegant solution is provided by discrete-time digital filtering, in this case performed by taking an analog-weighted sum of successive output bits (nonrecursive digital filtering). In this way the effective filter cutoff frequency changes to match changes in the clock frequency. In addition, digital filtering lets you go to extremely low cutoff frequencies (fractions of a hertz) where analog filtering becomes awkward.

To perform a weighted sum of successive output bits simultaneously, you can simply look at the various parallel outputs of successive shift-register bits, using resistors of various values into an op-amp summing junction. For a lowpass filter the weights should be proportional to $(\sin x)/x$; note that some levels will have to be inverted since the weights are of both signs. Because no capacitors are used in this scheme, the output waveform consists of a set of discrete output voltages.

The approximation to Gaussian noise is improved by use of a weighting function over many bits of the sequence. In addition, the analog output then becomes essentially a continuous waveform. For this reason it is desirable to use as many shift-register stages as possible, adding additional shift-register stages outside the exclusive-OR feedback if necessary. As before, pullups or MOS switches should be used to set stable digital voltage levels (CMOS

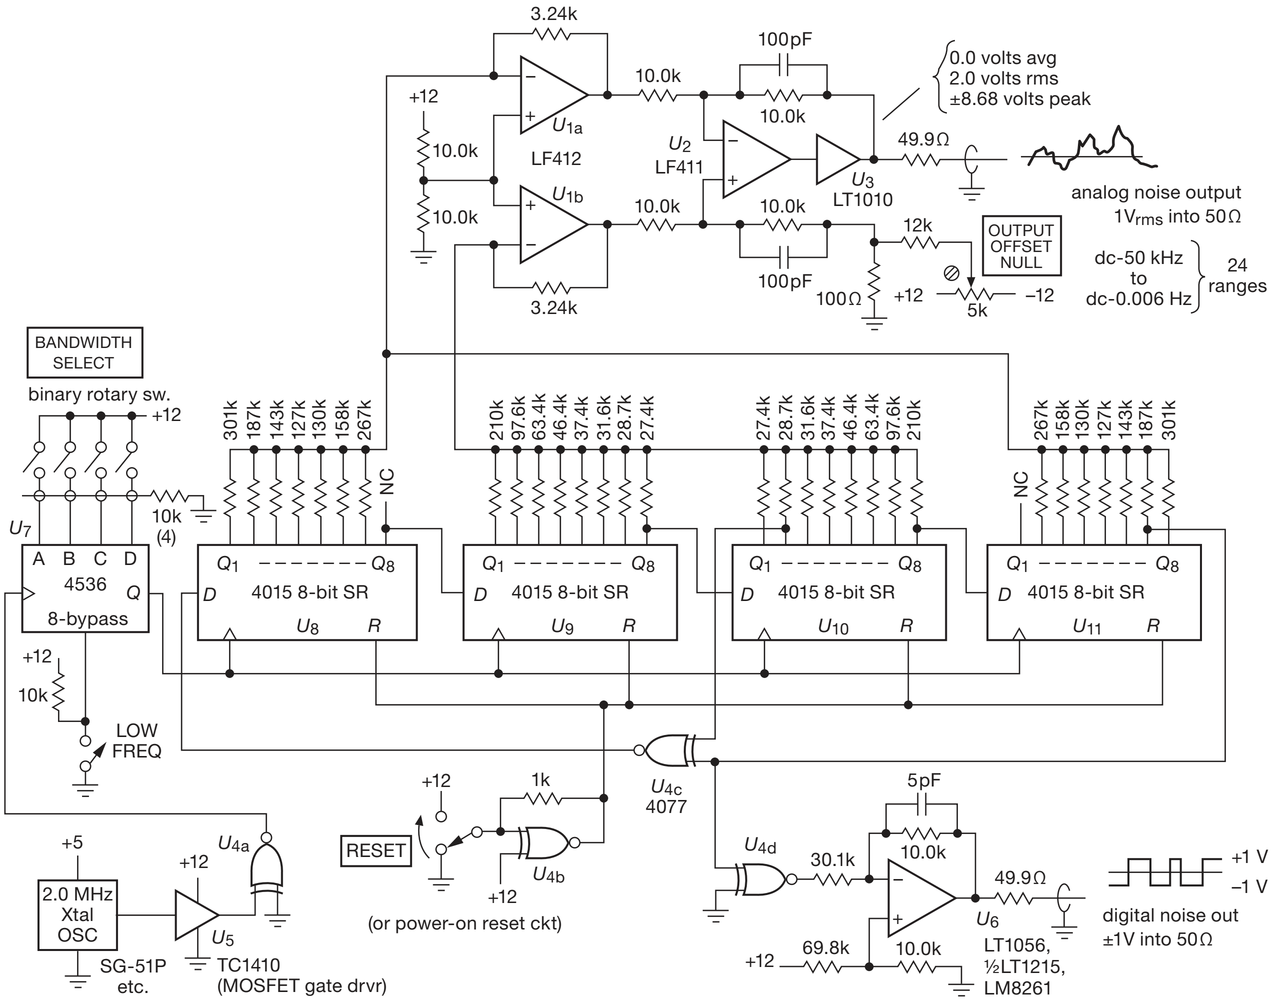

Figure 13.119. Wide-frequency-range laboratory pseudo-random noise source, inspired by Hewlett Packard's Model 3722A Noise Generator ("A precision digital instrument," in the parlance of its time, 1967). If you want to stick with discrete logic but need greater bandwidth, you could substitute 74LV164A 8-bit shift registers (with guaranteed clocking up to 125 MHz with a 5 V supply), with corresponding circuit changes throughout. Or you could use a fast cPLD or FPGA (§11.3.3) – but having gone that far, you might as well implement the digital lowpass filter in a DSP (digital signal processor) chip. Following this thread one step further, you could just code the whole thing in a fast microcontroller (§11.3.5 and Chapter 15), and use its on-chip D-to-A converter to generate the band-limited analog noise output.

logic is ideal for this application, because the outputs saturate cleanly at $V_{\rm DD}$ and ground).

The circuit in Figure 13.119 generates pseudorandom analog noise, with bandwidth selectable over an enormous range, using this technique. A 2.0 MHz crystal oscillator drives a 14536 24-stage programmable divider, generating selectable clock frequencies going from 1.0 MHz down to 0.12 Hz by factors of 2. A 32-bit shift register is connected with feedback from stages 31 and 18, generating a maximal-length sequence with 2 billion states (at the maximum clock frequency the register completes one cycle in a half hour). In this case we have used a $(\sin x)/x$ weighted sum over 32 successive values of the sequence. Op-amps U_{1a} and U_{1b} amplify the inverted and noninverted terms, respectively, driving difference amplifier U_2. The gains are chosen to generate a 1.0 V rms output with no dc offset into a 50 Ω load impedance (2.0 V rms open circuit). Note that this noise amplitude is independent of the clock rate, i.e., the total bandwidth. This digital filter has a cutoff at about $0.05 f_{\rm clock}$, giving a white-noise output spectrum extending from dc to 50 kHz (at maximum clock frequency) down to dc to 0.006 Hz (at minimum clock frequency), in 24 steps of bandwidth. The circuit also provides an unfiltered output waveform, going between +1.0 V and −1.0 V.

There are a few interesting points about this circuit. Note that an exclusive-NOR gate is used for feedback so that the register can be simply initialized by bringing it to the state of all zeros. This trick of inverting the serial input signal makes the excluded state the state of all 1s (rather than all 0s as with the usual exclusive-OR feedback), but it leaves all other properties unaffected.

A weighted sum of a finite number of bits cannot ever produce truly Gaussian noise, since the peak amplitude is limited. In this case it can be calculated that the peak output amplitude (into 50 Ω) is ±4.34 V, giving a "crest factor" of 4.34. That calculation is important, by the way, because you must keep the gains of U_1 and U_2 low enough to prevent clipping. Look carefully at the methods used to generate an output of zero dc offset from the CMOS levels of +6.0 V average value (LOW=0 V, HIGH=12.0 V).

13.14.6 Wrapup

A few comments about shift-register sequences as analog noise sources.[138] You might be tempted to conclude from the three properties of maximal-length shift registers listed earlier that the output is "too random," in the sense of having exactly the right number of runs of a given length, etc. A genuine random coin-flipping machine would not generate exactly one more head than tail, nor would the autocorrelation be absolutely flat for a finite sequence. To put it another way, if you used the 1s and 0s that emerge from the shift register to control a "random walk," moving forward one step for a 1 and back one step for a 0, you would wind up exactly one step away from your beginning point after the register had gone through its entire cycle, a result that is anything but "random".

However, the shift-register properties mentioned earlier are true only of the entire sequence of $2^n - 1$ bits, *taken as a whole*. If you use only a section of the entire bit sequence, the randomness properties closely approximate a random coin-flipper. To make an analogy, it is as if you were drawing red balls and blue balls at random from an urn initially containing K balls in all, half red and half blue. If you do this *without replacing them*, you would expect to find approximately random statistics at first. As the urn becomes depleted, the statistics are modified by the requirement that the total numbers of red and blue balls must come out the same.

You can get an idea how this goes by thinking again about the random walk. If we assume that the only nonrandom property of the shift sequence is the exact equality of 1s and 0s (ignoring the single excess 1), it can be shown that the random walk as described should reach an average distance from the starting point of

$$X = [r(K-r)/(K-1)]^{1/2}$$

after r draws from a total population of $K/2$ ones and $K/2$ zeros. Because in a completely random walk X equals the square root of r, the factor $(K-r)/(K-1)$ expresses the effect of finite urn contents. As long as $r \ll K$, the randomness of the walk is only slightly reduced from the completely random case (infinite urn contents), and the pseudorandom sequence generator is indistinguishable from the real thing. We tested this with a few thousand PRBS-mediated random walks, each a few thousand steps in length, and found that the randomness was essentially perfect, as measured by this simple criterion.

Of course, the fact that PRBS generators pass this simple test does not guarantee that they would satisfy some of the more sophisticated tests of randomness, e.g., as measured by higher-order correlations. Such correlations also affect the properties of analog noise generated from such a sequence by filtering. Although the noise amplitude distribution is Gaussian, there may be higher-order amplitude correlations uncharacteristic of true random noise. It is said that the use of many (preferably about $m/2$) feedback taps (using an exclusive-OR parity-tree operation to generate the serial input) generates "better" noise in this respect.

Noise-generator builders should be aware of the 4557 CMOS variable-length shift register (six input pins set its length, any number from 1 to 64 stages); you have to use it in combination with a parallel-output register (such as the '4015 or '164) in order to get at the n tap; another useful chip is the HC(T)7731, a quad 64-bit shift register (256 bits in all) that runs to 30 MHz (min). Noise-generator builders should be even more aware of the ease with which programmable logic devices (cPLDs or FPGAs) can be coaxed into PRBS duty, as we illustrate in Chapter 11. Microcontrollers will do the job, too, but a PLD solution will be faster.[139]

When going for absolute maximum speed, though, you may want to fall back on good ol' discrete logic: As an admirable example, the CG635 "Synthesized Clock Generator" from Stanford Research Systems[140] can deliver a

[138] We are indebted to our late colleague Ed Purcell for these insights.

[139] And a full-custom chip fastest of all... if you can afford the $50k buy-in.

[140] Who obligingly provide full schematic diagrams and parts lists for the instrument.

7-stage PRBS (i.e., 2^7-1 states) at rates to 1.55 GHz.[141] This they do with some elegant tricks: (a) they use MC100EP emitter-coupled differential logic in an array of individually clocked flip-flops; this stuff is *fast* – the D-flops (MC100EP52D) have a setup time of 0.05 ns, zero hold time, and 0.33 ns (typ) propagation time; (b) they use differential clock and data lines (quiet, and fast); (c) the speed bottleneck is the XOR propagation time (0.3 ns), so they do a neat trick, namely (d) they arrange the FFs in a circle, with the data going around clockwise, and the clock going counterclockwise. This has the effect of delaying the clock to the first stage, relative to the clocking of the last two stages, by about 0.25 ns, thus allowing the XOR's (delayed) output to meet the first FF's setup requirement. And the cute geometry causes the clocks of the successive FFs to advance by about 0.05 ns each, thus effectively distributing the pain evenly around the array. Figure 13.120 shows how those clever folks laid out the printed circuit board to make it all happen.

13.14.7 "True" random noise generators

We remarked at the outset that algorithmically generated "noise" cannot be truly random – after all, you can *predict* exactly what's coming if you know the algorithm. Volumes have been written about this.[142] If you want *genuine* noise, you've got to look elsewhere.

A good place to start is some *physical* process (like radioactive decay) that is random *in principle*, and of course unpredictable. Circuit designers do not ordinarily include radioisotopes in their toolkits; but there are other physical processes that do just fine. For example, the noise voltage generated during avalanche conduction in a bipolar junction. We used this in the circuit responsible for the random byte collection that is shipped with the CD-ROM from *Numerical Recipes*, and available from Amazon. Figure 13.121 shows the circuit. Here is the description immortalized on the CD-ROM, where also are found the ∼250 MB of what author William Press modestly refers to as "still the best 'random' bits anywhere:"

> Professor Paul Horowitz, of Harvard University, kindly constructed for us an electronic source of physical randomness. The analog noise source is a transistor junction that is biased to function as an avalanche diode. Physically, the noise current from this junction is generated by the random creation of electron-hole pairs in the junction, due to thermal noise (and, ultimately, quantum mechanical processes). Experimentally, the output of the device, viewed with a spectrum analyzer, is flat from close to dc out to 50 MHz.
>
> The "Hororan" circuit [Figure 13.121] samples the amplified analog voltage from the noise junction at a rate that is 8 times the desired baud rate for output (the latter typically 38.4 kbps or 115.2 kbps). The sample duration ("aperture") is very short, about 2 nanoseconds for the LT1016 latched comparator, so there is plenty of aliasing of the higher available frequencies into the sampled value. If the sample voltage is positive, a digital "1" bit is generated; if it is negative, a digital "0" bit is generated. The collected bits are continuously exclusive-OR'd (XOR) into a register. After every eight bits are collected, the state of the register is output as one bit in the raw file. After every eight output bits, the next two output bits are discarded during the formatting of the required RS-232 stop and start bits. The digital XOR and start/stop formatting functions are performed by a 26V12 PAL, whose programming is included here.
>
> It is intentional that we do not do any more complicated digital processing (mixing, scrambling, encrypting, etc.) within the Hororan box, because we want to be able to measure, and characterize, the degree of randomness coming out of the box. The box indeed has a measurable nonrandomness in its 1-point statistic. That is, the number of output 1s and 0s are not exactly equal but differ by, typically, a few parts in 10^4. (Indeed, the box has a trim adjustment to minimize this nonrandomness.) Notice that it requires several times 10^8 collected bits even to measure this bias convincingly – but we have satisfied ourselves that it is present. The bias drifts slowly with time, presumably in response to thermal and other environmental changes.
>
> We are unable to find, in numerical experiment, any trace of nonrandomness in the higher-point statistics of the raw collected bits. In particular, we have not been able to find (in several times 10^9 collected bits) any 2-point nonrandomness, either in the autocorrelation at small lags, or in the power spectrum at likely frequencies such as 60 Hz or its first few harmonics. On the basis of the physical construction of the Hororan box, we believe that M-point statistics with $M>2$ (with the exception of high-point statistics that are

[141] Other sequence lengths commonly used for bit-error testing are $2^{23}-1$ and $2^{31}-1$.

[142] For example, Volume 2 of Donald Knuth's comprehensive classic, *The Art of Computer Programming*.

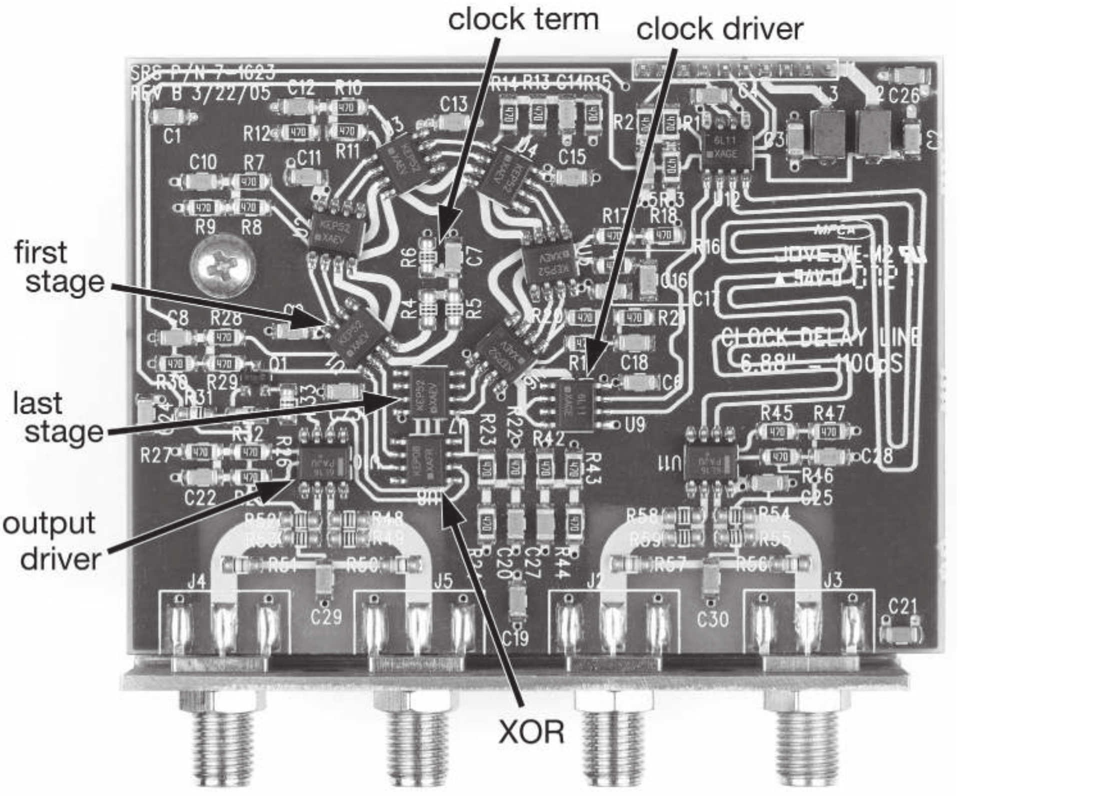

Figure 13.120. Racetrack layout of fast (to 1.55 Gbps) 7-bit PRBS, implemented with 100EP-series discrete LVPECL flip-flops and gates. Data goes clockwise, clock goes counterclockwise, and it all works!

the result of slow drifts in the 1-point bias) should be strongly decreasing with M. The reason is essentially that the transistor junction has no “memory” and has an internal timescale on the order of the reciprocal of its 50 MHz bandwidth.

Thus, while the output of the Hororan box is demonstrably non-random, we believe that its true “entropy per bit” is convincingly bounded as being close to 1 (the fully random value). If $1-e$ denotes the entropy per bit in a large file of N bits (a more detailed definition is given below), then we think that, with a high degree of experimental certainty (there is no way to “prove” this mathematically) we have $e < 0.01$.

Incidentally, the raw output of the Hororan box easily passes all of the tests in Marsaglia’s “Diehard battery of tests.”

To return to that CD-ROM: the output of this hardware was merely the starting point (the “collection phase”) for a complex sequence of operations on the way to the final published bytes: the “perfection phase” consists of multiple passes and shuffling through triple-DES encryption, XOR-ing with freshly collected bytes between each pass and again at the end. A full description can be found on the CD-ROM itself, in a folder labeled “Museum.”

13.14.8 A “hybrid digital filter”

The example of Figure 13.119 revisits the interesting topic of *digital filtering*, discussed earlier in §6.3.7. What we have here is simply a 32-sample finite-impulse-response (FIR) lowpass filter, in this case implemented in hybrid fashion – the samples are *digital* (logic HIGH or LOW, in the 32 flip-flop outputs of the shift register U_8–U_{11}), but the weighted sum is performed as an *analog* summing of currents into a pair of op-amp (U_{1ab}) summing junctions. In the more general case, a digital filter would operate on data representing a sampled analog waveform, with each sample represented as a multi-bit quantity (e.g., 16-bits for each channel, in the case of stereo CD audio), sampled at a rate sufficient to retain the full input frequency range of interest (for CD audio $f_{\rm samp}$=44.1 kHz, about 10% above

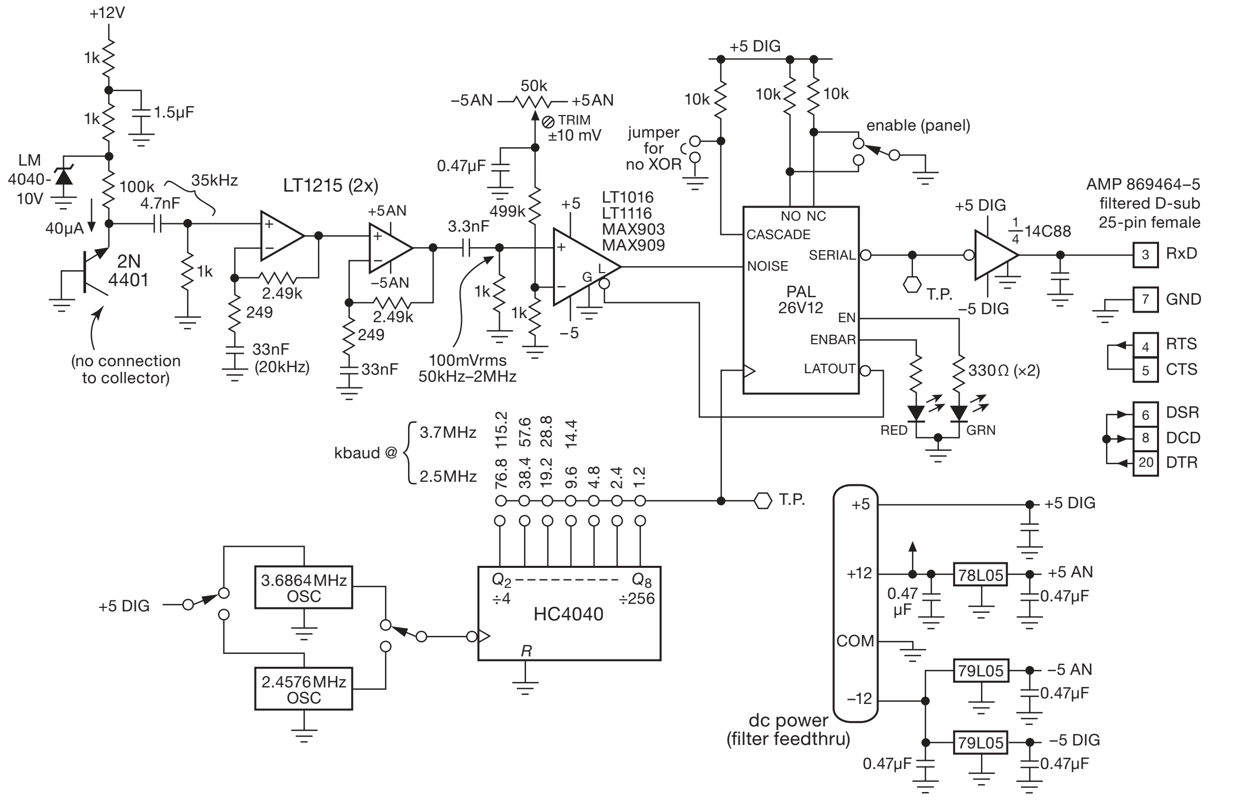

Figure 13.121. Using a physical process (base–emitter avalanche breakdown) to generate random bytes.

the minimum critical rate of 2×$f_{\max}$). And the weighting and summing would be done purely digitally (i.e., numerically), in multipliers and adders. Note however that high-quality digital processing does not *require* that the initial analog-to-digital sampling produce large word sizes: the discussion of delta–sigma conversion earlier in this chapter (§13.9) is a fine illustration of a "1-bit" digitized data stream, upon which digital filters can do their magic.

Additional Exercises for Chapter 13

Exercise 13.10. Why can't two n-bit DACs be used to make a $2n$-bit DAC by just summing their outputs proportionally ($\mathrm{OUT}_1 + \mathrm{OUT}_2/2^n$)?

Exercise 13.11. Verify that the peak output of the pseudorandom noise generator (Figure 9.94) is ±8.68 V.

Review of Chapter 13

An A-to-I summary of what we have learned in Chapter 13. This summary reviews basic principles, facts, and application advice in Chapter 13.

¶A. DACs and ADCs – Performance Parameters.

The subject of conversion between analog and digital signals dominated the chapter, with extensive description of the internals of ADCs and DACs, their performance, and example applications. Essential ADC performance parameters include resolution (number of bits), accuracy (linearity, monotonicity, stability, ENOB,[143] and spur-free dynamic range), speed (conversion time and latency), input range, output format (serial I^2C or SPI; or parallel), reference (internal or external), packaging, and additional features such as internal programmable-gain amplifier. The essential DAC performance parameters are similar, but include output type (voltage or current), glitch energy, and variants such as multiplying DAC (MDAC) or programmable internal digital scaling.

¶B. DAC Types.

The choice of converter for a particular application should be based mostly on its performance parameters (¶A), rather than on the method of conversion. But it's important to know about a converter's inner workings so that you won't be caught unaware by its idiosyncrasies.

Resistor-string DAC. This simplest technique (§13.2.1) consists of a series string of 2^n equal-value resistors, biased by a stable voltage reference, with digitally controlled MOS switches that pick off the dc voltage at a chosen tap as selected by the n-bit binary input code. These inexpensive DACs range from 8 to 16 bits of resolution; the output is strictly monotonic (a desirable feature for a digital control loop).

R–2R ladder DAC. This popular technique (§13.2.2) exploits the binary-weighting property of an R–$2R$ ladder (Figure 13.5), requiring only $2n$ (rather than 2^n) resistors and switches to create an n-bit DAC. These converters are inexpensive, but not inherently monotonic (although there are many that guarantee monotonicity). Their integral nonlinearity (INL) is generally superior to resistor-string DACs, making them better for precise voltage-setting applications.

Current-steering DAC. In contrast to these voltage-output converters (resistor string and ladder types), the current-steering DAC (§13.2.3) excels in speed, and also permits easy combining of outputs. It uses an array of n switches to steer a set of binary-weighted currents (Figure 13.6). These DACs are wickedly fast, but their current output is limited in compliance; if you tack on a transresistance amplifier to create a voltage output, it will limit the dynamic performance (speed and settling time). Best to drive a load that wants a current input, or simply drive a 50 Ω load resistor (75 Ω for video), appropriate for RF and high-speed applications. *A caution*: the stability and initial accuracy of current-output DACs can be quite poor if you are foolish enough to ignore the matched internal feedback resistor; see the warning in §13.2.5 and the correct use of feedback shown in Figure 13.9.

Delta–sigma DAC. This technique (§§13.9 and 13.9.8), sometimes called a "1-bit DAC," is a two-step process in which a bitstream is first produced in an integrating digital modulator, then lowpass filtered to produce the analog output voltage; see the block diagram in Figure 13.50. It is popular in professional audio, where it can deliver stunningly linear high resolution output signals, for example dual (stereo) 20-bit resolution at 192 ksps. The delta–sigma technique is popular also for ADCs; in the pro-audio arena, for example, a popular part is the CS5381 dual 24-bit 192 ksps converter (§13.9.11D).

Multiplying DAC. An MDAC (§13.2.4) accepts a varying $V_{\rm ref}$ input, specifying both a voltage range (usually bipolarity, e.g., -15 V to $+15$ V) and a reference-multiplying bandwidth (typically a megahertz or more). An MDAC permits digital amplitude control of signals within its bandwidth, and it lets you do ratiometric measurements with an imprecise reference voltage. A caution: capacitive feedthrough severely limits the bandwidth when operated with small-value digital codes; see Figure 13.7.

Pulse-width modulation and F-to-V conversion. When driving a load that is inherently slow (for example, a heater), a simple and effective form of D/A conversion is PWM (§13.2.8). Related techniques are F/V converters and rate multipliers (§§13.2.9 and 13.2.10).

¶C. DAC Application Examples.

In conversion applications the devil is very much in the details. In this chapter we explored four real-world applications, revealing their satanic complications.

(1) A four-channel general-purpose laboratory source (§13.3.1) illustrated precision and stable low-noise design,

[143] Where the "effective number of bits" ENOB=$1.44\log_e(V_{\rm span}/V_{\rm n(rms)})$. As explained in nice detail in Analog Devices' tutorial MT-003 ("Understand SINAD, ENOB, SNR, THD, THD+N, and SFDR so you don't get lost in the noise floor"), ENOB is related to SINAD (signal-to-noise+distortion) by the relation ENOB=(SINAD$-$1.76 dB)/6.02, where SINAD (in dB) is given, in terms of rms quantities for signal, noise, and distortion, by SINAD=$20\log_{10} S_{\rm rms}/(N{+}D)$.

with an external current-to-voltage configuration providing flexible output ranges.

(2) A simpler eight-channel voltage source (§13.3.2) is easily designed with a fully integrated voltage-output DAC (LTC2656); it lacks the flexible output range capability of the previous example, along with some degradation in terms of noise and stability.

(3) A nanoamp-scale bipolarity current source of wide compliance (§13.3.3) is a circuit of considerable subtlety, offering low noise and low drift while sourcing or sinking nanoamps over a range of ±10 V. There's additional teaching here, on the subject of floating current sources in general.

(4) A precision bipolarity coil driver (§13.3.4) illustrates a DAC application that pushes the limits of resolution (20 bit, i.e., parts-per-million), with corresponding control of noise and stability. This example includes plenty of discussion of requisite amplifier and reference choices, and of loop compensation and stability.

¶D. DAC Choices.

For highest linearity, delta–sigma DACs are best, with accuracy and linearity to 20 bits at audio speeds, and sometimes with excellent dc specs as well (e.g., TI's millisecond-speed 20-bit DAC1220); however, watch out for broadband and clock noise (the DAC1220 has $\sim$1000 nV/$\sqrt{\text{Hz}}$ at 1 kHz, compared with $\sim$10 nV/$\sqrt{\text{Hz}}$ for resistor ladder converters).

For high-accuracy applications at medium speed, there are many excellent R–$2R$ and linear ladder DACs, for example TI's DAC8552 (dual 16-bit, serial in, voltage out, ext ref, very low glitch, 10 μs settle; DAC8560/4/5 similar, with internal ref); or ADI's AD5544 or TI's DAC8814 (quad 16-bit MDAC, serial in, current out, 0.5–2 μs settle with external I-to-V op-amp); or LTC's LTC1668 (16-bit, parallel in, differential current out, 20 ns settle into 50 Ω as "voltage out"); or TI's DAC9881 (18-bit serial in, rail-to-rail voltage out, ext ref, low-noise, 5 μs settle).

For the highest speed you can't beat current-steering converters, for example the TI DAC5681/2 (16-bit, 1 Gsps) or the ADI AD9739 (14-bit, 2.5 Gsps).

¶E. ADC Types.

As with DACs, the choice of converter for a particular application should be based mostly on its performance parameters (¶A), rather than on the method of conversion. As with DACs, though, it's important to know about a converter's inner workings so that you won't be caught unaware by its idiosyncrasies.

Flash, or "parallel." In this simplest technique (§13.6) the analog input voltage is compared with a set of fixed reference voltages, most simply by driving an array of 2^n analog comparators, to generate an n-bit result, with resolutions to n=8 bits and speeds to 20 Gsps (not in the same device). Variations on this theme include pipelined or folded architectures, in which the conversion is done in several steps, each of which converts the "residue" of the previous low-resolution conversion. These converters top out at 16-bit resolution and speeds to several Gsps (not in the same device); the pipelined architecture creates latency, which can be as much as 20 clock cycles.

Successive approximation. In this technique (§13.7) successive trial codes (generated by internal logic) are converted to voltages by an internal DAC and compared with the analog input voltage. It requires just n such steps to do an n-bit conversion. The internal DAC can be implemented as a conventional n-stage R–$2R$ resistor ladder, or, interestingly, as a set of 2^n binary-scaled capacitors; the latter method is known as a *charge-redistribution* DAC. SAR-type converters are intermediate in speed and accuracy (flash converters are faster; delta–sigma converters are more accurate). The input must be stable during the conversion (thus requiring some form of input track-and-hold); SAR converters can have missing codes.

Voltage-to-frequency. This technique (§13.8.1) produces an output pulse train (or other waveform) whose frequency is accurately proportional to the analog input voltage. In an *asynchronous* V/F the oscillator is internal and free-running; a *synchronous* V/F requires an external source of clock pulses, gating a fraction of them through such that the *average* output frequency is proportional to the analog input. V-to-F converters can be used for simple control of averaging loads (like a heater); but they barely deserve listing as an ADC, and are best thought of as a primitive approximation to the superior delta–sigma converter (see below).

Single-slope integration. In this technique (§13.8.2) an internally generated analog ramp (capacitor charged by a current source) goes from zero volts to the analog input voltage, timed by counting pulses from a fast fixed-frequency clock; the count is proportional to the value of the analog input. Single-slope integration is not particularly precise, yielding that turf to dual- or multi-slope integration (see below). But it is used in applications such as pulse-height analysis, where speed and uniformity of adjacent codes is required; it is also used for time-to-amplitude conversion (TAC).

Dual-slope and multi-slope integration. These techniques (§§13.8.3, 13.8.4, and 13.8.6) are variations on single-slope integration, effectively eliminating errors from comparator offsets and component stability. In *dual-slope integration* the capacitor is ramped up for a fixed time with a current proportional to the input signal, and ramped back down with a fixed current; the latter time interval is proportional to the analog input. In *quad-slope integration* the input is held at zero while a second such "autozero" cycle is done. The so-called *multi-slope* technique is somewhat different, with a single conversion consisting of a succession of fast dual-slope cycles (in which the input is integrated continuously, combined with subtractive fixed-current cycles), and with a correction based upon the partial-cycle residue at both ends. In some aspects it's a close cousin of the delta–sigma method (next). These integrating ADC methods are ideal for low-speed (milliseconds) high-resolution (20–28 bits) voltmeter-style measurements.

Delta–sigma ADCs. In this technique (§13.9) a *modulator* converts the oversampled analog input voltage to a serial *bitstream*; then a digital lowpass filter accepts that bitstream as input, producing the final *n*-bit digital output. In its simplest form the modulator consists of an integrator acting on the difference between the analog input voltage and the value of the 1-bit output serial bitstream, to determine the next output bit. Variations include higher-order modulators (a succession of weighted integrators), or bitstreams that are several bits wide, or both. Delta–sigma converters deliver excellent resolution (to 24 bits) and conversion rates to a few megasamples per second. They are hugely popular in professional audio.

¶F. ADC Application Examples.

In this chapter we illustrated several application examples.
(1) A fast flash ADC (§13.6.2), driven differentially, illustrated input filtering and low-jitter clock generation.
(2) A low-noise high-stability 18-bit successive-approximation converter with a 2 Msps conversion rate (§13.7.3) illustrated careful input conditioning to achieve low noise and low drift.
(3) Three applications of delta–sigma converters (Figures 13.66, 13.67, and 13.68) illustrated a wide range (±10 V) multiplexed converter with good accuracy (18 bits or better); an industry-standard 24-bit $\Delta\Sigma$ converter of good noise, drift, and linearity specifications, and with chopper-stabilized programmable-gain amplifier for accurate measurements of low-level signals; and a pro-audio conversion application, where dc accuracy and latency are largely irrelevant, instead featuring excellent channel matching and with audio-type output formats.

In this chapter we illustrated further conversion examples, including some unusual ADCs and DACs (§13.11), and a few conversion *system* examples (§13.12). The latter included a multiplexed 16-channel data-acquisition system (§13.12.1), a parallel multichannel successive-approximation data-acquisition system (§13.12.2), and an analogous parallel multichannel delta–sigma data-acquisition system (§13.12.3). The last two examples included both external and integrated multichannel solutions, in tutorial narratives.

¶G. ADC Choices.

For low-speed (to kilosamples/sec) and high-accuracy (to 24 bits or more) applications, integrating converters (dual-slope, multislope) are best; there are also some excellent delta–sigma converters (which can be thought of as integrating converters).

For moderate-speed applications (to several Msps), both delta–sigma and successive-approximation converters are competitive, with resolution to 20 bits or more; delta–sigma converters have significantly longer latency.

For high-speed (100s of Msps) choose pipelined flash converters, mindful of their high latency. And for the highest conversion rates (>250 Msps) some variant on folding flash gets you to 8–12 bits and 3 Gsps. Simple flash is the fastest, but you pay the price in resolution (e.g., the Analog Devices HMCAD5831: 3-bit conversion at 20 Gsps).

¶H. Phase-locked Loops.

The chapter continued with the important mixed-signal subject of PLLs (§13.13), circuits in which feedback forces a signal derived from a voltage-controlled oscillator to match an input signal's frequency. PLL applications include frequency multiplication and frequency synthesis, clock generation and recovery, and demodulation of AM, FM, and digitally modulated signals. In addition to a voltage-controlled oscillator (VCO), the essential components of a PLL (Figure 13.85) are (a) the phase detector and (b) the loop filter.

The *phase detector* (PD) compares the phases of the input signal and the VCO-derived signal, generating an output signal representative of their relative phase. The simplest phase detector (type I) multiplies the input signals. It is applicable to either analog or digital input signals; for the latter it is just an exclusive-OR gate (Figure 13.86). The other common phase detector (type II) generates output pulses according to the relative timing of transitions at its two inputs (Figure 13.87). It works only with digital signals. Type II phase detectors have the benefit of locking with zero phase difference, and of introducing no ripple at the phase-detection frequency; however, they are more sensitive to input signal jitter than type I phase detectors.

The *loop filter* smooths the PD's output, with a time constant that sets the loop's response; the latter should be long compared with the comparison frequency, but fast enough to follow changes in the input frequency as required by the PLL's application. To clarify this last point, you'd want a long time constant if the PLL has a low-noise VCO and is used to generate a clean stable clock from a noisy input reference of fixed frequency; but if you want the PLL to follow a wobbling input frequency (e.g., clock recovery from a tape or disk drive) you would make the loop fast enough to respond to the changing input frequency. *A caution*: there's an inherent 90° lagging phase shift in the PLL: a measurement of phase is used to adjust frequency, but phase is the integral of frequency. So a simple lowpass loop filter (which introduces additional lagging phase shift, asymptotic to 90°) creates a marginally stable loop. The solution is to slow the rolloff in the region of unity loop-gain (a "zero," in the language of *s*-plane analysis; see the discussion in Chapter *1x*), as seen in Figure 13.98.

The procedure for designing the loop filter is illustrated in §13.13.3. And the use of PLLs for the important applications of frequency synthesis, analog and digital demodulation, pulse synchronization, and laser offset locking is discussed in some detail in §13.13.6.

¶I. Pseudorandom Digital Noise.

The chapter concluded with the fascinating topic of the generation of deterministic pseudorandom bit sequences (PRBSs) from linear feedback shift registers (LFSRs). These find application in communication channel testing (eye diagrams, see for example Figure 12.131) and in spectrum-spreading applications in digital communications (e.g., the transmitted navigational signals from GPS). And, they're just plain fun. The basic technique (described in some detail also in Chapter 11, in §11.3) is a clocked shift register whose input is derived from an XOR combination of two (or more) carefully chosen bits of the register (Figure 13.111).

As demonstrated in Chapter 11, PRBS generators are easily made with a tiny bit of PLD logic, or some microcontroller code, or even just a few logic chips (e.g., a 74HC7731, 74HC164, and 74HC86, clocked at 25 MHz, makes a PRBS whose cycle length is more than 10^{62} years; that's 10^{52} times the age of the universe). The output sequence can be lowpass filtered to generate an analog noise source of settable bandwidth; see the analog-filtered colored noise source in Chapter 8 (Figure 8.93) and the hybrid digitally-filtered white noise source of Figure 13.119.

Pseudorandom noise is not truly random, even though its statistical properties may mimic genuine randomness as measured by various tests (see §13.14.6), rendering it suitable for some applications. To generate honest random bit sequences you need to exploit the random properties of some physical process like β-decay in unstable isotopes. More convenient for the circuit designer is something like thermal noise in resistors, or avalanche noise in semiconductor junctions; the latter is illustrated in §13.14.7.

COMPUTERS, CONTROLLERS, AND DATA LINKS

CHAPTER 14

In this chapter and the next we deal with the interesting subjects of computers and controllers (with the common alternative names of *microcomputers* and *microcontrollers*). These are huge subjects, and we do not attempt a complete treatment. Rather, our primary interests, in the context of electronic circuit design, are (a) how to interface external electronics to an existing computer, and (b) how to use a microcontroller as an "embedded" piece of electronics within a custom electronic device or instrument.

In this chapter, then, we look at computers and data *buses* (the mechanism for data interfacing), to understand how they work and how to create a data interface. Along the way we review, briefly, some basics of computers – their architecture, processor and memory hardware, bus timing, and instruction set – and we illustrate interfacing with hardware and code for simple input and output "ports" attached to a classic parallel data bus.[1] We end with a review of popular serial data buses: FireWire, USB, CAN-bus, Ethernet, and wireless (WiFi, Bluetooth, Zigbee).

In Chapter 15 we'll deal with embedded microcontrollers, the inexpensive and wonderful chips that let you put the intelligence of a computer into pretty much anything electronic.

Some terminology

Mainframes, CPUs, minicomputers, microcomputers, microprocessors, microcontrollers – what are all these names, anyway? History is partly to blame for this proliferation of confusing terms, because names like "microcomputer" were created (with understandable excitement) to describe a computer in which the central processor (the central processing unit, CPU) was integrated onto a single chip (the "microprocessor"), rather than constructed from a board full of smaller logic chips (as it was in a "minicomputer" or "mainframe" of the time).

This is no longer a big deal, and the important distinction is between *computers*, which are used primarily for computational processing of data, versus embedded *controllers*, which are incorporated within other electronic devices that are not themselves computers. Examples of the former are PCs, laptop and notebook computers, and the larger "mainframe" computers. Examples of controllers are the chips that run your electric toothbrush, bathroom scale, television and stereo sets, and the like.[2] In general, the microprocessors used in computers are optimized for computational performance, tend to be expensive, and require support complex "chipsets" in order to function. By contrast, the microcontrollers intended for embedded design trade off computational performance in favor of standalone capability, with as many peripheral functions as possible integrated onto the same chip; they tend to be inexpensive, low power, and completely self-sufficient. Figure 14.1 dramatically illustrates the progress in miniaturizing computer processors for embedded applications[3].

Generally speaking, with the computers we talk about in this chapter, the design of the computer itself (including the integration of memory, disks, and I/O, as well as system programming and utility program development) has been taken care of by the manufacturer (and suppliers of compatible hardware and software). The user need worry only about special-purpose interfaces and the job of user programming. By contrast, in an embedded controller application, the circuit design and choice of hardware, along with all programming, are done by the designer. Computer manufacturers are generally committed to providing system and utility software as part of a complete computing system (often including peripherals), whereas the manufacturers of microcontrollers (semiconductor companies) generally see the design and marketing of newer and better chips as their central tasks.

[1] We've chosen the PC104/ISA bus, both because of its simplicity, and its stability as an entrenched standard in the PC104 embedded PC world.

[2] Sometimes the line is a bit blurry: the processor inside a cable television "set-top" box or Blu-ray™ player, for example, is doing heavy processing of digital video (decryption, decompression, format conversion), yet the box is not a "computer."

[3] And a decade later the same $5 gets you a 100 MHz ARM microcontroller with 1 MByte of flash memory, 80 kBytes of SRAM, 47 parallel I/O ports, 11 channels of 10-bit ADC, a 10-bit DAC, six 16-bit timers, three I^2C and four SPI serial ports, four PWM controllers, four UARTs, and three USARTs. What's not to like about Moore's Law!

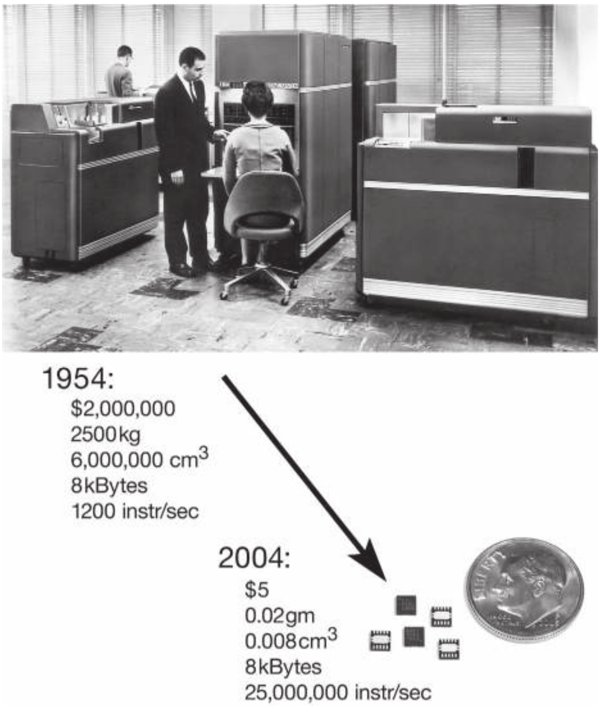

Figure 14.1. From mainframe to microcontroller: 50 years of computer progress (mainframe photograph courtesy IBM Corporation).

14.1 Computer architecture: CPU and data bus

In spite of rapid change in the field of computers and microprocessors, there are important basic ideas, many of which carry over to digital electronics generally. These are most easily understood from a look at a traditional bus-oriented architecture, shown in the block diagram of Figure 14.2.

The idea is to link all the connected devices via a shared set of lines – a data "bus" – rather than a rat's nest of direct connections. It uses far fewer wires; and, because traditionally the CPU was responsible for most transactions anyway, it was not necessary to have separate data paths to achieve good performance.[4] So, for example, if the CPU wants to store a byte at some address in random access memory (RAM), it would put the address and the data onto a set of bus lines (called ADR and DATA), then it would assert a WRITE signal; the RAM recognizes the address, and accepts the byte. If the CPU instead wants to fetch a byte, it would put the address only, then it would assert a READ signal; the RAM, recognizing a request for data from one of its addresses, responds by putting the corresponding byte on the DATA lines. Likewise for transfers to or from other bus-attached devices (each of which listens for its assigned range of addresses).

To understand what's going on, let's review the components in Figure 14.2, taking it from left to right.

14.1.1 CPU

The central processing unit, or CPU, is the heart of the machine. Computers do their computation in the CPU on chunks of data organized as computer *words*. Word size can range from 4 bits to 64 bits or more, with 32- and 64-bit word sizes being the most popular in contemporary computers. A *byte* is 8 bits (half a byte, or 4 bits, is sometimes called a "nybble"). A portion of the CPU called the *instruction decoder* interprets the successive instructions (fetched from memory), figuring out what should be done in each case. The CPU has an *arithmetic logic unit*, or ALU, that can perform the instructed operations, such as add, complement, compare, shift, move, etc., on quantities contained in *registers* (and sometimes in *memory*). The *program counter* keeps track of the current location in the executing program. It normally increments after each instruction, but it can take on a new value after a "jump" (branch) or a "call" instruction. The *bus control circuitry* handles communication with memory and I/O. Most computers also have a *stack pointer register* (more on that later) and a few *flags* (carry, zero, sign) that get tested for conditional branching. All high-performance processors also include *cache* memory, which holds values (both data and instructions) recently fetched from memory for quicker access.

Contemporary high-performance microcomputers exploit "parallel processing," in which several interconnected CPUs (each with multiple ALU paths) achieve greater computational power; high-density chips integrate this into a "multicore" architecture. However, to keep our discussion simple, and recognizing our interest in *interfacing* to a computer (rather than designing one), we consider only the

[4] This kind of single "multidrop" parallel bus was widely used throughout the minicomputer era (e.g., the DEC "Unibus") and well into the microcomputer era (in the form of the IBM "industry standard architecture" bus, or ISA, which is still used in the PC104 embedded-PC standard). But buses have evolved into more complex creatures, and contemporary PCs have multiple buses and connecting bridges, with names like "Front Side Bus," PCI and PCIe, "Northbridge," and "Southbridge," designed to optimize high-speed communication (such as memory transfers) without being slowed down by low-speed communication (such as peripherals). Also, as we'll see later, in spite of the elegance and economy of shared lines, a "point-to-point" (rat's nest) connection scheme is actually much better than a shared multidrop bus for high-speed communication.

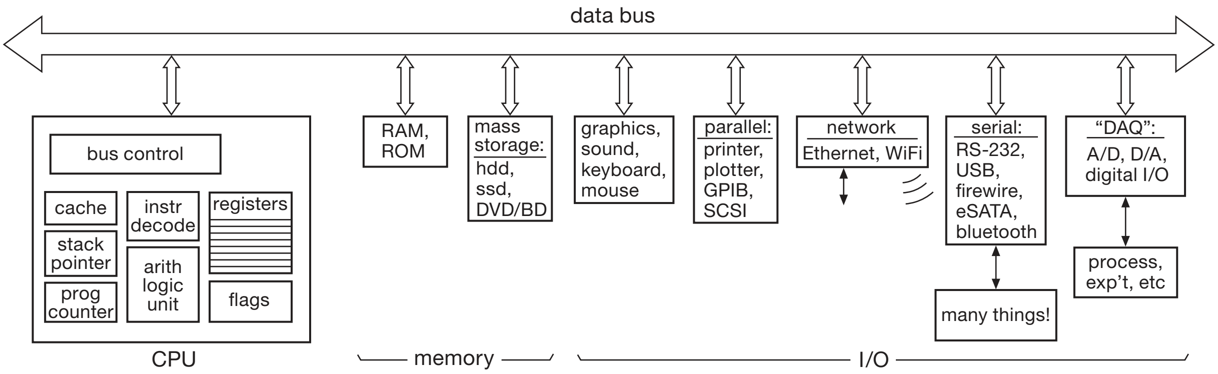

Figure 14.2. Traditional bus-oriented computer.

single-CPU machine, executing instructions serially: it's a world of relentless "read, do, write" operations.

14.1.2 Memory

All computers have some fast "random-access" memory,[5] called RAM (it used to be called "core," because tiny magnetic cores held the data, one bit per core). In an inexpensive computer this would typically amount to several gigabytes, whereas an embedded micro*controller* typically incorporates much less, as little as 4K–64K.[6] This memory can typically be read and written in about 100 ns. The high-density RAM modules usually used in computers (called DRAM[7]) are *volatile*, which means that its information evaporates when power is removed (maybe it should be called "forgettory"!). All computers therefore include some nonvolatile memory, usually "flash ROM" (read-only memory), to bootstrap the computer, i.e., get it started from a state of total amnesia when power is first turned on. (That nonvolatile memory additionally holds the entire program, in the case of an embedded controller.) Much more about memory in §14.4.

To get or store information in memory, the CPU "addresses" the desired word. Most computers address memory by bytes, beginning at byte 0 and going sequentially through to the last byte in memory. Since most computer words are several bytes long, you are usually storing or fetching a group of bytes at a time; this is usually expedited by having a data bus that is several bytes wide.

Both programs and data are kept in memory during program execution. The CPU fetches instructions from memory, figures out what they mean, and does the appropriate things, often involving data stored somewhere else in memory. General-purpose computers usually store programs and data in the same memory ("von Neumann architecture"), and in fact the computer doesn't even know one from the other. (Amusing things start to happen if a program goes awry and you "execute" data!) Embedded controllers, on the other hand, often use a "Harvard architecture," with separate data and program memory, the latter in non-volatile (usually flash or EEPROM) storage for obvious reasons.

Because computer programs spend most of their time looping through a relatively short sequence of instructions, you can enhance performance by providing a small, but fast, *cache* (pronounced "cash") memory, in which you routinely store copies of the most recently used memory locations. A cached CPU checks its local cache first, before fetching from (slower) main memory; when looping through familiar territory, you often achieve a cache "hit" rate of 95% or better, dramatically improving execution speed.

14.1.3 Mass memory

Computers intended for program development or computation, as opposed to embedded controllers, use nonvolatile mass storage devices such as hard disks (HDDs or

[5] So named because you can access data at any address in equal time, as distinguished from something like a shift register or FIFO.

[6] When used to describe memory sizes, K doesn't mean 1000, but rather 1024, or 2^{10}; thus, 16K bytes (16 KB) is actually 16,384 bytes. We employ the lowercase symbol k to mean 1000.

[7] For *dynamic* RAM: a form of memory in which data bits are stored, briefly, as a voltage state on tiny on-chip capacitors, whose charge must be periodically "refreshed." By contrast, *static* RAM ("SRAM") holds each bit as a flip-flop state, requiring no refresh. DRAM is more compact, requiring one transistor per bit ("1T"), versus 6T for SRAM. Both SRAM and DRAM are volatile, as contrasted with flash ROM or EEPROM ("E-squared").

hard-disk drives: magnetic), solid-state disks (SSDs, or solid-state drives: nonvolatile semiconductor “flash” memory), and removable optical disks (CD, DVD, Blu-ray); the latter come in both read-only and rewritable forms, whereas HDDs and SSDs are always rewritable. We’ve learned, through past editions of this book, that statements about the impressive performance of “modern” electronics invariably look silly within just a few years.[8] So we simply point out, as a historical datapoint, that we’re in the era of terabyte hard disks, 16 GB flash ROMs, and 1 GB RAM chips (factors of 10^3–10^4 larger than reported in our previous edition).

14.1.4 Graphics, network, parallel, and serial ports

These are standard items in most computers, needed for communication with the user, with the network, and with external hardware. We presume the reader to be generally familiar with them. Worth noting, however, is the trend away from parallel interfaces (like internal IDE and SCSI, and external “LPT” printer ports), in favor of fast serial interfaces (SATA, USB, FireWire, Ethernet), the latter providing comparable (or better) performance, along with simplified wiring and reduced electrical noise. We’ll talk about parallel-port and serial-port communications later, beginning in §14.5.

14.1.5 Real-time I/O

For experiment or process control and data logging, or for exotic applications such as speech or music synthesis, you need A/D and D/A devices that can communicate with the computer in “real time,” i.e., while things are happening. The possibilities are almost endless here, although a general-purpose set of multiplexed A/D converters (ADCs), a few fast D/A converters (DACs), and some digital “ports” (serial or parallel) for exchange of digital data will permit many interesting applications.[9] Such general-purpose peripherals are commercially available for most popular computer buses, both internal (e.g., PCI and PCIe) and external (USB, FireWire, Ethernet), as exemplified by the extensive offerings from National Instruments. There is increasing usage of external ports, with the advantage of simplicity, flexibility (e.g., use of laptop computers and smartphones, with no access to internal buses), and reduced digital-noise contamination. If you want something fancier, such as improved performance (higher speed, more channels) or special-purpose functions (tone generation, frequency synthesis, time-interval generation, etc.), you may have to build it yourself. This is where a knowledge of bus interfacing and programming techniques, which is always helpful, becomes essential.

14.1.6 Data bus

Communication between the CPU and memory or peripherals takes place on a *bus*, a set of shared lines for exchange of digital words. The use of a shared bus vastly simplifies interconnections, since otherwise you would need multiwire cables connecting every pair of communicating devices.[10] With a little care in bus design and implementation, everything works fine.

Buses have evolved over time, reaching such levels of speed and complexity that interfacing now requires considerable expertise. For this reason we are going to adopt an older and simpler bus, called PC104/ISA, which makes interfacing a simple job. The ISA bus was originated in the IBM PC, and as the PC104 bus it is alive and well, and supported by more than 75 manufacturers. A colleague, when asked its likely lifetime, replied “PC104 will bury us all.”[11]

In general, a data bus contains a set of DATA lines (generally the same number as bits in a word – 8 for small processors and controllers, 16 to 64 for more sophisticated microcomputers), some ADDRESS lines for determining who should “talk” or “listen” on the line, and a bunch of CONTROL lines that specify what action is going on (data going to or from the CPU, interrupt handling, direct memory access transfers, etc.). All the DATA lines, as well as a number of others, are *bidirectional* – they’re driven by three-state devices, or in some cases by open-collector gates with resistor pullups somewhere (usually at the end of the bus, where they also serve as terminators to minimize reflections; see §12.10.1) and Appendix H); pullups may be necessary with three-state drivers also, if the bus is physically long.

[8] In our first edition (1980) we were excited about several-megabyte hard disks, 2 KB EPROMs, and 8 KB RAM; a decade later we were even more excited by several-hundred-megabyte hard disks, 128 KB EPROMs, and 512 KB RAM.

[9] And don’t overlook the humble “sound card” (often integrated onto the motherboard), for lab use in noncritical audio-rate applications where dc coupling is not needed. The best of these can do 192 kb/s multichannel sampling at 16-bit resolution.

[10] This idea is repeated within the CPU itself, where internal data buses are used for communication between the arithmetic logic units (ALUs) and the registers (for example). And, in the case of a microcontroller, where “peripherals” like A/D converters and USB ports are integrated onto the same chip, the work of an external bus is carried out with on-chip buses.

[11] We think he meant that it will *outlive* us, not *kill* us. But we’re not sure.

Three-state or open-collector devices are used so that devices connected to the bus can disable their bus drivers, because in normal operation only one device is asserting data onto the bus at any time. Each computer has a well-defined protocol for determining who asserts data, and when. If it didn’t, total chaos would result, with everyone shouting at once. (Engineers cannot resist personalizing electronic circuits, in spite of advice like “Don’t anthropomorphize computers – they don’t like it.”)

We’ll return to the bus in detail, with 8-bit PC104 interface examples. First, though, we need to look at the CPU’s instruction set.

14.2 A computer instruction set

14.2.1 Assembly language and machine language

To understand bus signals and computer interfacing, you’ve got to understand what the CPU does when it executes various instructions. At this point, therefore, we would like to introduce the instruction set that goes with the Intel x86-family processors used in PC104 computers. Unfortunately, the instruction sets of most real-world microprocessors tend to be rich with complexities and extra features (including the ghosts of processors past), and the Intel x86 series is no exception. However, since our purpose is only to illustrate bus signals and interfacing (not fancy programming), we’ll take a shortcut by laying out a subset of x86 instructions. By leaving out the “extra” instructions we’ll wind up with a compact set of instructions that is both understandable and complete enough to do most any programming task. We’ll then use it to show some examples of interfacing and programming. These examples will help convey the idea of programming at the “machine-language” level, something quite different from programming in a high-level language like C or C++.

First, a word on “machine language” and “assembly language.” As we mentioned earlier, the computer’s CPU is designed to interpret certain words as instructions and carry out the appointed tasks. This “machine language” consists of a set of binary instructions, each of which may occupy one or more bytes. Incrementing (increasing by one) the contents of a CPU register would be a single-byte instruction, for example, whereas loading a register with the contents of a memory location would usually require at least two bytes, perhaps as many as five (the first would specify the operation and register destination, and four more would be necessary to specify an arbitrary memory location in a large machine). It is a sad fact of life that different computers have different machine languages, and there is no standard whatsoever.

Programming directly in machine language is extremely tedious, because you wind up dealing with columns of binary numbers, each bit of which has to be bit-perfect, so to speak. Instead, you can represent each instruction in its *assembly-language* readable-text form, using easily remembered mnemonics for the instructions, and symbolic names of your own choosing for memory locations and variables. This assembly-language program, consisting of a plain text file, is then massaged by a program called an *assembler* to produce as its output a finished program in machine-language *object code* that the computer can execute. Each line of assembly code corresponds to one machine-language instruction, which translates to a few machine-language bytes (1 to 15 bytes, for the x86). The computer cannot execute the assembly-language (text) instructions directly. To make these ideas concrete, let’s look at our subset of the x86 assembly language and do a few examples.

14.2.2 Simplified “x86” instruction set

The x86-family processors (Intel, AMD, VIA) have a rich, and somewhat idiosyncratic, instruction set; part of its complexity stems from the designers’ objective to maintain compatibility with the original 8080 8-bit processor. Later and more sophisticated processors in the x86 family (e.g., Pentium, Core 2, i3/i5/i7, Xeon) have many additional instructions but can still execute the original x86 instruction set. We’ve gone through those instructions with a machete, keeping just 10 arithmetic operations and 11 others (Table 14.1).

A. A quick tour

Some explanations: the first six arithmetic instructions in Table 14.1 operate on pairs of numbers (“2-operand” instructions), which we’ve abbreviated as *b,a*, and which can be any of the 5 pairs listed in the table footnotes; *m* means the contents of a memory location, *r* means the contents of a CPU register (there are 8 in the original 8086), and *imm* means an *immediate* argument, which is a number stored in the next 1 to 4 bytes of memory following the instruction. Thus, for example, the instructions

```
MOV   count,CX
ADD   small,02H
AND   AX,007FH
```

Table 14.1 Simplified x86 Instruction Set

Instruction		What you call it	What it does
arithmetic			
MOV	*b,a*	move	$a \to b$; a unchanged
ADD	*b,a*	add	$a + b \to b$; a unchanged
SUB	*b,a*	subtract	$b - a \to b$; a unchanged
AND	*b,a*	and	a AND $b \to b$ bitwise; a unchanged
OR	*b,a*	or	a OR $b \to b$ bitwise; a unchanged
CMP	*b,a*	compare	set flags as if $b - a$; a,b unchanged
INC	*rm*	increment	$rm + 1 \to rm$
DEC	*rm*	decrement	$rm - 1 \to rm$
NOT	*rm*	not	1's complement of $rm \to rm$
NEG	*rm*	negate	negative (2's comp) of $rm \to rm$
stack			
PUSH	*rm*	push	push *rm* onto stack (2 bytes)
POP	*rm*	pop	pop 2 bytes from stack to *rm*
control			
JMP	*label*	jump	jump to instr *label*
J*cc*	*label*	jump conditional	jump to instr *label* if *cc* true
CALL	*label*	call	push next adr, jump to instr *label*
RET		return	pop stack, jump to that adr
IRET		return from int	pop stack, restore flags, return
STI		set interrupt	enable interrupts
CLI		clear interrupt	disable interrupts
input/output			
IN	AX,*port*	input	*port* → AX (or AL)
OUT	*port*,AX	output	AX (or AL) → *port*

Notes: *b,a*: any of *m,r* *r,m* *r,r* *m,imm* *r,imm*
rm: register or memory, via various addressing modes
cc: any of **Z NZ G GE LE L C NC S NS**
label: via various addressing modes
port: byte (via imm) or word (via DX)

have arguments of the form *m,r*, *m,imm*, and *r,imm*, respectively. The first copies the contents of register `CX` to a memory location that we've named "count"; the second adds 2 to the contents of another memory location called "small"; the third clears the top 9 bits of 16-bit register `AX` while preserving the bottom 7 bits unchanged (a so-called *masking* operation). Note Intel's argument convention: the first argument is replaced with or modified by the second argument.

The last four arithmetic operations in the table take only a single operand, which can be the contents of either a register or memory. Here are two examples:

```
INC   count
NEG   AL
```

The first adds 1 to the contents of memory-location "count," and the second changes the sign of the contents of register `AL`.

B. A detour: addressing

Before continuing, a word on registers and memory addressing. The original 8086 claimed to have eight "general-purpose" registers, but after reading the fine print you'll realize that most of them also have special uses (Figure 14.3). Four of them (`A`–`D`) can be used either as single 16-bit registers (e.g., `AX`; think of "X" as "extended") or as a pair of byte registers (`AH, AL`; "high" and "low" halves).[12] The `BX` and `BP` registers can hold addresses, as can the `SI` and `DI` registers, and tend to be used for addressing (see below). Special looping instructions (which we omitted from our short list) use register `C`, and multiply/divide and I/O instructions make analogous use of registers `A` and `D`.

Data used in instructions can be immediate constants, values held in a register, or values in memory. You

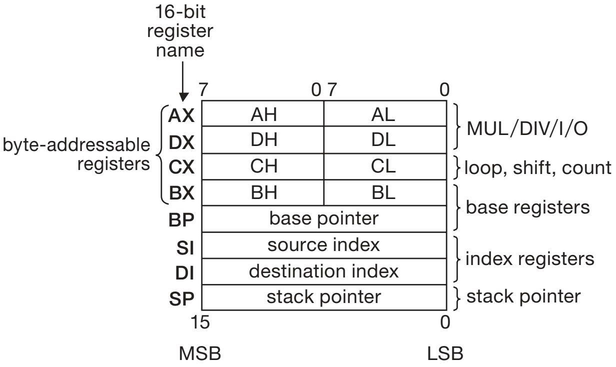

Figure 14.3. 8086 general-purpose registers.

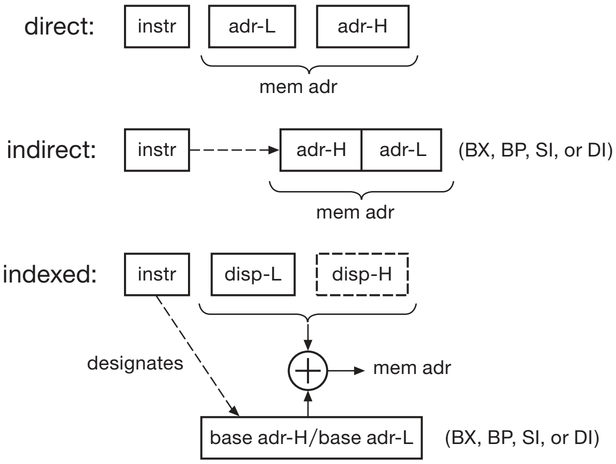

Figure 14.4. Some addressing modes.

[12] Later x86 CPUs extended these to 32 bits and to additional 64-bit registers.

specify immediates by value, and registers by name, as in the examples above. To address memory, the x86 provides six addressing modes, three of which are described by the diagrams in Figure 14.4. In assembly language you can just name the variable *directly*, in which case its address gets assembled as a pair of bytes immediately following the instruction; you can put the variable's address in an addressing register (BX, BP, SI, or DI), then use an instruction that specifies addressing *indirectly* through the register; or you can combine these actions, adding an immediate *displacement* to the value in a designated addressing register to get the variable's address. The indirect mode is faster (assuming the address has already been loaded into an addressing register) and much better if you want to do something to a whole set of numbers (a *string* or *array*). Here are a few addressing examples:

```
MOV   count,100H     (direct,immediate)
MOV   [BX],100H      (indirect,immediate)
MOV   [BX+1000H],AX  (indexed,register)
```

The last two assume you've already put an address into BX. The last instruction copies the contents of AX to a memory location 4K (1000 hex) higher than where BX points in memory; we'll give an example shortly, showing how you could use this to copy an array.

There's one other complexity of x86 memory addressing that we've swept under the rug: the “address” generated by any of these addressing modes is not actually the final address, as should be obvious from the fact that the address register BX has only 16 bits (which can address only 64K bytes of memory). In fact, it's called an *offset*; to get an actual address, you add to the offset a 20-bit *base* formed by shifting left 4 bits the contents of a 16-bit *segment register* (there are four such registers). In other words, the x86 lets you access groups of 64K bytes of memory at a time, with the location of those “segments” within a total memory size of 1MB set by the contents of the segment registers. The use of 16-bit addressing in the 8086 was basically a big mistake, inherited from earlier generations of microprocessors. Newer processors (80386 onward, and recent designs in other CPU families) are done right, with 32-bit or 64-bit addressing throughout.[13] Rather than complicate our examples, we'll simply ignore segments entirely; in real life you would, of course, have to worry about them.

C. Instruction-set tour (continued)

The *stack* instructions PUSH and POP come next. A stack is a portion of memory, organized in a special way: when you put data onto the stack (a *push*), it goes into the next available spot (“top” of the stack); and when you retrieve data (a *pop*), it is taken from the top, i.e., it is the item last pushed onto the stack. Thus a stack is a consecutive list of data, stored last-in, first-out (LIFO). It may help to think of a lunchroom tray dispenser.

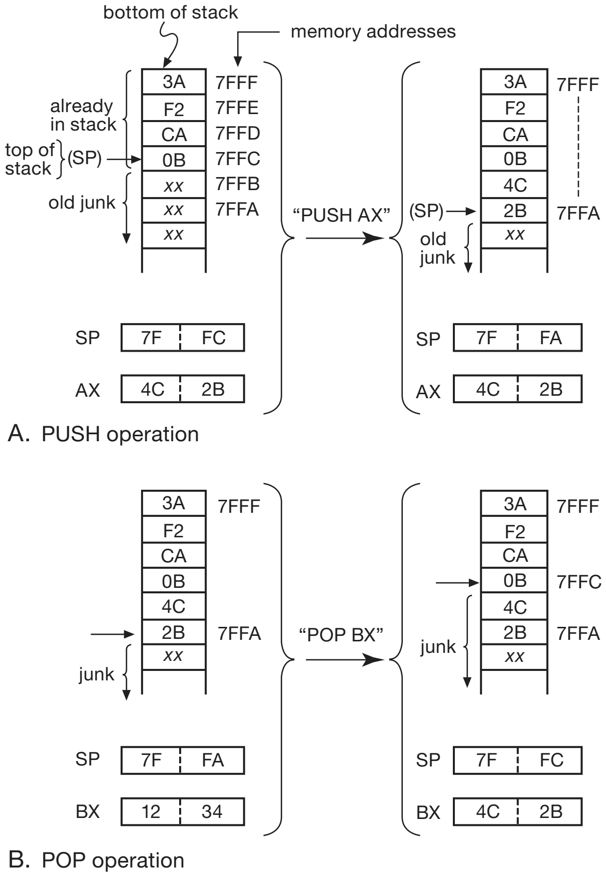

Figure 14.5. Stack operation: A. effect of PUSH (illustrated with register AX); B. effect of POP (illustrated with register BX.

Figure 14.5 shows how it works. The stack lives in ordinary RAM, with the CPU's *stack pointer* (SP) keeping track of the location of the current “top” of the stack. The 8086 stack holds 16-bit words and grows *down* in memory as you push data onto it. The SP is automatically decremented by 2 before each PUSH, and incremented by 2 after each POP. Thus, in the example, the 16-bit data in register AX is copied onto the top of the stack by the

[13] And with an additional level of indirection (virtual memory implemented with page tables) on the way to the actual physical memory. But you didn't really want to know about that, right?

Program 14.1

```
        MOV  BX,1000H      ;put array address in BX
        MOV  CL,100        ;initialize loop counter
LOOP:   MOV  AX,[BX]       ;copy array element to AX
        MOV [BX+400H],AX   ;then to new array
        ADD  BX,2          ;increment array pointer
        DEC  CL            ;decrement counter
        JNZ  LOOP          ;loop if count not zero
NEXT:   (next statement)   ;exit here when done
```

instruction PUSH AX; the SP is left pointing at the last byte pushed. POP reverses the process, as shown. As we will see, the stack plays a central role in subroutine calls and interrupts.

JMP causes the CPU to depart from its usual habit of executing instructions in sequential order, detouring instead to the instruction that you jump to. Conditional jumps (there are ten possibilities, indicated generically as J*cc*) test the flag register (which lives in the CPU and whose bits are set according to the result of the most recent arithmetic operation), then either jump (if the condition is true) or execute the next instruction in sequence (if the condition is not true). Program 14.1 shows an example. It copies 100 words from the array beginning at 1000 hex to a new array beginning 1kB (400H) higher.

Note the explicit loading of the pointer (to address register BX) and the loop count (to CL). The actual array of words had to move through a register (we chose AX) because the 8086 does not permit memory-to-memory operations (see the instruction set notes). At the end of the 100th pass through the loop, CL = 0, and the jump nonzero (JNZ) instruction no longer jumps. This example will work, but in practice you would probably use one of the x86's faster *string move* instructions. Also, it's good programming practice to use symbolic names for sizes and arrays, rather than constants like 400H and 1000H.

The CALL statement is a subroutine (or "procedure" or "function") call. It's like a jump, except that the return address (the address of the instruction that would have come next, except for the intervening CALL) is pushed onto the stack. At the end of the subroutine you execute a RET statement, which pops the stack so the program can find its way home (Figure 14.6). The three statements STI, CLI, and IRET have to do with interrupts, which we'll illustrate with a circuit example later in the chapter. Finally, the I/O instructions IN and OUT move a word or byte between the A register and the addressed port; more on this shortly.

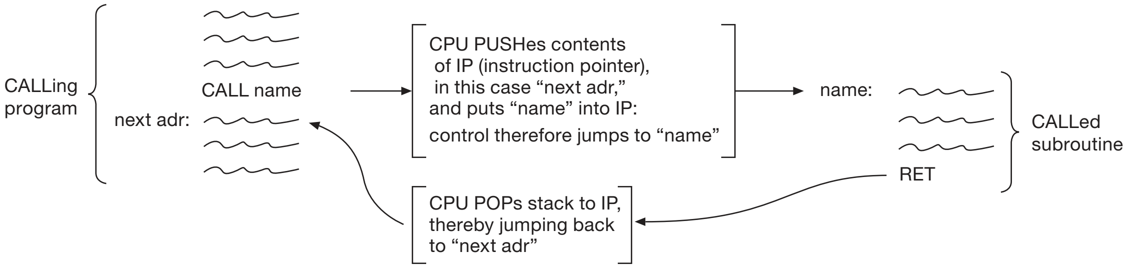
14.2.3 A programming example

As the array-copy example above suggests, assembly language tends to verbosity, with a lot of little steps needed to do a basically simple thing. Here's another example. Suppose you want to increment a number, *N*, if it equals another number, *M*. This will typically be a tiny step in a larger program, and in higher level languages it will be a single instruction:

```
if (n==m) n++;         (C, C++, Java)
if n==m:               (Python)
  n+=1
IF (N.EQ.M) N=N+1      (FORTRAN)
if n=m then n:=n+1;    (Pascal), etc
```

In x86 assembly language, it looks like Program 14.2. The assembler program will convert this set of mnemonics to machine language, generally translating each line of assembler *source code* to one *object code* instruction (occupying several machine-language bytes), and the resultant machine-language code will get loaded into successive locations in memory before being executed. Note that it is necessary to tell the assembler to assign some storage space for variables. This you do with the assembler *pseudo-op* "DW" (define word) (called a *pseudo*-op because it doesn't produce any executable code). Unique symbolic labels (e.g., NEXT) can be used to tag instructions; this is usually done only if there is a jump to that location (JNZ NEXT). Giving some locations understandable (to you!) names and adding comments (separated by a semicolon) make the job of programming easier; it also means that you have a chance of understanding what you've written a few weeks later.

Programming in assembly language can still be a nuisance, but it is sometimes preferable to write short routines in it, callable from a higher-level language, to code tight loops, or to handle unusual I/O. Assembly-language programs often run faster than programs compiled from a



CALLing program
CALL name
next adr:
CPU PUSHes contents of IP (instruction pointer), in this case "next adr," and puts "name" into IP: control therefore jumps to "name"
name:
CALLed subroutine
RET
CPU POPs stack to IP, thereby jumping back to "next adr"

Figure 14.6. CALL operation.

higher language, so they are sometimes used where speed is crucial (e.g., the innermost loop of a long numerical calculation). To a great extent the development of the powerful C and C++ programming languages has minimized the occasions when you must use assembly code. In any case, you can't really understand computer interfacing without understanding the nature of assembly-language I/O. The correspondence between mnemonic assembly language and executable machine language is explored further in the student manual[14] in the context of microcontroller programming.

14.3 Bus signals and interfacing

A typical microcomputer data bus has 50–100 signal lines, devoted to the transfer of data, addresses, and control signals. The PC104/ISA bus is typical of a small machine, with 53 signal lines and 8 power and ground lines. Rather than throw them at you all at once, we will approach the subject by building up the bus, beginning with the signal lines necessary for the simplest kind of data interchange (programmed I/O) and adding additional signal lines as they become necessary. We will give some useful interface examples as we go along, to keep things comprehensible and interesting.

The PC104 bus signals are carried from board to board on a 64-pin (2 rows of 32 pins each) stack-through connector: it is a socket on the top side, and a plug on the bottom. Figure 14.7 shows a PC104 stacked pair, with CPU above a fast high-resolution ADC peripheral board.

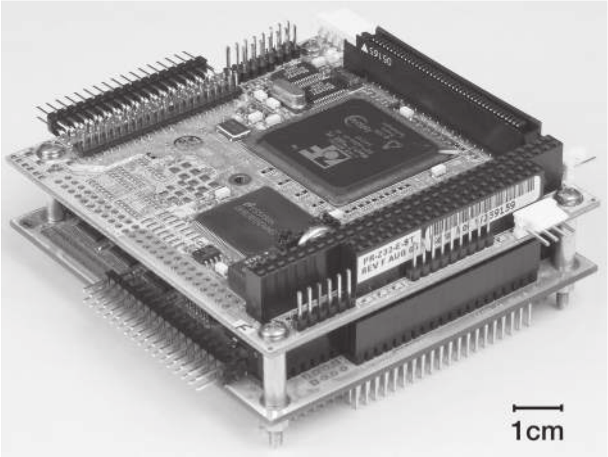


Figure 14.7. A PC104 CPU motherboard (top), with attached fast ADC (bottom). The Diamond Systems CPU includes serial and parallel I/O, USB, video, keyboard, mouse, hard-disk and floppy interfaces, and network ports; the Chase Scientific peripheral includes a pair of 14-bit 10 Msps ADCs, along with digital ports and memory. The PC104 stack-through bus can be seen along the southeast edge: 2×32 pins for the 8-bit bus, plus 2×20 pins for the 16-bit extension – voilà, 104 pins in all.

14.3.1 Fundamental bus signals: data, address, strobe

To move data on a shared (party-line) bus, you have to be able to specify the data, the recipient, and the moment when data is valid. Thus a minimum bus must have DATA lines (for the data to be transferred), ADDRESS lines (to identify the I/O device or memory address), and some STROBE lines (which tell when data is being transferred). There are usually as many DATA lines as bits in the computer word, so a whole word can be transferred at once. In the 8-bit PC104,[15] however, there are only eight DATA lines (D0–D7); you can move a byte in one transfer, but to move a 16-bit word you have to do two transfers. The number of ADDRESS lines determines the number of addressable devices: if the bus is used for both I/O and memory (the usual situation) there will be 16 to 32 ADDRESS lines

[14] Hayes and Horowitz: *Learning the Art of Electronics – a Hands-On Course*, Cambridge University Press, 2015.

[15] The PC104/ISA specification allows both 8-bit and 16-bit buses; we will use the 8-bit version, for simplicity.

Program 14.2

```
n  DW 0     ;n (a "word") lives here, and
m  DW 0     ;m lives here, both initialized to 0

        MOV  AX,n   ;get n
        CMP  AX,m   ;compare
        JNZ  NEXT   ;unequal, do nothing
        INC  m      ;equal, increment m
NEXT:   (next statement)
          o
          o
          o
```

(corresponding to a 64 KB to 4 GB address space); a bus used for I/O only might have 8 to 16 ADDRESS bits (256 to 64K I/O devices). PC104/ISA talks to both memory and I/O on its bus, and has 20 ADDRESS lines (A0–A19), corresponding to a 1 MB address space.

Finally, data transfer itself is synchronized by pulses on additional "strobing" bus lines. There are two ways in which this can be done: by having separate READ and WRITE lines, with a pulse on one or the other synchronizing data transfer; or by having one DATA STROBE line (DS) and one READ/WRITE′ line (R/W′), with a pulse on DS synchronizing data transfer in a direction specified by the level on the READ/WRITE′ line. PC104/ISA uses the first scheme,[16] with (active-LOW) READ/WRITE lines called IOR′, IOW′, MEMR′, and MEMW′; there are four because the PC distinguishes between memory and I/O addresses, with individual pairs of READ/WRITE strobes for each.

These bus signals – DATA, ADDRESS, and the four strobes – would normally be all you need to do the simplest kind of data transfers. However, on the PC104 bus you need one more, called ADDRESS ENABLE (AEN), to distinguish normal I/O transfers from what's called "direct memory access" (DMA). We'll get to DMA in §14.3.10; for now, all you need to know is that AEN is LOW for normal I/O, and HIGH for DMA. We now have 33 bus signals: D0–D7, A0–A19, IOR′, IOW′, MEMR′, MEMW′, and AEN. Let's see how they work.

14.3.2 Programmed I/O: data out

The simplest method of data exchange on a computer bus is known as "programmed I/O," meaning that data is transferred via an IN or OUT statement in the program (the directions for IN and OUT are among the few things on which all computer manufacturers agree: IN always means *toward* the CPU, and OUT always means *from* the CPU). The whole process of data OUT (and memory write) is extremely simple and logical (Figure 14.8). The ADDRESS of the recipient and the DATA to be sent are put onto the respective bus lines by the CPU. A write strobe (IOW′) is asserted (LOW) by the CPU to signal the recipient that data is good. On the PC104/ISA 8-bit bus, the address is guaranteed valid beginning ∼100 ns before IOW′, and the data are guaranteed valid ∼500 ns before the end of IOW′ (and for another 25 ns thereafter). To play the game, the peripheral looks at the ADDRESS and DATA lines. When it sees its own address, it latches the information on the DATA lines, using the trailing edge of the IOW′ pulse as a clocking signal. That's all there is to it.

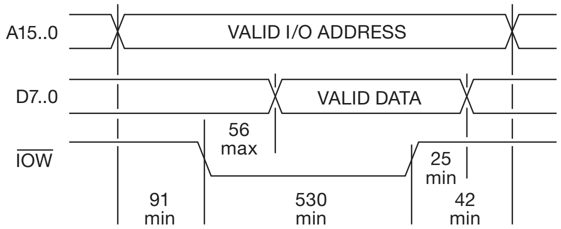

Figure 14.8. I/O WRITE cycle. Timing is in units of nanoseconds. Note that timing diagrams like these are rarely drawn to scale.

A. Example: byte-wide register

Figure 14.9 shows this simple logic: the box labeled "adr decode" produces a HIGH "adr match" output when the address lines A15..0 contain the peripheral's assigned address; this enables the gate to produce an output pulse when IOW′ goes LOW (signaling a write to the peripheral), the trailing edge of which clocks the outgoing data into the byte-wide D-register. You can summarize this compactly

[16] Because historically Intel processors used that scheme; Motorola chose R/W′ and DS.

by saying "the data is clocked into the register by the write pulse, qualified by the decoded address." Note that we've used the *trailing* edge of IOW′ to clock the D-register: that is because the data is not yet valid on the leading edge, but is guaranteed valid by the trailing edge – in fact, the data has a generous setup time of $\geq$474 ns (and a hold time of $\geq$25 ns) relative to that edge. We've shown also the analogous gating for the alternative "Motorola" bus signal pair of direction and timing (R/W′ and DS′), which replaces the "Intel" pair of IOR′ and IOW′.

The assembly code for this interface is outrageously simple. If we want to send out the byte that's already in register AL, this is all it takes:

```
OUT 3F8h, AL ;(send to port adr = 3F8 hex)
```

The processor springs to action, with the prescribed bus hardware response of Figure 14.8: first it asserts the specific address 3F8 (hex)[17] on address lines A9..0, then it asserts IOW′ and puts the byte in AL onto the data lines D7..0, and finally it disasserts IOW′, then the data and address. Then it obediently fetches and executes the next instruction.

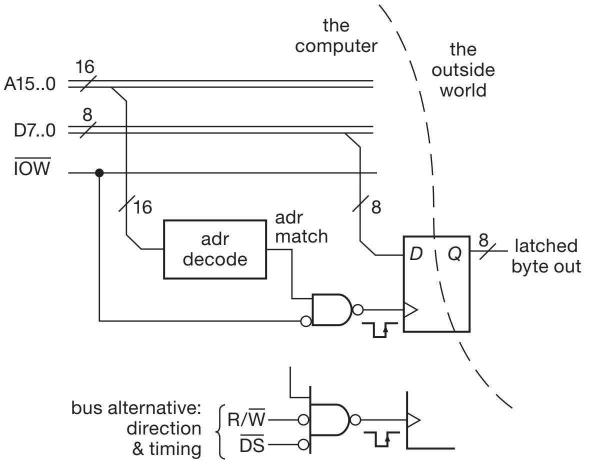

Figure 14.9. Programmed data out: a byte asserted by the CPU onto the data lines is clocked to an external device by the write pulse, if the address lines hold the peripheral's assigned address. For simplicity we've ignored the PC104's quirky AEN signal (see Figure 14.10).

B. Example: 16-bit XY vector graphic display

A more complete (and interesting) example is shown in Figure 14.10, where we've interfaced a pair of high-resolution (16-bit) D/A converters to the PC104 8-bit bus, for example to drive a high-resolution vector graphic display screen. This might be used in conjunction with a high-resolution (up to 64k×64k!) *XY* oscillographic display device that accepts analog *x* and *y* input voltages and that plots the corresponding point by unblanking the trace at each point when a *z*-input logic level is asserted.

The Analog Devices AD660 DACs have a pair of internal 8-bit registers that you load by asserting an enable (HBE′ and LBE′ for high and low byte) while clocking the WR′ line; after that you transfer the pair to the internal 16-bit register that holds the value being converted to an output voltage (Figure 14.11). This scheme prevents false outputs: it lets you transfer the 16-bit values one byte after another, and then transfer them all, simultaneously, to the actual DAC output. It does, however, add a bit of complexity, when compared with the simple byte-wide register output port of Figure 14.9.

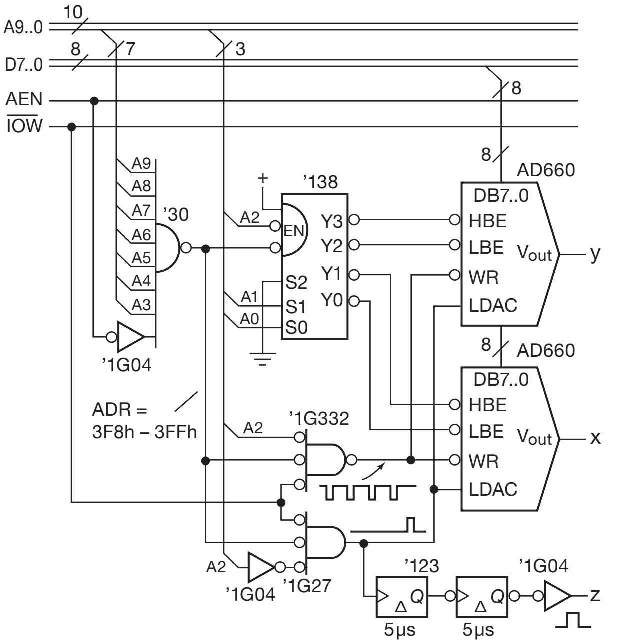

Figure 14.10. Dual-channel 16-bit DAC interface on the PC104 8-bit bus.

For this interface we use 8 successive bytes (addresses 3F8h–3FFh, or binary 11 1111 1xxx), choosing "base address" 3F8h (binary 11 1111 1000). The 8-input NAND detects this address range, qualified by the AEN bus signal asserted LOW.[18] Its output enables the '138 1-of-8 decoder (§10.3.3D), which responds to the two low-order address lines (A1 and A0) to enable the successive HBE′ and LBE′

[17] We trust the reader will forgive our unlucky address choice: 3F8h is the x86's default serial port.

[18] AEN is asserted HIGH to signal a *DMA transfer* (§14.3.10); so for ordinary programmed I/O it must be LOW.

during byte-wide writes to addresses 3F8h, 3F9h, 3FAh, and 3FBh. After loading, these bytes are transferred to the business end of the DAC by a write to address 3FCh, which causes the lower gate to generate an LDAC (load DAC) pulse when it sees the IOW′. Note that this last "write" needs no data; the circuit ignores D7..0, and just uses the IOW′, qualified by address 3FCh.[19] The LDAC pulse also generates a delayed "*z*-axis" unblanking pulse, providing time for the DACs and vector display screen to settle before displaying each x, y point.

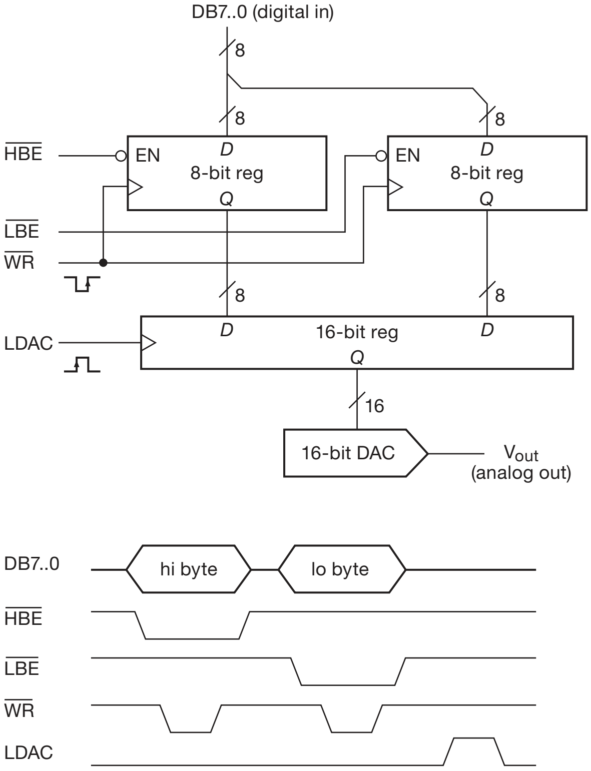

Figure 14.11. Block diagram and timing sequence of the double-buffered AD660 16-bit ADC with byte-wide parallel data input.

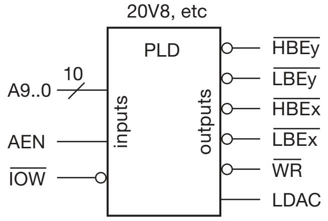
In practice you would probably combine all the logic, including address decoding, into a programmable logic device (PLD, Chapter 11), as in Figure 14.12; you might additionally include jumpers to set the base address.



```
DACSEL = a9 & a8 & a7 & a6 & a5 & a4 & a3 & !aen;
wr_bar = DACSEL & iow_bar & !a2;
ldac = DACSEL & iow_bar & a2;
lbex_bar = DACSEL & !a2 & !a1 & !a0;
hbex_bar = DACSEL & !a2 & !a1 & a0;
lbey_bar = DACSEL & !a2 & a1 & !a0;
hbey_bar = DACSEL & !a2 & a1 & a0;
```

Figure 14.12. The logic of Figure 14.10 fits easily into a Lilliputian PLD like the 20V8. The code is written with logical assertion, assuming that active-LOW polarities are so defined in the HDL header file.

14.3.3 Programming the *XY* vector display

The programming to run this interface is straightforward. Program 14.3 shows what you do. The addresses of the first *x* and *y*, and the number of points to be plotted, have to be available to the program. The display program will probably be a subroutine, with those parameters passed as arguments in the subroutine call. The program puts the addresses of the *x* and *y* arrays (i.e., the address of the first *x* and *y*) into address pointer registers `SI` and `DI`, and the number of points to be plotted into `CX`. It then enters a loop in which successive x, y pairs are sent to I/O ports 3F8h and 3FAh. The *x* and *y* 2-byte pointers are advanced each time around, and the counter is decremented and tested for zero, which indicates that the last point has been displayed; the pointers and counter are then reinitialized, and the process begins again. The *x* and *y* values are each 2-byte (16-bit) integers; the code fetches them each with a single `MOV` (implicit in the use of the 16-bit internal `AX` register), and sends each out as two successive write-cycle transfers on the 8-bit bus. The x86 processors store multibyte quantities in successive memory locations in the byte order smallest-to-largest,[20] beginning always on an even-numbered byte. That is why we assigned the LBE and HBE pair addresses as shown.

A couple of important points: once started, this

[19] Actually, qualified by any address in the range 3FCh–3FFh, because the 3-input gate ignores A1 and A0, in what we call "lazy address decoding."

[20] Known as "little-endian," to be distinguished from the alternative scheme of "big-endian" whose byte order is largest-to-smallest in successive memory locations; see §14.8. (OK, it's a corny pun – but, hey, we didn't invent it, so don't shoot the messenger.)

program displays the x, y array forever. In real life the program would probably check the keyboard to see if the operator wants the plot terminated. Alternatively, the display could be terminated after a specified time had elapsed, or by an "interrupt," which we will discuss shortly. With this sort of *refreshed* display there usually isn't time to do much computing while displaying. A display device refreshed from its own memory takes that burden off the computer, and this is generally a better method. Nevertheless, if the objective is to make a precision plot for photographic hard copy, this program and interface would do the job.[21]

14.3.4 Programmed I/O: data in

The other direction (data *in*) of programmed I/O is similar. The interface looks at the ADDRESS lines as before. If it sees its own address (and AEN is LOW), it puts data onto the DATA lines coincident with the IOR′ pulse (Figure 14.13). Figure 14.14 shows the correspondingly simple hardware. This interface lets the processor read a byte latched in the '374 *D*-type register, which conveniently has three-state outputs.[22] Because the clock input and data inputs of the register are accessible to an external device, the register could hold just about any sort of digital information (the output of a digital instrument, A/D converter, etc.). The line labeled "ADR=200h" comes from an address decoder (e.g., a PLD, or discrete gates, that produce a HIGH when A9..0 contain binary 10 0000 0000); from now on we'll omit such minor implementation details.

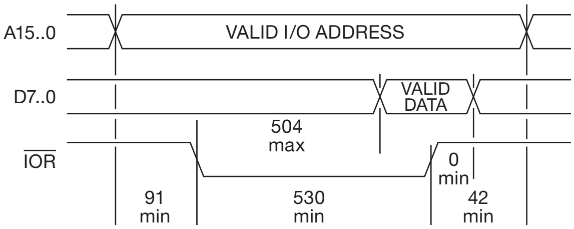


Figure 14.13. I/O READ cycle. Timing is in units of nanoseconds.

When an "IN AL,200H" instruction is executed, the CPU asserts 200_H (hexadecimal 200, sometimes written 0x200) on A9..0, waits a while, then asserts IOR′ for 530 ns. The CPU latches what it sees on the DATA lines (D7..0) at the trailing edge of IOR′, then disasserts A9..0. The peripheral's responsibility is to get the data onto D7..0 at least 26 ns before the end of IOR′; that's pretty relaxed timing, since it has known that data is being requested from it for at least 504 ns. With typical gate-logic propagation times of 10 ns, 500 ns looks like forever (an indication of its birthdate in 1981, an era of more relaxed timing).

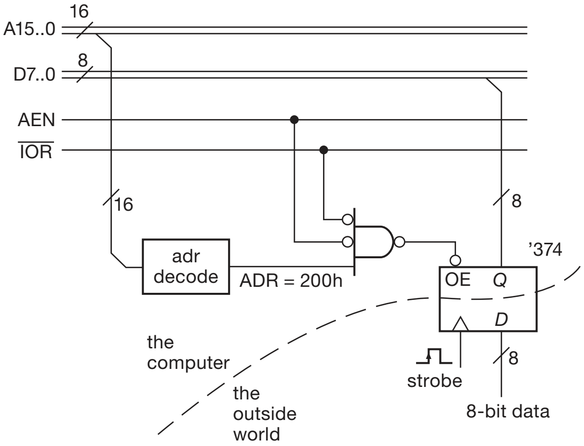

Figure 14.14. Programmed data in: an external device asserts its data on the data lines during the IOR′ pulse if the ADDRESS lines hold the peripheral's assigned address. The '374 is an octal *D*-register with three-state outputs.

A. Bus signals: bidirectional versus one-way

From the two examples we've done so far, you can see that some bus lines are *bidirectional*, for example the DATA lines: they are asserted by the CPU during write, but asserted by the peripheral during read. Both CPU and peripheral use three-state drivers for these lines. Others, like IOW′, IOR′, and the ADDRESS lines, are always driven by the CPU with standard two-state (active pullup) driver chips. It is typical of data buses to have both kinds of lines, using bidirectional lines for data that goes both ways and one-way lines for signals that are always generated by the CPU (or, more accurately, generated by the associated bus control logic). There is always a precise protocol, like our rules for asserting or reading according to IOW′, IOR′, and ADDRESS, to prevent "bus contention" on these shared lines.

Of the PC104 bus signals so far, only the DATA lines are bidirectional; the ADDRESS lines, AEN, and READ/WRITE

[21] In a more sophisticated implementation you might generate *software* z-axis pulses: you would assign a port address (say 3FDh) with a flip-flop to which you would write a HIGH bit followed, after a timed delay, by a LOW bit; the pulse width and delay would be created with CPU timers. Alternatively, you could decorate our circuit with a programmable hardware z-axis pulse generator, using a port address with a byte-wide register so that software could instruct the hardware to set the delay and width.

[22] It is for this very reason – this common use of shared (bused) data lines – that many chips include three-state outputs, controlled by an output enable (OE′) control pin.

Program 14.3

```
          ;routine to drive 16-bit xy DAC port
INIT:   MOV  SI,xpoint   ;initialize x pointer
        MOV  DI,ypoint   ;initialize y pointer
        MOV  CX,npoint   ;initialize counter

RASTER: MOV  AX,[SI]  ;get x word (2 bytes)
        OUT  3F8H,AX  ;send out (2 byte xfers)
        ADD  SI,2     ;advance x word pointer
        MOV  AX,[DI]  ;get y word (2 bytes)
        OUT  3FAH,AX  ;send out (2 byte xfers)
        ADD  DI,2     ;advance y word pointer
        OUT  3FCH,AL  ;load x and y to DAC
        DEC  CX       ;decrement counter
        JNZ  RASTER   ;not done, send more
        JMP  INIT     ;done, start over}
```

strobes are one-way from the CPU. (Lest we give the wrong impression, we should point out that more complex computer systems permit other riders on the bus to become bus "masters." Obviously in such a system nearly all bus signals must be shared and bidirectional. The PC104/ISA bus is unusually simple.)

14.3.5 Programmed I/O: status registers

In our last example, the computer can read a byte from the interface any time it wants to. That's nice, but how does it know when there's something worth reading? In some situations you may want the computer to read data at equally spaced intervals, as determined by its "real-time clock." Perhaps the computer instructs an ADC to begin conversions at regular intervals (via an OUT command), then reads the result a few microseconds later (via an IN command). That might suffice in a data-logging application. However, it is often the case that the external device has a mind of its own, and it would be nice if it could communicate what's happening to the computer without having to wait around.

A classic example is an alphanumeric input keyboard. You don't want characters to get lost; the computer has to get every character, and without much delay. With a fast device like a disk or high-speed serial interface the situation is even more serious; data must be moved at rates up to many megabytes per second without delay. There are actually three ways to handle this general problem: status registers, interrupts, and direct memory access. Let's begin with the simplest method – status registers – illustrated by the keyboard interface in Figure 14.15.

In this example, the raw "ASCII keyboard" is a simple device: when a key is struck, it puts the corresponding byte onto its output data lines (KQ7..0) and generates a short output pulse on STB, as shown.[23] We use the STB (for "strobe") to clock that byte-wide character code into an octal *D*-type register. We rig up the standard programmed data-in circuit, as shown, using the three-state outputs of the octal *D*-register to drive the DATA lines directly. The input labeled KBDATA_SEL′ comes from the usual address decoding circuit of the sort used in the previous examples, and it goes LOW when the particular address chosen for

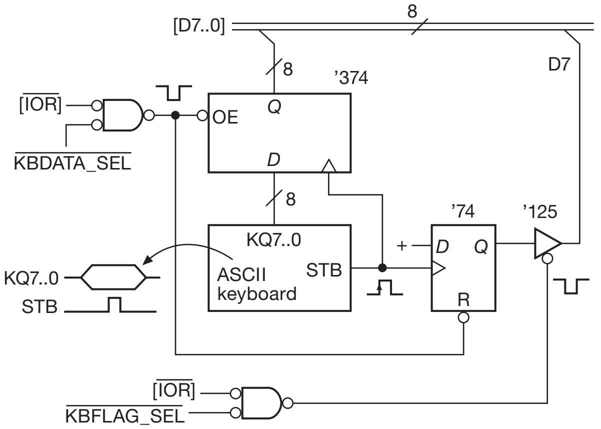

Figure 14.15. Keyboard interface with status bit. Brackets indicate PC104 bus signals.

[23] This keyboard lacks the intelligence of contemporary units, which generally include an onboard processor to convert the key codes to a bit-serial format, typically delivered via the USB hardware interface. Its very lack of intelligence, however, permits us to display our own.

this interface appears on the ADDRESS lines of the bus (in combination with AEN disasserted LOW).

What's new in this example is the flip-flop, which gets set when a character is struck, and cleared when a character is read by the computer. It's a 1-bit *status* register: HIGH if there's a new character available, LOW otherwise. The computer can query the status bit by doing a data IN from the other address of this device, decoded (with gates, decoders, or whatever) as KBFLAG_SEL′. You need only one bit to convey the status information, so the interface drives only the most-significant bit (MSB) on the bus (D7), in this case with a '125 three-state buffer. (*Never* drive a bidirectional line with an active-pullup (two-state) output! *Never!*) The line coming into the side of the buffer symbol is the three-state output enable, asserted when LOW, as indicated by the negation bubble.

This circuit could be implemented with standard logic, as indicated. Alternatively, it (and the address decoding logic) would fit easily in a small PLD (for example an XC2C32, XC9536, ATF2500, Mach4032, or even a lowly 22V10).

A. Program example: keyboard terminal

The computer now has a way to find out when new data is ready. Program 14.4 shows how. This is a routine to get characters from the keyboard, whose data port address is KBDATA (it's good programming style to define the actual numerical port addresses – which correspond to what the hardware decodes as KBDATA_SEL, etc. – in some statements near the beginning of the program, as shown); each character is "echoed" on the computer's display device (port address = OUTBYTE). When it has gotten a whole line, it transfers control to a line-handling routine, which might do just about anything, based on what the line says. When it's ready for another line, it types an asterisk "prompt." This sort of protocol should make sense to you if you've had some experience with computers.

The program begins by initializing the character buffer pointer (BP), by moving the *address* of the buffer that we just allocated to the address register BP. Note we can't just say "MOV BP,charbuf" because that would load the *contents* of charbuf, not its address; in x86 assembly language you use the word "offset" in front of a memory label to signify its address. The program then reads the keyboard status bit via an IN instruction, ANDs it with 80h to keep only the status bit (this is called "masking"), and tests for zero. Zero means the bit isn't set, so the program loops. When a nonzero status bit is detected, it reads the keyboard data port (which clears the status flag flip-flop), stores it consecutively in the line buffer, increments the pointer (BP), and calls the routine that echoes the character to the screen. Finally, it checks to see if the line was terminated by a carriage return (CR): if it wasn't, it goes back and loops on the keyboard status flag again; if it was a CR, it transfers control to the line handler, after which it prints an asterisk and begins the entire process anew.

A subroutine has been used to display a character, since even that simple operation requires some flag checking and masking. The routine first saves the byte into AH, then reads and masks the screen's busy flag. A nonzero result means the screen is busy, so it keeps checking; otherwise it restores the character to AL, sends it to the screen's data port, and returns.

Some notes on the program. (a) We could have omitted the keyboard flag-masking step, because the MSB (where we put the flag bit in our hardware) is the sign bit; thus we could have used the instruction JNS KFCHK. However, this trick works only for testing the MSB and thus is somewhat specialized. (b) In keeping with good programming practice, the carriage return symbol (0Dh) and asterisk probably should be defined constants, similar to KBMASK. (c) The line handler probably should be a subroutine, also. (d) Characters will be lost if the line handler takes too long; this leads us to the more elegant approach of *interrupts*, which we'll take up shortly. (e) Keyboard and terminal handlers are used so often that microprocessor operating systems provide built-in handlers, accessed through "software interrupts" (we'll see them later); thus our program may not even be needed.

B. Status bits generalized

This keyboard example illustrates status bit protocol; but it's so simple that you may come away with the wrong idea. In an actual peripheral interface of some complexity, there will usually be several flags to signal various conditions. For example, in an Ethernet interface you will normally have individual status bits indicating a successful packet transmission, or (if you're not so lucky) any of various mishaps that may have occurred. As a specific example, Microchip's ENC28J60 Ethernet Controller IC has a 56-bit transmit status register; bit 20 indicates a "Transmit CRC Error," described as "The attached CRC in the packet did not match the internally generated CRC."[24]

For peripherals of modest complexity, the usual procedure is to put all the status bits into one byte or word, so that a data IN command from the status register gets all bits at once. Typically you would have a bit indicating any of a set

[24] These things can get humorously arcane: bit 27 ("Transmit Excessive Defer") signifies "Packet was deferred in excess of 24,287 bit times."

Program 14.4

```
          ;keyboard handler -- uses flags
KBDATA  equ ***H       ;put kbd data port adr here
KBFLAG  equ ***H       ;a different port for kbd flag
KBMASK  equ 80H        ;kbd flag mask
OUTBYTE equ ***H       ;put disp port adr here
OUTFLAG equ ***H       ;another for disp port flag
OUTMASK equ ***H       ;disp port busy mask

charbuf DB 100 dup(0)  ;allocates buffer of 100 bytes

INIT:   MOV  BP,offset charbuf   ;init char buf pntr
KFCHK:  IN   AL,KBFLAG  ;read kbd flag
        AND  AL,KBMASK  ;mask unused bits
        JZ   KFCHK      ;flag not set -- no new data
        IN   AL,KBDATA  ;flag set -- get new kbd byte
        MOV  [BP],AL    ;store it in line buffer
        INC  BP         ;and advance pointer
        CALL TYPEIT     ;echo last char to display
        CMP  AL,0DH     ;was it carriage return (0Dh)?
        JNZ  KFCHK      ;if not, get next char
LINE:     o             ;if so, do something with line
          o             ;keep at it
          o             ;don't quit now
          o             ;done at last!
        MOV  AL,'*'
        CALL TYPEIT     ;type a "prompt" -- asterisk
        JMP  INIT       ;get another line

                        ;routine to type character
                        ;types and preserves AL
TYPEIT: MOV  AH,AL      ;save the char in AH
PCHK:   IN   AL,OUTFLAG ;check printer busy?
        AND  AL,OUTMASK ;printer flag mask
        JNZ  PCHK       ;if busy check again
        MOV  AL,AH      ;restore char to AL
        OUT  OUTBYTE,AL ;type it
        RET             ;and return
```

of error conditions as the MSB of the status word, so a simple check of sign tells if there are *any* errors; if there are, you test specific bits of the word (by ANDing with masks) to find out what's wrong. Furthermore, in a complex interface you probably wouldn't have the status bits reset "automatically," as we did with our single bit; instead, a data OUT statement might be used, each bit of which clears a specific flag.

Exercise 14.1. With our keyboard interface there is no way for the computer to know if it missed a character. Modify the circuit so there are two status bits: CHAR_READY (that's what we have already) and LOST_DATA. The LOST_DATA flag should be readable as D6 on the same status port as CHAR_READY; it is 1 if a key was struck before the previous character was fetched by the computer, 0 otherwise.

Exercise 14.2. Add a section of code to Program 14.4 to check for lost data. It should call a subroutine called LOST if it detects lost data; otherwise the program should work as before.

14.3.6 Programmed I/O: command registers

To summarize, a status bit (or a collection of bits: a status register) reports a condition to the CPU (when asked). Going in the opposite direction, the CPU can send out a bit (or collection of bits) to a peripheral, to tell it to do something. This is called a *command* bit (or command register). A simple example might be a bit that tells an *xy* positioning stage to move to the coordinates that have been deposited in a pair of data registers of the peripheral by a pair of previous programmed OUT statements. Or, taking the example of our Ethernet controller, the CPU deposits to a pair of registers in the IC the beginning and ending addresses of the data packet to be transmitted; then it sets a particular command bit (bit 3, to be exact) in the chip's "ECON1" register, which opens the floodgates by commanding the chip to send the packet out on the Ethernet port. The chip does as it has been told (in this case using DMA for highest speed; see §14.3.10), and reports back to the CPU (when asked; or more aggressively by using an *interrupt*; see next subsection) via the status registers.

14.3.7 Interrupts

The use of status flags just illustrated is one of three ways for a peripheral device to "tell" the computer when some action needs to be taken. Although it will suffice in many simple situations, it has the serious drawback that the peripheral cannot announce that some action needs to be taken – it has to wait to be asked by the CPU, via a data IN command from its status register. Devices that need quick action (such as disks or latency-sensitive real-time I/O) would have to have their status flags queried often, and with several such devices in a computer system the CPU would soon find itself spending most of its time checking status flags, as in the last example.

Furthermore, even with continual status flag checking you can still get in trouble: in the last example, for instance, the CPU will have no trouble keeping up with someone typing at the keyboard when it is in the main (flag-checking) loop. But what if it spends 1/10 second in the line-handling portion? Or what if the interfaced device is a slow one, making the program wait for its busy flag to clear?

What is needed is a mechanism for a peripheral to *interrupt* the normal action of the CPU when something needs to be done. The CPU can then check the status register to find out what the trouble is, take care of what needs to be done, and go back to its normal business.

To add interrupt capability to a computer, it is necessary to add a few new bus signals: at least one shared line for peripherals to signal an interrupt, and (usually) a pair of lines by which the CPU can determine who interrupted. As luck would have it, the PC104/ISA is not a very instructive example, because it does not implement a full interrupt capability. What it lacks in power, though, it more than makes up for in simplicity; implementing hardware interrupts in a PC104 peripheral interface is like falling off a log.

Here's how it works: the PC104 bus has a set of six *interrupt request* lines, called IRQ3–IRQ7 and IRQ9. They are active-HIGH inputs to the CPU's support circuitry. To make an interrupt, you simply bring one of the lines HIGH. If interrupts are enabled in general (along with the particular IRQ you assert), the CPU will break off after its next instruction, then (after saving its flags and current location onto the stack) jump to an "interrupt-handler" program somewhere in memory. You write the handler to do what you want (e.g., get keyboard data), and you can put the handler anywhere you wish, because the CPU figures out where to jump by looking for the handler's 4-byte address in a special ("vector") location in low memory. That location depends on which IRQ you've asserted; for the x86 it is given in hex by 20+4*n*, where *n* is the interrupt level. For example, the CPU would respond to an interrupt on IRQ2 by jumping to the (4-byte) address stored in locations 28h through 2Bh (it's just like indirect addressing, except that the address is found in memory rather than in a register); of course, you would have cleverly arranged for the starting address of your handler to be there. At the end of your handler you execute an IRET instruction, which causes the CPU to restore the preexisting flag register and jump back to wherever it was when the interrupt happened.

A. Example: keyboard interface with interrupts

Let's illustrate by adding interrupts (Figure 14.16) to our keyboard interface circuit of Figure 14.15. We've kept the flag bit ("character ready") and programmed I/O circuitry essentially as before, except that we've ORed the flag clear with a new bus line, RESET, a bus signal that is momentarily asserted HIGH when the computer is turned on. This signal is generally used to force your flip-flops and other sequential logic into a known state at power-up. Obviously it should reset a flag that indicates a valid byte is ready to be claimed (and that, in our new interface, will further cause an interrupt).

The new interrupt circuitry consists of a three-state driver to assert IRQ3 when a character is ready. That's all the new hardware you need. Although not strictly necessary, we've added the capability to disable the interrupt driver buffer by sending a data byte with D0 LOW to the KBFLAG port address. This would be used if you wanted to plug in another peripheral with interrupts at the same IRQ level, allowing only one peripheral to use its interrupts at any given time (later we'll have further explanation on this awkward point).

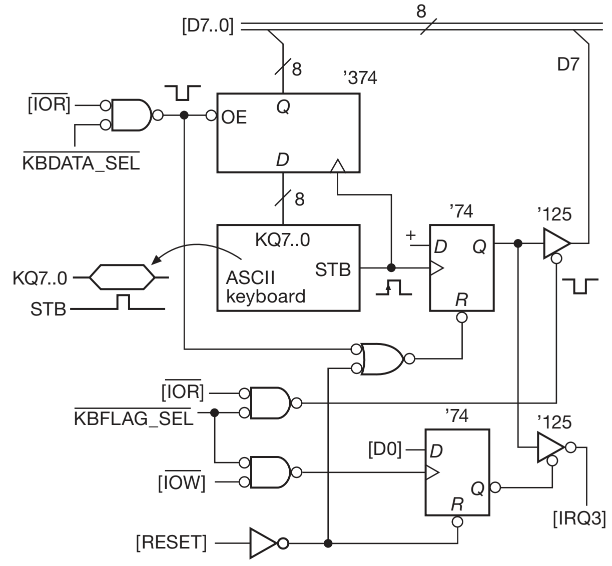

Figure 14.16. Keyboard interface with status bit and interrupt.

14.3.8 Interrupt handling

The PC104 bus signals, derived from the original IBM PC, make interrupt handling particularly easy, though limited in flexibility compared with the general (and more sophisticated) method described below (§14.3.9). The bus signals require, in addition to the CPU itself, some interrupt control circuitry on the motherboard.[25] This "support-chip" circuitry does most of the hard work, which consists of prioritizing, masking, and asserting vectors (we'll describe these after finishing the example). The CPU, for its part, recognizes the interrupt and responds by saving the instruction pointer and flag register, disabling further interrupts, then making a jump via the corresponding address stored in the low-memory vector area. Your handler program does the rest, namely: (a) saves (pushes) any registers you'll be using (remember that the interrupted program can't prepare for the interrupt, since it can happen anywhere in the running program – it's a bolt out of the blue); (b) figures out what needs to be done, by reading status registers if necessary; (c) does it; (d) restores the saved registers from the stack; (e) tells the interrupt control circuitry that you're done (by sending an "end-of-interrupt" byte 20h to its register at I/O address 20h); and, finally, (f) executes a return from interrupt instruction `IRET`; this causes the CPU to restore the old flag register that it saved on the stack and to jump (via the old instruction pointer it saved on the stack) back to the program that was interrupted. Somewhere in the program, you must have (g) loaded the handler's address into the vector location corresponding to the IRQ level used by the hardware and told the interrupt control hardware to enable interrupts at that level.

Program 14.5 shows the code for the keyboard with interrupt. Here's the overall scheme: the main program sets things up, then loops on a flag (in memory, not hardware) that the interrupt handler sets when it recognizes a carriage return; when the main program sees that flag set, it goes off and does something with the line, then returns to the flag-checking loop. The handler, entered at each interrupt, puts a character into the line buffer, sets the flag if it was a carriage return, then returns.

Let's look at the program in some detail. After defining port addresses and the all-critical vector location for IRQ3, it allocates 100 bytes (initially filled with zeros) for the character buffer. The actual program execution begins by putting the buffer address in address register SI, zero in the end-of-line flag, and the address of the handler (which begins with `KBINT`) in location 2Ch. To enable level-3 interrupts in the interrupt controller, we clear bit 2 of its existing mask (`IN`, `AND`, `OUT`); then we enable CPU interrupts and send a 1 to `KBFLAG`, which enables the three-state driver. Now we're running. The program then loops, with interrupts secretly happening right under the main program's nose, until it mysteriously finds the "buflg" set. It resets the pointer and flag immediately (in case another interrupt occurs soon), then gobbles up the line. It would be well advised either to move quickly or to copy the line to another buffer, since another interrupt (with a new byte to go in the buffer) could come along in a few milliseconds; in that time you can execute a few hundred thousand instructions, however, more than enough to copy the line.

The interrupt handler is a separate little piece of code, with no entry from the main program. It gets entered upon a level-3 interrupt, via its address that we initially loaded into 2Ch. It knows exactly what it has to do, and it does it without complaining: it saves `AX` (because it plans to clobber it), reads the character from the keyboard data port, puts it in the buffer, increments the pointer, echoes the character to the screen, sets the flag if it was a carriage return, sends end-of-interrupt to the interrupt controller, restores `AX`, and returns.

If you look back at our list of handler tasks above, you'll see that we omitted just one step, namely, reading status flags to figure out which of several actions needed to be done. That's unnecessary here, though, because there's only one reason to interrupt, namely that a new keyboard character needs to be read. (The programmer obviously has

[25] Which was done by an 8259 interrupt-controller IC on the original PC motherboard.

        IRET           ;and return
```

to understand under what conditions the hardware makes an interrupt, and what is required to service the interrupt.)

A few notes on this program: first, even though we're using interrupts, the program seems as dumb as before – it loops continually on the end-of-line flag. However, it could be doing other things, if there were things to do. In fact, it does just that beginning at statement LINE, where it processes the finished line; during that time, interrupts make sure that new characters are put into the buffer, whereas they would have been lost in our previous example without interrupts.

This brings up a second point, namely, even with interrupts we're still in trouble if the program is doing things with the previous line when the next line has been completely entered. Of course, *on the average* the program simply has to keep up with keyboard entry; but you could have a situation in which the line user occasionally spends a lot of time, and you need to buffer more than one line temporarily. One solution to this is to make a copy to a second buffer or to alternate between two buffers. An elegant alternative is to organize input as a queue, implemented as a "ring buffer" (or "circular buffer"), in which a pair of pointers keeps track of where the next input character goes, and from where the next character is removed. The interrupt handler advances the input pointer, and the line user advances the output pointer. Such a ring buffer might typically be 256 bytes long, permitting the line handler to get behind by a few lines.

A third point concerns the interrupt handler itself. It's usually best to keep it short and simple, perhaps setting flags to signal the need for complicated operations in the main program. If the handler does become long-winded, you risk losing data from other interrupting devices because interrupts are disabled (at that level and below) when the CPU jumps into the handler. The solution in this case is to re-enable interrupts *within* your handler with an STI instruction, after doing the critical things that have to be done first. Then, if an interrupt occurs, your interrupt handler will itself be interrupted. Because flags and return addresses are stored on the stack, the program will find its way back, first to your handler, finally to the main program.

14.3.9 Interrupts in general

Our keyboard example illustrates the essence of interrupts – a spontaneous hardware request for attention by a peripheral, producing a program jump to a dedicated handler routine (usually resulting in some programmed I/O), followed by a return to the code that was interrupted. Other examples of interrupting devices are real-time clocks, in which a periodic interrupt (often 10 per second, but 18.2 per second in the original PC from which the PC104 bus derived) signals a timekeeping routine to advance the current time; another example is a printer port, which interrupts each time it is ready for a new character. By using interrupts, these peripherals let the computer interleave other tasks simultaneously; that's why you can be typing while your PC is printing a file (and, of course, keeping proper time throughout).

The PC104/ISA bus does not, however, illustrate the full generality of interrupts. As we saw, it has a set of six IRQ lines on the 8-bit bus (there are five more on the 16-bit extension), each one of which can be used only for a single interrupting device. The IRQ lines are numbered according to priority; in the event of multiple interrupts, the lowest-numbered interrupt is serviced first. And several of the IRQ lines are preassigned to essential peripherals, leaving precious few available. Furthermore, the interrupt is *edge-triggered*, which frustrates any reasonable possibility of using wired-OR to combine several peripherals on a single IRQ line. Evidently the original IBM PC designers, not anticipating the need for shared interrupts, designed a far-from-optimal interrupt scheme.

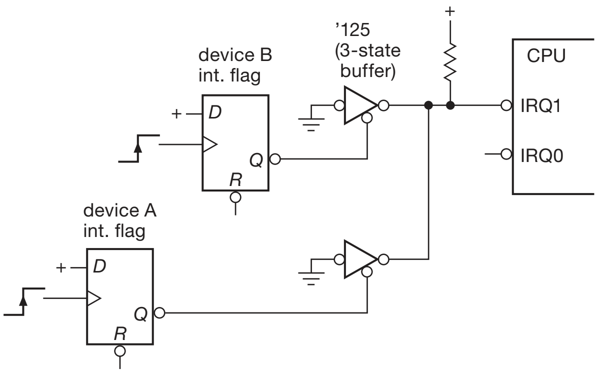

Figure 14.17. Sharing a level-sensitive interrupt line via wired-OR.

A. Shared interrupt lines

The usual interrupt protocol, as implemented on many microcomputers, circumvents these limitations. Look at Figure 14.17. There are several (prioritized) IRQ-type lines; these are active-LOW inputs to the CPU (or its immediate support circuitry). To request an interrupt, you pull one of the IRQ′ lines LOW, using an open-collector (or three-state) gate, as shown (note the trick for using a three-state gate to mimic an open-collector gate). The IRQ′ lines are shared, with a single resistive pullup, so you can put as many devices on each IRQ′ line as you want; in our example, two ports share IRQ1. You would generally connect a latency-sensitive (impatient) device to a higher-priority IRQ′ line.

Because the IRQ′ lines are shared, there could always be another device interrupting on the same line at the same time. The CPU needs to know who interrupted so it can jump to the appropriate handler. There is a simple way, and a complicated way, to do this. The simple way is called *autovectored polling* and is used nearly universally (though not on the PC104 bus). Here's how it works.

Autovectored polling

Some circuitry on the CPU board instructs the microprocessor that it is to use autovectoring, which works just like the PC104 – each level of interrupt forces a jump through a corresponding vectoring location in low memory. You put the addresses of the handlers in those locations, just as in our previous example.

Once in the handler, you know which level of interrupt you're servicing; you just don't know which particular device caused the interrupt. To find out, you simply check the status registers of each of the devices connected to that level of interrupt (a device never requests an interrupt without also indicating its need by setting one or more readable status bits). If a bit is set indicating that something needs to be done, you do it, including whatever it takes to cause the device to disassert its IRQ′: some devices (like our keyboard) clear their interrupt when read, whereas others may need a particular byte sent to some I/O port address.

If the device you serviced was the only one interrupting at that level, that IRQ′ will now be HIGH on returning to the interrupted program, and execution will continue. However, if there had been a second interrupting device at the same level, that IRQ′ line would still be held LOW (by the wired-OR action of the shared IRQ′ line) on return from the service routine, so the CPU would immediately autovector back to the same handler. This time the polling would find the other interrupting device, do its thing, and return. Note that the order in which you poll status registers effectively sets up a "software priority," in addition to the hardware priority of the multiple IRQ′ levels.

Interrupt acknowledgment

We shouldn't leave the subject of interrupts without mentioning a more sophisticated procedure for identifying who interrupted – *interrupt acknowledgment*. In this method, the CPU doesn't need to poll the status registers of possible interrupters because the interrupting device *tells* the CPU its name, when asked. The interrupter does this by putting an "interrupt vector" (usually a unique 8-bit quantity) onto the DATA lines in response to an "interrupt-acknowledge" signal that the CPU generates during the interrupt processing.

Nearly every microprocessor generates the needed signals. The sequence of events goes like this.

(a) The CPU notices a pending interrupt.
(b) The CPU finishes the current instruction, then asserts (i) bus signals that announce an interrupt, (ii) the interrupt level being serviced (on the low-order ADDRESS lines), and (iii) READ-like strobes that invite the interrupting device to identify itself.
(c) The interrupting device responds to this bus activity by asserting its identity (interrupt vector) onto the DATA lines.
(d) The CPU reads the vector and jumps into the corresponding unique handler for the interrupting device.
(e) The handler software, as in our last example, reads flags, gets and sends data, etc., as needed; among its other duties, it must make sure the interrupting device disasserts its interrupt.
(f) Finally, the interrupt handler software returns control to the program that was interrupted.

Sharp-eyed readers may have noticed a flaw in the procedure just outlined. In particular, there has to be a protocol to ensure that only one device asserts its vector, since there may be several simultaneous interrupting devices at the same IRQ level. The usual way to handle this is to have a bus signal (call it INTP, "interrupt priority") that is unusual in not being shared by devices on the bus, but rather is passed along *through* each device's interface circuit, beginning as a HIGH level at the device closest to the CPU and threading along through each interface. That's called a "daisy chain" in the colorful language of electronics. The rule for INTP hardware logic is as follows: if you have not requested an interrupt at the level being acknowledged, pass INTP through to the next device unchanged; if you *have* interrupted at that level, hold your INTP output LOW. Now the rule for asserting your vector goes like this: put your vector number onto the data bus when requested by the CPU only if (a) you have an interrupt pending at the level being acknowledged, and (b) your input INTP is HIGH. This guarantees that only one device asserts its vector; it also establishes a "serial-priority" chain within each IRQ level, with devices electrically closest to the CPU getting serviced first.

There is a nice alternative to the serial daisy-chain method of interrupt acknowledgment: instead of threading a line through each possible interrupter, you bring individual lines back from each one to a priority encoder (§10.3.3E), which in turn acknowledges the interrupt by asserting the identity of the highest-priority interrupting device. This scheme avoids the nuisance of daisy-chain jumpers.

In most microcomputer systems it isn't worth implementing the full-blown interrupt acknowledgment just described. After all, with 8-level autovectoring you can handle up to eight interrupting devices without polling, and several times that number with polling. Only in large computer systems, in which you demand fast response with dozens of interrupting devices present, might you succumb to the complexity of the interrupt-acknowledgment protocol. However, it is important to realize that even simple computers may be using vectored interrupt acknowledgment *internally*. For example, the simple 6-level autovector interrupt scheme of the PC104 is actually generated by an interrupt controller support chip that lives close to the CPU and generates the proper interrupt acknowledgment sequence just described (see below).

B. Interrupt masks

We put a flip-flop in our simple keyboard example so that its interrupts could be disabled, even though the interrupt controller chip itself lets you turn off ("mask") each level of interrupt individually. We did that so that some other device could then use IRQ3. For a bus with shared (*level*-sensitive) IRQ′ lines, it is especially important to make each interrupt source maskable, using an I/O output port bit. For example, a printer port normally interrupts each time its output buffer is empty ("give me more data"); when you've finished printing, though, you don't care. The obvious solution is to turn off printer interrupts. Since there might be other devices hooked to the same interrupt level, you must not mask that whole level; instead, you just send a bit to the printer port to disable its interrupts.

C. How the PC104 ISA interrupts got the way they are

The ISA bus was created by the IBM PC's designers, and adopted without change (but with a different connector) by the PC104 consortium. The 8086/8 microprocessor used in the original IBM PC actually implemented the full vectored interrupt-acknowledgment protocol. To keep things simple, however, the PC designers used an 8259 interrupt controller IC on the motherboard. The way it was used in the PC, it had a set of IRQ inputs from the I/O bus card slots (that's where you make your interrupt requests), and it connected to the microprocessor's data bus and signal lines. When it received a request on an IRQ line from a peripheral, it figured out priority and went through the whole business of asserting the corresponding vector onto the data bus. It had a mask register (accessible as I/O port 21h) so that you could disable any specified group of interrupts.

The 8259 let you select (through software) either *level*- or *edge*-triggered interrupts on its IRQ input lines, according to a byte sent to a control register (I/O port 20h). Unfortunately, the PC designers decided to use edge triggering, probably because that makes it a little easier to implement interrupts (for example, you can just connect the real-time clock's square-wave output directly to IRQ0). If they had selected level-sensitive interrupts instead, you would be able to hang multiple interrupting devices on each IRQ′ line, with software polling as described above.

There is a partial solution to this problem. As long as there is an IRQ line available, you *can* combine several interrupting devices on a single PC board, with logic to generate edge-triggered interrupts on that single IRQ line. But, since the interrupting devices have to know about each other, you can't use this scheme for independent plug-in peripherals. Furthermore, you still use up an IRQ line per card, so in a complicated system there will not be enough to go around.

D. Software interrupts

The Intel x86-series of CPUs have an instruction ("`INT n`," where `n` is 0–255) that allows you to produce the same kind of vectored jump as an actual hardware interrupt. In fact, among its 256 possible jump vectors are duplicates of the eight levels of IRQ-requested hardware interrupts (`INT 8` through `INT 15`, to be exact). Thus, you can make a "software interrupt" from a program statement.

Don't confuse this with the externally triggered hardware interrupts we've been talking about. Software interrupts turn out to be a handy way of implementing vectored jumps from user code into system software. But they are not real interrupts, in the sense of a hardware call for attention from an external autonomous device. On the contrary, you build these into your software, you know when they are coming (that's why you can pass arguments through registers), and they are merely the response (albeit identical with what follows a true interrupt) of the CPU to its own code. You might think of software interrupts as a clever way to extend the instruction set.

14.3.10 Direct memory access

There are situations in which data must be moved very rapidly to or from a device. The classic examples are fast mass-storage devices like magnetic and optical disk drives, and network connections. Interrupt-initiated programmed processing of each data transfer in these examples would be both awkward and, worse, too slow. For example, data comes from a typical magnetic disk drive at sustained rates up to 500MB per second. With the bookkeeping involved in handling an interrupt, the situation would be hopeless, even if the disk were the only interrupting device in the system. Devices like disks and tapes (not to mention real-time signals and data) can't stop in midstream, so a method must be provided for reliably fast response and high overall byte transfer rates. Even with peripherals with low average data transfer rates, there are sometimes requirements for short *latency*, the time from initial request to actual movement of data.

The solution to these problems is direct memory access (DMA), a method for direct communication from peripheral to memory. In some microcomputers the communication is actually handled by the CPU hardware, but that doesn't really matter. The important point is that no programming is involved in the actual transfer of data; bytes are moved between memory and peripheral via the bus, without program intervention. The only effect on the executing program is some slowing down of execution time, because DMA activity "steals" bus cycles that would otherwise be used to access memory for program execution. DMA usually involves more hardware complexity in the interface itself, and is not generally used unless necessary. However, it is useful to know what can be done, so we describe briefly what you need to make a DMA interface. As with interrupts, the PC104/ISA bus uses a streamlined DMA protocol, with a "DMA controller" chip on the motherboard doing the hard work for you, thus making a DMA interface relatively straightforward. We first explain the more usual "bus mastership" method of DMA, then the PC104's simplified DMA protocol.

A. A typical DMA protocol

In DMA transfers, the peripheral requests access to the bus via special "bus request" lines (prioritized like the IRQ lines) that are part of the bus. The CPU gives permission and releases control of address, data, and strobing lines. The peripheral then asserts memory addresses onto the bus and either sends or receives data, one byte at a time, according to the strobes it asserts; in other words, it takes over the bus (it becomes "bus master") and acts like a CPU, directing data transfers. The DMA bus master is responsible for generating addresses (usually a block of successive addresses, generated with a binary counter) and keeping track of the number of bytes moved. The usual way to do this is to have a byte counter and an address counter in the interface. These are initially loaded from the CPU, via programmed I/O, to set up the DMA transfer desired. On command from the CPU (via a command bit, written with programmed I/O), the interface makes its DMA request and begins to move its data. It may release the bus between each byte (allowing the CPU to sneak a few instructions in), or it may take the more antisocial approach of keeping the bus for a block of transfers. When all transfers are complete, it releases the bus for the last time and notifies the program that it is finished by setting a status bit and requesting an interrupt, whereupon the CPU can decide what to do next.

Getting data or programs from disk storage is a common example of DMA transfer: the executing program asks for some "file" by name; the operating system software translates this into a set of programmed data OUT commands to the disk interface's control (or "command") register, byte count register, and address register (specifying where to go on the disk, how many bytes to read, and where to put them in memory). Then the disk interface finds the right place on the disk, makes a DMA request, and begins moving blocks of data to the specified place in memory. When it's done, it sets bits in its status register to signify completion and then makes an interrupt. The CPU, which has meanwhile been executing other instructions (or possibly just waiting for data from the disk), responds to the interrupt, finds out from the status register of the disk interface that the data are now in memory, and then goes on to the next task. Thus, programmed I/O to the interface (the simplest kind of I/O) was used to set up the DMA transfer, DMA itself (stealing bus cycles from the CPU) was used for rapid transfer of data, and an interrupt was used to let the computer know the task was done. This sort of I/O hierarchy is extremely common, especially with mass-storage devices; you can expect maximum DMA transfer rates of hundreds of megabytes per second on a contemporary microcomputer bus like PCI express.

B. DMA on the PC104/ISA bus

The PC104/ISA bus, the descendant of an earlier (and simpler) time, has a simpler DMA protocol. A support chip that accompanies the microprocessor includes a DMA controller (an 8237 on the original IBM PC), with built-in address and byte counters, along with the logic to disable the CPU and take over the bus. A peripheral that wants to do DMA, therefore, doesn't have to generate addresses and drive the bus. Instead, it signals the controller (via one of the three DRQ1–DRQ3 "DMA request" lines), which in turn responds by returning the corresponding DACK0–3′ ("DMA acknowledge"). The controller then controls the transfers, asserting address and strobing lines, with the peripheral asserting (or receiving) data to (or from) memory. In this whole process the memory sees nothing unusual going on, since addresses and memory strobes (MEMW′ or MEMR′), normally supplied by the CPU, are supplied by the DMA controller, and if it's DMA *to* memory, data are supplied by the peripheral. The peripheral, on the other hand, knows something special is happening because it requested DMA access (and received confirmation via DACK′); so when the DMA controller asserts IOR′ (or IOW′), the peripheral supplies (or accepts) successive bytes. You might wonder why some innocent bystander peripheral doesn't get hurt in the DMA process, since both I/O strobes and addresses are being asserted, whereas the addresses are in fact the *memory* addresses that go with the memory strobes MEMW′ or MEMR′ asserted by the controller; they have nothing to do with I/O port addresses. The secret is our old friend AEN, specifically added to the bus just to solve this problem. AEN is asserted HIGH during DMA transfers, and all I/O port addressing must be qualified by ANDing with AEN LOW to prevent spurious responses to DMA memory addresses.

Even with the use of a separate controller chip, you still have to set up the starting address, byte count, and direction for the impending DMA transfer. These data go to the DMA controller, which is obliging, having a set of registers that you write (via programmed I/O) from the CPU. It's all pretty straightforward, except for some complexity created by a proliferation of "modes" (single transfer, block transfer, etc.). The PC104/ISA bus has a rather modest DMA capacity, about 2 μs per byte transferred; and, as with interrupts, the PC104 bus is sparse on DMA channels.

14.3.11 Summary of PC104/ISA 8-bit bus signals

Through our examples – programmed I/O, interrupts, and DMA – we've seen most of the PC104 bus signals, which make a "multidrop" tour through the stacked peripherals (Figure 14.18). Table 14.2 lists the full bus, with pin connections. For completeness we summarize them all here, beginning with the ones we've already met.

A19–A0: Address lines Three-state, out from bus master, active-HIGH. All 20 lines are used to address memory (with MEMR′ and MEMW′ as strobes, analogous to IOR′ and IOW′), but only the 16 least significant lines are used during I/O access (64K port addresses); I/O devices should qualify address with AEN LOW.

D0–D7: Data lines Three-state, bidirectional, active-HIGH. Asserted by CPU during memory or I/O write; asserted by memory during memory read or DMA from memory; asserted by I/O port during I/O read or DMA to memory.

IOR′, IOW′, MEMR′, MEMW′: Data strobes Three-state, output only, active-LOW. Asserted by bus master during read or write. On *writes*, data should be latched on trailing (rising) edge, qualified by address; on *reads*, data should be asserted during the strobe (and ready before the trailing edge), qualified by address.

AEN: Address enable Two-state, output only, active-HIGH. Asserted by CPU during DMA cycles. I/O ports must not respond with normal address decoding to IOR′ and IOW′; instead, I/O port that received DACK′ looks at IOR′ or IOW′ to put or take DMA data bytes to or from DATA lines.

IRQ2–IRQ7: Interrupt request Two-state, input only, rising-edge-triggered. Asserted by interrupting device. Prioritized, with IRQ2 highest, IRQ7 lowest. Maskable in the interrupt controller, via CPU write to port 21h. Each IRQ level can be used by only one device at a time.

RESET: Reset driver Two-state, output only, active-HIGH. Asserted by CPU during power-on. Used to initialize I/O devices to known startup state.

DRQ1–DRQ3: DMA request Two-state, input only, active-HIGH. Asserted by I/O device requesting DMA channel. Prioritized, with DRQ1 highest, DRQ3 lowest. Acknowledged by DACK1′-DACK3′.

DACK0′–DACK3′: DMA acknowledge Two-state, output only, active-LOW. Asserted by CPU (DMA controller) to indicate grant of corresponding DMA request.

ALE: Address latch enable Two-state, output only, active-HIGH. The 8088 used a multiplexed data/address bus, and this signal corresponds to the 8088's strobing signal, used by latches on the motherboard to latch the address. Can be used to signal beginning of a CPU cycle; usually ignored in I/O design.

CLK: Clock Two-state, output only. This is the CPU's clocking signal; it's asymmetrical, $1/3$ HIGH and $2/3$ LOW. The original PC used a 4.77 MHz clock, but higher speeds are common. CLK is used to synchronize wait-state requests (via IOCHRDY), in order to stretch an I/O cycle for slow devices.

OSC: Oscillator Two-state, output only. This is a 14.31818 MHz square wave, which can be used (when divided by 4) as a color-burst oscillator for color display.

TC: Terminal count Two-state, output only, active-

Table 14.2 PC104/ISA 8-bit Bus Signals

Signal	Qty	Active	Type[a]	Direction CPU[b] ↔ I/O	Pin #	Function
A[19..0]	20	H	3S	→	A12..21	address (A15..0 for I/O)
D[7..0]	8	H	3S	↔	A2..9	data
IOR#	1	L	3S	→	B14	I/O read strobe
IOW#	1	L	3S	→	B13	I/O write strobe
MEMR#	1	L	3S	→	B12	memory read strobe
MEMW#	1	L	3S	→	B11	memory write strobe
AEN	1	H	2S	→	A11	DMA address signal
IRQ[7..2]	6	↑	2S	←	B21..25, B4	interrupt request
RESET	1	H	2S	→	B2	power-on reset
DRQ[3..1]	3	H	2S	←	B16,6,18	DMA request
DACK[3..0]#	4	L	2S	→	B15,26,17,19	DMA acknowledge
ALE	1	H	2S	→	B28	"address latch enable"
CLK	1	–	2S	→	B20	CPU clock
IOCHCK#	1	L	OC	←	A1	I/O error — makes NMI
IOCHRDY	1	H	OC	←	A10	pull LOW for wait states
OSC	1	–	2S	→	B30	14.31818 MHz
TC	1	H	2S	→	B27	DMA terminal count
GND	4		PS		A32;B1,31,32	signal & power gnd
+5V	2		PS		B3,29	+5V supply
+12V	1		PS		B9	+12V supply
−5V	1		PS		B5	−5V supply
−12V	1		PS		B7	−12V supply

Notes: (a) OC = open-collector; PS = power supply; 2S = 2-state (active pullup); 3S = 3-state. (b) address, data, and read/write lines can be driven by bus master (e.g., during DMA).

HIGH. Tells I/O port that a DMA block data transfer is complete. A DMA device must qualify it with DACK′ for the channel in use, since TC is asserted when any of the DMA channels finishes a block transfer.

IOCHK′: I/O channel check Open-collector, input only, active-LOW. Generates highest-priority interrupt (NMI, "nonmaskable interrupt"); used to signal error condition from some peripheral. CPU figures out who's in trouble by device polling (§14.3.9A); each peripheral that can assert IOCHCK′ must therefore have a status bit that can be read by the CPU.

IOCHRDY: I/O channel ready Open-collector, input only, active-HIGH. The processor generates "wait states" if requested by a slow peripheral (that pulls it LOW) before the second CLK rising edge of a processor cycle (normally four CLKS). Used to extend bus cycle for slow I/O or memory.

GND, +5 Vdc, −5 Vdc, +12 Vdc, −12 Vdc: ground and dc supplies Regulated dc voltages that are bused for use by peripheral interface cards. Check the specifications of the host processor for power limitations, which are machine dependent. Generally speaking, there should be enough power to run anything you can stack onto the PC104 bus.

14.3.12 The PC104 as an embedded single-board computer

The PC104 standardized bus has been implemented in numerous single-board computers (SBCs), with an impressive variety of compatible peripheral cards; these are created by more than 100 manufacturers. These little boards often wind up as *embedded systems*, that is, dropped into instruments as part of their intelligent design. Figure 14.19 shows a view looking down into the access hatch of a complex optical detector system on an astronomical telescope: there's a PC104 SBC, running embedded Linux from its piggyback flash-memory "disk." This particular SBC (from Diamond Systems) includes Ethernet and serial ports (and other stuff not used here). The box on the left is an Ethernet media converter that lets us use optical fiber back to the control room; that's a good idea when your observatory

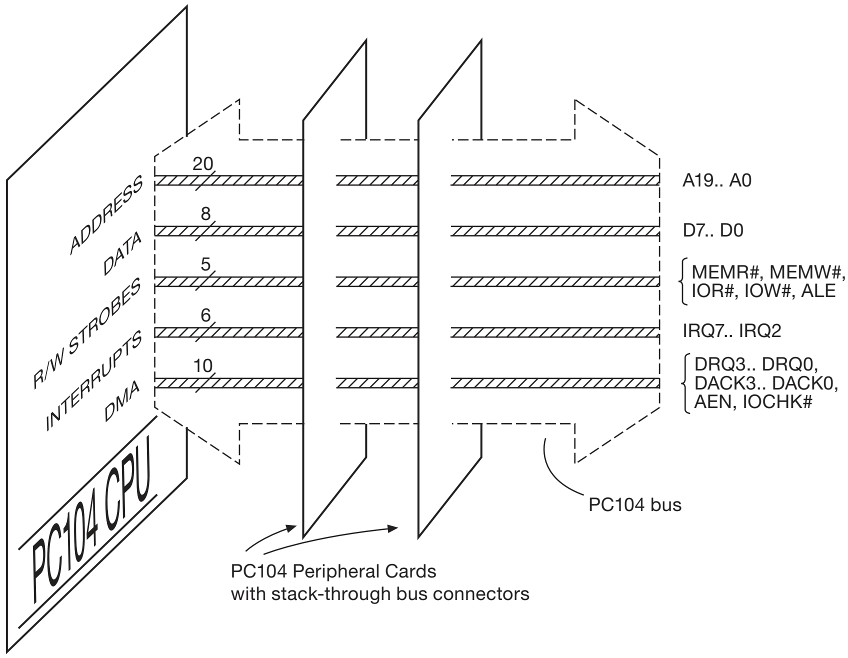

Figure 14.18. The PC104 parallel multidrop bus, making its grand tour.

is on a mountaintop (that's where people build them), because those thrilling lightning displays you get in the summertime can zap everything that is connected by wire cabling.

14.4 Memory types

As we remarked back in §14.1.2, computers need fast "random-access" memory (i.e., memory in which you can get to any data directly, as compared with the sequential access of data stored on magnetic tape), which usually takes the form of *dynamic RAM modules*. These are the skinny circuit boards that plug into memory sockets on the computer motherboard, with typically 240 contacts along the mating edge. The most common variety currently is the "SODIMM" (small-outline dual-in-line memory module, 3×13.3 cm), on which is mounted an array of individual DRAM chips, with module capacities up to several gigabytes (organized as a 64-bit- or 72-bit-wide parallel data path). These are what you want if your task is simply to populate a commercial motherboard – just make sure you have chosen compatible memory modules from the bewildering variety[26] (check the computer motherboard specs and/or the online product finder from manufacturers like Corsair, Crucial, or Kingston).

But there's lots more to know if you want to understand what's going on, and if you want to be able to design your own systems that need memory. In this chapter section we'll discuss the various kinds of memory: static RAM, dynamic RAM, and non-volatile memory types like "flash RAM."

14.4.1 Volatile and non-volatile memory

For many applications there's no need to retain memory contents when power is turned off. A computer, for example, freshly loads its operating system, application programs, and data into working memory during the boot process, so it's OK if that memory is volatile. Those

[26] Characterized by *too many* parameters: form factor (e.g., SIMM, RDIMM, SODIMM), pin count (e.g. 200, 204, or 240 pins), density and data width, ECC or non-ECC, buffered or unbuffered, SDRAM generation (SDR, DDR, DDR2, DDR3, DDR4, DRDRAM), clock speed (e.g., PC3-10600) and data rate (e.g., 1333 MT/s), CAS latency (e.g., CL=4), voltage (e.g., 1.5 V), single or double rank, registered or unregistered, and parity or no parity. There are literally hundreds of choices, most of which will not work in a given motherboard. As a specific example, this footnote is being written into some portion of four banks of 1 GB density 64-bit wide DDR2 PC2-6400 CL=4 (5-5-5-15-2T) 1.9 V unregistered and unbuffered SDRAM with no parity and no ECC, on 240-pin SODIMMs.

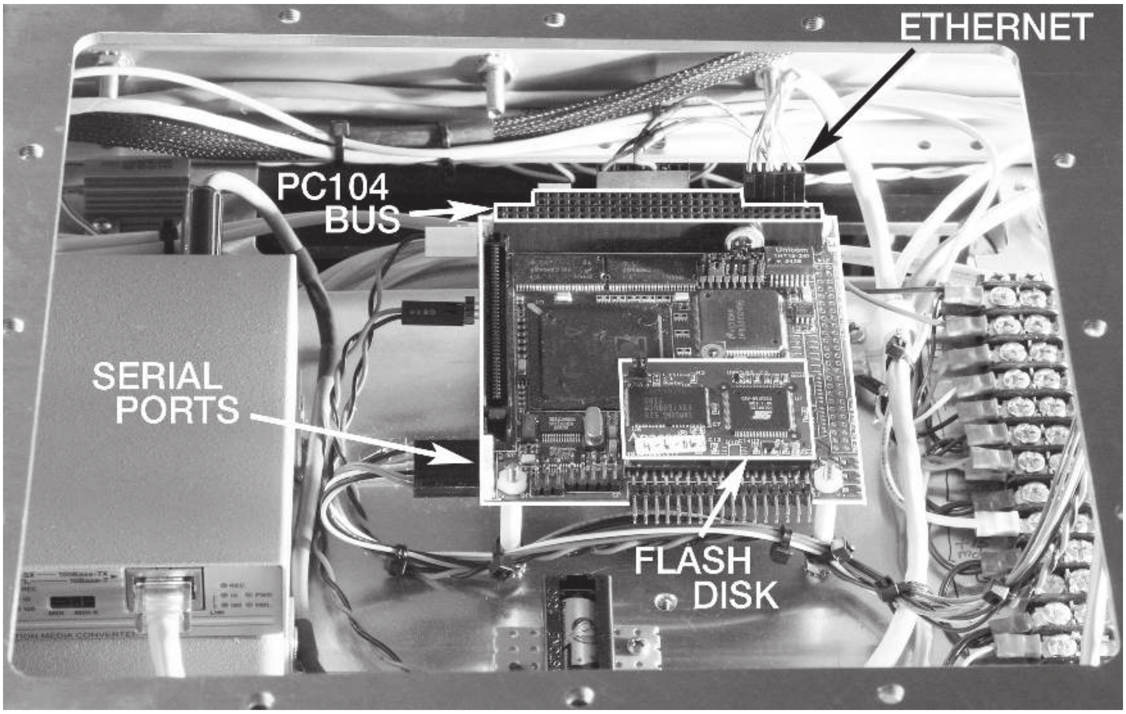

Figure 14.19. PC104 single-board computer embedded in an astronomical instrument.

programs and data must, of course, be retained somewhere when power is off, and that is the function of non-volatile mass memory, usually in the form of a hard disk (rotating magnetic storage) or a "solid-state disk" (a misnomer: it's an array of flash-memory chips, wrapped up in a disk-like enclosure for compatibility).[27] By accepting volatile memory you gain in speed, density, endurance (number of erase/write cycles before wearout), and price compared with those of currently available non-volatile technologies, as we'll see. Both static RAM (SRAM) and dynamic RAM (DRAM) are volatile,[28] whereas flash RAM and EEPROM (along with some interesting new technologies) are non-volatile.

14.4.2 Static versus dynamic RAM

Static RAM stores bits in an array of flip-flops, whereas dynamic RAM stores bits as charged capacitors. A bit once written in a SRAM stays there until rewritten or until the power is turned off. In a DRAM the data will disappear in less than a second, typically, unless "refreshed." In other words, a DRAM is always busy forgetting data, and it is rescued only by periodic clocking through the "rows" of the two-dimensional pattern of bits in the chip. For example, you have to access each of 8192 row addresses in a 1 Gb DRAM every 64 ms (an average rate of one row every 7.8 μs).

You might wonder what would possess anyone to choose a DRAM: by not using flip-flops, the DRAM saves space, giving you more data on a chip and at something like a tenth the cost.

Now you might wonder why anyone would choose *static* RAM (fickle, aren't you?). The major virtue of SRAM is its simplicity, with no refresh clocks or timing complexity to worry about (the refresh cycle competes with normal memory access cycles and must be properly synchronized). Thus, for a small system with only a few memory chips, the natural choice is SRAM. Furthermore, SRAM's zero quiescent current (compared with significant idling current in standard DRAM) makes it desirable for battery-powered devices. In fact, CMOS static RAM, backed up with a battery when main power is off,

[27] In a small system, for example an embedded processor of the kind we'll see in the next chapter, the "mass memory" more often takes the form of a single flash-memory chip, or (better) some flash memory included on the microprocessor ("micro*controller*") chip itself.

[28] The volatile memories have no wearout mechanism – you can read and write to your heart's content.

constitutes an alternative nonvolatile memory (with advantages in speed and endurance). A further advantage of SRAM is its availability in very high-speed versions (access time of 8 ns or less in asynchronous versions; clock rates of 400 MHz or more in synchronous versions). Finally, as we'll see, there is a class of memory known as *pseudostatic* RAM (PSRAM), which combines the low cost and high density of DRAM with the low power and simple interface of SRAM; it might well be described as "a DRAM in SRAM's clothing." Let's take a closer look at both SRAM and DRAM.

14.4.3 Static RAM

Static RAM stores each bit in a flip-flop cell (Figure 14.20): the flip-flop itself consists of a pair of cross-connected inverters (each made from a complementary pair of pMOS and nMOS switches), with two additional nMOS transmission gates to couple it to the outside. The latter are switched on to convey the flip-flop's state to a pair of complementary *bit lines* (which drive a differential latching *sense amplifier*) during a READ, and to assert (overwrite) the flip-flop state (according to the levels present on the bit lines) during a WRITE. This is known as a "6T" (six-transistor) SRAM cell.

As with most varieties of memory, SRAM bit cells on a single chip are organized into multibit "words" that are read or written as a group. Common widths range from 8 bits to 32 bits, often accompanied by additional parity bits (thus 9-, 18- or 36-bit widths). These words are further organized logically into an array of rows and columns, as shown in Figure 14.21, such that the selected word's bit cells are coupled to the respective bit-line pairs (and sense amps) according to the word's multibit address. The figure represents a 4 Mb SRAM (512 k 8-bit words[29]), organized as eight planes (one for each bit) of 1024 rows and 512 columns.

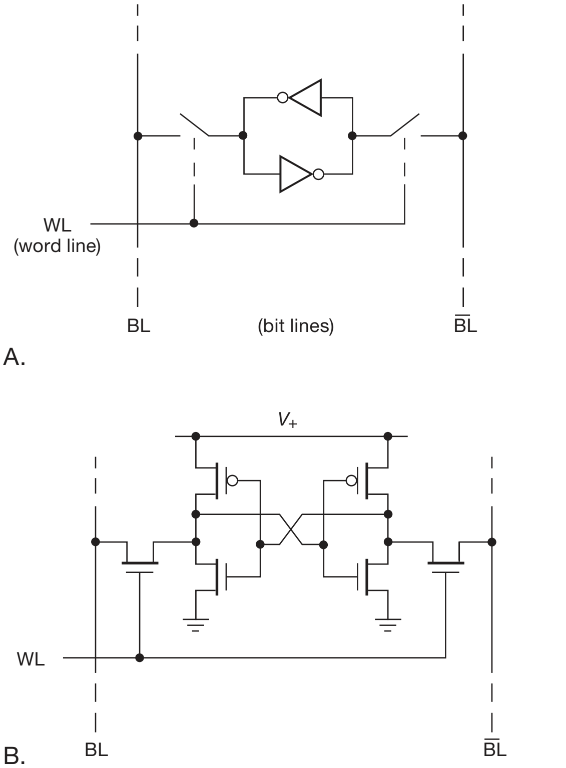

Figure 14.20. Static RAM holds each bit in a four-transistor CMOS flip-flop, read or written by a pair of one-transistor transmission gates. WL, word line; BL, bit line.

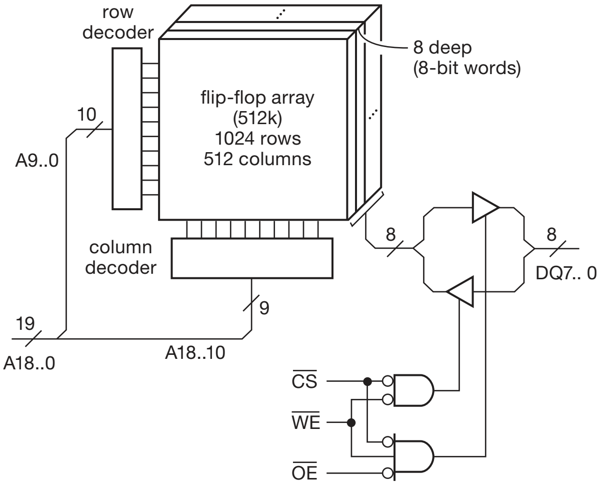

Figure 14.21. Asynchronous SRAM architecture: an array of 6T bit cells with an *n*-bit parallel address, and simple control by WE′, CS′, and OE′. Word widths of 8 bits and 16 bits are most common.

A. Asynchronous SRAM timing

Traditional SRAM is asynchronous, meaning that there is no clocking input; instead, you apply address, data, and control signals with proper timing, and data comes out (READ cycle) or is written (WRITE cycle) accordingly. Using asynchronous SRAM is as easy as falling off a log: to

[29] We follow common usage here, with "Mb" (megabit) signifying 2^{20} bits, about 5% more than a *decimal* million (10^6). Purists prefer to use the prefix "Mi" (pronounced mebi, contraction of "mega binary") to mean 2^{20}, to keep pure the essence of mega as a good old-fashioned million. They would say that this memory is 4 Mib, or half a mebibyte; some would think they are speaking with food in their mouths.

READ a word, you assert the address, chip enable (CE′), and output enable (OE′); the requested data obligingly appears on the three-state data lines a maximum of t_{AA} (address-access time) later. To WRITE a word, you assert address, data, and CE′, then follow (after a minimum of an address setup time, t_{AS}) with a write enable (WE′) pulse; valid data are latched into memory at the end of the WE′ pulse. Figures 14.22 and 14.23 show the actual timing constraints for a fast static RAM (t_{AA}=8 ns, t_{AS}=0 ns), of the sort you might use in a switch or router, or as an external memory cache. The "speed" of the memory is set by the time from assertion of valid address to valid data (for READ) or to completion of the write cycle (for WRITE), assuming the other signals (CS′, WE′, and OE′) are asserted when needed.

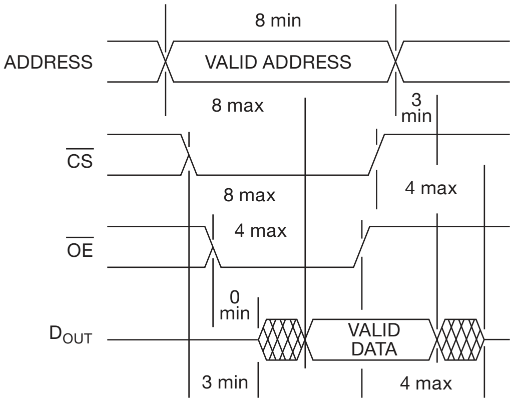

Figure 14.22. Asynchronous SRAM read cycle (during which WE′ is held HIGH). The numbers shown are guaranteed worst-case timings, in nanoseconds, for this 512 kB fast (8 ns) SRAM (Samsung K6R4008V1D-08).

Static RAM is currently available in sizes up to 16 Mb, with word widths of 1 to 32 bits. Variations include memories with separate input/output pins, memories with very low current drain (~1 μA standby, ~1 mA when operating at 1 MHz), and memories with dual-port access (independent address lines, data lines, and control lines, sharing the same stored memory, with "semaphores" for software handshaking between ports).

For whatever it's worth, note that you don't have to hook up SRAM data lines to corresponding numbered data lines of a processor (or any other device needing memory) – you can scramble them any way you want, since they get unscrambled when you read back what you wrote.

B. Pseudo-static RAM

Static RAM has the advantages of a simple control interface and very low power consumption. But its six-transistor

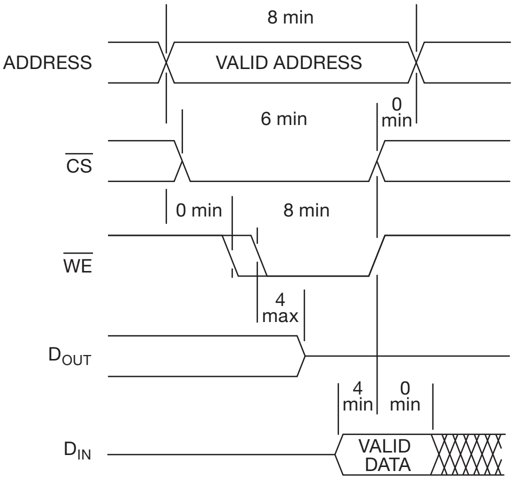

Figure 14.23. Write-cycle timing for the same memory as in Figure 14.22.

cell uses more area than the analogous one-transistor/one-capacitor DRAM cell (discussed below), so it costs more per bit and you can't put as much memory on a chip of a given size. However, the denser and less-expensive DRAM requires periodic refreshing, and, along with its multiplexed address scheme, it presents a more complicated interface.

Pseudo-static RAM combines their best features: it combines a DRAM core with hidden refresh logic, and wraps the combination in an interface that mimics the clean and simple asynchronous SRAM (Figure 14.24). It's a "DRAM in SRAM's clothing." Currently you can get

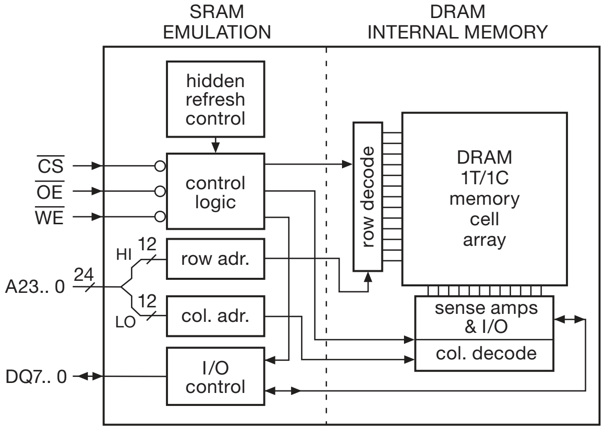

Figure 14.24. "Pseudostatic RAM" looks for all the world like a classic asynchronous SRAM. But its simple external interface conceals the truth: an efficient 1T/1C DRAM core, wrapped in an SRAM-emulating layer of logic (complete with hidden refresh).

PSRAM in densities up to 128 Mb; some are even drop-in compatible with asynchronous SRAM (i.e., identical pinout and function). They have access speeds of ∼50 ns, but faster (∼20 ns) in sequential "page-mode" accesses. (The refresh is hidden from the outside, and fast enough not to interfere at all with the speed or timing of asynchronous SRAM-like accesses. It is completely "invisible.") Because of the hidden refresh activity, the standby current is of order ∼100 μA. There's also a "deep power-down" mode in which the current can be as low as a few microamps; the bad news is that it's so deep you lose the refresh and therefore the stored data.

Although the standby current of PSRAM is significantly higher than the best you can do in micropower conventional SRAM, it's just fine for mobile applications like cellphones, with their typical battery capacity of ∼1000 mAh. The result is that pseudo-static RAM has largely replaced conventional asynchronous SRAM, except for applications like memory caches that require the blazing speed (≤10 ns) of fast SRAM.

C. Synchronous SRAM

In previous chapters we sang the praises of synchronous clocked logic, with its benefits in terms of noise (things have settled down before each clock), predictable performance, pipelined architectures, lack of metastability, and so on. So, why is it that SRAM is *asynchronous*?

It doesn't have to be. You can wrap a synchronous clocked state machine, complete with its data registers, around the intrinsically asynchronous memory-array core. Then you've got *synchronous* SRAM.[30] Because it is clocked, the speed of synchronous SRAM is given as a maximum *frequency*; currently available devices have speeds in the range of 100–400 MHz, and contain from 1 Mb to 72 Mb on a single chip, with word widths in factor-of-2 multiples of 9 bits (i.e., 9, 18, 36, and 72 bits, which include a parity bit with each byte).

Synchronous SRAM (and, even more so, synchronous DRAM, as we'll see) is a more complicated beast than its simple asynchronous sibling: these devices have complex modes, for example double data-rate transfers (using both clock edges, see Figure 14.25) and fancy methods of bursting and interleaving data; so you have to worry about mode bits and the like. And, of course, you've got a pretty fast clock (differential), with data going in and out in steps of just a few nanoseconds. Put another way, synchronous SRAM was devised for the highest speed and throughput, so the blessing of synchronous operation is mixed with the curse of fast clocks and tight timing margins.

14.4.4 Dynamic RAM

As we remarked earlier, you can save a lot of space on the chip by going to a one-transistor memory cell (with the state held on a small capacitor) if you're willing to carry out the periodic refresh of the capacitor's charge. That's dynamic RAM, with its "1T1C" memory cell (Figure 14.26). This is the workhorse of contemporary memory, with sizes of several gigabits per chip, typically supplied as plug-in memory modules with capacities currently up to 16 GB (128 Gb).[31]

As with SRAM, traditional DRAM memory was *asynchronous*, with timing a bit trickier than the simple SRAM, especially when refresh was added to the mix. And, as with SRAM, a synchronous variant (SDRAM) was created by wrapping a synchronous clocked state machine around the intrinsically asynchronous array of DRAM memory cells. One might say that "an SDRAM is an asynchronous DRAM in synchronous clothing." Asynchronous DRAM is history, now. But it's worth looking at, briefly, to understand what's going on inside the now-dominant synchronous DRAM.

A. Asynchronous DRAM

Figure 14.27 shows in simplified form a 16-word by 1-bit asynchronous DRAM, laughably small by any real-world standard, but just right for explaining how it works. The nMOS transistors each have a small capacitor (of order 30 femtofarads) from channel (call it the drain) to ground, and are arrayed as four rows and four columns. The row drivers use the latched row bits (high half of the address) to bring the corresponding nMOS gate terminals HIGH, turning on those transistors and therefore connecting their capacitors to the column lines, which in turn connect to a set of latching sense amplifiers (SA's). The output of one of the sense amps is selected by the latched column bits (low half of the address), passing through the bidirectional multiplexer to the output/input buffer. (Dynamic memory multiplexes the address bits, halving the number of address lines.)

Here's how it works. Let's take a READ cycle first, assuming that the various capacitors (one per bit) have been

[30] And the analogous thing is done with dynamic RAM, as we'll see, creating SDRAM in its many flavors: SDR (single data rate), DDR (double data rate), DDR3, DDR4, etc.

[31] *This* month, anyway; we've been riding Moore's law now for four decades, and we are certain that this will prove hopelessly quaint by the time the ink is dry.

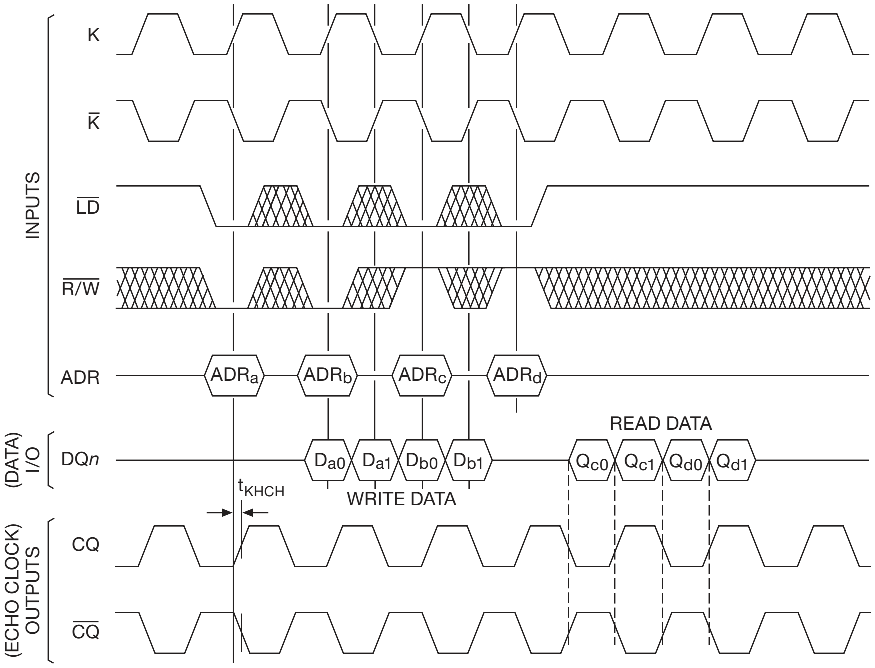

Figure 14.25. Synchronous SRAM timing, with double data-rate (DDR-2) clocking during both READ and WRITE. Data is clocked in two-word (successive addresses) bursts: for WRITE cycles the input data must be presented on both edges of the input clock $K/\overline{K}$, one cycle after the address is loaded; for READ cycles the data emerges 1.5 clock cycles after address loading, on both edges of the "echo clock" $CQ/\overline{CQ}$ (which regenerates the input clock $K/\overline{K}$, with a slight delay t_{KHCH}).

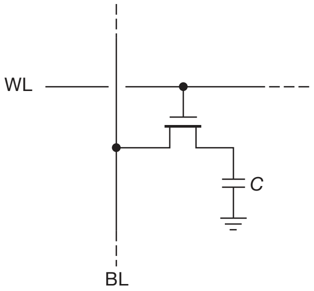

Figure 14.26. Dynamic-RAM "1T1C" bit cell. Each bit is held as a charged ($\sim$1 V) or discharged (0 V) capacitor, whose state is read, written, or refreshed by a bit line (BL) when asserted by a controlling word line (WL). Typically $C \approx 30$ femtofarads (1 fF=10^{-15} F).

previously written, therefore either positively charged (to $\sim$1 V), or uncharged. Look at Figure 14.28, where we've shown the basic (single-address) READ and WRITE cycles for standard 70 ns asynchronous DRAM.[32] The address lines are multiplexed, with the two high-order address bits (row address) asserted first, along with a row-address strobe (RAS′). Those bits are latched, causing the gates of the selected row to go HIGH, turning on the MOSFET transmission gates, and thus coupling the respective capacitors to the column sense amplifiers (SA). The sense amplifiers are latching devices, here drawn notionally as feedback noninverting amplifiers. (In practice they are implemented as flip-flops that begin the cycle in a balanced state and become unbalanced by the bit-capacitor charge that is switched into them.[33]) During this part of the DRAM cycle the sense amplifiers in each column do two things: they latch into the state of the bits that were held in the cells of

[32] There are additional modes, with names like "page mode" and "extended data out," for more efficient access to data from several consecutive addresses.

[33] In a further dose of reality, things are a bit more complicated: the sense amplifiers are *differential*, and the DRAM array is usually built in a "folded-bit" arrangement so that any given row line activates only the even or odd cells; the inactive (neutral) bit line floats at the "precharge" level ($V_{\mathrm{DD}}/2$) and acts as a reference voltage by which the balanced sense amplifier compares the ΔV "bump" up or down from the capacitor's charge in the respective bit cell. The ΔV is quite a bit less than the $\pm$0.5 V you might expect, owing to the additional $\sim$200 fF capacitive loading of the bit line and sense amplifier: in practice, memory designers aim for $\Delta V \geq 100$ mV, for a clean readout of 0 or 1 by the sense amplifier.

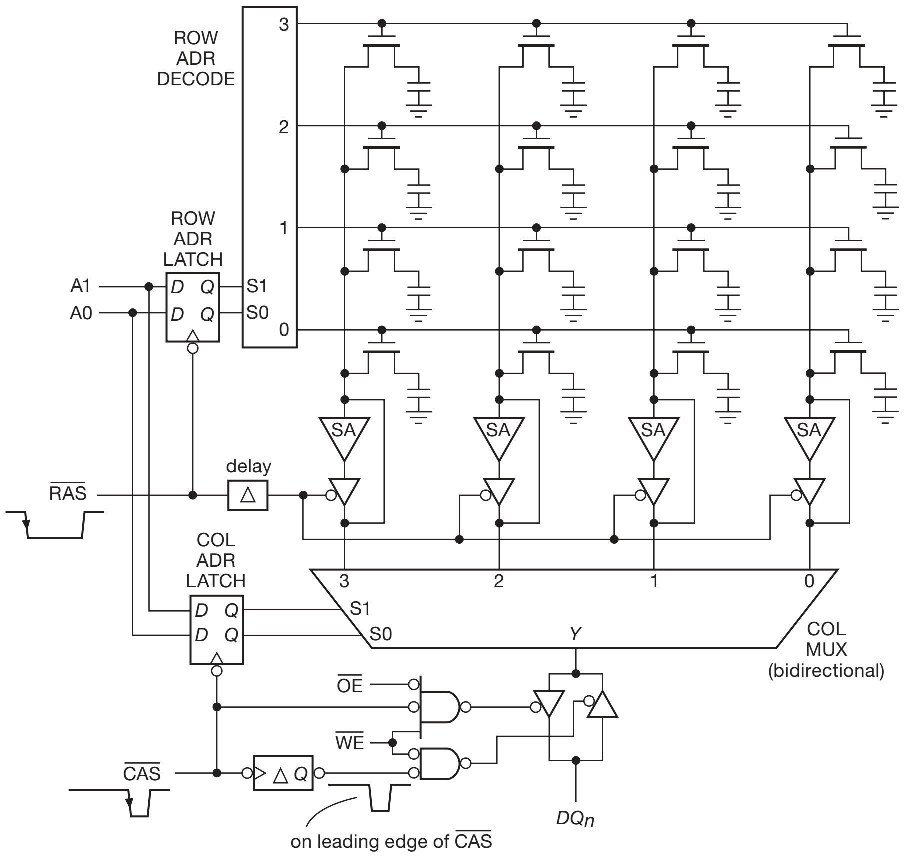

Figure 14.27. Asynchronous DRAM architecture, here illustrated with a tiny 4×4 array of 1-bit "words." The address lines are multiplexed, with row and column addresses registered internally. The latching sense amplifiers (SA's) read (and refresh) the state of the row-addressed bit lines during a READ cycle. During a WRITE cycle they are instead overdriven by the input data on the same shared input/output data line *DQ*0.

the selected row; and they "refresh" those cells by asserting their latched level back onto the respective cell capacitors.

In the second half of the DRAM cycle the address lines carry the two low-order address bits (column address), latched by the column-address strobe (CAS′). That latched address causes the column multiplexer to select the output from the selected sense amplifier, which (because WE′ is disasserted) is asserted onto the bidirectional (input/output) data line (the single DQ0 here, in this 1-bit wide memory; most DRAMs are wider, with word sizes of 4, 8, or 16 bits). The memory is *asynchronous*, meaning (as with asynchronous SRAM) that the valid data appears on the data line(s) with some guaranteed maximum delay time following assertion of the various addresses and strobes. In contrast to the now-universal *synchronous* DRAM (next subsection), there's no master clock.

The WRITE cycle is similar, but with input data and WE′ asserted around the leading edge of CAS′; the WE′ line causes the data line DQ0 to become an input, whereupon the asserted data level forces (overrides) the selected sense amplifier into the state of the data input. That latched state then charges (or discharges) the respective bit cell capacitor.

Look at Figure 14.27 again. Once a row has been activated (in the RAS part of the cycle) and a column has been selected for reading (or writing), there's no reason to repeat the same row address if you want to read (or write) other columns within that same row. That's the idea behind "page-mode" and "extended-data-out" cycles; and it's of great practical utility, because computer memory accesses usually involve bursts of multiple successive addresses (for sequential instructions, data arrays, and so on).

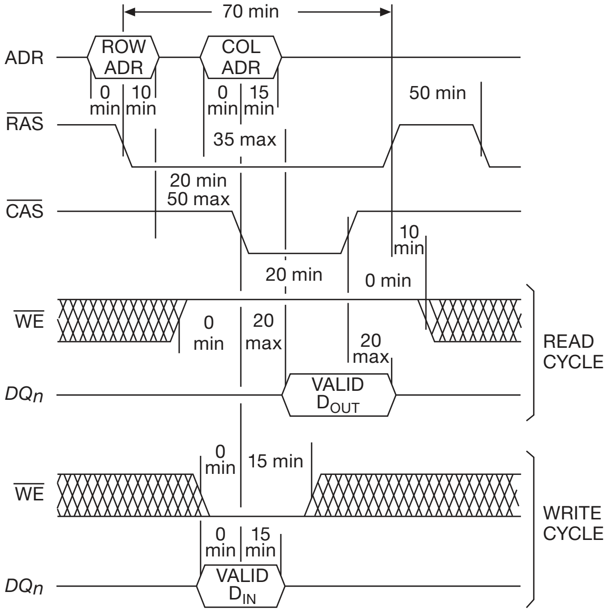

Figure 14.28. Asynchronous DRAM timing. RAS′ and CAS′ are the row and column address strobes for the multiplexed address. As with asynchronous SRAM, data in/out is not tied to a clocking edge; rather, it obeys worst-case timing specifications (here shown for standard 70 ns memory).

B. Synchronous DRAM

As we remarked above, all DRAM currently in common use is of the synchronous variety ("SDRAM"), in which an externally supplied clock signal[34] controls a synchronous state machine that is wrapped around the intrinsically asynchronous DRAM memory core. The original single-data-rate (SDR) SDRAM has evolved through several generations, with names like DDR (double data-rate, i.e., clocking data on both clock edges), DDR2, DDR3, and DDR4. The clock transitions are used for the obvious things: to load the row and column addresses and to clock data in (WRITE) or out (READ). Synchronous DRAM is usually operated in "burst mode," with multiple data words from consecutive column addresses clocked out in sequence (see the MODE description, below).

Unlike asynchronous DRAM, SDRAM is a complicated beast, with a set of "commands" (also clocked) that determine what is happening. These commands are defined by three bits, which rather curiously use the legacy signal names RAS′, CAS′, and WE′ that originated with asynchronous DRAM. Here, however, these three input signal bits, set up before the next clocking edge, determine what happens on that clock edge. Look at Figure 14.29, where we've listed five basic commands. "Activate row" loads a row address, with subsequent "READ" and "WRITE" commands loading a column address and initiating the corresponding data transfer. During such transfers (which may be 4-, 8-, or 16-bits wide, according to the particular chip's architecture), the data moves out or in at the clock rate (SDR, as in Figure 14.29), or at double that rate (DDR), as timed by the clock.

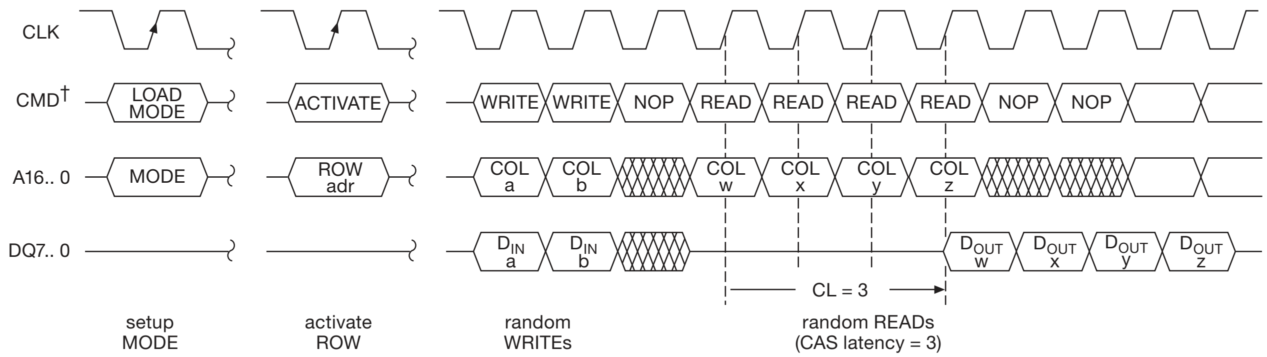
However, note particularly the timing of a READ: although data moves out at the full clock rate, there is a delay (*latency*) of several clock cycles from assertion of the column address to the corresponding data. This is the "CAS latency," illustrated in Figure 14.29 for the case of CL=3. A given memory chip will specify (through its part number) a minimum CAS latency for a specified clock frequency (for example, an MT47H128M8HQ-25E is a 128 MB 8-bit-wide DDR2 SDRAM in a 60-ball FBGA package with CL=5 at t_{clk}=2.5 ns). Because the rest of the system needs to know (and agree on) the actual CAS latency, you tell the chip what CAS latency to use by sending it a "LOAD MODE" command (i.e., a clock cycle, during which RAS′, CAS′, and WE′ are all held LOW), with the mode defined by the bits asserted on the address lines. The mode includes not only the CAS latency, but also bits defining whether it's single-address access or burst mode (for the latter, a choice of two, four, or eight consecutive words), and some other control options that you really don't want to hear about. In a further bit of complication, some varieties of SDRAM (e.g., DDR2) have a clock latency during WRITE cycles; logically enough, that's called "write latency" (WL), which you respect by asserting the data delayed by WL clocks after the column address is clocked in.

Because it is clocked, the speed of synchronous DRAM is given in terms of *frequency*, with labels like "DDR3-1600." That would describe a double-data rate SDRAM, conforming to the DDR3 standard, with data clocked on both edges of an 800 MHz clock. Currently available devices have data rates in the range of 400–1600 MT/s (megatransfers per second), and contain from 1–4 Gb on a single chip, with word widths of 4, 8, or 16 bits. The next generation (DDR4) raises the transfer rate to 1600–3200 MT/s, and raises single-chip densities to 16 Gb or more.

14.4.5 Nonvolatile memory

Nonvolatile memory (NVM) – data storage that is retained in the absence of dc power – is essential in many everyday applications, for example (a) startup ("boot") code, and

[34] At these high speeds it's invariably configured as low-voltage differential: CK and $\overline{CK}$.



†CMD is given by $\overline{\text{RAS}}$, $\overline{\text{CAS}}$, and $\overline{\text{WE}}$:

	$\overline{\text{RAS}}$	$\overline{\text{CAS}}$	$\overline{\text{WE}}$	ADR lines
ACTIVATE ROW	L	H	H	row address
READ	H	L	H	column address
WRITE	H	L	L	column address
NOP	H	H	H	—
LOAD MODE	L	L	L	mode bits

Figure 14.29. Synchronous DRAM uses an external interface whose operations are synchronized by an externally applied clock. The simplest "single data rate" (SDR) SDRAM hijacks the RAS′, CAS′, and WE′ for use as a 3-bit command. Shown here are random (as opposed to *burst*) writes and reads for SDR SDRAM. Burst-mode operation is far more common, with data from several consecutive column addresses being clocked on successive clock edges (or on *both* edges, in the case of the popular DDR ("double-data rate") SDRAM.

various settings, in a general-purpose computer; (b) resident firmware for any device that uses an embedded processor; or (c) temporary storage on a USB "thumb drive" of documents, images, or other files. The semiconductor memories we've seen above are unsuitable, because they lose their stored data when dc power is removed.

One solution to the problem is to provide a battery, so power is never lost. That's "battery backed-up" memory (which is commonly used to store computer settings, where it's sometimes called, simply, "the CMOS"). The good news is that you can use any kind of memory with a micropower data-retaining standby mode (usually static or pseudostatic RAM), which means that you don't need to worry about limitations that afflict many forms of non-volatile memory, for example the leisurely (∼ms-scale) program or erase times, or the endurance (limited number of write cycles, typically $\sim 10^5$–10^6). The bad news is that you've got to provide a battery and make sure it is not discharged.[35]

The other solution is some form of truly non-volatile storage. This is a very active area of semiconductor development, with most current devices using some form of charge storage on a MOSFET's "floating gate" (e.g., the ubiquitous "flash memory" in USB thumb sticks, in all manner of consumer electronics, and in computer solid-state drives known as SSDs). This is impressive technology, with single-chip storage capacities currently up to 1 Tb, data retention of at least 10 years, and retail prices as low as $0.50 or less per gigabyte. But, as we'll see, floating-gate (FG) storage has some drawbacks, notably a finite number of erase/write cycles (endurance) and a relatively slow write (and erase) access time (∼milliseconds); by contrast, standard SRAM and DRAM have unlimited endurance, and equally speedy read and write speeds (∼10s of nanoseconds). Some NV technologies in development may remedy these shortcomings; they go by names like ferroelectric RAM (FRAM), magnetoresistive RAM (MRAM), and phase-change RAM (PRAM).

In the following subsections we describe briefly some of the precursors to current non-volatile memory technology; then we'll look at the 800-pound gorilla in the room, namely floating-gate flash memory.

[35] Not a completely trivial task: we bought four motherboards from a major manufacturer, all of which lose their CMOS settings if incoming ac power is lost for more than a few hours. This is quite an inconvenience (there are roughly 25 settings that must be restored), probably caused by a batch of chips with out-of-spec leakage current or minimum retention voltage.

A. Legacy non-volatile memory

Mask ROM

First there was "mask ROM," which consists of gates with a hardwired connection pattern, built-in from birth, that cannot be altered. It's a fixed lookup table. And it's very much "read-only" (hence "ROM"). This is still a useful method for putting a conversion table, for example, into a custom IC. It's certainly non-volatile; but it's not really what we imagine as useful NV storage.

PROM

Next came programmable read-only memory (PROM), which you can program, once, in the field. It's also called "fuse ROM," because it uses an array of tiny on-chip fuses (metallic or semiconductor), which are selectively blown out to leave the desired fixed memory pattern. The subsequent development of reprogrammable (erasable) NV memory rendered PROM obsolete.

EPROM

Erasable programmable memory came next. Here the bit pattern is held on tiny capacitors, in the form of buried "floating gates" that alter the threshold voltage of the associated MOSFETs (Figure 14.30); this is the same technology as that used in contemporary flash memory. The "control gate" is then used to read out the stored bit: when the floating gate is charged (negatively) with electrons, the threshold voltage is several volts positive, whereas an uncharged floating gate produces a negative threshold voltage (therefore conduction with the control gate at 0 V). Because there's no connection to the floating gate, you use tricks for writing and erasing: to write, negative charge is put onto the gate by a process called "channel hot-electron injection" (CHE), which involves running drain current with elevated drain voltage (12–20 V); to erase you expose the chip to UV light for several minutes, which erases the entire chip at once. The erase process requires a transparent quartz window to let the UV light in (hence the alternative name, UV EPROM); the associated hermetically sealed ceramic packaging makes these things expensive, and large. And, they had to be removed from the circuit for erasure and reprogramming. These were made obsolete by in-circuit *electrically* erasable non-volatile memory.

OTP EPROM

What a magnificently self-contradictory name: "One-Time-Programmable Erasable Programmable Read-Only Memory! (Engineers *do* have a sense of humor, though perhaps a bit twisted.) OTP EPROM was the answer to the problem of EPROM packaging cost, namely, to put a UV-erasable EPROM in an inexpensive plastic package. The only (!) drawback is that the package is opaque, so you can't erase the thing. What we did, in those days, was to buy one or two of the pricey UV EPROMs, use them to develop and test the program, then program the plastic parts with the fully debugged code. These devices, too, became obsolete with the development of electrically erasable non-volatile memory.

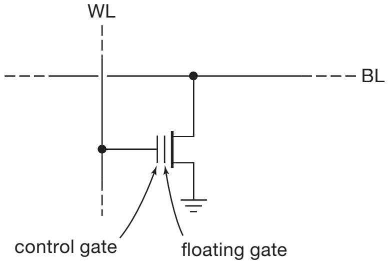


Figure 14.30. "Floating-gate" bit cell, used in non-volatile memories such as EEPROM and flash ROM. Data is written to the floating gate by tunneling or hot-electron injection; its charge alters the threshold voltage, as read out by the control gate and bit line. The leakage currents out of the floating gate are so low that data is retained for at least ten years, requiring no power or refresh.

B. Electrically-erasable non-volatile memory

EEPROM

The modern era in non-volatile memory was ushered in with the electrically erasable programmable read-only memory[36] (EEPROM, or "E-squared"). No more UV sunbaths! No more removing and replacing the ICs – these puppies are *in-circuit* reprogrammable! The trick here is to use elevated voltages to discharge the floating gate, by a quantum-mechanical phenomenon known as *tunneling* (in which a particle, here an electron, with insufficient energy to overcome the potential barrier of the gate insulator can, under the right circumstances, just magically appear on the other side[37]). It's officially called Fowler–Nordheim tunneling, usually abbreviated F-N. EEPROMs include on-chip charge pumps to generate the elevated voltages needed to program like UV EPROMs and to erase via F-N

[36] Another name is EAROM – electrically alterable read-only memory.

[37] A macroscopic analogy: you need to get your oxcart over the Khyber Pass, but, because of poor planning, you lack an ox. Hoping for a miracle, however, you give the cart a shove. There is, according to quantum mechanics, a finite probability that the cart will vanish from your hands, and reappear on the other side of the pass. For oxcarts the probability is awfully small (and that's a real understatement!); but it works fine for electrons hoping to find their way to the buried gate.

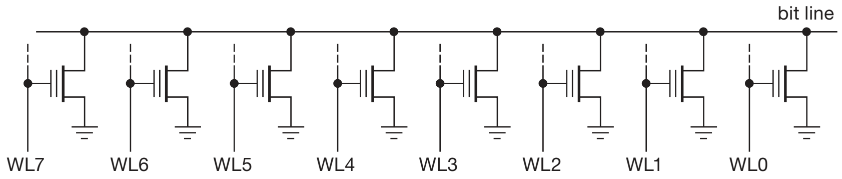

Figure 14.31. NOR flash memory, with its parallel arrangement of bit cells.

tunneling. Voilà – *in-circuit* programming (i.e., writing) and erasing.

EEPROMs use a memory-cell configuration (for example, a two-transistor bit cell) that permits bits or words to be erased and reprogrammed individually. That's a nice flexibility, but the circuitry that allows this flexibility takes up space that could be used for additional storage. The subsequent development of *flash* memory exploited a one-transistor bit cell, with its higher density (see flash memory, below); the price you pay is that erasure is carried out in much larger *blocks*, by way of their substrate contact.

EEPROMs, in common with flash memory, have a limited endurance, usually in the range of 10^5–10^6 erase/write cycles. Erasure and writing are slow (∼10 ms), compared with reading (∼100 ns). They have been largely superseded by flash memory. However, the flexibility of single-byte (or even single-bit) rewritability makes EEPROMs well suited for retaining small amounts of data, for example calibration parameters (think of a bathroom scale's strain gauge), settings (that scale, again: pounds or kilograms), or lookup tables (still thinking of that scale…which needs correction for ambient temperature). EEPROM for those kinds of applications is usually included on the same chip as the microcontroller itself (see Chapter 15). You can get standalone EEPROMs, also; these usually use a serial protocol (SPI, I^2C, UNI/O, Microwire), so they fit in a tiny package (SC-70, DFN, etc.). There's a good selection from companies like Atmel and Microchip, with densities from 128 bits to 1 Mb. They're inexpensive, too – a 1 kb I^2C EEPROM costs $0.17 in quantity, and twice that for a 64 kb part.

The EEPROM's intrinsic flexibility (erase/write individual bits or bytes) requires more silicon than the denser flash memory, with its *sector*-wide erase/write. Let's take a look.

C. Flash memory

Flash memory discards the bit or byte writability of EEPROM, instead performing block-sized erase. The good news is that it's faster (it erases "in a flash," hence the name), if you want to erase many bytes. The bad news is that you cannot modify smaller amounts of data (though external logic, with some SRAM, can fake it so that you don't realize what's going on inside). But the big news is that the chip is denser, particularly in the form known as NAND flash, so you get a lot of memory on a single IC (up to 1 *tera*bit, currently; though the innards aren't an honest "chip," but rather a "stack" of thinned chips). Currently available flash memory comes in two flavors, called NOR and NAND.

NOR flash

Figure 14.31 is a simplified view of the bit-cell arrangement used in NOR flash memory, which was the original flash architecture. Because the storage transistors are in parallel, you read out by gating off all except the selected transistor. The floating gate cells are programmed via channel hot-electron injection (the same as with EPROM). However, as with all varieties of flash memory, erase must be done a block (or "sector") at a time, with the block's elevated substrate voltage causing F-N tunneling from the floating gates. Typical block sizes are 4–64 kB, often flexibly configured with several different block sizes on one chip. NOR flash uses a simple parallel SRAM-type interface (sometimes providing a choice of asynchronous or synchronous modes), and can be used directly to hold executable code. Note, however, that the limited endurance, as well as the sector-size erase, means that the executable code must treat the memory as read-only. Currently available NOR flash devices come in densities from about 1 Mb–1 Gb.

NAND flash

By contrast with NOR, the designers of NAND flash intended it as a dense mass-storage device, more akin to a magnetic hard drive. It's the memory that's used in USB thumb drives, compact flash (CF) cards, secure digital (SD) cards, solid-state drives (SSD), and the on-chip code memory used in microcontrollers (μC; see Chapter 15). The name NAND derives from the series connection of bit cells (Figure 14.32), which are read by holding HIGH all gates except the selected transistor; the selected transistor then determines the conduction of the series string, according to the charge on its floating gate. Both erasing and writing use tunneling; erasing is done in sectors. What's not obvious is the greater density you get with a series connection: no space-hogging source or drain contacts are needed, except at the ends of each string. To keep the pin count down, NAND uses a serial command interface; and, like NOR flash, it erases in sectors. Note, however, that a device like a USB thumb stick includes a memory controller, so that the electrical and timing details of erasing and data read/write are invisible to the external interface. Likewise, the specification for SD flash cards requires that they include not only the native SD interface protocol, but also the standard SPI (serial peripheral interface) protocol that is included in most contemporary microcontrollers.[38] Memory controllers used for flash storage devices do more than merely obey the rules: they use tricks like "wear leveling" (cycling through different blocks of storage to minimize reuse) to circumvent the endurance-limiting effects of insulator damage caused by tunneling; and they detect bad and degraded cells, whose addresses they then write to locations in sector 0 of the memory chip so that future memory accesses are diverted to spare cells.

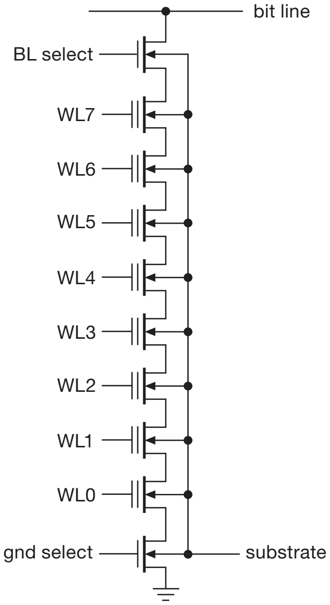

Figure 14.32. NAND flash memory, with its series arrangement of bit cells.

In a daring ploy to multiply memory density, manufacturers of NAND flash are using what's politely called "multilevel cell" (MLC) or "triple-level cell" (TLC) storage. Put bluntly, this means putting partial levels of charge on the floating gate, which are then read out by measuring the approximate threshold voltage. Current implementations use four (MLC) or eight (TLC) levels, therefore 2 or 3 bits per transistor. (Should we call this a "$\frac{1}{2}$T" or "$\frac{1}{3}$T" cell?!) This is scary stuff – your precious data is held on partially charged tiny floating gate capacitors, whose level of charge must not change too much during the next few years. To get a sense of the scale, the roughly 0.3 femtofarad capacitance must not leak (or acquire) more than ~3000 electrons in, say, 3×10^8 seconds (ten years). That's one electron per *day*! It's a miracle the stuff works at all.[39]

Currently available NAND flash comes in densities up to 1 Tb per IC; to get those densities, the manufacturers use 2-bit MLC storage, and multiple chip stacking within one IC package. To us, it is astonishing that a single IC can hold the equivalent of 16 bytes of information for every person on Earth.[40]

D. Future non-volatile memories

Flash memory is great stuff. But it has finite endurance, and the erase/write process is slow. An ideal non-volatile memory would be "SRAM without the volatility." That is, it would have random read and write access at full speed, unlimited endurance, and long retention.

There are several technologies being explored; the following appear to be the most promising.

Ferroelectric RAM (FRAM, FeRAM, or F-RAM)

A ferroelectric material is the electric analog of a ferromagnetic material; that is, it holds the state of electric polarization. The idea is to make a 1T1C-style DRAM bit cell, but with the capacitor replaced with a thin film of ferroelectric material (e.g., a few atom layers of strontium bismuth titanate). You write a bit as with DRAM, applying a field across the film. Readout is different, however: you read "destructively," by sensing whether a write changed the state (producing a pulse of current); then you restore the state.[41] FRAM potentially can deliver random

[38] The actual protocol that goes over the SD-card SPI interface isn't trivial, because it must support memory operations such as read, write, erase, check status, and so on. But it's straightforward, and you can get libraries for popular microcontrollers such as AVR and ARM (see Chapter 15).

[39] But it *does*! The several gigabytes of figures and text for this book edition made many journeys between office and home, in the form of partially charged femtofarad bits.

[40] We predict, with considerable confidence, that by the time you read this the bytes/IC will have increased far more than the people/Earth.

[41] This is analogous to the method used with the magnetic-core memory of yesteryear, in which the core's state was read by forcing it to a

read and write speeds of $<$50 ns, many-year retention, and very high endurance. Companies like Fujitsu and Cypress are currently manufacturing FRAM, offering serial interface devices (SPI and I^2C) to 2 Mb with claimed endurance of 10^{14} cycles, and parallel (asynchronous SRAM-emulating) devices to 4 Mb. An example of the latter is the MB85RE4M2T, with specified random read and write cycle times of 150 ns, ten-year retention at 85°C, and (drumroll) endurance of 10^{13} read and write cycles (that's 300 years, at 1000 read/writes per second.

Magnetoresistive RAM (MRAM)

Magnetoresistance is the change of electrical conductivity of a material under an applied magnetic field. Variations of the effect ("giant magnetoresistance," "colossal magnetoresistance," "tunnel magnetoresistance") are used in magnetic disk readout heads, an improvement over the traditional coil-based readout (which generates a voltage proportional to *changes* in flux, rather than to flux itself) that has led to an explosion in hard-disk capacity. It's possible to fabricate tiny on-chip magnetoresistive cells (complete with some ferromagnetic material), written by pulsing a current, and read out by its magnetoresistance.

MRAM has been "in development" for many years, with some recent production parts. For example, Everspin (spinoff from Freescale) offers 8-bit and 16-bit word size MRAMs, with densities to 16 Mb. Their MR2A16A, for example, is a 4 Mb 16-bit-wide non-volatile MRAM, with a standard asynchronous SRAM parallel interface. It has specified read and write cycle times of 35 ns, 20-year retention, and (big drumroll) claimed "unlimited" endurance; it costs $20 in unit quantity. Other companies involved in MRAM include Hitachi, Hynix, IBM/TDK, Infineon, Samsung, and Toshiba/NEC (where a 1 Gb MRAM is rumored). MRAM is not cost competitive with flash, by a long shot; it's still at the starting gate – but it's worth keeping an eye on.

Phase-change RAM (PRAM or PCM)

Certain metallic alloys ("chalcogenide glasses") exhibit a large difference of electrical resistance between their crystalline and amorphous (glass-like) states. This can be exploited to make memory cells, in which the phase-change alloy is heated in controlled ways to convert between the two states. Heating sounds like a slow and diffuse process, but at the small scales here (tens of nanometers) things happen locally, and in tens of nanoseconds. Phase-change memory is being pursued by companies like Samsung, Micron, IBM, and STMicroelectronics, and some prototype samples have been shipped (e.g., a 128 Mb, 90 nm PRAM from Numonyx). No claims of unlimited endurance, yet; but PRAM potentially offers high-density non-volatile memory with fast read and write cycle times.

14.4.6 Memory wrapup

Encapsulating the long-winded narrative above, we can summarize the current state of memory and its usage this way.

- Much of the time the problem has been solved for you.
  - Microcontrollers (Chapter 15) include on-chip memory, both flash (for non-volatile program storage), SRAM (for working memory), and, often, EEPROM (for parameters, tables, etc.).
  - Computer motherboards are configured to use fast SDRAM, as plug-in SODIMM (or other form-factor) cards; just follow instructions and you'll be fine.
  - Field-programmable gate arrays (FPGAs) without on-chip flash are configured to accept a configuration code from an attached serial flash memory, well specified in their datasheets.
- The simplest volatile memory is asynchronous SRAM, or its popular look-alike, pseudo-static RAM. Standard SRAM and PSRAM speeds are ∼50 ns, with "fast" SRAM speeds around 10 ns; the latter are good for external cache memories, while the former are still used in niche applications like high reliability medical electronics. Micropower SRAM can retain data at standby currents of ∼1 μA, and, for leisurely applications, run at currents of ∼1 mA.
- Synchronous SRAM has a more complicated interface, but runs at high clock speeds (to 400 MHz, combined with double data rate); good for external cache.
- Synchronous DRAM, in its double data rate varieties, is the favorite for fast computer working memory. Generally used as plug-in modules, but can be used as bare ICs, for example in conjunction with an embedded microprocessor (or FPGA with internal microprocessor core) in a stand-alone application like a wireless router, game console, display panel, or set-top box.
- Flash NAND is the current winner for dense non-volatile storage, and dominates in modules (USB thumbsticks, CF and SD cards) and as a hard-disk replacement (SSD), as well as for on-chip (microcontrollers, and application-specific ICs) and on-board (consumer electronics, video, network, etc.) applications. A particularly easy-to-use

known state, sensing if there was a change of state, then restoring (if needed) the original state.

form is provided by serial-interface flash, both as standalone ICs and, pleasantly, in the form of the SD card (which has an SPI-compatible interface); you can hook these serial memories directly to most microcontrollers, which include an integrated 3-wire SPI port.

- Flash NOR has the merit of a standard asynchronous SRAM interface, so you can substitute them for SRAM and execute read-only code directly.
- The byte rewritability of EEPROM is well suited to storage of parameters and tables, particularly where only a modest amount of data is involved.
- There is hope, in some recent technologies, for finding memory's holy grail: full-speed non-volatile memory with unlimited endurance. (We had that, a half-century ago, with magnetic-core memories. They're OK, if you're happy with cycle times measured in microseconds, densities measured in kilobytes, and prices in kilodollars. But, we've become jaded by the dazzling speed, density, and low cost of semiconductor memory; there's no going back... .)

14.5 Other buses and data links: overview

The PC104/ISA peripheral bus that we've seen in detail exemplifies a *parallel* multidrop bus architecture, with a group of shared DATA lines, ADDRESS lines, and some STROBE signals that signal direction and timing of data transfer (along with additional lines for interrupts and DMA). It originated more than 25 years ago, and has been superseded by faster and wider parallel buses, notably the PCI and PCIe[42] peripheral buses used in contemporary PCs.[43]

But the generality of a parallel data bus extends far beyond the innards of computer motherboards. Parallel data transfers, sharing the PC104's concepts of data–address–strobe, are used more generally in electronic devices for data transfer among devices such as liquid-crystal displays, video processing chips, and analog/digital converters, as we'll illustrate shortly. These connections between circuit devices often omit cumbersome addressing, and are better thought of as parallel data *links*. True parallel buses, however, can also extend to *external* data-hungry peripherals such as tape and disk storage, or test and measurement instrumentation, in the form of the SCSI or general-purpose interface buses (GPIBs).

And then there are the increasingly popular *serial* buses and data links, going from the simple (and slow) legacy RS-232 ("COM" port), to the fast USB and FireWire protocols. Serial links send their data bits sequentially, rather than as a byte-wide (or more) wholesale multibit transfer; so you might expect them to suffer in speed. Remarkably, however, fast serial protocols recover most of that speed by using low-voltage differential signaling at very high bit rates. A fine example is the evolution of the 16-bit ATA (also called IDE, or PATA) parallel disk link (a total of 40 wires, in the once-familiar ribbon cable) into a serial "SATA" link with just two pairs in a skinny cable. The SATA link is actually the *faster*: it can transfer up to 6 gigabits/second, whereas the now-obsolete "PATA" tops out at 1 gigabit/second.

More speed in a *serial* link – how can that be? Differential low-voltage signaling certainly helps, but there are two additional factors favoring serial links like SATA: (a) such links are "point-to-point" (one driver at the transmit end and one receiver at the other end), rather than "multidrop" (one driver somewhere on the bus and multiple receivers along the bus); and (b) unlike a multiwire parallel bus, a single serial line has no timing *skew* (the scatter of propagation times between the clock lines and the several data lines). These factors really matter at contemporary data rates of gigabits per second: (a) At such speeds the bus lines are electrically "long" (electrical signals travel ∼20 cm in a nanosecond in cables and on circuit boards), and so you've got to think of bus wires as *transmission lines* (Appendix H), on which multiple taps (called "stubs") act as impedance mismatches and generate a sequence of reflected signals; by contrast, a point-to-point connection has but one recipient, permitting good impedance matching. And, (b), at these speeds the unavoidable timing skew sets an upper limit on data clocking rates (as revealed by an "eye diagram" – Figure 14.33) in parallel buses, nicely circumvented in serial links in which the clock is recovered from the data stream itself. As it turns out, the advantages of controlled impedance and absence of timing skew outweigh the advantages of parallelism.

This move from parallel (and multidrop) to serial (and point-to-point) is seen broadly: in computer buses (PCI → PCIe), in disk interfaces (PATA → SATA; SCSI → SAS), in Ethernet cabling (coaxial multidrop → twisted-pair point-to-point), and in external buses (e.g., GPIB → USB). In addition to performance benefits, these serial

[42] PCIe is a hybrid: serial communication on a set of parallel "lanes."

[43] The latter are considerably more complex; we chose the PC104/ISA for its simplicity, and also because it is well supported in contemporary PC104 offerings, which will likely ensure its survival well beyond the lives of its forgotten contemporaries. The latter had names like Unibus, STD bus, EISA bus, MicroChannel, Q-bus, Multibus, VAX BI, NuBus, Futurebus, and Fastbus.

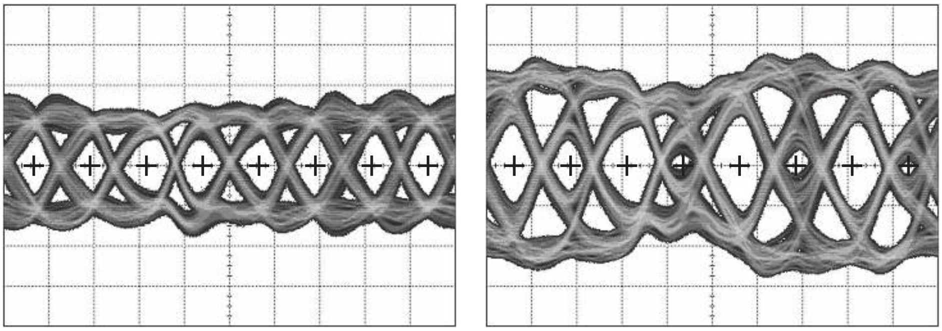

Figure 14.33. An *eye diagram* is formed from persistent ’scope captures of the voltage on a single data channel, triggered by the clock (whether recovered by the receiver or transmitted along with the data). This actual ’scope capture shows the signal at the far end of a 60 cm length of 0.085″ semi-rigid coax, driven by an 11.2 Gb/s (!) pseudorandom data stream. Left: with transmit equalization – the open “eyes” indicate adequate signal margin at the equally spaced clocking points (indicated with a “+” symbol). Right: without transmit equalization – a good example of a bad eye. Horizontal: 71.4 ps/div; vertical: 125 mV/div, differential. Oscilloscope bandwidth should extend to the 3rd (or even the 5th) harmonic of the clock frequency to display an accurate eye diagram. (Courtesy Hayun Chung.)

links are less expensive, with their small connectors and cabling.

Note that these serial links, though lacking address lines, can act logically like classical addressed buses, by streaming addressing bits along with the data. Examples are USB, FireWire, SAS (serial attached SCSI), and eSATA (external SATA).

Finally, serial protocols are commonly used for communication between ICs; these have names like SPI (Serial Peripheral Interface), I^{2}C (Inter-IC), and JTAG (Joint Test Action Group).

Table 14.3 provides a helpful (we hope) organization and summary of the characteristics of commonly used data buses and links. In this section we’ll look at these buses and data links, with examples to put some meat on the bones.

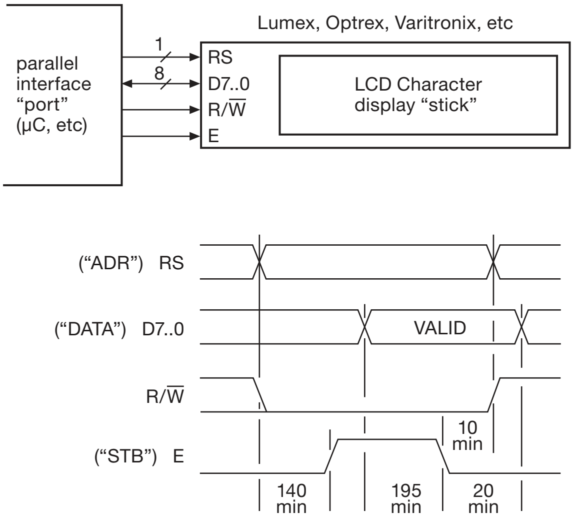

Figure 14.34. LCD module with parallel interface, with WRITE-cycle timings (in ns). The READ cycle is similar, but with R/W′ asserted HIGH (and D7..0 asserted by the LCD).

14.6 Parallel buses and data links

14.6.1 Parallel chip “bus” interface – an example

The familiar LCD “character displays” that you see on many devices originated with a simple parallel bus, which has become a standard (they now come also in serial bus variants). It is very simple: 8 DATA lines (D7..0), 1 (!) ADDRESS line (“RS”), a R/W′ line, and a data STROBE (“E”). The DATA lines are bidirectional; the other three are one-way, as shown in Figure 14.34. The 1-bit RS (address) selects either the display’s internal *instruction* register (adr=0) or its *data* register (adr=1). We saw these earlier, in Chapter 12 – see, for example, Figure 12.78.

The operation is simplicity itself: a character is written to the display by setting its target address to the data register (RS=1=HIGH), asserting R/W′ LOW, then putting its *character code byte* on the DATA lines and pulsing the strobe line E. The display is then “busy” (which you can find out by doing a READ from address 0: the BUSY flag is returned as bit D7); you can send the next character when BUSY becomes false.

That’s how you send characters. You can also do things like clearing the display, advancing the cursor, or determining where successive characters are displayed, by writing *command bytes* to the instruction register (adr=0). For example, writing 01h clears the display; writing 10h moves

Table 14.3 Common Buses and Data Links[a]

	Par/Ser	PP/MD[b]	Mb/s (max)[d]	Devices per ch	Address bits	Length max (m)	Hot swap?	Used for	Comments
computer internal									
PC104/ISA	P8,16	MD		-	20, 24	-	N	peripheral cards	original IBM PC/XT (ISA), in PC104 format
PCI	P32,64	MD	1000, 2000	-	32	-	N	peripheral cards	obsolescent

USB 3.0	S	PP	4800	127	-	3	Y	...including solid-state drives	full-duplex on added SuperSpeed pairs
Ethernet	S	PP	10, 100, 1000	1	48	100[h]	Y	computer network	original coax was multi-drop
WiFi	S	PP	6 to 54, to 600[i]	1	48	180	Y	wireless ethernet	IEEE 802.11a, g, n
Bluetooth	S	PP	1, 2, 3	8	48	10	Y	wireless perhiperals	range: 1m at 1mW to 100m at 100mW
Zigbee	S	MD	0.045, 0.25	240[j]	64	30	Y	small nearby wireless devices	15-hop mesh network, IEEE 802.15.4
CAN	S	MD	1.0, 0.01	64	note k	1k, 40	Y	auto, factory floor, lab	8-byte payload per packet
LIN	S	MD	0.02	16	note l	40	Y	automobile	one wire, sub-network under CAN
inter-chip									
parallel[c]	P4,8,16	MD	to 3000	NA	-	-	-	general purpose, fast	
LVDS	S	PP	to 6000	NA	-	-	-	IC to IC, backplane, fast	
I^2C / SMBus	S	MD	0.01,0.1,0.41,3.4	112	7	-	-	IC to IC, addressable	2-wire bidirectional, with handshake and adr
SPI	S	MD	>20[g]	1	-	-	-	simple IC to IC	4-wire, full-duplex, no handshake, no address
JTAG	S	PP	~100	many	7	-	Y	diagnostic, program loading	IEEE 1149.1
1-wire	S	MD	0.1	many	64	100	Y	sensors	Dallas; power and data on one line!

Notes: (a) there are more! these are commonly used, and likely to endure. (b) PP= point-to-point, MD = multidrop. (c) generic, no standards. (d) assumes no overhead. (e) PCIe uses multiple parallel "lanes" of unidirectional serial links; the number of lanes is written "Xn": X1, X2, X4, X8, X16. Each lane accommodates 4 or 6 Gb/s. (f) yes for SCA-2 connectors. (g) chip dependent, no established standard. (h) 100base-Tx. (i) four 64-QAM spatial streams, 40 MHz channel width. (j) up to 65534 is possible. (k) with DeviceNet protocol layer. (l) communication initiated by master.

the cursor one character to the left; and writing 06h specifies that each successive character is written to the right of the previous character. The same protocols are used in a compatible display variant that substitutes a handsome "vacuum-fluorescent" technology. See §12.5.3; or take a look at §15.10.4 to see a frivolous example.

14.6.2 Parallel chip data links – two high-speed examples

The LCD hardly needs the extra speed of a parallel bus; in fact, its interface permits byte transfers to be carried out as two successive half-byte (4-bit "nybbles") transfers. But sometimes you really need the speed, for example with a really fast digital-to-analog converter like the one shown in Figure 14.35. The 8-bit AD9748 DAC converts at rates up to 210 Msps (megasamples/sec), so you've got to feed it new bytes every 5 ns. The chip obliges by having a byte-wide input port, combined with a differential clock input that accepts high-speed LVDS (low-voltage differential signaling). Unlike the LCD, this is not a *bus* in any sense, because there's no bidirectional communication and no addressing (not even a chip select or enable pin, as with the LCD). Note the speedy timing, with setup and hold times of 2.0 ns and 1.5 ns.

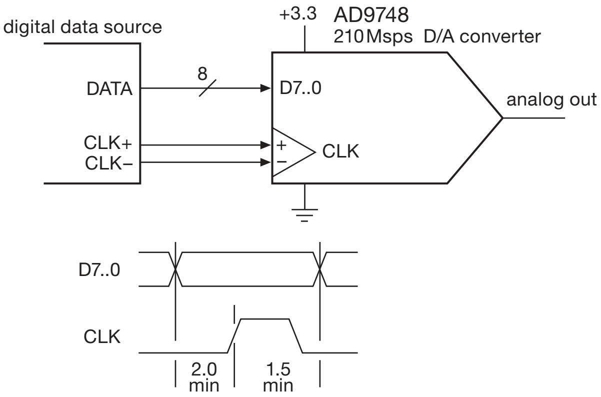

Figure 14.35. Fast parallel data link to a 210 Msps DAC.

Figure 14.36 shows another example with similar speed requirements – a video encoder chip that can handle the full bandwidth demands of high-definition video – but additionally with the need to specify literally hundreds of associated video parameters (such as video input and output formats, color and contrast corrections, test patterns, and so on). So, it has a 16-bit wide parallel input port, with frenetic nanosecond-scale setup and hold times. But it also has a leisurely serial port, which can accept either the I^{2}C or SPI serial protocols and which provides access to the ∼250 internal byte-wide configuration registers for setup. This hybrid approach takes advantage of the flexibility and compactness of a serial bus, while at the same time using a dedicated parallel input port to accept a firehose of digital video data.

We discuss serial buses and data links in §14.7, below.

14.6.3 Other parallel computer buses

As we remarked above, the buses within computers that are used to move data to peripherals and to memory have evolved, and continue to evolve. Contemporary buses like PCI and PCIe move data quickly (1 Gb/s to 32 Gb/s), with widths of 16 to 64 bits. PCIe ("PCI express") is actually a parallel/serial hybrid, and is emblematic of a shift toward *serial* data communication: the PCI that it replaces used a conventional bidirectional multidrop parallel data path (32 or 64 bits wide, with 32 address bits), whereas the newer PCIe uses 1 to 16 "lanes" of unidirectional point-to-point serial-link pairs, each of which runs at a speedy 2.5 Gb/s (PCIe v.1), 5 Gb/s (v.2), or 8 Gb/s (PCIe v.3). Timing is carried with the data, on each serial link, by coding the data so that the recipient can carry out "clock recovery" without separate clocking or strobing signals.[44] This is necessary for high bitrate communication; otherwise timing *skew* (the *difference* in propagation times of the clock and the several data lines) limits the maximum bit clocking rate.

Parallel data buses exist also within the silicon chips themselves: all processors contain internal data paths to send data among the registers and arithmetic units, to and from the on-chip memory caches, between the processor and external memory, and so on; you'll see names like

[44] PCIe uses "8b/10b" encoding, with each 8-bit byte sent as a 10-bit symbol, to generate a dc-balanced and "run-length-limited" bitstream in which there are never more than five consecutive 1s or 0s.

AMBA and Wishbone. As processors grow in speed, their external buses have followed; the current configuration is a fast and wide "Front Side" bus (FSB), which requires support chips ("Northbridge" and "Southbridge," likely to merge into a single unified support chip) to split off separate buses for memory, fast peripherals (PCIe bus), and slower peripherals (SATA, PCI, USB, Ethernet).

Another trend in contemporary computer designs is the integration of more functions, and more complexity, within the processor chip itself. Thus we have the delightful and inexpensive micro*controllers*, with their spectrum of on-chip "peripherals," ready to drop into a circuit or instrument with hardly a thought of buses or interfacing. Embedded microcontrollers are the subject of the next chapter.

Yet another approach dispenses with the dedicated processor altogether, exploiting the power of configurable logic (Chapter 11) in massive FPGA "system-on-a-chip" (SoC) devices. These permit flexible system design (including on-chip "soft" processor cores, internal buses, memory, and peripherals), with plentiful wide-bandwidth I/O pins. An example is the Xilinx Virtex series of FPGAs, topping out at several million flip-flops, tens of MB of on-chip RAM, and more than 500 LVDS differential ports. In additional to soft configurable SoCs, there are application-specific standard parts (ASSPs, see §11.4.2) for many consumer applications. For example, there's Broadcom's BCM7405 "Multiformat HD Digital Video/Audio SoC for Satellite, IP and Cable STBs with Picture-in-Picture" (the title says it all[45]).

14.6.4 Parallel peripheral buses and data links

Although the industry is moving from parallel to serial buses, there are still a few parallel buses in use.

A. PATA (IDE)

The 16-bit-wide PATA (parallel ATAPI, also called IDE) was for many years the standard connection to internal hard disk and optical (CD, DVD) drives. The wide 40-wire ribbon cables and connectors are somewhat cumbersome, and even after the introduction of 80-wire cables (adding interleaved ground lines to improve signal integrity) the data rates topped out at 133 MB/s (∼1 Gb/s). PATA is obsolete, replaced with the serial SATA format.

B. SCSI

The 8/16-bit parallel small computer system interface dates from the 1980s, with enhancements in speed and signaling format (originally 5 V single-ended, with low-voltage differential added subsequently[46]), and was until recently the preferred interface for high-performance disks and tape storage devices. Internal SCSI buses use 68-wire ribbons with dual-row socket headers; external SCSI uses shielded multipair cable with high density 68- or 80-pin connectors.[47] Although SCSI bandwidth improved with each generation, it has been overtaken in speed and convenience by the serial formats: SAS (serial-attached SCSI), and SATA.

C. GPIB

The IEEE-488 general purpose interface bus was originated by HP for control and readout of test and measurement equipment; many instruments (e.g., from Agilent, Keithley, National Instruments, and Stanford Research Systems) continue to support GPIB control. It uses a robust stackable 24-pin connector and permits lengths to 20 meters. You can get GPIB adapter cards for the PCI and PCIe computer buses; or you can get adapters such as Ethernet-to-GPIB and USB-to-GPIB.

D. Printer ("Centronics") port

Last (and least) is the parallel "printer port" (LPT port), which was standard for two decades, beginning with the original IBM PC, where its I/O address was 378h (and still is). It was also used for external modems and for software "dongles." The original parallel interface was unidirectional (data OUT, with a few handshake lines), but extensions of the standard (IEEE 1284: ECP, EPP) made it bidirectional, faster, and more bus-like. It is quite thoroughly

[45] But in case you want to hear more, the product page has this to say: "The BCM7405 is a high-performance, high definition (HD) satellite, cable, and IP set-top box DVR System-on-Chip solution. It combines a fast 1100-DMIPS MIPS32/MIPS16e-class CPU, high-speed graphics processing, including video scaling and motion adaptive deinterlacing, a very flexible data transport processor, an MPEG-4/VC-1/MPEG-2/AVS-compliant video decoder, a programmable audio decoder, six video DACs, stereo high-fidelity audio DACs, dual Fast Ethernet ports, one with integrated PHY, triple USB 2.0, a PCI 2.3/Expansion Bus, a high-speed 400-MHz DDR2 memory controller, and a peripheral control unit that provides a variety of set-top box control functions. Integrated in 65-nm technology, it offers one of the highest levels of single-chip system performance available for STB applications."

[46] Differential signaling requires twice as many wires, but it is superior in terms of low crosstalk, excellent noise immunity, and far smaller ground and supply noise (because of balanced transitions); these improved characteristics let you use relatively small voltage swings, with correspondingly smaller drive currents.

[47] The miniature high-density connectors that were developed for advanced forms of parallel SCSI have come to be very useful in other fields, such as I/O connectors for computer DAQ boards for laboratory use by National Instruments and others. These are made by HRS Hirose, Honda Connectors, and others.

obsolete: printers use USB or Ethernet connections. Computers now rarely include a parallel port; if you need such a connection, you can get USB-to-parallel adapters.

That said, however, the parallel port (emulated with a USB adapter, say) is the simplest way to wiggle some bits from a PC. If you're running some version of Windows, you'll need a driver[48] that lets you get at the hardware (these operating systems don't let you get at hardware ports directly, as you were able in the good ol' days of DOS). Then you can write really simple code, like this example of Python[49] running in terminal mode:

```
>>> import parallel
>>> p = parallel.Parallel() # open LPT1
>>> p.setData(0x55)
```

You can use a compiled language, instead; some folks we know are fond of PowerBASIC, in which you can use in-line assembly language in a BASIC subroutine to send a value out to an addressed port. It looks like this:

```
Sub PortOut(ByVal PortNum as word, Byval Value
as byte)
   ASM MOV AL, Value
   ASM MOV DX, PortNum
   ASM OUT DX, AL
End Sub
```

14.7 Serial buses and data links

Serial buses and data links have several important advantages, two of which we saw earlier: (a) the convenience of fewer wires in the cable and connector (think of a skinny USB cable, compared with the elephant's trunk of GPIB or SCSI), as well as fewer pins on the driver and receiver chips; (b) high intrinsic bitrate, because of absence of timing skew (self-timed via clock recovery) and clean line termination (if point-to-point). In addition, (c) a one-wire serial link is easily conveyed by optical fiber or by wireless transmission. And, if you want parallel bits at either end, there are chips generically known as SERDES (serializer–deserializer, pronounced "ser′-deez"), which convert a serial stream to parallel, and vice versa (see also §12.8.4 and §12.10.3). As examples of the latter, FTDI Ltd. offers the popular FT245 and FT2232, which convert between a relatively low-speed USB and a simple byte-wide parallel port, with a built-in first-in, first-out (FIFO) buffer; high-speed examples include the DS92LV18 18-bit SERDES (with speeds to 1.2 Gbps), or the generic SERDES used in the PHY (physical layer – i.e., the driver–receiver–switch ICs) of gigabit ("1G") and 10 gigabit ("10G") Ethernet links.

In the subsections that follow we describe most of the important themes in serial links, with examples from those in common use. As with the parallel buses, we look first at internal serial protocols (chip-to-chip, and within an instrument), then at the external serial buses. Within these categories we've ordered them roughly by increasing complexity, e.g., going from the simplest (and slow) 4-wire clocked link (SPI) to the complex (and fast) 1-wire 8b/10b-coded clock-recovery links used in SATA and PCIe.

See the next chapter for specific chip suggestions to implement these protocols with a microcontroller.

14.7.1 SPI

The serial peripheral interface (SPI) was introduced by Motorola, and is widely used for communication *between ICs* (for which the other popular standard is I^2C, discussed below).[50] It is organized as a master–slave protocol (like the PC104 bus), but uses only 4 wires (Figure 14.37): one clock, two data lines (one in each direction), and a chip select. They are named SCLK, MOSI (master out, slave in), MISO (master in, slave out), and SS′ (slave select; active LOW).[51] There are several ways of hooking things up, but most commonly the scheme of Figure 14.38 is used: the clock and data lines are bused to all slave chips

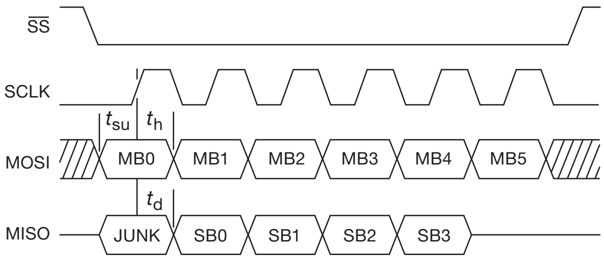

Figure 14.37. A typical SPI protocol, with bits in both directions clocked on the rising edge of SCLK. With SPI, the quantity and meaning of the bits are specific to the slave device, which here accepts 6 input bits from the master (MB5..0), and simultaneously outputs 4 other bits (SB3..0).

[48] Examples are DirectIO.exe, or InpOut32.dll.

[49] "setData(value)" is one of several bit-banging function calls in the pyParallel API; the documentation describes it as "Apply the given byte to the data pins of the parallel port."

[50] You see SPI and I^2C on chips like sensors, converters, nonvolatile memory, analog switches, and digital potentiometers, to be controlled from a microcontroller, microprocessor, or other digital link.

[51] Sometimes with alternative naming: SDI, DI, or SI for data IN, and likewise for data OUT, with the signal names corresponding to the direction of data *at that IC*. For example, the MOSI pin on the master would connect to the DI pins on the slaves.

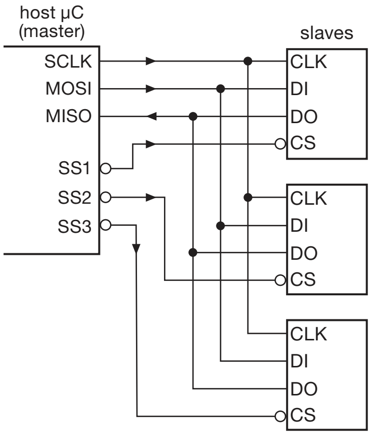

Figure 14.38. The common bused SPI configuration: clock and data lines are shared, with individual SS′ (slave-select) lines asserting the chip-select inputs of the corresponding slaves.

("multidrop"), with a separate dedicated select line to each slave.

The master controls all transfers, first asserting SS′ for the chosen slave IC (with the SCLK line in its resting state), then generating successive clock pulses, each of which enables a bitwise transfer of data on MOSI and MISO for that chip only. There is no fixed protocol for what the data represents, how many bits are to be sent, etc. What happens, instead, is that a particular chip specifies the meaning of the serial bits sent to it and of the bits it simultaneously sends back.

To give an example, the AD7927 is a 12-bit ADC of modest speed (200 ksps), with a built-in 8-input multiplexer, and with a SPI serial port (Figure 14.39); the latter both controls the conversions (e.g., selecting the input channel, voltage range, output coding, etc.) and also delivers the converted digital outputs. This particular chip loads the first 12 input bits (after SS′ assertion, which also initiates conversion) into its control register (ignoring later bits), and it simultaneously sends back the result of the previous conversion as a 16-bit string, as shown in Figure 14.39.[52] See Figure 15.21 for some examples of SPI peripheral chips that are well suited to microcontroller applications.

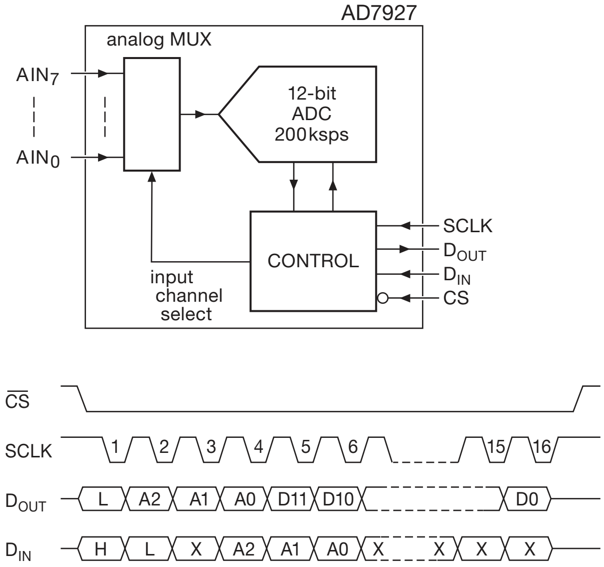

Figure 14.39. An 8-channel ADC with SPI control and readout. The protocol shown is the simplest of several allowed modes: the master's CS′ starts a conversion, whereupon the slave outputs both the channel address (3 bits) and the converted value (12 bits); the master simultaneously sends the address of the next input channel to be converted.

A. Some comments

The SPI protocol is free form in its content (how many bits are sent, and what they mean), as this example illustrates. SPI doesn't have any intrinsic addressing to designate where data is going within the target chip, so the usual scheme is to send a string of bits that gets shifted into sequential internal bit locations, with the datasheet defining how they sort out internally (the popular I^{2}C alternative, below, takes a different approach). Some chips may be write-only (e.g., an LCD with serial input), others read-only (e.g., the Maxim MAX6675 thermocouple-to-digital-converter chip, with SCLK, MISO, and SS′ only: you don't tell *it* what the temperature is, it tells *you*). Some chips may invert the clock polarity, and also which edge clocks the data (this produces four possibilities, known as SPI *modes*; the above illustration used mode-2). SPI has simple timing, and full-duplex data transfers (i.e., in both directions simultaneously and independently); it has no required "handshake": a master can send lots of data – to a nonexistent chip!

Because SPI (and SPI-like variants) do not conform to a well-defined standard, you have to read carefully the datasheet specifications for each interfaced chip. You'll discover, in addition to the polarity modes already mentioned, that the maximum (and minimum!) clock speeds can range from a few kilohertz to many megahertz. The AD7927, for example, specifies f_{SCLK}=10 kHz (min), 20 MHz (max). With several SPI chips in a system, you

[52] The AD7927 can do numerous additional tricks, such as cyclically converting a prescribed arbitrary sequence of input channels; you program that sequence by loading a "shadow register," which you access through two bits of the control register.

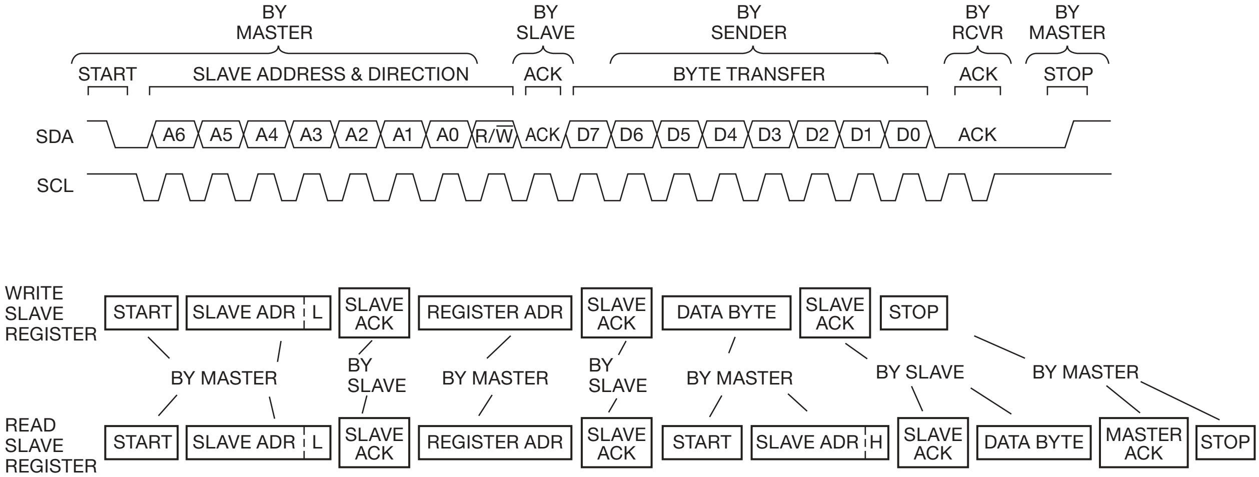

Figure 14.40. The I^{2}C 2-wire protocol (upper waveform pair): all transfers are in 8-bit groups, with a 1-bit acknowledgment (ACK). The first byte after START is always the master's assertion of the slave address (A6..0) and direction (R/W′); subsequent bytes flow from sender to receiver (depending on that first R/W′), asserted by sender and acknowledged by receiver. The master can access registers within a slave device by sending their internal address as a data byte, as shown in the lower block diagrams; both a WRITE and a READ are illustrated, the latter requiring a "repeated START" to create a READ after writing the register's address in the initial transaction.

may have incompatibilities among them that force you to write code to assert and disassert port bits "by hand" (this is called *bit-banging*, rather than using the microcontroller's built-in SPI interface).

A widely used alternative to SPI is the I^{2}C peripheral interface, discussed next.

14.7.2 I^{2}C 2-wire interface ("TWI")

The Inter-Integrated-Circuit (IIC, I2C, or I^{2}C) serial interface bus was originated by Philips (now NXP), for communication between chips.[53] It differs from SPI in several ways: (a) it uses only 2 wires, which are bused to all slave ICs (there is no separate chip select like the SS′ that is used in SPI); (b) addressing is sent (first) on the same line as data is sent or received; (c) the bus is "half-duplex" – that is, data can move in only one direction at a time (the direction is specified by a bit following the address); (d) although I^{2}C is a master–slave architecture (like SPI), any device on the bus can become master when the current master relinquishes control (by sending the stop bit that terminates its session with a particular slave).

Figure 14.40 shows the protocol. The 2-wire I^{2}C bus consists of a clock line (SCL) and a data line (SDA), both with resistive pullups to V_+. SCL is asserted by the master, whereas SDA is bidirectional: it is asserted by the master to specify the slave's address (7 bits) and the direction of transfer (1 bit); the slave then sends an acknowledge (ACK) bit, following which one or more data bytes move from master to slave, or from slave to master (always clocked by the master), depending on the direction-of-transfer bit that was specified initially with the slave's address. The session ends when the master sends a stop bit following the last byte transferred.[54] START and STOP commands are created by violating the normal convention of "data can change only during clock LOW."

To give an example, the AD7294 "12-bit Monitor and Control System with Multichannel ADC, DACs, Temperature Sensor, and Current Sense" is a do-everything chip for applications such as automobiles, industrial controls, and cellular base stations (Figure 14.41). It isn't the fastest kid on the block – a mere 300,000 conversions per second on its ADC – but it will keep an eye on the whole shop, reporting back to the mother ship via an I^{2}C port. The 44-page datasheet tells you how to communicate with its

[53] The closely related SMBus enforces tighter standards, both in protocol and in its electrical signaling.

[54] You can think of this whole process as the serial analog of a PC104/ISA data transfer: in the latter, the master asserts address on the A19..0 lines, and direction on the IOW′/IOR′ lines. If a WRITE, the master asserts the data on the bidirectional D7..0 lines; if a READ, the addressed slave asserts the data on those same line. In either case the transfer is clocked by the master's IOW′/IOR′ strobe. In I^{2}C the same steps take place, but in serial sequence on the single bidirectional SDA data–address–direction line, clocked by the single unidirectional SCL clock line.

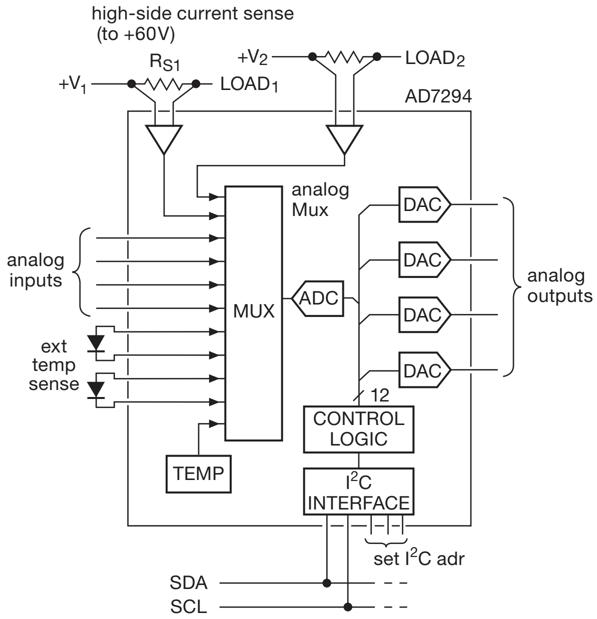

Figure 14.41. A multifunction monitor chip, rich with features but of modest speed only, with I^{2}C control. The master can reach each of the 40 internal registers by sending the corresponding register address as the second byte of a transmission, as shown in Figure 14.40.

40 internal registers, with amusing names like “AlertRegisterA(R/W)” and “DATA$_{\text{HIGH}}$RegisterT$_{\text{SENSE}}$INT(R/W).” See Figure 15.22 for some examples of I^{2}C peripheral chips that are well suited to microcontroller applications.

A. Some comments

The 2-wire I^{2}C protocol is well defined and is economical of wiring, particularly when you need to include many chips on the bus, because the 2 wires carry all data, addressing, and clocking. In addition, it allows the slave to slow down the master by doing “clock-stretching” (by holding SCL LOW; this is called *flow control*), and it allows multiple bus masters. It is particularly well suited to tasks in which you want to take aim at a particular register in a chip that is endowed with many; with the AD7294, for example, you would have a 3- or 4-byte transaction: the first byte is the chip’s bus address, the second is the address of the chip’s internal register, and the last byte (or two) is a write (or read) to (or from) that internal register.

B. Comparison with SPI

When compared with SPI, however, I^{2}C is a more complex protocol, and not as well suited to steady high-rate streaming of data. The flexibility of multiple bus mastership brings with it the problems of contention and arbitration. You have to give multiple devices unique addresses, which is commonly handled by including some dedicated pins to select among a built-in set (e.g., the AD7294 has 3 pins by which you can select any address from 61h to 7Bh), thereby defeating some of the advantage of low pin count. And the flexibility of addressing, bidirectional data, and bus mastership complicates debugging, as compared with the dead-simple SPI protocol.

Which to use? The choice is usually determined by the peripheral chip, which usually supports only one protocol or the other, whereas most microcontrollers include hardware support for both SPI and I^{2}C (and if they don’t, you can always do bit-banging in software).

14.7.3 Dallas–Maxim “1-wire” serial interface

The ultimate in reducing the number of wires is achieved in the 1-wire™ (plus ground) interface devised by Dallas (now merged with Maxim).[55] The single wire carries serial data and addresses, and also *power!* The way it does all this is by having data bits sent, bidirectionally, as brief pulses to ground, with each slave device having an on-chip capacitor to retain power. The goal is simplicity in interconnection to devices like temperature sensors, memory, converters, battery management, and so on (Figure 14.42). With only ground and data, the devices can be packaged in what Maxim calls iButton™, which looks just like a coin cell battery.

The protocol goes like this: multiple slave devices all bridge the common data line and ground, controlled by a master device (microcontroller or other digital interface). The line is pulled up to +5 V, which powers the slave devices and permits any device to assert a momentary LOW. The master initiates all transactions, asserting addresses and then either sending or receiving data. Data is encoded as pulse widths: a short pulse ($<15\,\mu$s) for 1, and a long pulse (60 μs) for 0. If the master is sending, it simply asserts the bits with the corresponding pulse widths; if it is receiving, it sends the short pulse corresponding to a 1, and the addressed slave responds by either doing nothing (releasing the line to +5 V, therefore signaling a 1), or by holding the line low for 60 μs, creating a long pulse (therefore signaling a 0).

Each 1-wire device has a unique 64-bit address, given to it at the time of manufacture, which includes a byte indicating the type of device. The master resets the slaves

[55] Plenty of details in their Application Notes AN147, AN148, AN155, AN159, AN244, AN1796, and AN3358.

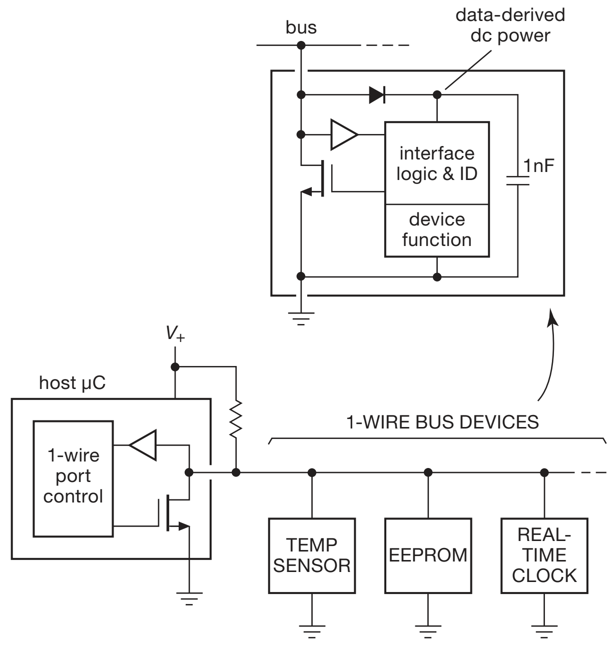

Figure 14.42. The 1-wire™data bus originated by Dallas–Maxim. An internal capacitor maintains slave power during the brief LOW data pulses.

with a long pulse (all "pulses" are LOW, i.e., to ground), then queries the bus to learn the attached addresses. The master can send broadcast messages to all attached devices, or it can carry out transactions with particular devices, according to their unique addresses. As with the I^{2}C bus, that address is sent (by the master) on the data line, followed by the data to be sent or received.

The Dallas–Maxim 1-wire bus can be used for connections to sensors, etc., outside of an instrument. It's normally limited to a maximum network distance of 30 meters, but it can work up to 500 meters with an appropriate driver (see AN244); and extensions by Ethernet are possible.

14.7.4 JTAG

A useful chip interface, with an interesting history, is the JTAG (Joint Test Action Group) standard, also known as "boundary scan," or IEEE 1149.1. It was devised in the 1980s to deal with the thorny problem of testing for component or connection failures in circuit boards using the then-new surface-mount and multilayer technologies; these made it increasingly difficult to get at the IC pin connections, not to mention the innards of the chips themselves. As such, it provides a way to look at the registers and data paths within the chips, using a simple 4-wire serial bus; that lets you pinpoint what is broken without having to unsolder multiple parts to get at the problem.

JTAG turned out to have additional utility as a general-purpose serial interface, akin to SPI and I^{2}C, because of the way it accommodates an internal state machine in the target device for controlling data transfers. Among other applications, it is now widely used to program and debug microcontrollers in-circuit (e.g., ARM and AVR series), and to program cPLDs, FPGAs, and nonvolatile memory (flash, EEPROM), as well as other chips that include nonvolatile memory (e.g., the Maxim DS4550, where it coexists with an I^{2}C port).

The basic scheme is shown in Figure 14.43. A clock line (TCK) and a mode-select line (TMS) are bused to all devices; the other two lines are daisy-chained through the chips, and are called data in (TDI) and data out (TDO).[56] TDI bits are clocked in on the rising edge of TCLK, and TDO bits are clocked out on the falling edge. The mode bits, which define what TDI and TDO will be doing, are clocked in on TCLK's rising edge. (There is also an optional bused reset line, not surprisingly called TRST.) The bus runs at speeds in the range of 1–100 Mb/s, depending on the particular target chip(s).

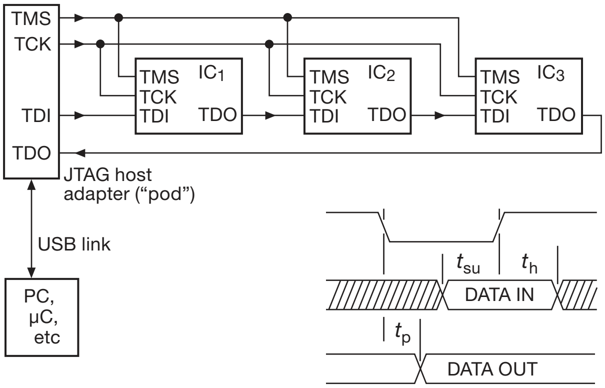

Figure 14.43. The JTAG "boundary scan" interface uses a pair of unidirectional bused lines (clock: TCK; mode select: TMS), and a daisy-chained data line passing through each slave (TDI, TDO).

Many PLDs and microcontrollers now use a JTAG port for programming; typically you get a programming "pod" that connects to a host computer via USB, and has a socket header to mate with a pin header on the target device's board. Sadly, the header configuration has not been standardized, although it's easy enough to make an adapter. However, the software that the chip manufacturers provide

[56] The letter "T" preceding each signal stands for "test," an indication of what the originators had in mind.

usually forces you to use their specific pod when talking to their chips. You use such vendor-supplied software, or open-source software, to load the compiled code into the target, and to carry out in-circuit real-time debugging, both via the same JTAG port.

14.7.5 Clock-be-gone: clock recovery

The SPI, I^{2}C, and JTAG serial links above, each use a separate clock line to time the data bits (SCLK, SCL and TCK, respectively). However, it is possible to do *clock recovery* from the data itself, if you arrange things correctly. This not only reduces the number of lines, it also permits higher ultimate data rates, because there is no issue of timing skew between clock and data. The remaining internal serial links (and, later, the external serial links) employ clock and data recovery (engineers' lingo: "CDR") from the transitions on the data line(s). The reader may wish to look ahead to §§14.7.9–14.7.12 for helpful information on how coding is used to make this work.

14.7.6 SATA, eSATA, and SAS

SATA is serial-ATA, and SAS is serial-attached SCSI. These are the fast serial buses for internal and external storage (disk, tape, and optical drives); they are replacements for the obsolete ATA (retroactively called PATA, or sometimes IDE) and SCSI, respectively. They share the same connector (though SAS offers additional connector types) and are hot-pluggable. Maximum data rate is currently 6 Gb/s, with upgrade paths to 12 Gb/s. SAS has some performance features not found in SATA, and is thus aimed at server (as opposed to consumer) applications; it basically continues the (parallel) SCSI protocol, but running on a serial connection interface.

These interfaces use low-voltage differential signaling, with 8b/10b encoding and clock recovery, and allow hot-swapping (although this feature requires operating system support to work correctly).

External SATA (eSATA) is an extension of the standard, for attaching external storage devices to a computer with SATA, using the same protocols. The physical connectors are different, however, being designed for greater ruggedness and signal integrity. External devices connected via eSATA currently require separate power, a nuisance likely to be remedied by the "Power Over eSATA" initiative.

14.7.7 PCI Express

PCI Express ("PCI-E," or "PCIe") was introduced in 2004, as a successor to the parallel PCI bus (and its brethren, PCI-X and AGP), for interfacing to peripheral cards on a computer motherboard. It replaced the wide (32- or 64-bit) multidrop parallel architecture with a set of point-to-point serial "lanes," each lane consisting of two LVDS differential pairs (one pair for 1-bit serial communication in each direction, see §12.10.3). With multiple lanes there is parallelism (in that sense it is a hybrid), but the communication is basically serial, with 8b/10b coding and clock recovery, etc.

PCIe has blazing speed: currently 4 Gb/s *per lane* (PCIe v2.0, double that of the original version 1.1), with 1 to 16 lanes. Thus you could have up to 64 Gb/s to an x16 slot, if the hardware at both ends could handle it.

Let us take a brief aside, to wonder how we've come to this elaborate scheme, given the elegance of the traditional parallel bus with its economical sharing of data lines (as in the PC104/ISA bus). Roughly, it goes like this: in the beginning (say the 1970s) integrated circuits were not dense, and the DIP packaging limited the pin count to 16 pins (often) or 40 pins (occasionally). They also were not terribly fast, running at clock speeds of 10 MHz or so. These circumstances favored the shared parallel bus – less wiring, fewer driver–receiver pins, and still plenty of bus speed.

As chips became faster, and humans demanded more speed, the parallel buses were enhanced, with more width (the 8-bit ISA bus was broadened to 16 bits, then expanded to EISA: 32 bits), and, at the same time, with more speed. This was successful, up to a point. That point was near when the performance of the parallel PCI bus (the successor to the ISA family) had grown from its original 32 bits at 33 MHz (thus 133 MB/s) to 64 bits at 133 MHz ("PCI-X," 1064 Mb/s). A further enhancement ("PCI-X 2.0") quadrupled the speed, but was not widely adopted. Problems of timing skew and of reflections from the multidrop stubs prevented further gains from the bus. By this time (2003) computer designers saw a better way, namely the serial point-to-point PCIe architecture.

Of course, PCIe has its challenges: consider a motherboard with a couple of x16 slots (a common configuration, even in inexpensive computers). Each slot requires 32 differential pairs (64 wires), so you've got to connect to 128 wires, and deal with 4 Gb/s (actually, 5 Gb/s raw, because of the coding overhead) on each of the 64 pairs. That function (along with the memory bus) is carried out in the Northbridge chip, which has hundreds of pins and the necessary speed and complexity for the task: it even has its own heatsink. And one must not ignore the fabrication technology needed to connect all these pins: even inexpensive motherboards routinely have a half-dozen wiring layers, with traces 0.12 mm (5 mils) wide.

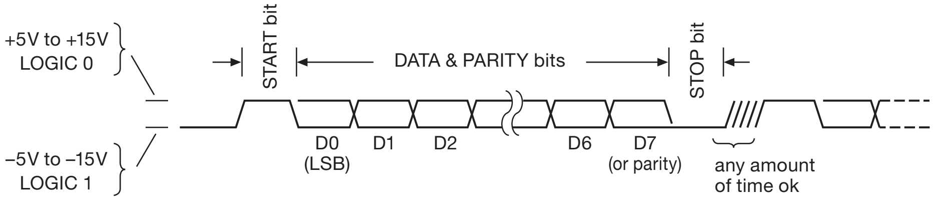

Figure 14.44. RS-232 serial data-byte protocol, which uses signal levels of both polarities. The two states are sometimes called *mark* (negative, logic 1) and *space* (positive, logic 0). You sometimes hear the descriptive phrases "LSB first" and "inverted levels."

In a sentence, then, the demand for greater bus performance coincided with the ability to proliferate point-to-point connections, to bring about the evolution from the elegant shared parallel bus... to the elegant coded point-to-point serial links!

This is clearly an area where casual circuit designers dare not tread – better just to buy some smarter person's finished design!

14.7.8 Asynchronous serial (RS-232, RS-485)

Turning now to *external* serial buses, we look first at the original (and long-lived) *asynchronous* serial link – used in the now-obsolete RS-232 serial port. We discussed RS-232 (and also RS-422 and RS-485) back in Chapter 12 (§12.10.3A), with emphasis on the physical layer (waveforms, noise immunity, and the like). Here we revisit RS-232, in the context of computer communication. These serial ports were popular for connection to external modems and to alphanumeric terminals like the legendary VT-100 (dismissively called *dumb* terminals). They have largely disappeared from computers, but you can get USB-to-RS-232 adapters; and you can get cards that plug into the internal bus and create a gaggle of RS-232 ports. The RS-232 designation ("Recommended Standard #232") refers to the *electrical* signaling scheme, which inconveniently uses voltages of both polarities to signal 1s and 0s (Figure 14.44; see also §12.10.4). However, the physical link need not be RS-232 – it can be the differential (and unipolarity) RS-422 or RS-485, or it can be an optical fiber (for galvanic isolation and immunity from environmental transients), or it can even be a 20 mA *current loop* (which is most often used for *analog* signaling).[57]

Whatever the physical transport medium, the signaling is straightforward: the transmitter rests in the *mark* state (logical 1), and springs to action with a START bit (logical 0, or *space*), followed (usually) by 8 data bits (which optionally may be 7 data bits plus a parity bit), followed by one or two trailing STOP bits (logical 1). The transmitter and receiver must agree on the bit rate and parity (if any); a common protocol, for example, is 9600 baud and "8N1," which means 8 bits, no parity, and one stop bit, transmitted at a rate of 9600 bits/s.[58] (Because of the overhead of the framing START and STOP bits, each byte during 8N1 transmission requires 10 bits, for a maximum net payload rate of one tenth of the baud rate, or 960 bytes/s.)

With this simple asynchronous serial coding, the receiver (whose clock runs at several times the baud rate) is triggered by the transition at the beginning of the START bit, waits for half a bit cell to be sure the START pulse is still present, then examines the bit value at the middle of each data cell (using the agreed upon baud rate interval); the STOP bit terminates the character, and is the resting state if no new characters are sent immediately. By resynchronizing on the START bit of each character, the receiver doesn't require a highly accurate clock; it need be only accurate and stable enough for the transmitter and receiver to stay synchronized to a fraction of a bit period over the duration of one character, i.e., an accuracy of a few percent.

There is one slight logical flaw in this pretty scheme, namely that a receiver may not be able to synchronize properly (that is, identify START/STOP) in an uninterrupted stream of data bytes. The best proof of this conjecture is a long sequence of the letter "U," which has the unfortunate distinction of being encoded as 01010101 (55h): plug that into Figure 14.44 (with the usual 8N1 setting) and you'll get... a *square wave*! A more serious flaw is the lack of standardization at the physical (electrical) level of RS-232: connector gender, hardware handshaking signals, and flavor of device ("DCE" and "DTE"; see Table 14.4 for official signal names and pin assignments). This is an eternal source of confusion because, too often, two RS-232 devices when connected together, won't work. We've all struggled with this, and readers have even complained to *us* (hey, give us a break, we didn't design RS-232; but we

[57] These alternatives permit longer cable runs (up to ∼1 km) and, in the case of RS-422/485, a multidrop bus topology.

[58] The serial asynchronous standard permits a wider range: 5 to 8 data bits, with optional parity; so it would be legal to specify 8E1, for example. In practice you rarely see anything but 8N1.

Table 14.4 RS-232 Signals

	Pin number		Direction		
Name	25-pin	9-pin	(DTE ↔ DCE)	Function (as seen by DTE)	
TD	2	3	→	transmitted data	} data pair
RD	3	2	←	received data	
RTS	4	7	→	request to send (= DTE ready)	} handshake pair
CTS	5	8	←	clear to send (= DCE ready)	
DTR	20	4	→	data terminal ready	} handshake pair
DSR	6	6	←	data set ready	
DCD	8	1	←	data carrier detect	} enable DTE input
RI	22	9	←	ring indicator	
FG	1	-		frame ground (= chassis)	
SG	7	5		signal ground	

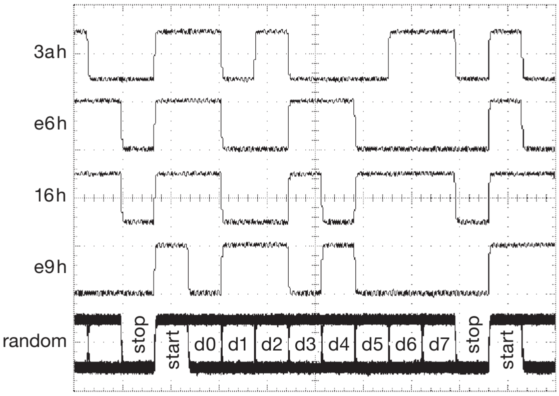

Figure 14.45. Captured RS-232 waveforms from a random byte generator, 8N1 at 14.4 kbaud into a 2.2 nF load. The bottom waveform is an accumulation of multiple bytes, whereas the top four are single bytes (with indicated values). Horizontal: 100 μs/div; vertical: 10 V/div.

did at least provide a guide to "serial cables that actually work" – see Figure 10.17 in the previous edition of this book.). With finicky USB-to-RS232 emulators replacing the disappearing COM ports on contemporary computers, the problem has only gotten worse.

Figure 14.45 shows some 'scope captures of RS-232 waveforms: four single-byte captures from a stream of random[59] bytes, and a multibyte capture showing the invariant START and STOP bits.

The most common use of asynchronous serial links has been for alphanumeric data, in the standardized 7-bit ASCII (American Standard Code for Information Interchange) code of printable characters that is the norm for alphanumeric representation (Table 14.5).[60] However, any binary data can be so conveyed; you just won't be able to read it or print it directly. And serial communication via RS-232 is quite alive and well: many bench instruments include an RS-232 port for control and data transfer; and the serial format provides an easy way to communicate with microcontrollers (Chapter 15) with their (nearly universal) built-in serial ports (UARTs, universal asynchronous receiver–transmitters). See §12.10 for a discussion (with waveforms) of driver and receiver ICs.

14.7.9 Manchester coding

You don't need to frame data bytes with synchronizing START and STOP pulses, however, as long as you arrange

[59] *Truly* random: we fed analog noise to a comparator; see §13.14.7, and the "Museum" section on the *Numerical Recipes* Source Code CDROM (or www.nr.com).

[60] Standard ASCII has 128 characters, including the 32 "nonprinting" characters in the first column of Table 14.5. There are "extended ASCII" 8-bit character encodings that double the number of characters to include alphabetic characters from other languages, for example ë (decimal code 235), as well as symbols such as ° and ± (codes 176 and 177) and £ (code 163). A warning: there are multiple such extensions, for accommodating different language groups (some are gathered into Std. ISO-8859; others are proprietary); so they should be used with caution. Most software will accept these encodings, which you enter by holding the `alt` key while entering the 3-digit decimal code with a leading zero (thus `alt`-235 for e-umlaut). You can use this method also to enter (rather than act upon) any of the standard ASCII characters, including the nonprinting characters; thus, to enter a CR (carriage return) you would type `alt`-013. And good programming editors (such as Notepad++, UltraEdit, or Emacs) accept the insertion of control characters, in addition to displaying what's there. Try it!

Table 14.5 ASCII Codes

non-printing					printing			printing			printing

things so that there are enough transitions in a serial data stream so that the receiver can recover a clocking signal. A simple (though not terribly efficient) example is Manchester coding (Figure 14.46).

The successive bits are transmitted at fixed rate, with a required transition in the middle of each cell: a “1” is LOW-to-HIGH, and vice versa. There may or may not be a transition at the beginning of a cell, as required by the data. The guaranteed transitions at the bit rate facilitate clock recovery (with a phase-locked loop, or delay-locked loop), and the signal is dc balanced, so it can be transformer coupled.

Receiver synchronization with Manchester coding is not completely trivial, since, for example, a continuous sequence of 1s creates a simple square wave. If the receiver chooses the wrong phase, it will interpret the stream as 0s. However, the presence of mixed 1s and 0s disambiguates the clock recovery, because the wrong phase creates violations of the required mid-cell transitions.

Manchester coding is used in low-speed Ethernet (10base-T), which carries 10 Mb/s in one direction on a cat-5 twisted pair (two pairs are used, for full duplex).[61]

[61] When faster Ethernet standards were created, the bandwidth-inefficient Manchester coding (100% overhead, compared with the stream of data bits themselves) was replaced with 4b/5b encoding (a 25% bandwidth overhead), conveyed with 3-level voltage signaling, still on a single twisted pair. The next step – to 1 Gb/s – required 5-level signaling and the simultaneous use of four pairs (with a “hybrid” coupler, permitting each pair to carry signals simultaneously in both directions).

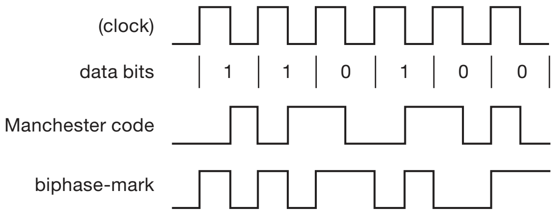

Figure 14.46. Biphase encodings. For Manchester ("biphase-level") coding, every bit cell has a transition in the middle, in a direction set by the bit's value; you can think of Manchester code as the exclusive-OR of a clock (not transmitted) and the data. For biphase-mark coding, the bit value is encoded as presence or absence of a mid-cell transition, following a mandatory transition at the beginning.

Because it is wasteful of bandwidth (by a factor of 2), the better "8b/10b" coding (see below) is used instead for high-performance self-clocking serial links such as SATA, HDMI (high-definition multimedia interface), PCIe, and gigabit Ethernet.

14.7.10 Biphase coding

Manchester is a special case of what is called *biphase coding*, and in fact is sometimes called *biphase-level*, to distinguish it from biphase-mark, biphase-space, and differential biphase codes. These all share the common feature of having a transition at every bit cell to facilitate receiving clock recovery. However, the latter three codes, which are closely similar to each other, have an important advantage over the vanilla Manchester code, namely that they are insensitive to an inversion of polarity (as can happen with transformer-coupled signals). Let's see how this works.

Look at the popular biphase-mark code in Figure 14.46: there is a required transition at the beginning of each cell, and a transition in mid-cell for a transmitted 1 (but no transition for a 0). It is the encoding of bits as the presence or absence of *transitions* (rather than as defined polarities, as in Manchester coding) that makes the biphase-mark code unambiguous, even with a polarity inversion of the transmitted levels.

Biphase-mark coding is used in digital audio links such as AES3, S/PDIF and Toslink, and in some magnetic stripe codes. It goes by the alternative names of *Aiken Biphase* or *F2F* coding.

14.7.11 RLL binary: bit stuffing

A simple serial scheme with reduced bandwidth is to transmit the data bits directly, adding occasional bits to ensure transitions by which the receiver can synchronize its clock oscillator. "Sending the bits directly" has the acronym NRZ (non-return to zero), with numerous variants, notably NRZI (non-return to zero inverted) in which the encoded stream changes state for an input 0, but stays put for an input 1.[62]

The trouble with either scheme is that there can be long runs of data that cause no transitions in the encoded stream: a string of 1s (or of 0s) for NRZ, or a string of 1s for NRZI. This is bad not only for clock recovery, but also because it extends the transmission band to low frequencies, complicating transformer coupling. The way to fix this is to modify the data (either before or after coding) in order to limit the length of successive output states with no transitions. This is called *run-length limiting* (RLL).

There are various RLL coding schemes in use, for example 8b/10b encoding (coming next) in which each 8-bit string of data is encoded into a well-chosen 10-bit stream to be transmitted; or the 8-to-14 ETF code used for optical compact discs (in which the run length is bounded at both ends: $2 \leq \text{RL} \leq 10$). The simplest RLL scheme, though, is probably simple "bit stuffing," as used, for example, in the USB serial link. USB uses NRZI with bit stuffing to limit encoded runs to six consecutive 1s or 0s. This is done by inserting ("bit-stuffing") a 0 into the raw binary data stream after a run of six 1s, forcing a transition in the NRZI-encoded stream. The receiver, of course, knows to ignore a 0 that is preceded by six 1s in the decoded stream. Although the worst-case overhead could be 16% (for a data stream of all 1s), in fact the overhead is less than 1% with random input data.

14.7.12 RLL coding: 8b/10b and others

A more sophisticated way of generating run-length limited serial streams involves encoding the binary data stream in blocks, according to relatively complex algorithms that bound the encoded runs, while additionally controlling the spectral shape, and perhaps adding robustness against errors. For example, DVD optical discs use a scheme called EFMPlus, in which 8-bit groups of data are encoded into 16 serial bits, the latter run-length limited to $2 \leq \text{RL} \leq 10$, while simultaneously shaping the spectrum.

The 8b/10b scheme is a popular code in the serial bus and data link world, being used in FireWire, SATA/SAS,

[62] These history-encrusted terms are somewhat confusing (suggesting, for example, that NRZI is related to NRZ by inversion of the code or the data). We prefer the terminology used by Sklar: NRZ-L ("NRZ-level," for NRZ), and NRZ-M ("NRZ-mark," for NRZI).

gigabit Ethernet, DVI and HDMI, and in the multiple "lanes" of the internal PCIe (PCI Express) versions 1 and 2.. It encodes 8-bit input data groups into 10-bit serial stream bits, using the flexibility (of multiple possible 10-bit codes for each 8-bit input group) to balance the number of 1s and 0s: it keeps a running tally of bit inequality, and chooses accordingly. The resulting serial stream is guaranteed to have no more than five sequential 1s or 0s; and the number of 1s and 0s in any string of 20 or more serial bits is guaranteed to differ by no more than 2. An analogous 4b/5b code is used in 100 Mbps Ethernet.

8b/10b coding is used also in some serializer-deserializer chipsets, for example the CY7C924. However, the simpler asynchronous NRZ scheme, framed by START and STOP pulses, is used in other high-performance SERDES chips, for example the DS92LV18 series from TI. They claim that it's better, because the receiver will lock to random data without interrupting traffic with PLL training patterns and without a loss-of-lock feedback path from receiver to transmitter. The legacy 9600-baud asynchronous serial communication is thus reborn as a *gigabaud* serial link.

14.7.13 USB

The Universal Serial Bus (USB) was introduced in 1995, with the goal of simplifying connections between computers and peripherals by having a unified serial connection. It initially supported "low-speed" and "full-speed" devices (1.5 Mb/s and 12 Mb/s, respectively) in USB version 1, adequate for devices such as keyboard and mouse, and relatively modest speed transfers to external memory devices such as flash "thumb drives." Version 2 added a "hi-speed" category (480 Mb/s), suitable for serious data transfer to external hard drives, optical storage, and the like. Version 3 adds two "SuperSpeed" shielded twisted pairs (and a piggyback pair of connector pins), delivering both full-duplex communication and another factor of ten in speed (up to 4.8 Gb/s). And the latest revision – USB 3.1 – doubles the speed (to 10 Gb/s), increases the dc power options (to 5 V at 2 A, or optionally as much as 5 A at 12 V or 20 V), and promotes a new and greatly improved "type-C" connector.

USB versions 1 and 2 are organized as half-duplex master–slave, with point-to-point electrical connections via a 4-wire cable that carries power and ground, and one differential pair of data. The cable is unsymmetrical, with an *A* end (host, or master) and a *B* end (slave); each type (*A*, *B*) comes in a full-size and a mini-size version, the latter for connection to small equipment such as cameras and PDAs. A USB network is a star topology, with multiple devices connected via USB hubs, which replicate the host (*A*) sockets, allowing multiple slaves (up to a total of 127 devices from a single host controller port); see Figure 14.47. The supplied power is rather modest – a maximum of +5 V at either 100 mA ("low-power") or 500 mA ("high-power")[63] – and a single link can be no longer than 5 m (but can be extended with hubs, to a total of 20 m). USB version 3.0 introduced full-duplex (and higher speeds), along with somewhat greater (but not enough, in our opinion) dc power – up to 900 mA; happily, version 3.1 addresses that shortcoming, permitting as much as 10 W at 5 V, and an astounding 100 W at 20 V. USB devices are "hot-pluggable," with ground and power connecting before the signal lines.

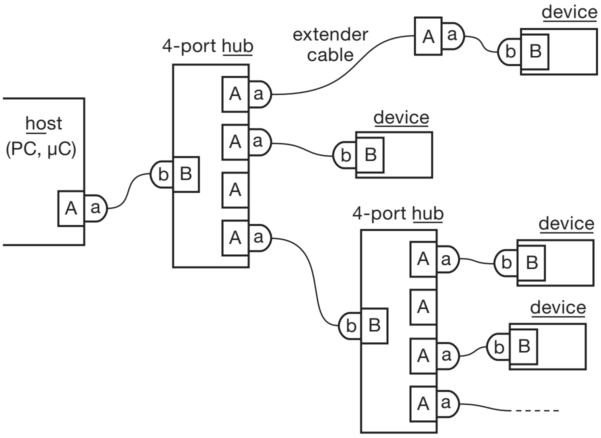

Figure 14.47. USB is a master–slave serial interface, arranged in a star topology (as opposed to a serial repeater topology like FireWire), with up to five repeater "hubs." The individual links are asymmetrical cables, with *A* at the master end and *B* at the slave end (a full-size pair is shown in Figure 1.123); here *a* and *b* represent plugs, *A* and *B* sockets. Individual links are limited to 5 m length (including passive extender cables), but an active hub resets the "ruler." An interesting variant (not shown) is the OTG (on-the-go) USB port, a chameleon that can masquerade as either an A or a B port.

14.7.14 FireWire

FireWire, known officially as IEEE 1394, was introduced also in 1995, and was designed as a high-speed serial bus for audio, video (including high-definition), and disk storage. It emerged from the starting gate with a 400 Mb/s full-duplex transfer rate (compared with USB's 12 Mb/s half-duplex), and with significant dc powering through its cable

[63] A USB device is allowed only low power, when first connected, and it must negotiate for high-power status. If successful, the controller turns on a 500 mA-capable power source. Table 12.4 lists a few protected power-switch ICs popular for this purpose.

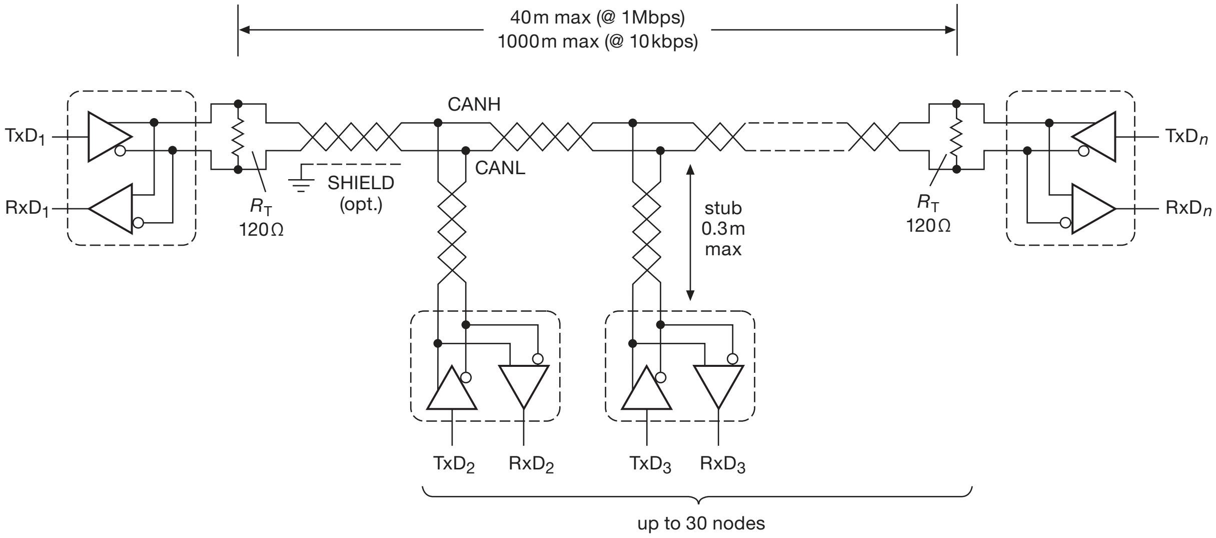

Figure 14.48. The Controller Area Network (CAN) is a multimaster, multidrop architecture that is used widely in automotive and factory-floor applications. It is optimized for short "broadcast" messages, and operates well in noisy environments.

(up to 45 W and 30 V, compared with USB's paltry 2.5 W). Subsequent revisions increased the data rate to full-duplex 800 Mb/s (FireWire 800), with a factor of four (to 3.2 Gb/s) promised in the next revision.

FireWire allows multiple hosts and peer-to-peer communication; its cables are symmetrical, and connect devices in a bused (repeater) configuration. Individual links can be no longer than 4.5 m (for FireWire 400), but can chain through repeaters to a total of 72 m. FireWire 800 permits longer links through copper, Cat-5e network cable, or optical fiber. Like USB, FireWire connections are hot-pluggable; sadly, however, FireWire has been largely overtaken by recent revisions of USB.

FireWire provides plenty of dc power, and works well with streaming media such as high-definition video. We have found FireWire both faster and more stable than USB. It has a nice robust connector design[64] that can be plugged in "blind," owing to its asymmetric shape. In spite of FireWire's technical advantages, the USB standard is becoming dominant, probably because of the complexity, hardware cost, and royalty burdens of FireWire.[65]

14.7.15 Controller Area Network (CAN)

Everyone knows about USB and FireWire; but who has heard about the *CAN* bus? This bus, sometimes simply called "CAN," was originated by Bosch in the 1980s for automotive use and is now standardized as ISO 11898. It's all over the place. Several protocols have been layered on top of the CAN physical layer, notably DeviceNet™, which is in common use on factory floors.[66]

Unlike the other buses in this chapter, CAN can operate over distances to a kilometer (helpful for the factory application). It's not a point-to-point electrical link (like PCIe, Ethernet, or USB). Rather it's an egalitarian "multi-master" bus, accommodating up to 30 transceiver nodes along its length; that is, it is a "multidrop" bus (see Figure 14.48). The maximum bitrate is 1 Mbps for distances up to 40 m, dropping gradually to 10 kbps at the maximum specified bus length of 1000 m.

CAN is optimized for short "broadcast"-like transmissions, limited to 8 user data bytes per packet (plus some signaling overhead), directed to no one in particular. As the helpful Kvaser website (www.kvaser.com/can/) explains, a CAN message conveys the following sentiment: *"Hello everyone, here's some data labeled X, hope you like it!"*[67] This is just what you want in certain data acquisition and control networks: for example, a sensor generates a stream of temperature values and wants to tell the world about

[64] Said to be inspired by the kid-tested connector used in the Nintendo GameBoy.

[65] Which, however, managed to ship its billionth node in 2008!

[66] You'll find CAN in places other than the car and factory; one of our colleagues bought a laser scanning microscope (Zeiss Duoscan), and found... CAN bus!

[67] That's the sentiment; but these messages are *short!* – you'd run out of bytes partway into the second word.

them, but doesn't particularly care who is listening.[68] And it has the pleasant property of being completely quiet electrically when there's nothing to send – this in contrast to chatty buses like USB, FireWire, and Ethernet, which like to mumble incessantly to themselves (and to the rest of the world).

One way to think of this is that the CAN bus (and its extensions into the microprocessors on the bus) represents a "parameter space" that is constantly and automatically updated by the members of the bus. Thus, whoever needs to know the engine temperature (including a computer that you just clipped onto the bus for diagnosing a bug) just looks at the value that has been written into its engine temperature "mailbox."

Electrically, you can think of CAN as a differential version of an open-collector bus: the signal pair (called CANH and CANL) takes the form of a twisted pair (usually shielded – "STP"), terminated at both ends in its characteristic impedance (usually 120 Ω). In the quiescent state both lines rest at ∼2.5 V, and that's where they stay unless some node is talking. When that happens, data is driven onto the line pair in a curious asymmetric signaling scheme (Figure 14.49): a logic "0" is asserted by taking CANH ∼1 V higher (to ∼3.5 V) and CANL lower (to ∼1.5 V), generating a ∼2 V differential signal. But to assert logic "1," the talker does not reverse the sense of drive current, but rather *releases* drive current, which lets both lines of the pair go to their ∼2.5 V resting state. These two signaling states are called *dominant* (bus driven, logic 0) and *recessive* (bus released, logic 1 or inactive).

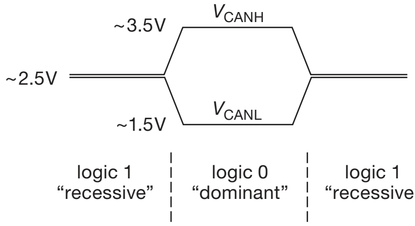

Figure 14.49. The CAN bus is differential, with an asymmetric signaling mode that simplifies arbitration.

This curious scheme was devised to simplify bus arbitration: there's no master controller in charge; instead any node can initiate a transmission, as long as it has seen the bus resting (recessive) for some minimum time. It then asserts its message bits sequentially, monitoring at the same time the state of the bus (every node must include a receiver). Of course, it's possible that another node has also initiated transmission. Such a "collision" is detected easily enough, because one of the transmitters will see a dominant (asserted, logic 0) state when it intended to send a recessive (disasserted, logic 1) state. It is then required to back off and try retransmission later.

The result is that, if there's a collision, the sender that generates the longest string of initial 0s gets the bus. This prioritizes the senders, because the initial bits of any message contain the sender's 11- or 29-bit message identifier, with lower numbers taking priority. And note especially the nice feature of the dominant–recessive scheme: the priority sender's message is not damaged by the collision (figure out why). In the acronym-studded language of networks, this is a "CSMA/CD+AMP" protocol.[69]

The CAN standard specifies good tolerance to common-mode noise, requiring correct operation at least from −2 V to +7 V, but extended by many transceiver ICs to ranges of −7 V to +12 V, or −12 V to +12 V. And ISO 7637 prescribes a torture test consisting of a train of ±150 V nanosecond-scale pulses that a transceiver must survive. In addition, you can use an inexpensive diode and zener protective device like the NUP2105 or NUP2202 (see ON Semi's App. Note AND8169; see also §12.1.5). For long bus runs, however, it's best to provide true galvanic isolation (avoiding ground loops mandates that there be only one ground point).

In keeping with its original intended automotive use, the CAN bus includes robust error-detection mechanisms: at the *bit* level there's bit monitoring (with error flagging if a disagreement), and detection of a "bit-stuffing" error (an opposite bit must be inserted after 5 consecutive bits of the same level). And at the *message* level there is a CRC (cyclic redundancy checksum), along with checking of an ACK (acknowledge) field and of a set of certain designated message bits (a "form check") that must be recessive. By this mechanism a transmitter can know if its message was corrupted and needs to be resent.

You can get plug-in CAN interface cards for standard computer buses such as PCI/PCIe, PC/104, and PCMCIA, and adapters from USB. And many microcontrollers (e.g., Atmel's AT90CAN series) include an on-chip CAN protocol controller. At the component level there are many manufacturers of CAN transceiver chips (most are powered from a single +5 V, but some work at +3.3 V). You

[68] And, conversely, it's inefficient for transmitting large blocks of data (for example, digitized audio or video) between two nodes. You also would not use it to link two processors in the same box.

[69] Well, at least it's shorter than the tongue-twister "carrier-sense multiple-access with collision detection and arbitration on message priority."

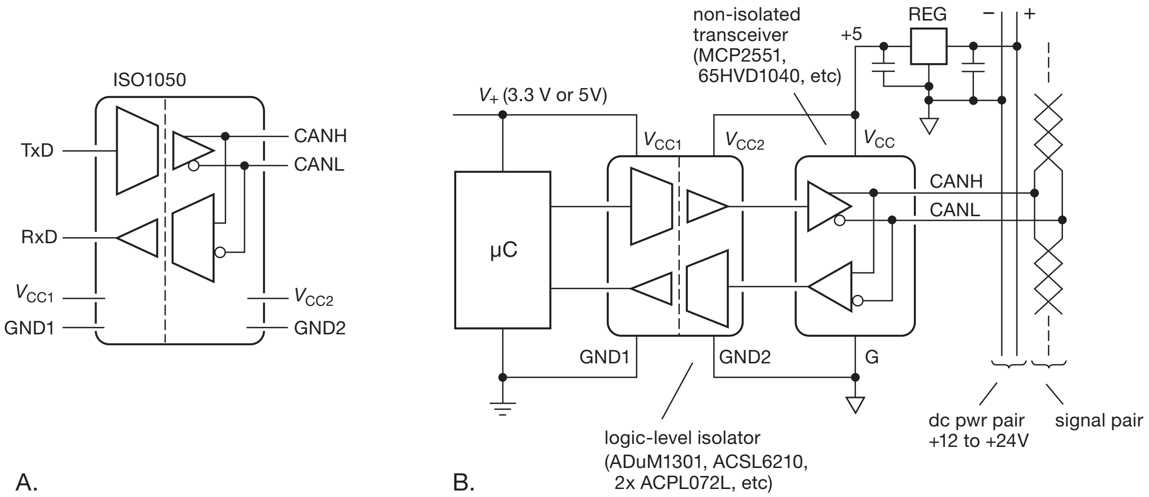

Figure 14.50. A. You can get single-chip galvanically isolated CAN transceivers, like TI's ISO1050, a good idea for long runs or noisy environments. B. Standard CAN cables include a second wire pair for isolated power, which you can use to power the bus side of the transceiver's isolation barrier. Here we've used a logic-level isolator between a microcontroller and the non-isolated CAN transceiver, the latter powered (along with the bus side of the isolator) from regulated +5 V derived from the bus dc power pair.

can also get galvanically isolated transceiver chips (e.g., the TI ISO1050, Figure 14.50), a good idea with long buses or noisy environments: you can power the bus side with an independent +5 V supply, or you can take advantage of the bused power pairs that often are included (for just such remote powering) along with the shielded and controlled-impedance signal pairs in CAN bus cables (e.g., Belden 3082/84 or Alpha 6451/52).

There are a couple of simplified CAN variants in use: single-wire CAN dispenses with CANL, and is limited to 40 kbps. And the closely related single-wire LIN (local interconnect network) bus dispenses with the regulated 5 V supply altogether, using a pullup to the +12 V battery and open-collector closure to ground; it's limited to 20 kbps. These inexpensive and simplified variants are sometimes used as a sub-bus in a CAN system; they both employ slew-rate limiting for reduced susceptibility to noise.

There is no defined CAN connector, but there are several common implementations, including a 9-pin D-subminiature, a 10-pin header, and a 4-pin open connector.[70]

14.7.16 Ethernet

Ethernet[71] is ubiquitous – those colorful telephone-like "RJ-45" network jacks – we all love it, we've mentioned it numerous times (for example in §12.10.3B, and in §14.7.9 in connection with Manchester coding), and we'll be mentioning it again in the next chapter. It was developed back in the 1970s at Xerox's famed Palo Alto Research Center ("Xerox PARC"), and at the physical layer (PHY) consisted originally of a shared coax cable (first "thick wire," officially called 10Base5; later "thin wire," or 10Base2), terminated at both ends, and tapped into by each node. Every node used transformer coupling, connecting right at the coax (no long stubs allowed), and (as with the CAN bus) there was a protocol for sensing collisions and backing off before retransmitting. To work properly in the face of inevitable (and data-destructive) collisions, there was established a minimum packet length (now standardized by IEEE Std. 802.3 as 74 bytes), and a maximum cable length (about 200 m for thin wire).

In contemporary practice the shared coaxial cable has been replaced with a point-to-point unshielded twisted-pair cable (UTP; Cat-5e or Cat-6), one end plugging into

[70] See www.interfacebus.com/Design_Connector_CAN.html and www.interfacebus.com/Can_Bus_Connector_Pinout.html. Additional information about the CAN bus can be found at www.kvaser.com/can/, www.can-cia.de, TI's App. Note SLOA101A, and Analog Devices' AN-770A.

[71] The whimsical name was chosen to convey the spirit of an all-present data-conveying medium, analogous to the "luminiferous ether" through which it was (incorrectly) thought that light traveled, before it was disproven by Michelson and Morley's famous experiment of 1887. With characteristic computer-nerd humor, the first two networked computers were named Michelson and Morley.

a computer's Ethernet NIC (network interface card), say, and the other end into a multiport "switch."[72] The latter buffers and forwards valid packets onward, without bothering uninvolved nodes. Ethernet, so configured, is collisionless.[73] Contemporary Ethernet is carried over twisted pair or optical fiber; standard speeds are 10 Mbps, 100 Mbps ("Fast Ethernet"), and 1 Gbps ("Gigabit Ethernet"), with evolution to 10 Gbps and 100 Gbps. And there is talk of *tera*bit Ethernet. As we remarked in §14.7.9, the evolution of higher speeds over twisted pair required some ingenuity: the slow stuff (called 10Base-T) uses Manchester coding and 2-level signaling, with one pair in each direction. To go to 100 Mbps (100Base-TX), 4b/5b coding is used, with 3-level signaling, again with one pair in each direction. Gigabit Ethernet (1000Base-T) uses 8b/10b coding, with all four pairs used in *both* directions (via a "hybrid"). These are descriptions of the *physical* layer; higher levels of the 7-layer OSI (open systems interconnection) network hierarchy don't know (and don't care) what's going on down there, so you can upgrade the hardware to your heart's content.

Twisted-pair Ethernet links are limited in length to ~100 m owing to signal degradation and attenuation. Fiber does much better – to a kilometer or so with multimode fiber, and tens of kilometers with single-mode fiber.[74] You can get "media converters" to change between copper and fiber, or copper and wireless; some of these incorporate rate conversion as well. Look at the Ethernet offerings from Allied Telesis, TRENDnet, StarTech, or IMC Networks; or the broad range of converters and extenders (including products for USB and serial, in addition to Ethernet) from B&B Electronics. See also Chapter 15 for interface component suggestions, such as the Lantronix XPort or Silicon Labs 28-pin CP2201 chip (to which you can simply add an RJ-45 jack with an integrated transformer and indicator LEDs).

Ethernet is so widely supported that it has become the dominant communications medium between computers and within local-area networks (LANs). Instrument manufacturers took notice, and it's rare to find a contemporary electronic instrument without an Ethernet port, both for instrument control and for data readout. (Nearly all of the 'scope waveforms in this volume were pulled in through our lab's LAN, from a Tektronix TDS3000-series 'scope, by pointing a browser at the instrument's IP address.) And, in a pleasant development, a standard is emerging in instrument control (the LXI standard: LAN eXtensions for Instrumentation), making communicating with contemporary instruments quite simple, especially when compared with the proliferating varieties of USB drivers. Ethernet is making its way into the industrial arena, with "industrial" variants that add features catering to the needs of real-time control.[75]

14.8 Number formats

We wind up this chapter with a short riff on number formats, meaning the way that numbers are represented internally during computation, or exchanged via digital media or communications ports. The scene is summarized in Figure 14.51, with some explanation in the following paragraphs.

14.8.1 Integers

Signed integers are always represented in 2's complement, using either 1, 2, or 4 bytes, or occasionally 8 bytes, as shown. The most-significant bit (MSB) tells the sign, even though 2's complement is not the same as sign–magnitude representation (e.g., -1 is 11111111, not 10000001; see §10.1.3). You can think of 2's complement as offset binary with inverted MSB; alternatively, you can think of it as an integer with the bit values as shown in Figure 14.51. Programming languages let you declare variables as *unsigned* integers, in addition to 2's complement signed integers. A 2-byte unsigned integer can have values from 0 to 65535. Quite apart from the number format itself, there's the hardware interface issue about how you pack integer data into a computer's larger word. For example, the binary integer

[72] This is a *star* topology, compared with the *bus* topology of coax Ethernet.

[73] Before switches were widespread and inexpensive, people used "hubs," which simply rebroadcast each packet to all connected nodes. With hubs you get collisions; with switches you don't.

[74] But twisted-pair Ethernet has a nice feature: it lets you send dc power ("Power over Ethernet," PoE), which is handy when connecting to remote devices like wireless access points, IP phones, or surveillance cameras. It uses the same signal pairs, applying the ~48 V dc as common-mode "phantom power" between the two pairs, picked off between the transformer center taps at the remote end. Audio engineers have been using the same trick, for ages, to power their microphones.

[75] For example, implementations of the IEEE Std. 1588 "Precision Time Protocol" (PTP), which allows time synchronization to ~100 ns via Ethernet (with dedicated hardware, for example the NSC DP83640 MAC/PHY chip, or included in embedded microcontrollers like TI's Luminary Stellaris ARM Cortex M3). PTP is currently being implemented by the LXI standard for interoperability between LAN-based instruments, as well as by several Ethernet-based Fieldbuses such as Profinet and CIP (Common Industrial Protocol).

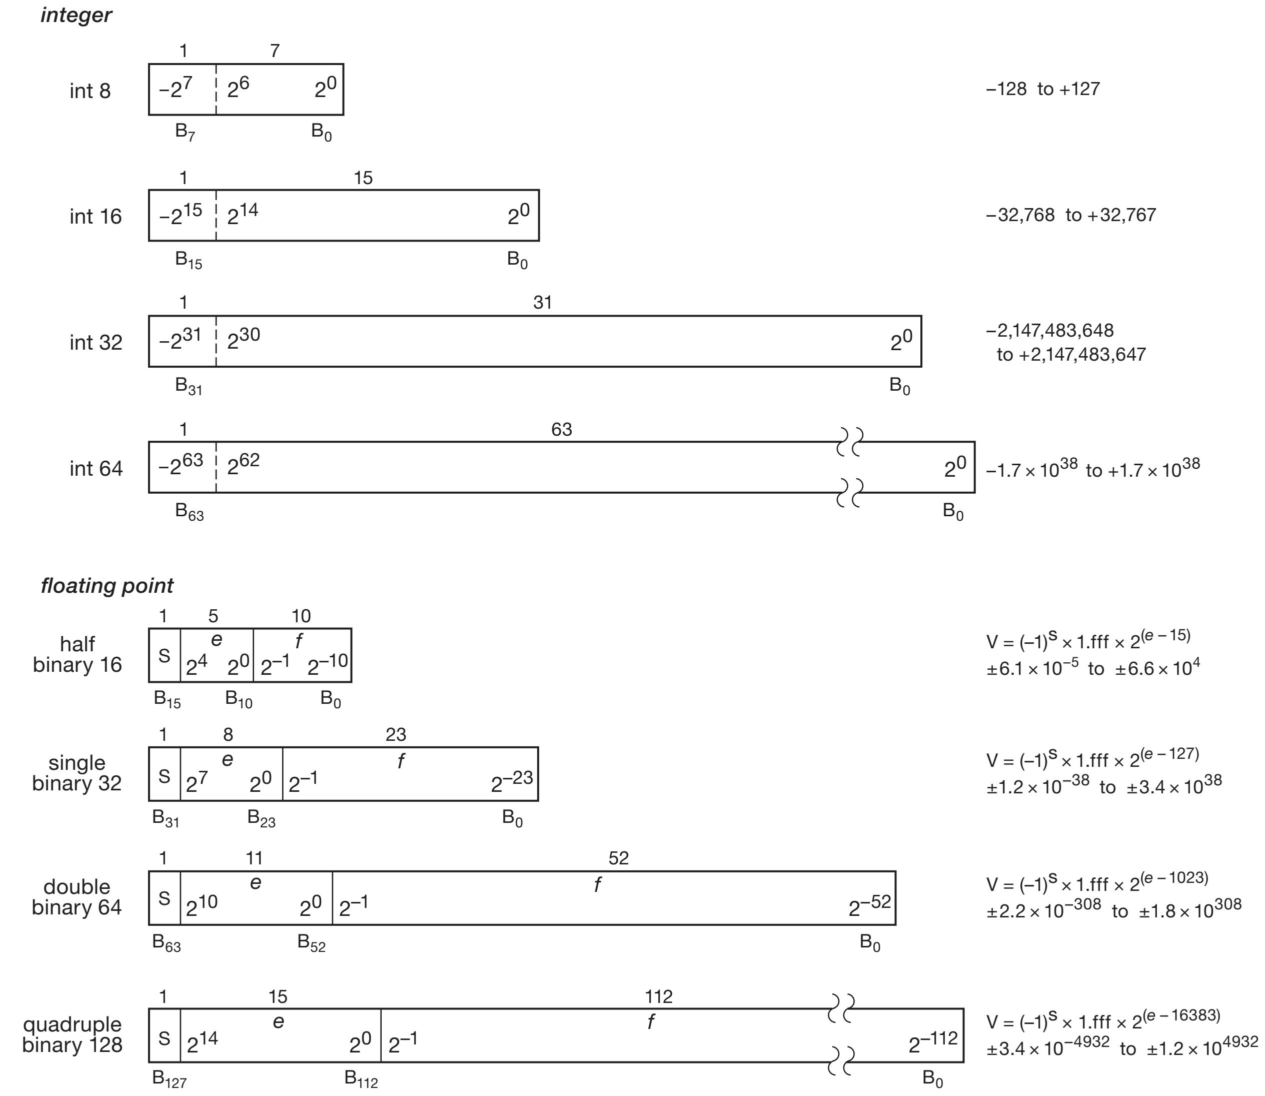

Figure 14.51. Commonly used number formats. The symbol "*e*" is the unsigned binary-integer value of the exponent field, used as shown to determine the value *V* of the various floating-point formats.

output from an ADC could be right-justified, so numbers go from zero up to the converter's full scale (0 to 4095, for a 12-bit ADC). But it's arguably better to left-justify the data, and think of the stored quantity as a *fraction*. This has a nice benefit, namely, if the ADC resolution is subsequently improved, it simply adds additional low-order fractional bits (rather than increasing the full-scale value).

14.8.2 Floating-point numbers

Floating-point numbers (sometimes called *real* numbers) are most commonly represented and stored as 32-bit ("single-precision") or 64-bit ("double-precision") quantities.[76] The bad news is that there are several incompatible representations in use. The good news is that the floating-point standard blessed by the IEEE (Std. 754-2008) has been implemented by nearly all processor families and is in nearly universal use.

Figure 14.51 shows the IEEE floating-point formats in detail. To see how it goes, look at the 32-bit single-precision format: it has 1 sign bit, 8 exponent bits, and

[76] Augmented by giant 128-bit ("quadruple precision"), and diminutive 16-bit (you guessed it – "half precision") formats.

23 bits of fraction. The exponent tells the power-of-2 that the fraction (see below) should be multiplied by. The exponent is "biased" by adding 127, so that the exponent field 01111111 corresponds to an exponent of 0; exponents thus go from −127 to +128. The fraction itself uses an interesting trick, originated by DEC in their floating-point format. A floating-point number in binary can always be written in the form $\mathrm{f.fff}\times 2^e$, where f.fff is the (base-2) mantissa ("significand") and e is the (power-of-2) exponent. To maximize the precision you get with a given number of mantissa bits, you "normalize" it by shifting the mantissa left (and decrementing the exponent) until the leading bit is nonzero, thus casting it in the form $1.\mathrm{fff}\times 2^e$. Now, here's the "hidden-bit" trick: because the resulting normalized significand always has a nonzero MSB, it would be redundant to display it; i.e., you don't store 1fff in the number, just the fff, with the leading 1 assumed. The resulting number gains one bit of precision, and has a range of $\pm 1.2\times 10^{-38}$ to $\pm 3.4\times 10^{38}$.

Exercise 14.3. Show that the range of normalized floating-point numbers is as claimed, by constructing the smallest and largest numbers.

The IEEE double-precision format is similar, but with the significand precision more than doubled (by attaching 29 more bits) and with the exponent fortified by an additional 3 bits, giving the range of numbers shown in the figure. If you like double precision, you'll love the additional dynamic range and accuracy of the whopping 128-bit quadruple-precision format, with its dazzling 113 bits of fraction, aided and abetted by a 15-bit exponent.

At the other end, a newly popular format is the 16-bit "half-precision" format (which some people call a "minifloat"). It squeezes sign, exponent, and fraction into a 2-byte word. The largest values in this format are ±65504. This isn't a whole lot more than you can do with a 16-bit signed integer (±32767), so it might seem pointless. Not so: the smallest value of IEEE minifloat is $\pm 6.1\times 10^{-5}$. So, you get a large *dynamic range*, albeit without great precision.[77]

This last point is worth a bit more explanation. The IEEE half-precision floating-point format (officially called "binary16") represents numbers spanning nine orders of magnitude, with an approximately uniform *fractional* step size of ∼0.06%. Unlike an integer representation, the fractional changes do not get coarser as you go to small values (figure out why). And this is a good characteristic for quantities that are perceived logarithmically, such as illumination or sound intensity.

The IEEE format allows non-normalized numbers also, to give some additional range at the small end, at the expense of precision (these have the exponent bits set to all zeros, which changes the interpretation of the fraction to 0.fff). For single-precision (binary32) floating, the range of these "denormalized" numbers then goes down to $\pm 1.4\times 10^{-45}$; but the steps become fractionally larger as you hit bottom. The standard also defines zero (both e=0 and fff=0; thus there are two zeros, +0 and −0), infinity (e = all 1s, fff=0; therefore both signs), and a curious class of reserved quantities known officially as NANs ("not a number").

A. Number storage in memory

Microprocessor designers like to express their individuality by storing numbers in memory in peculiar orders. Intel-originated processors store multibyte integers beginning with the least-significant byte in the lowest-numbered memory byte; Motorola (Freescale) processors do it the other way around.[78] Some processors (e.g., the popular ARM core) are ambidextrous (therefore "bi-endian"). And, to add a bit more confusion, some processors use one byte order for integers and the other for floating-point numbers. Endian-ness is of more than academic interest; it can matter, for example, when sending data to a peripheral via SPI or I^{2}C. Lots of luck!

[77] Characteristics that are particularly useful in applications such as video imaging. In fact, it was devised by Industrial Light & Magic for just such uses. The half-float format is supported in graphics processor chips, which are becoming popular for large-scale computation. These chips, with hundreds of fast processing cores, are challenging traditional CPUs; throw a few dozen of them in a box, and you've got yourself a pretty impressive supercomputer.

[78] Engineers get their jollies by calling these "little-endian" and "big-endian," respectively.

Review of Chapter 14

An A-to-J summary of what we have learned in Chapter 14. This summary reviews basic principles, facts, and application advice in Chapter 14.

¶A. Processors and Data Buses.

This first of two processor-oriented chapters dealt with the subject of computer architecture and the interfaces (buses) over which data is exchanged, whereas the subsequent chapter is devoted to the use of microcontrollers as "embedded" components within a circuit or instrument. Given the omnipresence of computers in contemporary life, the reader is likely to be familiar with much of the material in this chapter.

¶B. Bus-oriented Computer Architecture.

In a classic computer architecture (§14.1) the processor unit (CPU or MPU) executes instructions fetched from memory, moving data on a set of lines called a *bus* (Figure 14.2). The instructions encode what is to be done, and the processor does it, as interpreted by its *instruction decoder*. Within the processor is an *arithmetic logic unit* (ALU), responsible for arithmetic and logical operations (e.g., ADD or COMPARE) performed on data held in *registers*; a *program counter*, which holds the memory address of the current instruction; a set of *flags* that are set according to the result of the last operation and which are tested for conditional branching; a *stack pointer* to address memory sequentially for temporary storage (e.g., of return address during interrupts and function calls); and, often, a *cache memory* to hold recent data and instructions for quicker access.

¶C. Peripherals.

A computation-oriented microprocessor (as would be used in a server or desktop computer) communicates with off-chip peripherals through one or more buses, whereas a processor aimed at embedded applications (a micro*controller*, Chapter 15) trades off some computational finesse by integrating instead a set of on-chip peripherals and memory. Typical peripherals include nonvolatile mass storage such as hard disk (hdd) and solid-state disk (ssd), random access memory (RAM), video graphics, network interface (Ethernet), data acquisition and control (ADC, DAC, digital I/O), and serial ports such as USB and SATA.

¶D. Instruction Set and "Machine Language."

A given processor is designed to interpret certain groups of bytes, taken together, as *instructions*, and to carry out the corresponding tasks (§14.2). Such *machine language* instructions can be of various lengths; for the Intel x86 32-bit processors, for example, instructions range from one to fifteen bytes in length. Programming directly in machine language is too tedious for humans; instead each instruction can be represented in a readable text-formatted *assembly language*, with understandable mnemonics (e.g., `ADD AX,BX`, which adds to the quantity held in register AX the quantity held in register BX). A program called an *assembler* then converts the assembly-language program (a text file created by the programmer, or by a *compiler* from a program written in a high-level language like C) into the processor's native machine language.

To illustrate processor instructions we chose the Intel x86, displaying a pared-down instruction set (§14.2.2 and Table 14.1). There are *arithmetic* instructions (for example `ADD`), *conditional branch* instructions (for example `JNZ label`, jump on non-zero), stack instructions (`PUSH` and `POP`), and I/O instructions (for example `OUT port,AX`). Along with the instructions, you've got to understand *addressing*, the various ways that locations in memory or registers can be designated. In the x86 language the basic possibilities are *direct* (the address itself), *indirect* (an address pointing to the place in memory where the address itself is held), *indexed* (a numerical offset from a base address, useful for "moving pointer" accesses to sequential addresses), and *immediate* (a numerical quantity contained within the multibyte instruction itself).

¶E. PC104/ISA: a Parallel Bus.

Bus interfacing can be a complicated business, with elaborate negotiation protocols and the like. To keep things simple we chose the legacy PC104/ISA 8-bit parallel bus (§14.3), an outgrowth of the original IBM PC bus that has been adapted to the industrial PC104 embedded system standard. It is in widespread use, and it illustrates well the basics of a multidrop bus (and parallel data transfer in general); for reference, the full set of bus signals is listed in §14.3.11.

WRITE cycle. To move some data out to a peripheral (a "write cycle"), the bus master (here the CPU) asserts the data onto a set of 3-state DATA lines (D0–D7) and the target address onto the ADDRESS lines (A0–A15), then it pulses a "write" line (IOW′), see Figure 14.8. The peripheral's corresponding hardware (Figure 14.9) responds by latching the data (on D0–D7) by clocking with IOW′ if it sees its unique address (on A0–A15). This transaction takes place automatically when the CPU executes an `OUT` instruction to the peripheral's address.

READ cycle. To fetch data from a peripheral (a "read cycle"), the bus master asserts the peripheral's address, but does not assert the (3-state) data lines; instead it pulses a "read" line (IOR′) and latches the data it finds on D0–D7 (asserted by the addresses peripheral) at the end of IOR′; see Figure 14.13. The peripheral's corresponding hardware (Figure 14.14) responds by asserting its data onto D0–D7 by enabling 3-state drivers with IOR′ if it sees its unique address (on A0–A15). This transaction takes place automatically when the CPU executes an IN instruction from the peripheral's address.

Command and status bits. The "data" that the CPU fetches during a read cycle can be ordinary data (e.g., a byte from an ADC); but it can instead indicate a status (e.g., new ADC data is available to be fetched). Such status data is essential in most cases; see, for example, the simple keyboard interface in Figure 14.15, where a flip-flop is set when a new character is struck and cleared when a character is read; its status is readable on bit D7 of its peripheral address (KBFLAG). The corresponding program code (§14.3.5A) repeatedly reads that *status byte*, looping until it finds bit 7 set, whereupon it fetches a data byte from the keyboard's data address (KBDATA) and appends it to data stored in a string buffer in memory. In analogous manner, bits that are sent *to* a peripheral can indicate an action to be initiated by that peripheral; these are *command* bits, for example to tell and ADC to begin conversion, or a serial port to send a data byte. Multiple status (or command) bits can be grouped into a status (or command) *register*, each bit of which can have its own function.

Interrupts. The use of status bits lets the CPU find out if action needs to be taken, but it has to ask (by reading the status register). Such *polling* is one way for a peripheral to signal the CPU; the alternative is the *interrupt*, in which the peripheral asserts one of several dedicated bus lines (called IRQ*n* on the PC104 bus). This signals the CPU's hardware, which (if interrupts are enabled) causes program execution to break off from what it's doing and jump to an "interrupt handler" routine; see §§14.3.7–14.3.9 for hardware and software examples.

Direct memory access. Most efficient of all for rapid transfer of multiple bytes (e.g., reading a whole file from disk) is DMA, in which the successive bus addresses and control pulses are generated by hardware, and thus do not require the processor cycles needed for the READ or WRITE cycles of *programmed I/O*; see §14.3.10.

¶F. Other Parallel Buses.

The PC104/ISA internal multidrop computer bus is slow (less than 10 MB/sec), and was superseded by the **PCI** (peripheral component interconnect) multidrop bus, which reached 2 Gb/s in its 64-bit-wide incarnation. A PCI interface is considerably more complex than the simple PC104 described in ¶E, requiring some negotiation with the PCI controller, etc. PCI is now obsolete, having been replaced by the point-to-point serial PCIe, (see ¶H). For connection to disks, the legacy parallel interfaces are **IDE** (also called ATAPI or PATA) and **SCSI**; both are obsolete, having been replaced by serial buses: SATA and SAS. The original printer interface was parallel (a 25-pin D-connector or 36-pin "Centronics" micro-ribbon connector), replaced by serial buses (USB or Ethernet). And for connection to laboratory instruments the **GPIB** (general-purpose interface bus, originated by HP as the HPIB) is still alive and, well, surviving; it's a bit awkward, though, with its thick cables and hunky connectors. Most lab instruments now support Ethernet and USB. These and other buses are listed in Table 14.3.

¶G. Parallel Data Links.

At the much simpler level of data transfer between ICs on a circuit board (say between an embedded microcontroller and an ADC) the parallel bus's data–address–strobe protocol becomes very simple: for a point-to-point connection (i.e., a single peripheral chip) all you need are a byte-wide (or 4-bit-wide) data path plus direction and strobe; see for example Figure 14.34. This is hardly a *bus* – it's really just a data link.

Apart from some IC interfaces of this kind, and the wide and speedy CPU "Front-Side bus," nearly all parallel buses and data links have fallen by the wayside, yielding their dominance to *serial* buses and links (¶¶ H, I); ironically, a single serial link is usually faster than the byte-wide parallel link it replaces, with a lot less wiring and (for external interfaces) permitting much skinnier cabling.

¶H. Serial Buses.

There are many advantages to a *serial* data connection (§14.7): fewer wires, fewer pins on the driver and receiver chips, clean termination (in a point-to-point connection, i.e., a single driver and a single receiver), lack of timing skew (self-timed via clock recovery), and the flexibility of using an optical fiber or wireless channel. Counterintuitively, contemporary serial links deliver higher data throughput than their parallel forebears. For example, the last of the parallel disk interfaces topped out at 1–2 Gbps (PATA and SCSI, 16 bits wide), whereas their serial successors (SATA and SAS, a single differential pair in each direction) deliver 6 Gbps.

In the computer world the common *internal* serial buses are the **SATA** (serial ATA), **eSATA** (external SATA, a short extension of SATA), and **SAS** (serial-attached SCSI) disk buses, and the **PCIe** (PCI express) motherboard bus (see §§14.7.6 and 14.7.7). The latter is a hybrid of sorts – unlike the earlier parallel multidrop PCI bus, PCIe is point-to-point and serial (a differential pair in each direction), but it runs multiple such "lanes" to each motherboard slot, labeled with "×" (commonly ×1, ×4, and ×16, but also ×8 and ×32). Each lane can deliver up to 8 Gbps, with separate clock recovery at the receiver.

For communication *external* to the computer the common serial buses are USB, FireWire, Ethernet, and CANbus. In its current revision (3.0) **USB** (§14.7.13) is full duplex (a differential pair in each direction) with speeds to 3.2 Gbps; this improves on the previous version (2.0) which is half duplex with speeds 480 Mbps. FireWire (IEEE 1394, §14.7.14) is full duplex, with versions supporting 400 and 800 Mbps (and with rates to 3200 Mbps included in the standard).

Ethernet (§14.7.16) is the bus of choice for computer networks; the original coaxial multidrop 10 Mbps versions (10base2, thinnet, and 10base5, thicknet) have long since been replaced by full-duplex point-to-point twisted pair connections (10base-T, 100base-TX, 1000base-T), which both circumvent the problem of collisions and offer data transfer speeds to 1 Gbps.

CANbus (§14.7.15) is an industrial-strength multidrop and multimaster bus used in automotive and factory environments; it's robust, and permits links up to 1 km, though at greatly reduced data rate (10 kbps versus its 1 Mbps for links less than 40 m long).

¶I. Serial Data Links.

Largely superseding the parallel data transfer between ICs on a circuit board (¶G) are the popular serial data links: SPI, I^{2}C, and JTAG. **SPI** (§14.7.1) is drop-dead simple, with a master–slave architecture comprising three wires shared among multiple slave chips: one data wire in each direction (MOSI, MISO) and a clock (SCLK); there's a separate slave-select line (SS′) needed for each slave device; see Figure 14.38. A selected device receives data (MOSI) and sends data (MISO) on each clock, see Figure 14.37. There's no universal SPI standard, so you have to conform to each chip's protocols according to its datasheet. Take a look at Figure 15.21 in the next chapter to see some SPI peripheral chip examples.

By contrast, **I^{2}C** (§14.7.2) is a more sophisticated multidrop serial link, with two wires only (SDA, data; SCL, clock); there's a well-defined protocol by which the master (the microcontroller) communicates both target address and data direction to the various slave devices. The minimal wiring and communication flexibility of I^{2}C is offset by the need to give each device a unique address, and by the problems of contention and arbitration on the shared lines. Take a look at Figure 15.22 in the next chapter to see some I^{2}C peripheral chip examples.

The **JTAG** bus (§14.7.4), originally intended for in-circuit testing and debugging, has become a popular interface for loading and debugging microcontroller code, and for programming nonvolatile on-board memory. It buses a shared clock (TCK) and mode line (TMS), and daisy-chains a data line (TDI in to each device, TDO out); see Figure 14.43. You connect to the JTAG bus with a programming "pod" that attaches to a USB port on your host PC.

And don't forget the good ol' **RS-232** "serial COM port" link (§14.7.8), still widely supported by microcontrollers. You can talk to them with a PC running a terminal emulator, connected with a USB-to-RS232 adapter like FTDI's TTL-232R-3V3 or TTL-232R-5V (3.3 V and 5 V, respectively).

¶J. Memory.

Any talk of computers is incomplete without a discussion of *memory*, set forth in §14.4. The ideal memory would have fast random-access, persistent retention without power (i.e., nonvolatile), and infinite endurance (number of read–write cycles); ideally it should also be low power, inexpensive, and compact. Real-world memory has not yet achieved these goals, at least in a single memory type.

The current popular favorite in *nonvolatile* memory (§14.4.5) is **flash NAND** (the stuff of USB memory sticks, camera memory cards, and solid-state drives). It is limited in speed and endurance, and must be written or erased in sectors; but it's outrageously inexpensive (∼$0.50/GB in single quantities). For retention of small quantities of data there's **EEPROM**, whose 2-transistor cell permits single-bit or -byte erasability. Some new technologies that may deliver near-infinite endurance are **FRAM** (ferroelectric RAM), **MRAM** (magnetoresistive RAM), and **PCM** (phase-change memory, also called PRAM).

Contemporary memory types with fast access and infinite endurance are all *volatile*: SRAM (static RAM) and DRAM (dynamic RAM). The basic **SRAM** is an array of addressable 6-transistor ("6T") flip-flops (Figures 14.20 and 14.21), configured for asynchronous or synchronous (i.e., clocked) operation; see §14.4.3. Static RAM has a simple interface, fast access, and zero quiescent current, but its 6T cell takes up lots of space, so its density is considerably lower than that of dynamic RAM. For this reason a class of pseudo-static (**PSRAM**) memory has become popular: it exploits a hidden refresh mechanism to bring the density of DRAM to the simple interface of SRAM; it's a DRAM in SRAM's clothing. SRAM and PSRAM memories are useful in small or low-power systems where only a modest amount of memory is needed.

The other volatile memory type is **DRAM** (§14.4.4), an array of tiny ($\sim$30 femtofarads) capacitors whose charge state holds one bit, addressed with an array of MOSFETs such that only one transistor is needed per bit, both for readout and for charge retention ("refresh"); this is a "1T1C cell" (Figures 14.26 and 14.27). DRAMs require periodic refreshing, and, having originated as asynchronous memory chips, they are now used in their synchronous (**SDRAM**) varieties: **SDR** (single data-rate), and evolving **DDR** (double data-rate) versions (**DDR2**, **DDR3**, and **DDR4**). DRAM has infinite endurance, fast access, high density, and low cost, and it is used for the main memory in PCs, laptops, and all variety of consumer electronics (e.g., cable and satellite boxes). It's what you get when you buy a DIMM module for your computer; these things are currently costing about \$5–\$10/GB.

MICROCONTROLLERS

CHAPTER 15

15.1 Introduction

As we remarked in the previous chapter, microcontrollers are essentially stand-alone processors, intended to be *embedded* into some electronic device that is definitely not a "computer."[1] They are inexpensive and easy to use, and they let you put the intelligence of a computer into pretty much anything electronic. In so doing, they trade off some of the terrifying speed of computer-oriented processors in favor of built-in memory and peripherals.

To expand on this point, nearly all microcontrollers (including those that cost less than a dollar) include both data memory (static RAM) and non-volatile program memory ("flash") on-chip; many include additional non-volatile EEPROM for holding calibration data, system configuration settings, and so on.[2] Better still, you can choose among integrated "peripherals": communication links such as SPI, I^{2}C, USB, Ethernet, Bluetooth, and ZigBee; buses such as PCI and PCIe, SATA, PCMCIA, flash-memory cards, and external memory; analog interfaces such as comparators, multiplexed ADCs, DACs, and video and imaging sensors; and special-purpose interfaces such as pulse-width modulators, LCD drivers, GPS, digital audio, and WiFi.

To put it another way (Figure 15.1), a microcontroller includes within it the "CPU + memory + peripherals" that required an external data bus and separate components in the previous chapter. (You *can* implement an external data bus with a microcontroller, if you want to; but it's better to choose a microcontroller that has what you want on-chip.)

Of course, in an embedded system you don't boot up from a disk – you don't even *have* a disk! That's why the program memory is included on the controller, and also why it must be non-volatile: your dishwasher needs to know what it is supposed to do, even after a power failure. Because microcontrollers are built into the target device (and generally not removable from the circuit board) they must be programmable (and reprogrammable) *in-circuit*. You program them via an "in-circuit serial programming" interface ("ICSP," usually SPI or JTAG), with a hardware interface "pod," controlled by software running on a host computer.

Microcontrollers are fun, and easy. Think of them as a circuit "component," like an op-amp. The analogy is good: just as the op-amp is the universal analog component, the microcontroller might be thought of as the universal digital component.[3] And a microcontroller plus a few other components (e.g., a USB connector, the programming header, a few lights and buttons, and perhaps an alphanumeric LCD) put onto a small circuit board, is a "universal block" whose function is flexibly programmed to do whatever you want. The microcontroller manufacturers happily provide such objects (sometimes called "development kits," which often include programming hardware and software; see Figure 15.24 on page 1090), to encourage you to adopt their wares. There are also third-party and open-source products, such as "Ethernut" and "Arduino".[4] The former includes an Ethernet port; the latter offers serial, USB, SPI, and I^{2}C ports, with an optional stackable Ethernet adapter.

Let's launch into microcontrollers with a concrete example.

[1] A recent publication from Maxim Integrated Products (App Note 3967) begins with the sentence "The heart of today's advanced electronic products is a microcontroller (μC) that communicates with one or more peripheral devices." As a friendly amendment, we'd probably omit the word "advanced."

[2] *EEPROM* permits rewriting (or erasing) individual stored bytes, as contrasted with *flash* memory, in which erasure (required before rewriting) can be done only on a block of bytes at once. That is why the lower-density EEPROM is better for storing user data, whereas the higher-density flash is best for infrequently rewritten program code. Both memory types are non-volatile and in-circuit programmable, though flash typically has less rewriting "endurance," e.g., 10,000 erase–write cycles for flash, versus 100,000 for EEPROM.

[3] Although experienced users of FPGAs might well argue that *their* chips are "more universal": you can put a microcontroller "soft core" into an FPGA, but not vice versa.

[4] Here are a few more: BeagleBoard & BeagleBone, Odroid, Raspberry Pi, and Teensy.

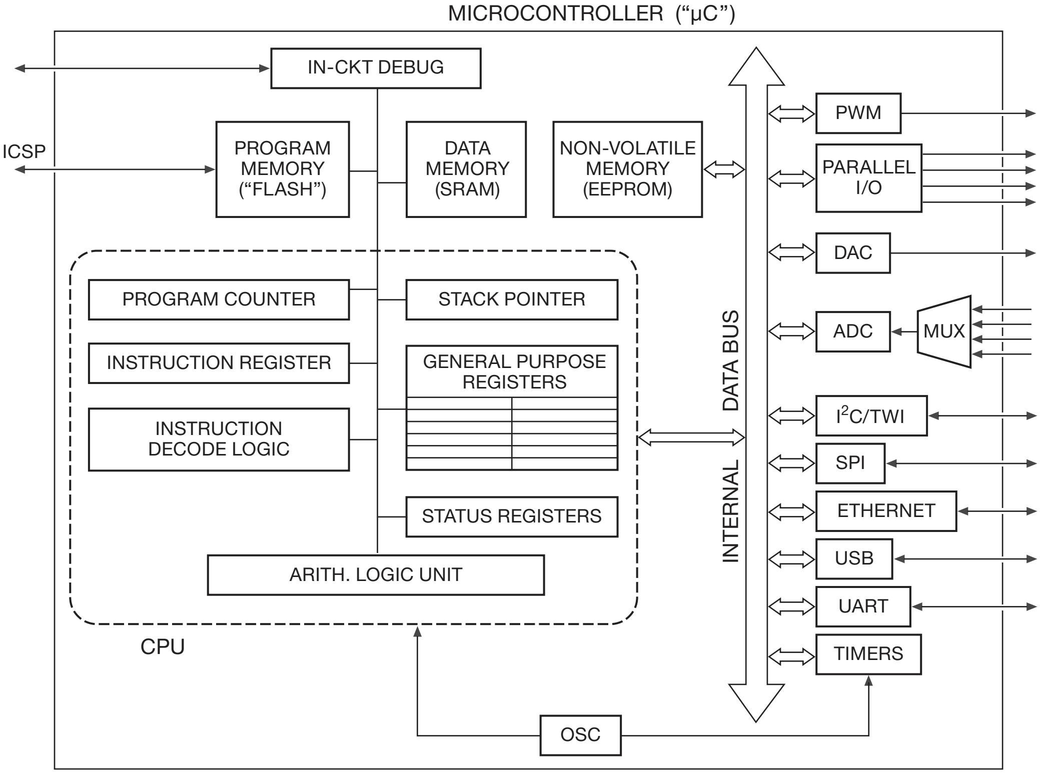

Figure 15.1. A microcontroller integrates memory and “peripherals” onto the same chip as the CPU. ICSP stands for “in-circuit serial programming.”

15.2 Design example 1: suntan monitor (V)

We’ve visited this indispensable device for the beachgoer, first in Chapter 4 (where we explored three purely analog implementations), then again in Chapter 13 (with a photocurrent-integrating ADC). Those illustrated nicely the use of discrete analog and digital electronics. We conclude our pursuit of the perfect suntan integrator in this chapter, with (naturally) a microcontroller implementation. We take a first stab at it here, with a bit of refinement later in the chapter.

To review, the task is to inform the sunbather when to turn over (or go home), after having received the desired accumulated dose of sunlight, using as input a photodiode’s current (which is proportional to suntanning intensity). The beachgoer sets the target FSE (full-sunlight-equivalent) dose with a pot, on a scale of 0–90 min FSE, pushes the START button, and begins the bake cycle. A piezo buzzer beeps when the job is complete.

15.2.1 Implementation with a microcontroller

An classic (but uninspired) way to approach this is to convert the current to a voltage (with op-amp and feedback resistor), then use the microcontroller’s on-chip ADC to generate digitized samples, which are then integrated numerically. But there’s a simpler (and better) way, easily implemented even in a 50-cent microcontroller. Look at Figure 15.2. The idea is to use the photocurrent to ramp the

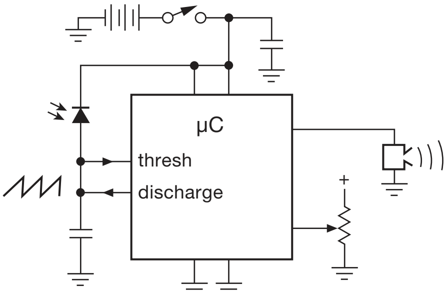

Figure 15.2. Suntan monitor, simply implemented with a microcontroller (μC).

voltage on a capacitor, then use the microcontroller's analog comparator to trigger a short discharge pulse on a three-state digital output port.[5] This generates a sawtooth whose frequency is proportional to light intensity; the microcontroller integrates this by simply counting cycles, sounding the horn at the desired terminal count, which it derives from a measurement of the "dose" pot's setting. A digital input-port bit senses the START button, and a digital output-port bit activates the piezo buzzer.

Not only is this simpler than the humdrum $I \rightarrow V \rightarrow$ADC method, it is better: converting a current to a proportional voltage requires good dynamic range (and therefore very low offset voltages) to integrate accurately at low light intensities, whereas this $I \rightarrow f$ oscillator preserves accuracy by generating a fixed-amplitude sawtooth with excellent linearity at low currents. This departure from the usual modular engineering design approach illustrates nicely the sort of "holistic" creativity that microcontrollers stimulate in their devotees.

The circuit of Figure 15.2 is by far the simplest of the five iterations of a suntanning circuit, though, of course, there is the task of writing and downloading the embedded code (which we'll look at next). Before we do that, let's flesh out the circuit in all its glory – component values, choice of controller, PINs, etc. There's plenty to learn by doing this; in an important sense, dealing with the details and the compromises they compel is the essence of electronic circuit design.

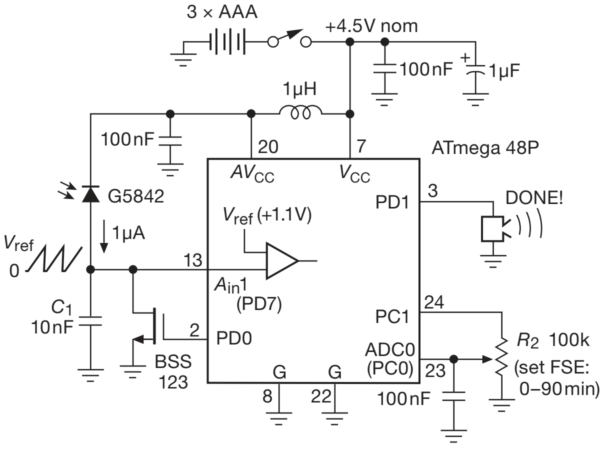

Figure 15.3. Detailed circuit of the suntan monitor. See Figure 4.93 for information about the G5842 GaAsP photosensor.

Figure 15.3 is a complete implementation, using parts available at the time this is being written. Let's look at some details.

A. Choice of microcontroller

This gadget doesn't demand much, in terms of speed or peripherals, and nearly all microcontrollers include a comparator and an ADC. However, we want low current consumption, and we'd like to run directly from a battery, without a voltage regulator. We chose this part because it is the smallest of the "picoPower" series of Atmel's AVR controllers, which have the virtue of low-power operation even when running from +5 V.[6] It operates from 1.8–5.5 V, and draws about 35–170 μA supply current (over that range of supply voltages) when running from its internal 128 kHz oscillator.

B. Discharge circuit

Although you could probably get away with using a three-state output to discharge the oscillator's capacitor directly (Figure 15.2), the worst-case specifications would deny you the satisfaction of a job well done: they specify a maximum leakage current of $\pm 1\,\mu$A, comparable to the photocurrent in sunlight. You could choose a larger photocell, with correspondingly higher photocurrent; but an external *n*-channel MOSFET does the job nicely.[7] Here we've used a small BSS123 *n*-channel MOSFET as an external switch. It's a good choice: it has a satisfyingly low threshold, with ∼0.5 A drain current at 2.5 V of gate drive, and a worst-case leakage of 10 nA at V_{DS}=20 V. It's stocked widely, priced at $0.05 in quantity.[8]

C. Dose-setting potentiometer

The simple diagram biased the pot from the positive supply rail. But good design requires its bias current to be large compared with the 1 μA input leakage spec, which adds significant power drain. We can do better, though, by powering the pot only when we need to, i.e., when reading its value. That's easy – just tie its topside to a digital output-port bit; when the software sets that bit HIGH, the internal *p*-channel pullup brings it to $+V_{CC}$.

[5] You could arrange things to do the discharge on the same pin as the threshold comparison, by dynamically changing a bit in the register that sets the port-bit modes.

[6] Many controllers run at low power when operated at low supply voltage (say 1.8 V), but not at 3–5 V, as here.

[7] You could, instead, be reasonably confident that the typical leakage current is probably less than 10 nA, particularly since the specifications are given over the full temperature range of −40°C to +85°C; furthermore, semiconductor manufacturers are notoriously conservative when specifying leakage. You don't have to worry about the comparator's input pin, though: its specified leakage current is 50 nA (max).

[8] The BSS123 is similar to the 2N7000 and 2N7002 (see Table 3.4a).

D. Bypassing and decoupling

Figure 15.3 is decorated with decoupling capacitors, perhaps a bit conservatively. We decoupled the analog supply rail (AV_{CC}) from the noisy digital V_{CC} with the *LC* filter recommended in the datasheet. We also bypassed the pot readout, because it is biased from an equally noisy digital output. Finally, we used a parallel combination of supply-rail bypass capacitors to maintain low impedance over frequencies. (The series inductance and resistance of large-value capacitors reduce their effectiveness at high frequencies, remedied here by the smaller 100 nF ceramic bypass capacitor; see Chapter *1x*). Once again, we could probably get away with less, particularly since we need very little accuracy (∼6 bits) from the part's too-good internal 10-bit ADCs, for which the bypass specifications were intended. But we like to play it safe.

E. Oscillator

There isn't one! That's because this controller, in common with many, includes internal oscillator options; for this chip there are two internal oscillators (8 MHz and 128 kHz), of modest accuracy (±10%).

15.2.2 Microcontroller code ("firmware")

The embedded software, called *firmware*, needs to do several tasks, namely,

(a) initializations at power-up (set up I/O port modes, ADC and comparator modes, and reset state of output port bits);
(b) assert V_{CC} to the pot, wait 25 ms, read its voltage, then disassert;
(c) use the measured voltage to compute the terminal count of oscillation cycles from the sawtooth oscillator, corresponding to the integrated sunlight exposure set by the pot;
(d) use the comparator output state to increment the cycle counter and to generate capacitor discharge pulses;
(e) when the counter reaches the computed terminal count, activate the piezo buzzer.

In addition, there are some operating characteristics (for example, oscillator frequency) that are not under program control and that are set instead at the time the program code is downloaded to the device. More, soon, about programming these so-called "fuses."

A. Pseudocode

We've written this in somewhat more detail in Pseudocode 15.1; pseudocode is a less formal substitute to a graphical *flowchart*, with more readable text.

A bit of explanation: the code begins with some **Setup** tasks. That is because contemporary microcontrollers are richly endowed, with built-in peripherals, operating modes, pin function options, and the like.[9] This flexibility and power are both a blessing and a curse. The blessings are obvious. The curse extracts its revenge, in requiring you to configure all those options. That is done by setting or clearing bits in an array of registers whose function is to configure and control the device's options. This particular processor has 256 such internal registers, with some 40 bytes worth of configuration and control bits. You generally don't have to worry about most of them, because they default to reasonable values; but you do have to set up the range and mode of the ADC and comparator, and the port bit directions.

The program code is executed on power-up, and is obliged to do first this fussy up-front housekeeping: microcontroller port bits can individually be configured as inputs or outputs (under program control), which you specify by setting bits in a port direction register (if an input, you can also enable or disable internal pullup). The setup code continues by initializing the buzzer output bit LOW and the discharge pin HIGH, and concludes with choice of ADC and comparator voltage references, scaling, and input sources. There are a few other configuration bits that have to be set, specifically the clock source (external or internal), the clock frequency, and the clock divider ratio. For this particular microcontroller, these "fuse" bits are set during hardware device programming, rather than in the executable program code.[10]

Next it **Initializes** LOW the two output port bits (beeper, discharge transistor drive), and defines (and clears) a register variable that will hold the accumulating COUNT from the sunlight-proportional sawtooth oscillator. Now we **Read** the pot that sets the target dose: set PC1 to put V_{CC} across the pot, wait 25 ms, start the ADC, hang on its busy flag, then read the high byte of the 10-bit conversion (we really don't need better than 0.5% on this job), power down the pot, and compute the corresponding terminal count. The latter assumes a nominal 100 Hz full-sunlight sawtooth, ($\sim 1\,\mu$A photocurrent), and a full-scale setting of 90 minutes.

All this has taken a fraction of a second. Now we

[9] For example, this processor's pin 28 is bit 5 of byte-wide bidirectional port C; it can also be used as an analog input to the ADC (via the internal 8-input multiplexer), or as the SCL serial clock, or as a "pin-change interrupt" source.

[10] For high-pincount microcontrollers it's common to see a few pins used to determine what happens at boot-up, with program control then in charge of those parameters.

Pseudocode 15.1 Suntan monitor pseudocode

```
Setup
    Variables: Define 32-bit integers count and termcount
    Low Power: Disable unused peripherals
    Ports: Set as outputs PC1 (pot bias), PD0 (cap discharge) and PD1 (buzzer);
        set as analog inputs PC0 (pot readout) and PD7 (cap voltage);
        initialize PD1 LOW (buzzer off), and PD0 HIGH (cap held at gnd)
    Analog modes: Set comparator mode & bandgap ref;
        set ADC ref to Vcc, ADC mode to left-adjusted, and MUX to channel 0

Read "bake" setting
    Setbits PC1 (power to pot) and ADEN (ADC enable); wait 100 ms
    Start ADC conversion (setbit ADSC)
    Wait while ADSC=1 (busy), then read unsigned 8-bit result ("bake")
    Clearbits PC1 and ADEN, and disable ADC to save power
    Compute termcount=360000 x bake/256

Count Cycles
    Wait while comparator is HIGH ($V_{\mathrm{cap}} < V_{\mathrm{ref}}$), then:
        setbit PD0, then clearbit PD0 (software discharge pulse)
        increment count
        if count<termcount, repeat Count Cycles
        otherwise set bit PD1 (buzzer), clear 10 sec later
```

Count cycles of the sawtooth, whose ramp is generated by the photocurrent, abruptly discharged by a software pulse (HIGH, then LOW) to the MOSFET. Because there's nothing else to do anyway, we've used simple polling of the comparator's output bit, rather than the more elegant alternative of a counter-driven interrupt (our comparator mode setup disabled its interrupt). When the count reaches the computed target we turn on the beeper and hang "forever" (that is, until the bakee switches the thing off; restart at your peril – twice-baked human!).

B. Detailed C-code

Program 15.1 is a listing of the C-language source code. It should be readable by fluent C programmers, though there are a few quirks associated with microcontrollers. The `io.h` and `fuse.h` files contain the idiosyncratic register definitions, functions, etc., that deal with peculiarities such as fragmented address spaces and with bit variables. Bit twiddling in ports and registers is common in microcontroller applications; it's done here by OR and AND masking, getting the bit positions from the `defines`, and creating the OR mask with "1<<n" and the AND mask with "∼(1<<n)". (For example, `PORTC1` has value 1, as defined in `io.h`; so the program statement "`#define POT (1<<PORTC1)`" sets `POT` equal to 0x02.) And a tricky *gotcha*: in an application like this, in which values are read from memory-mapped ports (such as a comparator or ADC), it is essential to declare those variables as `volatile` to prevent the compiler from "optimizing" away the reload from the associated port. This has been done for you in the `io.h` file, for the standard predefined memory locations; but you'd need to do it for any custom memory-mapped variables you create.

C. Some comments

(a) We used the power-on switch to initiate the timing cycle; another way to handle this is to use a pushbutton that brings an input pin to ground; you could poll that input bit, or you could use a level-sensitive interrupt. The latter is more elegant and has the benefit that the processor could put itself into a micropower (<1 μA) "sleep" state when done; the processor would then wake up upon a pin LOW interrupt. In principle you could even omit the power switch! We'd advise against that, though, because the only recovery from a crashed processor would be to remove the battery. We've all experienced commercial electronic devices (answering machines, cameras, DVRs) that occasionally freeze up, requiring a "cold reboot" by removing the battery or unplugging the device.

Program 15.1

```
#include <avr/io.h>
#include <avr/fuse.h>
#include <util/delay.h>

#define DISCHARGE  (1<<PORTD0)
#define BUZZER     (1<<PORTD1)
#define POT        (1<<PORTC1)

int main() {
    long  termcount, count;  // Total timer counts and running counter

    // Power saving measures
    PRR = ~(1<<PRADC) & ~(1<<PRSPI); // Shut off peripherals except ADC & SPI
    DIDR0  = 0x3f;  // Disable digital input buffers on analog pins

    // Setup the pins
    DDRD   = DISCHARGE | BUZZER;  // Set two pins to output, rest to input
    DDRC   = POT;         // Set the POT pin to output, rest to input
    DIDR0 |= (1<<ADC0D);  // Use PC0 as ADC0 -- the ADC input
    DIDR1 |= (1<<AIN1D);  // Use PD7 as AIN1 -- the comparator input
    PORTD  = BUZZER;  // Hold cap low, and start with buzzer off

    // Comparator Setup
    ACSR = (1<<ACBG); // Set the reference to the band gap (needs 70 us)

    // Read the desired exposure duration
    PORTC |= POT;  // Turn on the top of the resistor divider.
    _delay_ms(25);  // Delay 25 ms for 10RC settle
    ADMUX  = (1<<REFS0) | (1<<ADLAR); // Use Vcc ref; left-adjusted result
    ADCSRA = (1<<ADEN) | (1<<ADSC);  // Enable, and start ADC

    /*** Wait until ADC conversion is done. ***/
    while ( ADCSRA & (1<<ADSC) ) { }

    termcount = (360000L * ADCH) >> 8; // Convert ADC result to timer count
    PORTC &= ~POT;  // Turn off the top of the resistor divider
    ADCSRA &= ~(1<<ADEN); // Disable ADC
    PRR |= (1<<PRADC);  // Enable power-reduction for ADC

    /*** Wait until desired sunlight exposure ***/
    for (count = 0; count < termcount; count++) {
        // Wait for cap to charge, then comparator output goes low
        while(ACSR & (1<<ACO)) { }
        PORTD |= DISCHARGE;  // Discharge the capacitor
        PORTD &= ~DISCHARGE; // And release it to recharge
    }

    // Buzz for 10 seconds
    PORTD |= BUZZER;     // Power the buzzer
    _delay_ms(10*1000);  // Delay 10 seconds
    PORTD = BUZZER;      // Turn off buzzer

    // Loop forever
    while (1) { }
}
```

(b) We polled the comparator to determine when the sawtooth reached the trigger voltage; you could, instead, use an interrupt. There’s no benefit here, however, because there’s nothing else to do anyway: with an interrupt you would discharge the capacitor and increment the counter in the interrupt service routine, while the main program would simply loop on testing the value in the counter.

(c) Microcontrollers are *smart*! With hardly any work we can add all kinds of cool features to this puppy: an LCD display with a “progress bar” to show the state of your tanning; a readout of sunlight intensity; an MP3 music player; a game of solitaire or scrabble. . . (but we digress: you get the point).

D. Downloading the code

The last step is to “program” the part (i.e., download the compiled code and set the fuses). Here’s what you do.

(a) Connect the pod to the appropriate pins on the microcontroller (via a programming header), and to the PC (through serial or USB).

(b) Power up your board.

(c) Use the software on the PC to verify that the pod detects the correct device.

(d) Decide on the fuse-settable options,[11] and program them.

(e) Select the location of the compiled HEX file on the PC, and download it into the microcontroller flash memory; optionally select a HEX file with the EEPROM contents and download it.

(f) The pod should automatically reset the chip and begin running your program. At this point you can remove the pod. When you power cycle your board, your code will run, no strings attached.

E. Human-interface review

Our astute colleague Jim MacArthur offered the following commentary.

> If this book were about human interface (HI) design, design example #1 would be a textbook case of *spec drift*. The specification couldn’t have been simpler: Duplicate the functionality of the analog solution. And yet, as your HI tester will doubtless tell you, this solution differs from the analog one in one important way: If you adjust the pot in the middle of the cooking cycle, the analog solution pays attention, whereas the digital one does not.[12] The HI person would then go on, rather annoyingly, to prove that 47% of the users will operate the device in precisely that way – turning it on and then adjusting the pot – and that 13% of those customers will return the unit without trying to figure it out, costing your company millions of dollars. . . and you your bonus. The lessons are: (a) Never *ever* ship a consumer product without a human interface tester’s blessing. (And that way, they take the blame.) (b) Analog designs are not as easy to simulate in the digital domain as they might first appear.

F. Design review

After the embarrassing HI experience, a full design review was scheduled. Someone remarked that anything sitting on the sun-baked sand would get very hot, to which someone else replied “Tell the user, who’s sitting on a beach chair, to put the monitor in the shade underneath.” This suggestion received a (wordless) withering stare. Moving along, the design temperature was set at 85°C. That’s pretty hot, and (with a doubling every 10°C) the BSS123’s leakage current would rise to an unacceptable 3.2 μA (64× greater than the datasheet’s 50 nA typ at 25°C). Oops! Interestingly, the μC’s comparator is OK, because its 50 nA input spec extends to 85°C; similarly the photosensor’s dark current (50 pA at room temperature) would increase to about 3 nA, also OK.

Exercise 15.1. Find an alternative to the BSS123 MOSFET reset switch: one possibility is to adapt the method of Figure 13.49 to a microcontroller. *Hint*: Replace U_2, U_3, and U_4 with the processor. Recall that the voltage at “X” doesn’t matter. In that design we suggested an LMC6842 op-amp, which specifies 10 pA maximum input bias at 85°C; that’s fine here, but the op-amp’s supply current is 1 mA, dominating the battery drain. See if you can find a better choice.

15.3 *Overview of popular microcontroller families*

For the simple suntan monitor, we chose a controller from the popular Atmel 8-bit AVR series. We like them, because they exemplify a clean architecture, with plenty of general-purpose registers and a flat address space. They come in multiple package styles, including the through-hole dual in-line package (DIP) that we favor for quick prototyping. They are also well supported in terms of software tools, including open-source C-language compilers that are not too encumbered with controller-specific idiosyncrasies.

What other controllers are out there? We offer a listing of contemporary offerings below, with a bit of

[11] For the AVR these include brownout voltage level, on-chip debug on/off, clock source (internal, external square wave, external crystal, etc.), JTAG enable, SPI enable, and watchdog timer enable.

[12] The software could, of course, be modified to “pay attention.”

commentary. This should be considered a snapshot in time, as microcontrollers constitute one of the faster-changing areas of electronic technology.[13] You might keep in mind the characteristics of an ideal microcontroller:

- plenty of on-chip flash (reprogrammable program memory) and RAM
- small versions available in easily prototyped DIP (or SMT on DIP adapter)
- internal oscillator
- minimum external parts count to get started
- fast, low power consumption, wide supply voltage range
- inexpensive programmer, serial or USB
- in-circuit programming
- free programming software
- free assemblers and compilers
- free Integrated Development Environment (IDE) to tie it all together
- in-circuit debug/emulate through the IDE
- open-source toolchain that runs in Windows, Mac, Linux
- active user community

AVR *(Atmel)* 8-bit RISC[14]; clean architecture, 32 general-purpose registers; in-circuit debugging; open-source (Linux, GCC, Arduino) tools supported by Atmel and integrated into their software; some chips include USB; many package styles (including DIP); available as hybrid/FPGA (Atmel); least expensive, less than $0.50; competes with Microchip's PIC. 32-bit series: AVR32.

Programmers: simple serial ($12); Atmel AVR Dragon USB in-circuit debugger ($50). Arduino boards with USB power and programming are $20–$30. AVR Butterfly board with LCD and buzzer ($20). *Our recommendation for getting started.*

PIC *(Microchip)* 8, 16, and 32-bit; high-speed and low-power versions; some in-circuit debugging; many development kits; many package styles (including DIP); FPGA soft core; long time favorite of hobbyists; least expensive, less than $0.50.

8-bit: PIC10F, 12F, 16F, 18F. 16-bit: PIC24, dsPIC30, dsPIC33. 32-bit: PIC32MX.

Some chips include integrated USB or Ethernet MAC and PHY. Free chip samples from Microchip. The older 8-bit families, especially PIC16F84, used to be extremely popular (newer compatible versions have internal oscillators). Assembly-language coding can be tricky, owing to memory banking, a single accumulator, conditional skip (rather than jump) instructions, and an 8-level call stack in hardware (not RAM); but timing of instructions and interrupts is very predictable.

The 10F–16F devices are partially supported by C compilers by SourceBoost and Hi-Tech C, with prices ranging from free (limited versions) to $3000. Only 18F and above are well suited for C programming, and are supported by Microchip's C compilers (a free limited version is available to students). The 16-bit devices have the stack in RAM and no bank switching, and can be programmed with a variant of the GCC C-compiler. The 32-bit devices use an industry standard MIPS core (similar in features to the ARM), with a Microchip C compiler based on GCC.

ARM *(multivendor)* 32-bit RISC with optional 16-bit instructions; ARM Cortex M3, ARM7, and ARM9 series; least expensive, around $2; high-performance; in-circuit debugging; large range of included functions and I/O; open-source C/C++ with GCC and Eclipse debugging GUI (graphical user interface), also Arduino software for ARM-based *Due*; flat memory model that is easy to program; pincount $\geq$28 only (no DIP). Some can be programmed through USB, but need JTAG pod ($50) to debug. Available as prebuilt header boards from multiple vendors ($30), protoboards ($60); also Arduino Due (pronounced "doo-way," $50), UDOO (udoo.org, $99), Raspberry Pi ($30), Odroid ($65), and others.

Manufacturers: ADI, Atmel, Broadcom, Cypress, Freescale, Infineon, Microsemi, NXP, Renesas, Samsung, Silicon Labs, ST, TI, Toshiba; available as hybrid/FPGA (Altera SoC series, Xilinx Zynq series). From 8-bit replacements to iPhones. Pipelining and complex instructions provide lots of speed, but less predictable running time. *Would be our recommendation for getting started, if prototyping a design on your own board were easier.*

8051 *(multivendor)* 8-bit; evolution of early μC; mature development tools and development kits; some quirkiness in C-code, owing to complex address space; some in-circuit debugging (Silicon Labs); legacy instruction set limits memory, register, and I/O options; many package styles (including DIP); FPGA soft core. Good free development software (limited), e.g., "Ride" IDE (www.raisonance.com): C-compiler, assembler, simulator.

Rabbit *(Rabbit)* Emphasis on Ethernet and WiFi; available as modules, or as bare chips; C-language IDE; development kits and tools; popular.

[13] Stay abreast by looking at magazines like *Circuit Cellar*, *EDN*, and *Electronic Products*; distributors like DigiKey and Mouser; or do a search for "<μCname> tutorial" or "getting started with <μCname>."

[14] Reduced instruction-set computer; the opposite is a complex instruction set, CISC.

MSP430 *(TI)* Micropower 16-bit RISC; popular for low-power, RF, and LCD controllers; many package styles (including DIP). JTAG programming ($75–$100); open-source compiler MSPGCC and free code-size-limited versions of commercial compilers.

SH-4 *(Renesas, formerly Hitachi)* 32-bit RISC; smallest package is QFP-208 (LQFP-48 for the SH-2); popular in motor and engine control. M16C/R8C are 16-bit, available in DIP.

Coldfire *(Freescale, formerly Motorola)* Embedded 32-bit 68000-like architecture; no packages smaller than 64-LQFP; GNU C compiler; development kits (Tower System).

ST6/7 *(STMicroelectronics)* 8-bit, available in DIP; ST9/10 are 16-bit, smallest package LQFP-64. STR7/9/32 are 32-bit ARM7/9/Cortex, smallest package VFQFN-36 or LQFP-48.

PowerPC and MIPS *(multivendor)* Used in high-end embedded systems such as automobiles, networking, and video; by contrast, ARM dominates in cellphones and PDAs.

Blackfin *(Analog Devices)* 16/32-bit RISC plus DSP; fast and high-end, optimized for audio, video, and imaging. Easier than some other high-end controllers. Open-source GNU compilers, uClinux, FreeRTOS.

Propeller *(Parallax)* 8-core, 32-bit parallel processors; dc–80 MHz; small line of DIP-40/44 or SMD; philosophy of "why have lots of built-in hardware peripherals like UARTs and SPI when you can put eight real processors in there, give them all access to the I/O, and write good libraries to bitbang everything from mice and keyboard interface to analog video (VGA/NTSC)."

PSoC *(Cypress)* 8-bit microcontroller with configurable analog blocks: Op-amp, ADC/DAC, filter, modulator, correlator, peak detector, etc.

XMOS *(XMOS Ltd.)* Event-driven multithreaded 32-bit processors, with events and threading in hardware up to 400 MIPS; programming in XC, C/C++, assembly; free development tools.

15.3.1 On-chip peripherals

All microcontroller families include on-chip program and data storage, and timer/counters. They generally offer a selection of options such as comparator, ADC, and DAC; I^{2}C, SPI, and CAN buses; UARTs, USB and Ethernet; and support for external LCD, pulse-width modulation (PWM), video, and wireless devices. Here is a listing of some on-chip or low-level support found in contemporary microcontrollers, roughly in order of increasing level of complexity:

A. Low complexity

ADC, DAC, Analog Comparator
CANbus
Debug (JTAG or proprietary 1- or 2-wire interface)
I^{2}C / SMBus / TWI ("Two-Wire Interface")
Interrupts, sometimes with priority
Keypad matrix scan
Keyboard (serial), mouse
LCD (bare)
PWM
Real-Time Clock
SIM Card / Smart Card serial interface
Synchronous Serial Ports (SSPs): SSI, SPI, SSI Microwire
Timer, counters, watchdog
UART (RS232, RS485, IrDA), some with modem control

B. Mid-level complexity

AC97 (Intel Audio 20-bit 96 ksps stereo PCM)
Bluetooth wireless
Compact Flash (CF card)
Ethernet
External SRAM
GPS
I^{2}S (Inter-IC Sound: CD to DAC at 2.8 Mbps)
IrDA (high speed, to 4 Mbps)
Motor control, shaft encoder
PCMCIA[15] ("PC card")
S/PDIF (AES/EBU) audio (Dolby Digital or DTS surround)
SD/MMC flash cards
USB 1.1 (Host or Device, to 12 Mbps)
ZigBee wireless

C. High complexity

Camera and image sensors (CMOS, CCD)
External DRAM/SDRAM
Graphics display (bare color LCD)
MMU (Memory Management Unit) with OS protec
MPEG4 encode/decode
Operating System (Linux, Windows CE, Palm)
PCI, PCIe

[15] Sometimes translated as "Personal Computer Manufacturers Can't Invent Acronyms."

Storage Drives: ATA, IDE, SATA
USB 2.0 high speed (480 Mbps)
Video (NTSC, PAL, VGA, DVI, DV)
WiFi (802.11)

We predict, with considerable confidence, that the list will expand and that some items will be demoted.

We turn now to four more design examples to illustrate some common ways in which microcontrollers are used in embedded circuit design. These examples deal with
(a) ac power control (in which a microcontroller switches line power, under the direction of a serial link);
(b) a frequency synthesizer (in which a microcontroller runs errands between a user and a direct-synthesis chip that only understands cryptic serial commands);
(c) a precision temperature controller;
(d) a stabilized 2-wheel pseudo-Segway™contraption (which its inventor calls a "Psegué").

15.4 Design example 2: ac power control

At our astronomical observatory we have a dozen or more ac-powered devices that we need to control remotely – things like dome and telescope drives, mirror heaters, lights and cameras, power supplies for detectors and processors, and the like. Building a circuit to do this is a breeze with a microcontroller. And a benefit to having some intelligence in the control box is that it can remember a default configuration, and it can report status information (which outputs are powered, how much current they are using, and so on).

Let's do a fairly simple example here, namely a controller to switch 110 Vac power on two outlets, with readback of the commanded state, and with confirming readback that the actual ac output is present. In addition to remote control via serial RS-232 or USB, it will also permit "local" control via switches on its panel; some LEDs there will indicate which outputs are powered.[16]

15.4.1 Microcontroller implementation

Figure 15.4 shows the circuit. For variety we chose a modest member of the popular PIC family; the particular part (PIC16F627, DIP-18, $2) includes the needed serial port UART (universal asynchronous receiver–transmitter), an internal oscillator, nonvolatile data memory (EEPROM) that guarantees endurance of a million erase/write cycles, and plenty of digital port pins. We don't need much of anything else that the manufacturer has thrown in (analog multiplexer, comparator, PWM hardware, 20 MHz speed), but the microcontroller costs just $1.50, a small fraction of the total parts cost, so, hey, why complain.

The easiest way to switch ac power from a logic signal is to use a *solid-state relay* (SSR; see §§12.7.5 and 12.7.6), which consists of a sealed module containing an optocoupled SCR or triac. These devices are available from many manufacturers.[17] They accept a logic-level dc drive (often specified as 3–15 Vdc, or 3–32 Vdc), drawing somewhere in the range of 3–15 mA. The output is well isolated (typically specified as 3.5–5 kV), and most SSRs implement zero-voltage turn-on and zero-current turn-off. Typical load ratings are 10 A or 20 A at 280 Vac, but you can get standard units up to 100 A and 660 Vac.

In our example we've use a digital port bit to drive the SSR, configured to power on logic LOW; that choice of polarity is good here, because the port pins specify a typical saturation voltage of ∼0.35 V when sinking the required 15 mA, versus ∼1.3 V (below the positive rail) when *sourcing* that current. A panel LED rides along, indicating relay drive.

Solid-state relays have some leakage current when off, typically specified in the range of 0.1–10 mA; so we've bridged the switched ac with a 15k resistor.[18] The ∼8 mA current through it, when on, is used to light a panel LED (indicating delivery of ac to the load), and also to drive an opto-isolator to signal the microcontroller that all is well. This optocoupler is designed for ac operation, with its internal back-to-back LEDs; this particular unit has 5 kV isolation, 50% minimum current transfer ratio (ratio of phototransistor output current to LED drive current), and costs about $0.25 in moderate quantity.

Exercise 15.2. What is the purpose of the 1k resistor? Why is a diode needed across the indicator LED?

Moving back to the microcontroller circuitry, we've taken advantage of the internal "weak pullup" digital input mode (specified as 50–400 μA) for the input switches: a momentary contact pushbutton (for initiating local control), and a pair of spring-return momentary-contact lever

[16] If you want to save time (and cheat yourself out of an education), you can instead just throw money at the problem: there are nicely engineered units to do this job, for example from Pulizzi Engineering (Eaton Corporation) or APC (Schneider Electric). We opted for the educational opportunity, thanks in part to a grant from the Shulsky Foundation.

[17] For example, Crouzet, Crydom, Magnecraft, Omron, Opto22, P&B, and Teledyne.

[18] We measured the off-state leakage for two SSRs, and found ∼2 mA and ∼6 μA for two Crydom 240 Vac SSRs (a D2425 and EZ240D18, rated at 25 A and 18 A, respectively). They specify worst-case leakages of 10 mA and 100 μA, respectively.

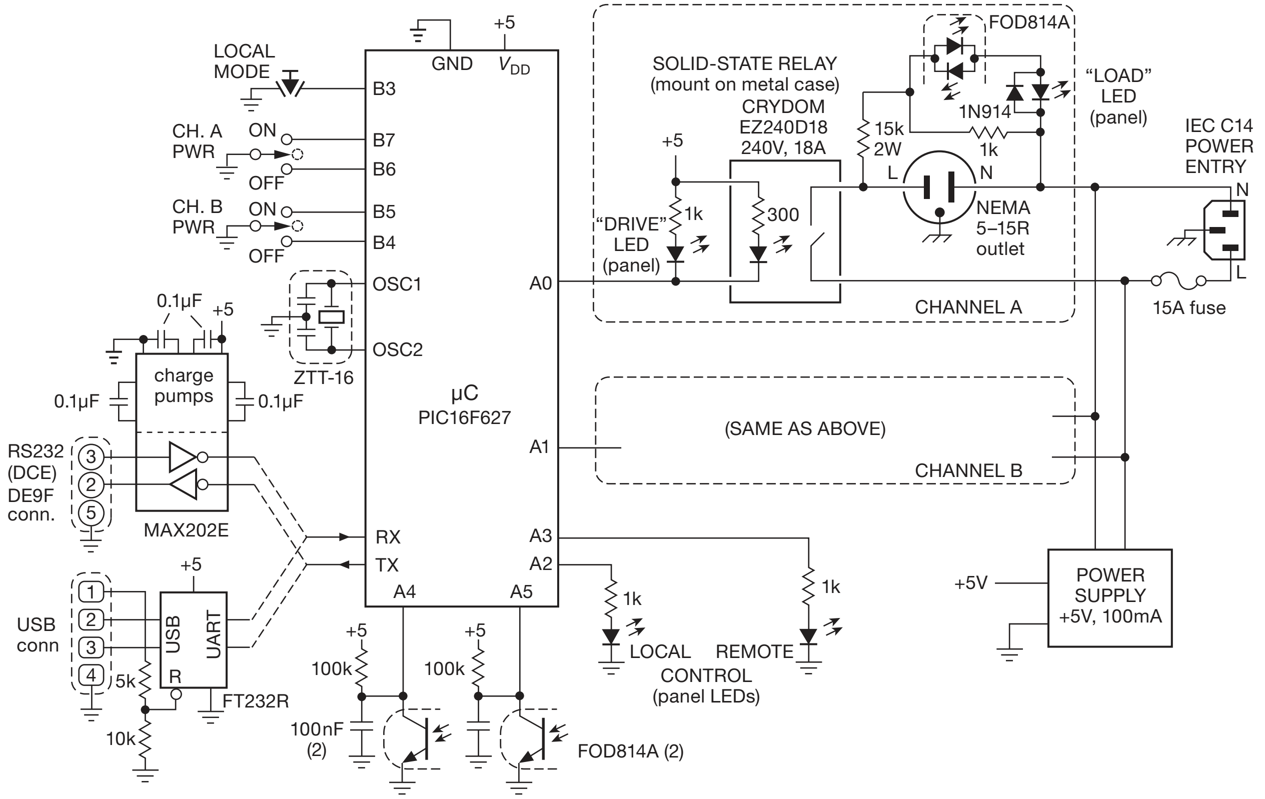

Figure 15.4. Dual ac-power control box, with remote (serial) or local controls. The SSR dissipates 10 W at a load current of 10 A, so it needs adequate heat-sinking. A mechanical relay could be used instead (e.g., Panasonic ALE12B05, contact rating of 277 Vac and 16 A, with faston tabs like the Crydom SSR). For the latter you'll need a transistor to drive its 80 mA coil; but the good news is its price: $1.60 in unit quantities, compared with $35 for the SSR.

switches for commanding the outputs on or off while in local control. A pair of panel LEDs indicate whether the unit is under local control (i.e., panel switches) or remote control (i.e., from a host computer, connected to this device via RS-232 or USB serial links).

We chose this particular controller partly on the basis of its internal oscillator…and then we discovered that it isn't accurate enough! The specified accuracy is ±7%, not good enough for 8N1 asynchronous serial communication: as explained in §14.7.8, the receiving device has to sample the 8 data bits in the middle of each bit cell, using its own asynchronous baud clock, having synchronized to the START bit at the beginning of each byte. So a 7% clock rate error between transmitter and receiver slides the last (8th) bit sample clear into the preceding or following bit cell.

The solution is either to use an external oscillator of adequate accuracy (for example, a crystal oscillator module, which costs about $2), or to put an external bare crystal or ceramic resonator across the OSC1 and OSC2 pins that the microcontroller provides for this purpose. We chose the latter, using a convenient 3-pin resonator that includes the necessary capacitors; this puppy costs about $0.40, with a specified accuracy of ±0.5%.

This microcontroller has an internal UART that makes serial communication pretty simple.[19] The only external hardware needed to connect directly to a host computer RS-232 "COM" port is a level translator (RS-232 levels are bipolarity; see §14.7.8). We chose the popular MAX202, which runs from the single +5 V supply, and creates the needed ±10 V with an internal charge pump voltage doubler–inverter; it requires four 0.1 μF capacitors.

[19] Although getting any microcontroller's UART settings right (timer mode and division ratios, serial data mode, interrupts, enables) is usually tricky. The best bet is to copy, shamelessly, the settings from the example that is invariably given in the applications section of the datasheet (more like a data*book*: typically 300–400 pages!), provided, no doubt, in the expectation that you stand only a small chance otherwise of getting it right.

If you don't want to be bothered with such details, you can spring for the MAX203 with internal capacitors; but you'll pay about \$5, compared with \$0.75 for the bare-bones translator. Faced with this choice, most designers go the cheaper route.

If you want to communicate via USB, you've got several choices. You could choose a microcontroller with internal USB support, for example the PIC18F2450. The complexities of USB should not be underestimated, however. You need to deal with USB protocols, either with custom software drivers, or implemented using one of the sixteen established "device classes" such as human interface device (keyboard, mouse), mass-storage device (flash or disk memory), printer, imaging device (camera), communications device (Ethernet). An attractive and simpler approach is to stick with the asynchronous serial design and use a well-engineered interface chip such as the FT232R, which is intended for exactly this kind of application and which costs about \$4.[20] It has the virtue of working well, and it comes with all the necessary drivers and other software for the host computer; that's what you use initially to set up parameters like baud rate and mode, which the chip's EEPROM then remembers.

Likewise you can adapt this circuit's native UART interface to Ethernet, with the use of a commercial Ethernet-to-serial module like the Lantronix XPort. This elegant device looks like a somewhat elongated RJ45 (Ethernet jack), with all the electronics packed inside; it even has the usual green and yellow network activity indicator lights. It costs about \$50.

We end the circuit tour with the microcontroller end of the opto-isolators. These have a floating phototransistor output, which we use to pull a pair of digital port input bits LOW when LED current flows at the ac-sensing end. (The LEDs shut off for a portion of each half-cycle, of order 1 ms, hence the 100 nF capacitors to hold the digital inputs LOW during those brief interruptions.) It's tempting to exploit the internal "weak" pullups, but they're not weak enough: according to the specifications, the pullup current can be as large as 0.4 mA, which would require 1 μF capacitors to keep the voltage at the input ports below 0.4 V during the $\sim$1 ms gaps. The solution here is to repudiate such bullying tactics: to regain control of the situation we turned off the internal pullups, and used "even weaker" external pullups whose 50 μA current requires only 0.1 μF capacitors.

15.4.2 Microcontroller code

The coding for the ac power control is straightforward. Take a look at the Pseudocode 15.2: at power-up you disassert port bits that would energize the relays, configure the port bits (as inputs or outputs, and with or without pullups), set up the serial-port baud rate and mode, and enable the hardware reset both on power dip ("brownout") and on program crash ("watchdog"). Then the monotonous daily life of this microcontroller consists of perpetual polling of the (not-debounced) switch inputs, looking for any change of state from the previous scan, along with a kick to the watchdog.[21] (It's a good thing that microcontrollers don't get bored.) Assertion of the LOCAL-mode pushbutton causes the device to go into local mode, in which other buttons are acted on, as indicated. The program in Pseudocode 15.2 performs a "software debounce" by delaying the next scan of switch inputs for 10 ms following the first detection of any change.

This main loop runs forever. But the serial port has not been ignored: during setup, the UART has been configured to generate an interrupt on receipt of an input character. So an incoming command on the serial port causes program diversion to the interrupt handler, where the seven possible commands (each consisting of a single byte printable character) are parsed and acted on. Those actions mostly consist of setting or clearing a single bit (either in a port, to control a relay; or a register, to set the local/remote mode). The "s" (request for status) command is more interesting, requiring the processor to collect the four bits indicating relay status (both the commanded output bit that drives the relay, and the optocoupled ac indication, for each of the two channels), and the mode bit; those are masked and shifted into a register, then sent back as a single binary byte.

A. Some comments

(a) Microcontrollers generally include some non-volatile data memory, which could be used to save the state of the outputs in the event of power failure or reboot; this controller has 128 bytes of EEPROM for this purpose.

[20] You can get it in several physical incarnations, for example, a cable with a USB connector on one end (in which the chip is concealed) and a 9-pin serial connector (with RS-232 voltage levels) on the other; alternatively, you can get it with flying leads at the serial end, configured for 3.3 V or 5 V logic-level operation, upgraded part. The upgraded part number is FT2232.

[21] Most engineers persist in calling this "kicking the dog." But our quirky colleague Frank Cunningham has pointed out that what you're really doing is *petting* the dog: when you kick a dog, it barks immediately; when you pet a dog, it barks only when you stop petting it.

Pseudocode 15.2 ac power control pseudocode

```
Setup
    Ports: disassert (setbits) relay outputs (A0, A1)
        setports LEDs (A2, A3) and relays (A0, A1) as outputs
        setports switches (B3–B7) and opto (A4, A5) as inputs
        set switch input ports (B3–B7) as weak pullups
        set up UART: baudrate, 8N1, interrupts, enable
    Low Power: disable unused peripherals
    Automatic Reboot: enable "brownout reset" and watchdog

Switch Polling Loop
    read switches (port B)
    if (any switchbit has changed)
        if localmode switch (B3) asserted, set mode=local
        if mode=local and any switch went H→L
            turn ON or OFF that relay output
        delay 10 ms ("software debounce")
    kick the watchdog
    repeat Switch Polling Loop

Serial Interrupt Handler
    get character
        if "r" or "R", set mode=remote
        if "l" or "L", set mode=local
        if "s" or "S", assemble 5-bit status byte and send
    if mode=remote
    if "A", turn on A relay
        if "a", turn off A relay
        if "B", turn on B relay
        if "b", turn off B relay
```

(b) It is best to keep interrupt service routines short and simple; in particular, you would avoid tasks that tie up the processor in the service routine while waiting for a slow peripheral to complete (e.g., a serial port!), because that may cause the main loop to miss a switch-input event. Here it's OK, though, because every serial-port command and every response is a single byte, so the routine does not have to wait for a busy flag to clear.[22]

15.5 Design example 3: frequency synthesizer

Our next example illustrates a common application of embedded microcontrollers, namely their use to manage communications between an instrument panel (or computer interface) and some circuitry that requires digital programming and control. Figure 15.5 shows a two-channel frequency synthesizer, using one of the elegant direct digital synthesis (DDS) chips from Analog Devices (§7.1.8). We've chosen the AD9954 (one of the three dozen current DDS offerings), which synthesizes a high-quality sinewave via internal table lookup and D/A conversion. It can generate output frequencies from dc to 160 MHz, with resolution set by the 32-bit "tuning word"; that corresponds to ∼0.1 Hz when a 400 MHz internal oscillator is used to clock the chip. Although you can get faster DDS chips, this one has excellent spectral purity, owing to its 14-bit output DAC; this translates to a clean output sinewave,

[22] There is a standard, known as SCPI (Standard Commands for Programmable Instruments), that specifies a set of commands, and a syntax, for communicating with programmable instruments. SCPI is a bit wordy, but it is clear, and it has been widely adopted by manufacturers of electronic instruments (e.g., Agilent, Fluke, Keithley, LeCroy, Rohde & Schwarz, and Tektronix). For example, to read a voltage you could send the command `MEASure:VOLTage:DC?` (the lowercase characters are optional). The measurement response is returned in a defined format.

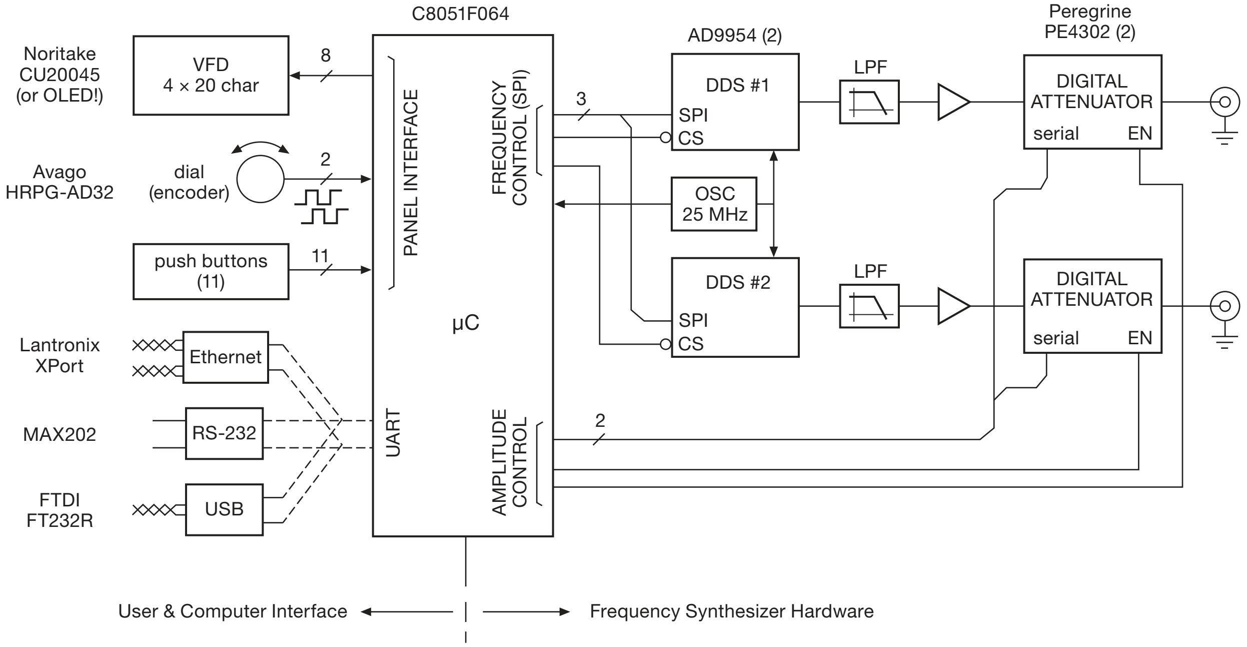

Figure 15.5. A microcontroller is ideal for interfacing between digitally programmed chips (here a pair of DDS frequency synthesizers, with programmable attenuators) and a set of human-operated panel controls and displays. And the μC's serial interface makes it easy to add remote computer control (here a pair of DDS frequency synthesizers, with programmable attenuators, see Figure 15.6).

with low phase noise and "spurs" (spurious frequency components).

This DDS chip, which costs about $25, won't do much of anything until you program it through its 4-wire SPI port. You could imagine interfacing the DDS to a laptop computer and running some software on it so you can program the chip for the frequency you want. But what you'd really like is a nice set of human-usable panel controls – a knob to dial up the frequency and amplitude and a numeric display to show those values (Figure 15.6). That's best done with an embedded microcontroller. And, of course, that controller can accept inputs via a USB or Ethernet port, so once you've built this instrument you can add remote digital control as well.

The block diagram (Figure 15.5) shows the microcontroller riding herd over the DDS chips (via their SPI serial ports) and the digital attenuators (via a similar 2-wire protocol, described in their datasheet). The synthesizer chips need an accurate 400 MHz clock reference. This is generated by its internal phase-locked loop (PLL) frequency multiplier from an external lower-frequency reference; we chose a 25 MHz crystal oscillator (with ×16 on-chip multiplication), which conveniently can clock the microcontroller as well.

On the user side there are buttons and a dial (an optical "incremental rotary encoder") for entering and changing parameters (frequency, amplitude, phase); and there's a vacuum fluorescent 4-line character display (VFD) that is pin compatible with the more usual LCD shown in the photograph, for telling the user what's going on. VFDs cost more than LCDs, but they are gorgeous. Remote control communicates through the on-chip serial UART, which requires only a voltage translation for a legacy RS-232 port; or you can use a smart serial format conversion device like the FT-232 from FTDI (for USB) or the XPort from Lantronix (for Ethernet).[23]

Although shown casually in the block diagram, there is additional detail in these user interface connections. The rotary encoder, for example, generates a pair of square waves, in 90° quadrature, from which you can figure out in which direction (and by how much) it has rotated. Inexpensive encoders use mechanical contacts, so you have to worry about the usual contact bounce. We've gone first class here, though, with an optical encoder (it lasts forever) that generates clean logic-level outputs (no bounce!). The

[23] Additional Ethernet interface devices are available from companies such as Digi International, Ipsil, Connect One, and WIZnet.

corresponding firmware simply notes the level on the other line when it senses a transition on either of the two inputs.

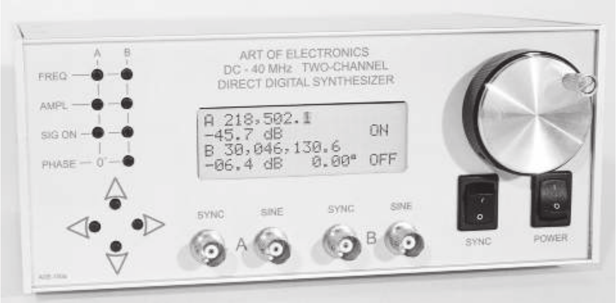

Figure 15.6. Dual DDS frequency synthesizer of Figure 15.5, with panel controls (eleven buttons and one rotary encoder dial) and readout. (Designed, built, coded, and documented with excellence by Jonathan Wolff; see www.artofelectronics.com/synthesizer)

The pushbuttons are mechanical, and prone to contact bounce; they must be debounced in software, as with the previous ac power control example. We've connected each button to its own input port pin (configured with weak internal pullup), which is the simplest configuration (though not the most economical). This particular microcontroller has 59 digital port pins scattered around its 100-pin package (Figure 15.7), so we're unlikely to run out. The alternative is a matrix-switch configuration, with row and column lines that are bridged by the individual switches, which here would require four fewer pins; we'll discuss that, along with other wrinkles, shortly.

15.5.1 Microcontroller code

The microcontroller's tasks are, briefly:
(a) set-up port bit modes, UART parameters and interrupt, SPI port, and watchdog;
(b) initialize DDS chips and attenuators to last stored state (held in nonvolatile memory), and send current operating parameters (frequency, amplitude, phase) to VFD display;
(c) execute forever a main loop that kicks the watchdog, checks for rotary dial movement, for button actuations, and for a serial command flagbit (set by the serial interrupt handler), and acts accordingly;
(d) service UART interrupts (independent of the main loop) by appending characters to a line buffer, and setting a software flag ("serial_cmd") upon receipt of a newline character (end of command).

The listing in Pseudocode 15.3, though somewhat abbreviated for this example, spells this out in greater detail.

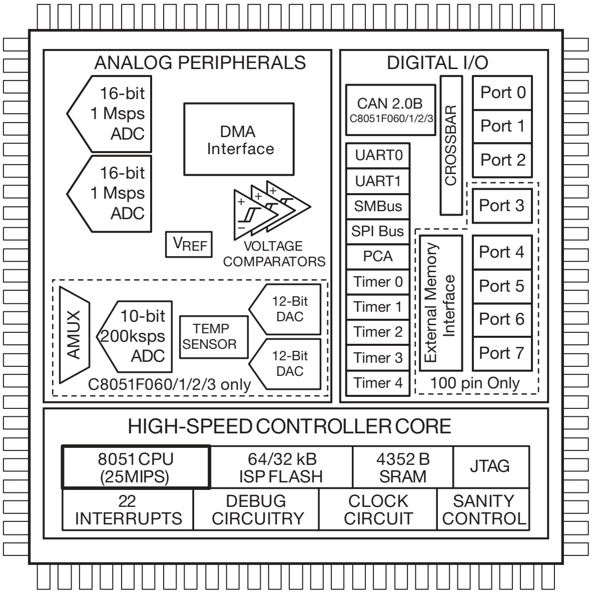

Figure 15.7. The venerable 8051 has come a long way since its 1980 debut, with many added functions, and one clock cycle per instruction (the original required 12) in contemporary variants like the C8051F060 series from Silicon Labs, from which this diagram is adapted, with their permission. (Curiously, the 328-page datasheet reveals nothing about the meaning or function of "sanity control.")

A. Some comments (Hardware)

(a) The block diagram shows relatively simple amplitude control, with a digital attenuator providing 0–30 dB attenuation in 0.5 dB steps. You can do much better, in range, step size, and calibration, by using the intelligence and memory of the microcontroller: the synthesizer in the photograph uses two additional layers of amplitude control, namely a fixed 30 dB attenuator that is switched in to reach 60 dB, and fine adjustment (±6%) of the DDS chip's "reference current" (via an EEpot) to provide 0.1 dB resolution. One further trick is needed to make this all worthwhile: the user initially calibrates the instrument, by reporting measured signal levels at several frequency and amplitude settings over the full range, as prompted by the firmware; the microcontroller stores this calibration data in nonvolatile memory, retrieving it to produce a linear and accurate output-amplitude characteristic.

(b) The DDS output waveform updates at the internal reference clock frequency, in this case f_{ref}=400 MHz, generating successive samples of the output "staircase" approximation to a sinewave. The resultant output signal, settable from 0 to 160 MHz, contains spurious out-of-band frequency components, the lowest of which is at

Pseudocode 15.3 Synthesizer pseudocode

```
Setup
    Ports: setports pushbuttons and rotary dial as input
        setports to attenuator as outputs
        setports to VFD as outputs or inputs
        set up UART: baudrate, 8N1, interrupts, enable
        set up SPI port
    Automatic Reboot: enable brownout and watchdog timer (timeout=1s)
    Read Stored State: copy NV-stored state to active registers
        clear and reload VFD and DDS from active registers

Main Loop
    kick the watchdog
    read switches and rotary dial
    if (any debounced switchbit has changed)
        if (freq, ampl, or phase), set new mode
        if (up/down arrow or rotary dial), increment/decrement that register
            refresh DDS or attenuator, and display
    if (serial_cmd bit) parse command, clear serial_cmd bit
            increment/decrement corresponding register
            refresh DDS or attenuator, and display
    repeat Main Loop

Serial Interrupt Handler
    append character to line buffer
    if newline, set flagbit serial_cmd
```

$f_{\mathrm{spur}}=f_{\mathrm{ref}}-f_{\mathrm{out}}$. That's why lowpass filters are needed at the DDS's DAC outputs; typically you'd use an *LC* multisection elliptic filter with a sharp cutoff characteristic at $f_c \sim 180$ MHz. The DAC outputs are differential *currents*, best filtered with a symmetrical differential filter, an example of which is shown in the 40-page datasheet.

(c) With dual DDS chips set to the same frequency, you can control the phase difference between the two outputs, providing the chips have a common reference clock. This particular DDS accepts a 14-bit phase offset word, equivalent to steps of 0.22° in relative phase.

(d) We used individual port input bits for each pushbutton, with a common ground return, a perfectly reasonable approach here with only 11 buttons, and a microcontroller with 100 pins. The alternative is to use a row and column *matrix*, with the switches bridging the intersections (Figure 15.8). Here the column lines are driven by output pins, and the rows are connected as inputs with internal pullups. To poll the switches the microcontroller pulls the column lines successively LOW, observing the returned input levels from the row lines; debouncing is done in software, as it was with dedicated input lines. Matrix encoding is efficient when you have many switches, because the number of I/O pins used is the sum of the number of rows and columns, rather than their product. In some cases, moreover, you are forced to do it this way, because the switch array is built as a matrix; an example is a 4×4 hexadecimal keypad. One caution: a matrixed keypad generates false outputs if three (or more) keys are pressed simultaneously; figure this out for yourself.

B. Some comments (Firmware)

(a) Having a microcontroller in charge provides a nice opportunity to add features and functions that you wouldn't even think of otherwise. For example, the synthesizer in the photograph implements a nice algorithm (which we have not seen elsewhere) for determining how the digits are controlled by the dial and the buttons. The left- and right-arrow buttons do the obvious thing, namely choosing the ("active") digit being modified; and the up and down buttons increment and decrement that digit (with carry or

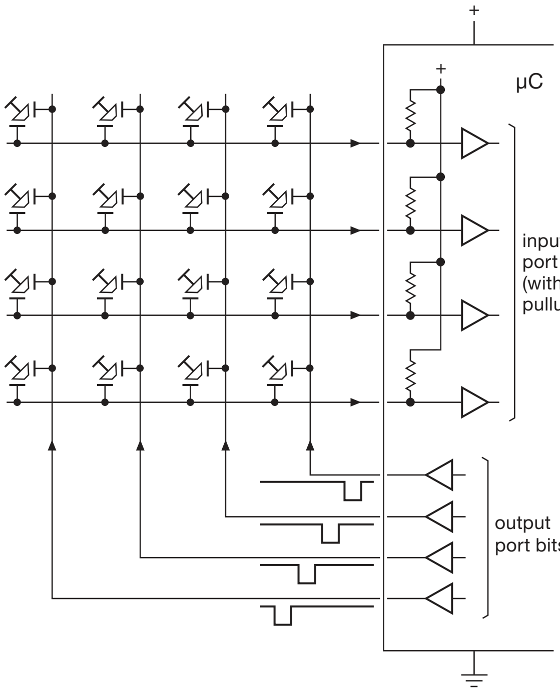

Figure 15.8. An array of switches can be polled in a row and column matrix arrangement, here illustrated with a 4×4 keypad. This reduces the number of port pins to $N_{\text{matrix}} = r + c$, compared with the $N_{\text{indiv}} = r \times c$ required for individual dedicated readouts.

borrow), assuming that you want to set an exact frequency. But the dial is treated differently: if you move the active digit leftward, the dial acts on that digit and zeros all digits to the right, on the assumption that you want to move the frequency faster, and without the baggage of leftover less-significant digits. On the other hand, moving the active digit rightward and spinning the dial preserves the more significant digits to the left, on the assumption that you are zeroing in on the target frequency. We wish commercial instruments would use this sensible algorithm!

(b) Just as with a computer's mouse, the panel dial's motion is translated by an acceleration algorithm, so that a fast spin of the dial takes you farther and faster.

(c) The firmware takes care of capturing initial calibration data and interpolating from that data during subsequent operation, as described above. A microcontroller lets you program frequency sweeps – linear ramps, cyclic ramps, or nonlinear sweeps (e.g., a logarithmic sweep, with equal time per octave).

(d) And, of course, a reprogrammable microcontroller lets you fix bugs, and dream up new features (with new bugs).

15.6 Design example 4: thermal controller

Here's an example of embedded control in the service of, well, *control*: imagine we want to hold steady the temperature of a well-stirred liquid bath, in which we've put both a heating element and an accurate temperature sensor. At first glance the solution seems easy: just apply plenty of feedback, using as the error signal the difference between the measured temperature (as reported by the sensor) and the desired target temperature. Raise the loop gain until the temperature error is small enough, just as you would with an op-amp voltage amplifier.

This is a classic "control" problem, encountered in industrial settings such as chemical plants (temperature and flow control), manufacturing and robotics (motion control), and the like (Figure 15.9). Simple feedback works poorly in such situations, because the controlled system has time delays (and therefore lagging phase shifts) that promote oscillation; and reducing the loop gain to prevent such oscillation leaves too little loop gain, so the controlled system both deviates from the desired condition and moves slowly to correct disturbances.

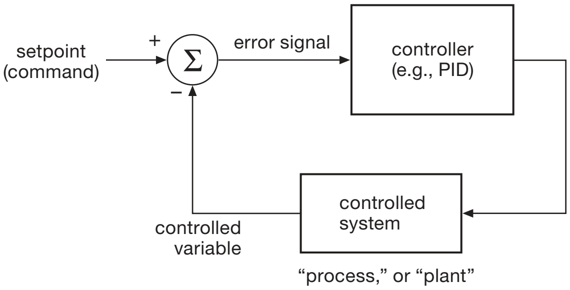

Figure 15.9. Classic control (or "servo-") system. For our example the setpoint is the desired temperature, the "plant" is the heater–waterbath–sensor, and the controller is implemented with a microcontroller. The μC's input compares the desired and actual temperature, and its PWM output powers the immersion heater.

There is a large literature on this subject, and on the feedback principles underlying the "tuning" of a controller to match the properties of the controlled system (called, curiously, the "plant," probably in a throwback to the industrial revolution). The general approach is to construct (with analog or digital methods) a so-called "PID" (proportional, integral, differential) controller, in which the error signal versus time is subjected to those three processes, and then combined in carefully chosen proportions to create the correction signal that is applied to the controlled system. The procedure for tuning the coefficients is basically straightforward (though it is considered by many to be a mysterious art), and is best understood with a Bode plot like those in Chapter 4. Although it's easy to make amplifiers, integrators, and differentiators with op-amps, microcontrollers are naturally suited to PID control; they have added benefits, too, such as the ability to report status, to accept and modify tuning parameters, and to carry out nonlinear control algorithms.

15.6.1 The hardware

Popular temperature sensors include a thermocouple (a junction of two dissimilar metals, which generates a voltage, typically 20–40μV/°C), a thermistor (a resistive material of negative temperature coefficient, typically -4%/°C), a silicon-based temperature sensor IC (that exploits the -2.1 mV/°C negative tempco of a diode's forward drop), or a platinum RTD ("Resistance Temperature Detector," a wirewound resistor, usually standardized at 100 Ω at 0°C, whose resistance increases by 0.385%/°C). These sensors differ in temperature range, accuracy and stability, speed of response, size, and cost. For this example (and without excessively opening this substantial can of worms) we chose the RTD, primarily for its good stability; it also has excellent linearity, and a wide operating temperature range (-200°C to +600°C). As with other temperature sensors, it is available in a nice waterproof probe assembly. At the other end – the heater – a power resistor is all you need, once again in a submersible package (an "immersion heater").[24]

There are several possibilities for the heater drive. The simplest way is to turn it on when you need heat, and off when you don't. This is called a "bang-bang" controller, and it's the way home heating systems work. It's guaranteed to produce a cycling of the temperature about the target, which is less than ideal. It is efficient, however, because the drive transistor operates as a switch, with very little power dissipation.

A better way, if the system permits, is proportional control. Here we could use a linear power output stage, varying the heater drive in a continuous manner, according to the controller's command. The drawback is that the linear driver stage has to dissipate lots of power. This is where pulse width modulation fits in. By operating the output driver as a switch, at, say, 10 kHz,[25] and varying the duty cycle (the ON fraction of each switch cycle), we get the best of both worlds: proportional control, and minimal driver dissipation. For this reason PWM is popular in other "linear" applications, for example audio amplifiers (see §2.4.1C) or motor drives.

Figure 15.10 shows the circuitry for a microcontroller temperature controller. Looks simple enough, but as usual the devil (and the joy) is in the details.

A. The sensor

We chose a generous -50°C to +150°C nominal range of control, over which the standardized "100 Ω" RTD temperature probe's resistance goes from 80 Ω to 160 Ω, approximately.[26] To keep the effects of self-heating negligible, we used a 2 mA bias current, which produces corresponding voltages of 160 mV and 320 mV across the RTD, and a maximum self-heating dissipation of just 0.6 mW.

These are smallish voltages, compared with typical ADC conversion ranges of 1.25 V, 2.5 V or 5 V; so we need some gain, and we need an offset, to match the ADC's full-scale span. A bridge arrangement, as shown, produces a differential signal without the offset; we've chosen the resistor ratios for zero (differential) output at mid-scale (+50°C), so the differential signal goes from -80 mV to +80 mV. Note the 4-wire ("Kelvin") connection, to eliminate effects of cable and contact resistance. Now we need some gain.

B. The frontend amplifier

Microcontrollers come in such variety that you can usually find one with just the features you want. The ADuC800-series and ADuC7000-series of "analog microcontrollers" from Analog Devices is aimed at sensitive conversion applications, and this particular part has just the combination needed here: a true differential input stage, followed by a programmable gain low-noise amplifier and 16-bit ADC[27] that can be operated in a precision "chopping" mode (analogous to chopper op-amps) for low dc offset and drift. The datasheet includes tables of converter accuracy versus conversion rate, showing 15 bits of resolution for the ±80 mV range at 50 conversions/sec in chopping mode; that corresponds to 6 millidegrees, plenty good enough for this job.

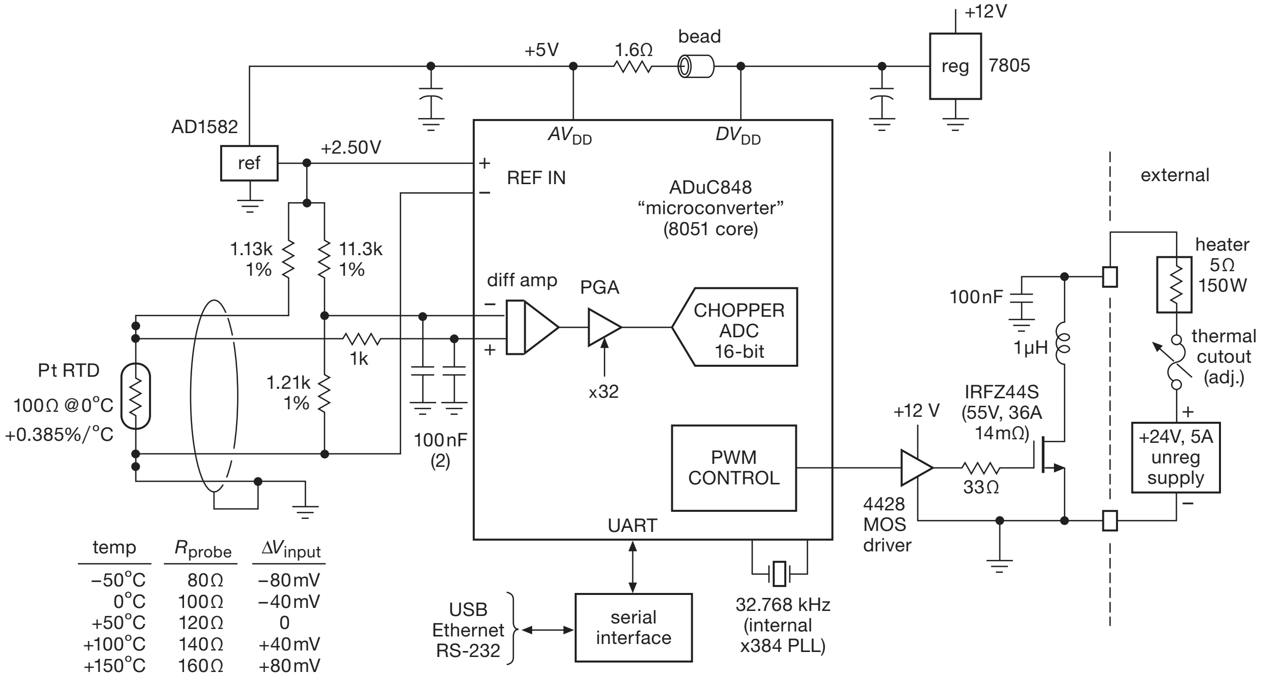
Without such a convenient microcontroller (which Analog Devices calls a "microconverter"), the alternative is to use a differential instrumentation amplifier, preferably one

[24] A good place to find these things in the impressive *Temperature Handbook* from Omega Engineering.

[25] Commercial temperature controllers intended for use in systems with large thermal mass and slow response typically perform their PWM at very low frequencies, in the Hz region or slower, allowing the use of a relay rather than an electronic switch output.

[26] Accurate tabulations of Pt-RTD resistance list nominal values of 80.31 Ω and 157.33 Ω at these temperatures, typically accurate to a few tenths of an ohm.

[27] The ADuC848 has a 16-bit ADC; the similar ADuC847 has a 24-bit ADC, and the ADuC845 has two 24-bit ADCs.



temp	R_{probe}	ΔV_{input}
−50°C	80Ω	−80mV
0°C	100Ω	−40mV
+50°C	120Ω	0
+100°C	140Ω	+40mV
+150°C	160Ω	+80mV

Figure 15.10. Temperature controller, with platinum RTD sensor and linear PWM heater. The ADuC848 "microconverter" includes a 16-bit ADC and programmable gain differential amplifier, aimed at analog applications requiring accuracy and low noise. The resettable thermal cutout is a good safety feature in the event of hardware or firmware failure.

with input common-mode range to its negative rail so it can be run from a single +5 V supply. Most instrumentation amplifiers (Table 5.8) don't have that feature; but a suitable candidate is the AD623 (Analog Devices strikes again!), which also has rail-to-rail output swing and can run from a single +3 V to +12 V supply.

Figure 15.11 shows how you would use it here, to drive the analog inputs of a more generic microcontroller: the output reference pin is tied to the midpoint (+1.25 V) of the desired conversion range, so that the differential input signal range of ±80 mV is mapped to the 0 to +2.5 V range of a generic single-ended ADC. (We could instead ground the reference pin, and replace the 1.21 kΩ resistor in Figure 15.10 with 1.0 kΩ, thereby balancing the bridge at the low temperature end.) For a situation like this, where you need accurate amplification of low-level signals, you can generally expect better performance with a dedicated instrumentation preamplifier, as compared with a bare microcontroller. However, the ADC in the particular microcontroller we chose is exceptional, and in fact has better accuracy and drift specifications than the outboard preamplifier: it specifies typical voltage offset and drift (in chopping mode) of 3 μV and 0.01 μV/°C, compared with the instrumentation amplifier's corresponding values of 25 μV and 0.1 μV/°C.[28]

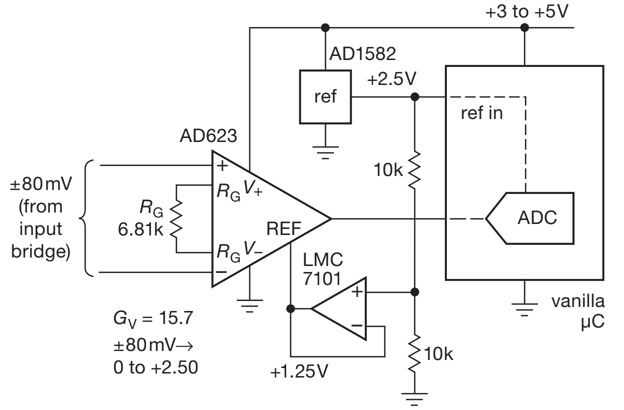


Figure 15.11. As an alternative, an outboard differential "instrumentation amplifier" could be used to map a small differential signal range (here ±80 mV) to the single-ended input range (here 0 to +2.5 V) of a generic microcontroller. In such an implementation, the gain-setting resistor sets the span, and the "reference" input pin sets the output to midscale when the input is balanced.

[28] In fairness it should be noted that the chopping process, which is re-

C. Clock and power supplies

The ADuC848 asks for a 32.768 kHz external crystal, with its on-chip PLL ×384 clock multiplier generating the primary core clock of 12.58 MHz (the controller has the requisite 12 pF on-chip capacitors, so the only external component is the crystal itself). The chip comes in +3 V and +5 V versions, with internal brownout detection and power-on reset, along with a watchdog timer. We chose the 5 V version, with a +2.50 V ADC reference. The 3-terminal reference (AD1582) need not be of great precision or stability, because the input circuit is ratiometric: the ADC's digital output is in fact independent of the reference voltage. The *RL* network decouples digital noise from the analog supply voltage, as recommended in the datasheet.

D. Pulse-width modulation

As we remarked earlier, this PID control loop operates with quasi-linear control of the heater, achieved by rapidly switching the heater full ON and OFF while adjusting the duty cycle (fraction of a cycle during which it is ON); that's called PWM (pulse-width modulation). That way we get the benefits of linear control, along with the efficiency of saturated switching. For an application like this, with its long thermal time constants, the heater won't know the difference between PWM and honest linear voltage drive.

In a purely analog world, you'd create the PWM switch drive signal with an analog comparator: one input gets a fixed-frequency sawtooth, the other gets a more slowly changing "feedback voltage" (indicating the need for more or less average output) that sets the duty cycle (Figure 15.12A). The latter might be simply proportional to the error, or in a more complicated system it might come from an analog PID like that in Figure 15.14. Here we use the microcontroller to do the same job *numerically*, by comparing a counter's incrementing value (the sawtooth) with a second number (the feedback) that is within the counter's range. In a μC without built-in PWM support, you would have to do this in software; see Exercise 15.3. The ADuC848, however, includes hardware to make PWM a breeze: you initially set the counter's range (maximum count) by loading a 16-bit unsigned number into a terminal count register (called PWM1); the incrementing count is continually compared with the (slowly changing) 16-bit feedback value resident in another register (called PWM0), creating a HIGH PWM output on a port pin (called P2.5) when the PWM count is less than the feedback (Figure 15.12B).[29]

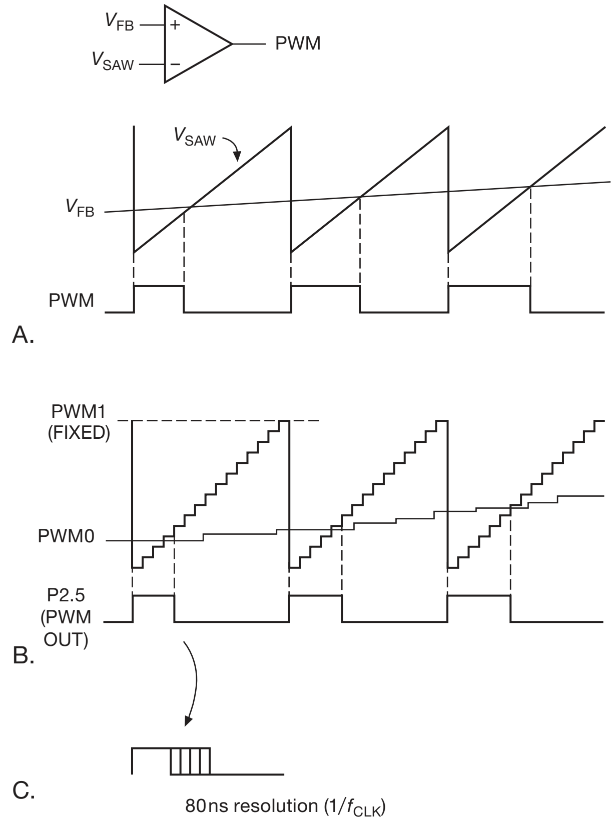

Figure 15.12. Pulse-width modulation (PWM). A. A slowly varying feedback signal V_{FB} is compared with a fixed-frequency sawtooth to produce the logic-level PWM output. B. Digital PWM substitutes a clocked counter and magnitude comparator. C. The digital PWM output has a granularity of $1/f_{CLK}$.

For this application we chose a maximum count of 1258_{10} (by loading hex 04EAh into internal register PWM1), to produce a PWM frequency of 10 kHz (the 12.58 MHz clock, divided by 1258). The PWM output pulses thus come at a 10 kHz rate, with widths corresponding to an integer number of 12.58 MHz clock pulses; that is, they are quantized with a step size of 1/12.58 MHz, or 80 ns (Figure 15.12C).

Exercise 15.3. Problem for a rainy Sunday: imagine you've already used the ADuC848's two PWM pins, and you need to create two more 8-bit software PWMs. You're given the register values, and during software PWM operation you have full control of the

sponsible for the excellent accuracy and stability, reduces the bandwidth and conversion rate. For our thermal-control application, with time constants of order 250 ms, speed is not a problem.

[29] This "Single Variable Resolution PWM" mode is one of six modes offered by this elegant chip. Such flexibility is unusual in your average microcontroller.

μC. Devise workable code, and see how fast the PWMs can run. The "Optimized Single-Cycle 8051 Instruction Set" and timings are given in the datasheet (page 20 of the current revision). The ADuC848 has a 12.58 MHz clock.

E. Output circuit

From a microcontroller output port you can't switch a load that is powered from 24 volts. And you *really* can't switch 5 amps! So we need a transistor switch, here implemented with a modest-sized power MOSFET. And, to drive its gate fully (to +12 V) and fast, we added a gate driver chip.[30] The 4428 is an industry-standard MOSFET driver, good for converting a logic-level input swing to a full-voltage swing at the gate; this inexpensive part (about \$1) has dual outputs (inverting and noninverting), good for 1.5 A of source or sink into the capacitive gate load. The particular transistor we chose (the IRFZ44, rated 55 V, 36 A, TO-220 power package) is inexpensive (~\$2), with R_{ON} sufficiently low (14 mΩ max, at V_{GS}=10 V) that we don't need a heatsink. A full 12 V gate drive minimizes the on-resistance, and the 1.5 A gate drive capability ensures fast gate rise and fall times, reducing MOSFET "class-A" dissipation[31] during switching.

A switching MOSFET with healthy gate drive produces rapid (nanosecond-scale) drain transitions, potentially generating substantial electromagnetic interference. The small output inductor and shunt capacitor form a lowpass filter of characteristic frequency 0.5 MHz, limiting output slew rate. This eco-friendly filter has an interesting side effect, however; namely, the production of an inductive positive-going voltage transient at each switch-off (Figure 15.13). Unless clamped, the inductive spike causes avalanche breakdown in the MOSFET. That sounds bad, but in fact power MOSFETs are tolerant of such abuse, with a specified repetitive avalanche energy rating limited primarily by heating effects (see the section on Pulse Energy in Power MOSFETs in Chapter *3x*, and the section on Transient Thermal Response in Chapter *9x*). For this circuit the periodic delivery of the $\frac{1}{2}LI^2$ energy stored in the inductor merely adds some allowable increment of MOSFET average power dissipation.

In total, then, there are three contributions to MOSFET heating: (a) I^2R_{ON} dissipation during conduction; (b) $I_{\text{D}}V_{\text{DS}}$ class-A dissipation during switching; and (c) $\frac{1}{2}LI^2f_{\text{osc}}$ repetitive avalanche dissipation at switch turn-off. The following exercise explores these quantitatively for this circuit example.

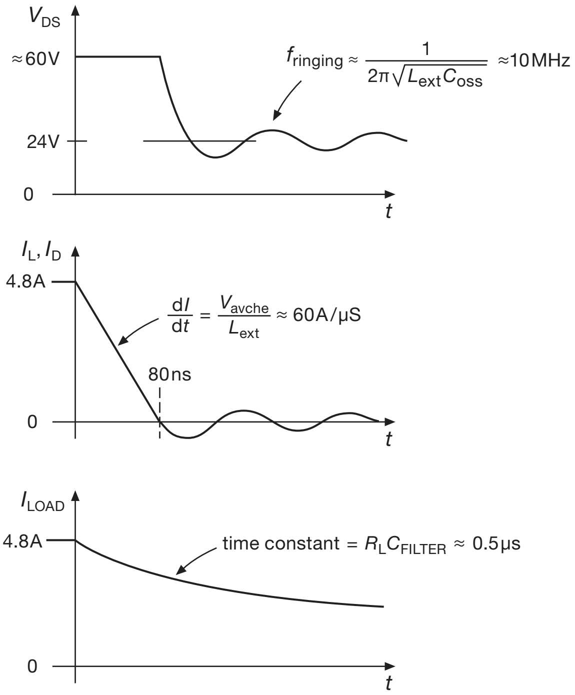

Figure 15.13. The output *LC* filter in the circuit of Figure 15.10 smooths voltage and current transients to the load (bottom graph); but the series inductor causes MOSFET avalanche breakdown at turn-off (top graph), during which the inductor current ramps to zero.

Exercise 15.4. Let's flesh out this last statement, in several steps.[32]

(a) What is the MOSFET power dissipation when it is ON, assuming R_{ON}=14 mΩ?

(b) Now calculate the average power dissipation contributed by class-A conduction during transitions, assuming the PWM is running at 10 kHz. For this calculation use a gate-to-drain ("Miller") charge of Q_{GD}=15 nC, and assume for the moment that we have been foolish enough to drive the gate directly from a logic output that is able to source and sink just 10 mA (which is considerably better than this μC's specs: a feeble 1.6 mA at 0.4 V sinking, and even feebler 80 μA at +2.4 V sourcing). You can assume a linear ramp of voltage and current, but to do the calculation properly you'll have to integrate the product $V_{\text{DS}}I_{\text{D}}$ over the duration of the ramp (and don't forget that there are two ramps per cycle).[33]

[30] See §3.5.4 and Tables 3.4b and 3.8 on pages 189–191 and 218 respectively.

[31] That is, the power dissipated during the transition times when the transistor is neither fully ON or OFF, and thus has both a substantial drain current and a substantial drain-source voltage drop.

[32] Refer back to §9.7.2 if you are unsure how to go about these calculations.

[33] Spoiler (if you want to skip the calculus): $E = V_{\text{P}}I_{\text{P}}T_{\text{ramp}}/6$ per ramp.

You should have found that the overall power dissipation is dominated by the class-A contribution during switching; in particular, the latter is nearly twice as much as the ON dissipation (580 mW versus 320 mW).
(c) The gate driver dissipates some average power, also; calculate it.
(d) Recalculate the average switching loss, assuming now a gate drive current of 1 A.
(e) Now calculate the contribution of inductor avalanche energy to the overall MOSFET power dissipation (we hope you'll agree that it is 115 mW).
(f) Check that the single-pulse avalanche energy is well below the datasheet's specification of 86 mJ (max).[34]
(g) Finally, under the assumption that the 1.5 A MOSFET gate driver has made the class-A dissipation negligible (compared with the conduction and avalanche losses), calculate the junction temperature rise above ambient, using the specified thermal resistance $R_{\Theta\mathrm{JA}}$=40°C/W for this surface-mount MOSFET on 6 cm^2 of copper pad. If you (and we) have done the calculations correctly, the answer should quell any residual anxiety. Note also that the actual average R_{ON} conduction dissipation will be less than calculated, because the duty cycle (fraction of time ON) had better be less than 100%, or we're in serious trouble!

This exercise reveals some of the essential engineering process of tradeoff and iteration that goes into even a simple-looking output circuit like this.
(a) We chose a MOSFET with low enough R_{ON} to permit surface mounting without a heatsink, if desired (the IRFZ44S version: 40°C/W, good for ∼1 W dissipation).
(b) Budgeting about 1/3 W for conduction loss sets the maximum load current at about 5 A.
(c) Then we chose the heater supply voltage to produce 100+ W, to get things heated quickly.
(d) We added the *LC* filter to suppress RFI above ∼1 MHz.
(e) Then we confirmed that the avalanche power dissipated in the MOSFET from periodic dumping of the inductor's stored energy added only a modest additional dissipation, and stayed well within the ratings.
(f) Finally, we added a gate driver IC to minimize class-A conduction losses, which otherwise would dominate. During this process we made numerous adjustments to the heater supply voltage (+12 V, +24 V), heater current (2.5 A, 5 A), and inductor size (1 μH, 5 μH, 10 μH), and toyed with the idea of using a MOSFET with lower R_{ON}, or even a TO-220 package MOSFET with a finned heatsink.

In the end we settled on the design shown in Figure 15.10 as a good overall compromise. However, it would be perfectly reasonable to choose a larger filter inductor, or run at higher current, or both, in which case you'd use a MOSFET with lower R_{ON}, perhaps in a larger package attached to a heatsink. The glib presentation of finished designs often conceals this kind of circuit design thinking.

15.6.2 The control loop

The microcontroller firmware's job is to implement a control loop, to maintain the bath at the desired "setpoint" temperature. Although this looks like plain ordinary feedback, of the sort used for an op-amp circuit, in reality it is bedeviled by thermal time delays; providing sufficient loop gain to stabilize the bath will invariably lead to thermal oscillations. This is a common problem in industrial control systems. As Jim Williams wrote,[35] "The unfortunate relationship between servo systems and oscillators is very apparent in thermal control systems."

The usual solution is what's known as a PID controller, in which ordinary proportional negative feedback (*P*) is augmented by negative feedback proportional to the rate of change of the error ("derivative," *D*), and also by a negative feedback term that grows with time according to the error ("integral," *I*). This can be done simply with op-amps, as shown in Figure 15.14.

The PID controller has to be "tuned" to the properties of the controlled system, to optimize the gains of the three feedback terms. An empirical procedure that works pretty well is the following: (a) with *I* and *D* terms turned off, increase the *P* gain until the system begins to oscillate, then back off a bit; the system will now exhibit overshoot and ringing, but not sustained oscillation, in response to a step change in setpoint; (b) now add *D* gain until the response to a step is critically damped;[36] (c) finally, while watching the error signal itself, add *I* gain to achieve minimum settling time.[37]

[34] As general guidance, if there's less than a factor-of-20 safety margin, you need to check the pulsed power dissipation using the MOSFET's specified "Transient Thermal Impedance." That's because datasheets use a particular set of operating conditions for their single-pulse avalanche spec; see §*3x.13*.

[35] In "Thermal techniques in measurement and control circuitry," Application Note 5, Linear Technology Corporation, December 1984.

[36] In the language of poles and zeros, you've brought in a zero to cancel the natural pole of lowest frequency in the physical system.

[37] Another way to tune a PID, which is due to Ziegler and Nichols (1942), uses the gain setting and frequency of oscillation in step (a) to determine, without further experimentation, the optimum *D* and *I* gains. We like the treatment in Tietze and Schenk's excellent *Electronic Circuits* (Springer, 2007).

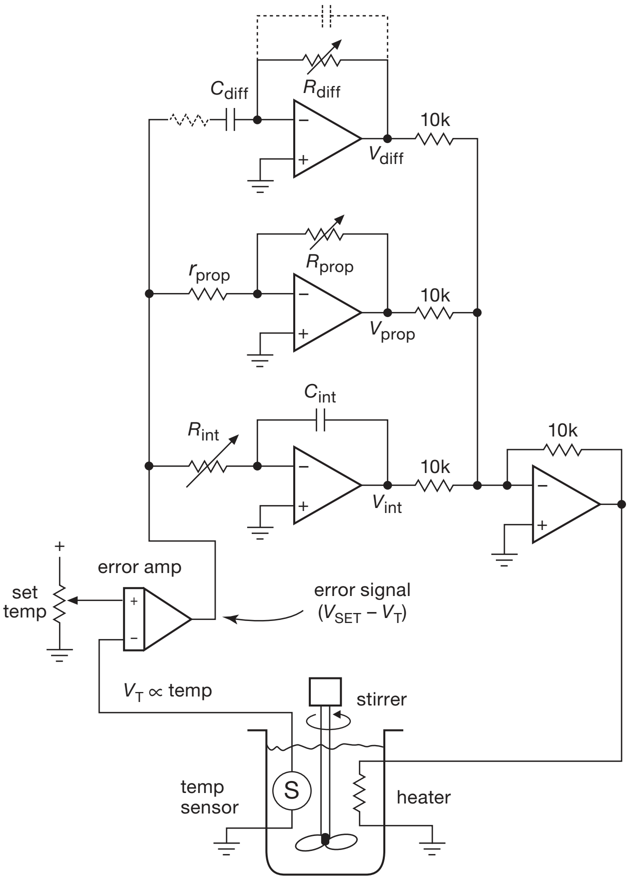

Figure 15.14. An analog PID control loop. The error signal (proportional to the difference between desired and actual temperature) drives an amplifier ("proportional"), an integrator, and a differentiator, with individual settable gains. Their combined outputs form the control signal to the heater. The dashed *R* and *C* are for differentiator stability. (You sometimes see the differentiator input taken separately from the upstream side of the error amplifier.)

15.6.3 Microcontroller code

The firmware to implement a PID in a microcontroller begins with the usual setups: ports, converters, timers, and communications. The interesting part is the main loop, where the measured temperature is digitized at equal time intervals (call the *n*th measurement T_n), and the results are used to compute numerically the *P*, *I*, and *D* outputs from the error "signal" $T_{\text{error}} = T_{\text{set}} - T_n$. The listing in Pseudocode 15.4 shows the simplest computation, assuming known tuning coefficients k_P, k_I, and k_D. In practice you would probably do some smoothing or filtering for the derivative term, which is prone to noise. You might also set up the ADC directly to perform periodic conversions, with polling or interrupts to signal the main loop's PID computation.

Pseudocode 15.4 PID main loop pseudocode

```
Initialize
    zero the integration accumulator: $I = 0$
Main Loop
    reset timer for 10 ms timeout
    read temp, compute nth $T_{\text{error}} = T_{\text{set}} - T_n$
    compute individual PID power output terms:
        $P = k_P T_{\text{error}}$
        $I = I + k_I T_{\text{error}}$
        $D = k_D(T_{\text{error}} - T_{\text{error}-1})$
        $T_{\text{error}-1} = T_{\text{error}}$
    combine and update PWM:
        $\text{PWM} = P + I + D$
    wait until timer times out
    repeat Main Loop
```

A. Some comments (algorithm)

The PID control loop, though of great popularity, is not the only game in town. In particular, there are nonlinear algorithms that, though difficult to treat mathematically, seem to work just fine. An interesting example is Steve Woodward's "take-back-half" (TBH) algorithm,[38] which has the nice feature of "one knob" tuning: you don't have to know anything about the "plant."

The control algorithm has two parts. It begins with a pure *I*-loop (controller output proportional to the integral of the error), which has the advantages of simplicity (only one "tuning" knob: the integrator gain), and of zero averaged error. However, the bad news is that the controlled variable oscillates about the target setpoint forever. Woodward's fix is to make a step correction at each zero crossing of the error, replacing the controller's current output with the average of current value and the value at the last zero crossing. We were curious how this would look, so we dragooned a student skillful in Mathematica (that's him in Figure 15.25 on page 1094) into running a numerical simulation of a TBH temperature controller. You can see the results in Figure 15.15, where we plot the controller output (heater power) and the response of the controlled system (sensor temperature). We started it up at ambient temperature (20°C), teasing out its transient behavior by switching the setpoint between the two values shown. For this simulation we used heater and sensor time constants of 0.5 s, a delay time (from fluid flow) of 0.1 s, and a thermal

[38] "Temperature controller has "take-back-half" convergence algorithm," *EDN*, page 90, September 15, 2005.

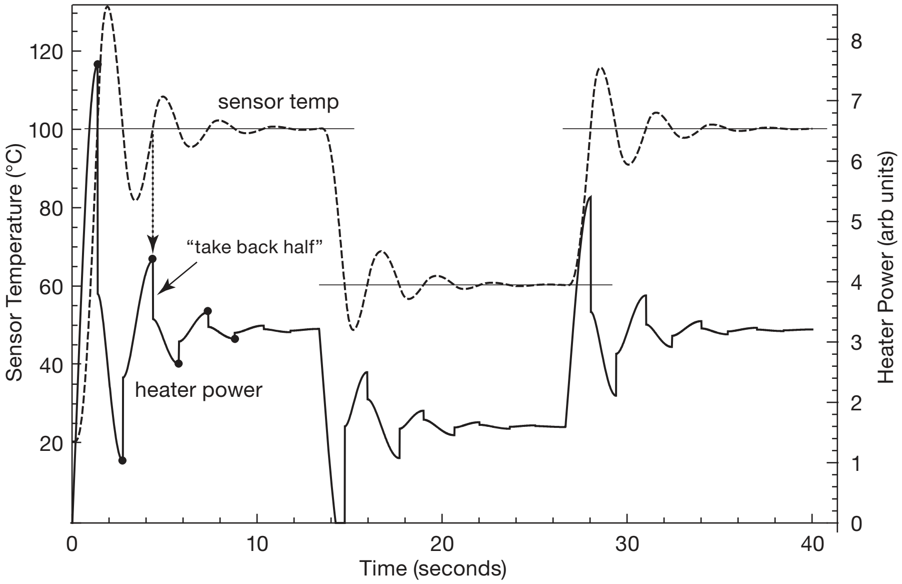

Figure 15.15. A nonlinear control algorithm: Steve Woodward's "take-back-half." This numerical simulation shows the behavior for a sequence of step changes in target temperature (alternating 60°C and 100°C). The controller is a pure integrator, but responds at each moment of zero temperature error (the black dots) by resetting its output (heater power) to the average of its current value and the value at the previous reset.

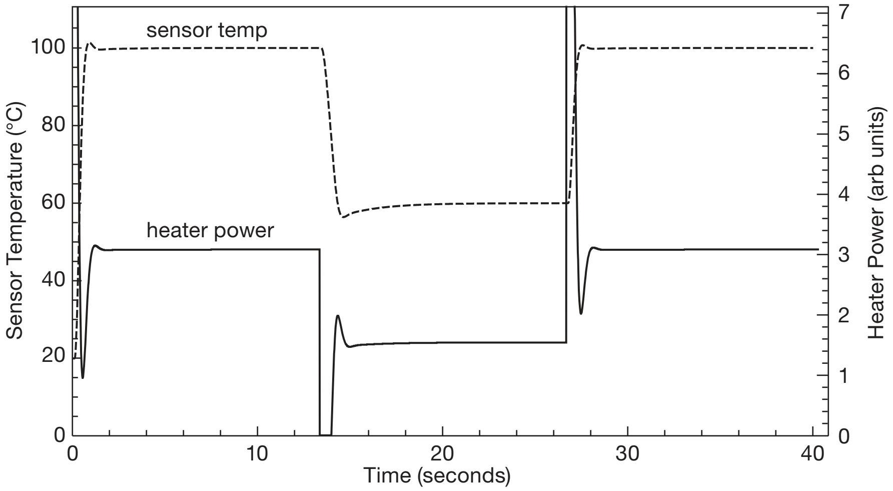

Figure 15.16. Numerical simulation of the system of Figure 15.15, this time with a classic tuned PID controller.

relaxation time to ambient temperature of 0.5 s. The one "knob" (integrator gain) was set to produce a reasonable convergence.

Having set up the TBH simulation, we couldn't resist running a classic PID. After fooling around with the tuning (*three* knobs, this time), we got the results shown in Figure 15.16. The PID does a considerably better job than TBH; but it requires some skill in tuning to find the P, I, and D coefficients suited to the specific parameters of each controlled system.

B. Some comments (Hardware):

This example illustrates how a particularly good choice of microcontroller can greatly simplify the hardware (and coding): this microcontroller combines a good ADC (real 16-bit performance), with the low offset and drift you get with chopping, and an internal differential amplifier of programmable gain, so that the low-level RTD input can be used directly. The differential reference input makes it easy to rig up true ratiometric conversion, insensitive to variations of the reference voltage source. And internal PWM hardware dramatically eases the coding burden.

We've kept the block diagram lean, so as not to distract from the essentials of the analog input circuitry, and the PWM output drive circuitry. But it's easy enough to add some of the creature features shown in previous microcontroller examples: an LCD display of setpoint and actual temperatures; a keypad or thumbwheel entry for parameters such as a simple setpoint, or a more complex time/temperature profile; indicator LEDs and alarm buzzers for fault conditions, and the like.

15.7 Design example 5: stabilized mechanical platform

The final microcontroller example is fun – a motor-driven stabilized two-wheel contraption (which its inventor calls a *Psegué*), shown in action in Figure 15.17.

This thing is a tricycle without its front wheel, therefore unstable without active feedback. The prototype is, of course, Dean Kamen's "Segway™ Personal Transporter" that delighted the world at its debut in 2001. Weird and wonderful homemade variants are sprouting up, propelled by the enthusiasm of the lively hobbyist–nerd community. One such hobbyist is the young man who lives across the street, who asked if he could hang out in our lab to try out his ideas for making a stabilized motorized platform. We doubted he would succeed; we were wrong.

Figure 15.18 shows the system he finally arrived at (after some amusing mishaps). It is a digital PID control loop, implemented in an NXP ARM7 microcontroller. The latter comes nicely packaged on a 6 cm square board, which includes voltage regulators, connectors for analog, digital, and serial ports, and LCD display; it is called the MINI-MAX/ARM-C, sold by BiPOM Electronics for $100.

To sense the platform's instantaneous angle, Jesse used a two-axis solid-state accelerometer, rotated 45° to the vertical, feeding a difference amplifier. The output voltage is proportional to the sine of the platform angle, passing through zero when the platform is horizontal. This provides the analog input for the proportional and integral terms of the PID loop; for the derivative term he used a gyro, whose output is directly proportional to the rate of change of tilt. You steer this thing by pushing the vertical post sideways, which squeezes a pair of resistive force sensors under the post's base. The microcontroller has a Bluetooth link, for playing around with the loop parameters while riding. Figure 15.19 shows the hardware.

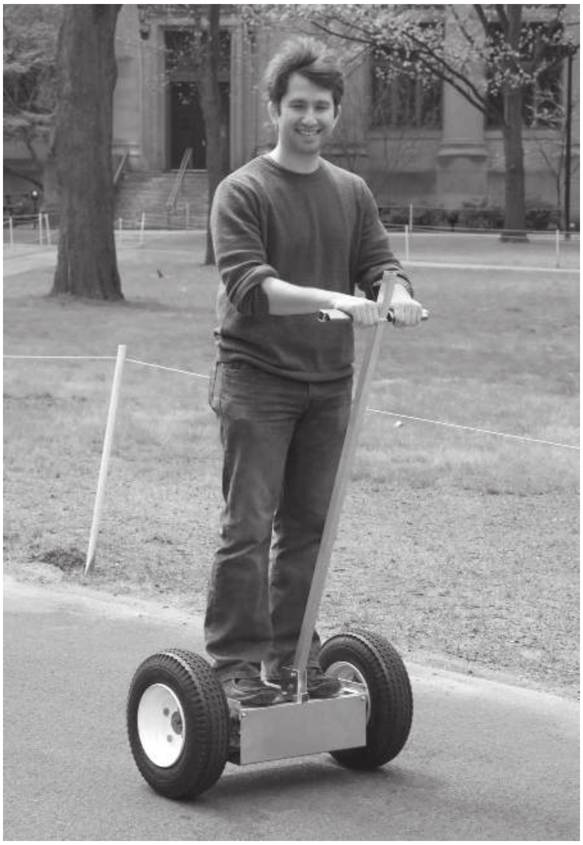

Figure 15.17. Stabilized two-wheel contraption, demonstrated by its creator (Jesse Colman-McGill).

On the output side the microcontroller drives a pair of H-bridge dc motor drivers with PWM logic outputs, as commanded by the PID loop. The dc permanent-magnet gearmotors are substantial beasts, able to put out nearly a horsepower.

The PID loop is paced by one of the microcontroller's internal timers, operating at a 100 Hz heartbeat. The basic PID controller is augmented by some gimmicks that were arrived at by experiment, for example, an extra boost to get the thing moving from a dead stop, and some modifications to the PID gains according to the measured load. A fancy name for such unauthorized patches to the basic PID is *heuristics*; whatever you call them, they're needed, and with some luck they can work well. See Pseudocode 15.5.

Pseudocode 15.5 Psegué main loop pseudocode

```
Main Loop
    reset timer for 10 ms timeout
    read sensors
        tilt-sensing accelerometers (2)
        rotation-sensing gyro
        steering force sensors (2)
    compute PID with speed-dependent parameters
    apply heuristic rules
        dead-zone correction
        threshold boost
        load-dependent PID gain multiplier
    send updated torque command to motors
    if (logging) increment log_loop_count
        if (log_loop_count=10) log data & clear log_loop_count
    TimerCheck: if (timer not expired)
        if (command byte from wireless input FIFO buffer)
            append to line buffer
                if (newline) parse & execute
        write logging byte to wireless output FIFO buffer
    repeat TimerCheck
    repeat Main Loop
```

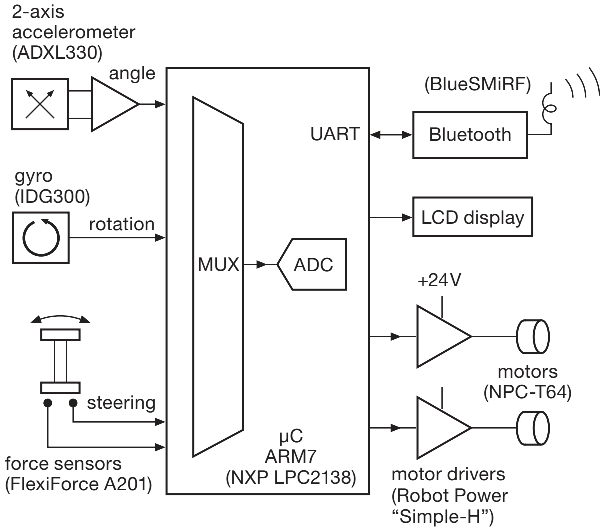

Figure 15.18. Block diagram of the stabilized scooter. The use of prefabricated hobbyist modules (gyro, accelerometer, wireless, microcontroller board, and motor drivers) simplified construction and wiring. The actual part numbers are in parentheses.

15.8 Peripheral ICs for microcontrollers

Our experience in electronics engineering comes from the real world, where an enormous variety of measurements and interactive control are needed. Having a programmable microcontroller is good, and having lots of built-in interfacing circuitry is great – but the world is bigger than that. When we talk about the rubber meeting the road, what we need is a tire, a wheel, and other specialized devices that aren't included inside a microcontroller.

In this section we've created three drawings that show sixty examples of specialized interface devices, complete with sample part numbers. It's our hope that you'll point your browser at Octopart, etc.,[39] and read the datasheets for some of these parts, as inspiration for searching out additional examples and alternative parts.

DACs and ADCs are a common peripheral for interact-

[39] Octopart is an excellent parts locator, showing availability and pricing of components at stocking distributors; the site also includes datasheets for most parts. An especially valuable feature is the ability to see the status of parts, and their activity at various distributors. If a part has been discontinued, you'll still find out what it was once possible to make (and what its specs were), and you can hope someone else will have created a similar part. *One caution*: as of this writing, Octopart only lists components that are carried by distributors, and not those sold directly from the factory. If Octopart doesn't show a part, that doesn't mean you can't get it. Sometimes the factory has to be your source, even for mainstream manufacturers who also sell through distributors. We have found that in most cases the manufacturers make it easy to buy directly, even in small quantities.

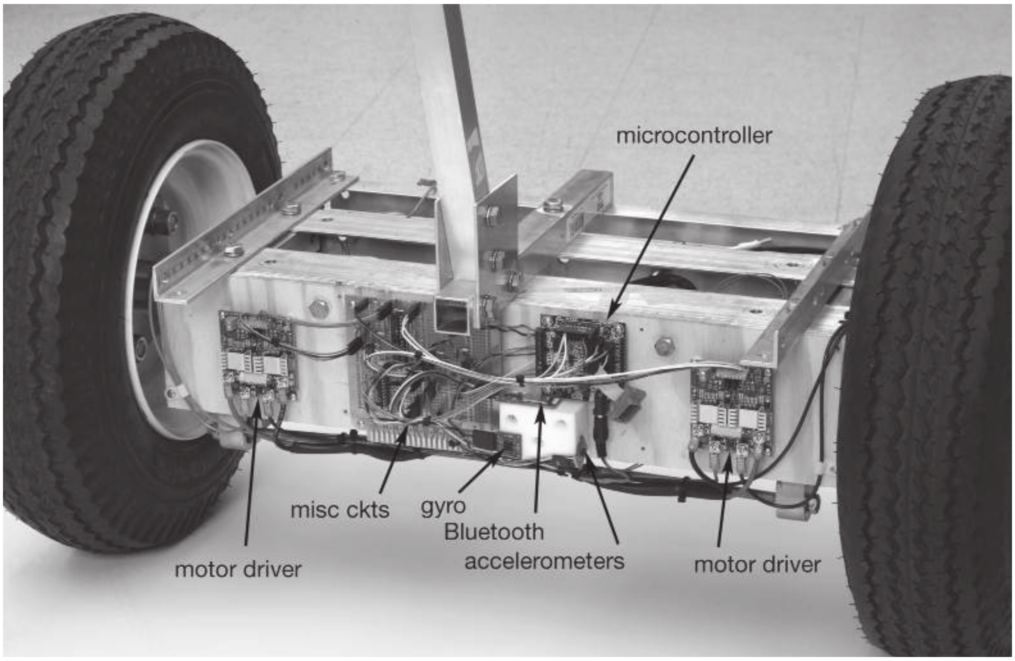

Figure 15.19. Closeup of the sensors and electronics. The difference signal from the accelerometer pair (each inclined 45° to the vertical) is a measure of fore–aft tilt angle, and the gyro provides a direct measure of the time derivative of tilt. The gel-cell batteries live in the space behind the electronics.

ing with real world stuff; if that's all you're interested in at the moment, use Tables 13.2, 13.3 and 13.11 (DACs), and Tables 13.5, 13.6 and 13.9 (ADCs). These tables include columns indicating SPI, I^{2}C, or other interface methods.

When designing a gadget with an embedded microcontroller, there are lots of "devil in the details." We could prattle on for pages about how to connect to many wonderful peripheral devices. Instead we present a guided tour and navigation aid, in the form of Figures 15.20–15.22, tagged with numbers to match the brief outlines that follow. We've put plenty of cross references to relevant discussions elsewhere in the book, along with some selected part numbers. We've broken it down into several figures, because there's so much stuff that you can attach to a microcontroller: devices that can connect directly to the μC (Figure 15.20); devices that connect to an SPI bus or its near relatives (Figure 15.21); and devices that connect to an I^{2}C bus (Figure 15.22). Your programming quality-of-life may be improved if your microcontroller includes a built-in interface for your chosen bus, like the one in Figure 10.86.

15.8.1 Peripherals with direct connection

Figure 15.20 shows a microcontroller, heavily encrusted with devices that connect easily to standard "internal peripherals" such as digital I/O port pins, serial communication ports (UART, USB, Ethernet), ADCs and DACs, PWM outputs, and the like. It also shows important support chips such as power control, watchdog, and external oscillator. In outline form we've collected some explanatory comments, useful part numbers, and references to relevant discussions elsewhere in the book.

A. Outline for Figure 15.20

1. **Power-source selector.** If the system runs from battery power, an ICL7673 with two *p*-channel MOSFETs makes a nice power selector, acting as an ideal diode-OR, automatically connecting to the higher of the two voltages. For rechargeable battery management see §*9x.2*.
2. **Power supervisor, power-ON-reset, watchdog.** Brownout protection, don't let the μC do anything important if its supply voltage is too low; reset it. See §10.8.1B, and Table 10.6 on page 756. There's a huge variety of choices available. Take a look at the ADM705 and TPS3306 supervisory ICs (which include a watchdog) and the ADM691 series (which also incorporate a battery-backup-switch feature).

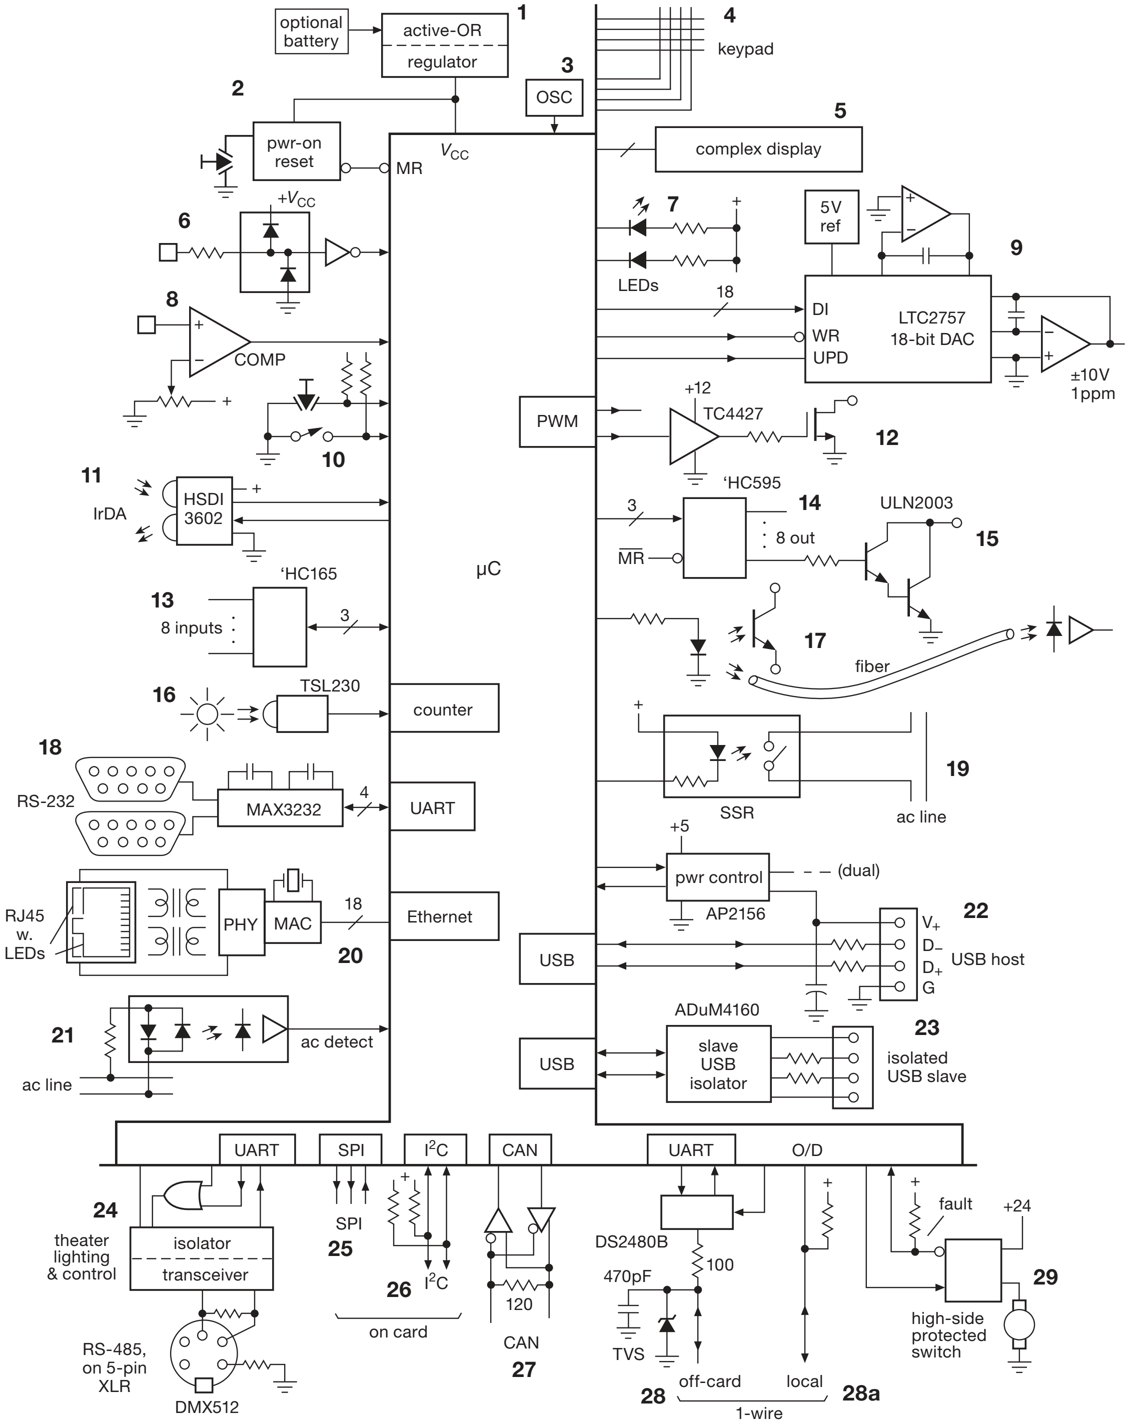

Figure 15.20. An assortment of peripheral devices that can be connected to a well-endowed microcontroller. Some of the devices require specialized interface circuits within the controller. The interface items marked with bold numbers **1** to **29** refer to descriptive paragraphs in §15.8.1.

3. **μP oscillator.** Internal, see §§15.2.1E and 15.9.3. External, see §7.1.6 for choices and cautions.
4. **Keypad scanning techniques.** See Figure 15.8.
5. **Panel-display choices.** LED, LCD, CFD, tricks. See §§10.6.2, 12.5.3, 14.6.
6. **Logic inputs, external.** Protect μC against ESD with separate user-repairable input gates, and the instrument's programmed μC survives; see §12.1.5.
7. **LED and indicator outputs.** See §§12.4, 12.4.5A, 12.5.1.
8. **Analog threshold detection, discriminators.** See §§12.1.7 and 12.3, and Table 12.2 on page 819.
9. **DACs.** See §§13.2 and 14.6.2, and Tables 13.2 on page 893 and 13.3 on page 894; fast 18-bit accurate parallel DAC LTC2757.
10. **Switch and pushbutton inputs.** See §12.1.4.
11. **IrDA infra-red transceiver.** HSDI-3602.
12. **Power MOSFET switches.** See §§3.5, 12.4, and 15.6, and Table 3.4b pages 189–191. MOSFET driver ICs, logic to 12 V MOSFET gate drive, see §3.5.3; classic TC442x family (see Figure 3.97 and Table 3.8 on page 218). For PWM see also §15.6.2 and §*9x.5*.
13. **8-bit parallel-in shift register.** See Figure 12.40, suited for onboard use. 74HC165 (and other '165 logic ICs), \$0.35, compare with a simple 8-bit I^{2}C expander chip at ~\$2.30.
14. **8-bit parallel-out shift register.** See Figure 12.40, e.g., 74HC595 logic IC, \$0.32; also check out the 74HC594 and '567, which have a double buffer. For SR chips with built-in power drivers (e.g., TI's TPIC6C595), see §12.4 and Table 12.3.
15. **Darlington and MOSFET driver ICs.** See §12.4. Drive loads with the venerable ULN2003 Darlington 7-unit array, \$0.33, or with individual logic-level MOSFETs, see Table 3.4a, on page 188. Some other useful driver ICs include the ULN2803, SN75468, TPL7407, MC1413, ULN2068 and TD62783.
16. **Light-intensity sensor.** TAOS TSL230 provides a light-to-frequency signal, allowing for easy, accurate measurements over six decades of light level. See Figure 12.81.
17. **Optical isolation.** See §12.7 and the drawings and part numbers in Figures 12.85–12.88. Logic optocoupler, jellybean H11L1, HCPL-2201. For long-distance optical-fiber data links, with connectors, see §12.7 and Figure 12.98.
18. **Serial data-communication interfaces.** RS-232, with ±7 V levels; see §12.10.4. Use the classic DS14C88 and DS14C89 chips, or for simplified operation on +5 V, second-sourced MAX232, \$0.90 from TI; or 15 kV ESD-protected MAX3232E runs from 3.3 V or 5 V, \$3. These have 2 Tx and 2 Rx, thus one port plus two control lines, or two ports. For RS-485, see §§12.10.3, 14.7.8. A typical transceiver chip is the LTC1485.
19. **ac power switch.** Isolated SSR, zero-crossing triac or back-to-back SCRs: see §§12.7, 15.4, and Figures 12.91–12.93. Available as low-current ICs, e.g., Fairchild MOC3043, \$0.80, or as powerful modules with screw terminals.
20. **Ethernet.** Protocol processing, transformer coupled, see §14.7.16 and Figure 12.124. Easy-to-use chip, Silicon Labs CP2201, about \$4.50 in qty 100. You'll also need a transformer (e.g., Pulse PE-36023) and an RJ-45 connector. Most folks buy these combined into one compact part, complete with two indicator LEDs, e.g., Pulse J00-0065NL, \$4.75.
21. **ac power detect.** To monitor relay outputs, blown fuse, respond to ac-line signals. Opto-isolated; see §12.7.7 and Figure 12.94A, e.g., MOC256.
22. **USB.** Supported by a controller in the μC, see Figure 10.86. USB hosts need a power supervisor with a 500 mA CL, etc., e.g., AP2156 dual (see Table 12.5). USB clients, see §§14.7.13 and 15.9.2.
23. **Isolated USB.** Analog Devices' ADuM4160.
24. **DMX512 theater lighting and control.** 5-pin XLR connectors, to 1200 meters. 250 kbaud (UART in μC), with OR gate for the packet-framing "MAB" symbol. Isolator and RS-485 transceiver, MAX1480 or MAX3480B, see §12.10.3. Near and far ends terminated. Theater electricians: with luck you'll be handed proper 120 Ω twisted cable. DMX512 is being superseded by DALI.
25. **SPI.** Serial microprocessor to chip interface. It's an SPI jungle out there, with many different interface rules grouped under the SPI label; read the IC datasheet very carefully. SPI interfaces are often implemented as individual bit-bang lines, and, as such, SPI may be more of an interface scheme than a multiple-device bus. See also §§14.7.1 and 15.8.2 (the next section).
26. **I^{2}C.** Chip-to-chip interface; multi-master. Two-wires, open-drain wired-AND operation, with pullup resistors; see §§14.7.2 and 15.8.3. Maximum bus capacitance 400 pF. Unlike SPI, the I^{2}C bus is well specified (and its use tightly controlled) for predictable results.[40]
27. **CAN-bus.** Two-wire bidirectional bus, differential signaling; see §14.7.15. Generally a CAN-bus

[40] The I2C-Bus Specification, Version 2.1, January 2000 (NXP Semiconductors).

transceiver is required, e.g., ON Semi's AMIS-42673 or AMIS-41683, and (if not built-in) an SPI-based controller like the Microchip MCP2515.

28. 1-wire bus. Power and bidirectional data signaling on one wire; see §14.7.3. Championed by Dallas, now Maxim. UART transceiver DS2480B. USB to 1-Wire, DS9490.

28a. Alternative simple 1-wire for μC to local chips, open-drain I/O and pullup resistor.

29. Power switches. High-side to 60 V, 550 A, protected, with fault feedback; see §12.4.4 and Table 12.5; e.g., BTS432, IPS6031.

15.8.2 Peripherals with SPI connection

Figure 15.21 shows a variety of available peripherals that communicate via a simple SPI serial 3-wire master–slave protocol. The SPI bus[41] (§14.7.1) normally consists of three lines: a clock (SCLK); data in (SDI), and data out (SDO′). But there needs to be an additional chip-select line from the processor to each slave device; this is usually called CS′, but it's sometimes called other names like load (LD), or enable (EN), etc. This signal, by whatever name, generally transfers the contents of the device's serial-input shift register into an internal data register when CS′ is disasserted (brought HIGH) after the data bits have been shifted in. You can dedicate one μC pin for the CS′ of each device, or you can save a few pins by using a 74LVC138 (or other '138) decoder IC; see §10.3.3D. Furthermore, some peripheral chips on a bus may require additional individual connections to the microcontroller; for example, for interrupts, to reset the device, etc.

Signal-name usage in SPI may seem inconsistent; for example, the controller's data-in pin (SDI) is connected to the slave device's data-out pin (which might be called DO). Similarly, the master's SDO pin is connected to the slave's DI. A better scheme is to name your signals unambiguously as MISO (master-in, slave-out) and MOSI (master-out, slave-in); see §14.7.1. Sadly, you won't find these names on most device datasheets.

As we stated before (§14.7.1) the SPI "standard" is badly fragmented. For example, in some SPI slaves a single pin may be used for sending data in both directions. This requires the controller to reverse the direction of a pin, so it can receive data back on the same pin that it used for sending a command.[42]

A. Outline for Figure 15.21

30. Touchscreen. *XY* position digitizer, pressure sensitive; see §13.11.2 and Figure 13.73: AD7873.

31. Serial EEPROM. 8-pin package, §14.4.5B: 25LC080A, AT25080, M24C02 (256×8, $0.09 in 2500-pc reel)

32. Accelerometer. Three-axis MEMS: ADXL345, Freescale MMA7455L.

33. SD card. "SecureDigital": SD,[43] miniSD, and some microSD memory cards; §14.4.5C. These cards communicate via standard SPI, so this interface consists simply of the socket, with no additional electronics needed! The miniSD and microSD cards have 10-pin connectors. Pin 1 is CS′; but it's also "card detect," with a 50k pullup resistor, to let you know that a card is plugged in. You pull pin 1 low to initiate SPI communication mode.

34. "SparkFun" modules. Wide selection of easy-to-use modules with through-hole connections; e.g., three-axis accelerometer (ADXL335), two-axis gyro rate sensor (LPY503A), or three-axis magnetometer (MAG3110 or HMC5883). Also see Adafruit modules (adafruit.com), e.g., OLED graphic displays available in both SPI and I^{2}C interfaces.

35. Digital pot. DCP, EEPOT; accurate ratio (∼1%), but overall tolerance typically ∼20%; low voltage; see §3.4.3E; e.g., 10kΩ, 10-bit, 1024-level MAX5481, $2.60.

36. Digital resistor. Resistance tolerance 1%, operates to ±16 V; e.g., AD5292. See the digital resistor section in Chapter *3x*.

37. ADCs. See §§13.11, 14.6.2, 14.7 and Tables 13.6–13.12; e.g., LTC2412, AD7927 (Figure 13.74), AD7734.

38. Digital capacitor. Give range and step size; see the digital resistor and capacitor sections of Chapter *3x*; quartz FLEcap: MAX1474.

39. ac power monitor. Including power factor, see §13.11.1: ADE7753, with 8052 μC, ADE7769; needs an *i*Coupler isolator, ADuM3260.

40. DDS RF frequency synthesizer. See §§7.1.8, 7.1.9C, 13.13.6, and 6.2 (on *LC* filters); e.g., AD9954.[44]

[41] Analog Devices' AN-877 is a useful application note, describing the use of the SPI bus in various of their high-speed conversion devices.

[42] And of course that data appears on the MOSI pins of the other bus riders. It's harmless enough, because their chip-select pins are disasserted; but it's ugly.

[43] *SanDisk SD Card Product Family, OEM Product Manual*, Table 3-2, and *Physical Layer Simplified Specification*, Version 2.00, Chapter 7.

[44] Analog Devices is a giant in Direct Digital Synthesis ICs.

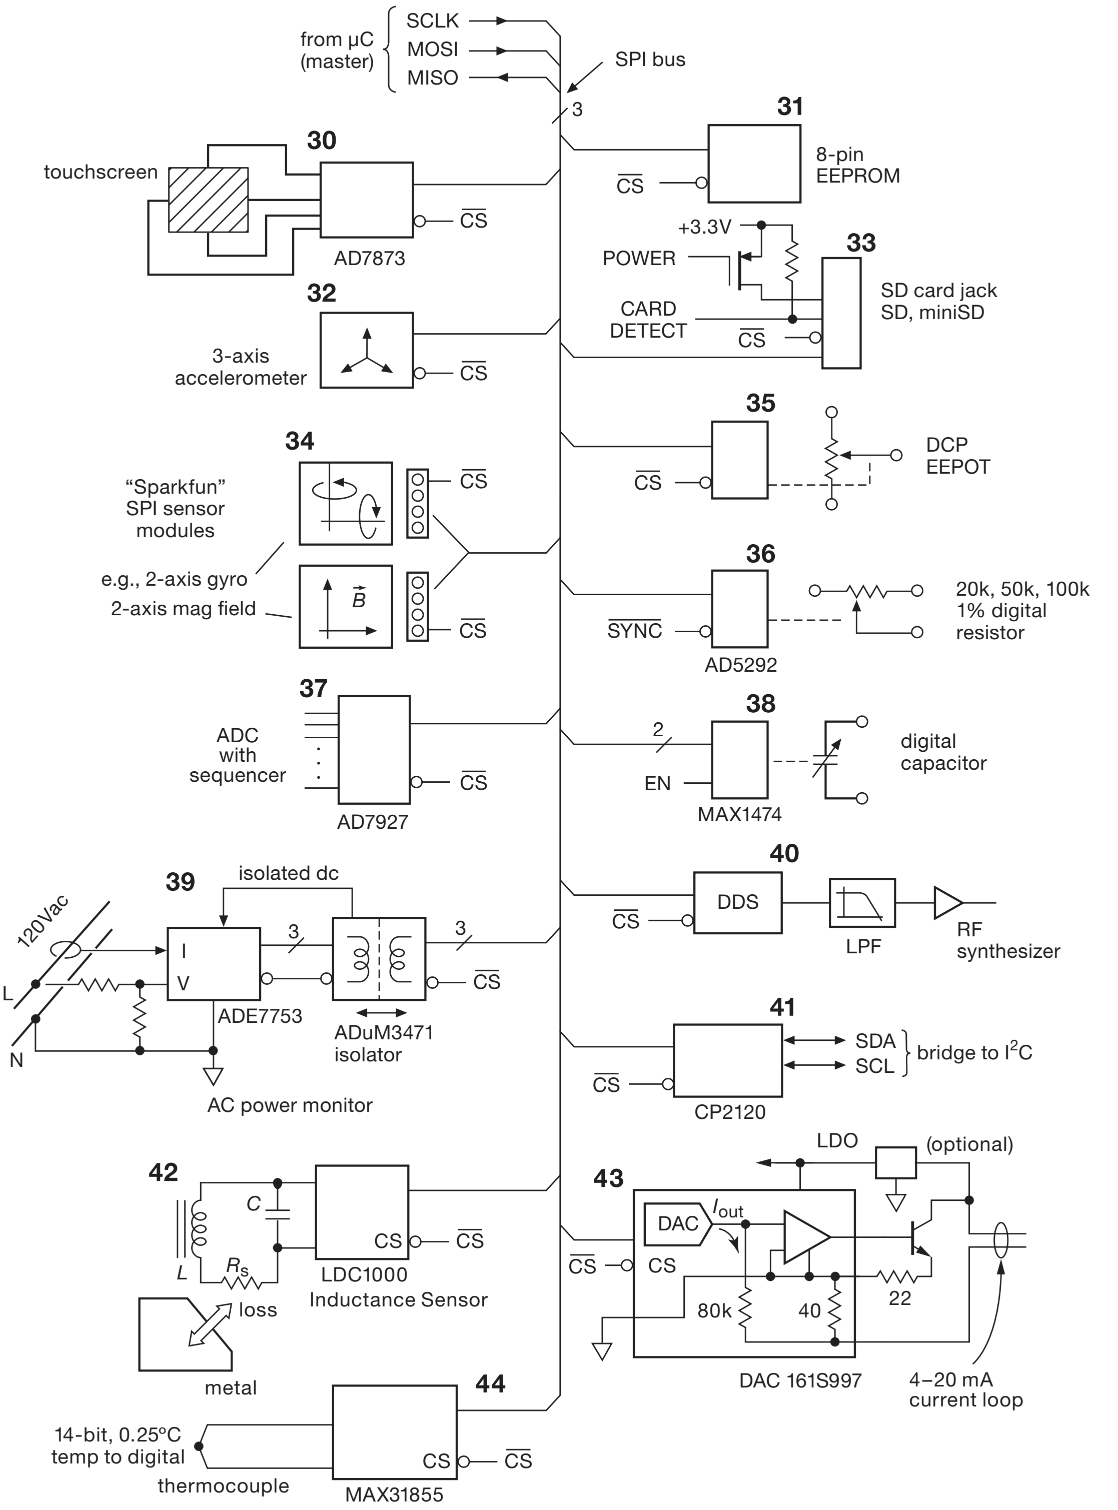

Figure 15.21. An assortment of SPI slave peripherals, well suited for microcontroller applications. The SPI interfaces marked with bold numbers **30** to **44** refer to descriptive paragraphs in §15.8.2.

41. SPI to I2C Bridge. Silicon Labs CP2120, Microchip MCP2515, NXP SC18IS600. See also next section, and §14.7.2.

42. Inductance sensor. See Table 13.12. TI introduced the first inductance proximity sensor IC, the LDC1000, which detects inductance and loss changes in an external *LC* resonant circuit. Operating frequency 5 kHz to 5 MHz.

43. 4–20 mA current loop. See §14.7.8 and Table 14.3. The DAC161S997 uses a 16-bit current-output DAC to program a precision current signal for conveying analog measurements in industrial environments.

44. Thermocouple ADC. The MAX31855 includes cold-junction compensation for seven types of thermocouples, and provides 0.25°C resolution from −270 to +1372°C (compare with Cirrus CS5532, suited for thermocouple use but lacking the valuable compensation, see Figure 13.67).

15.8.3 Peripherals with I^{2}C connection

We introduced the I^{2}C (sometimes written IIC) bus in §14.7.2, where its advantages and disadvantages were described in some detail. To summarize, I^{2}C is a multimaster half-duplex “packet-oriented” bus, intended for chip-to-chip serial communication (I^{2}C stands for inter-integrated circuit), with a well-defined addressing and data transfer protocol.[45] Compared with SPI’s 3-wire “bus” plus individual chip-select lines, I^{2}C is a true 2-wire bus. A data transfer goes like this. The master sends an initial byte containing a 7-bit address and a direction bit; the addressed slave responds with an acknowledgment bit, after which data bytes move from sender to recipient. The whole transaction is framed by unique START and STOP symbols.

I^{2}C is a more complex protocol than SPI, and requires each device on the shared bus to have a unique 7-bit address. It’s well suited for peripherals with lots of registers (you can send a register address as part of the packet), but its half-duplex nature and required addressing overhead make it less well suited to fast and continuous data streaming. In general, the choice is made by the manufacturer of the peripheral; most microcontrollers include support for both I^{2}C and SPI.[46]

A. Outline for Figure 15.22

45. Parallel-bit ports (“GPIO” – general-purpose I/O). Definable wires, interrupt: 8 bits, STMPE801; 24 bits, STMPE2401; consider also TI’s 16-bit TCA6416.

46. LED backlight. Smart backlight driver, fade, ambient-light responsive: ADP8860, ADP5501, with 4×4 keypad ADP5520.

47. Real-time clock (RTC). For example, NXP’s PCA8565 (0.65 μA at 1.8–3.3 V, 32 kHz xtal, with alarm and timer interrupts), or the fancier PCF2129 (which includes internal xtal and TCXO, selectable SPI or I^{2}C interface, and a nice time-stamp function to capture the time of an event even if your μC is sleeping) NXP’s PCF8563 and Seiko’s S-3590A are popular parts, and available for less than a dollar.

48. Clock synthesizer. See §13.13: ON-Semi FS714x, Silicon Labs Si5338 to 710 MHz, four LVDS out, with separate V_{CC} levels.

49. Three-axis accelerometer. MMA7660FC, $0.68, MMA7455L (I^{2}C mode), or a variety of I^{2}C modules from Adafruit, for example their MPL115A2 barometric pressure/temperature sensor, or L3GD20+LSM303+BMP180 10-DOF inertial measurement unit, $30. Many of the “shield” part numbers from AdaFruit and SparkFun match the IC part numbering of the mounted sensor ICs, which are available from distributors. The shields make it easy to experiment with these (generally tiny SMT) parts.

50. 8-pin EEPROM. See §14.4.5B: Microchip 24LC256 (32k×8, 2.5–5.5 V, low-cost $0.76), 24AA256 (1.8 V).

51. ADC subsystem. For example, AD7294: 12-bits, six inputs (3 temp, 2 current sense), four outputs, alarms, ($14), see Figure 14.41. The AD7730, intended for use with strain gauges, scales, etc., includes many functions (but uses the SPI interface), see Figure 13.75.

52. Stepping-motor position IC. For example, ON-Semi AMIS-30624 (both parallel and I^{2}C control options): has position memory, a sine table for 1/16 microstepping, speed ramps, two H-bridges, V_S to 29 V, 800 mA, max.

53. Touchscreen. ST’s STMPE811, $1.47.

54. Digitize video. NTSC and PAL composite, S-video, §14.6.2 and Appendix I; 8-bit TI’s TVP5150, $4; 10-bit dual 30 Msps TVP5147, $5.

[45] You’ll find statements like this in the datasheets of conforming I^{2}C peripherals: “I^{2}C is a trademark of Philips Corp. Purchase of I^{2}C components from [manufacturer] conveys a license under the Philips I^{2}C Patent Rights to use these components in an I^{2}C system, provided that the system conforms to the I^{2}C Standard Specification as defined by Philips.”

[46] For controllers without I^{2}C support, you can use an SPI-to-I^{2}C bridge (as in Figure 15.21), driven either with the microcontroller’s internal SPI hardware (if present) or with bit-banging via individual port pins. The bridge takes care of the fussy I^{2}C timing and half-duplex signal reversals.

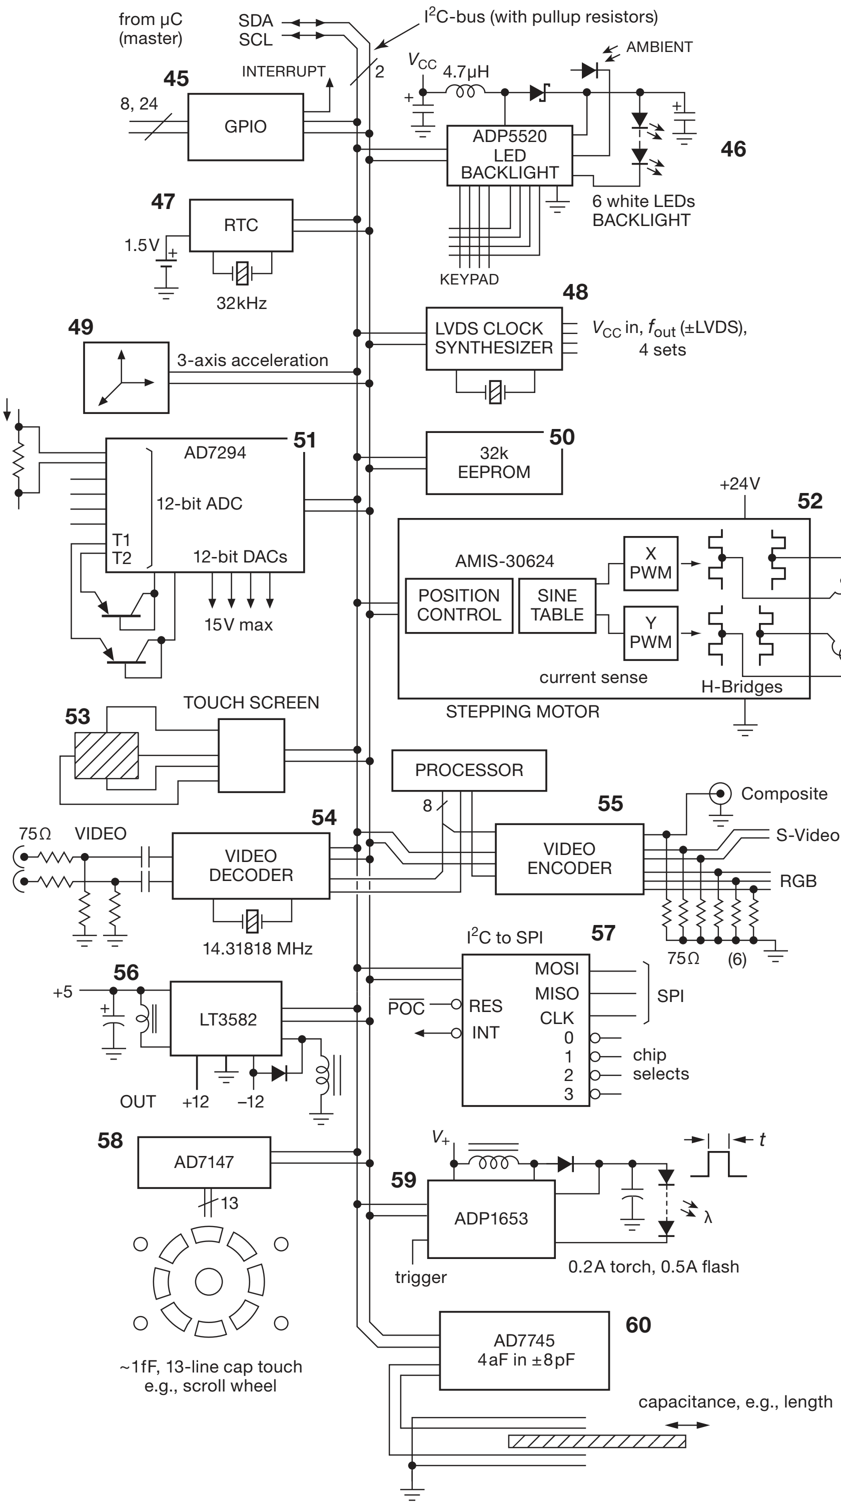

Figure 15.22. An assortment of I^{2}C bus peripherals, well suited for microcontroller applications. The I^{2}C interfaces marked with bold numbers **45** to **60** refer to descriptive paragraphs in §15.8.3.

55. Video generation. See §14.6.2: from pixel stream, Cirrus Logic CS4954; and for HD, Analog Devices ADV7390–93, see Figure 14.36.

56. Bipolar switching supply. See §9.6; Linear Technology's LT3582 is programmable in 25 mV steps to over ±12V (not all required parts are shown).

57. SPI controller. I^{2}C-bus to SPI bridge, see §§14.7 and 15.8.2. NXP's SC18IS602B, SPI master with four CS′ select lines.

58. Capacitance touch sensing. Analog Devices AD7147 provides 1 fF sensitivity on 13 input lines. Use to make touch pads of your own design, such as the scroll wheel shown. STMPE321 (three touch lines only), $1.30.

59. LED "torch" or flash. The ADP1653 boost converter (both parallel and I^{2}C options) has programmable current for a 200 mA torch (British for *flashlight*), or with timing for a 500 mA flash with trigger.

60. Precision capacitance sensor. Analog Devices AD-7745 has a 24-bit converter and provides 4 aF resolution with a ±8 pF range, for precision position measurement, etc. The AD7746 has two channels. See Table 13.12.

15.8.4 Some important hardware constraints

Microcontroller systems present some unexpected circuit and timing constraints that you have to worry about. Here are a few that come to mind; they are discussed in some detail elsewhere in the book, as indicated by the section references.

A. Low supply voltages

Fast microcontroller core logic continues to shrink in feature size, with correspondingly lower supply voltages. And microcontrollers, like their more computationally adept micro*processor* cousins, present the dc supply with abrupt load-current steps, going from standby to full current on time scales of nanoseconds. You need efficient buck converters (or point-of-load voltage ratio converters) with low output impedance and good step response; and liberal use of SMT bypass capacitors. See §*9x.3*.

B. Logic-level translation

You're generally dealing with multiple supply voltages in an embedded application, with some incompatible logic-level requirements. See §12.1.3 for lots of detail.

C. Critical peripheral timing

Some "high-maintenance" external peripherals require great attention to timing. In the upcoming section on software, we illustrate this with the example of a high-throughput multichannel ADC system (§15.9.2), which stresses the timing capabilities of a modest-speed microcontroller.

D. Dual dc supply sources: battery and ac line power

Portable devices run from internal batteries, usually rechargeable by an ac adaptor. You need seamless switchover, battery-charging and protection functions, and the like. See §*9x.2*.

E. Reset supervisor

The desk telephone of one of the authors crashes (!) if the buttons are pressed too lightly or too fast. It gets wedged and has to be rebooted (by unplugging the power). That's a design flaw (we had three of the same model, with the same behavior), remedied by careful design with a watchdog and reset supervisor. This task is complicated by use of several supply voltages (which present their own problems, for example proper sequencing during power-up and turn-off). See §10.8.1B.

15.9 Development environment

The five design examples earlier give a glimpse of the enormous range of applications for which microcontrollers are so well suited. But these wonderful gadgets won't do anything until you've loaded a program into them. For that, you've got to (a) do the program coding, and (usually) simulation; (b) load the program into the target in-circuit microcontroller; and (c) check out and debug, if necessary (it will be!), the loaded code. The detailed landscape of the software and hardware tools to do this (the "development environment") is continually improving. Here we summarize the current situation, advising as always that the practitioner should stay abreast of what's available, and affordable, in this rapidly changing area of electronics.

15.9.1 Software

The effective use of microcontrollers requires some investment in software tools (compilers, assemblers, debuggers) that run on some host-computer platform. Along with the cost of the tools comes a significant investment in time to learn how to use them. The great majority of contemporary programming is done in C/C++, although there is a place for programming at the assembly-language level.

A. C/C++

It's important to realize that there are vendor-specific variations in the C/C++ languages, when coding for a microcontroller: there are libraries that deal with the internal peripherals (SPI port, ADC, timers, and so on), and there are low-level issues such as the configuration of idiosyncratic memory spaces.[47] There are complications connected with timing (clock frequencies, baud rate, timer intervals), and also with processor word width (8/16/32 bits). The bottom line is that the code you are writing is not vanilla C, and consequently is not so easily ported from one microprocessor family to another.[48]

B. Assembly Code

Some microcontroller coding is done in the processor's native assembly code. This is fussy stuff, and it's generally not the right way to go when you are writing a program that is complicated, with complex branching and control, arithmetic functions, and the like. But it lets you get closer to the metal, with access to instructions (such as bit operations, or read–modify–write) that are inaccessible in a compiled language like C. And while it's perfectly OK to write in assembly code for simple microcontroller applications, you've got to remember that such code is difficult to port to a different processor family.

Assembly language coders can write highly optimized loops and timing-critical code (e.g., for a digital signal processor); and assembly-language routines can be invoked from C when needed.[49] Furthermore, a compiled program intended to run in stand-alone mode (i.e., without an operating system) will necessarily acquire some startup assembly code, put there by the development system, that performs tasks such as initializing memory and interrupt vectors, copying executable code from nonvolatile memory to internal RAM (if so instructed), and the like. It's helpful to be able to understand this code, particularly when debugging.

C. BASIC

The BASIC "Stamp" series, made by Parallax, Inc., are tiny (stamp-sized) circuit boards based around PIC or Ubicom (formerly Scenix) microcontroller variants that include a BASIC interpreter in the μC's built-in ROM. They also include a voltage regulator, crystal, and nonvolatile EEPROM for user program and data storage. They come in 14-pin SIP, and in 24-pin- and 40-pin-wide (0.6″) DIP, with prices beginning at \$30.[50] These modules include things like digital I/O port pins, PWM, serial port, and I^2C, supported by Parallax's extensions[51] to the BASIC language (called PBASIC); the PBASIC source code is not compiled, but it is stored in a compressed ("tokenized") form, from which it is executed by the on-chip interpreter. Typical BASIC commands occupy 2 to 4 bytes, in their compressed form, when loaded into the Stamp's EEPROM. Because these devices run an embedded *interpreter* (rather than executing compiled code), they are not terribly fast – a few thousand instructions per second – but their simplicity has made them quite popular.

People tend to think of BASIC as an inefficient language (in both speed and memory requirements) – but in fact there are BASIC *compilers* that create good assembly code that runs fast. They don't require a preloaded run-time interpreter program, and they target code for many popular microcontrollers (e.g., AVR, PIC, and ARM).[52]

The BASIC language provides easy access to microcontrollers for the unsophisticated or beginning programmer. Other manufacturers have moved into this niche: you can get, for example, stamp-sized boards with a 32-bit ARM7 that runs a *compiled* BASIC for \$50 (ARMexpress, from Coridium).[53]

[47] The 8051 architecture, for example, has internal and external code spaces, internal and external data spaces, bit-addressable areas, and special function registers. And, to complicate matters further, modern 8051 variants often have some *internal* "external" memory! The AVR and ARM processors are considerably simpler in this regard; the ARM, in particular, has a single "flat" address space.

[48] There are some pleasant exceptions to this complicated landscape, for example, the *Arduino* platform, which provides simple software and libraries that make programming as easy (or perhaps even *easier*) than the exemplary BASIC Stamp.

[49] But a *cautionary note* on inline assembly code within a C/C++ program: contemporary compilers will "optimize away" program code, assuming they know better than the human programmer; this can create serious havoc.

[50] Well, \$29 actually; but we are weary of being *nined* to death, so we routinely round away the trailing 9.

[51] For example, "BUTTON" debounces an input button, performs an auto-repeat, and branches to an address if the button is in a target state.

[52] Examples are GCBASIC (open source), Swordfish, Proton PICBASIC, mikroBasic, and microEngineering Labs PicBasic compiler for the PIC; BASCOM-AVR and the GNU compilers for the AVR; OshonSoft for PIC, AVR and Z80; and several compilers for the ARM family.

[53] Some other BASIC-programmed microcontrollers are BasicX (NetMedia), PICAXE (Revolution Education), KicChip, C Stamp (A-WIT Technologies), CUBLOC (Comfile Technology), and ZBasic (ZBasic/Elba).

D. Java, Python

Some microcontrollers, notably those with ARM cores, include some hardware support for languages like Java. And some interpreted scripting languages have been ported to microcontrollers. These interpreted languages are convenient for high-level jobs that are not time-critical, for example a user interface; but be cautious when counting on them for timing dependent tasks like robotic control. It's often better to devote a separate microcontroller for the latter, with appropriate real-time programming.

15.9.2 Real-time programming constraints

Programming a microcontroller is similar to ordinary computer programming, but with a few important differences. We've already mentioned things like the need to initialize "internal peripherals" through special-function configuration registers, vendor-specific language augmentations, and the fact that run-time code is often just a stand-alone program, without anything like the usual operating system.

An important additional constraint in many applications is the need to conform to critical timing. Some examples are an ADC that must take accurately periodic samples, a serial port (USB, say) whose timing must meet a tight specification, or the generation of analog video.

When you're not dealing with breakneck speeds, the built-in timers offer a good solution: in the first case, you might use one of the μC's internal timers, brought to an output pin, to trigger the ADC at some leisurely rate, say 10 ksps; and the ADC's conversion complete could generate an interrupt, so you can fetch the result. But if you're pushing the speed limits, you may have to resort to carefully coded assembly language, taking account of the microcontroller's execution speed (clocks per instruction). This is fussy stuff, and you have to take care to equalize timings on branches and loops. And the code you generate is not portable, depending as it does on clock speed and processor type.

Timing example: 16-bit serial ADC

To illustrate this with a specific example, consider the LTC1609 200 ksps 16-bit successive-approximation ADC with serial data output, which we saw in Chapter 13 as the back end of a 16-channel data acquisition system (§13.12.1, Figure 13.76). Among other things in systems like this, you need to worry about digital noise contaminating the analog input. To deal with this problem, this converter happily offers several modes: for example, in "internal clock mode" it generates the conversion clocking pulses, and you grab the serialized bits flying your way at exactly the right times; it's too fast for interrupts, so you have to code a highly constrained loop. In another mode, it does the conversion in a burst, while the interface is quiet; then you clock out the multibit data while the converter is idle.

Figure 15.23 shows how it works, in the internal clock mode. You initiate conversion with a CONV′ pulse, after which it gives you the serial data (MSB first, as with all successive-approximation converters) along with a clock. Although the timing is quite relaxed in terms of the speed of standard digital logic hardware (gates and flip-flops), it requires substantial minimum processor speed to handle properly in *software*.

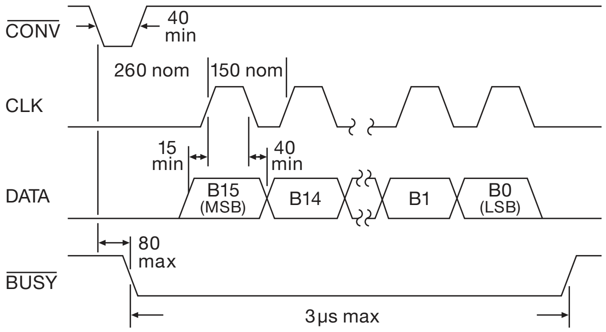

Figure 15.23. Serial data timing of the LTC1609 16-bit ADC when operating in "internal clock mode." Times are in nanoseconds.

Take a look at Pseudocode 15.6. The WAIT-FOR-DATA loop has to complete in 150 ns, which, as we'll see presently, requires at a minimum a processor with a ~30 MHz clock (with one instruction per clock, including a 16-bit shift instruction). Older PICs, etc., need not apply! Note that we command the channel switching and PGA (programmable gain amplifier) gain setting ("setup next channel") immediately after starting the current conversion, which may seem counterintuitive. But this is the right place to do that, because the PGA needs 2 μs to settle, and the ADC needs another 2 μs to acquire the PGA's output before the subsequent conversion is initiated. And we've got the time to send these setup commands, because there's a ~200 ns delay after CONV′ before the ADC starts gushing clocks and data.

After EXITing from this loop, you've got ~ 2 μs to do something with the data, and anything else that needs doing, before the converter is ready for its next conversion at its full speed of 200 ksps (of course, you're always free to run it slower).

Let's look more closely at the critical WAIT-FOR-DATA loop timing, taking it step by step. Our program takes one instruction to check if it's already gotten all the data bits,

Pseudocode 15.6 ADC serial loop pseudocode

```
Channel
        wait until timer
        set CONV′ LOW
        NOP
        set CONV′ HIGH
        setup next channel
Wait-for-data
        if BUSY′ HIGH, Exit
        if CLK LOW, repeat Wait-for-data
        get & shift data bit into 16-bit word
        repeat Wait-for-data
Exit
        store 16-bit word
```

another to see if a new bit is ready (ADC output clock HIGH), one to get it, and one to go back for more. Assuming a 30 MHz single-cycle CPU clock, this loop takes 133 ns. Let's follow what happens as the μC grabs the ADC data clocked every 150 ns. It grabs the first bit someplace in the ADC's 75 ns clock HIGH time, and about 17 ns earlier on each successive grab. After a few bits it's too early, landing in an ADC clock LOW; so it has to loop back, costing it 66 ns and pushing it close to the end of the 75 ns ADC clock HIGH. The μC takes another 33 ns to grab the data bit, approaching the end of the 40 ns ADC data-valid hold time.

As the μC grabs the successive 16 bits, it's all over the place – not a pretty sight. But we're blind and can't see; short of having enough time to add two more instructions and output a marker pulse, there's no way from the outside to see exactly when the processor does what it does. Instead, it's necessary to do a careful thought-process analysis, a common situation with real-time programming and time-sensitive tasks. In this case we'd realize what needs to happen, and we'd calculate the minimum processor clock speed from the worst-case timing situation. That would happen when the ADC output clock is tested just before a rising edge; the loopback and read takes 100 ns to complete, at which time the data bit has only 5 ns of guaranteed life remaining.

So a 30 MHz CPU clock appears marginally fast enough – but it's a close call. And we're in trouble if the ADC's period is shorter than the "typical" value of 150 ns, or if its duty cycle is less than 50%, making its HIGH time 60 ns, say, instead of the 75 ns we assumed. To get a better safety margin we would need a faster processor. Probably better, though, would be to add an outboard D-FF (e.g., an 'LVC1G74) clocked on the rising edge of CLK, to capture each bit and make it available to the μC throughout the full clock period of 150 ns. This would give us an extra 35 ns (plus the flip-flop's delay time of ~5 ns). If you don't need the processor speed for other reasons, adding a single flip-flop to relax the needed CPU clock frequency is a worthwhile tradeoff.

This example illustrates a common system design issue, namely the tradeoff between software (and processor cycles) and hardware. We could have used a pair of 'LVC595 or 'VHC595 shift registers (see §10.5.3) to clock in the 16 converted ADC bits, which the microcontroller then reads in byte-wise via a parallel port. This would reduce the software burden to fewer than ten instructions every 5 μs. But (apart from the coding task) program execution is free, whereas two chips take space and money; they also hog processor I/O pins. On the other hand, if you don't have much processor time available, or your processor is too slow, adding two chips makes good sense.

Standardized serial protocols

For standardized serial ports like UARTs, I^{2}C, Ethernet, or USB, the best approach is to use a microcontroller with dedicated internal hardware. A second choice would be an external "bridge" that converts between USB, say, and a standard serial UART (for example the chips made by FTDI). Hardy souls have been known to implement serial ports in assembly language, but it can be a real tour-de-force. A stunning example is Paul Starkjohann's implementation[54] of 1.5 Mbps USB (version 1.1) in assembly language on an Atmel AVR running with a 12 MHz clock, which required precisely eight instructions per serial bit, during which he had to extract the bit stream from NRZI-encoded data, complete with bit stuffing and end-of-packet characters. This was used by Thomas Baier to control a DDS RF generator, part of a complete vector network analyzer.

Quite apart from the challenge of getting the timing right, serial communication via USB involves plenty of software complexity, in the form of drivers and the like. You should not feel bad about using the plain ol' UART, perhaps with a bridge to USB (with drivers provided by the manufacturer).

15.9.3 Hardware

Contemporary microcontrollers use internal nonvolatile (flash-memory) storage for program code, which you load

[54] See `http://www.obdev.at/products/vusb/index.html` and `http://www.obdev.at/articles/implementing-usb-1.1-in-firmware.html`.

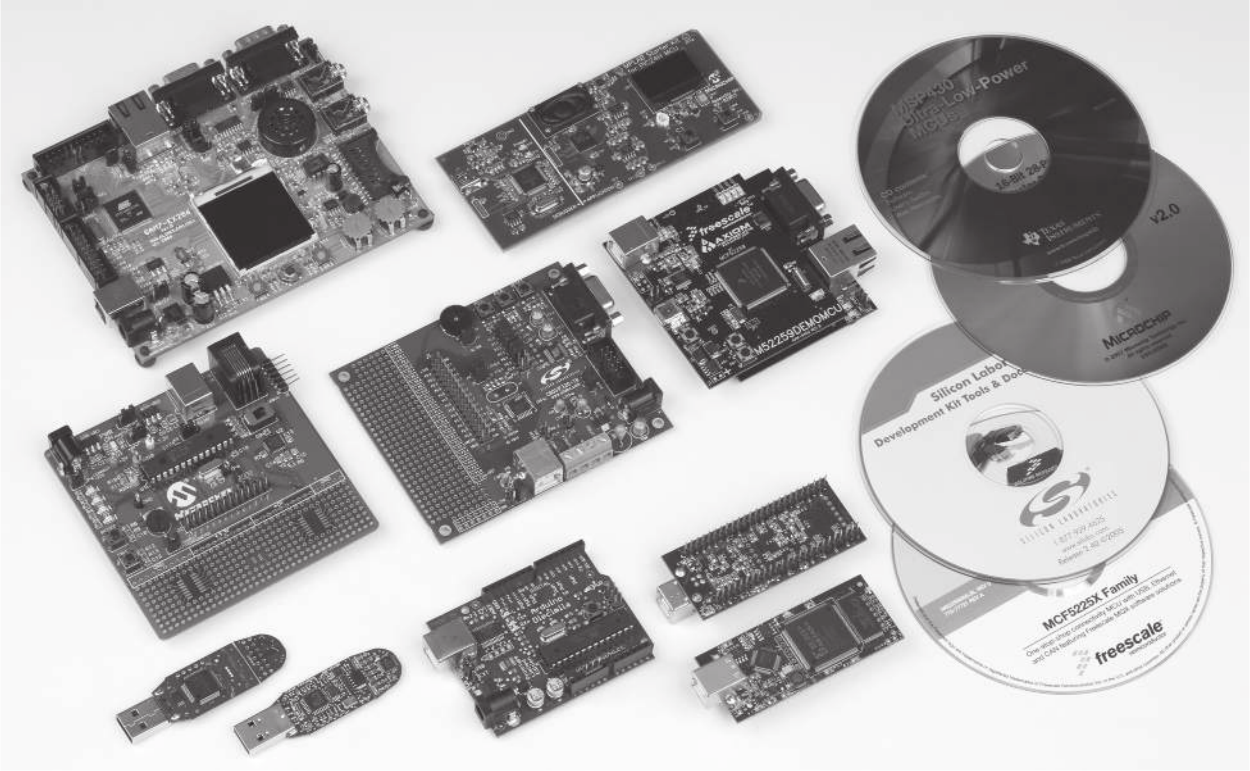

Figure 15.24. Development kits make it easy to get started with a microcontroller family; you get them from the chip manufacturers, or from third-party suppliers. They often include software, cables, and power adaptors. At the top are kits for an Atmel ARM and a Microchip PIC24H; across the middle are PIC24F, Silicon Laboratories C8051F320, and Freescale ColdFire (M52259); across the bottom are Texas Instruments MSP430 (two views), Atmel AVR (ATmega168), and an FPGA devkit (Xilinx Spartan-3E, two views). Suppliers other than the manufacturers are Olimex (ARM), Arduino (AVR), and DLP Design (Spartan).

(while the μC is in-circuit) by one of several methods. You usually do the loading[55] with a commercial "pod" (officially called a "device programmer"), which you buy from the chip manufacturer or third party. If you buy a development kit (Figure 15.24), it will often include a programming pod, along with software (for compiling, simulating, assembling, and loading), and with a circuit board on which there's a microcontroller and other hardware (digital and analog ports, LEDs, a serial port, a programming header, and perhaps some display device). Here are the several loading protocols:[56]

A. UART serial-port bootloader

Some microcontrollers include built-in serial port code (in ROM), so that they wake up listening for programming commands on the UART serial port (a "serial bootloader"). To activate this mode you have to assert one or more pins at reset to signal that you want to program via the UART, and thus put it into program mode. Examples include the Maxim–Dallas DS89C400 series, some Atmel AVRs, and some ARM7 controllers. The communication is via standard serial UART modes (usually 9600 8N1); however, because the microcontroller accepts (unipolarity) logic levels, not bipolarity RS-232, you have to use an interface chip (like a MAX232) between a PC's DE-9 serial-port connector and the target microcontroller.[57] You can, of course,

[55] Which, confusingly, is called "programming" the device. We reluctantly use that term here (interchangeably with "loading," in this hardware context), to mean *physically* programming the microcontroller's flash memory. Do not confuse it with the software programming task of writing the code.

[56] See §§14.5, §14.6.4, and 14.7.4 for more detail on UART, SPI, and JTAG serial data links.

[57] PC serial ports are fast disappearing; you can substitute a USB-to-RS232 adapter, or better, a USB-to-UART chip like the FT232R; the latter matches the logic-level needs of the μC, so no MAX232 style chip is needed.

write your own bootloader code and load it into normal user code memory, so that a microcontroller that permits overwriting the flash code memory can be reprogrammed through the UART. With this method, however, you won't be able to load an unprogrammed chip initially through the UART (the method used by the Arduino project).

B. SPI serial-port bootloader

Some microcontrollers (e.g., the smaller Atmel AVR series) implement a bootloader through the chip's SPI port.[58] Contemporary programming pods connect to the host PC via a USB connection, replacing earlier versions that used the parallel (printer) port, or the serial (RS232) "COM" ports. As with the serial-port bootloaders, you have to assert a pin during boot-up to activate the SPI bootloader. For the AVR controllers, for example, you assert RESET′.

C. JTAG serial-port bootloader

The JTAG serial boundary-scan protocol (§14.7.4), originally intended for test and debugging, is used as a flash-memory bootloader by some microcontrollers. Examples include the higher-pincount AVRs, ARM7, Silicon Labs C8051F series, and Maxim–Dallas MAXQ series. The JTAG port may be one of several choices, as it is with the high-pincount AVRs, which allow bootloading via either JTAG or SPI (as well as parallel programming).

D. Proprietary serial-port bootloader

Some microcontroller manufacturers use their own simple serial protocols, which do not conform to standards like SPI, I^2C, or JTAG. It hardly matters, though, because you generally just use the appropriate pod, as supported by the vendor's development environment. Some of the PIC (Microchip) controllers are programmed this way; and for some of them you must apply a high voltage (+12 V) on a pin called V_{PP} ("high-voltage" programming), while others let you use normal logic-level supply voltages ("low-voltage" programming).

E. USB serial-port bootloader

Microcontrollers that include USB support often implement a USB bootloader option. Examples are some Cypress controllers, and the Atmel ARM and AVR32UC3 series, which can load program memory upon boot from either the USB port, the JTAG port, or the UART.

F. Parallel loading

Finally, many microcontrollers provide a way to program the internal flash memory via a multiwire parallel connection. In some cases you must apply a higher voltage (e.g., +12 V) to one of the pins; this is sometimes called "high-voltage programming."

G. A "universal" pod?

The "Bus Pirate" project has what appears to be a great tool: for $30 you get a little USB-to-anything piece of hardware, with open-source support. You can open a terminal on your PC and pick from among 1-Wire, I^2C, SPI, JTAG, asynchronous serial (UART), MIDI, PC keyboard, HD44780 LCDs, generic 2- and 3-wire libraries for custom protocols, and scriptable binary bit-bang. You get software support for AVR, JTAG, and some flash-memory in-circuit serial programming. So it's useful for talking to many kinds of chips (not just microcontroller programming) – for example, when debugging the protocols for talking to some new "smart" chip that needs its operating modes set up (we spent plenty of time struggling with a smart alphanumeric LED display strip; this thing would have saved us hours). Bus Pirate version 4 is an upgrade that adds some features (e.g., OpenOCD JTAG mode); it currently costs $40 (`http://dangerousprototypes.com`).

H. Sawing off the branch...

You usually can choose which programming method to use when the μC supports several. However, in controllers where the bootloader can be overwritten, you can clobber the loader, and thus be forced to resort to parallel programming. There are other ways, also, to do what we call "sawing off the branch you're sitting on": we managed to do this with a small AVR chip, when we loaded a program that began by turning off most peripherals, *including the SPI*. That was a big mistake, because it disabled the only port available for serial bootloading. High-voltage parallel programming brought it back to the land of the living.

Another way to terminate your conversation with a microcontroller is to program it to use an external oscillator of the wrong type; that is, one that does not correspond to the actual hardware that is connected (bare crystal, ceramic resonator, or external oscillation signal from an outboard oscillator module). Some microcontrollers protect you from this trap: the Silicon Labs 8051-core processors and the ARM-core processors, for example, boot up in a known state, running from a slow internal oscillator; you have to specifically code any changes from this default. If you do it wrong, just fix the code, and reload from a cold boot.

[58] Which may be one of several bootloader ports on the same μC: the larger Atmel AVR parts, for example, allow bootloader programming via either SPI or JTAG. Additionally, some μCs let you install a custom bootloader in the μC's flash memory, which can bootload from the USB, UART, or Ethernet ports.

I. In-circuit debugging

Microcontrollers of recent design include on-chip hardware that lets you debug code during in-circuit execution, by setting breakpoints, examining registers and memory, single-stepping, and so on. (This used to be a big deal, requiring special processor chips outfitted with extra leads, and requiring also considerable outlay of cash.) In-circuit debugging generally uses the same ports as you use for program loading; so you just keep the programming pod attached and iterate a debug–reprogram cycle until it all works right.

Some processor families that currently include these features are the Atmel AVR, processors based on the ARM core, some PIC processors, and some 8051 derivatives (notably those from Silicon Labs).

15.9.4 The Arduino Project

We've mentioned the Arduino Project, approvingly, several times in this chapter. What, exactly, is it?

In the words of the website (www.arduino.cc), "Arduino is an open-source electronics prototyping platform based on flexible, easy-to-use hardware and software. It's intended for artists, designers, hobbyists, and anyone interested in creating interactive objects or environments. . . . The microcontroller on the board is programmed using the [C language with custom libraries] and the Arduino development environment. . . . Arduino projects can be standalone or they can communicate with software running on a computer."

In *our* words, the Arduino *hardware* is a well-designed set of inexpensive boards, based on Atmel microcontrollers (the ATmega AVR series, and the SAM3X ARM Cortex-M series), with all the right external components: USB port (with the FTDI chip to convert to the μC's serial pins), 5 V regulator, SPI port, PWM output, ADC and digital I/O pins, LEDs, and a few additional components. You can buy the standard board (currently called "Uno") assembled, for about $30 from hobbyist suppliers like Adafruit and SparkFun; you can also buy it as a kit or even etch your own (they provide CAD files in Eagle format, or an image file in $*$.png format).

And the *software* development environment is open-source and free: it's a full-blown C, using the GNU C compiler targeted at the AVR and ARM processors. The Arduino software is a simple, user-friendly GUI wrapper around this compiler; it runs on Windows, Mac OS, or Linux, and allows easy code editing and project management. The Arduino firmware (written in C) that runs on the device includes a bootloader that listens for communication over the USB serial link, and either downloads a new user program or times out after a second and runs the program already present in flash (code) memory.

There is a library of nice C functions that you can call from your own programs to do things like text I/O through the USB link, formatting numbers to be printed, setting up timers and interrupts, etc. For example, `val=analogRead(3)` puts the voltage read on analog pin 3 into the variable `val`.[59] Very little of this library code is tied to the Arduino hardware itself, and you can use it in your AVR-based projects. This works well because it's all open source and uses the open-source compiler.

Taken as a whole, the Arduino Project is simply all these components working together. An interesting metric of ease-of-use of any microcontroller hardware-plus-IDE might be the following: how long does it take, after you open the box, before it's doing something interesting? For the Arduino, the answer is "about 20 minutes": download the software, right-click to install the FTDI driver and mini-IDE; then open the Arduino program, type four lines, and off you go! And you don't have to know anything at all about hardware – the little board powers itself through the USB link – nor do you need any extra hardware (except for a standard USB cable).

There are Arduino look-alike products with special features. Many use the same microcontrollers, have the same shield (daughterboard) pinouts, and use the same or similar compilers. For example Linear Technology's "Linduino" board uses their LTM2884 USB isolation chip, providing an isolated USB 2.0 hub or USB peripheral (560 V peak or 2.5 kVrms for one second), complete with an isolated 5 Vdc (to 500 mA). The Linduino board also has LTC's standard DC590 interface board connector, and it's especially well suited for use with their high-resolution ADCs.

15.10 Wrapup

15.10.1 How expensive are the tools?

Both the microcontroller companies, and some third-party manufacturers, make it easy to get started. Many of them offer stripped-down development kits, typically in the range of $50–$200, consisting of (a) a programming pod, (b) a small board with the microcontroller and some trimmings (LEDs, serial port, USB port, analog I/O, and

[59] This ease-of-use comes with some loss of generality, for example in pin assignments.

programming header), and (c) software for compiling, assembling, loading, and debugging.[60]

The compiler that comes with such kits may be a free "evaluation" version of a more capable compiler that you can buy. For example, the inexpensive Silicon Labs kits come with a limited version of the commercial Keil compiler tools. It is full-featured, but limits you to 4 kB of compiled object code, and lacks the floating-point library. The unlimited Keil product lists for ∼\$2.5k, from which educational users receive large discounts. Similarly, the Raisonance software (see the 8051 description in §15.3) is available as a free download, again limited to 4 kB of object code, with the unlimited version priced comparably to the Keil product. Another purveyor of high-quality software tools is IAR Systems, with support for most of the popular microcontroller families: 8051, ARM, AVR, Coldfire, MAXQ, PIC, H8, and MSP430, among others. Other suppliers of compilers and debuggers for embedded systems include Green Hills Software, HI-TECH Software, Lauterback, and Rowley Associates.

In a pleasant development, the open-source community has ported the GNU C/C++ compiler to most operating systems, with the ability to target the AVR and ARM family microcontrollers. This free software, plus a programming pod, provides the least costly path to full-featured C-language microcontroller programming. Another encouraging trend is the growing acceptance by semiconductor manufacturers of the need for good software support. Traditionally the chip manufacturers have viewed software as a necessary evil, at best, which they would prefer to have someone else worry about; this seems, happily, to be changing. For example, Atmel integrated the GNU open-source tools into their Windows environment for compiling, simulating, and in-circuit debugging. And IBM's Eclipse open-source development environment has become popular, allowing both manufacturers and users to create plug-ins for specific families of processors. Two examples are Altera's NIOS soft-core μC Micrium, and the open-source ARM tools.

It's important to realize that the programming pods are not generally interchangeable across processor families. Pods aren't very expensive though, so this isn't a serious problem. In some cases the programming hardware allows more than one connection protocol. For example, the Atmel AVR Dragon, which connects to the host via USB and costs about \$50, lets you program in SPI, JTAG, parallel, and high-voltage serial modes; it also supports in-system debugging. The simpler AVR ISP pod supports SPI programming only. Programming pods are also sold by third-party and hobbyist suppliers such as Olimex Ltd and Sparkfun Electronics; you can find many more suppliers in the pages of enjoyable hobbyist publications such as *Circuit Cellar*, or *MAKE Magazine*.

15.10.2 When to use microcontrollers

Almost always!

Certainly for electronic systems that
(a) have character or graphic displays as part of their user interface;
(b) include chips requiring configuration of internal registers or operating modes;
(c) communicate with a host computer, stand-alone peripherals, network, or wireless devices;
(d) require some computation, storage, format conversion, signal processing, etc.;
(e) require calibration or linearization;
(f) involve sequencing events over time; or
(g) are subject to upgrades or feature revisions.
Microcontrollers should be considered even for traditional "analog" functions such as measurement and control, especially with the growing emphasis on analog-oriented internals in processors from companies such as Analog Devices and Cypress.

Programmable logic devices (PLDs, including FPGAs), by contrast, are generally preferred for tasks requiring critical timing or a high degree of parallelism. They are, however, considerably more difficult than microcontrollers to program and debug. Any system with PLDs will generally include a microcontroller as well; and the latter may take the form of a soft processor core (i.e., configured from the programmable resources in the FPGA) or a hard processor core (i.e., prewired within the "hybrid" FPGA). Examples of FPGA soft cores are the Actel ARM, Altera Nios-II, Lattice Mico, and Xilinx MicroBlaze; examples of prewired processors in hybrid FPGAs include and Altera's ARM, Atmel's FPSLIC with AVR, and Xilinx's PowerPC.

Another way to handle the dual demands of critical timing (e.g., in real-time video or wireless applications) along with the need for the versatility of an embedded microcontroller is to combine an application-specific standard product (ASSP; for example, an MPEG decoder, or cellphone RF subsystem) with a supervisory microcontroller.

[60] If you just want to dip your toe in, there are some demonstrator gadgets that let you program a few LEDs only; these usually plug into a USB port and cost around \$10. You can't do much with them, though, and it's better to go with the real devkits.

15.10.3 How to select a microcontroller

There's a real benefit to using a processor family that the people around you are using, and therefore have available the necessary software and hardware tools, and the experience. Then look at factors like these (depending on your application):
(a) Ports (analog, digital, and communication);
(b) internal functions (e.g., converters, PWM, bare LCD drivers, etc.);
(c) compute speed;
(d) flash, EEPROM, and SRAM memory size;
(e) package configurations;
(f) power dissipation, low-power clock modes, and suspend modes;
(g) software programming, simulation, and in-circuit debugging tools.
The compendium in §15.3 may provide a good starting point.

When choosing a particular part within a microcontroller family, the choices can be overwhelming. It's usually easiest to start with the "premium" part in the series; that is, the one with the fastest clock and most data (RAM) and code memory (flash ROM). It is often the case that most of the family consists of reduced versions of a few premium parts, perhaps with specialized peripherals.

Early microcontrollers were organized around an 8-bit word size, but now there are many 32-bit controllers. Some advantages of the latter (a flat address space, more powerful instructions) are partially offset by considerations like the complexity of startup,[61] somewhat higher prices, and widespread familiarity with the 8-bit processor families.

Even if you code everything in C, most of your troubles will be microcontroller specific: initializing on-board I/Os and peripherals at startup, setting the "fuse bits" (independent of the program code) that control voltage levels and clocking, or dealing with multiple memory pages and idiosyncratic memory locations for peripherals and their configuration. As a result, a simple microcontroller architecture having a flat memory space and standard header files will be much easier to use.

The quality and quantity of included libraries can be quite important; for example, the included libraries for TCP/IP, SPI, I^2C, etc., makes it easier to program a Rabbit microcontroller. This is also an important advantage for the Arduino Project, with the large community providing code that has grown around it. Similar comments can be made on the importance of choosing a microcontroller that has a stable compiler–debugger. Similarly, there are a number of advantages with selecting a microcontroller board that is set up to run Linux (such as the Gumstix Overo, or the BeagleBoard). They come with a very stable OS and low-level drivers, they have native preemptive multitasking, they have some nice debugging advantages (one can just use SSH or a serial terminal and get console access), and finally they have impressive hardware (including fairly high-performance graphics controllers).

15.10.4 A parting shot

In case we haven't made it completely evident, microcontrollers are, well, *fun*! Figure 15.25 shows a wacky example, namely Jason Gallicchio's Halloween hat from 2004: it resembles (not coincidentally) an electrified colander, complete with flashing LEDs and a stack of batteries on top. Its notable characteristic, though, is the ability to read the mind of its wearer. The photo shows what happens when the wearer's interlocutor replies to the question "What college do you go to?"

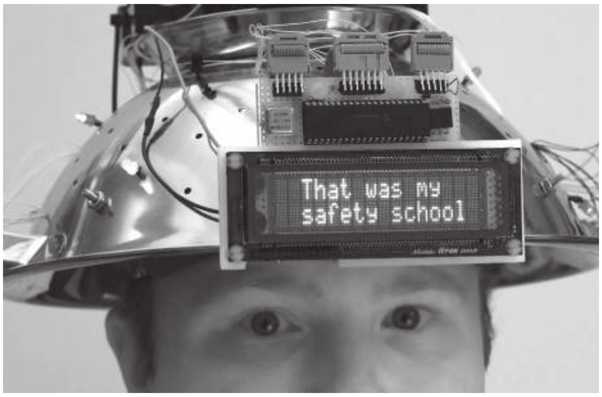

Figure 15.25. "This hat reads my mind."

[61] For example, an ARM peripheral needs a lot of code just to power it on, initialize it, connect it to the correct I/O pins, and so on.

Review of Chapter 15

The briefest of summaries, of Chapter 15's already brief treatment of microcontrollers.

¶A. Microcontrollers – the 10,000-foot View.

In 1960 the predictions of the future had folks flying around in jetpacks, traveling on supersonic passenger jets, and, most daring of all . . . *a push-button phone in every home!* Put another way, they extrapolated the technologies they knew (transportation, wired telephones), but they missed the Big One (microelectronics, and particularly embedded microcontrollers). We don't have the personal jetpacks, but we've got portable and instant interactive access to news, information, and people. Hey, we don't *need* no stinkin' jetpack!

Microcontrollers (μCs) are standalone processors with a full suite of peripherals integrated on a single inexpensive chip (Figure 15.1). You get substantial computational performance (32-bit processor, 100 MIPs, no problem), plus an assortment of ADCs, DACs, Ethernet, USB, PWM, LCD controller, SPI, multiple UARTs and timers, and of course on-chip program memory and SRAM, all in one chip for a price well below $10; see, for example, the now-vintage example in Figure 10.86, or take a look at NXP's implementations of the ARM Cortex-M4 MCU (microcontroller unit), for example the LPC4088 series. Microcontrollers are useless without their stored *firmware* programs, whose creation can be the major stumbling block to a successful design. So, along with the creation of silicon with stunning integration and performance, the industry has been developing and streamlining the integrated development environment (IDE) – the process of initial code development, simulation, loading onto the target device, and in-circuit debugging.

To the circuit designer, the microcontroller should be thought of as a circuit *component*, like an op-amp and sometimes even less expensive. Even in their simplest varieties they are particularly useful as interfaces between the user and the other circuitry (see for example Figure 15.5); and in their complex varieties they can carry out most of the instrument's functions (as in Figure 15.18). In this chapter we introduced the vast subject of microcontrollers with some illustrative examples, to give a sense of what's possible; we included with each its corresponding *pseudocode*, and for the first example (suntan monitor) we listed the detailed C-language code.

¶B. Popular Microcontroller Families.

In §15.3 we provided an annotated listing of contemporary favorites. The dominant species are the simpler AVR (Atmel) and PIC (Microchip) devices, and the go-to choice for higher performance is the hugely popular ARM-derived processors (licensed by ARM Holdings to more than a dozen semiconductor manufacturers). The latter are used in most of the world's smartphones. The attractive Arduino platform (§15.9.4) includes both AVR- and ARM-based single-board computers (SBCs).

¶C. External Peripherals.

Microcontrollers love to pull the strings of other chips, easily done with a few direct connections (Figure 15.20, §15.8.1), or with simple inter-chip serial buses like SPI (Figure 15.21, §15.8.2) and I^{2}C (Figure 15.22, §15.8.3). The figures and notes list and describe more than 50 useful peripheral devices.

¶D. Design Hints (Hardware).

The five design examples described in this chapter (suntan monitor, ac power control, frequency synthesizer, thermal controller, and stabilized mechanical platform) included plenty of circuit designs, with corresponding lessons. Here are some of them:

(a) Most μCs include on-chip ADCs, which are attractive when dealing with analog inputs; but don't ignore the simple on-chip comparator, which can sometimes promote both simplicity and better performance (Figure 15.3).

(b) A digital output port bit can happily drive external MOSFETs or BJTs directly (Figure 15.3) or with the assistance of an external gate-driver IC (Figure 15.10); it can also drive a solid-state relay (Figure 15.4).

(c) Don't overlook the simplicity of simple RS-232 serial communication; it's supported in all μCs, and it's alive and well in laptops and PCs running a terminal emulator and connected via a USB or Ethernet adapter (Figure 15.5).

(d) Pushbutton switches can be connected in a matrix arrangement, to minimize wiring (Figure 15.8); they are read with digital port bit polling.

(e) Microcontrollers intended for sensing and control let you connect directly to low-level sensors (Figure 15.11); their PWM output provides an easy way to implement proportional control.

(f) Most μCs include ADCs, making it easy to attach analog-output sensors (e.g., a gyro or accelerometer, Figure 15.18). You can find a zillion little gadgets of this sort at hobbyist sites like sparkfun.com or adafruit.com.

(g) And an easy way to get started is with the Arduino boards and software (§15.9.4); open the box, and you're up and running in 20 minutes.

¶E. Programming Hints (Firmware).

You need microcontroller-specific software tools (compiler, assembler, simulator, debugger) that run on a host

PC; and you need a hardware pod (§15.9.3) to load the object code onto the target μC and to run debugging tools. You also need to be aware of ways in which microcontroller programming differs from ordinary computer programming. Here are some hints:
(a) There are vendor-specific variations in C/C++ having to do with idiosyncrasies of on-chip peripherals (ports, timers, converters, etc.); you're not writing in vanilla C.
(b) The code for a μC must do a significant amount of initialization of modes and internal peripherals; this is fussy stuff, requiring dozens of perfectly configured bytes.
(c) You many need to program in assembly language for time-critical tasks; if so, watch out for too-smart compilers that try to optimize away your code.
(d) Products intended for manufacture should be reviewed and blessed by someone skilled in human interfaces (see §15.2.2E).
(e) Enable the watchdog! Well coded microcontrollers should not crash, but they do.
(f) Keep interrupt routines short; in a simple system you may not need interrupts at all.
(g) Internal timers can generate signals at output pins, very useful when you want to trigger external devices (e.g., an ADC) with constant time intervals (and similarly for on-chip peripherals).

¶F. When to use Microcontrollers.

Almost always! Certainly for electronic systems that (a) have character or graphic displays as part of their user interface; (b) include chips requiring configuration of internal registers or operating modes; (c) communicate with a host computer, standalone peripherals, network, or wireless devices; (d) require some computation, storage, format conversion, signal processing, etc.; (e) require calibration or linearization; (f) involve sequencing events over time; or (g) are subject to upgrades or feature revisions. Microcontrollers should be considered even for traditional "analog" functions such as measurement and control, especially with the growing emphasis on analog-oriented internals in processors from companies such as Analog Devices and Cypress.

Programmable Logic Devices (including FPGAs, Chapter 11), by contrast, are generally preferred for tasks requiring critical timing, or a high degree of parallelism. They are, however, considerably more difficult than microcontrollers to program and debug.

¶G. How to select a Microcontroller.

Look first at a processor family that the people around you are using, and therefore have available the necessary software and hardware tools, and the experience. Then look at factors like these (depending on your application): (a) ports – analog, digital, and communication; (b) internal functions (e.g., converters, PWM, bare LCD drivers, etc.); (c) compute speed; (d) flash, EEPROM, and SRAM memory size; (e) package configurations; (f) power dissipation, low-power clock modes, and suspend modes; (g) software programming, simulation, and in-circuit debugging tools. The compendium in §15.3 may provide a good starting point.

The quality and quantity of included libraries can be quite important (e.g., the Arduino Project, with the large community providing code that has grown around it). Likewise, it's desirable to choose a microcontroller that has a stable compiler–debugger.

When choosing a particular part within a microcontroller family, the choices can be overwhelming. It's usually easiest to start with the "premium" part in the series, that is, the one with the fastest clock and most data (RAM) and code memory (flash ROM). It is often the case that most of the family consists of reduced versions of a few premium parts, perhaps with specialized peripherals.

MATH REVIEW

APPENDIX A

Some knowledge of algebra and trigonometry is essential for a full understanding of this book. In addition, a limited ability to deal with complex numbers and derivatives (a part of calculus) is helpful, although not entirely essential. This appendix is meant as the briefest of summaries of complex numbers and differentiation, preceded by a collection of useful formulas from trigonometry, exponentials, and logarithms. It is not meant as a textbook substitute. For a highly readable self-help book on calculus, we recommend *Quick Calculus*, by D. Kleppner and N. Ramsey, Wiley, 2nd ed., 1985.

A.1 Trigonometry, exponentials, and logarithms

Here is a collection of useful formulas:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

is the solution of the quadratic equation

$$ax^2 + bx + c = 0.$$

$$\sin(x \pm y) = \sin x \cos y \pm \cos x \sin y,$$

$$\cos(x \pm y) = \cos x \cos y \mp \sin x \sin y,$$

$$\sin 2x = 2 \sin x \cos x,$$

$$\cos x \cos y = \frac{1}{2}\left[\cos(x+y) + \cos(x-y)\right],$$

$$\cos x \sin y = \frac{1}{2}\left[\sin(x+y) - \sin(x-y)\right],$$

$$\sin x \sin y = \frac{1}{2}\left[\cos(x-y) - \cos(x+y)\right]$$

$$e^{x+y} = e^x e^y,$$

$$e^{x-y} = e^x / e^y,$$

$$x^{a/b} = \sqrt[b]{x^a},$$

$$e^{\log_e x} = x,$$

$$\log_e(xy) = \log_e x + \log_e y,$$

$$\log_e(x/y) = \log_e x - \log_e y,$$

$$\log_e x^n = n \log_e x,$$

$$\log_e e^x = x,$$

$$\log_e x = \log_e 10 \log_{10} x \approx 2.3 \log_{10} x,$$

$$a^x = e^{x \log_e a}.$$

A.2 Complex numbers

A complex number is an object of the form

$$\mathbf{N} = a + ib,$$

where a and b are real numbers and i is the square root of -1; a is called the real part, and b is called the imaginary part.[1] Boldface letters or squiggly underlines are sometimes used to denote complex numbers. At other times you're just supposed to *know*!

Complex numbers can be added, subtracted, multiplied, etc., just as real numbers:

$$(a+ib) + (c+id) = (a+c) + i(b+d),$$

$$(a+ib) - (c+id) = (a-c) + i(b-d),$$

$$(a+ib)(c+id) = (ac-bd) + i(bc+ad),$$

$$\frac{a+ib}{c+id} = \frac{(a+ib)(c-id)}{(c+id)(c-id)} = \frac{ac+bd}{c^2+d^2} + \frac{bc-ad}{c^2+d^2}\, i.$$

[1] Electrical engineers depart from the universal convention of $i \equiv \sqrt{-1}$, using instead the symbol j in order to avoid duplicating the use of the symbol i (which designates small-signal current). We follow the EEs in this book, but not in this Math appendix. Were we to do so, we would likely be disowned by our math colleagues.

All these operations are natural, in the sense that you just treat i as something that multiplies the imaginary part, and go ahead with ordinary arithmetic. Note that $i^2 = -1$ (used in the multiplication example) and that division is simplified by multiplying top and bottom by the *complex conjugate*, the number you get by changing the sign of the imaginary part. The complex conjugate is sometimes indicated with an asterisk. If

$$\mathbf{N} = a + ib,$$

then

$$\mathbf{N}^* = a - ib.$$

The magnitude (or *modulus*) of a complex number is a real number with no imaginary part:

$$|\mathbf{N}| = |a+ib| = \sqrt{(a+ib)(a-ib)} = \sqrt{a^2+b^2},$$

i.e.,

$$|\mathbf{N}| = \sqrt{\mathbf{N}\mathbf{N}^*},$$

simply obtained by multiplying by the complex conjugate and taking the square root. The magnitude of the product (or quotient) of two complex numbers is simply the product (or quotient) of their magnitudes.

The real (or imaginary) part of a complex number is sometimes written as

$$\text{real part of } \mathbf{N} = \mathscr{R}e(\mathbf{N}),$$
$$\text{imaginary part of } \mathbf{N} = \mathscr{I}m(\mathbf{N}).$$

You get them by writing out the number in the form $a+ib$, then taking either a or b. This may involve some multiplication or division, since the complex number may be a real mess.

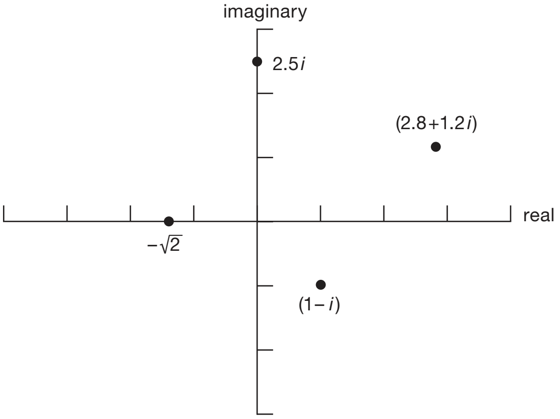

Figure A.1. Complex numbers in the "complex plane."

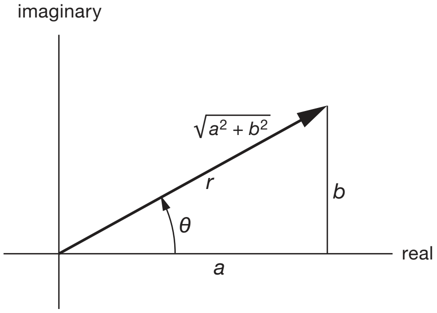

Figure A.2. Complex numbers, as magnitude and angle.

Complex numbers are sometimes represented on the complex plane. It looks just like an ordinary x, y graph, except that a complex number is represented by plotting its real part as x and its imaginary part as y, as shown in Figure A.1. In keeping with this analogy, you sometimes see complex numbers written just like x, y coordinates:

$$a + ib \leftrightarrow (a, b).$$

Just as with ordinary x, y pairs, complex numbers can be represented in polar coordinates; that's known as "magnitude, angle" representation. For example, the number $a+ib$ can also be written as (Figure A.2)

$$a + ib = r\angle\theta,$$

where[2] $r = \sqrt{a^2+b^2}$ and $\theta = \tan^{-1}(b/a)$. This is usually written in a different way, using the astonishing fact that

$$e^{i\theta} = \cos\theta + i\sin\theta.$$

(You can derive the preceding result, known as Euler's[3] formula, by expanding the exponential in a Taylor series.) Thus we have the following equivalents:

$$\begin{aligned} \mathbf{N} &= a + ib = re^{i\theta}, \\ r &= |\mathbf{N}| = \sqrt{\mathbf{N}\mathbf{N}^*} = \sqrt{a^2+b^2}, \\ \theta &= \tan^{-1}(b/a), \end{aligned}$$

i.e., the modulus r and angle θ are simply the polar coordinates of the point that represents the number in the complex plane. Polar form is handy when complex numbers have to be multiplied; you just multiply their magnitudes and add their angles (or, to divide, you divide their magnitudes and subtract their angles):

$$(r_1 e^{i\theta_1})(r_2 e^{i\theta_2}) = r_1 r_2 e^{i(\theta_1+\theta_2)}.$$

[2] Caution: the formula for θ returns values only between $-\pi/2$ and $+\pi/2$; the signs of both a and b, and not merely their quotient, are required for a correct value of θ in all four quadrants.

[3] Leonhard Euler, pronounced like "oiler."

Finally, to convert from polar to rectangular form, just use Euler's formula:

$$re^{i\theta} = r\cos\theta + ir\sin\theta,$$

i.e.,

$$\mathscr{R}e(re^{i\theta}) = r\cos\theta,$$
$$\mathscr{I}m(re^{i\theta}) = r\sin\theta.$$

(These can be used to easily derive the sum and difference of trigonometric functions, so you never have to remember those pesky formulas. Just work out $e^{i(x\pm y)}$.)

If you have a complex number multiplying a complex exponential, just do the necessary multiplications. If

$$\begin{aligned}\mathbf{N} &= a+ib,\\ \mathbf{N}e^{i\theta} &= (a+ib)(\cos\theta + i\sin\theta),\\ &= (a\cos\theta - b\sin\theta),\\ &\quad +i(b\cos\theta + a\sin\theta).\end{aligned}$$

When dealing with circuits and signals, the angular argument θ often takes the form of an evolving wave: $\theta = \omega t = 2\pi ft$; thus, for example, $V(t) = \mathscr{R}e(V_0e^{i\omega t}) = V_0\cos\omega t$, etc.

A.3 Differentiation (Calculus)

We start with the concept of a *function* $f(x)$, i.e., a formula that gives a value $y = f(x)$ for each x. The function $f(x)$ should be *single valued* i.e., it should give a single value of y for each x. You can think of $y = f(x)$ as a graph, as in Figure A.3. The derivative of y with respect to x, written dy/dx ("dee y dee x"), is the *slope* of the graph of y versus x. If you draw a tangent to the curve at some point, its slope is *dy/dx at that point*; i.e., the derivative is itself a function, since it has a value at each point. In Figure A.3 the slope at the point $(1,1)$ happens to be 2, whereas the slope at the origin is zero (we'll see shortly how to compute the derivative).

In mathematical terms, the derivative is the limiting value of the ratio of the change in y (Δy) to the change in x (Δx), as Δx goes to zero. To quote a song once sung in the hallowed halls of Harvard (by Tom Lehrer and Lewis Branscomb),

> You take a function of x, and you call it y
> Take any x-nought that you care to try
> Make a little change and call it delta x
> The corresponding change in y is what you find nex'
> And then you take the quotient, and now, carefully
> Send delta x to zero, and I think you'll see
> That what the limit gives us (if our work all checks)
> Is what you call dy/dx...
> It's just dy/dx.
>
> (*The Derivative Song*, sung to the tune of *There'll Be Some Changes Made*, W. Benton Overstreet).

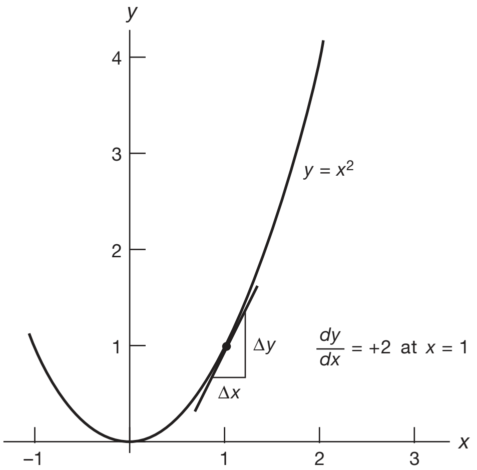

Figure A.3. A single-valued function: $f(x) = x^2$.

Differentiation is a straightforward art, and the derivatives of many common functions are tabulated in standard tables and automatically calculated in programs like Mathematica®. Here are some rules (u and v are arbitrary functions of x, and a represents a constant).

A.3.1 Derivatives of some common functions

$$\frac{d}{dx}a = 0$$

$$\frac{d}{dx}ax = a$$

$$\frac{d}{dx}ax^n = anx^{n-1},$$

$$\frac{d}{dx}\sin ax = a\cos ax,$$

$$\frac{d}{dx}\cos ax = -a\sin ax,$$

$$\frac{d}{dx}e^{ax} = ae^{ax},$$

$$\frac{d}{dx}\log_e x = 1/x.$$

A.3.2 Some rules for combining derivatives

Here $u(x)$ and $v(x)$ represent generic functions of x:

$$\frac{d}{dx}au(x) = a\frac{d}{dx}u(x),$$

$$\frac{d}{dx}(u+v) = \frac{du}{dx}+\frac{dv}{dx},$$

$$\frac{d}{dx}uv = u\frac{d}{dx}v+v\frac{d}{dx}u,$$

$$\frac{d}{dx}\left(\frac{u}{v}\right) = \frac{v\dfrac{du}{dx}-u\dfrac{dv}{dx}}{v^2},$$

$$\frac{d}{dx}\log_e u = \frac{1}{u}\frac{du}{dx}$$

$$\frac{d}{dx}\{u[v(x)]\} = \frac{du}{dv}\frac{dv}{dx}.$$

The last one is very useful and is called the chain rule.

A.3.3 Some examples of differentiation

$$\frac{d}{dx}x^2 = 2x,$$

$$\frac{d}{dx}(1/x^{\frac{1}{2}}) = -\frac{1}{2}x^{-\frac{3}{2}},$$

$$\frac{d}{dx}xe^x = xe^x+e^x \qquad \text{(product rule)},$$

$$\frac{d}{dx}e^{-x^2} = -2xe^{-x^2} \qquad \text{(chain rule)},$$

$$\frac{d}{dx}a^x = \frac{d}{dx}(e^{x\log_e a}) = a^x\log_e a \quad \text{(chain rule)}.$$

Once you have differentiated a function, you often want to evaluate the value of the derivative at some point. Other times you may want to find a minimum or maximum of the function; that's the same thing as having a zero derivative, so you can just set the derivative equal to zero and solve for x. For example, you can easily determine that the slope of the function plotted in Figure A.3 equals 2 at x=1, and that its minimum occurs at x=0 (where its slope is zero).

HOW TO DRAW SCHEMATIC DIAGRAMS

APPENDIX **B**

A well-drawn schematic makes it easy to understand how a circuit works, and it aids greatly in troubleshooting. A poor schematic only creates confusion. By keeping a few rules and suggestions in mind, you can draw a good schematic in no more time than it takes to draw a poor one. In this appendix we dispense advice of three varieties: general principles, rules, and hints. We have also drawn some real knee-slappers to illustrate habits to avoid.

B.1 General principles

- Schematics should be unambiguous. Therefore pin numbers, parts values, reference designators, polarities, etc., should be clearly labeled to avoid confusion.
- A good schematic makes circuit functions clear. Therefore keep functional areas distinct; don't be afraid to leave blank areas on the page, and don't try to fill the page. There are conventional ways to draw functional subunits; for instance, don't draw a differential amplifier as in Figure B.1, because the function won't be easily recognized. Likewise, flip-flops are usually drawn with clock and inputs on the left, set and clear on top and bottom, and outputs on the right.

B.2 Rules

- Wires connecting are indicated by heavy black dots; wires crossing, but not connecting, have no dot (don't use a little half-circular "jog"; it went out in the 1950s).
- Four wires must not connect at a point; i.e., wires must not cross *and* connect. You sometimes see this rule violated, but it's poor practice (because a missing or undersized dot is a different circuit).
- Always use the same symbol for the same device; e.g., don't draw flip-flops in two different ways (exception: assertion-level logic symbols show each gate in two possible ways).
- Wires and components are aligned horizontally or vertically, unless there's a good reason to do otherwise.

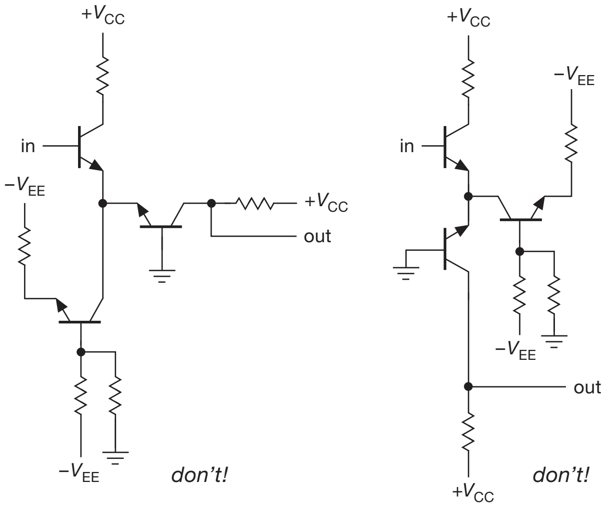

Figure B.1. Arrange components so that the function (here a differential amplifier) is clear. Don't corrupt the presentation to save space.

- Label pin numbers on the outside of a symbol, signal names on the inside.
- All parts should have values or types indicated; it's best to give all parts a label ("refdes"), too, e.g., R_7 or U_3.

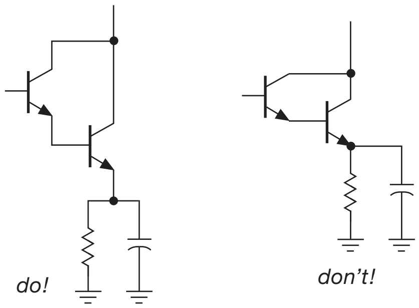

Figure B.2. Bring leads away from component symbols before connecting or jogging.

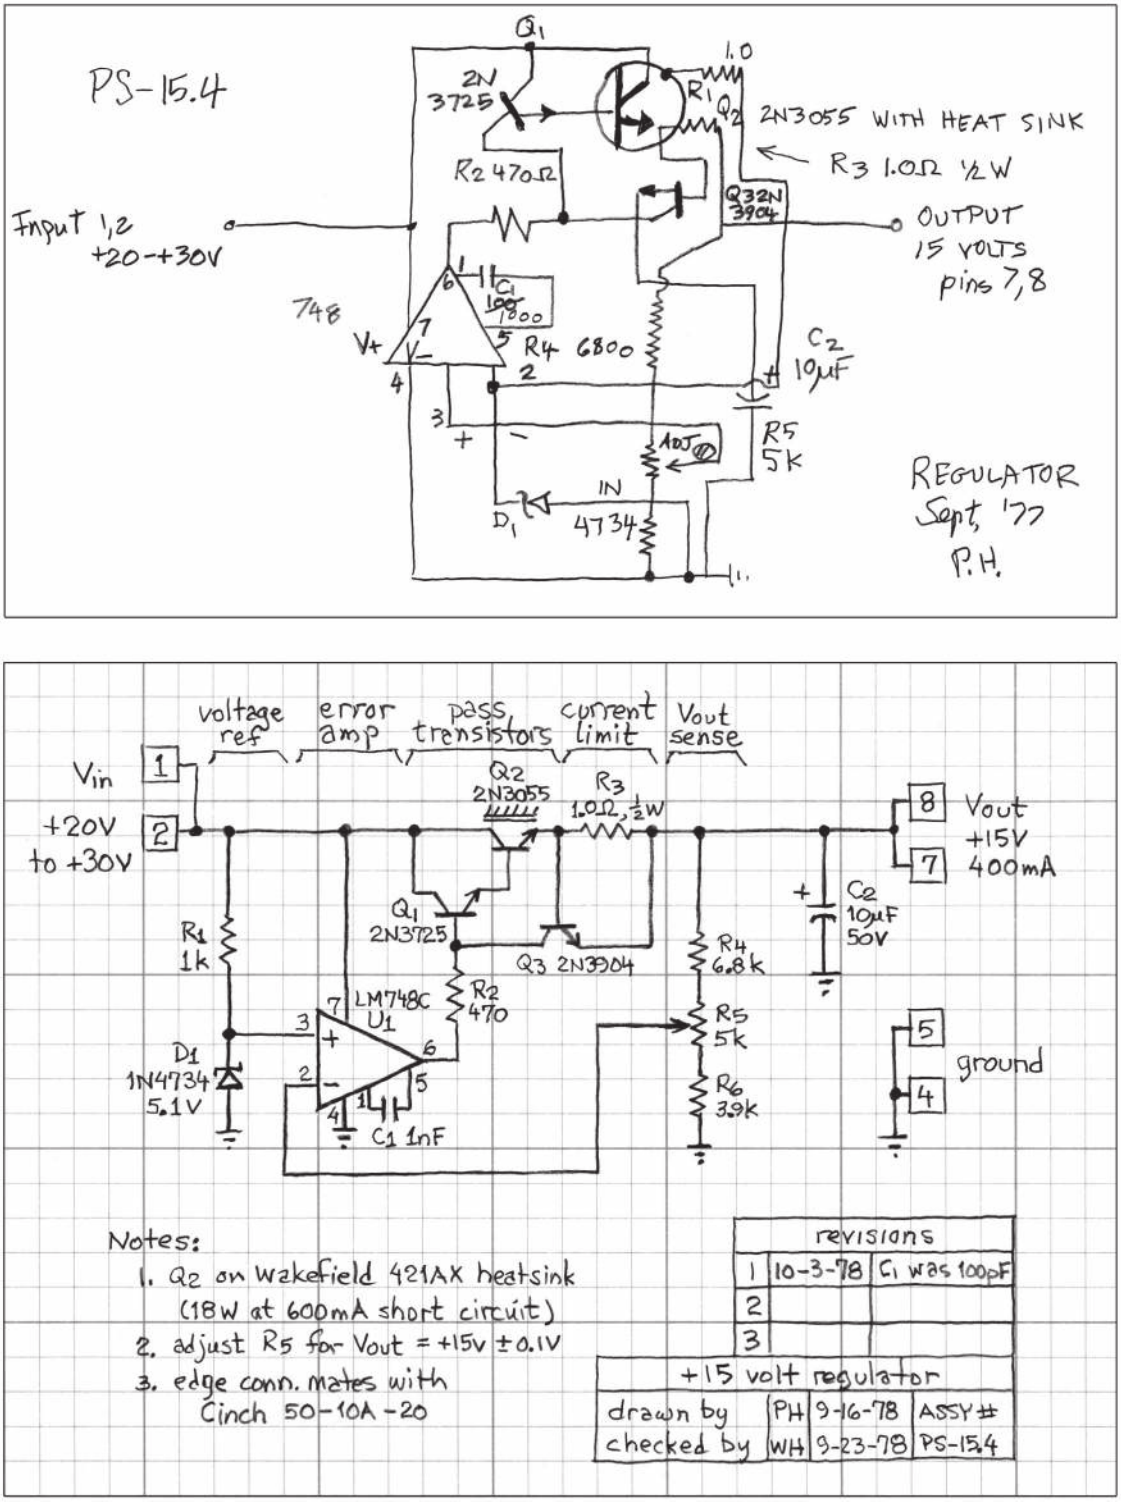

Figure B.3. Good drawing (perhaps too good) on "engineering paper," and *very* bad. Guess which is which.

B.3 Hints

- Identify parts immediately adjacent to the symbol, forming a distinct group giving symbol, label, and type or value.
- In general, signals go from left to right; don't be dogmatic about this, though, if clarity is sacrificed.
- Put positive supply voltages at the top of the page, negative at the bottom. Thus *npn* transistors will usually have their emitter at the bottom, whereas *pnp*s will have their emitter topmost.
- Don't attempt to bring all wires around to the supply rails, or to a common ground wire. Instead, use the ground symbol(s) and labels like $+V_{\text{CC}}$ to indicate those voltages where needed.
- It is helpful to label signals and functional blocks and show waveforms; in logic diagrams it is especially important to label signal lines, e.g., RESET′ or CLK.
- It is helpful to bring leads[1] away from components a short distance before making connections or jogs. For example, draw transistors as in Figure B.2.
- Leave some space around circuit symbols; e.g., don't draw components or wires too close to an op-amp symbol. This keeps the drawing uncluttered and leaves room for labels, pin numbers, etc.
- Label all boxes that aren't obvious: comparator versus op-amp, shift register versus counter, etc. Don't be afraid to invent a new symbol.
- Use small rectangles, ovals, or circles to indicate card-edge connections, connector pins, etc. Be consistent.
- The signal path through switches should be clear. Don't force the reader to follow wires all over the page to find out how a signal is switched.
- Power-supply connections are normally assumed for op-amps and logic devices. However, show any unusual connections (e.g., an op-amp run from a single supply, where $V_- =$ ground), and the disposition of unused inputs.
- It is very helpful to include a small table of integrated circuit (IC) numbers, types, and power-supply connections (pin numbers for V_{CC} and ground, for instance).
- Include a title area near the bottom of the page, with name of circuit, name of instrument, by whom drawn, by whom designed or checked, date, and assembly number. Also include a revision area, with columns for revision number, date, and subject.
- We recommend drawing schematics freehand on coarse graph paper (pale gridlines, five per inch, for example National® Brand "Engineer's Computation Pad" in "Eye-Ease"® green), or on plain paper on top of graph paper. This is fast, and it gives very pleasing results. Use dark pencil (we like HB hardness, 0.5 mm diameter) or ink; avoid ballpoint or felt-tip pen.

B.4 A humble example

As an illustration, we've drawn a humble example (Figure B.3) showing "awful" and "good" schematics of the same circuit; the former violates nearly every rule and is almost impossible to understand. See how many bad habits you can find illustrated. We've seen all of them in professionally drawn schematics! (We drew the "bad" schematic in an airport while waiting for a flight. It was an occasion of great hilarity; we laughed ourselves silly.)

[1] *Leads?* Yeah, sure. . . I'll just check with the boys down at the crime lab. They got four more detectives working on the case. They got us working in *shifts*. Hahahaha. . . *LEADS!*

RESISTOR TYPES

APPENDIX **C**

C.1 Some history

For a half century people used “leaded” (pronounced lēd′-ed) resistors: if you look inside a very old radio (before ∼1950), you’ll see colored cylindrical objects with some colored dots painted on them and with a wire wrapped around each end that comes off perpendicularly to the axis (“radial leads”). These carbon-composition resistors evolved into the standard carbon-comp “axial-lead” resistors (still cylindrical, but with colored stripes all the way around, and with the wires now sticking straight out each end) that were dominant through the last half of the 20th century (and that we recommended for noncritical applications in our previous book editions). Axial-lead resistors are still popular for some uses, such as easy breadboarding in the lab. They’re also used in applications that require very high resistance ($\geq$100 MΩ), or high voltage or power ratings, or for resistors of very high precision.

However, contemporary electronics has embraced surface-mount packaging, because of its high density (SMT devices are *small*, and you don’t have to take up space with holes for the leads). Surface-mount resistors, in common with other two-terminal SMT components (capacitors, inductors), are available in a range of package sizes, characterized by a 4-digit code giving their length and width in units of 0.010″; for example, an “0603” package is 0.06″×0.03″ (1.5 mm × 0.75 mm). We favor that size, or the larger 0805 package, for general prototyping of surface-mount circuits. The smaller packages (0402, 0201, and even “01005”) are a major pain – you basically have to work under a microscope (and don’t sneeze).

C.2 Available resistance values

You can’t get just any old resistance value. Available resistances fall into what’s called an EIA Standard Decade, named by the number of values per decade (thus E24 – used for 5% tolerance resistors – has 24 values, spaced approximately 10% apart; see below). Resistors with 1% tolerance are quite inexpensive these days, costing hardly more than an analogous 5% resistor,[1] so you might as well use 1% resistors by default. They come in the E96 set of standard values (96 values per decade, spaced approximately 2% apart; thus 481 values from 10 Ω through 1 MΩ, see below). Resistors of greater precision (e.g., 0.1%) are sometimes available in the **E192** superset,[2] and in convenient round-number values (e.g., 250, 300, 400, or 500) that are not included in the EIA sequences.

Here is the **E24** set of “5%” values (the **E12** subset, used for 10% components, is shown in **bold**):

10	16	**27**	43	**68**
11	**18**	30	**47**	75
12	20	**33**	51	**82**
13	**22**	36	**56**	91
15	24	**39**	62	**100**

And here is the **E96** set of “1%” values (the **E48** set, used for 2% components, or for a reduced set of 1% parts, is in **bold**):

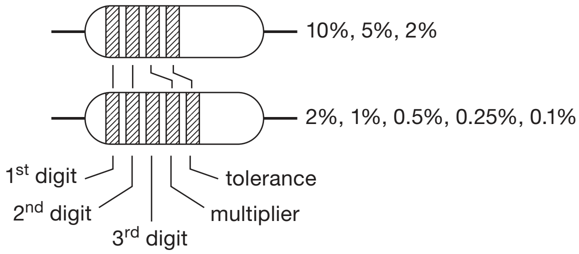
100	137	**187**	255	**348**	475	**649**	887
102	**140**	191	**261**	357	**487**	665	**909**
105	143	**196**	267	**365**	499	**681**	931
107	**147**	200	**274**	374	**511**	698	**953**
110	150	**205**	280	**383**	523	**715**	976
113	**154**	210	**287**	392	**536**	732	
115	158	**215**	294	**402**	549	**750**	
118	**162**	221	**301**	412	**562**	768	
121	165	**226**	309	**422**	576	**787**	
124	**169**	232	**316**	432	**590**	806	
127	174	**237**	324	**442**	604	**825**	
130	**178**	243	**332**	453	**619**	845	
133	182	**249**	340	**464**	634	**866**	

[1] For example, the Digi-Key catalog shows a full selection of Vishay/Dale CRCW-series surface-mount resistors, in sizes from 1210 down to 0201. For the convenient 0603 size, the current prices for 1% and 5% resistors are $0.025 and $0.023 apiece, respectively, in quantity 200. (You’ll pay about triple that, in quantity 10, and about a fifth as much, in a full reel of 5000 resistors.)

[2] The full E192 set, along with subsets, is nicely displayed at `http://www.logwell.com/tech/components/resistor_values.html`.

C.3 Resistance marking

Leaded resistors are marked in one of two ways: (a) with a set of four or five color bands, indicating resistance and tolerance; or (b) with a 4-digit resistance code, followed by a letter that indicates the tolerance. Surface-mount resistors use either (a) a 3- or 4-digit resistance code, or, for the smallest package sizes, (b) no marking at all!



color	digit	multiplier	tolerance	(tol. suffix)
black	0	1	–	
brown	1	10	1%	F
red	2	100	2%	G
orange	3	1k	–	
yellow	4	10k	–	
green	5	100k	0.5%	D
blue	6	1M	0.25%	C
violet	7	10M	0.1%	B
gray	8	–	0.05%	A, W
white	9	–	–	
gold	–	0.1	5%	J
silver	–	0.01	10%	K
(none)	–	–	20%	M
			0.02%	N, Q, P
			0.01%	T, L
			0.005%	V
			0.0025%	X
			0.002%	U
			0.001%	S

Figure C.1. The resistor color code, used on some axial-lead resistors (notably carbon-film and carbon-composition types). The resistance is read as a 2- or 3-digit integer (depending on resistor precision) followed by a band indicating the power-of-10 multiplier. For example, yellow-violet-orange-gold is 47 kΩ±5%, and yellow-white-white-black-brown is 499 Ω±1%. The alphabetic tolerance suffix is used on resistors with numerical printed resistance values.

Although it may seem diabolical to the beginner, the practice of color banding makes it easy to recognize resistor values in a circuit or parts bin, without having to search for a printed legend. Each color corresponds to a digit, in a sort of floating-point format (with the final digit indicating the power of ten); a last color band signifies the tolerance. See Figure C.1. Resistors with numerical markings use the same system, but with the digits themselves printed along the body of the resistor (for leaded resistors), or on the top side of a surface-mount package; a final letter signifies the tolerance, as shown in the figure.

C.4 Resistor types

The usual choices for general-purpose use are metal-film (axial-lead) or thick-film (surface-mount) parts. Thin-film surface-mount resistors offer improved characteristics (accuracy, stability, and ability to operate in cryogenic environments). For power applications you usually use wirewound resistors, either in an air-cooled ceramic package or a conduction-cooled ("Dale-type") metal package. High-value resistors ($>10\,\mathrm{M}\Omega$, say) are usually of metal-oxide construction (e.g., Ohmite "Mini-Mox" or "Super Mox," or Vishay RNX-series). Film resistors are not tolerant of high peak power; for such applications use something like ceramic or carbon composition, or other styles specified for peak-power use. For the utmost in stability and low temperature coefficient (tempco), you can't beat the excellent metal-foil types from Vishay. They exploit a clever design, in which the positive tempco of the resistive metal element (firmly attached to an insulating substrate) is cancelled by the negative strain-induced tempco caused by differential expansion of the substrate.[3] We've listed some comparative resistor properties in Table C.1; for much more detail see §*1x.2*.

General-purpose resistors are ridiculously inexpensive – thick-film surface-mount resistors cost a few cents apiece in small quantities, and just fractions of a cent apiece in full reel quantities (5000 pieces, for 0603 size). Distributors may be unwilling to sell fewer than 25 to 50 pieces of one value; thus an assortment box (e.g., from Yageo or Vishay/BC) may be a wise purchase. We particularly like the nice packaging and good pricing of the kits from SMT Zone (www.smtzone.com).

C.5 Confusion derby

Component markings should be clear and unambiguous. Sometimes it just ain't so! See Figure 1.130 for some real head-scratchers, both resistive and otherwise.

[3] Check it out: Felix Zandman's 1982 US patent #4,318,072, "Precision resistor with improved temperature characteristics."

Table C.1 Selected Resistor Types

	Resistor Type					
	carbon comp	**thick film**	**thin film**	**metal film**	**metal foil**	
	axial	SMT-0603	SMT-0603	axial	SMT	
Parameter	(RC-07)	(Vishay CRCW)	(KOA Speer RN73)	(RN-55D)	(Vishay VSMP)	**Units**
Tolerances	5%, 10%	1%, 5%	0.05%-1%	0.1%-1%	0.01%-1%	$\Delta R/R$
Temp coef	~1000	100, 200	5, 10, 25, 50, 100	50, 100	0.05 (typ)	ppm/C

Properties of selected resistor types. The legendary axial-lead “carbon-composition” resistors have been superseded by inexpensive metal-film (or carbon-film) types, with greatly improved properties (except for peak-power endurance, see Chapter *1x*). We like Vishay’s CMF-55 metal-film resistors (industrial version of MIL RN-55D). For most surface-mount applications the “thick-film” (a metal-ceramic composite) types are fine, though thin-film and metal-film resistors have somewhat better properties. The extraordinary Vishay “Z-foil” ultraprecision hermetically sealed resistor is listed to show the best that is currently available (but if you have to ask the price, you probably can’t afford it). It’s useful to note that a parameter like a voltage coefficient of 5 ppm/V corresponds to a change of 0.1% over a full 200 V operating range.

THÉVENIN'S THEOREM

APPENDIX D

In Chapter 1 we stated (but did not "prove") Thévenin's Theorem, namely that any two-terminal network whose internal circuitry consists solely of resistors, batteries, and current sources, interconnected in any manner whatsoever, is equivalent (and indistinguishable) from the two-terminal network consisting of a single battery V_{TH} in series with a single resistor R_{TH};[1] see Figure D.1. We did not prove it, because, in the spirit of this book, we don't *prove* anything; we show you how to design circuits, instead. We make an exception here, because it's nice to see *something* proved, right?

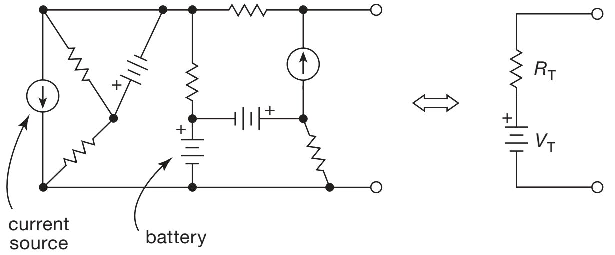

Figure D.1. Thévenin's Theorem: a single resistor in series with a single battery can mimic any mess of a two-terminal network made from resistors, batteries, and current sources.

D.1 The proof

For linear circuit elements (here resistors), the "nodal equations" (Kirchhoff's voltage law, KVL, and Kirchhoff's current law, KCL) are a set of linear equations. So we can find any circuit quantity (a voltage or a current), which depends on all the "independent sources" (batteries, current sources), by turning on each source in turn, and adding the partial contributions. (This is exactly analogous to using superposition to find, say, the electric field from a set of charges.) This technique is often useful in circuit analysis.

Here we wish to mimic the V versus I of the actual circuit with the (simpler) Thévenin equivalent of a single battery in series with a single resistor. Imagine we determine that V versus I function by applying an external current I_{ext} that flows through the two-terminal circuit, and observing the resultant V across those same two terminals. V depends on I_{ext} *and* on all the internal batteries (V_{int}) and current sources (I_{int}).

1. Set all $V_{\mathrm{int}} = 0$ and all $I_{\mathrm{int}} = 0$; that is, replace all internal batteries with short circuits and all current sources with open circuits. Now, with a given applied I_{ext}, observe V_1.
2. Define $R_{\mathrm{T}} = V_1/I_{\mathrm{ext}}$. (They must be proportional, by linearity.)
3. Now set $I_{\mathrm{ext}} = 0$, and turn on the internal batteries and current sources. Observe V_2, which we will call V_{T}.
4. Finally, by superposition it must be the case that

$$V\,(\mathrm{actual}) = V_1 + V_2 = I_{\mathrm{ext}} R_{\mathrm{T}} + V_{\mathrm{T}}.$$

This is true for all I_{ext}, and is exactly what you get with the Thévenin equivalent circuit, when connected to *any* load (which need not be linear); see Figure D.2.

To summarize: (a) you determine R_{T} and V_{T} by first finding the open-circuit voltage, which equals V_{T}; then (b) you find the short-circuit current, I_{SC}, which equals the ratio of V_{T} to R_{T}. In other words, $V_{\mathrm{T}} = V_{\mathrm{OC}}$ and $R_{\mathrm{T}} = V_{\mathrm{OC}}/I_{\mathrm{SC}}$. You do this by analysis, if you know the "black-box" circuit; or by measurement, if you don't.

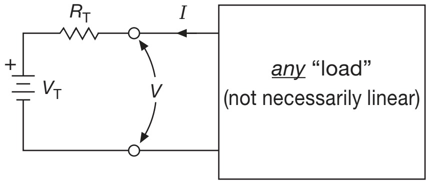

Figure D.2. The Thévenin equivalent circuit behaves exactly like the original network, regardless of the nature of the load.

D.1.1 Two examples – voltage dividers

Figures D.3 and D.4 show two simple examples, variations on the resistive divider. Interestingly, their Thévenin equivalent circuits are different, even though the resistor values and the open-circuit voltages are the same.

[1] A related theorem is Norton's, where the equivalent circuit consists of a resistor R_{N} in parallel with a current source I_{N}.

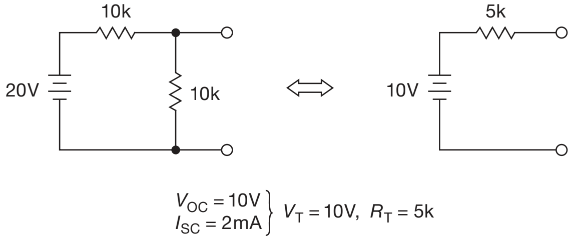

Figure D.3. Thévenin equivalent of a simple resistive divider. Note that R_T is the parallel resistance of the divider (as if the voltage source were replaced with a short circuit).

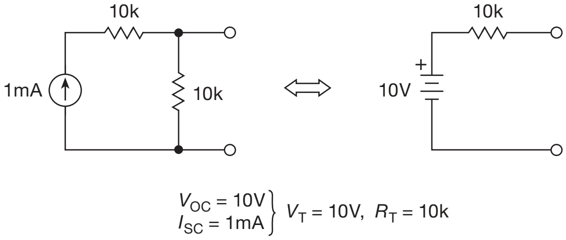

Figure D.4. Note that the Thévenin equivalent resistance is here *not* equal to the parallel resistance of the divider components. Instead it equals the value of the resistor across the output alone (as if the current source were replaced with an open circuit).

D.2 Norton's theorem

You can replace a Thévenin circuit with a Norton circuit, which consists of a current source I_N in parallel with a resistor R_N (Figure D.5). It is easy to show that $I_N = I_{SC}$ and $R_N = R_T$ $(= V_{OC}/I_{SC})$. So, for the two examples above, the Norton equivalents are as shown in Figure D.6.

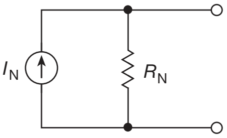

Figure D.5. Norton equivalent circuit: a current source in parallel with a resistor.

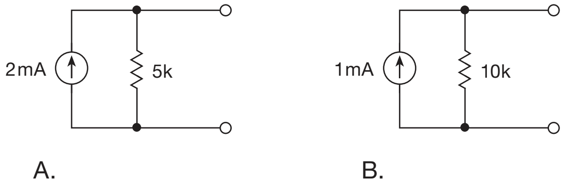

Figure D.6. Norton equivalents of the circuits of Figure D.3 (A) and Figure D.4 (B).

D.3 Another example

Figure D.7 shows a complicated-looking circuit, for which it is pretty easy to see that V_{OC}=25 V (the bottom of the 10k resistor sits at +10 V, and 1.5 mA flows into the top) and that I_{SC}=2.5 mA (10 V across the 10 k, plus the two current sources). From that you get the equivalent circuits shown.

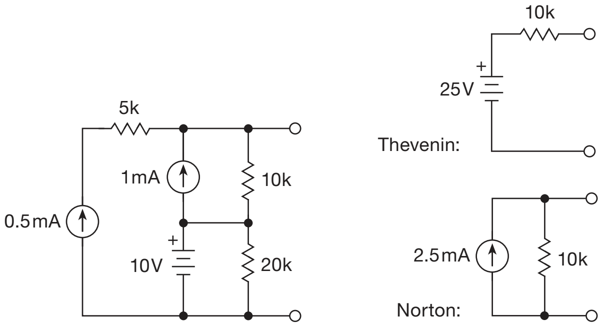

Figure D.7. Thévenin and Norton equivalents of a complicated-looking circuit.

$(G_i \equiv 1/R_i)$

Figure D.8. Millman's theorem for parallel circuits.

D.4 Millman's theorem

A related – and useful – tool is *Millman's Theorem* (also known as the parallel generator theorem), which is helpful when dealing with circuits with several parallel branches. It's shown in Figure D.8, where a set of input voltages V_i are combined via resistors R_i, producing an output voltage V_o. The latter is just $V_o = (\sum V_i G_i)/\sum G_i$, where the G_i are the conductances $G_i \equiv 1/R_i$. The input voltages V_i can of course include ground, forming a voltage divider. Millman's theorem, which comes from the more general class of network theorems, can be generalized to include input *currents* I_k, whose sum is added to the numerator (but whose series resistances, if any, do not appear in the denominator).

LC BUTTERWORTH FILTERS

APPENDIX **E**

Active filters (see Chapter 6) are convenient at low frequencies, but they are impractical at radio frequencies because of the slew-rate and bandwidth requirements they impose on the operational amplifiers. At frequencies of 100 kHz and above (and often at lower frequencies), the best approach is to design a passive filter with inductors and capacitors. (At UHF and microwave frequencies these "lumped-component" filters are replaced by stripline and cavity filters.)

As with active filters, there are many methods and filter characteristics possible with *LC* filters. For example, you can design the classic Butterworth, Chebyshev, and Bessel filters, each in lowpass, bandpass, highpass, and band-reject varieties. It turns out that the Butterworth filter is particularly easy to design, and we can present in just a page or two all the essential design information for lowpass and highpass Butterworth *LC* filters, and even a few examples.

E.1 Lowpass filter

Table E.1 gives the values of normalized inductances and capacitances for low-pass filters of various orders, from which actual circuit values are obtained by the frequency and impedance scaling rules

$$
\begin{aligned}
L_n(\text{actual}) &= \frac{R_\mathrm{L} L_n(\text{table})}{\omega},\\
C_n(\text{actual}) &= \frac{C_n(\text{table})}{\omega R_\mathrm{L}},
\end{aligned}
$$

where R_L is the load impedance and ω is the angular frequency ($\omega = 2\pi f$).

Table E.1 gives normalized values for two-pole through eight-pole lowpass filters for the two most common cases, namely (a) equal source and load impedances and (b) either source or load impedance much larger than the other. To use the table, first decide how many poles you need, based on the Butterworth response (graphs are plotted in Figure 6.30). Then use the preceding equations to determine the filter configuration (T or π; see Figure E.1) and component values. For equal source and load impedances, either configuration is OK; the π configuration may be preferable because it requires fewer inductors. For a load impedance much higher (lower) than the source impedance, use the T (π) configuration.

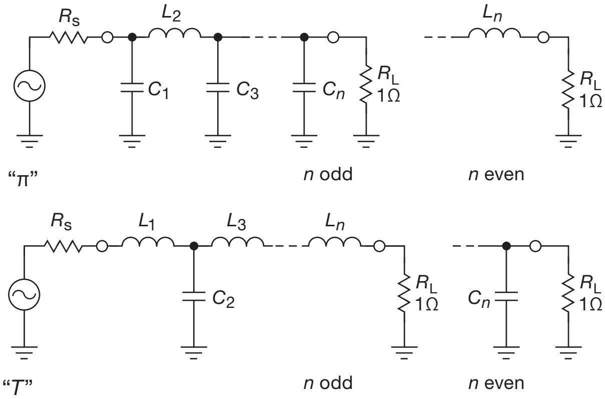

Figure E.1. π and T configurations. See Table E.1 and text.

E.2 Highpass filter

To design a highpass filter, follow the same procedure to determine which filter configuration to use and how many poles are necessary. Then do the universal lowpass to highpass transformation shown in Figure E.2, which consists simply of replacing inductors by capacitors, and vice versa. The actual component values are determined from the normalized values in Table E.1 by the following frequency and impedance scaling rules:

$$
\begin{aligned}
L_n(\text{actual}) &= \frac{R_\mathrm{L}}{\omega C_n(\text{table})},\\
C_n(\text{actual}) &= \frac{1}{R_\mathrm{L}\omega L_n(\text{table})}.
\end{aligned}
$$

E.3 Filter examples

Here are a few examples showing how to design both lowpass and highpass filters.

Example I. Design a five-pole lowpass filter for source

Table E.1 Butterworth Lowpass Filters[a]

Notes: (a) Values of L_n, C_n for 1Ω load resistance, and cutoff frequency (–3dB) of 1 rad/s. See text for scaling rules.

and load impedances of 75 Ω, with a cutoff frequency (−3 dB) of 1 MHz.

We use the π configuration to minimize the number of required inductors. The scaling rules give us

$$C_1 = C_5 = \frac{0.618}{2\pi \times 10^6 \times 75} = 1310\,\text{pF},$$

$$L_2 = L_4 = \frac{75 \times 1.618}{2\pi \times 10^6} = 19.3\,\mu\text{H},$$

$$C_3 = \frac{2}{2\pi \times 10^6 \times 75} = 4240\,\text{pF}.$$

The complete filter is shown in Figure E.3. Note that all filters with equal source and load impedances will be symmetrical.

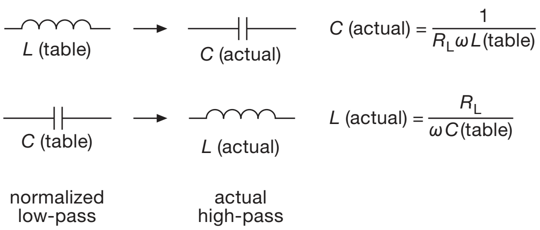

Figure E.2. Lowpass to highpass transformation.

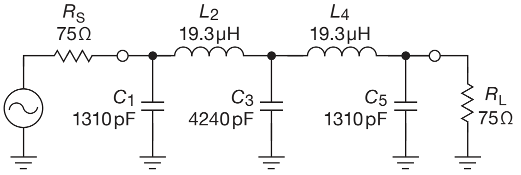

Figure E.3. Circuit for Example I. Five-pole 1 MHz lowpass with equal source and load impedances.

Example II. Design a three-pole lowpass filter for a source impedance of 50 Ω and a load impedance of 10k, with a cutoff frequency of 100 kHz.

We use the T configuration, because $R_S \ll R_L$. For R_L=10k, the scaling rules give

$$L_1 = \frac{10^4 \times 1.5}{2\pi \times 10^5} = 23.9\,\text{mH},$$

$$C_2 = \frac{1.3333}{2\pi \times 10^5 \times 10^4} = 212\,\text{pF},$$

$$L_3 = \frac{10^4 \times 0.5}{2\pi \times 10^5} = 7.96\,\text{mH}.$$

The complete filter is shown in Figure E.4.

Example III. Design a four-pole lowpass filter for a zero-impedance source (voltage source) and a 75 Ω load, with a cutoff frequency of 10MHz.

We use the T configuration, as in the previous example,

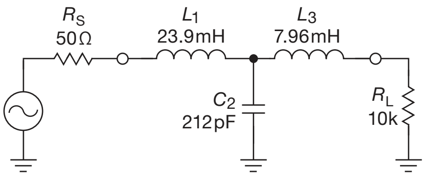

Figure E.4. Circuit for Example II. Three-pole 100 kHz lowpass with 50 Ω source and 10k load.

because $R_S \ll R_L$. The scaling rules give

$$L_1 = \frac{75 \times 1.5307}{2\pi \times 10^7} = 1.83\,\mu\text{H},$$

$$C_2 = \frac{1.5772}{2\pi \times 10^7 \times 75} = 335\,\text{pF},$$

$$L_3 = \frac{75 \times 1.0824}{2\pi \times 10^7} = 1.29\,\mu\text{H},$$

$$C_4 = \frac{0.3827}{2\pi \times 10^7 \times 75} = 81.2\,\text{pF}.$$

The complete filter is shown in Figure E.5.

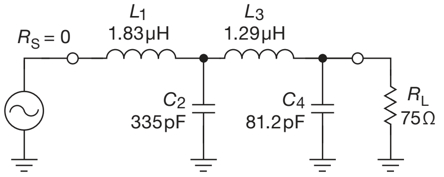

Figure E.5. Circuit for Example III. Four-pole 10 MHz lowpass with voltage source and 75 Ω load.

Example IV. Design a two-pole lowpass filter for current-source drive and 1k load impedance, with a cutoff frequency of 10 kHz.

We use the π configuration because $R_S \gg R_L$. The scaling rules give

$$C_1 = \frac{1.4142}{2\pi \times 10^4 \times 10^3} = 0.0225\,\mu\text{F},$$

$$L_2 = \frac{10^3 \times 0.7071}{2\pi \times 10^4} = 11.3\,\text{mH}.$$

The complete filter is shown in Figure E.6.

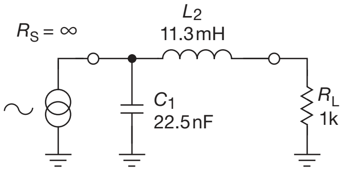

Figure E.6. Circuit for Example IV. Two-pole 10 kHz lowpass with current source drive and 1k load.

Example V. Design a three-pole highpass filter for 52 Ω source and load impedances, with a cutoff frequency of 6 MHz.

We begin with the T configuration, then transform inductors to capacitors, and vice versa, giving

$$C_1 = C_3 = \frac{1}{52 \times 2\pi \times 6 \times 10^6 \times 1.0} = 510\,\text{pF},$$

$$L_2 = \frac{52}{2\pi \times 6 \times 10^6 \times 2.0} = 0.690\,\mu\text{H}.$$

The complete filter is shown in Figure E.7.

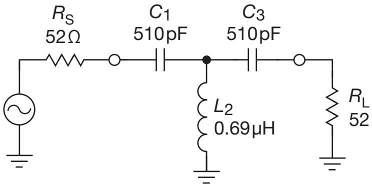

Figure E.7. Circuit for Example V. Three-pole 6 MHz highpass with equal source and load impedances.

We would like to emphasize that the field of passive filter design is rich and varied and that this simple table of Butterworth filters doesn't even begin to scratch the surface.

LOAD LINES

APPENDIX F

The graphic method of "load lines" usually makes an early appearance in electronics textbooks. We have avoided it because, well, it just isn't useful in transistor design the way it was in vacuum-tube circuit design. However, it is of use in dealing with some nonlinear devices (tunnel diodes, for example), and in any case it is a useful conceptual tool.

F.1 An example

Let's start with an example. Suppose you want to know the voltage across the diode in Figure F.1. Assume that you know the voltage-versus-current (V–I) curve of the particular diode (of course, it would have a manufacturing "spread," as well as a dependence on ambient temperature); it might look something like the curve drawn. How would you figure out the quiescent[1] point?

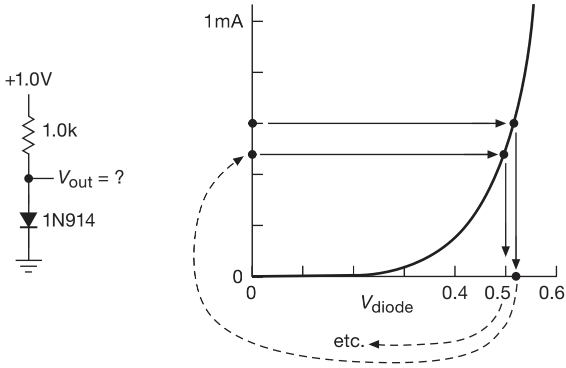

Figure F.1. Finding the operating point by iteration.

One method might be to guess a rough value of current, say 0.6 mA, then use the curve to get the drop across the resistor, from which you get a new guess for the current (in this case, 0.48 mA). This iterative method is suggested in Figure F.1. After a few iterations, this method will get you an answer, but it leaves a lot to be desired.

The method of load lines gets you the answer to this sort of problem immediately. Imagine *any* device connected in place of the diode; the 1.0k resistor is still the load. Now plot, on a V–I graph, the curve of resistor current versus device voltage. This turns out to be easy: at zero volts the current is just V_+/R (full drop across the resistor); at V_+ volts the current is zero; points in between fall on a straight line between the two. Now, on the same graph, plot the V–I curve of the device. The operating point lies on both curves, i.e., at the intersection, as shown in Figure F.2.

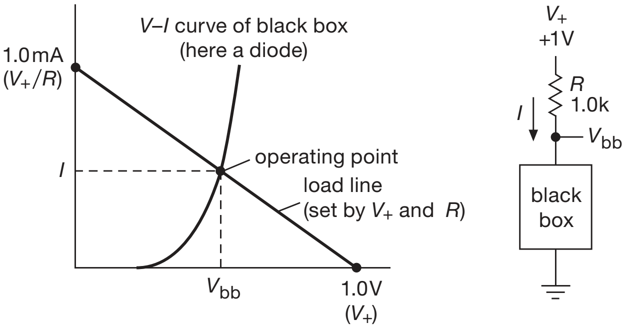

Figure F.2. A "load line" lets you find the operating point directly.

F.2 Three-terminal devices

Load lines can be used with a three-terminal device (tube or transistor, for example) by plotting a family of curves for the device. Figure F.3 shows what such a thing would look like for a depletion-mode field-effect transistor (FET), with the curve family parameterized by the gate-source voltage. You can read off the output for a given input by sliding along the load line between appropriate curves corresponding to the input you've got, then projecting onto the voltage axis. In this example we've done this, showing the drain

[1] The quiescent point, also known as the *operating point*, describes the various dc voltages and currents in a circuit with no ac signals applied.

voltage (output) for a gate swing (input) between ground and −2 V.

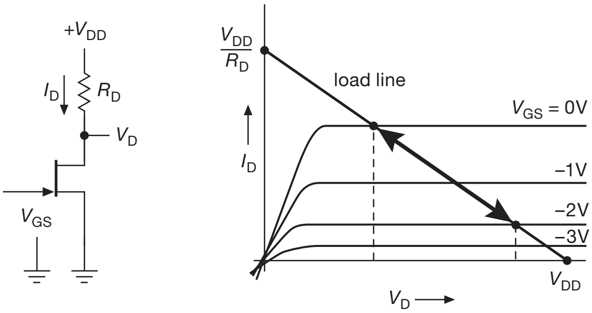

Figure F.3. Load-line solution for a three-terminal device.

As nice as this method seems, it has quite limited use for transistor or FET design, for a couple of reasons. For one thing, the curves published for semiconductor devices are "typical," with manufacturing spread that can be as large as a factor of five. Imagine what would happen to those nice load-line solutions if all the curves shrank to one-fourth their height! Another reason is that for an inherently logarithmic device like a diode junction, a linear load-line graph can be used to give accurate results over only a narrow region. Finally, the nongraphic methods we've used in this book are entirely adequate for handling solid-state design. In particular, these methods emphasize the parameters you can count on (r_e, I_C versus V_{BE} and T, etc.), rather than the ones that are highly variable (β, V_{th}, etc.). If anything, the use of load lines on published curves for transistors only gives you a false sense of security, since the device spread isn't also shown.

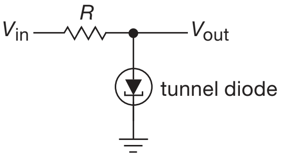

Figure F.4. The tunnel diode: a two-terminal nonlinear device with a region of negative resistance (see Figure F.5).

F.3 Nonlinear devices

Load lines turn out to be useful in understanding the circuit behavior of highly nonlinear devices. The example of tunnel diodes illustrates a couple of interesting points. Let's analyze the circuit in Figure F.4. Note that in this case, V_{in} takes the place of the supply voltage in the previous examples. So a signal swing will generate a family of parallel load lines intersecting with a single device V–I curve (Figure F.5). The values shown are for a 100 Ω load resistor. As can be seen, the output varies most rapidly as the input swing takes the load line across the negative-resistance portion of the tunnel-diode curve. By reading off values of V_{out} (projection on the x axis) for various values of V_{in} (individual load lines), you get the "transfer" characteristics shown. This particular circuit has some voltage gain for input voltages near 0.2 V.

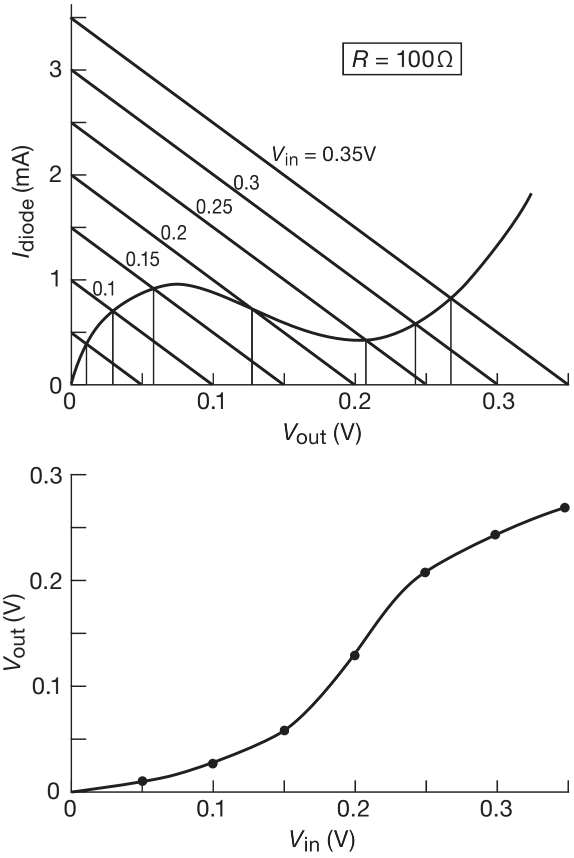

Figure F.5. Load lines and transfer characteristic for the tunnel-diode circuit.

An interesting thing happens if the load lines become flatter than the middle section of the diode curve. That happens when the load resistance exceeds the magnitude of the diode's negative resistance. It is then possible to have *two* intersection points, as in Figure F.6. A rising input signal carries the load lines up until the intersection point has nowhere to go and has to jump across to a higher V_{out} value. On returning, the load lines similarly carry the

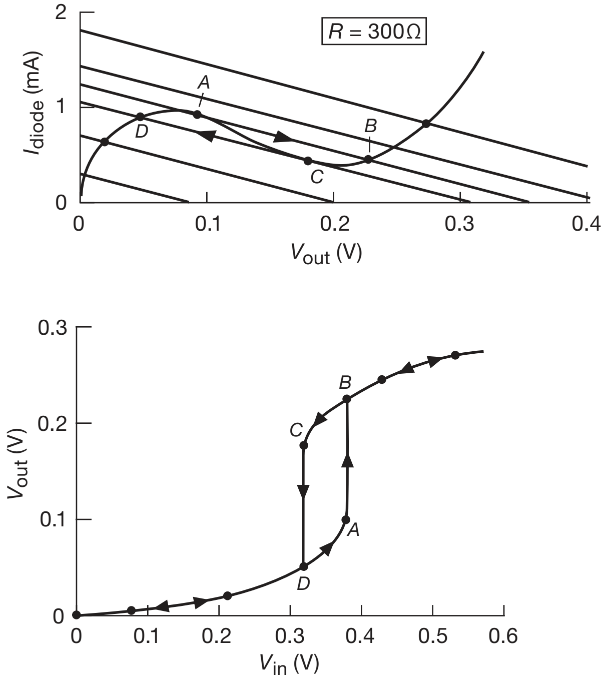

Figure F.6. Having $|R_{\text{load}}| > |R_{\text{neg}}|$ produces hysteretic switching behavior in the tunnel-diode circuit.

intersection point down until it must again jump back. The overall transfer characteristic has *hysteresis*, as shown. Tunnel diodes have been used in this manner as fast-switching devices (triggers).

THE CURVE TRACER

APPENDIX G

A handy instrument for exploring transistor behavior of both BJTs (Chapter 2) and MOSFETs (Chapter 3) is the *curve tracer*. Most simply, it plots collector current versus collector voltage for a family of equally spaced base currents (or, if you want to be an Ebers–Mollian, base *voltages*), and with a selectable current-limiting collector resistor.[1] Figure G.1 shows what you get from a random 2N3904, driven with seven successive base current steps of 5 μA each while sweeping the collector voltage from 0 to 50 V. You can see clearly the rise of beta with collector voltage, and the onset of breakdown somewhat below 50 V (maximum V_{CEO} is specified as 40 V). This particular curve tracer obligingly displays the scale factors, including "β per div," which is about 200 for this specimen (the datasheet specifies $100 \leq \beta \leq 300$ at I_{C}=10 mA). A curve tracer makes it easy to select closely matched pairs.

Sadly, the traditional curve tracer has disappeared from the product lines of most T&M (test and measurement) manufacturers, including the venerable Tektronix. You can still find them used, for example on eBay, for a thousand dollars or so. Agilent offers some pretty fancy contemporary instruments that will do the job, though it's best to be sitting down when you ask the prices; they go by names like Semiconductor Parameter Analyzer (model 4155C), or Power Device Analyzer/Curve Tracer (model B1505A).

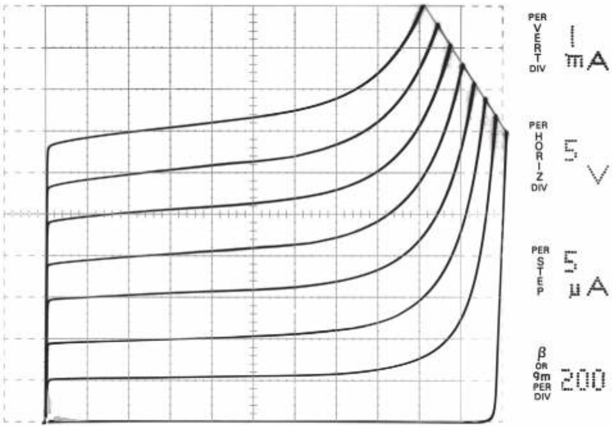

Figure G.1. Tektronix 576 Curve Tracer display of a 2N3904.

A less expensive alternative is to use a "source-measure unit" (SMU), a delightful instrument that lets you source voltages and currents to selected terminals of a device (or subcircuit), simultaneously measuring and logging other voltages or currents. You can program the excitation as dc, or ramps, steps, or pulses, and you can display the logged results via software running on an attached laptop computer; you can also save the logged data as a spreadsheet, to be manipulated to your heart's content. Take a look, for example, at Figure 8.39, or the figures in the "Power Transistors for Linear Amplifiers" section of Chapter *3x*, all of which plot data we collected with a SMU.

[1] You can run it as common base, if you like; and it has many amusing knobs to play with.

TRANSMISSION LINES AND IMPEDANCE MATCHING

APPENDIX H

H.1 Some properties of transmission lines

In §12.9 we introduced transmission lines, which most commonly take the form of *coaxial* cable ("coax"), for example the ubiquitous "BNC cables" (RG-58 cables with male BNC connectors at each end) that are used to run all manner of signals between instruments. As we remarked there, for low-frequency applications it is common (and correct) to think of such a cable simply as a well-shielded wire with ∼30 pF/ft of capacitance. However, at high frequencies (say those for which the cable is at least 1/20 of the wavelength) the behavior is fundamentally different: as a bizarre example, an open-ended cable ironically looks like a *short circuit* at a frequency for which the cable's electrical length is $\lambda/4$. For a 5-foot length of coax, that happens at about 32 MHz. An important consequence is that you can't just hook such a BNC cable from a signal generator to some high-impedance circuit under test and assume that it will provide a nice signal source at the circuit's input; instead you will see huge dips and bumps as you tune the frequency, because the generator sees a load impedance that varies from a short circuit (at odd multiples of 32 MHz) to an open circuit (at even multiples of 32 MHz). Perhaps surprisingly, if you were instead to connect a resistor of exactly 50 Ω across the circuit end of the cable, you would find that it now delivered a constant signal amplitude (equal to half the signal generator's open-circuit output amplitude) as you varied the frequency. This nonintuitive behavior is nicely illustrated in the measured data shown in Figure H.1. And even more nonintuitively, at the driving end of such a "terminated" cable the capacitance disappears entirely – you see instead a pure resistive load of 50 Ω!

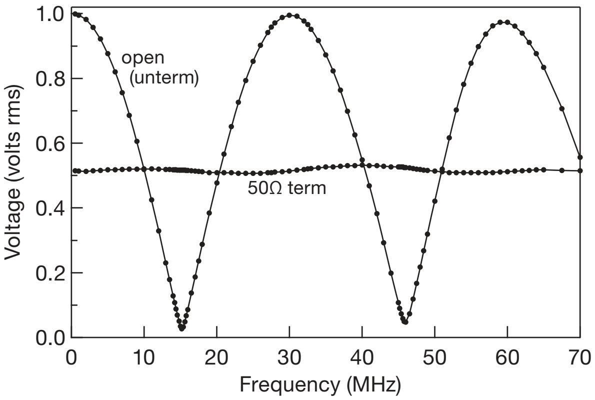

Figure H.1. Measured amplitude at the output connector of a sinewave oscillator of 1 V amplitude (open circuit), under two conditions: driving 10 feet of RG-58 (50 Ω) coaxial cable, open at the far end; and driving the same cable with a 50 Ω resistor connected across the far end.

H.1.1 Characteristic impedance

This simple example illustrates the importance of *termination*: coaxial cable is a form of *transmission line*, with a *characteristic impedance* Z_0 (which is always real: a resistance) that depends on only its physical construction:

$$Z_0 = \sqrt{L/C} = \frac{138}{\sqrt{\varepsilon}} \log_{10} \frac{b}{a} \text{ ohms},$$

where L and C are the inductance and capacitance per unit length, which as indicated depend on only the outer diameter, a, of the inner conductor, the inner diameter, b, of the outer conductor, and the dielectric constant, ε (relative to free space), of the insulating material that separates them. For a wave propagating along a transmission line, Z_0 is the ratio of signal voltage to signal current. The most popular coax line for general purposes is RG-58, with an impedance of 50 Ω (its dimensions are a=0.81 mm, b=2.95 mm, and ε=2.3, for which the above equation gives Z_0=51 Ω). This impedance has become the standard for radiofrequency use, except for video applications where the standard is Z_0=75 Ω; the corresponding popular cable type is called RG-59. In pulse electronics you sometimes see 93 Ω cable (RG-62).

The signal propagates along the cable at a speed

$$v_{\text{wave}} = \frac{c}{\sqrt{\varepsilon}} = \frac{1}{\sqrt{LC}},$$

which is a fraction $1/\sqrt{\varepsilon}$ times c (where c is the speed of light in vacuum, 3×10^8 m/s). The factor $1/\sqrt{\varepsilon}$ is called the *velocity factor*, and ranges from 0.66 (solid polyethylene) to 0.80 (polyethylene foam) for available flexible coaxial cables. In the absence of a dielectric the velocity factor is 1.0, i.e., waves travel at the speed of light in an air-spaced coaxial line. The "electrical length" seen by a propagating signal in a cable of physical length L is larger by the factor $\sqrt{\varepsilon}$, i.e., $L_{\text{elec}}{=}L_{\text{physical}}\sqrt{\varepsilon}$.

Note that the inductance and capacitance of the cable cannot take on any old values, because they are constrained such that their product LC is related to the speed of light. From this it is easy to show that if you know the characteristic impedance and the velocity factor then you can find the capacitance per unit length (or vice versa) by

$$C = \frac{\sqrt{\varepsilon}}{cZ_0} \text{ Farads/meter.}$$

For example, RG-8 has a specified impedance of 52 Ω, and a velocity factor of 0.66; the above equation then gives $C{=}97.1$ pF/m, or 29.6 pF/ft, in good agreement with the specified value of 29.5 pF/ft.

A. Twisted pair and PCB traces

Transmission lines are not *required* to be of coaxial geometry. An extremely popular form of contemporary transmission line is the *twisted pair*, which is just what it sounds like: a pair of insulated wires, gently twisted, and enclosed in an overall insulating jacket (often without any overall shield conductor). These may well be the dominant species of transmission line in our time, because they are the basic stuff of local area networks (LANs). You usually see four twisted pairs bundled into a single unshielded jacket; this is called "UTP" (unshielded twisted pair), and is the most common form of LAN cable. It is available also with a shield (shielded twisted pair, "STP"). Contemporary UTP and STP cables are 100 Ω nominal impedance, and are characterized (in terms of impedance and attenuation) for operation up to 10 Mbps (megabits per second) or 100 Mbps; these are called Category 3 and Category 5, respectively, and appear to differ primarily in the pitch of the twist. Those in the know refer to these casually as cat-3 and cat-5.[1] Ethernet LANs using these data rates are called "10baseT" and "100baseTX," the "T" standing for "twisted"; the corresponding designation for "thinnet" coaxial Ethernet is "10base2."

In high-speed electronics on a printed circuit board it's often necessary to treat connection traces as transmission lines. See the discussion in §*1x.1*, where we described the *microstrip* transmission line, which consists of a thin conducting strip on an outer printed circuit layer, with an underlying ground-plane layer. A popular variant adds a pair of ground-trace shepherds on either side – that's called a *grounded coplanar waveguide* (GCPW). There's also the completely enclosed *stripline* geometry, where the trace(s) are sandwiched between ground-plane layers.

H.1.2 Termination: pulses

A transmission line at low frequencies (wavelength much longer than the cable length) looks simply like a capacitance, typically of order 30 pF/ft. However, at high frequencies, or, equivalently, when dealing with signals with fast rise times, the behavior is different. In order to understand the curious behavior illustrated in Figure H.1, it's helpful to look first at what happens when a simple *pulse* is applied to a length of transmission line. Suppose we connect a fast pulse generator with 50 Ω output impedance (the standard output impedance of signal generators, function generators, and pulse generators) to a length of 50 Ω coax, shorted at the far end. The pulse at first disappears into an impedance Z_0 (thus the signal amplitude is half that of the unloaded generator), but after a round-trip travel time a reflected pulse of opposite polarity returns (Figure H.2). If the signal applied is instead a fast step, the effect of the reflection is to convert the step into a pulse (Figure H.3). An open-ended line produces a reflection of the *same* polarity, with the effects shown in Figure H.4. For arbitrary load resistance R the ratio of reflected to incident wave amplitude (the reflection coefficient) is given by

$$\rho \equiv A_{\text{r}}/A_{\text{i}} = (R - Z_0)/(R + Z_0).$$

Note that a termination resistance of $R{=}Z_0$ produces no reflection. A signal applied to such a terminated line is absorbed by the terminating resistor (as heat) and disappears forever. The signal source sees a loading resistance equal to Z_0. (It is for this reason that we did not have to worry earlier about the reflected pulses reflecting again from the pulse

[1] Higher performance standards include Category 5e ("e" for *enhanced*), and Category 6, propelled by the development of Gigabit Ethernet – literally 1 gigabit/sec over unshielded twisted pair – also known as 1000baseT. To achieve this data rate, all four pairs are used simultaneously with 5-level amplitude encoding.

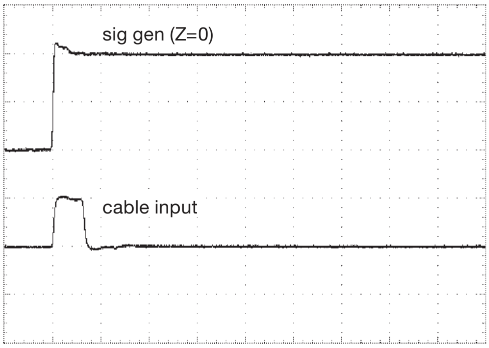

Figure H.3. 'Scope trace of a step waveform applied to an 8-foot length of RG-58A/U (solid polyethylene dielectric, velocity factor of 66%), shorted at the end. Vertical; 1 V/div; horizontal; 40 ns/div.

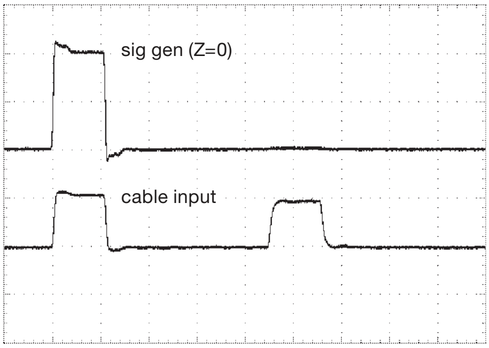

Figure H.4. 'Scope trace showing reflection from open-ended coax line. Same parameters as those in Figure H.2B.

generator – its 50 Ω source impedance swallows any signals returning from an improperly terminated cable, which is the reason most signal sources are standardized at 50 Ω impedance.)

A. Series termination

This last point – that returning (reflected) signals are completely absorbed if the signal source's impedance matches the line – leads to a nice technique called *series termination* (or *back termination*), frequently used for high-speed logic signals (and in other situations where the load has a high input impedance). Look at Figure H.5: a signal source in series with a resistor (equal to the line's impedance) drives a transmission line whose far end is unterminated (i.e., open). Now imagine a step input of amplitude V_{sig} at the signal source; it propagates down the line at half-amplitude, then reflects back from the far end at the full V_{sig} amplitude. Although any point along the line sees a two-step waveform, the surprising fact is that the waveform seen at the far end makes a single step from zero to the full V_{sig}; at that place the half-sized incident wave arrives at the same time that the half-sized reflected wave departs. This interesting behavior is demonstrated in the 'scope traces in Figure H.6.

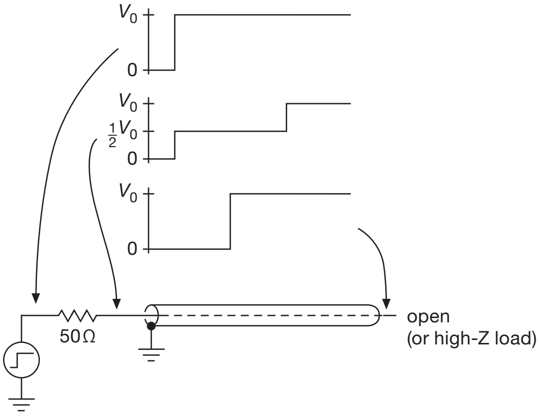

Figure H.5. Series termination of an open-ended line: the line is fed from a signal source of matched impedance; the half-sized step at the input propagates to the far end, from which it reflects in-phase to produce a returning step equal in amplitude to the *unloaded* amplitude of the generator. A high-impedance load at the far end sees only a single full-sized step.

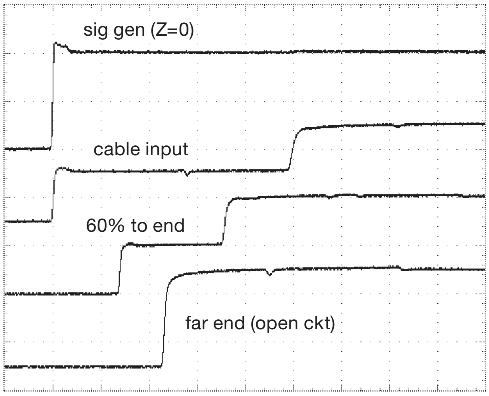

Figure H.6. 'Scope trace showing waveforms at cable input, midpoint, and far end, for series-terminated step input. The generator's zero-impedance signal is also shown; it was set to produce a 2 V step into an open circuit. The cable is 60 ft of RG-58/U (velocity factor of 66%), tapped at 36 ft with a high-impedance voltage probe. Vertical; 1 V/div; horizontal; 40 ns/div.

You can use this technique for sending CMOS logic signals through a length of coax: three paralleled 74HC buffers (for low source impedance, roughly 15 Ω) in series with a 33 Ω resistor nicely drives lengths of RG-174 or RG-316 (thin 50 Ω coax line), connected to the receiving gate at the far end *without termination*. The receiving gate sees

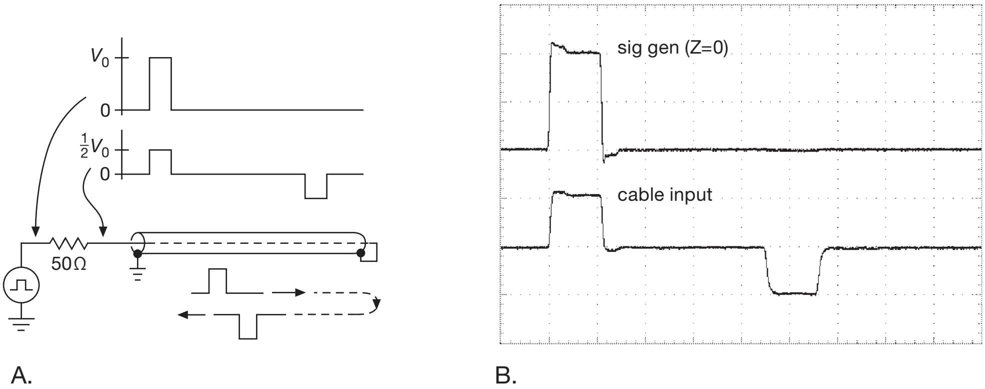

Figure H.2. A. A pulse driving a length of shorted transmission line reflects off the short and returns as a pulse of opposite polarity. B. Scope trace taken with 70 ft of RG-8/U with foam dielectric (velocity factor of 78%), shorted at end. Vertical; 1 V/div; horizontal; 40 ns/div. For this and following figures we used a high-impedance ’scope probe to avoid introducing additional transmission-line effects.

full-swing logic signals. This technique is often preferable to the matched-load alternative – directly driving a line that is terminated in 50 Ω – because with series termination the driver sees a load resistance twice as high (100 Ω in this case), and that only for the round-trip duration of the signal (after which the load becomes an open-circuit).[2] For very fast logic signals (e.g., ECL 100K, or contemporary high-speed CMOS processors, memory, and peripherals), it may be necessary to treat a circuit trace of just a few inches as a transmission line. Typically printed circuit board (PCB) trace impedances are in the range of 50 Ω to 100 Ω, but can be tailored to a specific impedance by proper choice of trace width and spacing above the ground plane; this specialty art is known as *microstrip* technique,[3] useful both for fast digital signals and for signals at frequencies above about 100 MHz (UHF and microwave).

This is all very nice in theory – but in practice you have to contend with sources of fast digital signals that are not matched to the line impedance. This happens often on digital PCBs where the digital output ports of speedy microprocessors and FPGAs are poorly matched to the PCB trace impedances. For example, a line driven by a signal of source impedance $Z_0/2$ produces lots of ringing at both ends of an unterminated line, including 33% overshoot at the far end; such ringing can produce false clocking.

To illustrate what this looks like, we drove a 2.4 m length of unterminated RG-58/U (Z_0=50 Ω) coax with a step input, probing both the input and output signals. We did this under two conditions: (a) when driven with a 50 Ω series termination at the input (i.e., a “back-terminated” line); and (b) when driven with a low-impedance (R_s=1.5 Ω) voltage step.

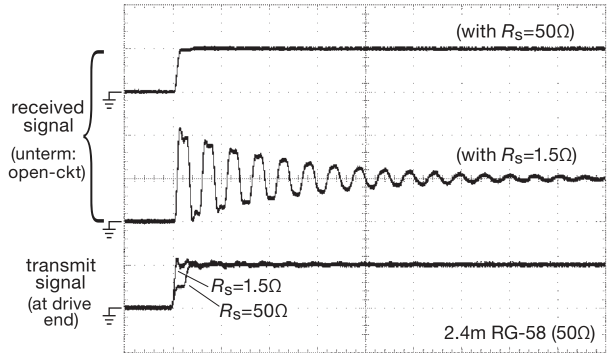

Figure H.7. Signals seen at the far end of an unterminated 8ft length of 50 Ω line when driven with a unit step from a 50 Ω source (top trace) and from a low-impedance source (middle trace). The corresponding signals at the driving end are shown at bottom. Horizontal; 100 ns/div.

Figure H.7 shows the results, where the drive signal’s open-circuit amplitude (call it V_{OC}) is displayed as one vertical division. The matched series termination generates a clean received step to V_{OC} (and an input waveform with initial step first to $V_{OC}/2$, then to V_{OC} after a round-trip delay, just as seen in expanded scale in Figure H.6). By contrast, the low-*Z* drive imposes a full V_{OC} step at the input, which is first seen at the far end at $2V_{OC}$ (because the non-inverted reflected wave doubles the amplitude of the arriving wave), subsequently brought nearly back to zero (one round-trip time later) by the inverted wave reflected from

[2] See §12.10, where several methods of driving cables with logic levels are described and illustrated.

[3] If you sandwich the signal-carrying conductors between a pair of ground planes, you’ve got a *stripline*; see §*1x.1*.

the low-impedance driver. This alternating pattern continues, damped both by cable loss and resistive loss in the 1.5 Ω driver. This signal is a mess! That's why it's worth some effort to match driver impedances to the characteristic impedance of lines whose length (given the signal rise times) qualifies them as transmission lines.[4]

B. A robust logic link

The sort of overshoot behavior seen in Figure H.7 can destroy logic circuits at the receiving end. You see this vulnerability particularly in the laboratory, where a low-impedance logic signal (or pulse-generator output) travels through a length of coax to a logic input on some instrument. The latter is often unterminated, to keep the input impedance relatively high (to prevent heavy loading and attenuation for a signal source unable to drive 50 Ω).

If you want to make your own designs bulletproof against this hazard, you can add a few components as shown in Figure H.8. At the receiving end, series resistor R_2 limits the current, safely clamped by the logic gate's internal protection diodes; the "speed-up capacitor" C_1 prevents loss of speed (1 kΩ into a typical input and wiring capacitance of 10 pF is an *RC* time constant of 10 ns, a near-eternity in the frenetic world of digital logic). It's always a good idea to include an input pull-down resistor (R_1) to ensure a defined logic level when the input is disconnected. In an abundance of caution we've added resistor R_3, whose job is to prevent a large positive overdrive from forcing the V_+ rail to a positive voltage that can damage other ICs; this could normally be omitted, but it would be a good idea in an instrument with an inviting BNC connector on the front and that contains only a few ICs powered from a small regulator (like a 78L05 – see §9.3.2, Figure 9.6, and Table 9.1) whose dc output can be easily overdriven.

At the driver end the parallel connection of several logic gates generates a drive impedance down in the neighborhood of 5–10 Ω, which the added series resistor R_o brings up to a driving resistance close to the cable's 50 Ω characteristic impedance. That's what you want, of course, and that alone is enough to give you peace of mind as a respectable series-terminated driver. But it never hurts to protect the receiver end, as just discussed: you never know when someone will drive it with a pulse generator, inadvertantly set to deliver *negative* pulses, or 20 V positive pulses (as happened in our laboratory recently).

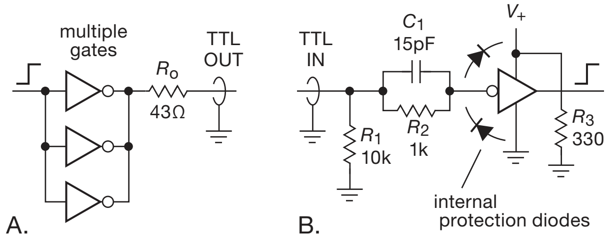

Figure H.8. A. Simple logic-level driver for series-terminated cable; B. Logic-level receiver protected against overdrive. Connect these together to form a complete signal path.

There's further discussion of cable driving and logic interfacing in Chapter 12, beginning at §12.10.

H.1.3 Termination: sinusoidal signals

We have been talking about signals propagating along transmission lines, for clarity using the particular case of pulses or voltage steps. Of course, a *sinewave* applied to a length of cable also produces reflections, unless of course the cable is properly terminated. The effect is to alter the input current, for an applied input voltage, in a way that depends on the (mismatched) load impedance Z_L, and also on the ratio of the signal's wavelength in the cable λ to the physical length of the cable l. The final effect is to produce an input impedance (complex in general) given by

$$Z_{\text{in}} = Z_0 \frac{Z_L + jZ_0 \tan(2\pi l/\lambda)}{Z_0 + jZ_L \tan(2\pi l/\lambda)}.$$

From this one can see that:
(a) a matched termination ($Z_L = Z_0 =$ [usually] 50 Ω) results in an input impedance equal to the characteristic impedance of the cable, independent of length or frequency;
(b) a quarter-wave line inverts the load impedance, i.e., $Z_{\text{in}} = Z_0^2/Z_L$;
(c) a half-wave line preserves the load impedance, i.e., $Z_{\text{in}} = Z_L$;
(d) a short length of open-circuited line $l \ll \lambda$ looks capacitive, viz., $Z_{\text{in}} \approx -j/\omega C'$, where C' (the effective capacitance) is the constant l/cZ_0;
(e) a short length of short-circuited line $l \ll \lambda$ looks inductive, viz., $Z_{\text{in}} \approx j\omega L'$, where L' (the effective inductance) is the constant $Z_0 l/c$.
The impedance-changing properties of transmission lines can be used to match impedances, though any such scheme will be frequency dependent; when you hear words like "stubs," you're dealing with transmission-line impedance matching. Virtuosos in this area make heavy use of network analyzers, and they will try to dazzle you with their

[4] An analogous effect in long-distance power transmission lines is known as the Ferranti effect; it is said that overvoltages caused by the Ferranti effect, if not properly compensated, can cause damage to power-line switch gear.

handsome "Smith Charts" (which are well beyond the humble scope of this book[5]).

When you have sinusoidal signals – with reflections – on a transmission line, you generate *standing waves*. That is, you can picture the net result of waves propagating in both directions (at the same frequency) as the sum of a nonpropagating (hence "standing") wave and some additional propagating wave. For example, an open-ended line produces a reflected wave of full amplitude; the result is a pure standing wave of the same frequency and twice the amplitude, with a maximum amplitude of oscillation at the open end (and repeating every half-wavelength), and complete nulls ("nodes" – places with no voltage) midway between. For a shorted-end line a similar thing happens, but the reflected wave is of opposite amplitude, producing a null at the far end (and repeating every half-wavelength), with maxima in between. (You get the same pattern if you tie a length of clothesline to a fence, then wiggle the end up and down at the right rate.) With a smaller termination mismatch you don't get complete cancellation anywhere.

Standing waves are not necessarily bad (though they are never[6] *good*!). But they do increase both the peak voltages and the resistive losses (see next section), relative to a matched line, for the same power transmitted. They are ordinarily seen as the symptom of a mismatched line. So in communications systems people try to minimize the *standing wave ratio* (abbreviated SWR, or sometimes VSWR – for *voltage* standing wave ratio – pronounced "VIZ-wahr"), which is defined as the ratio of the maximum amplitude to minimum amplitude:

$$\mathrm{VSWR} = \frac{V_{\max}}{V_{\min}} = \frac{A_\mathrm{f}+A_\mathrm{r}}{A_\mathrm{f}-A_\mathrm{r}},$$

where V is the ac (signal) voltage, measured at points along the line; and A_f and A_r are the amplitudes of the forward and reflected waves, respectively. Voltage measurements along a cable with no standing waves will give a constant amplitude (hence VSWR=1.0).

The VSWR is a real number, between 1.0 (perfect match, no reflected wave) and ∞ ("perfect mismatch," reflected wave amplitude equal to incident wave amplitude). In terms of the reflection coefficient ρ, the VSWR is just

$$\mathrm{VSWR} = \frac{1+|\rho|}{1-|\rho|}.$$

For a purely resistive mismatch we can use our earlier expression for ρ to find that

$$\mathrm{VSWR} = \begin{cases} R/Z_0 & \text{if } R > Z_0 \\ Z_0/R & \text{if } Z_0 > R. \end{cases}$$

From the VSWR you can find the magnitude (but not the phase) of the reflection coefficient:

$$|\rho| = \frac{\mathrm{VSWR}-1}{\mathrm{VSWR}+1}.$$

The VSWR is measured with a directional power meter. Knowing the values of forward and reflected power, you know from the defining equation above that

$$\mathrm{VSWR} = \frac{1+\sqrt{P_\mathrm{r}/P_\mathrm{f}}}{1-\sqrt{P_\mathrm{r}/P_\mathrm{f}}}.$$

H.1.4 Loss in transmission lines

In the real world of non-ideal transmission lines, things aren't quite as nice as we've led you to believe. Real transmission lines are *lossy*, meaning that signals are attenuated as they travel down the line; they are also slightly *dispersive*, meaning that signals of different frequency travel with slightly different speeds. The loss is *frequency dependent*: its value (often specified as attenuation in "dB per 100 ft") increases proportional to $\sqrt{f}$; i.e., a quadrupling of frequency doubles the loss (in dB) of a given length of line. This happens because the loss is dominated by the *skin effect*: when alternating current flows through a conductor, the current is not uniform throughout the bulk – it is confined to an outer layer (called the *skin depth*) of thickness $\delta{=}(\pi\sigma f)^{1/2}$, where σ is the conductivity and f is the frequency.[7] Because the skin depth decreases inversely with the square root of frequency, you have to quadruple the frequency to double the resistance (halve the skin depth),

[5] Smith charts are treated in the excellent reference *Fields and Waves in Communication Electronics* by Ramo, Whinnery, and Van Duzer (Wiley, 1994), as well as in the insightful and refreshing *Radio-Frequency Electronics* by Hagen (Cambridge University Press, 2009).

[6] Well, *hardly ever!* For operation over a narrow frequency range you sometimes exploit the impedance-changing properties of mismatched lines, which necessarily have standing waves. Examples are (a) the use of open or shorted lengths of line as high-Q capacitors or inductors, (b) a shorted half-wave or an open quarter-wave line used as an RF bypass capacitor, (c) an open half-wave or a shorted quarter-wave line used as an RF choke, (d) matching two different impedances (cables, signal sources, or loads) by interposing a quarter-wave section of transmission line whose characteristic impedance is the geometric mean of the two impedances being matched (this is analogous to a quarter-wave anti-reflection coating in optics), (e) the use of a slotted line and high-impedance probe for a direct measurement of wavelength, and (f) the use of transmission lines to make "ring hybrids" and "rat-race hybrids." We thank Jon Hagen and Darren Leigh for these applications of "good standing waves."

[7] To be precise, the current density decreases exponentially, falling to $1/e$ (37%) of its surface value at a depth equal to δ.

which is equivalent (in terms of loss) to doubling the length of the line. This explains the approximate slope of the attenuation curves for transmission lines (Figure H.9), where lines of larger diameter have lower losses. Dielectric losses contribute additional attenuation at the highest frequencies. The curves shown are for a matched line; if there are reflections (i.e., if the VSWR is greater than 1.0) then the loss, *for a given net power transmitted down the line*, will be greater.

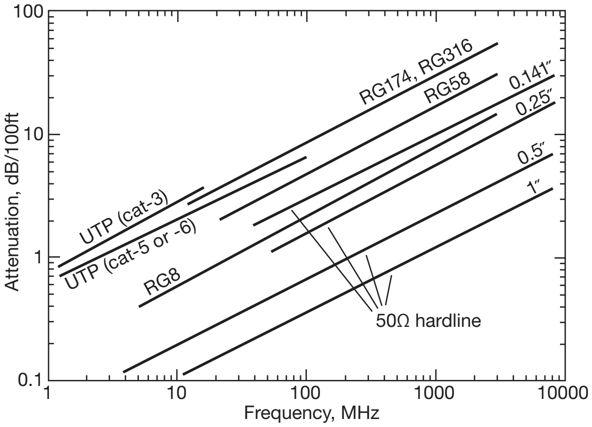

Figure H.9. Attenuation (dB/100 ft) as a function of frequency for several representative cable types.

It's useful to realize that skin-depth effects are significant even at low frequencies – current at the powerline frequency of 60 Hz is confined to a surface layer of roughly 1 cm in copper, for which the skin depth (in centimeters) at room temperature is given by $\delta(\mathrm{Cu}){=}6.6/\sqrt{f}$; you don't reduce power transmission losses much by using wire thicker than that. At radio frequencies the skin depth is so shallow (e.g., $\delta{=}10\,\mu$m at 40 MHz) that you can make low-loss connections, inductors, and so on, by silver plating a poor conductor. A common technique for shielding lightweight instruments and computers is to apply a thin metallic plating to a plastic enclosure. Figure H.10 plots the skin depth in copper conductors from 10 Hz to 10 GHz.

H.2 Impedance matching

Because you get reflections from unterminated (or incorrectly terminated) transmission lines, it's obviously a good idea to make sure you match impedances when you use coax lines whose electrical length is a significant fraction (at least 1/20, say) of the wavelength of the highest frequencies you're using. Stated in terms of time rather than frequency, you have to start worrying about termination when the round-trip propagation time is about 20% of the signal rise time.

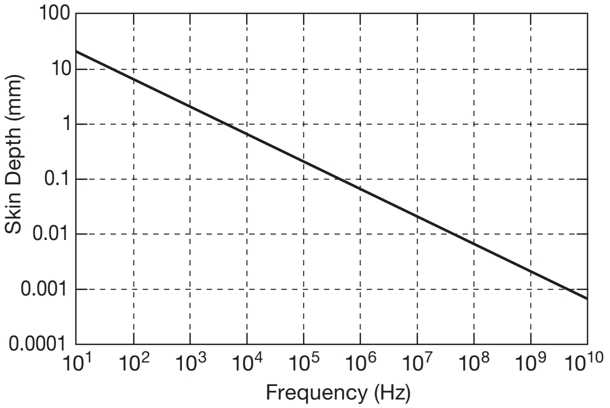

Figure H.10. Skin depth in copper as a function of frequency.

We've seen already that a simple way to do this is to terminate the line in its characteristic impedance (resistance), for example 50 Ω for most coax lines. Termination is not required at *both* ends, because a terminated end swallows any incident signals. Thus you can use a mismatched signal-source impedance to drive a line terminated at the far end; or, as we saw above, you can "series terminate" the driven end of a line whose far end is unterminated (i.e., fed to a load of much higher impedance than the line). The usual practice, however, is to terminate *both* ends in the line's characteristic impedance (a conservative instinct that ensures a minimum of reflections). For example, you usually use a 50 Ω cable to pipe the signal from a synthesizer or signal generator to a 50 Ω matched load at the far end; if your load is high impedance, you place a 50 Ω resistor across it (or use a 50 Ω coax feedthrough termination).

Sometimes you need to match a line to a load (or source) of a different impedance; for example, you might want to measure the properties of some 75 Ω video cable (that's the impedance that the video industry has chosen, much to the chagrin of the rest of the electronics community), and all you've got are 50 Ω test instruments. Or, you might want to match the output impedance of a high-frequency amplifier to a length of cable that goes to an antenna.

This brings us to the subject of matching networks. In the following subsections we treat (a) resistive (lossy) networks for broadband impedance matching and attenuation, (b) transformer (lossless) broadband matching, and (c) reactive (lossless) narrowband matching.

H.2.1 Resistive (lossy) broadband matching network

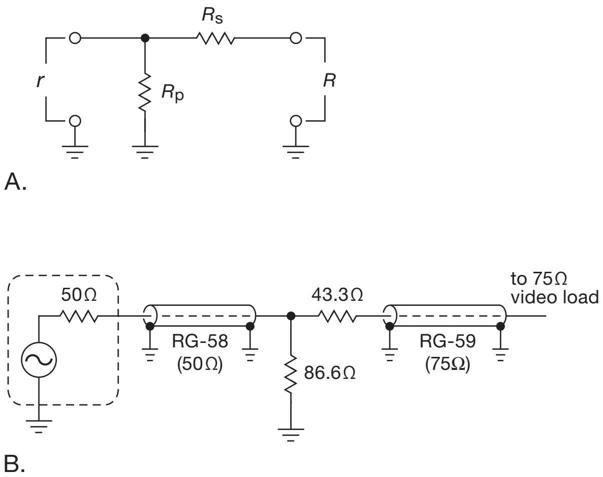

Figure H.11. A. A resistive *L*-network can match any pair of real (resistive) impedances; the parallel resistor R_p goes across the port of lower impedance r. B. Example of matching a 50 Ω signal source and cable to a 75 Ω video cable and load (with a loss of 5.72 dB).

You can easily figure out that two resistors (in the form of an "*L*-network," Figure H.11A) is all it takes to match a pair of impedances r and R (assumed resistive, as all cables are); both sides are happy – each sees a matched load. The values of the matching resistors are

$$R_p = r\sqrt{\frac{X}{X-1}},$$
$$R_s = r\sqrt{X(X-1)},$$

where r is the smaller impedance and X is the ratio of impedances: $X{=}R/r$. Taking the earlier example, you can match a 50 Ω test instrument to a 75 Ω coax line (the common variety is called RG-59) by putting 86.6 Ω across the 50 Ω port and connecting it to the cable through a 43.3 Ω series resistor (Figure H.11B).

The good news is that such a resistive *L*-network is frequency independent; the bad news is that it's lossy. It's easy to show that the loss is

$$\text{loss} = 20\log_{10}\left(\frac{\sqrt{X}}{X+\sqrt{X(X-1)}}\right)\ \text{dB}.$$

For example, the 50Ω-to-75Ω *L*-network above has a transmission loss of 5.72 dB for signals going in either direction. With a resistive match you have to accept this attenuation (this is sometimes called a *minimum loss pad*). We'll see below how to make lossless matching networks with transformers or with networks of *L*'s and *C*'s ("reactive matching networks").

As you might imagine, you can do even *worse*, in terms of loss, with a network containing more resistors! In particular, you can add another resistor, making either a "*T*" network or a "Pi" network, that matches two resistive impedances to each other, with loss greater than the minimum loss we found above. Although this isn't something you ordinarily want to do, there is a variation on that theme that is often useful; namely, a resistive attenuation network between a pair of already-matched impedances.

H.2.2 Resistive attenuator

In radiofrequency circuits you sometimes need to attenuate a signal level – for example, to avoid overdriving a stage of gain. In other situations you need to use a resistive attenuator to provide some isolation between an impedance-sensitive component like an amplifier, mixer, or cable, say, and a component that is not impedance matched; an example of the latter is a filter, which typically is impedance matched in its passband, but reflective (a severe mismatch) in its stopband. Some amplifiers will oscillate if their output directly drives a sharp filter.

The solution to these problems is a resistive impedance-matched attenuator. The two topologies are T and Pi, named for their appearance on a schematic diagram (Figure H.12). It is not difficult to derive the resistor values:

$$R_p = \frac{1+x}{1-x}R_0,$$
$$R_s = \frac{1-x^2}{2x}R_0, \qquad (\text{Pi}-\text{network}),$$

and

$$R_s = \frac{1-x}{1+x}R_0,$$
$$R_p = \frac{2x}{1-x^2}R_0, \qquad (\text{T}-\text{network}),$$

where x is given by the attenuation: $\text{atten(dB)}{=}-20\log_{10}x$ (or, equivalently, $x{=}10^{-\text{atten(dB)}/20}$), and Z_0 (assumed resistive) is the impedance at both input and output. Tabulated values for 50 Ω source and load impedances are given in Table H.1.

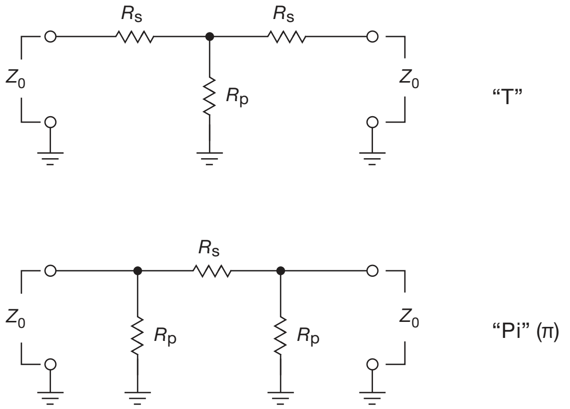

Figure H.12. Resistive T and Pi attenuators for equal input and output impedances.

H.2.3 Transformer (lossless) broadband matching network

If the unavoidable loss of a resistive matching network is unimportant in your application, that certainly is the simplest method. However, in many applications it is essential to minimize loss – for example, in a communications transmitter or in low-level circuits whose performance is limited by amplifier or thermal noise.

In that case you can use either a transformer or a reactive matching network; neither method provides coupling all the way down to dc, however. Transformer coupling is relatively broadband, but it is limited in impedance ratios; reactive matching, by contrast, flexibly matches impedances (including reactive impedances), but only around some chosen center frequency. We treat reactive matching in the next subsection.

Table H.1 50Ω T and Pi Attenuators

	Pi		T	
Attenuation (dB)	R_P (Ω)	R_S (Ω)	R_P (Ω)	R_S (Ω)
0	∞	0	∞	0
0.25	3.47k	1.44	1.74k	0.72
0.50	1.74k	2.88	868	1.44
0.75	1.16k	4.32	578	2.16
1.00	870	5.77	433	2.88

50	50.3	7.91k	0.32	49.7
55	50.2	14.1k	0.18	49.8
60	50.1	25.0k	0.10	49.9

Resistor values for T and Pi attenuators for use with 50 Ω source and load. The values shown can be scaled for use at some other impedance, assuming equal input and output impedances.

Transformers for use at signal frequencies are similar in principle to ordinary ac power transformers, that is, they use a pair of windings that are coupled magnetically, and whose turns ratio is the desired voltage ratio. The impedance ratio is then the square of the turns ratio. (For example, a transformer with a 1:4 primary:secondary turns ratio, driven with a 50 Ω signal source, would present an output impedance of 800 Ω, and should be loaded with that resistance.) However, because of the higher signal frequencies, it is necessary to use magnetic cores that do not have significant conductive paths for eddy currents. At audio frequencies the solution is to use the same sort of laminated metal stacks used in power transformers, but with much thinner laminations. At still higher frequencies, laminated cores are replaced either by powdered iron cores or by completely nonconducting magnetic "ferrite" materials. Because of the devastating effects of parasitic capacitance and inductance, transformers for use at high radio frequencies (say above 10 MHz) generally are constructed from transmission lines (coaxial or parallel) wound around a magnetic core.

Impedance-matching transformers are widely available commercially, though for special applications you may need to design and wind your own. At audio frequencies many manufacturers offer miniature impedance matching transformers with "telephone" bandwidths (200 Hz–4 kHz), or full audio bandwidth (20 Hz–20 kHz); impedances go from loudspeaker and microphone impedances (8–600 Ω) up to "hi-*Z*" values of 10k–50kΩ. There's further discussion in §8.10.

A nice series of radiofrequency transformers is made by North Hills, including models that transform 50 Ω or 75 Ω to impedances up to 1200 Ω; these cover the frequency range between 20 Hz and 100 MHz, with a typical frequency range of 1000:1 or more for a given transformer. For higher frequencies you can get broadband matching transformers from Mini-Circuits, covering the range of 4 kHz to 2 GHz with impedance ratios from 1:1 to 16:1, and with frequency ranges of 1000:1 or more for a given transformer. These are constructed with transmission-line techniques.

It is worth noting that transformer coupling provides *galvanic isolation*: input and output circuits need not share the same ground. This is particularly useful when you need to send a signal (or distribute a "house clock") between instruments whose individual cases are each grounded through their power cords or enclosure rails. We have seen several instances in which instrument "ground," in the same laboratory, differed by as much as *several volts* of 60 Hz ac. Here an isolated 50 Ω:50 Ω broadband transformer is ideal, for example the Mini-Circuits FTB1-6 (10 kHz–125 MHz) or the North Hills 0016PA (20 Hz–20 MHz).

H.2.4 Reactive (lossless) narrowband matching networks

You can match *any* pair of impedances, real or complex, with just two reactive components. The resulting match is perfect only at a single frequency, but "good enough" over some modest band of frequencies. This can be considered an alternative to (broadband) transformer matching, with considerably greater flexibility in target impedances. It is worth noting that a lossless match between impedances that are not purely real (i.e., that have a reactive component) will always be narrowband.

The simplest reactive matching network is an L-network with one inductor and one capacitor (Figure H.13). You can choose either the inductor or the capacitor as the parallel element, but the network must have the parallel reactance located across the port with the larger impedance. The design procedure is straightforward, and is nicely motivated and explained in Hagen (see Appendix N). It amounts to choosing the parallel reactance to produce (in combination with the higher port's impedance R_{high}) the correct lower resistance R_{low} as its real part, then using the series reactance to cancel the resulting reactance.

The procedure goes like this.

1. Calculate the quantity

$$Q_{\text{EL}} = \sqrt{\frac{R_{\text{high}}}{R_{\text{low}}} - 1}$$

(this will be twice the actual Q value, or frequency selectivity, of the matching network).

2. Now select the form of parallel reactance (i.e., inductor or capacitor), and set the magnitude of its reactance equal to $R_{\text{high}}/Q_{\text{EL}}$ at the center frequency. In other words, $L_{\text{parallel}}=R_{\text{high}}/2\pi f Q_{\text{EL}}$ or $C_{\text{parallel}}=Q_{\text{EL}}/2\pi f R_{\text{high}}$, respectively.
3. Finally, set the magnitude of the series reactance (i.e., capacitor or inductor, respectively) equal to $Q_{\text{EL}}R_{\text{low}}$ at the center frequency. In other words, $C_{\text{series}}=1/2\pi f Q_{\text{EL}}R_{\text{low}}$ or $L_{\text{series}}=Q_{\text{EL}}R_{\text{low}}/2\pi f$, respectively.

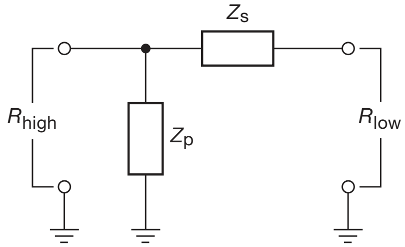

Figure H.13. Lossless reactive impedance-matching L-network.

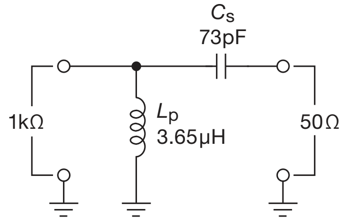

Figure H.14. Example of lossless network to match a 1 kΩ source impedance to a 50 Ω load, at a center frequency of 10 MHz.

As an example, let us match a 1000 Ω source (an amplifier output) to a 50 Ω load (an antenna) at a frequency of 10 MHz. We find Q_{EL}=4.36, and, choosing a parallel inductor at the input, L_{parallel}=3.65 μH and C_{series}=73 pF (Figure H.14). The Q of the resultant coupled network is equal to Q_{EL}/2, roughly $Q \approx 2$; its bandwidth is thus about 50% between half-power points, though the match is perfect only at the center frequency. Note that the Q rises with increasing impedance ratio, and that you have no control over it. The network becomes a narrow bandpass filter for very large impedance-transformation ratios.

If you want a higher Q, you can get it by adding another reactive component, to form a Pi (or T) network. You can think of this as a pair of L-networks, going to an intermediate impedance that is much lower (or higher) than either port impedance. Each L-section then has an impedance ratio greater than the final transformation, hence the higher Q value. You might think narrow bandwidth is bad, but in fact it is often desirable in communications circuits where you want to suppress out-of-band signal energy.

Alternatively, you can get lower Q than the simple L-network gives you by cascading a pair of Ls – a "double L." Here the impedance transformation is taken in two half-steps – each section's ratio is smaller than the final ratio, hence a lower Q.

H.3 Lumped-element delay lines and pulse-forming networks

The continuous transmission line with inductance and capacitance per unit length of L/l and C/l, respectively, can be approximated by an array of N discrete series inductors L and shunt capacitors C (Figure H.15). It is easy to show that the resultant circuit approximates a transmission line whose propagation time per element is $\tau_i{=}\sqrt{LC}$, and whose impedance is $Z_0{=}\sqrt{L/C}$; the total propagation time is $t_p{=}N\tau_i{=}N\sqrt{LC}$.

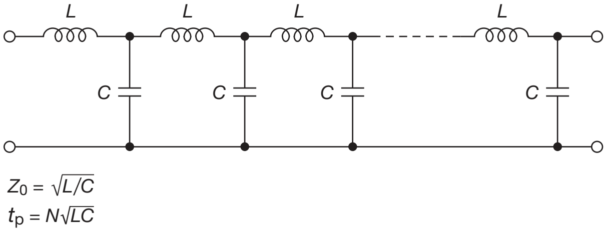

Figure H.15. Lumped-element delay line formed with an array of equal-value capacitors and inductors.

You can make a delay line this way, approximating a long transmission line. Roughly speaking, such a discrete approximation to a continuous transmission line will preserve details of the waveform only down to time scales of τ_i, or $1/N$th of the total propagation time. For example, a $1\,\mu$s lumped delay line with 20 LC sections will swallow details shorter than about 50 ns. It is a lowpass filter that attenuates frequencies above $f{=}1/2\pi\sqrt{LC}$.

Lumped-element delay lines were used in early analog oscilloscopes to allow time for the sweep to begin before the (delayed) signal reached the deflection circuitry; this let you see the triggering event (and a bit before). Later analog scopes used lengths of a helical-conductor coaxial line for the same purpose. Take a look at §H.4.3 for a bit more on this fascinating application.

Lumped delay lines are useful as *pulse-forming networks*, as shown in Figure H.16. Here the parallel capacitance of a set of LC delay sections is charged to a high positive voltage; then the "center conductor" of the coax equivalent is switched to ground with a high-voltage switching element such as a thyratron. The common terminal (analogous to the coax "shield") then produces a negative voltage pulse, of duration equal to *twice* the delay-line propagation time; its source impedance is just that of the delay line. This can drive a load directly; often it is converted to a different amplitude (and perhaps opposite polarity) with a pulse transformer, as shown. Pulse-forming networks find use in radar and other applications in which the pulse voltage and/or duration are inconvenient to produce with the analogous transmission-line circuit.

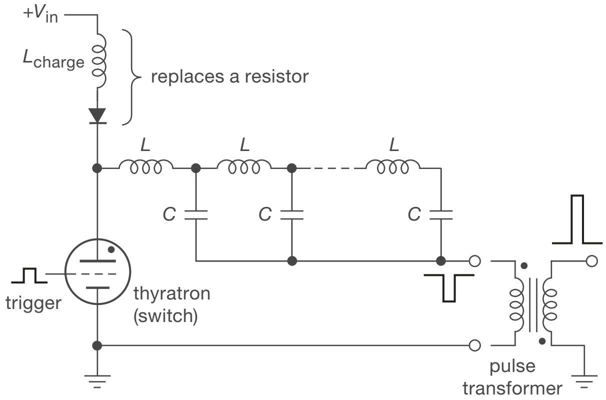

Figure H.16. Pulse-forming network for producing a high-voltage pulse of high energy. The thyratron is a special type of vacuum tube, containing a small amount of hydrogen or other gas, designed for switching really high voltages and high currents (10s of kV, 1000s of amperes: 10s of megawatts!). The inductor–diode fragment shown is a way to implement efficient "resonant charging" of a capacitor from a fixed dc voltage.

Shown also in this diagram is the method of "resonant charging," in which an inductor L_{charge} plus diode replaces the conventional charging resistor for the purpose of charging a capacitor C_{total} (the N capacitors in parallel). This has several benefits: (a) the charging wastes no energy, whereas resistive charging wastes exactly 50%; (b) it is complete after a time equal to half the period of the resonant circuit formed by L_{charge} and C_{total}; and (c) it charges the capacitor(s) to twice the supply voltage. Resonant charging is a clever technique, and it is used also in switching converters and power supplies, flashlamp circuits, and elsewhere.

H.4 Epilogue: ladder derivation of characteristic impedance

In a formal course on "waves" you are usually subjected to an analysis that uses Maxwell's equations to derive the relationship between the traveling $\vec{E}$ field and $\vec{B}$ field, from which follows the relation between voltage and current, and hence impedance. As a bonus you get the capacitance and inductance per unit length, and the speed of propagation.

But there's a nice "circuit" way to convince yourself that a properly terminated transmission line looks like a pure resistance (equal in value to its "characteristic impedance," for example 50 Ω), namely to model it as a discrete *LC* ladder (Figure H.17) consisting of little increments of length δx, each having a series inductance $\mathscr{L}\,\delta x$ and shunt capacitance $\mathscr{C}\,\delta x$, where $\mathscr{L}$ and $\mathscr{C}$ are the inductance and capacitance per unit length of the coaxial line. There are $l/\delta x$ of these in the whole length l of the line.

H.4.1 First method: terminated line

We start[8] by writing down the impedance looking into the last section of a terminated line ($\mathbf{Z}_1$ in Figure H.17), which will give us a condition on the ratio $\mathscr{L}/\mathscr{C}$ in order for $\mathbf{Z}_1$ to equal, approximately, R_0. Then we'll see that the impedance $\mathbf{Z}_{\text{in}}$ looking into the whole ladder converges exactly to R_0 as we convert the discrete ladder approximation to a continuous transmission line by taking the limit as δx goes to zero.

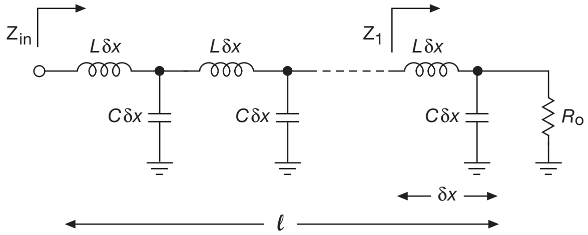

Figure H.17. *LC* ladder model of a transmission line of length l. We're ultimately interested in the limit $\delta x \to 0$, where the number of sections $N{=}l/\delta x \to \infty$.

Let's do it. $\mathbf{Z}_1$ is just the impedance of $\mathscr{L}\,\delta x$ in series with the parallel impedance of R_0 and $\mathscr{C}\,\delta x$:

$$\mathbf{Z}_1 = j\omega\mathscr{L}\delta x + \frac{R_0\cdot(-j/\omega\mathscr{C}\delta x)}{R_0 - j/\omega\mathscr{C}\delta x}$$

$$= j\omega\mathscr{L}\delta x + \frac{R_0}{1+j\omega\mathscr{C}R_0\delta x}$$

$$\approx R_0 + j\omega\delta x(\mathscr{L} - R_0^2\mathscr{C}),$$

where in the last step we've kept only the first term of the binomial expansion, i.e., $1/(1+\varepsilon)\approx 1-\varepsilon$.

The second term vanishes when $\sqrt{\mathscr{L}/\mathscr{C}}{=}R_0$, which is the formula for the characteristic impedance of a transmission line. But... not so fast – that term would have vanished anyway as $\delta x \to 0$; however, our transmission line would have vanished as well! What we need to do is to include the next-order binomial terms, and see what happens as we let δx go to zero, while holding the total line length l constant; the number of sections then increases, as $N{=}l/\delta x$.

You can do the math. You'll find that the next two terms add contributions[9] of order δx^2 and δx^3, making $\mathbf{Z}_1$ look like

$$\mathbf{Z}_1 \approx \left\{R_0 + \mathscr{O}(\delta x^2)\right\} + j\left\{\omega\delta x(\mathscr{L} - R_0^2\mathscr{C}) + \mathscr{O}(\delta x^3)\right\}$$

and so, cascading N such sections (where $N{=}l/\delta x$), with the condition $\sqrt{\mathscr{L}/\mathscr{C}}{=}R_0$, the higher order terms vanish as $\mathscr{O}(\delta x)$ and $\mathscr{O}(\delta x^2)$ (for the real and imaginary parts, respectively) as $\delta x \to 0$. Thus the input impedance of a transmission line of length l, terminated in its characteristic impedance (resistance) R_0, is pure resistive and equals R_0.

H.4.2 Second method: semi-infinite line

Here's a clever method[10] that doesn't require approximation or worries about convergence. The idea is to look into one end of a lumped-element transmission line that extends to infinity (Figure H.18), noticing that it looks just the same if we step one notch to the right. So, calling the (complex) input impedance $\mathbf{Z}_0$, we have, simply,

$$\mathbf{Z}_0 = j\omega L + \mathbf{Z}_0 \parallel \mathbf{Z}_\mathbf{C} = j\omega L + \frac{\mathbf{Z}_0\cdot(-j/\omega C)}{\mathbf{Z}_0 - j/\omega C}.$$

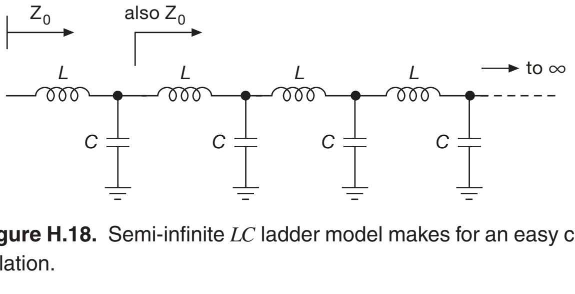

Figure H.18. Semi-infinite *LC* ladder model makes for an easy calculation.

[8] This treatment was inspired by Hagen's *Radio Frequency Electronics*; see Appendix N.

[9] They are $-R_0^3\omega^2C^2\delta x^2 + jR_0^4\omega^3C^3\delta x^3$, if you want to check your math (or ours!).

[10] Suggested to us by Jene Golovchenko.

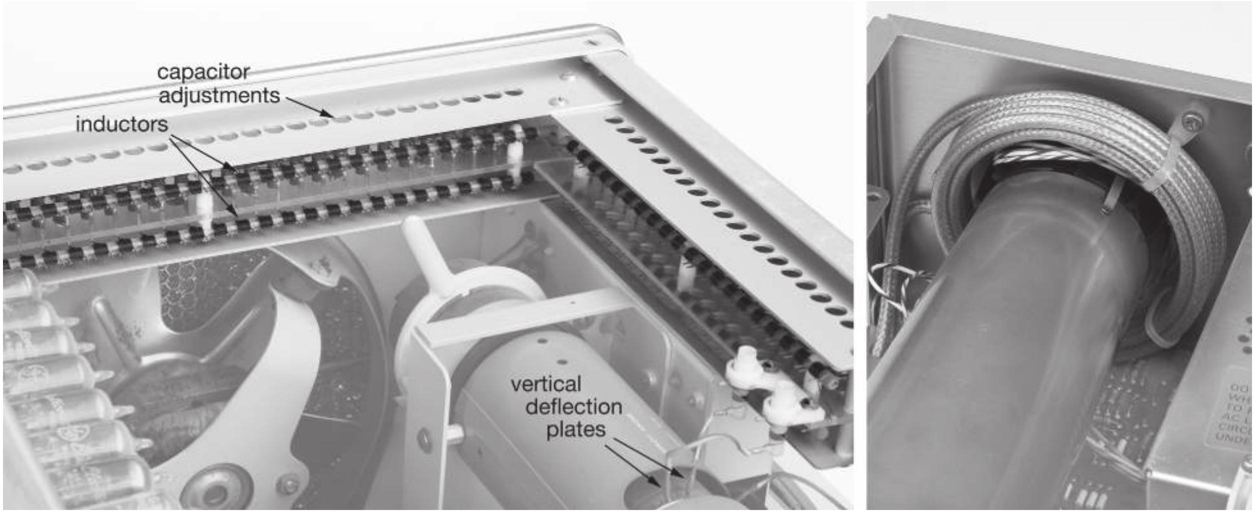

Figure H.19. Analog oscilloscopes used delay lines in the signal path, so you could see the triggering event. The 1959-vintage vacuum-tube Tektronix 545A (left) had a 30 MHz bandwidth, and used a two-channel lumped-element 200 ns delay line consisting of 50 inductor pairs and 50 (adjustable!) trimmer capacitors; (Figure H.20); their 1982 vintage solid-state 2213 'scope (right) had 60 MHz bandwidth, and used a 2.5 m length of spiral-conductor coaxial cable for its 100 ns delay line.

Multiplying through by the denominator of the last term and rearranging terms, we get a quadratic equation for $\mathbf{Z}_0$:

$$\mathbf{Z}_0^2 - j\omega L\mathbf{Z}_0 - L/C = 0,$$

with the solution

$$\mathbf{Z}_0 = j\omega L \pm \frac{\sqrt{4L/C - \omega^2 L^2}}{2}.$$

Now for the *coup de grâce*: we let the individual segments shrink toward zero while keeping the full line length. The individual L's and C's go to zero, but their ratio remains constant. Only the $4L/C$ term survives, giving us the (real) impedance $\mathbf{Z}_0 = \sqrt{L/C}$. No approximations!

H.4.3 Postscript: lumped-element delay lines

The clever designers of analog oscilloscopes, back in the dark ages of electronics, found a way to get the horizontal trace going *before* the triggering event, namely by delaying the displayed signal by ~100 ns, using a delay line.[11] The designers of early vacuum-tube 'scopes (like the legendary Tektronix 545A) used a lumped-element transmission line like the one in Figure H.19 to achieve the delay (200 ns in this case) that otherwise would have required more than 100 feet of cable; presumably they also felt some satisfaction in exploiting the theory they learned in an electronics course they had taken years earlier.[12] Later analog 'scopes replaced the lumped-element delay line with a cleverly engineered coax delay line with a pair of spiral inner conductors; its larger inductance per unit length increased the signal delay,[13] and, happily, increased the characteristic impedance as well. The photograph shows an example, where the cable has been stuffed into an empty space at the rear, conveniently wrapped about the CRT.[14] Figure H.21 reveals the inner secrets of this elegant differential-pair delay line, whose crisscrossing counterwound helical "center conductor" produces a delay of 12 ns/ft. And Figure H.22

[11] Digital 'scopes finesse this problem by using digital memory to store some pretrigger digitized samples.

[12] The capacitors in Figure H.19's lumped-element delay line are in fact connected to the *midpoint* of each inductor, as can be seen in the official schematic of Figure H.20. It turns out that this is a more efficient implementation of a finite lumped line, as explained to us over a dinner of fine conversation and Persian cuisine by Larry Baxter ("Mr. Capacitive Sensors"; see the book by the same name).

[13] By a factor of πnD, approximately, where n is the number of turns per unit length and D is the spiral diameter. Because the coarse-pitch spiral is closely surrounded by the shield, you can think of the signal as propagating, corkscrew fashion, *along* the spiral; that approximation then gives you this simple expression, without the need to calculate the inductance and capacitance per unit length.

[14] That's *cathode ray tube*, for those born in this millennium, and thus deprived of the opportunity to admire one.

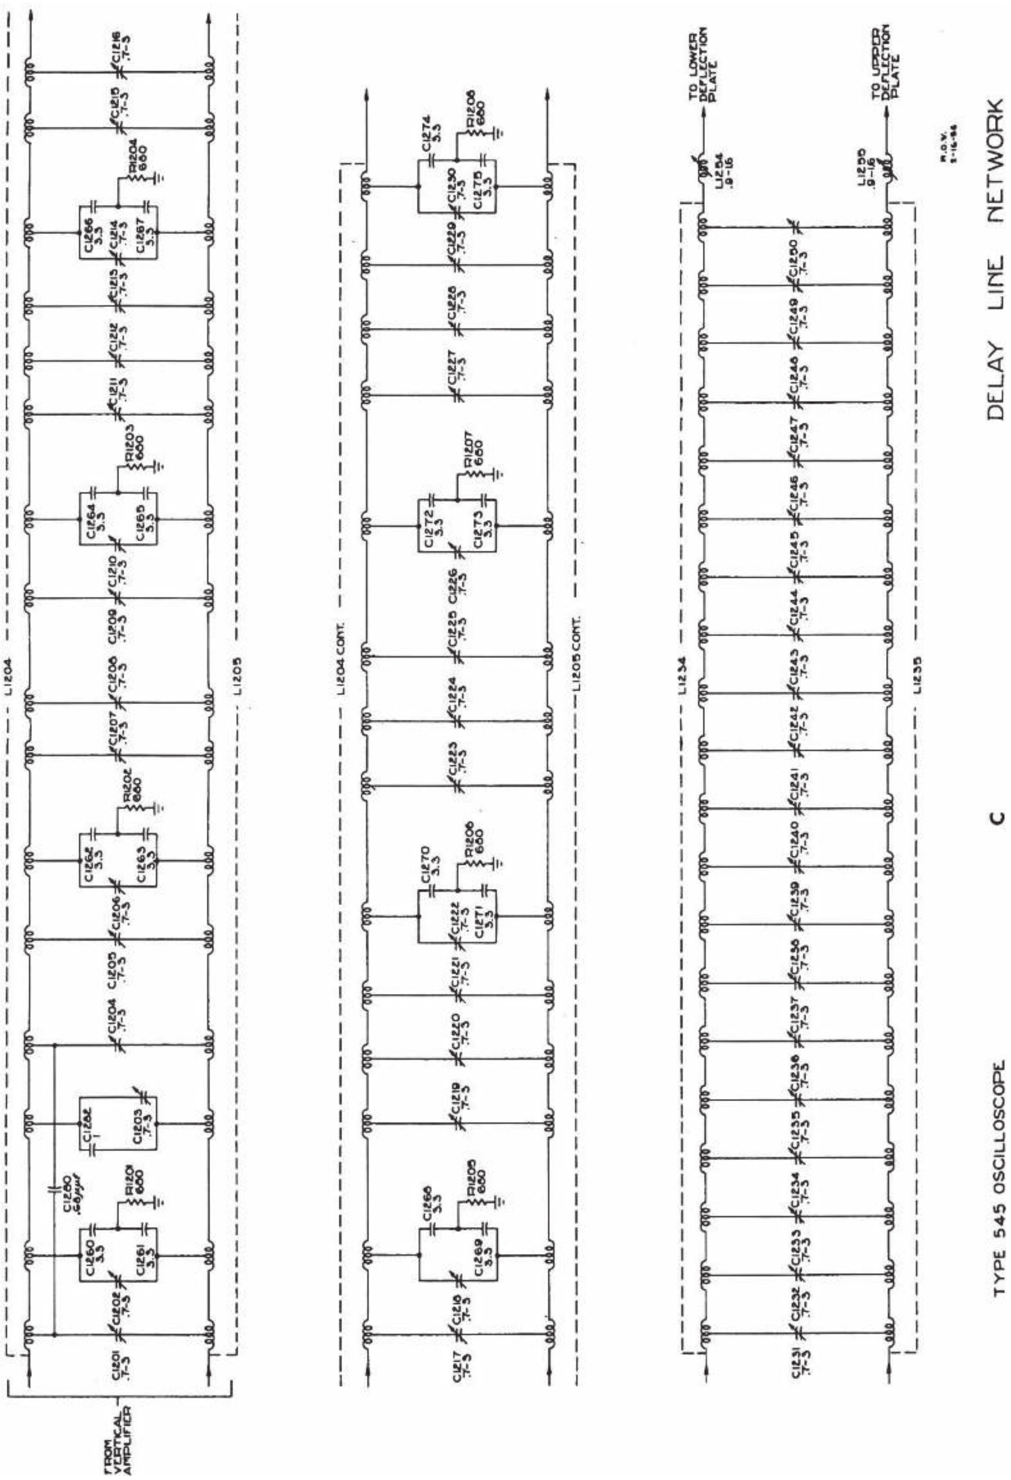

Figure H.20. Working hard to achieve perfection: Tektronix used fifty inductor pairs and fifty trimmers for the delay line in their type 545 ’scope (pictured in Figure H.19) from the 1950s. Reproduced with permission of Tektronix Inc.

shows the observed delay when a differential triangular pulse-pair waveform, launched into one end, is received at the other end.

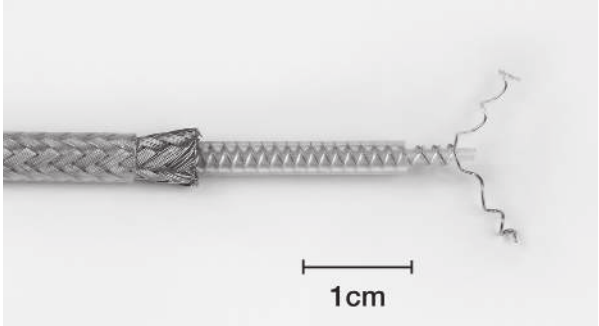

Figure H.21. We borrowed a Tektronix 2213 carcass from Brian Shaban, and, after a bit of surgery, look what we found inside! We measured a 100 ns delay, and a differential impedance of 155 Ω, for the 8.5 ft cable that used to live in this 'scope. The counterwound helix consists of two insulated 30 ga wires, with a pitch of 1.125 mm and an average diameter of 2mm, insulated from the surrounding braided shield of 3.25 mm inside diameter.

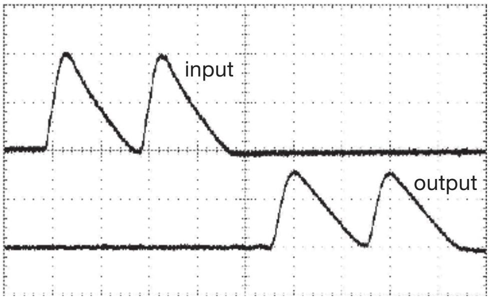

Figure H.22. We launched this analog waveform down the cable of Figure H.21 (well, what remained of it, anyway) to see the signal delay of ∼95 ns. The delayed signal is of good fidelity, with a test signal bandwidth somewhat greater than that of the 60 MHz 'scope. Vertical: 1 V/div; horizontal: 20 ns/div.

TELEVISION: A COMPACT TUTORIAL

APPENDIX I

This appendix evolved from a tutorial, originally written for a nontechnical audience.[1] It is organized as follows:

Television: video plus audio
Combining and sending the audio + video: Modulation
Recording analog-format broadcast or cable television
Digital Television: what Is it?
Digital Television: broadcast and cable delivery
Direct satellite television
Digital video streaming over internet
Digital cable: premium services and conditional access
Digital cable: video-on-demand
Digital cable: switched broadcast
Recording digital television
Display devices (CRT; LCD; plasma; OLED)
Video connections (analog; DVI/HDMI; DisplayPort)

I.1 Television: video plus audio

¶ 1. Television involves the remote delivery of a moving picture plus sound. It is accurate to think of the *sound* as continuous; however, the *picture* is captured, and then delivered, as a succession of still images, at a rate fast enough that the viewer perceives a scene of continuous motion.[2]

¶ 2. Television is distinguished further, of course, by the transmission of this movie-like content to the remote viewer. Originally this was carried out exclusively by terrestrial transmission, via radio waves, to the viewer's antenna and television set. Over time, other methods of transmission have been added – electrical cable,[3] optical fiber, direct satellite transmission via microwaves, and, of course, the Internet – along with recording methods such as magnetic videotape (Betamax, VHS, D-VHS), and optical discs (Laserdisc, VideoCD, DVD,[4] HD-DVD, Blu-Ray, and others).

I.1.1 The audio

¶ 3. The *audio* portion of television is perhaps more easily understood, as it differs little from ordinary sound-recording techniques. A microphone converts the instantaneous sound pressure variations into an electrical signal; that is, it creates as its output an electrical voltage that at each moment is proportional to the pressure of the sound wave to which it is exposed. Contemporary audio recording and delivery usually employs two or more microphones, creating "stereo" sound (i.e., two channels), or multichannel sound (e.g., "5.1 channel sound").

¶ 4. Traditionally these signals were processed, stored, and delivered by "analog" methods, which means simply that the signals were treated as smoothly varying voltages as they passed through the electronic innards of the amplifiers, recorders, modulators, and so on.[5] Contemporary "digital" technology does it differently: almost as soon as possible, the microphone's signal (the varying voltage that represents the sound) is converted to a succession of numbers (it is *digitized*), and everything that follows is some form of arithmetic on this torrent of numbers that come tumbling out. Only at the final stage – recreating the recorded sound for the listener – is the digital representation converted back to an analog voltage, and then, in the loudspeaker, to a reproduction of the original sound pressure wave.

¶ 5. Just to give a sense of the quantity of numbers involved, in the standardized recording technology of the

[1] Following the stylistic conventions of that audience, the paragraphs are numbered sequentially.

[2] For conventional cinema-style movies, the rate is 24 frames/second; television in the United States uses a rate of approximately 30 frames/second.

[3] Known technically as *coaxial transmission line*.

[4] "Digital Versatile Disc."

[5] Common analog recording technologies, now nearly obsolete, include the vinyl record (where the audio signal waveform is embossed as small displacements of a fine groove), and the audio cassette tape (where the audio signal waveform is recorded as patterns of magnetization on a thin layer of magnetic oxide coating on a flexible plastic tape).

compact disc (CD), the instantaneous sound is *sampled* at a rate of 44,100 times per second (in both stereo channels simultaneously), and each such sample pair is converted ("digitized") to a 16-bit binary number.[6] So the bits are tumbling out at a rate of $2\times 44{,}100\times 16 = 1{,}411{,}200$ bits per second, or nearly 100 million bits per minute.[7]

¶ **6.** One might ask why any sane person would want to deal with such a quantity of numbers, when the original analog representation of the sound was so much simpler – just a pair of voltages that were varying at most 20,000 times per second.[8] The reasons are several, but they boil down to the contemporary ease and economy of digital processing, combined with the higher efficiency and quality of storage and transmission of audio (and video) that has been properly digitized. To get a sense of those advantages, one need only marvel at the gorgeous images transmitted daily from planetary probes visiting Mars and Saturn – images that are free of "snow" and other artifacts irreparably added to analog transmission by the effects of unavoidable electrical interference – to appreciate the benefits of error-free digital transmission. And, to get a sense of the density of digital storage, we note that a contemporary 5″ optical disc (dual-layer Blu-ray disc) holds 80 hours of CD-quality audio, or ten times that amount if modestly "compressed," compared with a mere hour's storage of analog audio on the 12″ vinyl LPs of yesteryear.[9]

I.1.2 The video

¶ **7.** The *video* is by far the more complicated part of television. The challenge is to reproduce a scene with motion, in color, while preserving adequate fidelity and absence of artifacts. And this must be done within the resources of the storage and delivery channels – that is, with finite disk storage and speed, and with finite transmission (via broadcast tower, cable, Internet, or satellite) *bandwidth*.[10]

¶ **8.** Video systems begin with a camera that has an electronic sensor (analogous to a digital camera) and that converts the two-dimensional color scene on that sensor into a succession of *frames*, each of which represents the image at those successive times (for US TV, the rate is approximately 30 frames per second). In traditional *analog* television, the two-dimensional image is converted into an electrical signal by the following method: imagine a single frame, that is, a still picture. To keep it simple, imagine further that it is monochrome; that is, "black and white."[11] We begin at the upper left, and move horizontally across the picture, generating an electrical voltage proportional to the brightness at each point as we pass by. When we reach the right-hand border, we jump back to the left edge, continuing with another horizontal path, slightly below the first. See Figure I.1. We continue in this way until we reach the bottom right-hand corner, at which time we have scanned the entire frame once, in what is known as a *raster* ("grid" in German) pattern.[12]

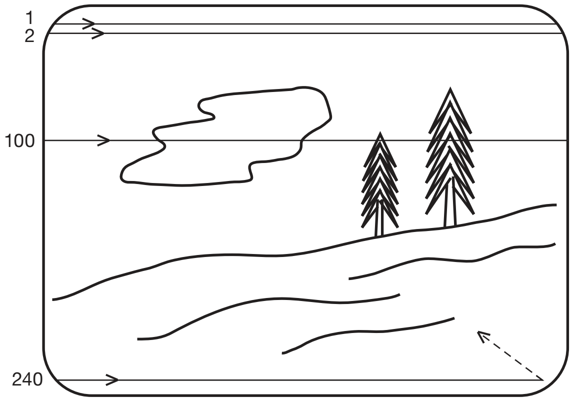

Figure I.1. A static two-dimensional image is "raster scanned" to create a video waveform (Figure I.2) representing intensity along the scan lines.

¶ **9.** What we have done, then, is to generate an elec-

[6] That is, a number ranging from −32768 to +32767, those bracketing the "full-scale" range of the recorded sound.

[7] The *recorded* bitrate is roughly triple this figure because of coding, error-correction redundancy, and the like.

[8] Or 20 kHz, the upper limit of human hearing; and that only for one of relative youth, such youth further possessed of sufficient wisdom to avoid deafening rock concerts.

[9] And a contemporary 3 terabyte 3″ magnetic hard drive that you can hold in your hand holds yet another factor of 60, or 50,000 hours of excellent quality (128 kbps AAC) compressed stereo audio; that's 15 years of 40-hour per week music!

[10] *Bandwidth* refers to the range of frequencies that can be carried on the cable or other transmission medium. It is technically accurate to think of this, for example, as the range of stations on the radio dial that could be carried with fidelity by a single electrical cable (or other medium). The term is sometimes used loosely to refer to rate of data transfer.

[11] Or, more accurately, *grayscale*.

[12] Traditional standard definition television (SDTV, usually called "NTSC," for National Television System Committee, and going back to the 1940s) in the United States divides the whole picture into 480 horizontal lines, along each of which roughly 640 features (picture elements, or *pixels*) could be resolved; a computer user would not be terribly impressed – he or she would say that standard NTSC television has only "VGA" resolution (i.e., 640×480).

trical representation, in time (a varying voltage proportional to brightness at each point in the image) of a single two-dimensional image; that is, we've converted a two-dimensional image into a one-dimensional output voltage. See Figure I.2.

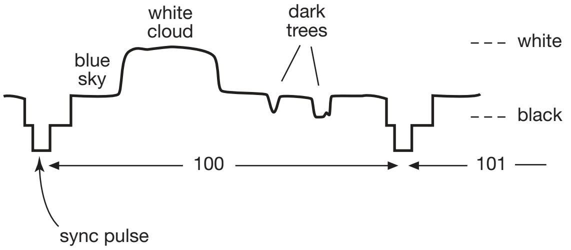

Figure I.2. A portion of the video waveform from Figure I.1, representing one of the 240 horizontal scan lines.

¶ **10.** This time-varying voltage is called the *video* signal, and it is the first step in creating a television image. In traditional NTSC analog television, this signal was transmitted by analog methods, after a process called *modulation* (more later), and was recovered and used by the television set to paint the picture on the screen, performing the same raster scan (left to right, top to bottom). Each frame follows in sequence, presenting a succession of 30 pictures per second on the television set's viewing screen.[13]

¶ **11.** To complete the video signal, it is necessary to add some synchronizing information, so the television set knows when to begin painting a frame, and also when each horizontal line begins. In traditional NTSC television this is done by adding a horizontal *sync pulse* at the beginning of each horizontal line, which is just a short[14] voltage pulse that, if it were in the middle of a picture, would be interpreted as "blacker than black." See Figure I.3 The television set detects these pulses and uses them to synchronize its scanning across each line. Likewise, a unique *vertical sync pulse* is transmitted for each field which informs the television set when to return to the top to begin painting the next field or frame (see Figure I.4. The complete video picture signal, with its added sync pulses, is called *composite video*.

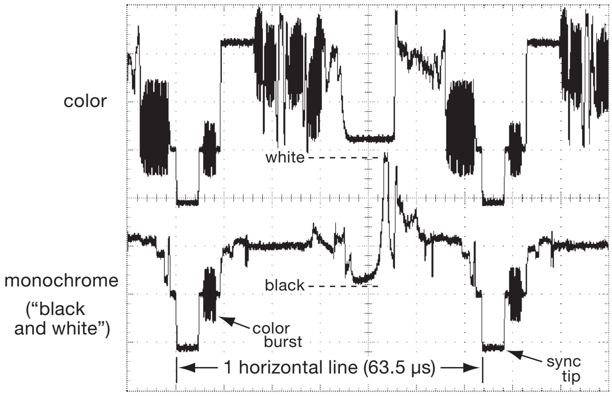

Figure I.3. Composite analog video signal of one horizontal line, framed by horizontal sync pulses. The brightness ("luminance") is represented by its amplitude. Color is accommodated by adding a modulated 3.58 MHz "chrominance" subcarrier, whose amplitude represents degree of saturation and whose phase encodes the colors.

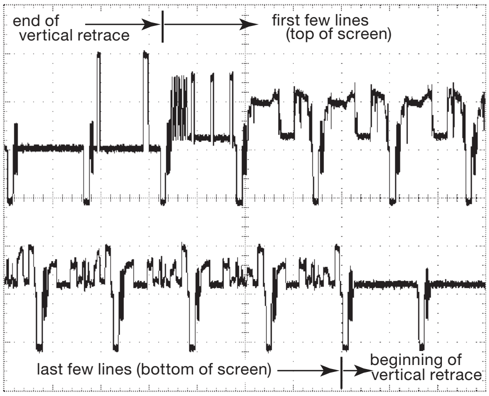

Figure I.4. The vertical retrace (beginning of a new field) is signaled by a set of tailored sync pulses, the first and last of which are shown here.

I.2 Combining and sending the audio + video: modulation

¶ **12.** Continuing for the moment with traditional NTSC television (as opposed to *digital* television, whose standards are known as *ATSC*, set by the Advanced Television Systems Committee, and which will be explained later), the composite video, along with the audio, must now be

[13] To complicate things, NTSC uses a method known as *interlacing*, in which a coarser raster – omitting every other horizontal line – is performed at twice the rate. Thus, in standard NTSC US television, the viewer sees 60 pictures ("fields") per second, each of which has only 240 horizontal lines; two such fields, with their interlaced lines, form one complete 480-line frame. This is sometimes called a "480i" format, to distinguish it from formats with higher resolution (e.g., high-definition TV, HDTV, with 720 lines or 1080 lines, or "4K Ultra HDTV," with 2160 lines), or from those without interlacing (which are known as *progressive*; e.g., *720p*).

[14] About 4.5 millionths of a second.

sent, via transmitting tower or cable, to the home viewer. Naively one might think of simply transmitting these signals "as is." This is not done, however, for at least two reasons: first, if the composite video signals were transmitted directly, then any two television signals would overlap and jam each other (because they would all share the same frequency band, namely that of the raw video signal itself); second, some wavelengths are more conveniently generated and propagated than others. For these reasons, the audio and video content of television signals (and, indeed, all communications and broadcast signals) are instead used to vary some aspect of a "carrier" wave, chosen at some specified wavelength. That carrier wavelength (or, equivalently, frequency) defines the "channel"; and the process of impressing the information (video and audio) onto the carrier wave is known as *modulation*.

¶ 13. Radio stations use the same technique: AM stations vary the strength (amplitude) of the carrier (hence "amplitude modulation"), whereas FM stations vary the frequency ("frequency modulation"). The carrier frequency itself defines the channel: in the US, AM stations are assigned to carrier frequencies between 520 and 1710 kilohertz (kHz, thousands of cycles per second), while FM is assigned to the band of carriers from 88 to 108 megahertz (MHz, millions of cycles per second). In the US, broadcast television begins at 54 MHz (Channel 2), and ends at 698 MHz (Channel 51), with gaps for FM, aeronautical, and other services.[15]

¶ 14. When information (video, for example) is modulated upon a carrier, the resultant signal spreads out and occupies a small band of frequencies. For example, when an FM station varies the frequency of its assigned carrier to carry its audio signal, the resulting signal occupies about 150 kHz. So FM stations are assigned channels separated by 200 kHz (to allow a "guard band" of 50 kHz in addition to their 150 kHz signal) – and that is why the frequencies of FM stations always end in an odd number after the decimal point (for example New York City's WNYC is at 93.9 MHz), ensuring a minimum spacing of 0.2 MHz (= 200 kHz).

¶ 15. Traditional analog NTSC broadcast television used a variant of AM for the picture signal (composite video) and, separately, FM for the sound signal.[16] The assigned TV channels are spaced apart by 6 MHz, each station being permitted to occupy nearly that amount, after allowing for a small guard band. Television sets "know" the frequencies allocated for each channel and tune to the correct frequency when the user chooses the channel number. For example, if (during television's analog era) one tuned to Channel 13 in the New York City area, the television set's electronics selected the station transmitting on 210 MHz (assigned by the FCC as Channel 13), namely WNET. The electronics in the set *demodulates* the received signal, recovering composite video and audio. The video, with its embedded sync signals, is used to paint the picture, frame after frame, while the audio is sent to the loudspeakers.[17]

¶ 16. Broadcast television (and radio) takes place on what is often called the "public airwaves." One needs only a television set (or radio) and an antenna to receive these over-the-air (OTA) public transmissions. Although some countries require licensing of receiving devices (radios and television sets), in the United States the broadcast services are freely available to anyone within range of a transmitting tower.

¶ 17. Depending on the distance and path from the broadcast station to the viewer, the "antenna" can be as simple as an indoor "bowtie" or pair of "rabbit ears," or as elaborate as a roof-mounted multi-element structure. Whatever its form, the antenna's function is to create an electrical signal on the feedline, induced by the speed-of-light broadcast signal passing by the antenna's site. Receiving antennas intended for broadcast television are designed to work over the range of frequencies used by broadcasters (see ¶13); thus the electrical signal delivered to the television set includes multiple stations, and it is the job of the TV tuner to select and process the channel to be viewed.

¶ 18. *Cable* television sends traditional analog TV channel signals in almost exactly the same way as broadcast. An evident difference, however, is that the channelized signals are received at the viewer's end from a coaxial cable (rather than being received by the viewer's television antenna), and then connected to the television set directly (i.e., to its normal antenna connector on the rear). Alternatively, for additional cable services (such as premium channels) the incoming cable connects to a "set-top box" (STB) provided by the cable company, the output of which is connected to the viewer's television set (or flat-screen monitor,

[15] You can download a gorgeous multicolor wall-sized spectrum allocation figure from `http://www.ntia.doc.gov/files/ntia/publications/spectrum_wall_chart_aug2011.pdf`.

[16] That is, the picture and sound signals are carried simultaneously on a pair of designated carrier frequencies within the single assigned television channel.

[17] In this primer we have ignored details associated with reproduction of *color* (versus black and white).

projector, etc.; see ¶56ff).[18] The channel *frequencies* are also somewhat different, with Channels 2–13 chosen the same as for terrestrial broadcast, but with the remaining channels reassigned to eliminate gaps; this can be done because the cable is a private world of its own, isolated so as not to interfere with, or be interfered by, other broadcast services.

¶ 19. A third difference is that some of the cable content is delivered as a subscription, for which the viewer pays additional fees; examples are premium services such as Home Box Office (HBO). These require some method for permitting or denying viewable delivery of selected channels or programs. Continuing for the moment with analog cable (whose days are numbered!), this can be done in several ways: the simplest is by installing filters (to block unsubscribed channel frequencies) at the utility pole, where the subscriber's cable splits off from the trunk running along the street;[19] A more sophisticated method involves scrambling the cable-borne analog signals of subscription programs,[20] and then instructing the set-top box (via digital communication from the cable provider to the individual STB) as to which programs may be unscrambled.

¶ 20. It is worth noting that cable companies have been required to carry the broadcast stations in their area, normally as analog cable channels.[21] Each such program occupies a cable channel (frequency). However, they may distribute additional services via digital methods ("digital cable") on additional channels (frequencies), which they much prefer; that is because, with digital methods, it is possible to carry up to *ten* NTSC-quality programs (i.e., SDTV, for Standard-definition TV) on a single channel. This is called *multicast*: the ability to carry multiple *programs* on a single channel (i.e., frequency). And, note that a cable can carry more than 100 such carriers – permitting more than 1000 simultaneous programs.

¶ 21. Previewing some additional characteristic of digital television: digital cable permits flexible subscriptions, with a program being authorized on-the-fly (e.g., pay-per-view, or video-on-demand). It also provides a natural mechanism for content protection via encryption. It allows for interactive participation, via a reverse channel back to the cable provider. It permits the delivery of high-definition content, with more than the 480 lines of NTSC (up to 1080 lines, at the highest quality currently supported). Finally, it provides a natural way to time-shift, pause, or replay live programs, via computer-type hard-disk storage.

¶ 22. Analog broadcast was sent into retirement in the United States in June of 2009, and all television broadcast delivery is now done by digital methods (more to follow). This conversion-to-digital process is taking place worldwide and will likely be complete by 2020 or earlier.

I.3 Recording analog-format broadcast or cable television

¶ 23. Video recording was complex and costly (and therefore confined to the broadcast studios) until 1975, when home video-recording devices were introduced in the US by Sony ("Betamax") and its competitors ("VHS," for video home system). These devices replicate the "front end" of a television set, to recover video and audio from the incoming signal (broadcast or cable), and use a clever spinning tape head arrangement[22] to capture on magnetic tape a reasonable replica of an NTSC analog television program. The technique is entirely analog (no digitization, no numbers) and records only onto special video-tape media (no computer media, no hard disks, etc.), as a magnetic recording (analogous to an analog audio tape recording; see the footnote at ¶4).

¶ 24. Videotape technology has been upstaged by digital alternatives such as optical disc recording (most famously in the form of DVDs and Blu-Ray discs – whether sold with prerecorded content, or recorded with a disk recorder), which creates a permanent copy of the video material; or by recording to a computer-type hard-disk drive (hdd), where the video copy is stored as a computer file. These digital methods require that the program material be converted from analog to digital form, if it is not already. (This is done internally and automatically in devices like TiVo®

[18] For better picture quality, the latter connection is usually made not to the set's antenna input (called "RF," for Radio frequency, meaning the modulated channels discussed above, in ¶¶12–15), but to special audio–video inputs, with names like *s-video*, *component video*, *composite video*, *DVI*, or *HDMI*; see ¶64ff. The latter pair are *digital* connections, discussed below in connection with digital TV.

[19] Vintage cable subscribers will remember calling the cable company to add a movie channel, whereupon a cable truck appeared, the cable guy went up the pole to fiddle with something (changing the filter), and, voilà, movies on your television!

[20] For example, by suppressing the horizontal sync pulses or inverting the video (interchanging black and white).

[21] Unless all subscribers are provided with STBs that can receive digital delivery.

[22] This is known as a "helical" tape head, which creates successive narrow slanted tracks across the slowly moving tape, each one holding one field of video. The use of a rapidly moving tape *head* eliminates the need for rapidly moving *tape*.

and other personal video recorders.) Digital television and digital video are discussed next.

I.4 Digital television: what is it?

¶ **25.** Just as an *audio* signal can be digitized (i.e., its instantaneous amplitude is measured, at rapid intervals, and converted to a succession of numbers), and subsequently transmitted, stored, or processed (¶¶4–6, above), so it is possible to digitize the *video* signal that represents successive frames of picture. Although one could imagine simply sending the digitized version of traditional NTSC as "digital TV," in practice one takes advantage of the enormous processing finesse of contemporary digital electronics to economize by *compressing* the raw video signal to a small fraction of its native size before it is delivered. The use of compression, along with the fact that a digital signal is "just numbers," permits the delivery of multiple programs on what would otherwise carry just a single video signal (program), typically by a factor of five to ten.

¶ **26.** There are several reasons for this improvement. One is the ability to detect and correct transmission errors by numerical techniques, allowing one to operate with received signal levels that are close to the "noise" (from interference, or signal loss owing to range or obstructions); with purely analog transmission a large received signal/noise ratio is necessary to reduce the visible effects of noise ("snow") to acceptable levels.

¶ **27.** A second reason is the spectral efficiency of digital transmission – or, more accurately, its improvement compared with the *inefficiency* of analog signaling. This can be seen in Figures I.5 and I.6, a pair of spectra taken directly off the home antenna of one of the authors in March of 2009, a time during the switchover to digital when both analog and digital broadcasts were taking place (see also Figure I.7).

¶ **28.** Compression aims to reduce by a large factor (tenfold or more) the quantity of numbers needed to describe the succession of picture frames, without significantly degrading the image quality. This seemingly impossible task takes advantage of redundancies in a moving picture, and of limitations in human visual perception.

¶ **29.** Contemporary digital-video compression is a rich and mathematically complex subject, the result of enormous effort in the applied mathematics and electrical engineering communities over the last several decades. But the basic tricks are easy enough to understand. The process begins by exploiting the fact that portions of an image near each other tend to be similar; so one can encode and send the (smaller) *differences* of brightness and color from a set of reference points, rather than the full description of brightness and color at each point. Likewise, successive frames tend to be similar, so one can define a sparse collection of index frames and send only the differences for intervening frames.[23] A further trick exploits the fact that the image often contains moving objects or a panning camera; so it is efficient to calculate "motion vectors" predicting

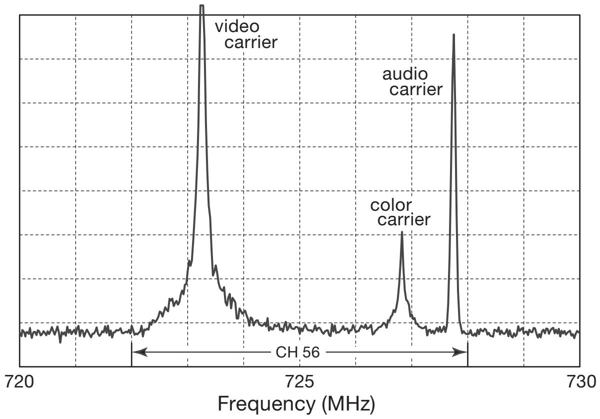

Figure I.5. The spectrum of 6 MHz-wide analog Channel 56 in Boston, as seen in May 2009. The video information resides in the sideband tails, while most of the transmitted power is wasted in the non-informational video carriers.

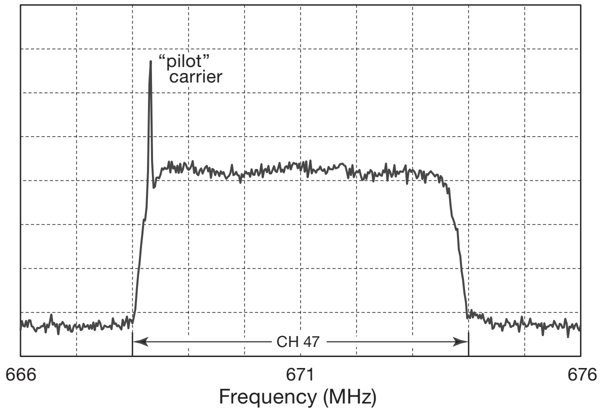

Figure I.6. Digital Channel 47, seen also in May 2009, fills its 6 MHz spectrum allocation with digitized video. It carries five times as many programs, with comparable (or better) picture quality.

[23] More precisely, it is the corrections from an *interpolated guess* between index frames (or reference points within a frame) that are sent.

the approximate motions, and then send only the (smaller) corrections from the predicted values.

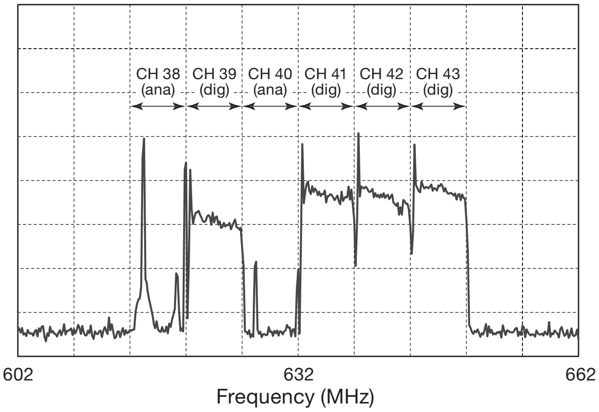

Figure I.7. A country in transition: RF spectrum of Channels 36–45 (each permitted 6 MHz of spectrum) as seen on our antenna feedline in Cambridge, Massachusetts, on May 6, 2009. Analog Channels 38 and 40 each carry one standard-definition (SDTV) program, whereas Digital Channels 39 and 41–43 can carry up to five SDTV programs each (though it's more common to see one HDTV and one SDTV program).

¶ **30.** These methods greatly reduce the needed bitrate (number of numbers per second), and they do so *without any loss of picture quality whatsoever* – they are "lossless." That is because the original digital image can be fully and exactly recovered by applying the numerical differences in the reverse order. However, further bitrate reduction is desirable (and often necessary), and this is accomplished by *lossy* compression. This consists essentially of discarding the less-important image information (from a psychovisual standpoint); the tradeoff is a somewhat degraded image (the degree of degradation depending on the degree of compression), which, however, can differ from the pristine original in ways that are hardly perceptible to the viewer.[24] The mathematics involves methods with names like discrete cosine transform, variable quantization, and Huffman coding; but the bottom line is that these methods permit a large reduction in bitrate with a relatively small reduction in perceived image quality.[25]

¶ **31.** The tradeoff of image quality with bitrate is gradual, and somewhere in the process a decision is made as to the desired final bitrate.[26] A major constraint is imposed by the fact that both digital broadcast and digital cable television in the US is sent on channels that conform to the same 6 MHz channel spacing that has been used for television since the 1940s. In practice (see ¶35, below) it is possible to send about 20 million bits per second (Mbps) on an over-the-air digital-broadcast channel, and nearly double that on a digital cable or satellite channel. A typical compressed bitrate for over-the-air NTSC-quality (SDTV) digital video is about 4 Mbps; thus digital-broadcast television stations are able to combine up to 5 or so NTSC-quality programs on a channel. (Recall that a frequency "channel" is no longer a single "program," because of multiplexing. More on this beginning at ¶33, below.) High-definition (HDTV) content requires nearly the full broadcast bitrate, so only one HDTV program can be broadcast on a channel. By contrast, cable or satellite systems, which are not constrained to MPEG-2 compression, are able to combine as many as eight HDTV programs onto one channel when using efficient H.264/MPEG-4 encoding. The second revision of the broadcast standard (ATSC 2.0) incorporates these more efficient codecs, as well as a host of transport and delivery enhancements that are aimed at mobile and interactive viewing, thus allowing over-the-air broadcasting to compete with services available on the internet.

¶ **32.** It is worth admiring the impressive bitrate reductions that these methods are achieving: a simple calculation[27] shows that digitizing an HDTV program without any compression would produce a bitrate of roughly 1000 Mbps, whereas contemporary compression methods reduce this to a modest (and deliverable) 20 Mbps, a 50-fold reduction! And comparable reductions are routinely achieved with SDTV.

[24] If such effects are noticeable, they are called *compression artifacts*; these are sometimes seen in over-compressed "jpeg" still photographs, as the patchy blocks or the "mosquito noise" around edges. Similar considerations apply to lossy audio compression, for example highly compressed "MP3" music files.

[25] The video-compression recipe currently used for all digital TV broadcasting in the US is named "MPEG-2" and described in the Advanced Television Systems Committee documents A/53 and A/54 (see www.atsc.org). An improved set of compression methods is incorporated in the set of standards known as MPEG-4; these are widely used by the cable and direct broadcast satellite services, as well as for video streaming over the internet.

[26] Which is permitted to vary, as program content changes. This is known as *variable bitrate*, or VBR, as distinguished from *constant bitrate*, or CBR.

[27] Bitrate $\approx$ 1080 lines × 1920 pixels/line × 30 frames/second × 16 bits/pixel = 995,328,000 bits/second.

I.5 Digital television: broadcast and cable delivery

¶ **33.** Over-the-air digital television broadcast and digital cable television both use traditional frequency "channels," upon which they put a stream of numbers (the compressed video described in ¶¶25–32, plus the associated digitized audio[28]), instead of the continuous analog waveform that was used in traditional NTSC television. Because of the economical bitrates produced by compression, there is adequate capacity on a single cable (or broadcast) channel frequency to accommodate several simultaneous programs. This is called multicasting, and permits up to four or five SDTV programs (a "multiplex") to be carried on a single broadcast channel frequency.[29] One can think of these as subchannels.[30]

¶ **34.** For either OTA digital broadcast or digital cable, the set-top box (STB) or equivalent hardware within the television set receives the multiple channel frequencies, each with its multiplex of programs. The STB or television knows the program assignments within each channel and is able to pull out the subchannel that the viewer selects, which it identifies by assigning a "virtual channel number." That is what the viewer chooses – it is displayed on the STB and on the screen during selection. For example, the viewer might select HBO, which is assigned a virtual channel (e.g. 82) and which might actually be just one of ten subchannel programs carried on one digital cable channel frequency. The STB then captures the HBO stream, decrypts and decodes its MPEG-2 encoding, and converts it to displayable video for a television monitor (or flat screen, etc.).

¶ **35.** In more detail, and in the language of digital television engineering, the delivery channel (digital broadcast or digital cable) is called the "transport stream," which can be thought of as a data pipe carrying some 20 Mbps (broadcast) or 38 Mbps (cable) in each frequency channel.[31] The ATSC specification dictates that the data put onto the transport stream must be broken into little *packets* of data, each of length 188 bytes and each belonging to an individual program. When multiple programs are sent on one transport stream, it is called a "multiprogram transport stream," or MPTS; if a single program, it's a "single-program transport stream" (SPTS). Repeating what was said earlier: a broadcaster can can put five standard-definition programs (or one HD and one SD program) onto a single broadcast channel's MPTS. The individual packets are identified by program, and they are interleaved in time (see Figure I.8).

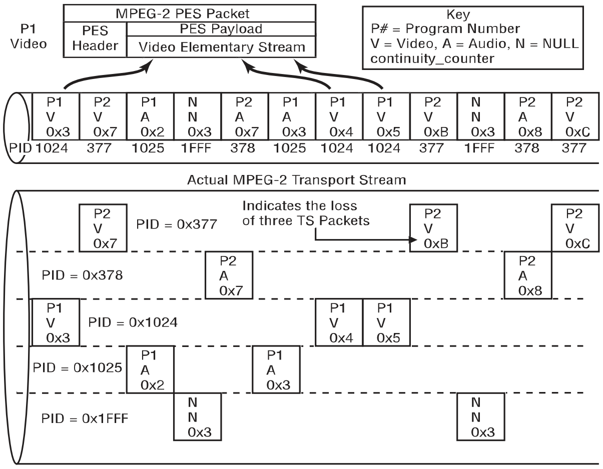

Figure I.8. Multiple programs can be interleaved into one digital transport stream, as a "multiprogram transport stream." Their individual video and audio packets are tagged with program identifiers (PIDs), by which they can be selected and reassembled (adapted from Figure 7.1 of ATSC Doc. A/54A, courtesy ATSC; readers are recommended to reference the current version of the standard or recommended practice available on the ATSC website).

¶ **36.** To put it another way, the several programs that will be put into a multiprogram transport stream (a "program multiplex") are cut into short pieces (packets, about 40 μs in length for digital cable), tagged with unique identifiers (called PIDs, for "program identifiers"), and then interleaved with the pieces (packets) from the other programs

[28] And also some "conditional access" (CA) information that enables legitimate subscribers to decrypt and view protected content; see ¶47.

[29] *Cable* delivery is more efficient, and permits as many as ten SDTV programs on a single channel.

[30] Because the cable (or broadcast channel) has a fixed total bitrate, the bitrates of the individual programs that are being multiplexed must be adjusted such that their total combined bitrate matches the channel capacity. This is called *bitrate grooming* and involves *null padding* (adding nulls, to increase a program's bitrate), on-the-fly compression (to reduce a program's bitrate), or even time shifting of program content (to prevent unlucky alignment of peak bitrates of the various programs). Digital television packets include "presentation time stamps," so it's OK to move things around a bit as they flow through the various digital pipes on their way to the television screen.

[31] The disparity has to do with the particular modulation schemes used: for broadcast it is called "8-VSB," whereas cable uses the more efficient "256-QAM" (pronounced "quahm"), thereby exploiting cable's better signal-carrying properties to carry roughly twice the information content.

that share the same transport stream. At the STB or television set the packets belonging to the selected program are identified ("filtered") by looking for their PIDs, and then reassembled into a single program transport stream to be decoded and displayed. In Figure I.8 there are two programs (P1 and P2), each with video (V) and audio (A), with their corresponding PIDs (1024, 1025, 377, 378); they are shown as the interleaved multiprogram stream at the top, and as filtered into their respective single-program streams at bottom.

I.6 Direct satellite television

¶ **37.** Satellites provide an alternative to over-the-air or cable/fiber delivery of television programming, and satellite delivery is particularly welcome in areas not served by wired broadband connections. This is known variously as direct-to-home (DTH), direct broadcast satellite (DBS), or broadcast satellite services (BSS), and exploits (usually) satellites in the geostationary constellation, i.e., in the equatorial "Clarke" orbit[32] of radius 42,200 km, where a satellite's period matches Earth's rotational period of 23h56m4s.[33] As surprising as it may seem, a single satellite with a ∼100 W transmitter can deliver a half-dozen high-definition programs (or 30 "standard-definition" programs) simultaneously to small dish antennas on houses everywhere in the continental US. Typical direct-broadcast satellites are equipped with a dozen or more such "transponders," and the receiving dish antennas use multiple "feeds" (as many as four, for DirecTV or DISH Network) to point at several satellites, making available many hundreds of television programs.

¶ **38.** Early DBS systems used a 4 GHz (C-band) downlink, and required large dishes (>3m diameter) and expensive RF electronics. Contemporary systems operate around 12 GHz (Ku-band), with mass-produced oval receiving dishes (typically 0.6m×0.8m) that incorporate several low-noise RF amplifiers, each with local oscillator, downconverting mixer, and IF amplifier in an integrated LNBF (low-noise block-downconverter plus feed) unit that sits at the focus of the parabolic dish. That's an impressive amount of hardware for $100.

¶ **39.** One may be puzzled by the peculiar orientation of home dish antennas – why are they sometimes pointed so low that they seem to be aimed at or below the horizon? There are two parts to the answer: first, the constellation of geostationary satellites spans an arc across the southern sky, populated worldwide with some 200 satellites; over the longitudes of the US alone there are some 35 satellites parked[34] in geostationary orbit. The line of satellites across the southern sky dips down to the horizon at its eastern and western ends.[35] Second (and technologically more interesting), the geometrical arrangement of the receiving dish is what's called an "offset-feed paraboloid." That is, the little conical feeds are offset below so they do not block the incoming signal. This makes the dish appear to be pointing some 25° lower than it is, thus the explanation for the apparently "subterranean" satellites. This peculiar arrangement is used to eliminate blockage of incoming signal by the feedhorns, and also to reduce the encroachment of thermal radio noise that is emitted by the surrounding environment – another bit of thoughtful design that enables successful direct satellite broadcasting.

¶ **40.** The individual transponder RF channels are 27 MHz wide, with as many as 32 such transponders on a satellite, which (with guard bands) adds up to a total downlink bandwidth of ∼1000 MHz. Satellite transponders typically use phase-shift keying (QPSK, 8PSK), with downlink bitrates of 40 Mbps per channel, adequate to deliver a half-dozen or more 1080i HD programs with efficient H.264/MPEG-4 encoding. The transponder channels are divided into two sets, one of each circular polarization at each transponder frequency, so that the total downlink spectrum occupied by a given satellite is about 500 MHz. This is downconverted in the LNBF to a pair of 500 MHz-wide IF bands, centered at 1.2 GHz and 1.9 GHz.

¶ **41.** Rather more hardware resources are expended on the *up*link, with steerable dishes of ∼10 m-diameter class (Figure I.9) illuminating the uplink receiving dishes at the satellite, with transmitted power of the order of hundreds of watts per transponder; dishes of that size produce diffraction-limited beam diameters of about 0.15°

[32] See "Extra-terrestrial relays – can rocket stations give world-wide radio coverage?" [Sir] Arthur C. Clarke, *Wireless World*, October 1945.

[33] Ha! You thought it was 24 hours. Not so – we're in orbit around the sun, which adds an extra 4 minutes (1/365th part of a day) to Earth's true rotational period (the *sidereal* day) to arrive at the 24-hour *solar* day (the average time from solar noon to solar noon).

[34] Hardly "parked," of course – they are in equatorial orbits, whizzing around the Earth at nearly 7000 miles per hour, to keep up with Earth's rotation.

[35] You can get a good sense of the satellite arc with with mobile apps like DishPointer or Satellite Locator: when you point your smartphone into the sky it shows the satellites as bright red circles (with their locations) on a red arc, superimposed on the camera view (with obstructing trees, etc.) seen by the mobile device.

($\theta \approx \lambda / D$), small enough to prevent illumination of a satellite in an adjacent orbital slot, but requiring some active steering to maintain alignment on the desired satellite. Direct-broadcast providers such as DirecTV and DISH Network like to position their satellites close enough along the Clarke belt so that a single dish with several feeds can capture the downlinked signals from several of them; for example, both DirecTV and DISH Network offer an oval dish with three feeds, targeting satellites separated by 10° (currently at 110°W, 119°W, and 129°W longitudes).

Figure I.9. A few of the several dozen transmitting antennas at EchoStar's Network's uplink facility in Cheyenne, Wyoming.

¶ 42. You hook the coax cables from the receiving dish to a set-top box (usually with DVR), similar to what's used for cable TV, but which is designed to power the LNBF electronics up there on the roof, to select from the dish's several feeds and polarizations, and to receive the intermediate-frequency (IF) bands coming down from the dish on standard 75 Ω video coax (quad-shielded RG-6, usually).[36] As with cable TV, the content providers control your available programming, via subscription-enabled decryption. Satellite systems are not bound by over-the-air terrestrial standards (e.g., MPEG-2 encoding), and they generally use more efficient schemes such as MPEG-4. When compared with cable or fiber television service, the inability to target millions of subscribers individually (along with the absence of a reverse uplink channel to the satellite) limits the possibilities for interactive services such as video-on-demand.

I.7 Digital video streaming over internet

¶ 43. With steady improvements in internet bandwidth (i.e., speed), it has become practical to deliver video (and associated audio) through the same internet infrastructure that serves personal computers and mobile devices (cellphones, tablets) with their email, web browsing, and so on. Some familiar examples of internet video streaming are news services such as CNN, government services such as NASA TV, movie streaming services such as Netflix and Hulu, and peer-to-peer services such as Skype. Just as with broadcast or cable delivery, the ultimate payload is a stream of numbers that constitute the video and audio content, in some efficient compressed format that takes advantage of sophisticated encoding schemes with names like "H.264" (also known as AVC, for advanced video coding), one of the current favorites. At the viewer's end the digital content is decoded[37] to recover the video and audio. For some services (e.g., Skype) a dedicated client program must be installed, whereas for others (e.g., NASA TV or CNN) a standard internet browser (such as Internet Explorer, Safari, or Firefox) suffices.

¶ 44. Compared with delivery via broadcast or cable, however, internet delivery of the time-critical video data presents some unique challenges. That is because data sent over the internet (via "Internet Protocol," IP) travels as independent packets of data, each typically some thousand bytes in length, and each including headers that specify its destination (IP address). Packets make their way through the multiply-connected nodes of the internet, and (usually) reach their destination. But there is no reserved pathway for a stream of packets (as there is for the "circuit-switched" architecture of the telephone system), and no guarantee of speedy delivery, sequential delivery, error-free delivery, or, indeed, of delivery of any sort. Various schemes are used to circumvent these evident deficiencies, for example by requesting retransmission of missing packets (they are numbered) or of corrupted packets (they include error-revealing "checksums"). These work well, and a data file that is downloaded via "TCP/IP"[38] is effectively guaranteed to be bit perfect.

[36] There may be an intervening module or two, with names like "multiswitch" or "node," to deal with selection of polarizations and IF-band stacking.

[37] Hence "codec," a contraction for coder–decoder, usually appended to the name of the compression scheme, e.g., "the H.264 codec."

[38] Transmission Control Protocol/Internet Protocol, a universally used standard for transfer of data that needs to be transported and reconstituted without error.

¶ **45.** Because of this disorganized "packet switching" of internet data, streaming video may suffer interruptions or intervals during which the average delivery rate is reduced. For this reason it is common for the receiving end to store ("buffer") a few seconds of video beyond what is currently being displayed; and if the internet delivery speed is inadequate (as evidenced by buffer underruns), the sender will reduce the data rate (thus delivering lower-quality video). Contemporary broadcast-quality high-definition TV (known as 1080i, meaning that the picture consists of 1080×1920 pixels, delivered 30 frames/sec) requires upward of 2 megabits/sec of download speed, available now in most homes with a broadband internet connection (cable, optical fiber, or telephone-line DSL[39]). That speed is well within the capability of wireless (Wi-Fi) connections, so high-definition video can be delivered to mobile devices such as laptop computers and tablets.

I.8 Digital cable: premium services and conditional access

¶ **46.** Cable television providers offer premium services, such as Showtime, HBO, and pay-per-view, for which the subscriber pays additional monthly fees. A subscriber whose subscription includes Showtime, for example, is able to view (and record, if the STB includes a DVR) programming delivered on Showtime channels. The cable provider needs a method to control each subscriber's access to the full channel lineup. Although each customer has a cable coming into the home (and therefore one could imagine that different content is sent to each home), in fact the same signal is sent to all the homes within a neighborhood group, known as a "service group."[40]

¶ **47.** To limit access within the full suite of distributed programming, the cable provider includes *conditional access* information along with the video and audio. This is done by including "CA" packets, along with the usual V (video) and A (audio) packets that comprise one program within the multiprogram transport stream. The STB includes decryption hardware, and uses the CA packets to provide the key information to unlock the encryption that is imposed on the video and audio packets by the cable company.

I.8.1 Digital cable: video-on-demand

¶ **48.** How is it possible to provide program material specifically for an individual subscriber, for example "on-demand" delivery of a previously broadcast program, or of a movie, on a cable network that serves an entire city?[41] Such services go by names like "video-on-demand" (VOD), and are made possible by the fact that the cable provider is able to tailor the actual signals carried on its cables that go to different groups of cable subscribers in an area.

¶ **49.** A cable network in a metropolitan area is more complex than one might at first imagine: rather than a city-wide distribution of common program material, the network is organized into smaller groupings of *nodes* and *service groups*. A service group consists of segments of cable, typically running past no more than 500 homes, carrying identical material; those signals are fed into the cable at a "node" in the neighborhood, which in turn is fed via optical fiber from a more distant "hub" at which the provider inserts the group of channels that is to go to that particular service group.

¶ **50.** The trick to providing individual on-demand material, then, is first to ensure that there are at least a few extra channels (in addition to the standard lineup) available to carry such content; and, second, to divide up the city into many service groups, so that those extra channels can carry a different suite of on-demand content to the different service groups. For example, suppose there are five channels available for on-demand material and that each can carry ten programs (as described earlier); if a service group includes 500 houses, of which 200 are cable subscribers, then the cable provider can satisfy 25% of those subscribers with simultaneous on-demand programming (because its five extra channels, each sending ten custom programs, deliver 50 simultaneous programs).

¶ **51.** On-demand programming requires also a reverse channel for each subscriber, so that the subscriber can select programming, and also pause (or fast-forward or rewind) the material. However, these reverse channels need carry only a few simple commands up to the provider (as opposed to the high-bitrate video coming down in response), and are easily accommodated in an "interactive" uplink signaling band of the cable network.

[39] Digital subscriber line, technology for bidirectional digital transport over analog telephone lines.

[40] See ¶49, below, for more details.

[41] The term *unicast* is sometimes used to distinguish such individual delivery from *broadcast*.

I.8.2 Digital cable: switched broadcast

¶ 52. Some cable providers use another service that exploits the flexibility inherent in the cable network's use of separate service groups, namely "switched broadcast." Switched broadcast delivers programs only when requested by viewers, on a service-group basis, as compared with delivering all programming to all customers. This allows the cable provider to offer more programming choices than could be carried simultaneously on the available number of channels.[42]

¶ 53. Although switched broadcast and VOD use similar methods to deliver their content to a subscriber, it is worth noting a difference: switched broadcast content is delivered whenever that program material is normally scheduled, and not at the whim of the subscriber; what distinguishes it from normal program material is that it is not put onto the service group's cable at all, if no one in that group has tuned to the program. Once a subscriber has tuned that program (causing it to be sent to that service group, on a particular subchannel), that same program is present on the cable serving any additional subscribers in that service group, on the same subchannel. By contrast, VOD is delivered on-demand, at the time requested by the subscriber; likewise, it can be paused, or fast-forwarded, etc. (tasks that are performed on-the-fly by the cable provider, not by the set-top box). That is possible because VOD content is being sent on a particular subchannel on the subscriber's service group only, and is available for the requesting subscriber only (via encryption and user-specific "entitlement control," in the case of protected content). The terms *narrowcast* and *unicast* are sometimes used to refer to service-group-specific cable delivery of these two varieties of content, namely scheduled ("linear") material, and interactive user-specific on-demand material, respectively.

I.9 Recording digital television

¶ 54. The conversion of analog material (audio and video of the real world) into digital form is hard work – but it makes the task of *recording* straightforward. That is because a single program received at the STB is, in essence, just a stream of numbers, which can be filtered from the multiprogram stream, assembled in a temporary memory "buffer," and written to a hard-disk file just like any computer file. In that sense, a set-top box with DVR is simply a special-purpose computer, with the usual processor, hard drive, etc., and having additional hardware to do the special STB tasks – receive the cable signal, generate the displayable output, take control commands from the infrared remote "clicker," and so on. A typical contemporary set-top box with DVR contains a dual-processor chip, 64 MB program memory, a 160 GB (minimum) hard drive, and various video-related additional hardware (input tuner, video memory, display and audio drivers, etc.). Along with buffering and storing the video and audio content, the STB controls the access, decryption, and re-encryption of the (protected) video content.

¶ 55. It is worth noting that any digital storage medium of adequate speed and capacity can be used to store digital video content; at the consumer level there are many "personal video recorders" (PVRs) that store programs on recordable DVDs or onto solid-state "flash" memory chips. There are also digital video tape recorders that can store both SDTV and HDTV onto a digital variant of VHS tape.

I.10 Display technology

¶ 56. For over half a century television images were displayed with a cathode-ray tube (CRT), in which electrons emitted from a hot cathode and accelerated to potentials of kilovolts were deflected (usually magnetically) to paint a raster, at the video frame rate, on a phosphor surface coated on the interior of the viewing face of the evacuated tube. The intensity was modulated with a grid electrode near the cathode. Early CRTs were monochrome (black and white); color tubes used arrays (triads or stripes) of red, green, and blue phosphors, aligned with a metallic mask so that electrons from each of three electron-emitting cathodes (or, in Sony's Trinitron, steered from a single electron gun) struck only one color of phosphor.

¶ 57. Cathode-ray tube displays worked; but they were heavy (over 100 lbs for a TV with 32″ display), bulky, and required fussy "convergence" adjustment to get the colors to track. Shortening the tube to reduce cabinet depth exacerbated the convergence and geometry problems. CRTs are now obsolete, replaced by several technologies, among them liquid-crystal displays (LCDs), plasma displays, and organic light-emitting diodes (OLEDs).

¶ 58. In an LCD a liquid-crystal layer is sandwiched between a pair of crossed optical polarizers; an applied electric field alters the polarizing properties of the layer, thus varying the optical transmission. In the classic display there's a uniform white rear illumination (from white LEDs, or from one or more cold-cathode fluorescent lamps – CCFLs – combined with diffusers and light pipe

[42] This is sometimes called *narrowcast*, versus broadcast or unicast.

material); an array of electrodes applies local electric fields to the image pixels, which are overlaid with red, green, and blue color filters. The array of liquid-crystal pixels act as video-rate dimmable shutters; all the light originates in the rear illuminator.

¶ 59. LCDs are dominant in computer displays and popular in televisions. They are thin (a centimeter or so) and bright. But they have somewhat limited dynamic range (or contrast ratio: ratio of maximum brightness to "maximum darkness") and speed, and their color balance and black level degrades when viewed off-axis. There have been great improvements in speed and in off-axis performance, owing to methods with names like in-plane switching (IPS), fringe-field switching (FFS), and the like. And the dynamic range can be improved by using LED-array backlighting, which can be dimmed locally and rapidly, adapting to the light and dark areas of the displayed image.[43]

¶ 60. For the most realistic rendering of cinematic material, however, the plasma display is superior to the LCD. It consists of an array of tiny cells, in each of which a switchable gas discharge generates ultraviolet light that causes a spot of phosphor to glow. A high-definition display of 1080×1920 pixels has three such cells for each pixel (one each with red, green, and blue phosphors) to generate the pixel's overall emitted color. Unlike an LCD (which filters an underlying light source), the cells of a plasma display generate the emitted light directly. You can think of it as an array of 6 million little CRTs (1080×1920×3), each one time-switched to achieve the required light intensity.

¶ 61. Plasma displays retain their color fidelity and contrast ratio regardless of viewing angle, and they have fast response. In larger sizes they are currently somewhat less expensive than LCDs. They are not as bright as LCDs, however, and a static pattern that is displayed for a long time can cause some image retention, or (in extreme cases) phosphor "burn." Their contrast ratio is very good, but not infinite, because the gas discharge in every pixel must be sustained at a low level (i.e., it cannot be switched off entirely) so that it can be rapidly modulated.

¶ 62. LCD and Plasma have dominated display technology, but the future is likely to be ruled by OLED (organic LED), a direct-emitting array of tiny LEDs (either in three colors, or white LEDs with filters). These emerged first in small displays (e.g., cellphones and camera viewfinders), but by 2014 they had made the big time, with full 4K "Ultra HD" resolution (3840×2160), and screen sizes to 65″ and beyond. Unlike earlier display technologies, OLEDs can be made flexible, and the current fad is *curved* TV screens (capable of 3D, if you're interested in that). OLED is likely to be the ultimate winner, because of their very high dynamic range (1,000,000:1), wide viewing angle, low power consumption, elegant form factor (3 mm thick, lightweight, and nearly borderless), and potential manufacture by an inkjet-like process. These have been winning Best of Show awards, and they deserve it.[44]

¶ 63. Two other technologies that looked good, but have fallen onto hard times, are field-emission display (FED) and surface-conduction electron-emitter display (SED). Both involve an array of phosphor cells (like the plasma display), but with electron (rather than ultraviolet) excitation of the phosphor. An SED prototype from Canon generated great enthusiasm[45] at the 2006 CES, but subsequent patent disputes and economic realities took their toll. FED and SED may rise again – but don't hold your breath.

I.11 Video connections: analog (composite, component) and digital (HDMI/DVI, DisplayPort)

¶ 64. What are all those incompatible cables, anyway? To add to the analog–digital confusion, the *consumer* market (of large-screen TVs and flat panels, etc.) and the *computer* market (of LCD monitors) have gone their (mostly) separate ways. Here's a quick rundown of the most-used connections; their connectors are pictured in Figure I.10.

¶ 65. In the *consumer television* world there are four types of connections (and connectors), the first two of which are nearly extinct.

Composite video. Low quality standard-definition (SDTV: 480i) analog video, recognizable by the yellow RCA-type connector ("phono jack"), usually bundled with an audio pair (red = right, white = left). The single yellow line carries bandwidth-limited luminance

[43] For marketing purposes these LCDs are sometimes called "LED TVs." Don't be fooled: it's an LCD, but with LED rear illumination replacing the CCFL. And it may or may not have local dimming – read the fine print.

[44] The reviewers are *gushing*: "The best picture I've seen on any TV, ever." (CNET), "The best-looking TV I've ever seen. Ever." (Digital Trends), and "The best direct-view display – of any size, at any price – we've ever laid eyes on." (HDTVtext, UK).

[45] A breathless review in SlashGear (19Oct2006) proclaimed "SED-TV is something that no amount of words can describe. It is something that must be SEEN to be believed; literally." and "SED-TV is the future of digital image displays; it's as simple as that."

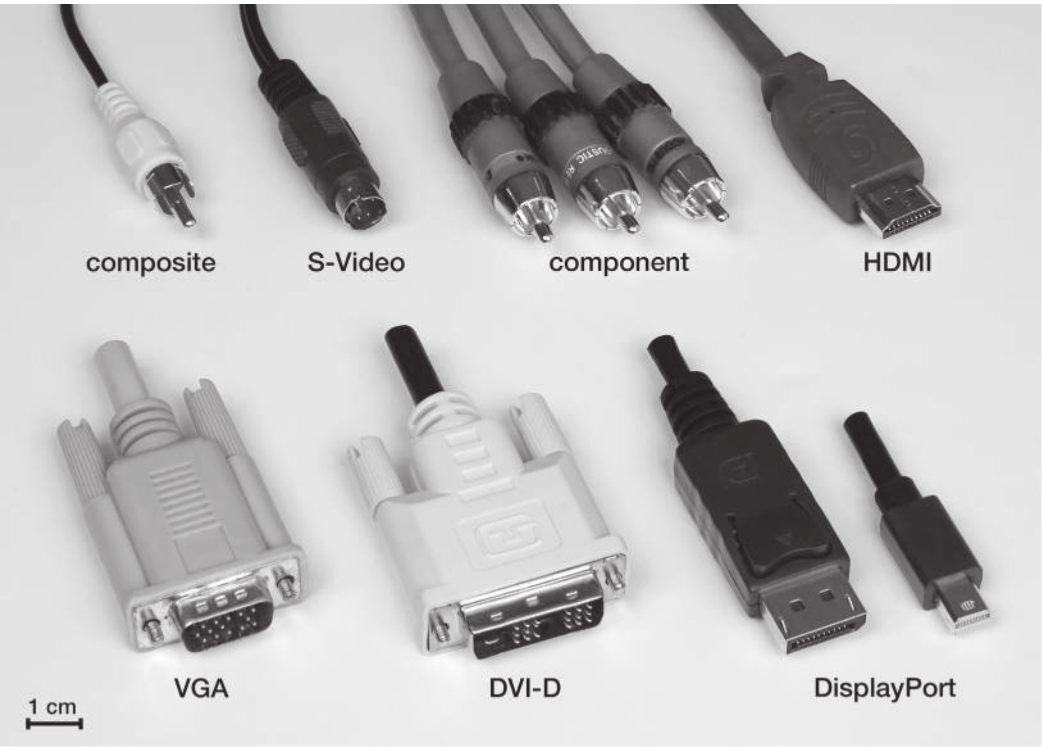

Figure I.10. Cable connectors for computer monitor and video signals. Top row: TV video connectors, from the legacy analog composite to contemporary HDMI high-definition digital video. Bottom row: computer monitor connectors, from the legacy analog VGA to the popular digital DVI and newer DisplayPort (standard and mini connectors).

("luma," abbreviated Y, essentially the grayscale image) and chrominance ("chroma," abbreviated C, the color difference signal pair that is modulated on a 3.58 MHz color subcarrier), along with line and frame synchronization pulses; it is sometimes called CVBS (composite video, blanking, and sync). Don't use such a connection unless there's nothing else available!

S-video. Somewhat better SDTV analog video, recognizable by the 4-pin miniDIN connector with fragile pins. It separates the luma (+ sync) and chroma signals, retaining more bandwidth. Avoid this one, too, unless you like fuzzy pictures.

Component video. Now we're talking! This analog format uses three 75 Ω coax lines, with (usually) RCA-type connectors (or, occasionally, BNCs) that are colored red, green, and blue, and that can carry full-bandwidth HDTV. The colors are misleading: the green line carries luminance (+ sync), while blue and red carry color *difference* signals. That is, the GBR-colored connectors denote "YPbPr," where Y is luminance (red+blue+green), Pb is blue-minus-Y, and Pr is red-minus-Y. As with composite and S-video, component video carries only video; the audio needs it own cables. Component video does not know, or care, about things like content protection; for that reason it is not embraced by content providers, who may prevent full-resolution HDTV (1080×1920) output on the component jacks (e.g., on a Blu-Ray player).

HDMI. A purely digital format, whose initials stand for high-definition multimedia interface. HDMI is the digital alternative to component video. It is recognizable by the flat 19-pin USB-like connector (sadly without any required latching mechanism), and electrically it is equivalent to the DVI-I computer-monitor format (see below). It carries both audio (up to eight channels, digitized to 24 bits, up to 192 ksps) and video (digitized at 8–16 bits per component, at rates adequate for full HDTV ("1080p," 1080×1920 progressive at 60 Hz; HDMI versions 1.4 and later support full "4K," 4096×2160, with 60 fps progressive from version 2.0). The video data is a digitized version of analog video: uncompressed numerical data representing the amplitude of the color components, sent over four twisted pairs (R, G, B, clock). HDMI supports digital content protection (HDCP, high-bandwidth digital content protection), a protocol by which an HD video source authenticates a display device before sending (encrypted) data, so you are allowed to view the full-resolution video. HDCP seems to work, most of the time anyway (though you may get annoying messages and glitches).

¶ **66.** In the *computer monitor* world there are three types of connections (and connectors) in wide use.

Analog VGA. Legacy analog link, recognizable by the 15-pin D-type connector with locking screws. VGA (for video graphics array) carries separate RGB analog signals, plus Hsync and Vsync (thus “RGBHV”). In contemporary implementations it also has an I^2C channel for monitor identification and control. VGA will work up to resolutions of 1600×1200 or so (there’s no specified limit, but you’ll see smearing going rightward of sharp features when pushing the resolution), but many monitors have abandoned VGA altogether in favor of the digital formats: DVI and DisplayPort.

DVI. Currently the standard digital interface, recognizable by the 29-pin (maximum) connector with locking screws, looking somewhat like a “VGA on steroids.” It is electrically similar to the more compact and inexpensive HDMI, above, that evolved from it for the consumer television market, and that includes audio (thus a single connection from a cable box or Blu-Ray player to the television monitor). It comes in several variants, all using the same connector (in which some pins may not be loaded): DVI-D is video-only, and comes in single-link and dual-link varieties (the latter needed for resolutions greater than 1920×1200 at 60 Hz, for example the 2560×1600 at 60 Hz used in 30″ displays); DVI-A is analog video only (for compatibility with analog monitors); and DVI-I (“integrated”) has both digital (single- or dual-link) and analog video. DVI, like VGA, carries no audio.

DisplayPort. Newer standard, intended to supersede DVI; it uses a 20-pin USB-like connector with latching mechanism, and supports very high data rates (up to 4.3 Gbps on each of four differential pairs, thus 17.3 Gbps). It departs from the “digitized-raster” scheme of DVI/HDMI, using instead a packetized data protocol; but it’s got enough bandwidth to handle the full video bandwidth of dual-link DVI (which can be converted to DisplayPort protocol). It supports up to 16 bits per color, and 8-channel audio at 24 bits and 192 ksps. It includes provision for fiber optics (instead of copper) for long cable runs (to 50 m or more), and it supports both existing 56-bit HDCP and its own DPCP (DisplayPort content protection, with stronger 128-bit AES encryption). The current revision of DisplayPort can handle 4K 60 fps progressive with ease.

SPICE PRIMER: GETTING STARTED WITH FREE ICAP/4 DEMO

APPENDIX **J**

Free SPICE is easy, and fun. It's available for several platforms (Macs, Linux, PCs). Here's how to get started in Windows.

J.1 Setting up ICAP SPICE

1. Download "ICAP/4Windows Demo" zip file (ICAP4Demo.zip) from intusoft.com.
2. Extract zip file to some temporary folder.
3. In that folder, double click (abbreviated hereafter as "**cc**") on setup.exe.
4. Launch ICAP/4 (you may have to be admin mode):
   (Programs → ICAP_4 Demo → Start ICAPS).

J.2 Entering a Diagram

- Add standard components with typing

R	resistor
C	capacitor
L	inductor
o	ground (the letter "oh," not the number)
v	signal or voltage source
Y	voltage test point.

  (These are case-insensitive: r = R, etc.)
- For a library component, Parts → Parts Browser,
  - browse by type, and subtype, or use Find,
  - then Place.
- Moving and orienting:
  - highlight component by click-hold, then can drag;
  - when highlighted, type + to rotate (90°CW), or − to flip 180°.
- Editing a component label:
  - highlight label by click-hold, drag to relocate;
  - when label highlighted, **cc** on label to edit values.
    - ∗ Note units multipliers: f, p, n, u, m, k, meg (not M).
    - ∗ Note that SPICE only needs the units *multiplier*, not the units themselves. For example, for a capacitor "1u" is OK for SPICE; but you can type "1.0uF" for clarity on the schematic, which SPICE will treat the same.
    - ∗ You can **cc** on the component, instead, to bring up the value dialog.
  - You can add parameters by entering the value and clicking Apply; this is necessary, e.g., for a voltage source (add dc or ac, give amplitude). Or you can click ≫Add≫, which also adds the parameter to the schematic drawing.
- Wires:
  - type w, then drag a wire between points;
  - you can drag multiple separate wires; ESC when done.
- Settings:
  - set "Rubberbanding" in Options, to maintain connections when dragging components.

J.3 Running a simulation

Can a passive circuit consisting only of resistors and capacitors have *voltage gain*? The surprising answer is yes. Let's use this simple example to illustrate an ICAP/4 SPICE entry and simulation.

J.3.1 Schematic entry

We launch ICAPS, and place two resistors (type the letter "r"), two capacitors (type the letter "c"), and a voltage source (type the letter "v") with the bottom terminal grounded (type the letter "o" right after typing "v"). If the pieces are too small to see on your screen, you can resize them by using Options→Zoom (or the function keys F6, F7, and F8). We drag them around to connect them as shown in Figure J.1, and add an output-voltage test point (type the letter "y" and change the label to Vout). We assign values by double clicking on each component, then entering the value in the value field (where "???" appears initially); note that pressing the Enter key after each value moves you along to another field in the dialog – you have to click OK to complete the operation.

For the capacitors we could have used microfarads (e.g., 0.01uF instead of 10nF); note that the "F" can be omitted, but including it makes the schematic marking clearer. For the voltage source we enter the value 1V (i.e., 1 volt) in the

"AC" field, and then we click on the ADD button so that the value shows on the schematic (SPICE uses the value, even if we do not ADD it; but it's nice to show it on the circuit diagram). As before, the unit symbol "V" can be omitted.[1]

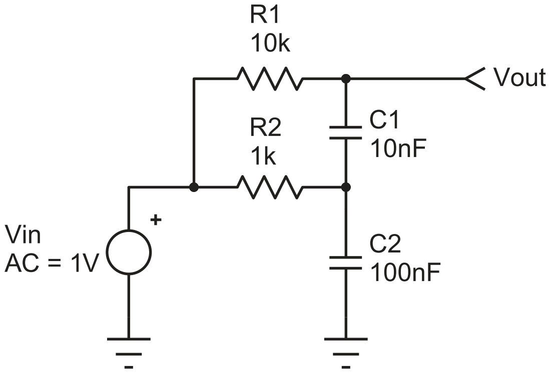

Figure J.1. An *RC* circuit with voltage gain! Schematic entry in Intusoft ICAP/4 is swift, taking no more than a couple of minutes. Printing the captured schematic to "Adobe PDF" produced this figure.

J.3.2 Simulation: frequency sweep

Now for the fun! We begin by saving the project to a folder of our choosing, using the File→Save As menu. Then we set up the simulation by Actions→Simulation setup→Edit (or by clicking on the button with a pencil over a wavy line). Choose and click "AC Analysis," then enter 20 points per octave, start at 100 Hz, end at 10 kHz (type 10k in the box), and click OK. Then click DONE. Now run the simulation by clicking on the little running person (or Actions→Simulate). This launches the Spice engine, with a small window ("IsSpice4") showing status and errors, and (if successful) a little graph of the result. Running the simulation also launches the "IntuScope" display program (which you can launch manually by clicking on the 'scope icon next to the running person, or by Actions→Scope). At this point there are multiple windows piled up, which you should resize and drag to convenient locations on the screen and then do Options→Save Preferences to stick them down. Now click the "Test Pts Only" box in the "Add Waveform" window that belongs to IntuScope, then highlight Vout[2] and click "Add." Voilà – this produces a nice plot of V_{out} versus frequency (see Figure J.2), with default axis labels, grids, and scaling. You can change the axis labels by double clicking on the label; and you can fiddle with the scaling in the "Scaling" window.

To add a plot of phase shift versus frequency, highlight "ph_Vout" in the Add Waveform window, click on the box labeled "With Like Traces" (unless you want a separate graph), and click "Add." We've done that to make Figure J.2, where we've also used the cursor tools on the IntuScope window to mark the point of maximum voltage gain.

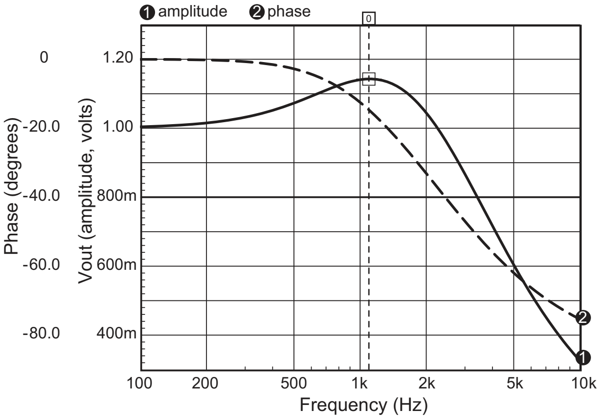

Figure J.2. "'Scope" output of the *RC* gain circuit, showing amplitude and phase ("AC Analysis") for the circuit of Figure J.1. The cursor indicates the peak of the voltage gain, $V_{\text{out}}/V_{\text{in}}$=1.142 at f=1.096 kHz. The original IntuScope output plotted phase in blue, which we've converted to a dashed black line; we enlarged the text, also, for readability.

J.3.3 Simulation: input and output waveforms

Do we really believe this gain-versus-frequency plot? Everyone knows that a simple *RC* network just mushes things out – shifted phase and reduced amplitude. We won't believe this thing has voltage gain unless SPICE shows us the actual input and output signal waveforms for a sinewave near the frequency of maximum voltage gain (and maybe not even then!).

Here's how you do it: first, add another voltage test point at the input ("y" again), and change the label to Vin. Then double click on the input voltage source and click on the field labeled "Tran Generators" (SPICE calls any old waveform, including a sinewave, a "transient"). Select SIN, set the peak amplitude to 1, the offset to 0, and the frequency to 1.096 kHz. Click OK, and OK. Then go to Simulation Setup (pencil over wavy line), deselect AC Analysis, and select Transient. In the Transient Analysis

[1] For SPICE's ac analysis, the frequency-sweep gain computation is performed with infinitesimal small-signal amplitudes, which are then normalized to the signal amplitude you specified. Here, for example, SPICE uses a signal amplitude much smaller than 1 V.

[2] Or, if you have not renamed the output to Vout, select from among the signals with names like v2, etc., in the Y Axis output list.

window that pops up, set Data Step Time to 1us, Total Analysis Time to 105ms, and Time to Start Recording Data at 100ms (this gives the circuit time to settle into its steady state). Leave the Maximum Time Step field blank (i.e., accept default value). Click the runner icon to run the simulation. At this point the IsSpice4 window should show a wiggly trace. Now go to the IntuScope window, clear the old graph by pressing the DEL key for each selected trace (you can save it, if you want, or start a new plot with File→New Graph), and Add "vin" and "vout" in the Add Waveform subwindow of IntuScope, with the "With Like Traces" box checked as before.

Not bad... but the waveforms look a bit jagged. If you zoom in (drag the box boundaries in the "Scaling" window) you'll see that there are only about 20 points plotted per cycle. We asked for 1 μs steps, but we're getting output at ~50 μs intervals! That's because we didn't constrain the Maximum Time Step in the Transient Analysis window. Go back now (Simulation Setup→Transient) and set Maximum Time Step to 1us. Then click on the running person (the simulation will take slightly longer, maybe a full second this time); then clear the old graph and Add the two waveforms in IntuScope (output first, to set scale, then input). You should see silky-smooth plots, as in Figure J.3. If you still have doubts about an *RC* circuit with voltage gain, you can hook up the circuit and check it out on a real-live oscilloscope, as we did (Figure J.4). Evidently this *RC* voltage-gain stuff is real!

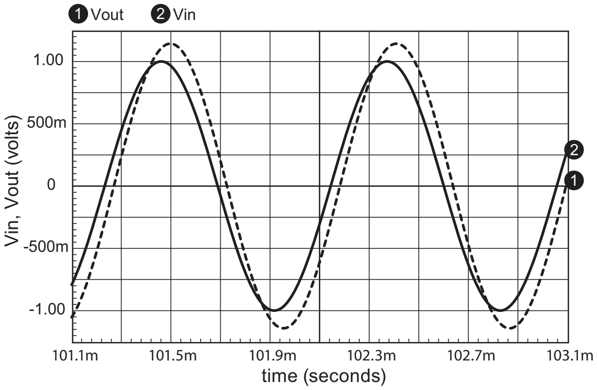

Figure J.3. "'Scope" output of the *RC* gain circuit, showing sinewave response ("Transient Analysis") at the frequency of maximum gain for the circuit of Figure J.1. The original IntuScope output plotted V_{out} in blue, which we've converted to a dashed black line; we enlarged the text, also, for readability, and adjusted the axis scales to match the scope trace.

J.4 Some final points

The ICAP/4 demo program includes ten "tutorial movies" (in the Help menu), which are mercifully short (about a minute each) and quite helpful for the beginner. Take ten minutes to view them! You'll learn, for example, that you can create many signal sources by going directly to Parts→Parts Browser→!Generators. You'll also learn some tricks to simplify schematic entry (copying, zooming), and ways to make the parts labels more readable ("tall," "wide," and "split" options). And by experimenting a bit you can discover that both the schematic and the simulation graphs can be copied ("Print") to the clipboard and then pasted into Word or Wordpad, where they exist as scalable graphics. If you Print to Adobe PDF you'll get a scalable graphic that can be cleaned up in Adobe Illustrator.

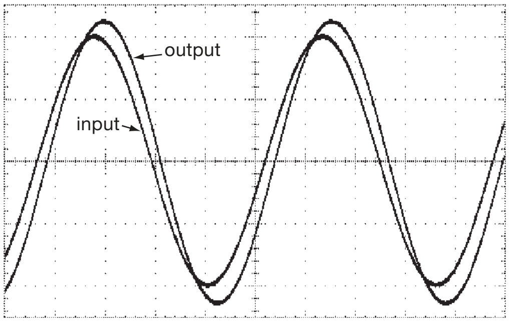

Figure J.4. A *real* 'scope (Tek TDS3044B) validates that crazy SPICE stuff! Horizontal; 200 μs/div; Vertical; 0.5 V/div.

We have been using the Intusoft "ICAP/4" full version of SPICE now for many years; it provides a convenient Windows-based schematic entry and simulation environment, which we use to explore circuit configurations. Typically we begin with a starting circuit design, making explanatory notations in a Word document as we go. We copy and paste the schematics and simulation graphics into the running text, making a "lab notebook" of sorts; see next.

J.5 A detailed example: exploring amplifier distortion

In Chapter *2x* ("BJT Amplifier Distortion: a SPICE exploration") we do some serious work with SPICE, in the form of an exploration of distortion in discrete BJT amplifier designs.[3] The amplifier stuff is lots of fun; and there are some nice SPICE tricks there revealed. Take a look!

[3] When we do this in real life, we like to paste circuit diagrams and screen shots of simulated performance into a Word document, annotating as we go. We've kept that spirit alive in the discussion in Chapter *2x*, albeit in the form of a LaTeX conversion of the original Word document.

J.6 Expanding the parts database

You can freely add SPICE models to the ICAP/4 parts library. An easy way to start the process is to download the folder AoE-PR from our website (www.artofelectronics.com), and place it under the default PR folder. Then do File→Update Part Database.

"WHERE DO I GO TO BUY ELECTRONIC GOODIES?"

APPENDIX K

Good question! Here are some hints, from our experiences.

I. Mail order and online

Digi-Key Corp (Thief River Falls, MN: 1–800–digikey). We used to say "*Get their catalog!!*" – but, sadly, they've abandoned paper, replacing it with an impressive search capability. You can get everything here, even in small quantities, with fast delivery. It's often worth designing with their webpage open in front of you. Online ordering and stock/price checking: www.digikey.com.

Mouser Electronics (www.mouser.com). Broad stocking distributor, with service comparable to Digi-Key's, and willingness to ship small quantities. Good selection of precision passives; and they are still printing a comprehensive paper catalog.

Newark Electronics + Farnell (1–800–2–newark; www.newark.com). Broadest stocking distributor, with service comparable to Digi-Key's and good selection of tools; paper catalog still in print.

"Stocking Distributors". These are the standard distribution channel for quantity buying; names like Allied (still publishing a paper catalog), Arrow, Avnet, FAI, Heilind, Insight, Pioneer, Wyle. Substantial minimum quantities – not generally useful for prototyping or small production.

Manufacturers' Direct. Many semiconductor manufacturers (Analog Devices, TI, Maxim,. . .) will not only send free samples with the slightest provocation, they will also sell in small quantities via credit card; check out Mini-Circuits for RF components, and Coilcraft for inductors, transformers, and RF filters.

Oddballs. Marlin P Jones, Jameco, B&D, Herbach & Rademan, Omnitron, ABRA, All Electronics; ephemeral collection of "surplus" stuff, some real bargains.

eBay (www.ebay.com). If you haven't been here, you've probably just arrived from Mars. LOTS of stuff, literally millions of items, an online auction. You can get plenty of electronic stuff, but CAVEAT BIGTIME EMPTOR. Feedback Forum helps.

Alibaba Small Pacific-rim companies that have stocks of obsolete components are easily found on Alibaba. You can place a quote request for a part number, and you'll get dozens of useful reasonably-priced suppliers.

II. Indexes and Locators

Octopart, FindChips, NetComponents (octopart.com, findchips.com, netcomponents.com). Give it a part number and it searches dozens of distributors, returning (sometimes unreliable) information on availability and pricing.

WhoMakesIt (www.whomakesit.com). A bit like the EEM catalog, helpful if you know the category of stuff you want, but not the manufacturer, etc.

Google (www.google.com). Our standard "portal," reads your mind and vectors you to the goodstuff. Helpful, sometimes, in finding parts and equipment manufacturers and vendors.

III. Local

Sometimes it's nice to shop in person; here are the sorts of places to go.

Radio Shack (www.radioshack.com). They call themselves "America's Electronic Supermarket"; we'd call them "America's Electronic Convenience Store." Their stores are everywhere, and they stock (pretty reliably) an idiosyncratic collection of parts and supplies, of uncertain quality or duration. However, in the changing marketplace of consumer electronics, their future path is unclear.

Electronics Flea Markets. Also known as "swap meets," perhaps somewhat in decline; two legendary meets are on opposite coasts: De Anza College (Cupertino, every second Saturday, March–October), and MIT (Cambridge, every third Sunday, April–October). What meets are three cultures (electronics, computers, hams); haggling is mandatory; caveat very emptor.

Electronics Surplus Supply Stores. These are incredibly cool! Several well-known haunts are Halted (www.halted.com; officially "HSC Electronics Supply"), in Santa Clara, Sacramento, and Santa Rosa; and Murphy's Surplus Warehouse (www.murphyjunk.bizland.com) in El Cajon.

IV. Miscellaneous

Obsolete ICs. Your best place to start is Rochester Electronics (www.rocelec.com), a wonderful place that apparently buys up inventories of ICs being discontinued. Jameco also has a lot of obsolete parts. Freetradezone has broker lists for obsolete parts. Also try Interfet (www.interfet.com), a manufacturer of small-signal FETs, including ones that the big guys have abandoned.

PC Board Manufacture. We like a place called Advanced Circuits, www.4pcb.com; you can get online quotes, and they do a good job and deliver pronto. Another inexpensive and fast PC house is Alberta Printed Circuits in Canada (www.apcircuits.com).

WORKBENCH INSTRUMENTS AND TOOLS

APPENDIX L

Here are some electronic favorites, stuff that we really like using when we design and build electronic circuits. It's best to check current catalogs and websites – much of this sort of equipment becomes obsolete with terrifying speed.

Soldering iron

Metcal MX-500 (not cheap; it will change your life!)
Weller WSL (less expensive, variable temp)

Desoldering station

Pace MBT201-SD

Surface-mount prototype and rework

Zephyrtronics Airbath and Airpencil
Metcal offers SMT "tweezers" and other goodies

Bench DMM

Keithley 2100 ($6\frac{1}{2}$-digit, with USB control & readout)
Agilent 34410A ($6\frac{1}{2}$-digit, with LAN & USB control & readout)

Pocket DMM

Amprobe 37XR-A (cheap, good enough)
Fluke 289 (not cheap, very good)
Agilent U1252A/53A (everyone's favorite lately)
"Smart Tweezers" (auto-ranging SMT tweezer-style meter, neat!)

Triple bench power supply

HP E3630A (excellent performance, reasonable price)

High-voltage bench power supply

SRS PS300-series (single and split, to 20 kV)

Device programmer (if needed; JTAG in-ckt is taking over, pods from mfgrs)
BP Microsystems 1610 (universal and reliable; lifetime free algorithm updates)

LCR meter

HP 4263B (a cheaper one is the SRS model SR720)

Analog oscilloscope

B&K Precision and Hameg still offer some models, to 200 MHz bandwidth

Digital oscilloscope

Tek DPO2024B (cheap "lunchbox"); DPO/MSO 3k-, 4k-, 5k-series
Agilent DSO/MSO 5k-, 6k-, and 7k-series (Agilent's answer to the "lunchbox")
Lecroy WaveRunner, WaveSurfer, WaveJet series (lot of models, do your homework)

Arbitrary function generator

Tek AFG3000-series (single and dual channel, to 240MHz and 2Gs/s)

Low-distortion function generator

SRS DS360 (0.01 Hz–200 kHz, 0.001% distortion)

RF and microwave synthesizer

Agilent N9310A
SRS SG380-series (2, 4, and 6 GHz models, low phase noise, see §13.13.6B)

Low frequency spectrum analyzer

SRS model SR785

RF spectrum analyzer

Agilent ESA series (depends on frequency range, and $$)

Source measure unit

Agilent B2900-series (single and dual channel)
Keithley 2600-series (single and dual channel)

Precision time and frequency standard

Symmetricom 4411A (uses GPS constellation)

Engineering software

Altium System Designer, OrCad, or Eagle (for schematic capture and layout; includes simulation)
Xilinx WebPack (for PLD and FPGA design), and analogous tools from Altera, Lattice, Actel, etc.
ICAP/4, LTspice ($0!), MicroCap 9, MMICAD, PSpice (for simulation)
FilterCAD ($0!, from LTC), FilterPro ($0!, from TI) (simple analog filter design)
MathCAD, MATLAB, Mathematica (engineering/math worksheets)
LabVIEW™ (virtual instruments; control of real instruments)

CATALOGS, MAGAZINES, DATABOOKS

APPENDIX M

Here are some recommendations for data books, catalogs, and magazines; some have become on-line services only (e.g., IC Master). You will need some of these if you want to practice electronic design.

"Master" catalogs

EEM (Electronic Engineer's Master) *lists all categories of electronic stuff*
IC Master *ditto, for ICs*
Octopart *excellent on-line part (and datasheet) finder*

Parts and equipment catalogs

Digi-Key Corp (a distributor), *wide range, quick delivery*
Mouser Electronics (a distributor), *wide range, quick delivery*
Newark/Farnell Electronics (a distributor), *best broad-line catalog*
Allied Electronics (a distributor), *similar to Newark*
TechniTool (a distributor), *measurement, assembly, and test tools*
Stanley Supply & Services, (a distributor) *equipment and supplies for assembly*
Keysight Technologies (Agilent, HP), *broadest manufacturer of test and measurement equipment*
Tektronix, *test and measurement equipment, especially scopes*
Fluke, *test and measurement equipment*
Stanford Research Systems (SRS) *test and measurement equipment; great documentation and app notes*

Magazines and tabloids

EDN, *keeps you up to date on new products and methods*
Electronic Design, *ditto; a bit thin, lately*
Electronic Products, *ditto, emphasis on products only*
EE Times, *tabloid format*
Computer Applications Journal, *microcontroller project mania*
Circuit Cellar Ink, *emphasis on microcontrollers*
Nuts and Volts, *quirky do-it-yourself, tabloid format*
Make Magazine, *cool stuff you can build*

Data books; short-form/design guides A starter selection, with product emphasis.
Altera: cPLD, FPGA
Analog Devices: all linear functions; converters; DSP
Atmel: PLDs and microcontrollers
Avago (←Agilent←HP←Avantek): opto, rf
Cirrus/Apex: power op-amps etc.
Cypress: memory, processors
Diodes Inc/Zetex: discretes, etc.
Fairchild: discretes, linear, digital
Freescale: processors, DSP, automotive
IDT, Micron, Samsung: memory
Infineon: discrete, power, processors, RF
Intel: microprocessors and microcontrollers
Linear Technology Corp: all linear functions
M/ACom: RF and microwave
Maxim/Dallas: linear, digital, μC
MiniCircuits: RF – broad line, inexpensive
NXP (Philips): logic, microcontroller
ON Semi/Sanyo: linear, logic, discrete
Renesas: discrete, memory, processors
TI/National/Burr–Brown: linear, logic, opto, power, processors, DSP
Xilinx: cPLD, FPGA

Datasheets (in *.pdf format) are available online from nearly every semiconductor manufacturer's website; try, e.g., www.analog.com, www.maxim-ic.com, www.linear.com, www.ti.com, etc.

Another way to find datasheets, prices, and availability is via a search website like octopart.com or findchips.com; these display price and inventory (and sometimes datasheets), and link you through to the stocking distributor.

Op-amps

Applications Manual for Operational Amplifiers, for Modelling, Measuring, Manipulating, & Much Else. Philbrick/Nexus Research (1965). Charming compendium from the originators of the first commercial op-amp; these are collectors' items, long out of print.[1]

Carter, B., and Brown, T. R., *Handbook of Operational Amplifier Applications*. Rework of the classic Burr–Brown handbook, described by Carter as a "treasure. . . some of the finest works on op amp theory that I have ever seen."

Frederiksen, T. M., *Intuitive IC op-amps*. Santa Clara, CA: National Semiconductor Corp. (1984). Extremely good treatment at all levels.

Graeme, J. G., *Applications of Operational Amplifiers: Third Generation Techniques*. McGraw-Hill (1987). One of the Burr-Brown series.

Jung, W. G., ed., *Op Amp Applications Handbook*. Newnes (2004). Fascinating history section, excellent up-to-date detail.

Jung, W. G., *IC op-amp Cookbook*. Howard W. Sams & Co. (3rd ed., 1986). Lots of circuits, with explanations. See also Jung's *Audio IC Op-amp Applications*.

Soclof, S., *Analog Integrated Circuits.* Prentice-Hall (1985). Detailed IC-designer information, useful for IC users as well.

Zumbahlen, H., *Linear Circuit Design Handbook.* Newnes (2008). Things you need to know from Analog Devices engineers.

[1] But happily resurrected at `http://www.analog.com/library/analogdialogue/archives/philbrick/computing_amplifiers.html`.

Audio

Duncan, B., *High Performance Audio Power Amplifiers.* Newnes (1996). Excellent review of professional audio power amplifier design.

Hickman, I., *Analog Electronics.* Newnes (2nd ed., 1999). Interesting overview, one wishes he had written more.

Hood, J. L., *The Art of Linear Electronics.* Newnes (1998). Audio electronics, including FM.

Pohlman, K. C., *Principles of Digital Audio*. McGraw-Hill (3rd ed., 1995). All aspects of digital audio; nonmathematical, an easy read.

Self, D., *Small Signal Audio Design.* Focal Press (2010). Audio design basics and tricks, with a special view from an industry master.

Strawn, J., ed., *Digital Audio Signal Processing*. A-R Editions Inc. (Madison, WI; 1985). The first article (by Moore) is a magnificent introduction to the mathematics of digital signal processing. Sadly, this volume is out of print.

Watkinson, J., *The Art of Digital Audio*. Focal Press (3rd ed., 2000). Another nice book on digital audio.

Filters and Oscillators

Hilburn, J. L., and Johnson, D. E., *Manual of Active Filter Design*. McGraw-Hill (1982).

Lancaster, D., *Active Filter Cookbook*. Howard W. Sams & Co. (1979). Explicit design procedure; easy to read.

Matthys, R. J., *Crystal Oscillator Circuits.* Wiley (1983), Krieger Publishing (revised, 1992).

Parzen, B., *Design of Crystal and Other Harmonic Oscillators*. Wiley (1983). Discrete oscillator circuits.

Williams, A. and Taylor, F., *Electronic Filter Design Handbook*. McGraw-Hill (4th ed., 2006). Practical filter design, with formulas, tables, and many examples.

Zverev, A. I., *Handbook of Filter Synthesis*. Wiley (1967). Extensive tables for passive *LC* and crystal filter design.

See also Graeme, J. G., under op-amp listings.

Power, Regulation, and Control

Basso, C. P., *Switch-Mode Power Supplies: SPICE Simulations and Practical Designs*. McGraw-Hill (2008). The title says it all.

Billings, K. and Morey, T., *Switchmode Power Supply Handbook*. McGraw-Hill (3rd ed., 2010). Highly readable and comprehensive treatment of an often-confusing topic.

Erickson, R. W. and Maksimovic, D., *Fundamentals of Power Electronics.* Springer (2nd ed 2001). Learn how to compensate an SMPS feedback loop.

Grover, F. W., *Inductance Calculations*. Dover (2009 reprint of the 1946 classic). Formulas, tables, and graphs for the inductance of just about anything.

Hnatek, E. R., *Design of Solid-state Power Supplies*. Van Nostrand Reinhold (1989). Switching supplies.

MacFadyen, K. A., *Small Transformers and Inductors.* Chapman & Hall (1953). Learn how to calculate leakage inductance in your transformers.

Maniktala, S., *Switching Power Supplies: A to Z.* Newnes (2nd ed, 2012). Filled with useful unusual material, like magnetics design with the all-important AC-resistance loss analysis.

Pressman, A., Billings, K., and Morey, T., *Switching Power Supply Design.* McGraw-Hill (3rd ed., 2009). Standard comprehensive book for a two-week introductory course in SMPS design.

Rogers, G. and Mayhew, Y., *Engineering Thermodynamics: Work and Heat Transfer.* Prentice-Hall (4th ed, 1996). Develop a better understanding of thermal management in electronics.

Snelling, E. C., *Soft Ferrites.* Butterworth–Heinemann (2nd ed, 1988). The bible for inductor and transformer design.

Optics and Light

Friedman, E. and Miller, J. L., *Photonics Rules of Thumb: Optics, Electro-Optics, Fiber-Optics, and Lasers*. McGraw-Hill (2003). What's *this* doing here? Well, it's an amazing collection of coolstuff, both serious and quixotic (e.g., "crickets as thermometers.")

Graeme, J. G., *Photodiode Amplifiers: Op Amp Solutions*. McGraw-Hill (1995). The low-down on transimpedance amplifiers.

Hobbs, P. C. D., *Building Electro-Optical Systems: Making It All Work*. Wiley (2nd ed., 2009). Great balance of theory and practice.

Lenk, R. and Lenk, C. *Practical Lighting Design with LEDs.* Wiley (2011).

Schubert, E. F. *Light-Emitting Diodes.* Cambridge University Press (2nd ed., 2006). LED device physics, practical devices, color physics.

Yariv, A., *Introduction to Optical Electronics*. Rinehart & Winston (1976). Physics of opto-electronics, lasers, and detection.

High-speed Digital and RF

Hagen, J. B., *Radio-Frequency Electronics: Circuits and Applications*. Cambridge University Press (2nd ed., 2009). Refreshingly different, an insight per page.

Johnson, H. and Graham, M., *High Speed Digital Design: A Handbook of Black Magic*. Prentice-Hall (1993). Ringing, cross-talk, ground bounce, etc. – a must-have if you're doing fast digital design.

Johnson, H. and Graham, M., *High Speed Signal Propagation: Advanced Black Magic*. Prentice-Hall (2003). Techniques for pushing the limits of high-speed signal transmission.

Johnson, R. C., ed., *Antenna Engineering Handbook*. McGraw-Hill (3rd ed., 1992). Comprehensive, excellent tables and design information.

Krauss, J. D. and Marhefka, R. J., *Antennas for All Applications*. McGraw-Hill (3rd ed., 2001). Highly readable and usable text.

Ramo, R., Whinnery, J. R. and Van Duzer, T., *Fields and Waves in Communication Electronics*. Wiley (3rd ed., 1994). A classic electricity and magnetism text, with emphasis on communications.

Roy, K. and Prasad, S., *Low-Power CMOS VLSI Circuit Design.* Wiley (2000).

Sevick, J., *Transmission Line Transformers*. Noble (4th ed., 2001). Practical guide to understanding and building RF transformers.

Digital Signal Processing and Communication

Bracewell, R. N., *The Fourier transform and its applications*. McGraw-Hill (3rd ed., 1999). The classic in this field.

Brigham, E. O., *The Fast Fourier Transform and its Applications*. Prentice-Hall (1988). Highly readable.

Oppenheim, A. V. and Schafer, R. W., *Discrete-Time Signal Processing.* Prentice-Hall (3rd ed., 2009). Well-received classic on digital signal analysis.

Sklar, B., *Digital Communications: Fundamentals and Applications*. Prentice-Hall (2nd ed., 2001). Fine introduction to all aspects of digital communications.

Logic, Conversion, and Mixed-signal

Best, R. E., *Phase-locked Loops*. McGraw-Hill (6th ed., 2007). Advanced techniques.

Brennan, P. V., *Phase-Locked Loops: Principles and Practice.* McGraw-Hill (1966).

Gardner, F. M., *Phaselock Techniques*. Wiley (1979). The classic PLL book: emphasis on fundamentals.

Kester, E., ed., *The Data Conversion Handbook*. Newnes (2004). Includes an excellent history of data conversion, and extensive detail on the nuances of conversion, timing, bandwidth, etc.

Lancaster, D., *CMOS Cookbook*. Howard W. Sams & Co. (2nd ed., 1997). Good reading, down-to-earth applications. Includes widely used (but rarely mentioned) M^{2}L (Mickey Mouse logic) technique.

Rohde, U. L., *Digital PLL Frequency Synthesizers*. Prentice-Hall (1983). Theory and lots of circuit detail.

Sheingold, D. H., ed., *Transducer Interfacing Handbook*. Analog Devices (1980).

Computers and Programming

Hancock, L. and Krieger, M., *The C Primer*. McGraw-Hill (1982). Introduction for beginners.

Harbison, S. P. and Steele, G. L., Jr., *C: A Reference Manual*. Prentice-Hall (1987). Readable and definitive; has ANSI extensions.

Wescott, T., *Applied Control Theory for Embedded Systems.* Newnes (2006). From the author of *PID without a Ph.D.*

Miscellaneous

Grätzer, G., *More Math into LaTeX*. Springer (4th ed., 2007). Best single reference on typesetting with LaTeX (the software typesetting language in which this book was written).

Kleppner, D. and Ramsey, N., *Quick Calculus*. Wiley (2nd ed., 1985). The title is honest, it's the fastest way to learn calculus. Don't be put off by the book's vintage (hey, calculus itself goes back almost four centuries).

THE OSCILLOSCOPE

APPENDIX O

The oscilloscope ("scope" for short) is, by far, the most useful and versatile electronic circuit test instrument.[1] As usually used, it lets you "see" voltages in a circuit as a function of time, triggering on a particular point of the waveform so that a stationary display results. Contemporary scopes are almost invariably *digital* (input signals are digitized, processed, and displayed), and they do (and usually *better*) what their analog ancestors did. To understand how to use an oscilloscope, we think it best to start with the traditional (and nearly extinct) 2-channel *analog* scope, for which we've drawn a block diagram (Figure O.1) and typical front panel (Figure O.2). Digital scopes carry forward nearly all of its features, to which they add an impressive array of capabilities (and a few hazards).

O.1 The analog oscilloscope

O.1.1 Vertical

Beginning with the signal inputs, most analog scopes have two channels; that's very useful, because you often need to see the relationship between signals. Each channel has a calibrated gain switch, which sets the scale of **VOLTS/DIVISION** *on the screen*.[2] There's also a **VARIABLE** gain knob (concentric with the gain switch) in case you want to set a given signal to a certain number of divisions. Warning: be sure the variable gain knob is in the "calibrated" position when making voltage measurements! It's easy to forget. The better scopes have indicator lights to warn you if the variable gain knob is out of the calibrated position.

The scope is dc-coupled, an essential feature: what you see on the screen is the signal voltage, dc value and all. Sometimes you may want to see a small signal riding on a large dc voltage, though; in that case you can switch the input to **AC COUPLING**, which capacitively couples the input with a time constant of about 0.1 second. Most scopes also have a grounded input position, which lets you see where zero volts is on the screen. (In **GND** position the signal isn't shorted to ground, just disconnected from the scope, whose input is grounded.) Scope inputs are usually high-impedance (1MΩ in parallel with about 20 pF), as any good voltage-measuring instrument should be.[3] The input resistance of 1 MΩ is an accurate and universal value, so that high-impedance attenuating probes can be used (as will be described later); unfortunately, the parallel capacitance is not standardized, which is a bit of a nuisance when changing probes.

The vertical amplifiers include a vertical **POSITION** control, an **INVERT** control on at least one of the channels, and an **INPUT MODE** switch. The latter lets you look at either channel, their sum (their difference, when one channel is inverted), or both. There are two ways to see both: **ALTERNATE**, in which alternate inputs are displayed on successive sweeps of the trace, and **CHOPPED**, in which the trace jumps back and forth rapidly (0.1–1 MHz) between the two signals. **ALTERNATE** mode is generally better, except for slow signals. It is often useful to view signals both ways, to make sure you're not being deceived.

O.1.2 Horizontal

The vertical signal is applied to the vertical deflection electronics, moving the dot up and down on the screen. The horizontal sweep signal is generated by an internal ramp generator, giving deflection proportional to time. As with the vertical amplifiers, there's a calibrated **TIME/DIVISION** switch and a **VARIABLE** concentric knob; the same warning stated earlier applies here. Most scopes have a **10× MAGNIFIER** and also allow you to use one of the input channels for horizontal deflection (this lets you generate those beloved but generally useless

[1] It is sometimes said that practitioners of other engineering disciplines are especially envious of EEs, because we are blessed with such a splendid instrument with which to visualize the happenings in our circuits.

[2] Note that the two channels can be set for different scale factors, offsets, and coupling. This goes also for digital scopes, which commonly have four channels.

[3] Scopes intended for high-frequency measurements, going beyond 100 MHz, say, offer also a 50 Ω input impedance option.

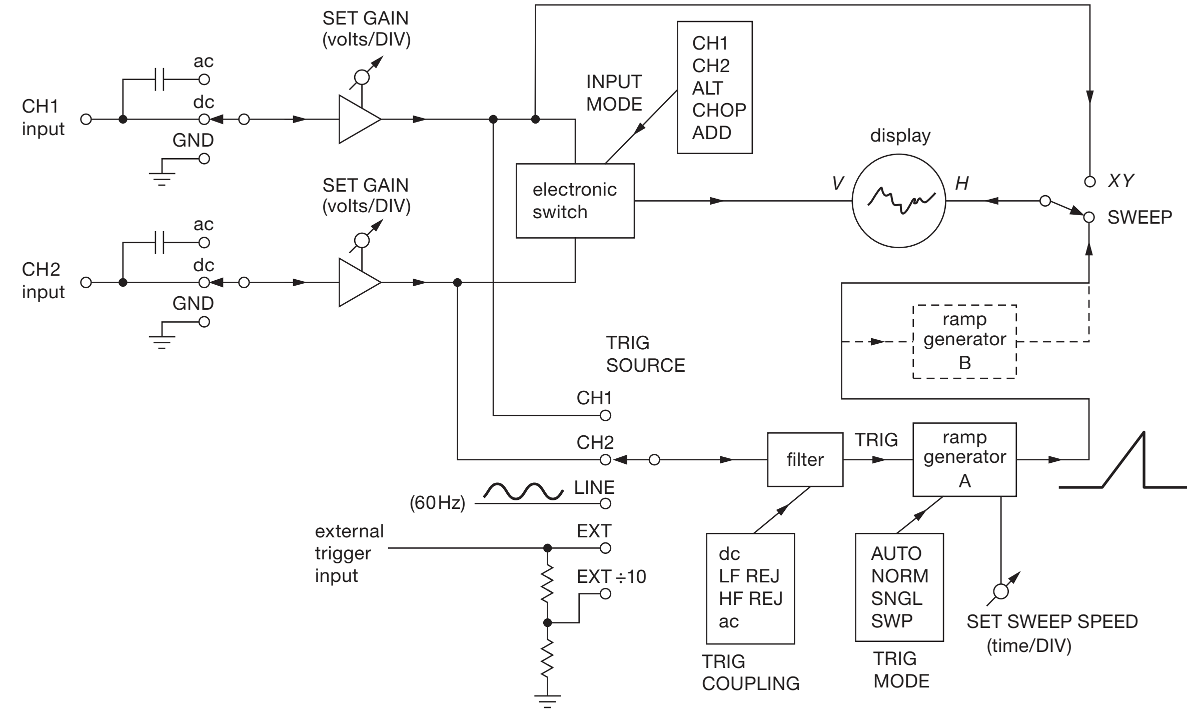

Figure O.1. Block diagram of a 2-channel analog oscilloscope.

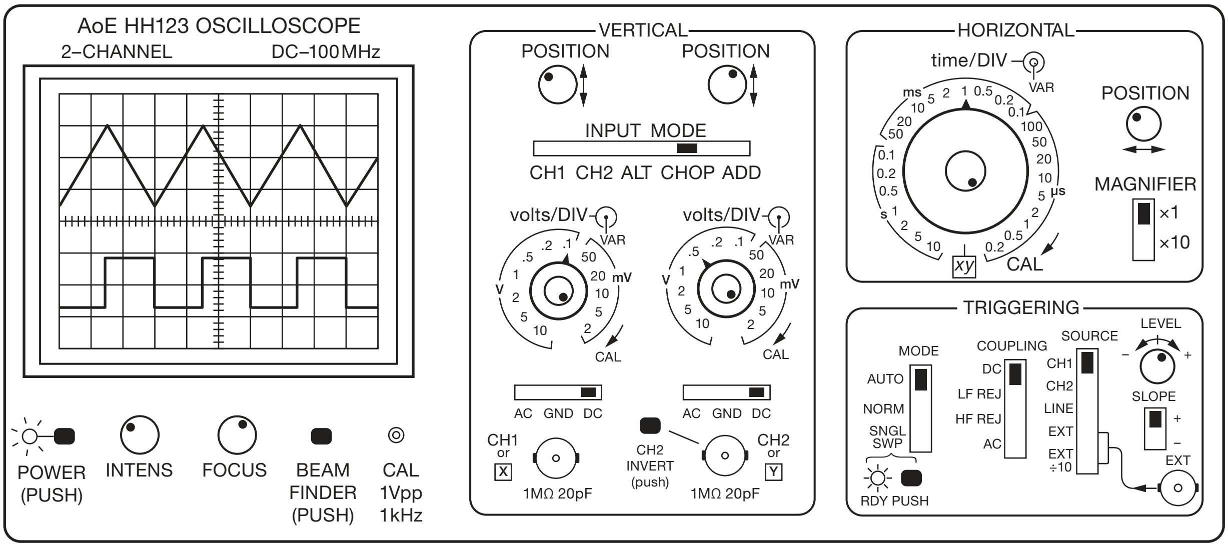

Figure O.2. Portrait of a 2-channel analog scope.

"Lissajous figures" featured in elementary books and science fiction movies).

O.1.3 Triggering

Now comes the trickiest part: *triggering*. We've got vertical signals and horizontal sweep; that's what's needed for a graph of voltage versus time. But if the horizontal sweep doesn't catch the input signal at the same point in its waveform each time (assuming the signal is repetitive), the display will be a mess – a picture of the input waveform superimposed over itself at different times. The trigger circuitry lets you select a **LEVEL** and **SLOPE** (+ or −) on the waveform at which to begin the sweep. You can see from the front panel that you have a number of choices about trigger sources and mode. **NORMAL** mode produces a sweep only when the source selected crosses through the trigger point you have set, moving in the direction (**SLOPE**) you have selected. In practice, you adjust the level control for a stable display. In **AUTO** the sweep will "free run" if no signal is present; this is good if the signal sometimes drops to small values, since the display won't disappear and make you think the signal has gone away. It's the best mode to use if you are looking at a bunch of different signals and don't want to bother setting the trigger each time. **SINGLE SWEEP** is used for nonrepetitive signals. **LINE** causes the sweep to trigger on the ac power line, handy if you're looking at hum or ripple in a circuit. The **EXTERNAL** trigger inputs are used if you have a clean signal available at the same rate as some "dirty" signal you're trying to see; it's often used in situations where you are driving some circuit with a test signal, or in digital circuits where some "clock" signal synchronizes circuit operations. The various coupling modes are useful when viewing composite signals; for instance, you may want to look at an audio signal of a few kilohertz that has some spikes on it. The **HF REJ** position (high-frequency reject) puts a low-pass filter in front of the trigger circuitry, preventing false triggering on the spikes. If the spikes happen to be of interest, you can trigger on them instead in **LF REJ** position.

Many scopes now have **BEAM FINDER** and **TRIGGER VIEW** controls. The beam finder is handy if you're lost and can't find the trace; it's a favorite of beginners. Trigger view displays the trigger signal; it's especially handy when triggering from external sources.

O.1.4 Hints for beginners

Sometimes it's hard to get *anything* to show on the scope. Begin by turning the scope on; set triggering for **AUTO**, **DC COUPLING**, **CH 1**. Set sweep speed at 1 ms/div, cal, and the magnifier off (×1). Ground the vertical inputs, turn up the intensity, and wiggle the vertical position control until a horizontal line appears (if you have trouble at this point, try the beam finder).[4] Now you can apply a signal, unground the input, and fiddle with the trigger. Become familiar with the way things look when the vertical gain is far too high, when the sweep speed is too fast or slow, and when the trigger is adjusted incorrectly.

O.1.5 Probes

The oscilloscope input capacitance seen by a circuit under test can be undesirably high, especially when the necessary shielded connecting cable is included. The resulting input impedance (1MΩ in parallel with 100 pF or so) is often too low for sensitive circuits and loads it by the usual voltage divider action; for example, at 10 MHz a 100 pF load looks like 160 Ω – ouch! Worse yet, the capacitance may cause some circuits to misbehave, even to the point of going into oscillation. In such cases the scope obviously is not acting like the "low-profile" measurement instrument we expect; it's more like a bull in a china shop.

The usual solution is the use of high-impedance "probes." In simplified form,[5] the popular 10× probe works as shown in Figure O.3. At dc it's just a 10× voltage divider. By adjusting C_1 to be $\frac{1}{9}$th the parallel capacitance of C_2 and C_3, the circuit becomes a 10× divider at all frequencies, with input impedance of 10MΩ in parallel with a few picofarads. In practice, you adjust the probe by looking at a square wave of about 1 kHz, available on all scopes as **CALIB**, or **PROBE ADJ**, setting the capacitor on the probe for a clean square wave without overshoot. Sometimes the adjustment is cleverly hidden; on some probes you twist the body of the probe and lock it by tightening a second threaded part. One drawback: a 10× probe makes it difficult to look at signals of only a few millivolts; for these situations use a "1× probe," which is simply a length of low-capacitance shielded cable with the usual probe hardware (wire "grabber," ground clip, handsome knurled handle, etc.). The 10× probe should be the standard probe, left connected to the scope, with the 1× probe used when necessary. Some probes feature a convenient choice of 1× or 10× attenuation, switchable at the probe tip.

Even with a 10× probe, the circuit loading may be unacceptable; after all, its improvement is just the same factor of ten by which it attenuates the input signal. You *can* get 100× probes, with correspondingly higher input

[4] Curiously, some scopes (for example the once-popular Tektronix 400 series) don't sweep on **AUTO** unless the trigger level is adjusted correctly.

[5] In practice the cable itself is made from resistance wire, to damp transmission-line effects (frequency peaking and transient reflections, see Appendix H), an elegant 1959 invention by Kobbe and Polits (US Patent 2,883,619); you also see tricks such as a series *RC* across the scope terminals (e.g., 500 Ω and a trimmer capacitor), to provide a transmission-line match at high frequencies.

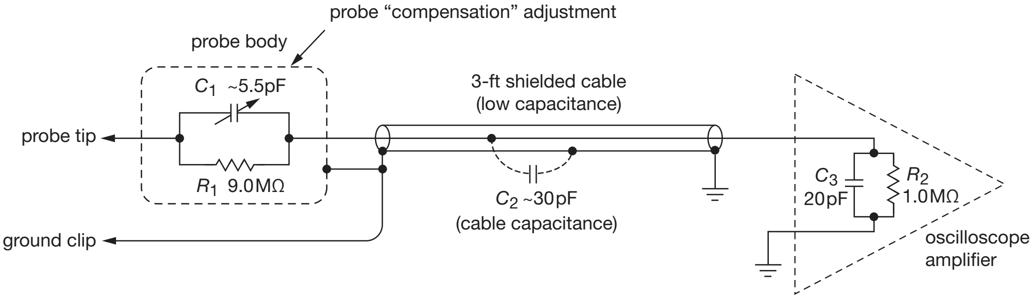

Figure O.3. A 10× passive scope probe attenuates signals by a factor of ten at all frequencies, conveniently raising the input impedance by the same factor. (In practice additional tricks are used to suppress transmission-line effects, see text.)

impedance (e.g., the Tektronix P5100 series), but these are intended primarily for viewing high-voltage signals (the scope itself is usually limited to a maximum of ±400 V at the input connector), and they do not excel in important features such as small physical size. What you do, instead, is to use an *active probe*, which uses a FET follower at the tip to achieve an input capacitance <1 pF.[6] Active probes, being intended for wideband use, are intended to drive a 50 Ω input (available on most high-speed scopes; if not, attach a 50 Ω pass-through terminator); they require a source of power, available at the scope's input connector (on digital scopes), or provided by a stand-alone box like the Tektronix 1103.

Any discussion of probes would be incomplete without a mention of *current* probes: these handy devices, when clipped around a wire in some circuit, convert the circuit's current to a voltage waveform that's displayed on the scope. The simplest current probes are inherently ac-coupled (they wrap a secondary winding around a magnetic split core that surrounds the one-turn wire "primary") and thus do not sense dc current; the fancier types use a combination of Hall effect and transformer coupling to achieve response down to dc. Examples of the latter are the Tektronix A622 (dc to 100 kHz) and the TCP312A (dc to 100 MHz); the latter requires the matching TCPA300 amplifier.

O.1.6 Grounds

As with most test instruments, the oscilloscope input is referred to the instrument ground (the outer connection of the input BNC connectors), which is usually tied electrically to the case. That, in turn, connects to the ground lead of the ac power line, via the 3-wire power cord. This means that you cannot measure voltages between the two arbitrary points in a circuit, but are forced to measure signals relative to this universal ground.

An important caution is in order here: if you try to connect the ground clip of an oscilloscope probe to a point in the circuit that is at some voltage relative to ground, you will end up shorting it to ground. This can have disastrous consequences to the circuit under test; in addition, it can be downright dangerous with circuits that are "hot to ground" (for example line-powered switching power supplies). If it is imperative to look at the signal between two points, you can make a differential measurement by inverting one input channel and switching to ADD, or you can use an external differential preamp (e.g., the LeCroy DA1855A). In desperate situations we have been known to "float" the scope by lifting the ground lead at the power cord, but this is *not recommended*, unless you really know what you're doing (and agree to waive any liability on our part).

Another caution about grounds when you're measuring weak signals or high frequencies: be sure the oscilloscope ground is the same as the circuit ground where you're measuring. The best way to do this is by connecting the short ground wire on the probe body directly to the circuit ground,[7] then checking by measuring the voltage of "ground" with the probe, observing no signal. One problem with this scheme is that those short ground clips are usually missing, lost! Keep your probe accessories in a drawer somewhere.

O.1.7 Other analog scope features

Many scopes have a **DELAYED SWEEP** that lets you see a segment of a waveform occurring some time after the trigger point. You can dial the delay accurately with a multiturn adjustment and a second sweep-speed switch. A delay

[6] One of our favorites is the Tektronix P6243, <1 pF and 1 GHz bandwidth.

[7] See the illustrations in Figure 12.32

mode known as **A INTENSIFIED BY B** lets you display the whole waveform at the first sweep speed, with the delayed segment brightened; this is handy during setup. Scopes with delayed sweep sometimes have “mixed sweep,” in which the trace begins at one sweep speed, then switches to a second (usually faster) speed after the selected delay. Another option is to begin the delayed sweep either immediately after the selected delay or at the next trigger point after the delay; there are two sets of trigger controls, so the two trigger points can be set individually. (Don’t confuse delayed sweep with “signal delay.” All good analog scopes have a delay in the signal channel, so you can display the event that caused the trigger; it lets you look a little bit backward in time! See the photographs of the analog delay lines in Figures H.19 and H.21).

A common feature of analog scopes is a **TRIGGER HOLDOFF** control; it inhibits triggering for an adjustable interval after each sweep, and it is very useful when viewing complicated waveforms without the simple periodicity of, say, a sinewave. The usual case is a digital waveform with a complicated sequence of 1s and 0s, which won’t generate a stable display otherwise (except by adjustment of the sweep-speed vernier, which means you don’t get a calibrated sweep).

All scopes (analog and digital) include some **BANDWIDTH LIMIT** vertical amplifier options (for simplicity, not shown in Figures O.1 and O.2), useful for reducing the amount of wideband “fuzz” on the displayed trace when you’re working with relatively slow signals.

During the height of the analog scope era, you could get scopes with on-screen “storage” (for single-shot capture) and scopes with an impressive array of plug-in modules that let you do lots of interesting stuff, including display of eight traces, or spectrum analysis, or accurate (digital) measurements of voltage and time on waveforms, and so on. Happily, these functions and many others (e.g., looking far backward in time from the triggering event) are now embodied in the dominant oscilloscope species, the *digital* oscilloscope. Let’s take a look.

O.2 The digital oscilloscope

Analog scopes are easy to use, but they are seriously limiting in what you can do. For example, (a) it’s hard to see a “single-shot” event; (b) you can’t store a trace, or compare a live trace with an earlier trace; (c) you can’t extract a trace for measurement or illustration; and (d) you can’t look back in time to see what happened before the triggering event.

Digital scopes effortlessly provide these and many other capabilities; and, because of the stunning capability and low cost of digital conversion and processing, they are, ironically, less expensive than an analog scope (if you can find one) of comparable bandwidth. The transition to usable and friendly digital scopes was rocky at first, but they are now ubiquitous and universal.

The basic scheme (Figure O.4) is to digitize the incoming signal after the frontend stages of programmable gain and bandwidth limiting, capture the samples in a fast circular buffer memory, and then use a processor (or multiple processors) to do all the signal processing, measurements, conversion to a meaningful display, user interface, and I/O. We’ll keep this section brief, and merely run through some capabilities of digital scopes.

O.2.1 What’s different?

In no particular order:

Front-end: The signal emerging from the (variable-gain) input amplifiers is digitized at some sampling rate f_{samp} (typically 1 Gsps or more, but always above the minimum Nyquist rate of $2f_{\max}$ when the scope is set at fast enough sweep rates to resolve the scope’s bandwidth $f_{\max}$. But – **important** – see “aliasing,” below). The digital samples, typically of 8 bits resolution, are stored at full speed into a *sample memory* (or “capture memory”), often of length 1 Mpt or more per channel (and reaching 1 Gpt at the high end). Note that, even though digital scopes let you zoom in after a trace is captured, the resolution depends on the vertical scale factor, because of the fixed bit depth of conversion.

Simultaneous on all channels: Digital scopes digitize all channels simultaneously; there’s no “alternate” or “chop.” Most digital scopes come in 2- or 4-channel flavors, augmented in “mixed-signal” scopes by sixteen or more 1-bit (i.e., logic-level) channels.

Pre-trigger: Because digitized input signals are pouring into memory, you can set a trigger condition (most simply, level and slope; but see “Smart trigger,” below) and, when it is satisfied, you’ve got substantial pre-history in the sample memory. From the user’s point of view, you can simply set the displayed trigger pointer to the right portion of the screen to reveal what came before. And you can walk backward or forward to your heart’s content through a saved single-shot capture (see “Single-shot capture,” below).

Display: The time interval between points on the *displayed* waveform (the “waveform interval”) is typically longer (often much longer) than the sampling interval

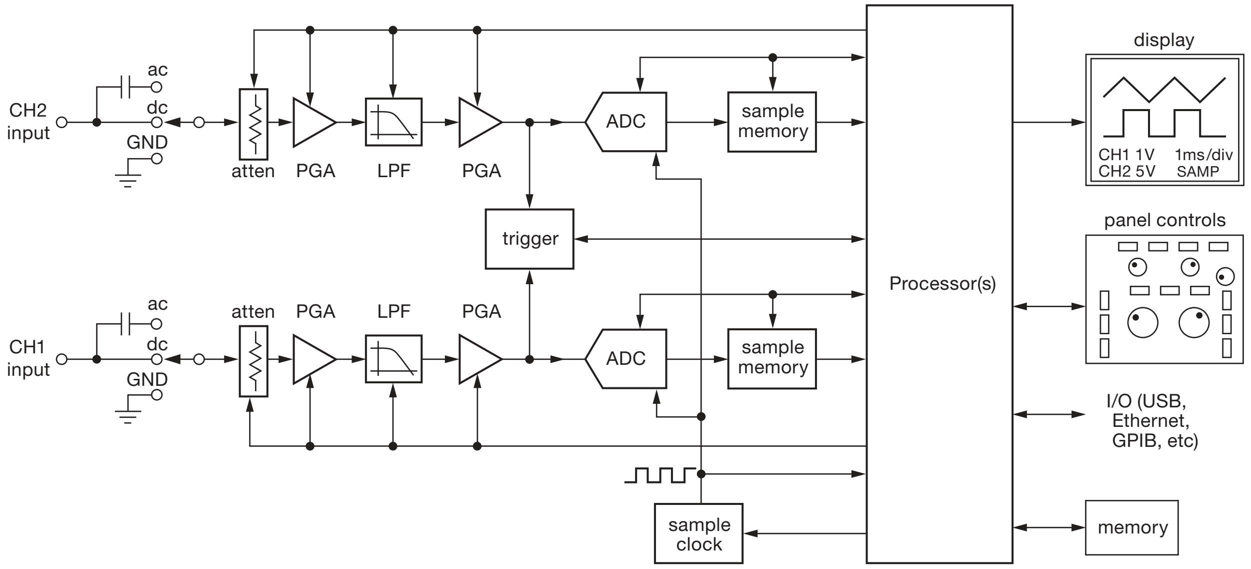

Figure O.4. Block diagram of a 2-channel digital oscilloscope.

$1/f_{\text{samp}}$. This allows for various modes of processing the sampled points to produce the displayed waveform, in particular:

sample one sample point per waveform interval is displayed; the rest are discarded. Simple, but susceptible to aliasing, see below.

peak detect the highest and lowest sampled points in two successive waveform intervals are displayed. Produces a thicker waveform, but no short spikes are lost.

envelope similar to peak detect, but combines min/max from multiple triggered acquisitions. Useful for seeing excursions from an ideal repetitive waveform.

average each point in the displayed waveform is the calculated average of single samples (as in sample mode) over many (a settable number, e.g, 2, 4, 8, ...512) triggered acquisitions. Greatly reduces noise, without reducing bandwidth, but requires a repetitive signal.

high resolution each displayed point is calculated as the average value of the multiple samples captured within one waveform interval. Provides higher resolution, and does not require a repetitive signal, but reduces bandwidth.[8]

Persistence: Engineers with gray beards wax poetic about the beautiful gradations of intensity with which analog scopes display waveforms. Digital scopes took a while to catch up, but now they trumpet their ability to do the same, with terms like “digital phosphor,” “persistence trace,” and “digital persistence.”

Single-shot capture: Digital scopes excel in single-shot capture. You can troll through the sampled data post-capture, either manually (by turning knobs for scrolling and magnifying) or with some helpful automated search tools (e.g., Tektronix’s “Wave Inspector” – the name says it all).

Slow sweep: Analog scopes are hopeless when you want to view a waveform that takes many seconds; digital scopes couldn’t care less. Use “rolling mode” at slow sweep rates.

Save/Recall: You can save one or more waveforms to memory, bring them back for comparison, etc. You can also save the scope’s *state* (i.e., settings).

Measurements: The data’s all there, so digital scopes have no problem measuring period, frequency, amplitude, time interval, duty cycle, etc. These measurements usually update continuously, and you can use settable horizontal and vertical cursors to define the measurement regions and intervals.

Math: Going further, digital scopes let you calculate products (e.g., to measure power from voltage and current), quotients (to normalize a waveform), jitter, histograms, frequency spectra, etc. Almost limitless possibilities,

[8] You can think of this as a “horizontal average” along one waveform capture, as compared with the “vertical averaging” of single sample points in successive stacked waveforms in *average* mode.

but you may prefer to extract the data and do the math offline.

I/O: You can send waveforms and data out (via connected Ethernet or whatever), and you can control the scope's operations remotely. A networked data-acquisition system!

Mixed-signal: Many digital scopes come with a bunch of 2-level channels (typically 16 or 32) along with the usual 2 or 4 full-resolution channels; so it works as a logic analyzer, but augmented by a few channels of clear waveform view. As with a traditional logic analyzer, you can trigger on a defined set of levels, and it can do bus decoding, bus triggering, and other fancy stuff for you.

Smart trigger: Good digital scopes let you trigger on just about any condition you can imagine: pulse width $<$, $>$, $=$, or $\neq$ to some value; runt pulses and glitches; setup or hold time violations; specified range of rise-times or falltimes; specified conditions or violations on serial buses; trigger after n events; and so on. (checkout the enjoyable reading in a datasheet from Tektronix, LeCroy, Keysight/Agilent, or Rohde & Schwarz)

Limit/Mask testing: You can set up a template and detect out-of-spec waveforms, for Go/No-Go testing on a production line; ditto for jitter and other measurable parameters.

Autoset: It's easy to get lost in this multi-dimensional wilderness; digital scopes provide a rescue button (autoset, autoscale, or some linguistic variant, depending on manufacturer), which will at least get something going on the screen (but see the Cautions, next).

Probe skew: When you're using several different probing systems (e.g., passive 10× probe, active FET probe, current probe) the signal delays can vary by tens of nanoseconds or more, completely disrupting the fidelity of the multichannel display (hey, you may be tricked into thinking you've got a violation of causality – effect precedes cause![9]).

Probe readout, Probe power: Probes for use with contemporary digital scopes have extra connections by which they communicate their attenuation factor (×1, ×10, ×100) and other useful scale factor information (e.g., the amps/div of a current probe); they use such connections also to send power to the probe (needed, for example, with FET active voltage probes or Hall-effect current probes). This can be an annoyance, though, if your scope's input connectors are of the wrong format (which happens even within one manufacturer's scope offerings).

O.2.2 Some cautions

There's not much not-to-like about digital oscilloscopes. But here are a few cautions, ways in which a digital scope can trick the unwary.

A. Aliasing

This one can fool even the experienced scope user: digital scopes are designed such that the *maximum* sample rate is always adequate for signals up to the scope's full bandwidth; but when you are running at a slower sweep rate in "sample" mode (i.e., one sample per displayed waveform point) the effective sample rate is much lower. So you may see some serious nonsense (jittery unstable signal, inability to trigger, weird change of waveform when sweep rate is changed, etc.) if there's a high frequency signal present.[10]

If you suspect aliasing, try speeding up the sweep, or changing to **PEAK DETECT** mode. Aliasing can be really annoying when you're dealing with signals that combine timescales (the classic one was analog television, with a 3.59 MHz color carrier on a ∼15 kHz horizontal line frequency).

B. Dead time

For human visual perception it's necessary to update the scope display at only ∼100 times per second or so. If the scope captures input waveform data only at that rate, the fraction of time that it's sensitive to important signal events (like a glitch or timing violation) may be exceedingly low. For example, at a middling sweep rate of 1 μs/div (thus 10 μs per sweep) a scope that's updating 100 times/second is active only 0.1% of the time.

When scope users became aware of this ugly secret, scope manufacturers went at it, and they now provide some measure of true update rate (usually in the form of "waveforms per second," typically in the range of 100,000–1,000,000). Be careful when evaluating such metrics, because there's more than a little "specsmanship" going on.[11]

[9] As does the protagonist in Asimov's delightful short story from 1960: *Thiotimoline and the Space Age*.

[10] Dare we admit? One of the authors was testing a circuit that operates at frequencies in the kilohertz range, driving it with a digital function generator at 1.0 kHz. Go out to lunch, come back, look at the waveform – the scope is broken, won't trigger, jittery waveform sliding left and right. Weird. Tried everything. Then noticed that the generator had defaulted to its 1.0 *mega*hertz setting. Ha! Problem solved (and I won't ever tell anyone how dumb I was).

[11] Ask your scope salesperson, they love to flame the lying competition.

C. Lost in a multidimensional vector space

Analog scopes are simple, and you can see the full state of the instrument just by looking at the knobs and indicators. No such luck with the immense capabilities of digital scopes. Early digital scopes were particularly troublesome, lacking annunciators and (mostly) knobs. They've improved enormously,[12] but it's still awfully easy to be sitting in front of a scope that just isn't triggering, or showing significant vital signs. It takes some keen intuition to know which menu to pull down (horizontal? trigger? mode?) to get to the problem. It may be as simple as triggering on the wrong channel; or it might be that you've left the display in **AVERAGING** mode, and lack of a stable repetitive trigger produces a bunch of garbage. And you can even waste a minute not realizing that the thing is in **SINGLE-SWEEP** or **STOP** mode.

D. The scope is lying to you

When observing signals with a digital scope, you may be victimized by a blessing (a vast array of measurement capabilities and settings) that becomes a curse (the scope's settings are not what you think). It's easy to forget some obscure but important settings that falsify the measurements you think you're making. For example, it's easy to forget (we've done it, often) that you've left an earlier **PROBE SKEW** compensation in effect, or that some channels still have **BANDWIDTH LIMIT** set. Such oversights corrupt your measurements in less-than-obvious ways that you may not notice for quite a while; and when you do, you're sentenced to serve time repeating the measurements properly.

[12] We are particularly fond of the "QuickMenu" feature that was introduced by Tektronix in their original TDS3000-series "lunchbox" scopes. Inexplicably, this highly useful feature has been eliminated (despite our howls of protest) in Tek's successor scopes. We've been badgering them ever since.

ACRONYMS AND ABBREVIATIONS

APPENDIX P

Electrical engineers are fond (*too* fond, some would say) of acronyms and abbreviations, a familiarity that every educated circuit designer must necessarily acquire. To assist in that education, and for handy reference, we here provide a lightly annotated list of terms used in this book.

ac: literally “alternating current” (i.e., alternating *voltage*); more generally a varying signal
AC(T): advanced CMOS (logic family)
A/D: analog-to-digital
ADC: analog-to-digital converter
ADI: Analog Devices Inc.
AES: Audio Engineering Society
AFC: automatic frequency control
AGC: automatic gain control
AGF: all-glass fiber
AHC(T): advanced high-speed CMOS (logic family)
ALS: advanced low-power Schottky (logic family)
ALU: arithmetic logic unit (in a processor)
ALV: advanced low-voltage (logic family)
AM: amplitude modulation
ANSI: American National Standards Institute
APD: avalanche photodiode
APF: all-plastic fiber
ARM: a popular processor architecture from ARM Holdings
ASIC: application-specific full-custom integrated circuit
ASCII: American Standard Code for Information Interchange
ASF: all-silica fiber
ASSP: application-specific standard product
ATA: advanced technology attachment (a disk interface; see PATA, SATA)
ATAPI: ATA packet interface (a generalized ATA)
ATE: automated test equipment
ATM: asynchronous transfer mode
ATSC: Advanced Television Systems Committee (digital TV standards)
AUC: advanced ultra-low-voltage CMOS (logic family)
AVC: advanced (low)-voltage CMOS (logic family)
AVR: a microcontroller family from Atmel Corp.
AWG: American wire gauge
AZ: auto-zero

BBM: break-before-make (switch)
BCD: binary-coded decimal
BGA: ball-grid array (an IC package)
BJT: bipolar junction transistor
BNC: bayonet Neill–Concelman (connector)
BPSK: binary phase-shifting keying
BRT: bias resistor transistor
BSS: broadcast satellite services
BV: breakdown voltage
BW: bandwidth

C0G: low tempco (stable) ceramic dielectric
CA: conditional access
CAN: controller area network (bus)
CANH: controller area network high (a CAN signal)
CANL: controller area network low (a CAN signal)
CBR: constant bitrate (coding)
CCD: charge-coupled device
CCFL: cold-cathode fluorescent lamp
CCM: continuous-conduction mode (in a power converter)
CD: compact disc (optical storage)
CDMA: code-division multiple access
CDR: clock and data recovery
CES: Consumer Electronics Show
CF: compact flash (memory card)
CFB: current feedback (op-amp)
CHE: channel hot-electron
CLB: configurable logic block
CML: current-mode logic
CMOS: complementary metal-oxide semiconductor
CMRR: common-mode rejection ratio
codec: coder–decoder
cPLD: complex programmable-logic device
CPU: central processing unit
CR: carriage return
CRC: cyclic redundancy checksum
CRT: cathode-ray tube
CSMA: carrier-sense multiple-access
CSP: chip-scale package

CTR: current transfer ratio
CTS: clear to send (in a serial link)
CVBS: composite video, blanking, and sync
CVSD: continuously variable-slope delta-modulation

DA: dielectric absorption
D/A: digital-to-analog
DAC: digital-to-analog converter
DAQ: data-acquisition system
DBS: direct broadcast satellite
dc: direct current (i.e., a fixed voltage)
DCE: data communications equipment (in a serial link)
DCM: discontinuous-conduction mode (in a power converter)
DDR: double data rate (memory)
DDS: direct digital synthesis
DFC: digital frequency converter
DIN: Deutsches Institut für Normung (a German standards organization); a connector series
DIP: dual in-line package
DIR: direction (a control signal)
DMA: direct memory access
DMM: digital multimeter
DNL: differential nonlinearity
DPCP: display-port content protection
DPDT: double-pole double-throw (switch)
DRAM: dynamic random-access memory
DSBGA: die-size ball-grid array (an IC package)
DSL: digital subscriber line (for data over telephone line)
DSP: digital signal processing (or processor)
DSR: data set ready (in a serial link)
DTE: data terminal equipment (in a serial link)
DTH: direct-to-home (satellite TV)
DTL: diode–transistor logic
DTR: data terminal ready (in a serial link)
DUT: device under test
DVI: digital visual interface (for digital video)
DVM: digital voltmeter
DVR: digital video recorder

EAROM: electrically alterable read-only memory
EAS: avalanche energy specification
ECL: emitter-coupled logic
EEPROM: electrically erasable programmable read-only memory
EIA: Electronic Industries Alliance (standards and trade organization)
EMF: electromotive force (∼voltage)
EMI: electromagnetic interference
ENOB: effective number of bits
EPROM: erasable programmable read-only memory
eSATA: external SATA interface
ESD: electrostatic discharge
ESL: equivalent series inductance
ESR: equivalent series resistance
ETF: 8-to-14 (digital coding)

FCC: Federal Communications Commission
FDNR: frequency-dependent negative resistor
FED: field-emission display
FET: field-effect transistor
FFS: fringe-field switching (an LCD display technology)
FFT: fast Fourier transform
FG: floating gate
FGA: floating-gate array
FIFO: first-in-first-out (memory)
FIR: finite-impulse-response (filter)
FM: frequency modulation
F-N Fowler–Nordheim tunelling
FOT: fiber-optic transceiver
FPBW: full-power bandwidth
FPGA: field-programmable gate array
FR-4: "flame-retardant 4" (glass-epoxy PCB material)
FRAM (also FeRAM, F-RAM): ferroelectric random-access memory
FSB: front-side bus (of a computer processor)
FSE: full-sunlight equivalent (you saw it here first!)

GAL: generic array logic
GBP, GBW: gain-bandwidth product
GCC: GNU C-compiler
GCPW: grounded coplanar waveguide
GDT: gas-discharge tube
GIC: generalized impedance converter
GMR: giant magnetoresistance
GND: ground
GPIB: general-purpose interface bus
GPL: graphical programming language; general public license (in GNU)
GPS: global positioning system
GPU: graphics-processor unit
GUI: graphical user interface

HAPD: hybrid avalanche photodiode (detector)
HBM: human body model
HC(T): high-speed CMOS (logic family)
HDCP: high-bandwidth digital content protection
HDD: hard-disk drive
HDL: hardware description language
HDMI: high-definition multimedia interface (for digital display)
HDTV: high-definition television
HI: human interface

HP: Hewlett–Packard
HV: high voltage

IC: integrated circuit
ICSP: in-circuit serial programming
IDC: insulation displacement connector
IDE: integrated development environment (for coding)
IEC: International Electrotechnical Commission
IEEE: Institute of Electrical and Electronic Engineers
IF: intermediate frequency (in RF receiver)
IGBT: insulated-gate bipolar transistor
IGFET: insulated-gate field-effect transistor
IIC (I^2C): inter-integrated-circuit (a serial bus)
IIR: infinite-impulse-response (filter)
INA: instrumentation amplifier
INL: integral nonlinearity (in A/D conversion)
I/O: input-output
IP: Internet protocol; intellectual property
IPS: in-plane switching (an LCD display technology)
IR: infrared
ISA: International Society of Automation (a standard-setting organization)
ISI: intersymbol interference

JFET: junction field-effect transistor
JTAG: Joint Test Action Group (an IC interface)

KCL: Kirchhoff's current law
KVL: Kirchhoff's voltage law

LAB: logic array block (in programmable logic)
LAN: local area network
LCD: liquid- crystal display
LCX: low-voltage CMOS crossvolt (logic family)
LDO: low-dropout (linear voltage regulator)
LE: logic element (in programmable logic)
LED: light-emitting diode
LFSR: linear feedback shift register
LIFO: last-in first-out (memory)
Li-ion: lithium ion (battery)
LIN: local-interconnect network (bus)
LNA: low-noise amplifier
LNBF: low-noise block-downconverter plus feed (for satellite TV)
LO: local oscillator (in RF receiver)
LPF: lowpass filter
LPT: line printer (a parallel port)
LS: low-power Schottky (logic family)
LSB: least-significant bit
LSI: large-scale integrated circuit
LUT: lookup table
LV: low-voltage (logic family)
LVC: low-voltage CMOS (logic family)
LVDS: low-voltage differential signaling
LVPECL: low-voltage positive emitter-coupled logic
LVX: low-voltage crossvolt (logic family)
LXI: LAN eXtensions for Instrumentation

μC: microcontroller
MAC: multiplier-accumulator; media-access control
MBB: make-before-break (switch)
MCU: microcontroller unit
MDAC: multiplying digital-to-analog converter
MEMS: microelectromechanical system
MFB: multiple-feedback (active filter)
MIPS: mega-instructions per second
MLC: multilevel cell (in nonvolatile memory)
MMU: memory management unit
modem: modulator-demodulator
MOS: metal-oxide semiconductor
MOSFET: metal-oxide semiconductor field-effect transistor
MOV: metal-oxide varistor (surge protector)
MPTS: multiprogram transport stream (in digital TV)
MPU: microprocessor unit
MRAM: magnetoresistive random-access memory
MRI: magnetic resonance imaging
MSB: most-significant bit
MSI: medium-scale integration
MUX: multiplexer

NAN: not a number
NC: normally closed (switch)
NECL: negative emitter-coupled logic
NEMA: National Electrical Manufacturers Association (a standards-setting organization)
NIC: negative-impedance converter; network interface card
NiCd: nickel cadmium (battery)
NiMH: nickel metal-hydride (battery)
NIST: National Institute of Standards and Technology
NMI: nonmaskable interrupt
NMR: nuclear magnetic resonance
nMOS: n-type metal-oxide semiconductor
NO: normally open (switch)
NP0: low tempco (stable) ceramic dielectric
NRZ: nonreturn to zero (data code)
NRZI: nonreturn to zero inverted (data code)
NSC: National Semiconductor Corporation (now part of TI)
NTC: negative temperature coefficient
NTSC: National Television System Committee (analog TV standard)
NV: nonvolatile

NVM: nonvolatile memory

O/C: open-collector (logic output)
OCXO: oven-controlled crystal oscillator
O/D: open-drain (logic output)
OEM: original equipment manufacturer
OLED: organic light-emitting diode
op-amp: operational amplifier
OSI: open systems interconnection (network hierarchy)
OSR: oversampling ratio
OTA: over-the-air (broadcasting)
OTP: one-time-programmable NV memory

PAL: programmable array logic
PARC: Palo Alto Research Center
PATA: parallel ATA interface
PC: printed circuit; personal computer
PCB: printed circuit board
PCF: plastic-clad fiber
PCI: peripheral component interface (a computer bus)
PCIe (also PCI-E): extended peripheral component interface
PCM: pulse-code modulation
PCMCIA: Personal Computer Memory Card International Association (a card interface standard)[1]
PDA: personal digital assistant
PECL: positive emitter-coupled logic
PEN: polyethylene naphthalate (a capacitor dielectric)
PFC: power-factor correction (in ac-powered converters)
PFD: phase-frequency detector
PFM: pulse-frequency modulation
PGA: programmable gain amplifier
PID: proportional-integral-differential (in control systems); program identifier (in digital TV)
PIN: positive-intrinsic-negative (diode)
PI/PO: parallel-in-parallel-out
PIR: passive infrared (detector)
PIV: peak inverse voltage
PLA: programmable logic array
PLC: powerline cycles
PLD: programmable logic device
PLL: phase-locked loop
pMOS: p-type metal-oxide semiconductor
PMT: photomultiplier tube
POF: plastic optical fiber
POL: point-of-load
pp: peak-to-peak (voltage)
PPS: polyphenylene sulfide (a capacitor dielectric)
PRAM: phase-change random-access memory
PRBS: pseudorandom bit sequence
PROM: phase-change read-only memory
PSRAM: pseudostatic random-access memory
PSRR: power-supply rejection ratio
PTAT: proportional to absolute temperature
PUJT: programmable unijunction transistor
PV: photovoltaic (light detector)
PVC: polyvinyl chloride (insulator)
PVR: personal video recorder
PWM: pulse-width modulation

QAM: quadrature amplitude modulation
QPSK: quadrature phase-shift keying

RAM: random-access memory
RCO: ripple-clock output
RD: receive data (in a serial link)
RF: radiofrequency
RFI: radiofrequency interference
RG-nn: "Radio Guide" (coax cable designators)
RGB: red–green–blue (video signals)
RISC: reduced instruction set computing
RLL: run-length limited (digital codes)
rms: root-mean-square
ROM: read-only memory
RRI: rail-to-rail input
RRIO: rail-to-rail input and output
RRO: rail-to-rail output
RTC: real-time clock
RTD: resistance temperature detector (or resistive temperature device)
RTI: referred to the input
RTL: resistor–transistor logic; register-transfer level (in an HDL)
RTO: referred to the output
RTS: request to send (in a serial link)

SA: sense amplifier
SACD: Super Audio compact disc
SAD: silicon avalanche device (i.e., a zener TVS)
SAR: successive approximation register
SAS: serial attached SCSI (interface)
SATA: serial ATA (interface)
SAW: surface acoustic-wave
SBC: single-board computer
SC: subscriber connector (a fiber-optic connector)
SCPI: Standard Commands for Programmable Instruments
SCR: silicon-controlled rectifier
SCSI: small computer system interface
SD: secure digital (memory card)
SDI: serial data in

[1] Whose awkwardness spawned jokes like "Personal Computer Manufacturers Can't Invent Acronyms."

SDO: serial data out
SDR: single data rate (memory)
SDRAM: synchronous dynamic random-access memory
SDTV: standard-definition television
SE: single-ended
SED: surface-conduction electron-emitter display
SEPIC: single-ended primary-inductance converter
SERDES: serializer–deserializer
S/H: sample-and-hold
SHV: "safe high voltage" (connector)
SI: serial input
SIP: single in-line package
SMA, SMB, SMC: subminiature RF coax connector series
SMI: small media interface (a fiber-optic connector)
SMPS: switch-mode power supply
SMT: surface-mount technology
SMU: source-measure unit
SNR: signal-to-noise ratio
SO: serial output; small-outline (IC package)
SOA: safe-operating area
SODIMM: small-outline dual-in-line memory module
SOIC: small-outline integrated circuit
SOT: small-outline transistor
SPDIF: Sony–Philips Digital Interconnect Format (for digital audio)
SPICE: "simulation program with integrated circuit emphasis" (analog circuit simulator software)
SPDT: single-pole double-throw (switch)
SPI: serial peripheral interface (a simple IC bus)
SPL: sound pressure level
sPLD: simple programmable logic device
SPST: single-pole single-throw (switch)
SPTS: single-program transport stream (in digital TV)
SR: slew rate
SRAM: static random-access memory
SSD: solid-state drive (an NV memory)
SSH: secure shell (a network protocol)
SSP: synchronous serial port
SSR: solid-state relay
ST: straight tip (a fiber-optic connector)
STB: set-top box (for cable or satellite TV)
STP: shielded twisted pair (cable)
SWR: standing-wave ratio (on a transmission line)

T&M: test and measurement
TAC: time-to-amplitude conversion
TBH: take-back-half (a control algorithm)
TCP: transmission control protocol (an Internet protocol)
TCXO: temperature-compensated crystal oscillator
TD: transmit data (in a serial link)
tempco: temperature coefficient
THD: total harmonic distortion
TI: Texas Instruments
TNC: threaded Neill-Concelman (connector)
TO: transistor outline (e.g., TO-92, TO-220)
TSSOP: thin-shrink small-outline package
TTL: transistor–transistor logic
TVS: transient voltage suppressor
TWI: two-wire interface (a serial bus)

UART: universal asynchronous receiver-transmitter
UDP: user datagram protocol (an Internet protocol)
UHF: ultrahigh frequency; also a legacy coaxial connector
UL: Underwriters Laboratories (a safety certification company)
UPS: uninterruptible power supply
USB: universal serial bus (a data interface)
UTP: unshielded twisted pair (cable)
UV: ultraviolet

VBR: variable bitrate (coding)
VCO: voltage-controlled oscillator
VCVS: voltage-controlled voltage-source (active filter)
VCXO: voltage-controlled crystal oscillator
VDE: Verband der Elektrotechnik, Elektronik und Informationstechnik (a German organization whose activities include safety standards)
V/F: voltage-to-frequency (converter)
VFB: voltage feedback
VFD: vacuum fluorescent display
VGA: video graphics array (640×480 analog video)
VHS: video home system (video recording)
VLSI: very-large-scale integration
VME: VERSAmodule Eurocard Bus (a card interface)
VOD: video-on-demand
VOM: volt-ohm-millimeter
VSWR: voltage standing-wave ratio (on a transmission line)
VU: volume unit (an audio level)

WL: write latency (in computer memory)

X7R: a ceramic dielectric
XLR: a professional audio connector series
XO: crystal oscillator

Y5V: a ceramic dielectric
YIG: yttrium–iron garnet

Z5U: a ceramic dielectric
ZCS: zero-current switching
ZVS: zero-voltage switching

INDEX
