## THE EDITORS

### ROBERT BABOIAN,

#### Editor

Robert Baboian is a corrosion consultant with RB Corrosion Service. He received his B.S. degree in chemistry from Suffolk University in 1959 and his Ph.D. in physical chemistry from Rensselaer Polytechnic Institute in 1964. He did postdoctoral research at the University of Toronto in 1964 and subsequently received a faculty appointment to Senior Research Associate in 1965. He joined the Materials and Controls Group of Texas Instruments, Inc. in 1966, where he established the Electrochemical and Corrosion Laboratory. He retired from Texas Instruments in December 1996 as Principal Fellow and Head of the Electrochemical and Corrosion Laboratory. The Principal Fellow position at TI is the company's highest honor for scientific and technical achievement. He is an ASTM Honorary Member, a Fellow of ASTM, NACE, and SAE, and was a Ford Foundation Postdoctoral Fellow in 1964.

Dr. Baboian has been dedicated to the research and development of corrosion resistant materials and devices, environmental effects on materials, and the use of electrochemical techniques in corrosion testing for almost 40 years. He holds 15 U.S. patents, is the editor of 13 books, and has authored over 170 technical publications. He has served on a number of Government and Academic Committees and has lectured throughout the world, and his services were donated by TI to the National Park Service as a corrosion consultant on the Statue of Liberty restoration program. Recently, he has researched the sinking of the *Titanic* and has proposed theories on corrosion mechanisms causing the failure.

Recognized for his active involvement in the technical community, Dr. Baboian has received the Cavanaugh Award and the Award of Merit from ASTM, the ASTM Dudley Award for publications, the ASTM LaQue Award for outstanding contributions to corrosion testing and evaluation, the Speller Award for outstanding contributions in corrosion engineering, and the T. J. Hull Award for publications from NACE, the Science and Technology Award of the Suga Weathering Technology Foundation in Japan, the Vittorio de Nora Award from the Electrochemical Society, the Francis L. LaQue Award for contributions to marine corrosion and prevention from the LaQue Center Sea Horse Institute, and the National Materials Advancement Award from the Federation of Materials Societies. He has served on the Executive Committee and the Board of Directors of ASTM and NACE and was the Chairman of the ASTM Board of Directors in 1987. He also has chaired ASTM Committee G-1 on Corrosion of Metals, the SAE Automotive Corrosion and Protection Committee, and the NACE Research Committee.

## SECTION EDITORS

### SHELDON W. DEAN, JR.

is currently the President of Dean Corrosion Technology, Inc., a consulting firm in Allentown, Pennsylvania that provides expert advice on matters involving corrosion of metals. He is also Editor in Chief of the *Journal of ASTM International*. He received his A.B. from Middlebury College and his B.S. and Sc.D. from the Massachusetts Institute of Technology. He has received the ASTM Award of Merit, the Charles B. Dudley Award, the Sam Tour Award, the Francis L. LaQue Memorial Award, the ASTM Committee on Publications Award for Excellence, the ASTM Committee G-1 Certificate of Appreciation, the NACE Frank Newman Speller Award, the NACE Fellow Honor, and was named a Fellow of the American Institute of Chemical Engineers and the Materials Technology Institute. He has served as chairman of ASTM Committee G-1 for four years. He also served on and chaired the ASTM Committee on Publications and the ASTM Board of Directors, and chaired the Finance and Audit Committee. He has also served on and chaired the Board of Directors of the Materials Technology Institute. He has 12 U.S. patents, 96 publications, and has co-edited eight books.

### HARVEY P. HACK

Dr. Hack is an Advisory Engineer for Northrop Grumman Corporation, where he does materials selection and corrosion control for underwater vehicles and systems for the Department of Defense. He received his B.S. and M.S. from Carnegie-Mellon University, and his Ph.D. in Metallurgy from The Pennsylvania State University. He is the recipient of the ASTM International Award of Merit, and is past Chairman of the Board of Directors of ASTM International. Dr. Hack has received the Distinguished Service Award from NACE International, the Francis L. LaQue Memorial Award from ASTM Committee G-1 on Corrosion of Metals, and the Francis L. LaQue Award from the Sea Horse Institute. He is a NACE Corrosion Specialist, Cathodic Protection Specialist, and Coatings Inspector, a Fellow of NACE International, ASTM International, the Washington Academy of Sciences, and the Institute of Corrosion in the United Kingdom, and is a Registered Professional Engineer in Maryland. Dr. Hack is the Associate Editor for the Materials Performance and Characterization section of the *Journal of ASTM International (JAI)*, is on the Materials Advisory Board for the National Air and Space Museum of the Smithsonian Institution, and is a past President of the Council of Engineering and Scientific Specialty Boards. Dr. Hack has approximately 70 publications and is the author, editor, or major contributor to five books. He is the author of a regular column on corrosion in *Underwater Magazine*.

### EDWARD L. HIBNER

is a Senior Metallurgist and Code Manager at Special Metals Corporation, formerly Inco Alloys International, in Huntington, West Virginia. He received his B.S. in Chemistry from Marshall University and in Metallurgy from the University of Cincinnati. He is the recipient of the ASTM Award of Merit, the ASTM Committee G-1 Francis L. LaQue Memorial Award, the ASTM Committee G-1 Certificate of Appreciation, and the NACE Fellow Award, and is currently Vice-Chairman and the Editorial Review Chairman of ASTM Committee G-1 on Corrosion of Metals. He has served as Chairman and as Trustee of the West Virginia Section of NACE International and is currently serving on the NACE MR0175/ ISO 15156 Maintenance Panel. He has extensive experience in alloy development for chemical process, flue gas desulfurization, marine, and oil field applications. He has written widely on materials applications and corrosion topics in these fields and has four patents and 60 publications. In addition to ASTM International, he is a member of the International Desalination Association, the Society for Petroleum Engineers, ASME International, SAE International, NACE International, and the Naval Submarine League.

### JOHN R. SCULLY

received his B.S., M.S., and Ph.D. in Materials Science and Engineering from Johns Hopkins University. While pursuing his Ph.D., he worked at David Taylor Naval Ship R&D Center in Annapolis, Maryland in the Marine Corrosion Branch. He then joined Sandia National Laboratory after a term as a Visiting Scientist at AT&T Bell Laboratories. In 1990, he joined the faculty of the Department of Materials Science and Engineering at the University of Virginia and is a full professor and co-directs the Center for Electrochemical Science and Engineering. Professor Scully received the 1985 A. B. Campbell Young Author Award from NACE. He has also been selected as a National Science Foundation Young Investigator, and has received the H. H. Uhlig Award from NACE and the William Blum Award from the Electrochemical Society. Professor Scully has published over 100 technical papers and edited several books on corrosion.

# Foreword

THE REVISED PUBLICATION, *Corrosion Tests and Standards: Application and Interpretation*, is sponsored by ASTM Committee G1 on Corrosion of Metals and edited by Robert Baboian, RB Corrosion Service. Section editors include Robert Baboian, Sheldon W. Dean, Dean Corrosion Technology, Harvey P. Hack, Northrup Grumman Corporation, Edward Hibner, Special Metals Corporation, and John R. Scully, University of Virginia. This is the second edition of Manual 20 in the ASTM Manual series.

# Preface

CORROSION CONTINUES to be a problem of worldwide importance. The second edition of this manual has been prepared and published to address this form of degradation. Corrosion is often neglected, but it seriously impacts our economy, jeopardizes human health and safety, and impedes technological progress. The most important factors in addressing corrosion and its control are: (1) recognizing and understanding the mechanisms, (2) developing solutions to the problems, and (3) implementing those solutions. Corrosion tests and standards are very significant in addressing each of these factors. Therefore, this manual includes guidelines for recognizing types of corrosion as well as fundamentals of testing and provides the tools required for making calculations, interpretations, and correlations. It serves as a source book of procedures, equipment, and standards used in testing.

The editor and section editors have coordinated the revision and update of this book so that most recent technologies are included in each section. In most cases, the original authors of chapters have made the revisions. In some cases, new authors needed to be chosen, or the editors performed that task. Users of the manual will find that it is an invaluable and instructive tool, as well as a source book on how to conduct corrosion tests, interpret results, and use standards.

The second edition of the manual is the result of a massive effort of planning, writing, reviewing, editing, production, and marketing. It would not have been possible without the outstanding efforts of the ASTM staff and the valuable and competent work of the editors and over 400 experts in the field that donated their time as authors and reviewers. They represent industrial, educational, and government organizations, and their contributions are greatly appreciated.

# Introduction

ASTM'S AWARD-WINNING Manual 20 has been revised and updated to include current and state-of-the-art technologies in corrosion testing and standardization. The editors of this manual have many years of experience in this field and are well qualified in leading the task to provide state-of-the-art information on this subject for corrosion scientists and technologists throughout the world. The work of 80 highly qualified chapter authors and numerous reviewers has resulted in a revised, expanded, and updated Manual 20 on Corrosion Tests and Standards, Application and Interpretation.

Corrosion is the chemical or electrochemical reaction between a material, usually a metal, and its environment that produces a deterioration of the material and its properties. The direct cost of corrosion in countries throughout the world is estimated to be between 3 % and 4 % of the gross domestic product of each country. For example, that cost in the United States was estimated to be \$276 billion annually, for recent years. It was determined that a significant portion of these costs could be avoided through the more effective use of existing technologies and the use of sound corrosion management techniques. This manual is a key resource in addressing both of these subjects.

Corrosion testing is one of the most important aspects of corrosion control because it is used to advance technology and to determine the most effective and economical means to achieve acceptable performance. A large number of factors affect corrosion behavior so that there is no universal corrosion test. ASTM and other organizations such as NACE, ISO, and others have standardized many tests and practices. However, industry, government, and academic laboratories sometimes utilize in-house tests. Thus, this Manual provides a valuable resource describing and listing a large number of tests ranging from highly accelerated laboratory tests to field service trials.

Since standards are universally recognized as an important tool in effective corrosion control management, this Manual not only provides information required to find and use proper standards in specific applications, it also includes a CD with almost 200 of the most widely used ASTM and NACE corrosion standards. All of the chapter authors have included important standards specific to their topic and the Manual includes lists of standards according to subject, of which the most important are included in the CD.

The revised Manual is organized into eight sections.

Section I on **General Information** (R. Baboian, Section Editor) provides tools necessary for the corrosionist to define,

interpret, and evaluate the technology. This section is greatly expanded and includes a unified numbering system for metals and alloys and their common names, standards terminology, a glossary of terms and acronyms, abbreviations and units symbols, International System of Units and matrix guide, general conversion tables, corrosion rate calculations and all necessary conversion factors, chemical and physical properties of materials, properties of water and moist air, chemical and electrolytic cleaning procedures for corrosion products, physical properties of gases, liquids and elements, and densities of metals and alloys.

Section II on **Testing and Evaluation** (R. Baboian, Section Editor) is designed to provide important information on planning and design of tests and interpretation of results. This topic provides a foundation for corrosion testing and the use of corrosion standards. It includes chapters on planning and design of tests, types of corrosion data, metallographic and surface analysis, statistical treatment of data and data computerization and computer applications.

Section III covers **Types of Tests** (H. Hack, Section Editor) including laboratory-accelerated tests, field tests, and service tests. The chapters in this section provide basic principles, describe test techniques and specific considerations such as specimen preparation, test duration and acceleration factors, and cite pertinent standards. Chapters included under laboratory tests are electrochemical, cabinet, immersion, high temperature, and high pressure. Field Tests chapters include atmospheric exposure, seawater, fresh water, and soil. Under service tests are industrial applications and high temperature environments.

Section IV on **Testing for Corrosion Types** (J. Scully, Section Editor) describes the major forms of corrosion, how to recognize them and factors of influence. Each chapter includes an overview of basic principles and also descriptions of test techniques, methods of evaluation of test results, and standards used for testing. Subjects included are uniform, pitting, crevice, galvanic, intergranular, exfoliation, erosion, cavitation, fretting, dealloying, stress corrosion, corrosion fatigue and hydrogen damage.

Section V on **Testing in Environments** (H. Hack, Section Editor) includes chapters on outdoor and indoor atmospheres, seawater, fresh water, soils, concrete, industrial waters, industrial chemical, petroleum, high-temperature gases, organic liquids, molten salts, liquid metals, corrosion inhibitors, in-vivo, and microbiological effects. Each chapter provides a descriptive overview of the environment and factors and variables affecting corrosion rates and mechanisms,

## 2 CORROSION TESTS AND STANDARDS MANUAL

unique characteristics of testing, descriptions of appropriate laboratory and field tests and lists of standards used for corrosion testing in these environments.

Section VI is on **Materials Testing** (E. Hibner, Section Editor). This section provides overviews of important tests used in evaluating the corrosion behavior of metals and alloys. In addition, this testing information provides the means for the development of new and improved corrosion resistant materials. Each chapter includes a discussion of the nature of the material, such as the effect of composition, alloying, metallurgical treatments, microstructure, surface effects and natural films on the corrosion behavior. The chapter also includes descriptions of tests used for specific types of corrosion for the metals and alloys, methods of evaluation of corrosion damage and standards used for corrosion testing of the various materials. The chapters are zinc, lead (and alloys), aluminum (and alloys), steels, copper (and alloys), nickel (and alloys), stainless steels, cobalt-base alloys, titanium, zirconium and hafnium, tantalum and niobium alloys, metallic coatings on steel, nonmetallic coatings, metal matrix composites, electrodeposits, and powder metallurgy materials.

Section VII on **Testing in Industries** (S. Dean, Section Editor) provides an overview of corrosion testing unique to each industry and how these tests are used to address corrosion problems. Included are descriptions of environments encountered and materials used in specific industries. Test methods for corrosion control and evaluation are described along with appropriate standards. Chapters in this section include automotive, commercial aircraft, military aircraft

and equipment, pipeline, highways, tunnels and bridges, marine piers and docks, electric power, nuclear power, steam generation, flue gas desulfurization, electronics, telecommunications, metal processing, chemical processing, pulp and paper, petroleum production and refining, food and beverage, water handling systems, medical and dental, and pharmaceutical.

Section VIII on **Corrosion-Related Standards** (H. Hack and R. Baboian, Section Editors) is a comprehensive list of standards developed by various organizations including the American Petroleum Institute, American Waterworks Association, ASME International, ASTM International, International Electrotechnical Commission, ISO, NACE International, SAE International, and the Steel Structures Painting Council. The standards are listed and grouped according to subject within each organization. The accompanying CD includes many of the ASTM and NACE corrosion standards.

The revised Manual 20 on Corrosion Tests and Standards is certain to serve as a valuable resource for those in industry, government, and academia. Acknowledgment is given to the many authors who wrote the chapters providing the important information in this revision. Also acknowledged are the reviewers who work anonymously to help maintain a high level of quality throughout the book. The work of the editors can only be completed through the dedication and competence of these persons.

**Designation: G 15-04**

## Standard Terminology Relating to Corrosion and Corrosion Testing<sup>1</sup>

This standard is issued under the fixed designation G 15; the number immediately following the designation indicates the year of original adoption or, in the case of revision, the year of last revision. A number in parentheses indicates the year of last reapproval. A superscript epsilon (ε) indicates an editorial change since the last revision or reapproval.

*This standard has been approved for use by agencies of the Department of Defense.*

### 1. Scope

1.1 This terminology covers commonly used terms in the field of corrosion. Related terms may be found in Terminologies D 16, D 4538, G 40, or other ASTM terminology standards. All terms defined by ASTM committees may be found in the *ASTM Dictionary of Engineering & Technology*.

### 2. Referenced Documents

#### 2.1 ASTM Standards:<sup>2</sup>

D 16 Terminology for Paint, Related Coatings, Materials, and Applications

D 4538 Terminology Relating to Protective Coating and Lining Work for Power

G 40 Terminology Relating to Wear and Erosion

### 3. Terminology

**AC impedance**—See **electrochemical impedance**.

**active**—the negative direction of electrode potential. (Also used to describe corrosion and its associated potential range when an electrode potential is more negative than an adjacent depressed corrosion rate [passive] range.)

**anion**—a negatively charged ion.

**anode**—the electrode of an electrolytic cell at which oxidation is the principal reaction. (Electrons flow away from the anode in the external circuit. It is usually the electrode where corrosion occurs and metal ions enter solution.)

**anode corrosion efficiency**—the ratio of the actual corrosion (weight loss) of an anode to the theoretical corrosion (weight loss) calculated by Faraday's law from the quantity of electricity that has passed.

**anodic inhibitor**—a corrosion inhibitor whose primary action is to slow the kinetics of the anodic reaction, producing a positive shift in corrosion potential.

**anodic polarization**—the change of the electrode potential in the noble (positive) direction due to current flow. (See **polarization**.)

**anodic protection**—a technique to reduce the corrosion rate of a metal by polarizing it into its passive region where dissolution rates are low.

**anolyte**—the electrolyte adjacent to the anode of an electrolytic cell.

**auxiliary electrode**—See **counter electrode**.

**breakdown potential**—the least noble potential where pitting or crevice corrosion, or both, will initiate and propagate.

**cathode**—the electrode of an electrolytic cell at which reduction is the principal reaction. (Electrons flow toward the cathode in the external circuit.)

**cathodic corrosion**—corrosion of a metal when it is a cathode. (It usually happens to metals because of a rise in pH at the cathode or as a result of the formation of hydrides.)

**cathodic inhibitor**—a corrosion inhibitor whose primary action is to slow the kinetics of the cathodic reaction, producing a negative shift in corrosion potential.

**cathodic polarization**—the change of the electrode potential in the active (negative) direction due to current flow. (See **polarization**.)

**cathodic protection**—a technique to reduce the corrosion rate of a metal surface by making it the cathode of an electrochemical cell.

**catholyte**—the electrolyte adjacent to the cathode of an electrolytic cell.

**cation**—a positively charged ion.

**caustic cracking**—stress corrosion cracking of metals in caustic solutions. (See also **stress-corrosion cracking**.)

**caustic embrittlement**—See **caustic cracking**.

**cavitation**—the formation and rapid collapse within a liquid of cavities or bubbles that contain vapor or gas or both.

**cavitation corrosion**—the conjoint action of cavitation-erosion and corrosion.

**cavitation damage**—the degradation of a solid body resulting from its exposure to cavitation. (This may include loss of material, surface deformation, or changes in properties or appearance.)

**cavitation-erosion**—loss of material from a solid surface due to mechanical action of continuing exposure to cavitation.

**chemical conversion coating**—a protective or decorative nonmetallic coating produced *in situ* by chemical reaction of a metal with a chosen environment. (It is often used to prepare the surface prior to the application of an organic coating.)

<sup>1</sup> This terminology is under the jurisdiction of ASTM Committee G01 on Corrosion of Metals and are the direct responsibility of Subcommittee G01.02 on Terminology.

Current edition approved Jan. 1, 2004. Published January 2004. Originally approved in 1971. Last previous edition approved in 2003 as G 15-03a.

<sup>2</sup> For referenced ASTM standards, visit the ASTM website, [www.astm.org](http://www.astm.org), or contact ASTM Customer Service at [service@astm.org](mailto:service@astm.org). For *Annual Book of ASTM Standards* volume information, refer to the standard's Document Summary page on the ASTM website.

- concentration cell**—an electrolytic cell, the emf of which is caused by a difference in concentration of some component in the electrolyte. (This difference leads to the formation of discrete cathode and anode regions.)
- corrosion**—the chemical or electrochemical reaction between a material, usually a metal, and its environment that produces a deterioration of the material and its properties.
- corrosion fatigue**—the process in which a metal fractures prematurely under conditions of simultaneous corrosion and repeated cyclic loading at lower stress levels or fewer cycles than would be required in the absence of the corrosive environment.
- corrosion fatigue strength**—the maximum repeated stress that can be endured by a metal without failure under definite conditions of corrosion and fatigue and for a specific number of stress cycles and a specified period of time.
- corrosion inhibitor**—a chemical substance or combination of substances that, when present in the proper concentration and forms in the environment, prevents or reduces corrosion.
- corrosion potential**—the potential of a corroding surface in an electrolyte relative to a reference electrode measured under open-circuit conditions.
- corrosion rate**—the amount of corrosion occurring in unit time. (For example, mass change per unit area per unit time; penetration per unit time.)
- counter electrode**—the electrode in an electrochemical cell that is used to transfer current to or from a test electrode.
- crevice corrosion**—localized corrosion of a metal surface at, or immediately adjacent to, an area that is shielded from full exposure to the environment because of close proximity between the metal and the surface of another material.
- critical anodic current density**—the maximum anodic current density observed in the active region for a metal or alloy electrode that exhibits active-passive behavior in an environment.
- critical humidity**—the relative humidity above which the atmospheric corrosion rate of some metals increases sharply.
- critical pitting potential**—the least noble potential where pitting corrosion will initiate and propagate. (See breakdown potential.)
- current density**—the electric current to or from a unit area of an electrode surface.
- current efficiency**—the ratio of the electrochemical equivalent current density for a specific reaction to the total applied current density.
- deactivation**—the process of prior removal of the active corrosive constituents, usually oxygen, from a corrosive liquid by controlled corrosion of expendable metal or by other chemical means, thereby making the liquid less corrosive.
- dealloying**—See **parting**.
- depolarization**—not a preferred term. (See **polarization**.)
- deposit corrosion**—localized corrosion under or around a deposit or collection of material on a metal surface. (See also **crevice corrosion**.)
- dezincification**—See **parting**; specific to copper-zinc alloys.
- differential aeration cell (oxygen concentration cell)**—a concentration cell caused by differences in oxygen concentration along the surface of a metal in an electrolyte. (See **concentration cell**.)
- diffusion limited current density**—the current density, often referred to as limiting current density, that corresponds to the maximum transfer rate that a particular species can sustain due to the limitation of diffusion.
- electrochemical admittance**—the reciprocal of the electrochemical impedance,  $\Delta I/\Delta E$ .
- electrochemical cell**—an electrochemical system consisting of an anode and a cathode in metallic contact and immersed in an electrolyte. (The anode and cathode may be different metals or dissimilar areas on the same metal surface.)
- electrochemical impedance**—the frequency dependent, complex valued proportionality factor,  $\Delta E/\Delta I$ , between the applied potential (or current) and the response current (or potential) in an electrochemical cell. This factor becomes the impedance when the perturbation and response are related linearly (the factor value is independent of the perturbation magnitude) and the response is caused only by the perturbation. The value may be related to the corrosion rate when the measurement is made at the corrosion potential.
- electrochemical noise**—fluctuations of the current, or both, originating from uncontrolled variations in a corrosion process.
- electrochemical potential (electrochemical tension)**—the partial derivative of the total electrochemical free energy of the system with respect to the number of moles of the constituent in a solution when all other factors are constant. (Analogous to the chemical potential of the constituent except that it includes the electrical as well as the chemical contributions to the free energy.)
- electrode potential**—the potential of an electrode in an electrolyte as measured against a reference electrode. (The electrode potential does not include any resistance losses in potential in either the solution or external circuit. It represents the reversible work to move a unit charge from the electrode surface through the solution to the reference electrode.)
- electrolysis**—production of chemical changes of the electrolyte by the passage of current through an electrochemical cell.
- electrolytic cleaning**—a process of removing soil, scale or corrosion products from a metal surface by subjecting it as an electrode to an electric current in an electrolytic bath.
- Electromotive Force Series (EMF Series)**—a list of elements arranged according to their standard electrode potentials, with “noble” metals such as gold being positive and “active” metals such as zinc being negative.
- embrittlement**—the severe loss of ductility or toughness or both, of a material, usually a metal or alloy.
- environmentally-assisted cracking**—the initiation or acceleration of a cracking process due to the conjoint action of a chemical environment and tensile stress.
- equilibrium (reversible) potential**—the potential of an electrode in an electrolytic solution when the forward rate of a given reaction is exactly equal to the reverse rate. (The equilibrium potential can only be defined with respect to a specific electrochemical reaction.)
- erosion**—the progressive loss of material from a solid surface due to mechanical interaction between that surface and a fluid, a multi-component fluid, or solid particles carried with the fluid.

- erosion-corrosion**—a conjoint action involving corrosion and erosion in the presence of a moving corrosive fluid, leading to the accelerated loss of material.
- exchange current density**—the rate of charge transfer per unit area when an electrode reaches dynamic equilibrium (at its reversible potential) in a solution; that is, the rate of anodic charge transfer (oxidation) balances the rate of cathodic charge transfer (reduction).
- exfoliation**—corrosion that proceeds laterally from the sites of initiation along planes parallel to the surface, generally at grain boundaries, forming corrosion products that force metal away from the body of the material, giving rise to a layered appearance.
- external circuit**—the wires, connectors, measuring devices, current sources, and so forth, that are used to bring about or measure the desired electrical conditions within the test cell.
- filiform corrosion**—corrosion that occurs under some coatings in the form of randomly distributed threadlike filaments.
- fretting corrosion**—the deterioration at the interface between contacting surface as the result of corrosion and slight oscillatory slip between the two surfaces.
- galvanic corrosion**—accelerated corrosion of a metal because of an electrical contact with a more noble metal or nonmetallic contactor in a corrosive electrolyte.
- galvanic couple**—a pair of dissimilar conductors, commonly metals, in electrical contact (See **galvanic corrosion**.)
- galvanic current**—the electric current between metals or conductive nonmetals in a galvanic couple.
- galvanic series**—a list of metals and alloys arranged according to their relative corrosion potentials in a given environment.
- galvanodynamic**—refers to a technique wherein current, continuously varied at a selected rate, is applied to an electrode in an electrolyte.
- galvanostaircase**—refers to a galvanostep technique for polarizing an electrode in a series of constant current steps wherein the time duration and current increments or decrements are equal for each step.
- galvanostatic**—an experimental technique whereby an electrode is maintained at a constant current in an electrolyte.
- galvanostep**—refers to a technique in which an electrode is polarized in a series of current increments or decrements.
- grain dropping**—the dislodgement and loss of a grain or grains (crystals) from a metal surface as a result of intergranular corrosion.
- graphitic corrosion**—the deterioration of metallic constituents in gray cast iron, which leaves the graphic particles intact. (The term “graphitization” is commonly used to identify this form of corrosion but is not recommended because of its use in metallurgy for the decomposition of carbide to graphite.)
- hot corrosion**—an accelerated corrosion of metal surfaces that results from the combined effect of oxidation and reactions with sulfur compounds and other contaminants, such as chlorides, to form a molten salt on a metal surface which fluxes, destroys, or disrupts the normal protective oxide.
- hydrogen blistering**—the formation of blisters on or below a metal surface from excessive internal hydrogen pressure. (Hydrogen may be formed during cleaning, plating, corrosion, and so forth.)
- hydrogen embrittlement**—hydrogen-induced cracking or severe loss of ductility caused by the presence of hydrogen in the metal.
- immunity**—a state of resistance to corrosion or anodic dissolution of a metal caused by thermodynamic stability of the metal.
- impingement corrosion**—a form of erosion-corrosion generally associated with the local impingement of a high-velocity, flowing fluid against a solid surface.
- impressed current**—an electric current supplied by a device employing a power source that is external to the electrode system. (An example is dc current for cathodic protection.)
- intensistatic*—See **galvanostatic**.
- intercrystalline corrosion*—See **intergranular corrosion**.
- intergranular corrosion**—preferential corrosion at or adjacent to the grain boundaries of a metal or alloy.
- internal oxidation**—the formation of isolated particles of corrosion products beneath the metal surface. (This occurs as the result of preferential oxidation of certain alloy constituents by inward diffusion of oxygen, nitrogen, sulfur, and so forth.)
- knife-line attack**—intergranular corrosion of an alloy, usually stabilized stainless steel, along a line adjoining or in contact with a weld after heating into the sensitization temperature range.
- local action corrosion**—corrosion caused by local corrosion cells on a metal surface.
- local corrosion cell**—an electrochemical cell created on a metal surface because of a difference in potential between adjacent areas on that surface.
- localized corrosion**—corrosion at discrete sites, for example, pitting, crevice corrosion, and stress corrosion cracking.
- long-line current**—electric current through the earth from an anodic to a cathodic area of a continuous metallic structure. (Usually used only where the areas are separated by considerable distance and where the current result from concentration-cell action.)
- Luggin probe or Luggin-Haber capillary**—a device used in measuring the potential of an electrode with a significant current density imposed on its surface. (The probe minimizes the IR drop that would otherwise be included in the measurement and without significantly disturbing the current distribution on the specimen.)
- macrocell corrosion**—corrosion of a metal embedded in porous media (for example, concrete or soil) caused by concentration or galvanic cells which exist on a scale at least as large as the smallest major dimension of the corroding item (for example, the diameter of a bar pipe).
- metal dusting**—accelerated deterioration of metals in carbonaceous gases at elevated temperature to form a dust-like corrosion product.
- metallizing*—See **thermal spraying**.
- microbial corrosion**—corrosion that is affected by the action of microorganisms in the environment.
- microbiologically influenced corrosion (MIC)**—corrosion inhibited or accelerated by the presence or activity, or both, of microorganisms.
- mixed potential**—the potential of a specimen (or specimens in a galvanic couple) when two or more electrochemical reactions are occurring simultaneously.
- noble**—the positive (increasingly oxidizing) direction of electrode potential.

**noble metal**—a metal with a standard electrode potential that is more noble (positive) than that of hydrogen.

**occluded cell**—an electrochemical cell created at a localized site on a metal surface which has been partially obstructed from the bulk environment.

**open-circuit potential**—the potential of an electrode measured with respect to a reference electrode or another electrode when no current flows to or from it.

**overvoltage**—the change in potential of an electrode from its equilibrium or steady state value when current is applied.

**oxidation**—loss of electrons by a constituent of a chemical reaction. (Also refers to the corrosion of a metal that is exposed to an oxidizing gas at elevated temperatures.)

**parting**—the selective corrosion of one or more components of a solid solution alloy.

**parting limit**—the minimum concentration of a more noble component in an alloy, above which parting does not occur in a specific environment.

**passivation**—the process in metal corrosion by which metals become passive. (See **passive**.)

**passivator**—a type of inhibitor which appreciably changes the potential of a metal to a more noble (positive) value.

**passive**—the state of the metal surface characterized by low corrosion rates in a potential region that is strongly oxidizing for the metal.

**passive-active cell**—a corrosion cell in which the anode is a metal in the active state and the cathode is the same metal in the passive state.

**pitting**—corrosion of a metal surface, confined to a point or small area, that takes the form of cavities.

**pitting factor**—ratio of the depth of the deepest pit resulting from corrosion divided by the average penetration as calculated from weight loss.

**polarization**—the change from the open-circuit electrode potential as the result of the passage of current.

**polarization admittance**—the reciprocal of polarization resistance ( $di/dE$ ).

**polarization resistance**—the slope ( $dE/di$ ) at the corrosion potential of potential ( $E$ )—current density ( $i$ ) curve. (It is inversely proportional to the corrosion current density when the polarization resistance technique is applicable.)

**potentiodynamic**—refers to a technique wherein the potential of an electrode with respect to a reference electrode is varied at a selected rate by application of a current through the electrolyte.

**potentiostaircase**—refers to a potentiostep technique for polarizing an electrode in a series of constant potential steps wherein the time duration and potential increments or decrements are equal for each step.

**potentiostat**—an instrument for automatically maintaining an electrode in an electrolyte at a constant potential or controlled potentials with respect to a suitable reference electrode.

**potentiostatic**—the technique for maintaining a constant electrode.

**potentiostep**—refers to a technique in which an electrode is polarized in a series of potential increments or decrements.

*poultice corrosion*—See **deposit corrosion**.

**Pourbaix diagram (electrode potential-pH diagram)**—a graphic representation showing regions of thermodynamic stability of species in metal-water electrolyte systems.

**primary passive potential (passivation potential)**—the potential corresponding to the maximum active current

density (critical anodic current density) of an electrode that exhibits active-passive corrosion behavior.

**protection potential**—the most noble potential where pitting and crevice corrosion will not propagate.

**redox potential**—the potential of a reversible oxidation-reduction electrode measured with respect to a reference electrode, corrected to the hydrogen electrode, in a given electrolyte.

**reduction**—the gain of electrons by a constituent of a chemical reaction.

**reference electrode**—electrode having a stable and reproducible potential, which is used in the measurement of other electrode potentials.

*rest potential*—See **open-circuit potential**.

**rust**—a corrosion product consisting primarily of hydrated iron oxide. (A term properly applied only to ferrous alloys.)

**sample**—a portion of material taken from a larger quantity and representative of the whole, to be used for test purposes.

*season cracking*—See **stress-corrosion cracking**.

**sensitization**—a process resulting in a metallurgical condition which causes susceptibility of an alloy to intergranular corrosion or intergranular environmentally assisted cracking in a specific environment.

**specimen**—a prepared portion of a sample upon which a test is intended to be performed.

**stray current corrosion**—the corrosion caused by electric current from a source external to the intended electrical circuit, for example, extraneous current in the earth.

**stress-corrosion cracking**—a cracking process that requires the simultaneous action of a corrodent and sustained tensile stress. (This excludes corrosion-reduced sections which fail by fast fracture. It also excludes intercrystalline or transcrystalline corrosion which can disintegrate an alloy without either applied or residual stress.)

*subsurface corrosion*—See **internal oxidation**.

**sulfidation**—the reaction of a metal or alloy with a sulfur-containing species to produce a sulfur compound that forms on or beneath the surface of the metal or alloy.

**Tafel slope**—the slope of the straight line portion of a polarization curve, usually occurring at more than 50 mV from the open-circuit potential, when presented in a semi-logarithmic plot in terms of volts per logarithmic cycle of current density (commonly referred to as volts per decade).

**thermal spraying**—a group of processes wherein finely divided metallic or nonmetallic materials are deposited in a molten or semimolten condition to form a coating. (The coating material may be in the form of powder, ceramic rod, wire, or molten materials.)

**thermogalvanic corrosion**—the corrosive effect resulting from the galvanic cell caused by a thermal gradient across the metal surface.

**transpassive region**—the region of an anodic polarization curve, noble to and above the passive potential range, in which there is a significant increase in current density (increased metal dissolution) as the potential becomes more positive (noble).

**tuberculation**—the formation of localized corrosion products that appear on a surface as knoblike prominences (tubercles).

**uniform corrosion**—corrosion that proceeds at about the same rate over a metal surface.

**weld decay**—not a preferred term. Intergranular corrosion, usually of stainless steels or certain nickel-base alloys,

that occurs as the result of sensitization in the heat-affected zone during the welding operation.

**working electrode**—the test or specimen electrode in an electrochemical cell.

*This standard is subject to revision at any time by the responsible technical committee and must be reviewed every five years and if not revised, either reapproved or withdrawn. Your comments are invited either for revision of this standard or for additional standards and should be addressed to ASTM International Headquarters. Your comments will receive careful consideration at a meeting of the responsible technical committee, which you may attend. If you feel that your comments have not received a fair hearing you should make your views known to the ASTM Committee on Standards, at the address shown below.*

# Glossary of Corrosion-Related Acronyms<sup>1</sup>

ABS	Acrylonitrile-butadiene-styrene plastics	FBC	Fluidized bed combustion
AC	Air-cooled	FBE	Fusion-bonded epoxy coating
AE	Acoustic emission	FC	Furnace cooled
AES	Auger electron spectroscopy	FCGR	Fatigue crack growth rate
ANN	Annealed	FEP	Fluorinated ethylene propylene polymer
AUSS	Austenitic stainless steel	FGD	Flue gas desulfurization
AVT	All volatile treatment for BFW	FPM	Fluorocarbon elastomers
BFW	Boiler feedwater	FRP	Fiber-reinforced plastic
BWR	Boiling water reactor	FSS	Ferritic stainless steel
CAB	Cellulose acetate-butyrate	GMAW	Gas metal arc welding
CCI	Crevice corrosion index	GTAW	Gas tungsten arc welding
CCT	Critical crevice corrosion temperature	HAZ	Heat-affected zone
CD	Current density	HB	Brinell hardness number
CDA	Corrosion data acquisition	HE	Hydrogen embrittlement
CF	Corrosion fatigue	HIC	Hydrogen induced cracking
CH	Cold work hardened	HK	Knoop hardness number
CHA	Cold work hardened, aged	HLLW	High level liquid waste (nuclear)
CN	Concentric neutral	HPW	High-purity water
CP	Cathodic protection	HR	Hot-rolled
CPP	Critical pitting potential	HRA	Hot-rolled, aged
CPT	Critical pitting temperature	HRB	Rockwell B hardness number
CPVC	Chlorinated poly(vinyl chloride)	HRC	Rockwell C hardness number
CR	Cold-rolled	HSC	Hydrogen stress cracking
CRA	Corrosion-resistant alloy	HSLA	High-strength low-alloy steel
CS	Carbon steel	HTR	Heat treatment
CSE	Copper/copper sulfate electrode	HVN	Vickers hardness number
CW	Cooling water	IGC	Intergranular corrosion
DCB	Double cantilever beam test	IGSCC	Intergranular stress corrosion cracking
DIMA	Direct imaging mass analyzer	IMMA	Ion microprobe mass analyzer
DSS	Duplex stainless steel	IOZ	Inorganic zinc coating
DTA	Differential thermal analysis	ISS	Ion scattering spectroscopy
DW	Distilled water	ISWS	Illinois State Water Survey tester
EC	Environmental cracking	KIC	Critical stress intensity
EDXA	Energy dispersive X-ray analysis	LAS	Low-alloy steel
EIS	Electrochemical impedance spectroscopy	LMC	Liquid metal cracking
ELN	Electrochemical noise technique	LSI	Langelier saturation index
EPMA	Electron beam microprobe analysis	MAS	Maraging steels
EPDM	Ethylene propylene elastomer	MCA	Multiple crevice assembly
EPR	Electrochemical potentiokinetic reactivation	MIC	Microbial induced corrosion
ER	Electrical resistance	MSS	Martensitic stainless steel
ESCA	Electron spectroscopy for chemical analysis	MT	Magnetic particle inspection
EW	Electric welded	NG	Nuclear grade
		NHE	Normal hydrogen electrode
		NMR	Nuclear magnetic resonance
		NPS	Nominal pipe size
		NT	Normalized and tempered

<sup>1</sup> See *NACE Corrosion Engineers Reference Book, Third Edition*, R. Baboian, Ed., NACE International, 2002, p. 33.

OCTG	Oil country tubular goods	SIMS	Secondary ion mass spectroscopy
OQ	Oil-quenched	SMAW	Shielded metal arc welding
OTEC	Ocean thermal energy conversion	SMLS	Seamless pipe or tubing
OZ	Organic zinc coating	SMYS	Specified minimum yield strength
PC	Polycarbonate	SRA	Stress relief anneal
PD	Pit depth	SRB	Sulfate-reducing bacteria
PE	Polyethylene	SRC	Solvent-refined coal
PFA	Perfluoro(alkoxy-alkane) copolymer	S/N	Fatigue test
PHSS	Precipitation hardenable stainless steel	SRE	Scanning reference electrode
PPC	Polymer modified portland cement	SS	Stainless steel
PP	Polypropylene	SSC	Sulfide stress cracking
PR	Polarization resistance	SSMS	Spark sources mass spectroscopy
PT	Dye penetrant survey	SSR	slow strain rate test
PTA	Polythionic acids	SSW	Substitute seawater
PTFE	Polytetrafluoromethylene	STA	Solution treated and aged
PU	Polyurethane	STEM	Scanning transmission electron microscopy
PVC	Poly(vinyl chloride)	STQ	Solution treated and quenched
PVDC	Poly(vinylidene chloride)	SW	Seawater
PVDF	Poly(vinylidene fluoride)	TEM	Transmission electron microscopy
PWHT	Post-weld heat treatment	TFE	Tetrafluoroethylene
PWR	Pressurized water reactor	TS	Tensile strength
QT	Quenched and tempered	TTS	Temperature, time, sensitization diagram
RH	Relative humidity	URD	Underground residential distribution systems
RSI	Ryzner saturation index	UT	Ultrasonic survey
RT	X-ray or gamma ray survey	UV	Ultraviolet spectroscopy
RTP	Reinforced thermoset plastics	VCI	Volatile corrosion inhibitor
RX	Recrystallized	WFMT	Wet fluorescent magnetic particle inspection
SAM	Scanning Auger microscopy	WQ	Water-quenched
SAW	Submerged arc welding	WOL	Wedge-opening load test
SBR	Styrene-butadiene rubber	XPS	X-ray photoelectron spectroscopy
SCC	Stress-corrosion cracking	XRD	X-ray diffraction
SCE	Saturated calomel electrode	YS	Yield strength
SEM	Scanning electron microscopy	ZRP	Zinc-rich paint

0.000 000 000 000 000 001 = $10^{-18}$	atto	a

<sup>a</sup>To be avoided where practical.

## Relationships among Some of the Units Commonly Used for Corrosion Rates<sup>2</sup>

Unit	Factor for Conversion to					
	mdd	g/m <sup>2</sup> /d	μm/yr	mm/yr	mils/yr	in./yr
Milligrams per square decimetre per day (mdd)	1	0.1	36.5/ <i>d</i>	0.365/ <i>d</i>	1.144/ <i>d</i>	0.00144/ <i>d</i>
Grams per square metre per day (g/m <sup>2</sup> /d)	10	1	365/ <i>d</i>	0.365/ <i>d</i>	14.4/ <i>d</i>	0.0144/ <i>d</i>
Micrometres per year (μm/yr)	0.0274 <i>d</i>	0.00274 <i>d</i>	1	0.001	0.0394	0.0000394
Millimetres per year (mm/yr)	27.4 <i>d</i>	2.74 <i>d</i>	1000	1	39.4	0.0394
Mils per year (mils/yr)	0.696 <i>d</i>	0.0696 <i>d</i>	25.4	0.0254	1	0.001
Inches per year (in./yr)	696 <i>d</i>	69.6 <i>d</i>	25400	25.4	1000	1

NOTE: *d* is metal density in grams per cubic centimetre (g/cm<sup>3</sup>).

<sup>1</sup> See ASTM E 380, Practice for Use of the International System of Units (SI) (The Modernized Metric System).

<sup>2</sup> Wranglén, G. An Introduction to Corrosion and Protection of Metals, Chapman and Hall, 1985, p. 233.

# Corrosion Rate Calculation (from Mass Loss)<sup>1</sup>

$$\text{Corrosion rate} = \frac{(K \times W)}{(A \times T \times D)}$$

where

$K$  = a constant (see below),

$T$  = time of exposure in hours to the nearest 0.01 h,

$A$  = area in  $\text{cm}^2$  to the nearest 0.01  $\text{cm}^2$ ,

$W$  = mass loss in g, to nearest 1 mg (corrected for any loss during cleaning (see 9.4)), and

$D$  = density in  $\text{g/cm}^3$ , (see Appendix X1 of ASTM G 1).

Many different units are used to express corrosion rates. Using the above units for  $T$ ,  $A$ ,  $W$ , and  $D$ , the corrosion rate can be calculated in a variety of units with the following appropriate value of  $K$ :

Corrosion Rate Units Desired	Constant ( $K$ ) in Corrosion Rate Equation
mils per year (mpy)	$3.45 \times 10^6$
inches per year (ipy)	$3.45 \times 10^3$
inches per month (ipm)	$2.87 \times 10^2$
millimetres per year (mm/y)	$8.76 \times 10^4$
micrometres per year ( $\mu\text{m/y}$ )	$8.76 \times 10^7$
picometres per second (pm/s)	$2.78 \times 10^6$
grams per square metre per hour ( $\text{g/m}^2 \cdot \text{h}$ )	$1.00 \times 10^4 \times D^a$
milligrams per square decimeter per day (mdd)	$2.40 \times 10^6 \times D^a$
micrograms per square metre per second ( $\mu\text{g/m}^2 \cdot \text{s}$ )	$2.78 \times 10^6 \times D^a$

<sup>a</sup>Density is not needed to calculate the corrosion rate in these units. The density in the constant  $K$  cancels out the density in the corrosion rate equation.

<sup>1</sup>See ASTM G 1, Practice for Preparing, Cleaning and Evaluating Corrosion Test Specimens.

# Corrosion Rate Conversion Factors

$$\text{Mils/year (mpy)} = C \times \frac{\text{weight loss}}{\text{area} \times \text{time}} \times K$$

$$\text{Millimetres/year (mm/y)} = 0.0254 \text{ mpy}$$

Weight Loss	Area	C Factors

	dm <sup>2</sup>	$198 \times 10^4$	$825 \times 10^2$	$118 \times 10^2$	2710	226
	m <sup>2</sup>	$198 \times 10^2$	825	118	27.1	2.26
	in <sup>2</sup>	$307 \times 10^5$	$128 \times 10^4$	$182 \times 10^3$	$420 \times 10^2$	3500
	ft <sup>2</sup>	$213 \times 10^3$	8880	1270	292	24.3

K is a density factor  
 K = 1.000 for carbon steel  
 K factors for other alloys  
 are given on the next page

EXAMPLE: A 5.0 square inch specimen of copper has a weight loss of 218 mg in 40 hour corrosion test.

$$\text{mpy} = 67.7 \times \frac{218}{5.0 \times 40} \times 0.88 = 65$$

$$\text{mm/yr} = 0.0254 \times 65 = 1.65$$

# Table 1—Overvoltage values

$$n = b \log i / i_0$$

## HYDROGEN OVERVOLTAGE

Material	Ovevoltage (Volts) at 1 ma/cm <sup>2</sup>
	25°C, 2 N H <sub>2</sub> SO <sub>4</sub>
Platinum (Platinized)	0.0005
Platinum (Smooth)	0.15
Palladium	0.05
Nickel	0.25
Iron	0.40
Tungsten	0.2
Molybdenum	0.15
Bismuth	0.70
Lead	1.2
Tin	0.65
Carbon	0.5
Aluminum	0.70
Mercury	1.15
Cadminum	0.9
Zinc	0.85
Gold	0.15
Silver	0.30
Copper	0.5

## OXYGEN OVERVOLTAGE

Material	Overvoltage (Volts) at 1 ma/cm <sup>2</sup>
	25°C, 1 N KOH
Platinum (Platinized)	0.52
Platinum (Smooth)	0.82
Nickel	0.53
Graphite	0.89
Gold	0.96
Silver	0.73
Copper	0.58

# Standard Reference Potentials and Conversion Table<sup>1</sup>

## Reference Potentials and Conversion Factors

Electrode	Potential (V) at 25°C		Thermal Temperature Coefficient <sup>A</sup> (mV/°C)
	$E'^B$	$E''^C$	
(Pt)/H <sub>2</sub> ( $\alpha = 1$ )/H <sup>+</sup> ( $\alpha = 1$ )(SHE)	0.000	...	+0.87
Ag/AgCl/1M KCl	+0.235	...	+0.25
Ag/AgCl/0.6 M Cl <sup>-</sup> (seawater)	+0.25	...	...
Ag/AgCl/0.1 M Cl <sup>-</sup>	+0.288	...	+0.22
Hg/Hg <sub>2</sub> Cl <sub>2</sub> /sat KCl (SCE)	+0.241	+0.244	+0.22
Hg/Hg <sub>2</sub> Cl <sub>2</sub> /1M KCl	+0.280	0.283	+0.59
Hg/Hg <sub>2</sub> Cl <sub>2</sub> /0.1M KCl	+0.334	0.336	+0.79
Cu/CuSO <sub>4</sub> sat	+0.30	...	+0.90
Hg/Hg <sub>2</sub> SO <sub>4</sub> /H <sub>2</sub> SO <sub>4</sub> <sup>D</sup>	+0.616	...	...

<sup>A</sup> To convert from thermal to isothermal temperature coefficients, subtract 0.87 mV/°C. Thus the isothermal temperature coefficient for Ag-AgCl is - 0.62 mV/°C.

<sup>B</sup>  $E'$  is the standard potential for the half cell corrected for the concentration of the ions.

<sup>C</sup>  $E''$  also includes the liquid junction potentials for a saturated KCl salt bridge.

To convert from one scale to another, add the value indicated.

<sup>D</sup> Potential given is for a range of H<sub>2</sub>SO<sub>4</sub> molalities as discussed in Ref (10).

From (E')	To SHE Scale	To SCE Scale (E')
H <sub>2</sub> /H <sup>+</sup>	...	-0.241
Ag/AgCl/1 M KCl	+0.235	-0.006
Ag/AgCl/0.6 M Cl (seawater)	+0.25	+0.009
Ag/AgCl/0.1 M Cl	+0.288	+0.047
Hg/Hg <sub>2</sub> /Cl <sub>2</sub> /sat KCl (SCE)	+0.241	...
Hg/Hg <sub>2</sub> Cl <sub>2</sub> , 1 M	+0.280	+0.039
Hg/Hg <sub>2</sub> Cl <sub>2</sub> , 0.1 M	+0.334	0.093
Cu/CuSO <sub>4</sub> sat	+0.30	+0.06
Hg/Hg <sub>2</sub> SO <sub>4</sub> /H <sub>2</sub> SO <sub>4</sub>	+0.616	...

### Example:

An electrode potential of +1.000 V versus SCE would be (1.000 + 0.241) ± +1.241 V versus SHE.

An electrode potential of -1.000 V versus SCE would give (-1.000 + 0.241) = -0.759 V versus SHE.

NOTE 1—Alloying elements at concentrations below 1 % by mass were not included in the calculation, for example, they were considered part of the basis metal.

NOTE 2—Midrange values were assumed for concentrations of alloying elements.

NOTE 3—Only consistent valence groupings were used.

NOTE 4—Equation 4 in ASTM G 102 was used to make these calculations.

# Values of Constants for Use in Faraday's Equation<sup>1</sup>

*Calculation of Corrosion Rate*—Faraday's Law can be used to calculate the corrosion rate, either in terms of penetration rate (CR) or mass loss rate (MR)

$$CR = K_1 \frac{i_{\text{cor}}}{\rho} EW$$

$$MR = K_2 i_{\text{cor}} EW$$

where

CR is given in mm/yr,  $i_{\text{cor}}$  in  $\mu\text{A}/\text{cm}^2$ ,

$K_1 = 3.27 \times 10^{-3}$ , mm g/ $\mu\text{A cm yr}$ ,

$\rho$  = density in  $\text{g}/\text{cm}^3$ , (see ASTM G 1 for density values for many metals and alloys used in corrosion testing),

MR =  $\text{g}/\text{m}^2\text{d}$ , and

$K_2 = 8.954 \times 10^{-3}$ ,  $\text{g cm}^2/\mu\text{A m}^2 \text{ d}$ .

Other values for  $K_1$  and  $K_2$  for different unit systems are given in the following table.

Rate				
A				
Penetration Rate Unit (CR)	$I_{\text{cor}}$ Unit	$\rho$ Unit	$K_1$	Units of $K_1^a$
mpy	$\mu\text{A}/\text{cm}^2$	$\text{g}/\text{cm}^3$	0.1288	mpy g/ $\mu\text{A cm}$
mm/yr <sup>b</sup>	$\text{A}/\text{m}^{2b}$	$\text{kg}/\text{m}^{3b}$	327.2	mm kg/A m y
mm/yr <sup>b</sup>	$\mu\text{A}/\text{cm}^2$	$\text{g}/\text{cm}^3$	$3.27 \times 10^{-3}$	mm g/ $\mu\text{A cm y}$
B				
Mass Loss Rate Unit	$I_{\text{cor}}$ Unit	$K_2$	Units of $K_2^a$	
$\text{g}/\text{m}^2\text{d}^b$	$\text{A}/\text{m}^{2b}$	0.8953	g/Ad	
mg/dm <sup>2</sup> d (mdd)	$\mu\text{A}/\text{cm}^2$	0.0895	mg cm <sup>2</sup> / $\mu\text{A dm}^2 \text{ d}$	
mg/dm <sup>2</sup> d (mdd)	$\text{A}/\text{m}^{2b}$	$8.953 \times 10^{-3}$	mg m <sup>2</sup> /A dm <sup>2</sup> d	

<sup>a</sup>EW is assumed to be dimensionless.

<sup>b</sup>SI unit.

\* – 760 mm Hg = 1 atmosphere =  $1,013,250 \text{ dyn cm}^{-2}$  =  $101,325 \text{ newtons m}^{-2}$  on the *Système International d'Unites*, adopted in a resolution, 11th General Conference on Weights and Measures, Paris, October 1960, the international unit of pressure is the Newton per square meter.

\*\* – The freezing point is zero degrees Celsius, exactly; the triple point of water is 0.001°C or 273.16°K.

\*\*\* – The boiling point.

# Dew Point of Moist Air<sup>1</sup>

The temperature drop required for condensation to occur at a specified air temperature and relative humidity is given in the table below. The temperature drops are mean values for the indicated air temperature ranges.

RH %	Air Temperature °C		RH %	Air Temperature °F	
	0-20	20-35		32-68	68-95
55	9	10	55	16	18
60	7	9	60	13	15
65	6	7	65	11	13
70	5	6	70	9	11
75	4	5	75	8	9
80	3	4	80	6	7
85	2	3	85	4	5
90	1.6	1.8	90	3	3
92	1.2	1.4	92	2.2	2.5
95	0.8	0.9	95	1.4	1.6
98	0.3	0.3	98	0.5	0.5

Example: At 30°C (86°F) and 80 % RH, a temperature drop of 4°C (7°F) would result in condensation.

Dew point temperatures of moist air as a function of air temperature and relative humidity are tabulated on the following four pages.

<sup>1</sup> See *NACE Corrosion Engineers Reference Book, Third Edition*, R. Baboian, Ed., NACE International, 2002, pp. 69-73.

# Chemical Cleaning Procedures for Removal of Corrosion Products<sup>1</sup>

Designation	Material	Solution	Time	Temperature	Remarks
C.1.1	Aluminum and Aluminum Alloys	50 mL phosphoric acid (H <sub>3</sub> PO <sub>4</sub> , sp gr 1.69) 20 g chromium trioxide (CrO <sub>3</sub> ) Reagent water to make 1000 mL	5 to 10 min	90°C to Boiling	If corrosion product films remain, rinse, then follow with nitric acid procedure (C.1.2).
C.1.2		Nitric acid (HNO <sub>3</sub> , sp gr 1.42)	1 to 5 min	20 to 25°C	Remove extraneous deposits and bulky corrosion products to avoid reactions that may result in excessive removal of base metal.
C.2.1	Copper and Copper Alloys	500 mL hydrochloric acid (HCl, sp gr 1.19) Reagent water to make 1000 mL	1 to 3 min	20 to 25°C	Deaeration of solution with purified nitrogen will minimize base metal removal.
C.2.2		4.9 g sodium cyanide (NaCN) Reagent water to make 1000 mL	1 to 3 min	20 to 25°C	Removes copper sulfide corrosion products that may not be removed by hydrochloric acid treatment (C.2.1).
C.2.3		100 mL sulfuric acid (H <sub>2</sub> SO <sub>4</sub> , sp gr 1.84) Reagent water to make 1000 mL	1 to 3 min	20 to 25°C	Remove bulky corrosion products before treatment to minimize copper redeposition on specimen surface.
C.2.4		120 mL sulfuric acid (H <sub>2</sub> SO <sub>4</sub> , sp gr 1.84) 30 g sodium dichromate (Na <sub>2</sub> Cr <sub>2</sub> O <sub>7</sub> · 2H <sub>2</sub> O) Reagent water to make 1000 mL	5 to 10 s	20 to 25°C	Removes redeposited copper resulting from sulfuric acid treatment.
C.2.5		54 mL sulfuric acid (H <sub>2</sub> SO <sub>4</sub> , sp gr 1.84) Reagent water to make 1000 mL	30 to 60 min	40 to 50°C	Deaerate solution with nitrogen. Brushing of test specimens to remove corrosion products followed by re-immersion for 3 to 4 s is recommended.
C.3.1	Iron and Steel	1000 mL hydrochloric acid (HCl, sp gr 1.19) 20 g antimony trioxide (Sb <sub>2</sub> O <sub>3</sub> ) 50 g stannous chloride (SnCl <sub>2</sub> )	1 to 25 min	20 to 25°C	Solution should be vigorously stirred or specimen should be brushed. Longer times may be required in certain instances.

<sup>1</sup> See ASTM G1, Standard Practice For Preparing, Cleaning, and Evaluating Corrosion Test Specimens.

#### 44 CORROSION TESTS AND STANDARDS MANUAL

Designation	Material	Solution	Time	Temperature	Remarks
C.3.2		50 g sodium hydroxide (NaOH) 200 g granulated zinc or zinc chips Reagent water to make 1000 mL	30 to 40 min	80 to 90°C	Caution should be exercised in the use of any zinc dust since spontaneous ignition upon exposure to air can occur.
C.3.3		200 g sodium hydroxide (NaOH) 20 g granulated zinc or zinc chips Reagent water to make 1000 mL	30 to 40 min	80 to 90°C	Caution should be exercised in the use of any zinc dust since spontaneous ignition upon exposure to air can occur.
C.3.4		200 g diammonium citrate ((NH <sub>4</sub> ) <sub>2</sub> HC <sub>6</sub> H <sub>5</sub> O <sub>7</sub> ) Reagent water to make 1000 mL	20 min	75 to 90°C	Depending upon the composition of the corrosion product, attack of base metal may occur.
C.3.5		500 mL hydrochloric acid (HCl, sp gr 1.19) 3.5 g hexamethylene tetramine Reagent water to make 1000 mL	10 min	20 to 25°C	Longer times may be required in certain instances.
C.3.6		Molten caustic soda (NaOH) with 1.5–2.0 % sodium hydride (NaH)	1 to 20 min	370°C	For details refer to Technical Information Bulletin SP29-370, "DuPont Sodium Hydride Descaling Process Operating Instructions."
C.4.1	Lead and Lead Alloys	10 mL acetic acid (CH <sub>3</sub> COOH) Reagent water to make 1000 mL	5 min	Boiling	...
C.4.2		50 g ammonium acetate (CH <sub>3</sub> COONH <sub>4</sub> ) Reagent water to make 1000 mL	10 min	60 to 70°C	...
C.4.3		250 g ammonium acetate (CH <sub>3</sub> COONH <sub>4</sub> ) Reagent water to make 1000 mL	5 min	60 to 70°C	...
C.5.1	Magnesium and Magnesium Alloys	150 g chromium trioxide (CrO <sub>3</sub> ) 10 g silver chromate (Ag <sub>2</sub> CrO <sub>4</sub> ) Reagent water to make 1000 mL	1 min	Boiling	The silver salt is present to precipitate chloride.
C.5.2		200 g chromium trioxide (CrO <sub>3</sub> ) 10 g silver nitrate (AgNO <sub>3</sub> ) 20 g barium nitrate (Ba(NO <sub>3</sub> ) <sub>2</sub> ) Reagent water to make 1000 mL	1 min	20 to 25°C	The barium salt is present to precipitate sulfate.
C.6.1	Nickel and Nickel Alloys	150 mL hydrochloric acid (HCl, sp gr 1.19) Reagent water to make 1000 mL	1 to 3 min	20 to 25°C	...
C.6.2		100 mL sulfuric acid (H <sub>2</sub> SO <sub>4</sub> , sp gr 1.84) Reagent water to make 1000 mL	1 to 3 min	20 to 25°C	...
C.7.1	Stainless Steels	100 mL nitric acid (HNO <sub>3</sub> , sp gr 1.42) Reagent water to make 1000 mL	20 min	60°C	...
C.7.2		150 g diammonium citrate ((NH <sub>4</sub> ) <sub>2</sub> HC <sub>6</sub> H <sub>5</sub> O <sub>7</sub> ) Reagent water to make 1000 mL	10 to 60 min	70°C	...
C.7.3		100 g citric acid (C <sub>6</sub> H <sub>8</sub> O <sub>7</sub> ) 50 mL sulfuric acid (H <sub>2</sub> SO <sub>4</sub> , sp gr 1.84) 2 g inhibitor (diorthotolyl thiourea or quinoline ethyiodide or betanaphthol quinoline) Reagent water to make 1000 mL	5 min	60°C	...

Designation	Material	Solution	Time	Temperature	Remarks
C.7.4		200 g sodium hydroxide (NaOH) 30 g potassium permanganate (KMnO <sub>4</sub> ) Reagent water to make 1000 mL <i>followed by</i> 100 g diammonium citrate ((NH <sub>4</sub> ) <sub>2</sub> HC <sub>6</sub> H <sub>5</sub> O <sub>7</sub> ) Reagent water to make 1000 mL	5 min	Boiling	...
C.7.5		100 mL nitric acid (HNO <sub>3</sub> , sp gr 1.42) 20 mL hydrofluoric acid (HF, sp gr 1.198–48 %) Reagent water to make 1000 mL	5 to 20 min	20 to 25°C	...
C.7.6		200 g sodium hydroxide (NaOH) 50 g zinc powder. Reagent water to make 1000 mL	20 min	Boiling	Caution should be exercised in the use of any zinc dust since spontaneous ignition upon exposure to air can occur.
C.8.1		150 g trisodium phosphate (Na <sub>3</sub> PO <sub>4</sub> · 12H <sub>2</sub> O) Reagent water to make 1000 mL	10 min	Boiling	...
C.8.2	Tin and Tin Alloys	50 mL hydrochloric acid (HCl, sp gr 1.19) Reagent water to make 1000 mL	10 min	20°C	...
C.9.1	Zinc and Zinc Alloys	150 mL ammonium hydroxide (NH <sub>4</sub> OH, sp gr 0.90) Reagent water to make 1000 mL <i>followed by</i> 50 g chromium trioxide (CrO <sub>3</sub> ) 10 g silver nitrate (AgNO <sub>3</sub> ) Reagent water to make 1000 mL	15 to 20 s	Boiling	The silver nitrate should be dissolved in water and added to the boiling chromic acid to prevent excessive crystallization of silver chromate. The chromic acid must be sulfate free to avoid attack of the zinc base metal.
C.9.2		100 g ammonium chloride (NH <sub>4</sub> Cl) Reagent water to make 1000 mL	2 to 5 min	70°C	...
C.9.3		200 g chromium trioxide (CrO <sub>3</sub> ) Reagent water to make 1000 mL	1 min	80°C	Chloride contamination of the chromic acid from corrosion products formed in salt environments should be avoided to prevent attack of the zinc base metal.
C.9.4		85 mL hydriodic acid (HI, sp gr 1.5) Reagent water to make 1000 mL	15s	20 to 25°C	Some zinc base metal may be removed. A control specimen (3.1.1) should be employed.
C.9.5		100 g ammonium persulfate (NH <sub>4</sub> ) <sub>2</sub> S <sub>2</sub> O <sub>8</sub> ) Reagent water to make 1000 mL	5 min	20 to 25°C	Particularly recommended for galvanized steel.
C.9.6		100 g ammonium acetate (CH <sub>3</sub> COONH <sub>4</sub> ) Reagent water to make 1000 mL	2 to 5 min	70°C	...

# Electrolytic Cleaning Procedures for Removal of Corrosion Products<sup>2</sup>

Designation	Material	Solution	Time	Temperature	Remarks
E.1.1	Iron, Cast Iron, Steel	75 g sodium hydroxide (NaOH) 25 g sodium sulfate (Na <sub>2</sub> SO <sub>4</sub> ) 75 g sodium carbonate (Na <sub>2</sub> CO <sub>3</sub> ) Reagent water to make 1000 mL	20 to 40 min	20 to 25°C	Cathodic treatment with 100 to 200 A/m <sup>2</sup> current density. Use carbon, platinum or stainless steel anode.
E.1.2		28 mL sulfuric acid (H <sub>2</sub> SO <sub>4</sub> , sp gr 1.84) 0.5 g inhibitor (diorthotolyl thiourea or quinoline ethyliodide or betanaphthol quinoline). Reagent water to make 1000 mL	3 min	75°C	Cathodic treatment with 2000 A/m <sup>2</sup> current density. Use carbon, platinum or lead anode.
E.1.3		100 g diammonium citrate ((NH <sub>4</sub> ) <sub>2</sub> HC <sub>6</sub> H <sub>5</sub> O <sub>7</sub> ) Reagent water to make 1000 mL	5 min	20 to 25°C	Cathodic treatment with 100 A/m <sup>2</sup> current density. Use carbon or platinum anode.
E.2.1	Lead and Lead Alloys	28 mL sulfuric acid (H <sub>2</sub> SO <sub>4</sub> , sp gr 1.84) 0.5 g inhibitor (diorthotolyl thiourea or quinoline ethyliodide or betanaphthol quinoline) Reagent water to make 1000 mL	3 min	75° C	Cathodic treatment with 2000 A/m <sup>2</sup> current density. Use carbon, platinum or lead anode.
E.3.1	Copper and Copper Alloys	7.5 g potassium chloride (KCl) Reagent water to make 1000 mL	1 to 3	20 to 25°C	Cathodic treatment with 100 A/m <sup>2</sup> current density. Use carbon or platinum anode.
E.4.1	Zinc and Cadmium	50 g dibasic sodium phosphate (Na <sub>2</sub> HPO <sub>4</sub> ) Reagent water to make 1000 mL	5 min	70°C	Cathodic treatment with 110 A/m <sup>2</sup> current density. Specimen must be energized prior to immersion. Use carbon, platinum or stainless steel anode.
E.4.2		100 g sodium hydroxide (NaOH) Reagent water to make 1000 mL	1 to 2 min	20 to 25°C	Cathodic treatment with 100 A/m <sup>2</sup> current density. Specimen must be energized prior to immersion. Use carbon, platinum or stainless steel anode.
E.5.1	General (excluding Aluminum, Magnesium and Tin Alloys)	20 g sodium hydroxide (NaOH) Reagent water to make 1000 mL	5 to 10 min	20 to 25°C	Cathodic treatment with 300 A/m <sup>2</sup> current density. A S31600 stainless steel anode may be used.

<sup>2</sup> See ASTM G1, Standard Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens.

## **Section II: Testing and Evaluation**

*R. Baboian, Editor*

# Planning and Design of Tests

*Stephen D. Cramer<sup>1</sup> and Barnie P. Jones<sup>2</sup>*

CORROSION TESTS ARE an important tool for evaluating the performance of materials used in scientific, industrial, engineering, consumer, and aesthetic applications, where corrosion was estimated to cost the U.S. economy \$276 billion in direct costs annually in 1998, or 3.1 % of the U.S. Gross Domestic Product [1–3]. Corrosion tests are widely used to evaluate the durability of materials of construction in reactive environments. They have a profound impact on society by the influence they have on the choice of materials used, for example, in chemical plants, drilling and mining equipment, energy production facilities, communications equipment, buildings, bridges, spacecraft, monuments, computers, food processing equipment, medical implants, automobiles, and manufacturing facilities. Corrosion tests evaluate a range of material degradation processes that affect the final performance of these materials and directly influence the materials chosen for these applications. These processes involve chemical and electrochemical reactions, and include mechanically assisted corrosion processes and synergies between wear and corrosion. Corrosion tests are used to examine the performance of materials, evaluate alternate materials, develop strategies for protection of materials, and determine the corrosivity of specific environments.

Typical corrosion and materials engineering requirements are shown in Fig. 1 for three stages in the evolution of a manufacturing process for the chemical process industries (CPI) [4]. Thorough corrosion test planning and design is essential to achieve satisfactory materials performance for each of these stages. Corrosion tests lay the foundation for obtaining adequate information on materials performance in the process environments, for ensuring resources are efficiently used, and that materials choices are compatible with long-term economic goals for the plant. The corrosionist is challenged to influence materials decisions in each of these stages. This is particularly true of the first stage where trends in process simulation have greatly reduced the time between research and development and plant design.

Corrosion test planning and design has been discussed by others [5–9]. This chapter provides a general background for planning and design of corrosion tests and the basic statistical considerations affecting the design of these tests.

While corrosion testing of metallic materials is the focus here, planning and design of environmental performance tests for nonmetallic materials, such as paints, plastics, ceramics, and refractories is similar. Specific corrosion test methods have been developed by ASTM International [10–12], NACE International [13], and the International Organization for Standardization (ISO) [14].

Corrosion test planning and design typically involves the following five steps:

- Define goals and objectives
- Design corrosion test
- Develop test protocol
- Engineer test
- Modify test

These steps are affected by the nature of the corrosion process, the types of data acquired, the analytical resources available, the statistical treatments to be applied, and the outcomes sought. Preliminary or early data can help determine whether the fifth step, modification of the test design, will be needed.

As with other technical endeavors, adequate and ongoing documentation is a necessary element of planning, designing, and conducting corrosion tests [15]. It is the basis for effective communications between management and the corrosionist from the earliest planning stages, ensuring agreement on goals and objectives and the availability of necessary resources. It provides a way to assess, review, and modify the test plan with regard to data quality objectives, use of resources, and the outcomes achieved. It provides the continuity for other investigators to continue and complete tests and to evaluate the results when personnel changes occur, especially when tests are conducted over long time spans.

## DEFINE GOALS AND OBJECTIVES

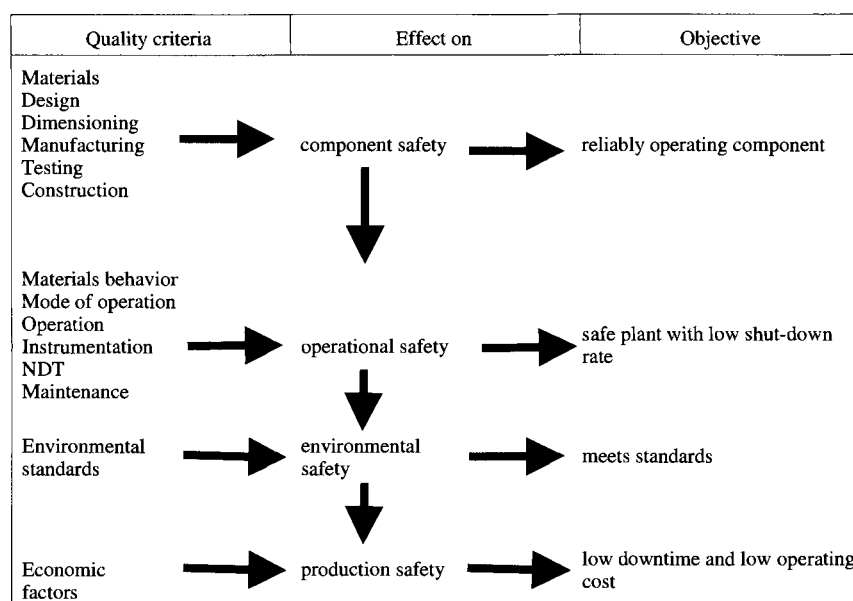

Clearly defined goals and objectives are needed if corrosion tests are to produce results that affect materials selection, and methods of corrosion protection and corrosion control. Goals and objectives define test purpose and what is to be achieved. Economic considerations are always a factor in defining goals and objectives, along with other considerations (workforce, public safety, and environment). Figure 2 shows some of the quality criteria that affect plant economics in the CPI. The criteria have been grouped

according to their effect on a hierarchy of safety factors that determine the long-term economic success of the plant. These safety factors are component safety, operational safety, and production safety, and represent, in increasing order of importance, the economic risks associated with the plant. Corrosion tests establish some of the quality criteria for these safety factors. The corrosionist must ultimately help balance the costs of corrosion control against the benefits to be achieved in each of these areas.

In the CPI, maintenance is one of the quality criteria in operational safety and involves the impact of corrosion on the service life of components, on plant productivity, and on maintenance strategies. Figure 3 shows how component exploitation and risk factors are affected by three different maintenance strategies, and the maintenance actions that result from these strategies. To be able to influence maintenance costs, the goals and objectives must be guided by pragmatic considerations of plant operation.

Failure analysis is an important aspect of corrosion testing since failed components inform the corrosionist about the severity of actual steady-state and transient operating conditions, improperly identified or selected materials, and faulty equipment design. Figure 4 outlines typical steps in failure analysis that are applicable to the CPI and other industries. At the heart of this process is testing to determine chemical, corrosion, and mechanical contributions to the failure and to validate the results of the analysis. Failure analysis is an effective means to lower maintenance costs and a strategy to limit risk to operational safety.

In each of these examples, the crucial issue for the corrosionist is to identify what information is to be generated by the corrosion test, and the connection of that information to production safety. While asking the right technical questions is a necessary element of the planning and design process, in an increasingly important sense, the definition of goals and objectives can reach beyond the corrosionists expertise and require input from the public. Thus, in addition

Component Exploitation and Risk Factors; Maintenance Action	Maintenance Strategy		
	Waiting for Component Failure	Preventive Maintenance	State of Component Monitored in Real Time
Component exploitation	<ul style="list-style-type: none"> <li>• operate up to failure</li> <li>• exploiting component 100 pct</li> <li>• redundancy necessary</li> </ul>	<ul style="list-style-type: none"> <li>• repair after assigned time intervals</li> <li>• exploiting component 60–80 pct</li> <li>• life time assignment necessary</li> </ul>	<ul style="list-style-type: none"> <li>• repair according to test of state</li> <li>• exploiting component 60–80 pct</li> <li>• diagnostic method necessary</li> </ul>

to the expected economic and safety issues, corrosion testing can involve legal [15], regulatory, health, and environmental issues. In this context, the goals and objectives may include not only technical but nontechnical factors. Ultimately, the goals and objectives may include standards of quality, quantity, and timeliness on matters that are both technical and nontechnical.

## DESIGN CORROSION TEST

Corrosion data are developed from service experience, field tests, pilot plant tests, and laboratory tests. Confidence in the reliability of corrosion data increases the more closely results are based on performance in similar or identical process environments, Table 1 [16]. Understandably, the most reliable information on corrosion performance is developed from service experience in identical or nearly identical process environments. Laboratory tests offer the flexibility of a broad range of standard and fundamental corrosion measurements. Sound practice requires that laboratory tests be verified by pilot plant tests and/or field tests before materials specifications are adopted.

Standard corrosion tests such as those developed by ASTM, NACE, and ISO often will address the technical requirements established in the goals and objectives though, in some cases, they may need to be modified. The quality of data produced by standard tests has been well established by critical evaluation and review, and results can readily be compared to others obtained using the same test. Even the highly specialized techniques used in fundamental corrosion research, while not especially amendable to standardization, eventually achieve codification through continued publication and use [9,17–20].

As a practical matter, corrosion tests are integrated with other functions in plant development at the laboratory and pilot plant stage in the ongoing process of specifying materials of construction, Fig. 5. At each stage the corrosionist must evaluate and re-evaluate the material properties and performance necessary to achieve the production safety (Fig. 2) defined by plant management. This is done by considering the operating environment, extremes in the operating environment, and startup and shutdown conditions. Table 2 identifies reasons why the corrosionist may consider selecting more expensive materials than those judged to provide adequate performance at the laboratory or pilot plant stage. Critical or key components in a process may warrant the added expense of more corrosion resistant materials.

The service conditions upon which materials selection is based are most often the nominal process or environmental conditions. However, transients at startup and shutdown,

**TABLE 1**—Corrosion data reliability levels [16].

Corrosion data source	
<ul style="list-style-type: none"> <li>Plant performance data obtained in identical processes</li> <li>Coupon or equipment data obtained in similar processes</li> <li>Laboratory coupon (including electrochemical tests) data obtained in simulated service conditions</li> <li>Published data in recognized journals</li> <li>Advertising literature from industrial sources</li> </ul>	

and during operating excursions, can produce service conditions that require consideration when selecting a material. Less obvious factors such as trace reactant levels, stray currents, mechanical energy bursts, or combinations of these may also be important. Finally, stability of corrosion products, inhibitors, and coatings must be considered. Potential-pH diagrams [21–23] are a valuable resource for showing conditions that may lead to corrosion, immunity, or passivity of metals in many applications.

Corrosion tests must address many types of corrosion [24,25]. These include uniform corrosion, galvanic corrosion, and various forms of localized corrosion, such as intergranular, crevice, or pitting corrosion, that can rapidly cause materials failure without apparent uniform damage. Mechanically-assisted corrosion, such as stress-corrosion cracking (SCC) [26], corrosion fatigue, erosion corrosion, and wear/corrosion synergism, are complex and important corrosion processes, about which better understanding is being achieved through ongoing research.

Corrosion tests are intended to identify materials that provide adequate corrosion performance and service life at a low materials cost. To ensure this, as noted earlier, corrosionists evaluate the performance of materials, the effectiveness of protection strategies (coatings, inhibitors, cathodic protection), and the mechanism and kinetics of corrosion processes in specific environments in service tests, pilot plant tests, and laboratory tests. Increasingly, materials costs are being evaluated in the context of component or structure service life. In this way, factors such as maintenance, repairs, replacement, rehabilitation, process downtime, and interest rates are added into the cost of providing adequate corrosion performance over the service life of the component or structure. Finding or producing the necessary data from corrosion tests for such

**TABLE 2**—Reason for selecting more expensive materials [4].

Concern	Importance
Component/material cost ratio high	moderate
Risk of pitting	high
Risk of stress-corrosion cracking	high
Environmental consequences	high
Safety consequences	highest
Key component failure results in plant shutdown	highest

an evaluation is often daunting, particularly since most corrosion testing is conducted over relatively short time frames relative to the service life of the component or structure. Nevertheless, with necessary assumptions regarding long-term corrosion performance, lifetime cost estimates can provide an effective means for evaluating materials choices.

Cited here are some corrosion studies requiring differing levels of planning and statistical design. Materials selection and protection strategies for specific environments are widely determined in pilot plant tests and by performance in service environments [27–31]. Understanding the mechanism and kinetics of specific corrosion processes under one set of conditions provides a fundamental basis for transferring that knowledge to related corrosion processes under somewhat different conditions [32,33]. Corrosion testing in specific environments includes acceptance testing for materials and for environments [34,35], corrosivity mapping [36], and modeling the effects of environmental factors on materials performance [37–40].

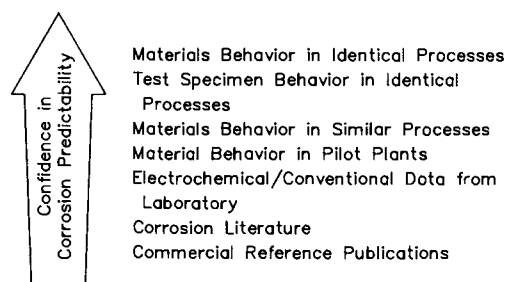

### Basic Statistical Topics

Corrosion test design should reflect the statistical basis of the data analyses (see ASTM G 16, Guide for Applying Statistics to Analysis of Corrosion Data; and E 1488, Guide for Statistical Procedures to Use in Developing and Applying ASTM Test Methods; or for a general statistical reference see Snedecor and Cochran [41]). Whether done intuitively or deliberately, this is a necessary step towards achieving the goals and objectives of the test. However, corrosion test design is more encompassing than the application of statistical methods alone. The design must efficiently provide the needed information. In this regard, the design should employ both statistical and economic types of analyses and address the range of technical and nontechnical issues that are important. Fortunately, most statistical designs are both efficient and economical.

Five statistical topics are introduced here in increasing order of complexity. They are:

- Probability sampling and randomization
- Determining the required numbers of observations
- Curve fitting and simple statistical modeling
- Designing experiments
- Statistical tests for experiments

These represent only a fraction of the techniques and approaches that are available to the corrosionist. Chapter 5, “Statistical Treatment of Data, Data Interpretation, and

**FIG. 5—Materials selection in research and development for CPI plant facilities [4]. © Copyright 1993 by NACE International. All rights reserved by NACE; reprinted by permission.**

Reliability,” covers some of these topics in detail and summarizes the statistical terminology (see also ASTM E 456, Terminology Relating to Quality and Statistics; and E 1325, Terminology Relating to Design of Experiments).

### Probability Sampling and Randomization

There are two related but conceptually different uses of probability sampling, sampling from a larger population, and randomization. Sampling from a population is usually intended to establish *external* validity, or to obtain a sample that can be used to make an inference to the larger population. An example might be quality control sampling of coated steel from a production line, corrosion resistance measurements on a medical implant, or samples of reinforced concrete from bridges of a particular type.

Randomization is largely an identical process, except its focus is on *internal* validity. An example might be random assignment of 48 prepared material specimens to three groups. In this example, three “samples” of 16 observations (specimens) each are drawn from the “population” of 48 material specimens. The purpose is to create three test groups that are equivalent and statistically independent of one another. In both situations, chance alone determines assignment of *observations* (observations and cases are interchangeable terms) to a given *sample* (the aggregate of observations or cases).

### Determining the Required Number of Observations

There are three considerations in determining the number of observations to be included in the case of sampling from a larger population or in randomization. One consideration is the variance in the dependent variable. Other things being equal, the larger the variance, the larger the required number of observations. A second consideration is the number of factors that will be included in any statistical analysis. The larger the number of variables, the more observations that are needed.

Finally, the level of precision required to successfully complete the study affects the required number of observations. Again, the same considerations apply in randomization and in sampling from a larger population: other things being equal, a large number of observations is needed to detect a small change or to obtain a higher level of confidence in the result. For example, larger samples are needed to accurately predict whether there is a difference in corrosion performance between two alloys with similar compositions. Also, since statistical tests and estimates are conditioned by probabilities, larger samples reduce the risk of drawing the wrong inference from a sample (see the discussion of probability distributions and confidence limits in Part II Chapter 5.)

The effect of replicate samples for each variable on statistical error and confidence is illustrated in Fig. 6. The top curve is the statistical confidence as a function of the number of observations per test variable, with the number of observations and the corresponding statistical confidence (as a percent) also shown in parentheses. The bottom curve is the statistical error, which was generated for three magnitudes of variability in the data. For large numbers of

FIG. 6—Statistical confidence and statistical error curves as a function of the number of observations per test variable [42]. © Copyright 2001 by NACE International. All rights reserved by NACE; reprinted by permission.

observations per variable, confidence in the results is high and the error is small regardless of the variability. For small numbers of observations per variable, the confidence decreases substantially and is sensitive to the number of observations taken. With only three observations per variable, the level of confidence is only 55 %, corresponding to a risk level of 45 %, i.e., a 45 % risk that the wrong conclusion may have been reached about corrosion performance or service life. When resources permit, some statisticians recommend 12–18 observations per variable corresponding to 90–93 % confidence in the data, or a 10–7 % level of risk [42].

### Curve Fitting and Simple Statistical Modeling

Often a relationship is sought between corrosion performance and some controllable variable, such as exposure time. Random error can produce enough scatter in the data to make visual curve fitting imprecise. What is desired is the best data fit. One way used frequently to accomplish a good fit is to use regression analysis to minimize the sum of the square of the data deviations about the fitted curve. This is the “method of least squares.” Many physical relationships are not linear functions. For example,

$$\text{logarithmic} \quad y = a + b \ln X \quad (1)$$

$$\text{exponential} \quad y = be^{ax} \quad (2)$$

$$\text{power} \quad y = bX^a \quad (3)$$

However, they can be put in linear form by data transformation. Fitting these functions by least squares is not necessarily straightforward, but fortunately there are user-friendly curve fitting software utilities included with most major spreadsheets and statistical packages that will find the best fit for these and other functions.

Another method is to use a polynomial in the independent variable and then use multiple linear regression, considering each power of the independent variable in the polynomial as a separate linear variable. Powers of a single independent variable can be used to fit a complex curve in two dimensions (Eq 4). For example, many growth processes in

nature, when charted over time, will tend to follow a sinusoidal curve as they transition from one state of equilibrium to another. This can be approximated using a third-order polynomial regression with one independent variable. With two independent variables, a complex surface can be fit in three dimensions. A second order example with two independent variables is given in Eq 5 and the approach can be extended to third and higher order models.

$$y = a + b_1X + b_{11}X^2 + b_{111}X^3 + \dots + b_{111\dots1}X^k \quad (4)$$

$$y = a + b_1X_1 + b_2X_2 + b_{11}X_1^2 + b_{22}X_2^2 + b_{12}X_1X_2 \quad (5)$$

An estimate for a multiplicative model (Eq 6) can be obtained through simple log transformations as shown in Eq 7.

$$y = aX_1^{b_1}X_2^{b_2}X_3^{b_3} \quad (6)$$

$$\ln y = \ln a + b_1 \ln X_1 + b_2 \ln X_2 + b_3 \ln X_3 \quad (7)$$

Each of these approaches will yield a best fit based on the criterion of least squares. A standard measure to express this is the coefficient of determination,  $R^2$ .  $R^2$  has a range from 0 to 1 and can be expressed as the ratio:

$$R^2 = 1 - SSE/SST \quad (8)$$

where:

$SST$  = sum of squared deviations of  $y$  from the mean of  $y$ .

$SSE$  = sum of squared deviations of  $y$  from the fitted curve or trend line.

However, in interpreting  $R^2$  and especially in comparing  $R^2$  values, it is important to keep in mind that a perfect fit can always be obtained with a sufficiently complex curve. An alternative is the "adjusted  $R^2$ ," which is a more realistic measure of goodness of fit and expressed as:

$$\text{Adjusted } R^2 = 1 - (n-1/n-p)SSE/SST \quad (9)$$

where  $n$  is the number of observations and  $p$  represents the number of predictors in the regression equation. Note that if  $p$  is greater than 1, the "adjusted  $R^2$ " will always be smaller than  $R^2$ .

## Designing Experiments

In statistical terms, the primary goal of an experimental design is to introduce controls that eliminate or significantly reduce statistical dependence between the factor of interest and other factors that might influence the test outcome or dependent variable. To illustrate, consider three variables:  $X$ ,  $Y$ , and  $Z$ .  $X$  is an experimental factor,  $Y$  is a test outcome measure or dependent variable, and  $Z$  is an independent variable that is correlated with both  $Y$  and  $X$ . For example, in atmospheric corrosion, the corrosion rate ( $Y$ ) is influenced by both temperature ( $X$ ) and rainfall ( $Z$ ). However, a wet season will also tend to be a cool one in the natural environment, so temperature and rainfall will be correlated, or confounded.

Controlling  $Z$  makes it possible to assess the influence that  $X$  and only  $X$  has on  $Y$ .  $Z$  is effectively controlled

**FIG. 7—Cyclic polarization curves from six nominally identical samples of UNS C10920 copper exposed to a high viscosity, high pH solution [42]. © Copyright 2001 by NACE International. All rights reserved by NACE; reprinted by permission.**

whenever  $X$  and  $Z$  can be made *statistically independent*, and this can be accomplished in a variety of ways. Referring back to the previous example, atmospheric corrosion experiments can be conducted in chambers, where both temperature and moisture (rainfall) can be controlled completely and independently, or experiments can be conducted in a climate where moisture does not vary significantly compared to temperature.

An experiment in which all other relevant variables are held constant is an effective approach when it can be achieved. However, all relevant factors may not be known. Furthermore, circumstances often preclude the ability to hold some variables constant. For example, there may be unforeseen factors that affect the course of a corrosion experiment, as in the polarization curves in Fig. 7 for nominally identical samples of copper (UNS C10920). Most of the curves indicate the copper will actively corrode in the solution. However, one curve indicates the copper will passivate over a narrow range of potentials. Had a structure or device been built based on the passive curve it would have failed unexpectedly. Fortunately, enough replicate curves were measured to show that the passive curve was the exception [42].

**Completely Randomized Designs**—The concept of randomization was discussed above in relation to probability sampling, and also with regard to two sample tests. Given sufficient sample size, random assignment of observations to two or more groups will tend to result in statistical independence between the groups. The larger the groups, the better the approximation to perfect statistical independence.

As an example, reinforced concrete slabs are prepared for an experiment to compare effectiveness of arc-sprayed zinc and titanium anodes. All the slabs will be put under impressed current cathodic protection, and exposed to controlled applications of chloride to the concrete to promote corrosion of the reinforcing bar. Slabs are assigned randomly to be coated with either arc-sprayed zinc or titanium. In this case, randomization is a desirable precaution to control small inconsistencies due to mixing of the concrete, the chemical composition of the concrete, or the distribution of aggregate in the concrete.

An important advantage of randomization is that it will effectively control not only factors that are known, but also factors that are not known. Consequently, randomization is particularly useful in studies where no well-developed knowledge base exists. The primary disadvantage of a completely randomized design is that, other things being equal, it requires more cases than other designs. In determining the required number of test cases for a completely randomized design, the same considerations apply that were discussed earlier in this chapter under "Probability sampling and randomization."

**Factorial Designs**—Sometimes more than one treatment variable is of interest in an experiment. Whenever an experiment involves the manipulation of two treatments, it is referred to as a factorial design. For example one might wish to test the effects of a chemical wetting agent on the conductivity of concrete at varying levels of relative humidity. A full factorial design involves testing all combinations of two or more treatment factors. A fractional factorial study excludes some treatment combinations [43].

**Block Designs**—As noted already, the primary disadvantage of a randomized design is the number of observations that may be required to effectively control other factors. The number of required observations can often be reduced through blocking. Blocking can be applied to single factor or multi-factor studies. Variables may be incorporated as blocking factors or as additional treatment factors. A treatment factor is usually part of the primary focus of an experiment, while a blocking factor is more typically a "nuisance" factor to be controlled. More important, a treatment factor is manipulated directly by the corrosionist, while a blocking factor is controlled indirectly through selection and organization of observations.

Consider the simplest case for blocking in which one particular independent variable is known to have a strong statistical relationship (correlation) with the dependent variable in an experiment. Observations can be sorted on that independent variable and formed into homogeneous groups. Treatments are then conducted within each of these homogeneous groupings of the blocking variable. Blocking effectively holds the criterion variable constant within blocks, and therefore the treatments will be statistically independent of the blocking variable. Also, because the blocking variable is known to be correlated with the dependent variable, blocking will reduce the variance of the dependent variable within blocks. It is this latter consequence of blocking that improves efficiency over a fully randomized design.

More than one variable can be used as blocking criteria, but adding blocking criteria increases the number of blocks, and this compounds the number of times an experiment must be replicated. Consider an experiment in which a treatment is administered at six levels. Consider further that two blocking factors have been selected, and that each of these has six levels. The minimum required cases for a randomized block design is  $6 \times 6 \times 6 = 216$ .

To illustrate randomized block designs, consider the following example: an experiment is conducted to test the effectiveness of two humectants (wetting agents) on the operation of impressed current cathodic protection systems on reinforced concrete bridges. There are 120 reinforced

concrete test slabs left over from other experiments, and we will assume for the purpose of illustration that they are suitable for use in this new test. The test slabs have been coated with either a carbon, titanium, or zinc anode, and as a result of a previous experiment they have been electrochemically aged to simulate in-service lives ranging from 0–20 years.

Conceptually, the simplest design would involve using all 120 test slabs in the experiment, and randomly assigning the slabs to three groups, one for each humectant, and one to serve as a control group. This would constitute a simple randomized experiment. However, the efficiency of the experiment could be improved by using a randomized block design. This would involve, as a first step, specifying levels of each blocking factor to include in the experiment. In this instance there are the three "levels" of anode type. In addition, three age categories can be established representing: young (0–6 years), medium (7–13 years), and old (14–20 years) slab electrochemical age. The advantage introduced by blocking is that it assures that two variables known to be important (anode type and slab electrochemical age) are forced to be independent of the treatment. Also, by grouping the blocked factor, variance is reduced.

The next step would be to assign slabs to the blocks based on the three levels of treatment (and control). Assignment should be random within the nine blocks defined by anode electrochemical age and anode type. A random process would assign three slabs within each of the nine blocks to the three levels of treatment/control; remaining slabs would be dropped from the experiment. This process requires only  $3 (\text{anode type}) \times 3 (\text{anode age}) \times 3 (\text{treatment/control}) = 27$  slabs. Organization of the experiment is described in Table 3.

This is the minimum number of slabs required for the experimental design. In some cases it might be advisable to include replications within blocks. The purpose of replications would be to preclude unanticipated attrition (e.g., a test accident) or to control unidentified variables through randomization. If the experimenter is confident that no uncontrolled or unidentified variables are present, there is no need for replications within blocks.

By using a randomized block design the number of test specimens was reduced from 120 to 27. However, to do so required some assumptions. One assumption was that no unidentified or uncontrolled variables were present to confound the experiment; hence there was no benefit in including replications within blocks. The second was that the factors used in blocking were in fact correlated with the treatment; if not, nothing was gained through blocking.

To improve the efficiency of the experiment even further one could go to an incomplete block design. An incomplete block design does not run all treatments in all blocks. The most extreme case is the Latin square design. In a Latin

TABLE 3—A randomized block experiment.<sup>a</sup>

Electrochemical Age	Anode Type		
	Carbon	Titanium	Zinc
Young	A <sub>11</sub> , B <sub>11</sub> , C <sub>11</sub>	A <sub>21</sub> , B <sub>21</sub> , C <sub>21</sub>	A <sub>31</sub> , B <sub>31</sub> , C <sub>31</sub>

Young	B <sub>11</sub>	A <sub>21</sub>	C <sub>31</sub>
Medium	A <sub>12</sub>	C <sub>22</sub>	B <sub>32</sub>
Old	C <sub>13</sub>	B <sub>23</sub>	A <sub>33</sub>

<sup>a</sup>A, B, and C represent humectant treatments.

square design each level of each blocking factor receives each treatment just once, as in Table 4. However, note that each row and each column contains all three treatments. The primary advantage of a Latin square is that the experiment can be conducted with nine specimens. One important disadvantage is that a Latin square requires two blocking factors, and both blocking factors, along with the treatment factor must have the same number of levels. However, the main disadvantage of a Latin square, and to some extent all incomplete block designs, is that interactions are confounded. For instance, suppose that the different humectant treatments affect the anodes very differently. What is actually an interaction between anode type and the treatment, would be impossible to disentangle from the effects of anode age.

### Statistical Tests for Experiments

In a statistically designed corrosion experiment the goal is to infer a cause and effect relationship between a treatment variable and a dependent variable. By whatever means this is achieved, there is an implicit assumption that, except for the treatment itself, there is an equivalence between the sample of units that received a treatment and the sample (controls) that did not. In statistical analysis of results from experiments, all tests start with this assumption of equivalence between or among groups in all regards except for the factors being tested. Experimental designs are intended to assure, or at least approximate, conditions that make that assumption credible.

The simplest category of testing in an experimental design is the two-sample test. There are a number of nonparametric tests that are appropriate for comparisons of two groups. The most familiar is the two-sample Chi square ( $\chi^2$ ) test, but there is also Fisher's Exact Test, the median test, Mann and Whitney's U, and many others [44]. Nonparametric tests are usually applicable when the dependent variable is categorical, but whenever the dependent variable will support computation of a mean, the most typical test to be applied is the difference of means test. If two groups are created through random assignment from a common pool, differences can be expected to be attributable to either sampling error or some external influence occurring subsequent to assignment. By effectively ruling out chance on the basis of probability, one is left with the implication that some factor subsequent to assignment accounts for the difference. In a well-designed experiment, the only possible candidate should be the treatment factor.

This same basic approach can be extended to any of the experimental designs discussed above using analysis of variance (ANOVA). ANOVA was developed early in the 1920s by the British statistician, R. A. Fischer, to apply statistical methods to agricultural experiments. In fact, the

F ratio is named for R. A. Fischer [41]. The simplest extension involves comparisons of three or more groups. Another involves introduction of more than one factor. Also, it should be noted that whenever more than one factor is included in an experiment, it becomes possible to test for interaction effects. Interaction refers to a situation in which the effects of two variables are nonadditive, or that the effect of one variable depends on the level of a second variable.

Analysis of variance becomes more complicated with more complex designs. It is often the case with incomplete block and fractional factorial designs that some or all interactions cannot be tested. In the case of more complex designs, it is advisable to consult an experienced statistician for assistance, both in the design of the experiment and in setting up the analysis.

### DEVELOP TEST PROTOCOL

A test protocol transforms the corrosion test design into a set of reliable and reproducible measurements that achieve the goals and objectives of the test. The test protocol may simply be a guide or "road map" to the raw or uninterpreted measurements defining methods and standards. When measurements must meet legal, regulatory, or customer challenges, the test protocol may be codified into a quality assurance (QA) plan [45,46]. The test protocol typically specifies criteria for precision, accuracy, completeness, representativeness, and comparability of the corrosion and related measurements. It can address sampling and analytical procedures, calibration procedures and standards, data reduction and processing methods, data validation, data reporting, and data audits.

Many of the measurements involved in corrosion tests are defined in standards to establish precision, accuracy, representativeness, and comparability [10–14]. Analytical techniques and measurements used to characterize the environment and corrosion product chemistry, and to evaluate coatings properties and inhibitor performance, are largely covered by "good laboratory practices" standards [45]. In addition, the requirements for certain analytical and environmental measurements used in regulatory efforts have been established in the Code of Federal Regulations (CFR) [47]. The corrosionist should become familiar with and use these sources of information as they apply to the goals and objectives of the study. Table 5 lists some of the ASTM standards that are more widely used by corrosionists.

### ENGINEER TEST

Engineering the test assures that materials, equipment, instrumentation, personnel, and supporting services are available and used in a timely and effective manner. The test plan must be examined with a clear understanding of problems that may arise to thwart its successful completion. Critical supplies, equipment, and schedule steps must be identified; options developed; tasks simplified; resources allocated; and adequate time allotted. The cost and effort of this step is usually recouped in a more efficient, trouble-free corrosion test.

Pilot plant and service tests may be more vulnerable to unforeseen difficulties as a consequence of constraints and demands from external technical and nontechnical sources. Laboratory tests avoid some of these difficulties because there is usually more flexibility in the allocation of supplies and equipment and in the scheduling of personnel. Certain common sense practices can improve laboratory, pilot plant, and service tests. Use good quality water for the preparation of aqueous solutions (systems are available at reasonable cost that routinely supply Type 1 water) (see ASTM D 1193, Specification for Reagent Water, part 9). Provide regulated and filter power for operating critical electronic instruments and computers. Establish a well-defined ground system for test equipment.

Support personnel provide a valuable base of additional experience and often serve as assistants to the investigator. To use support personnel effectively, they must understand the goals and objectives of the test, have adequate training, and clearly understand their role and responsibilities.

## MODIFY TEST

Test plan execution is the point where the corrosionist must cope with changes that affect resource allocation, personnel schedules, and goals and objectives. These changes may alter the test design, the nature of the results, and the analysis and interpretation of results. Even when external factors cause no changes, the investigator should examine data early in the test, incomplete as they may be, to ensure that the results will meet the goals and objectives of the test while time and resources may exist to modify the plan.

Many changes can be anticipated and their impact on the test plan minimized. Changes arise in the planning and design stage through interactions with others who manage, operate, oversee, study, maintain, or fund related technical areas. Changes that cannot be anticipated have a more significant impact on the plan. These can range from loss of personnel, damaged equipment, vandalism, major changes

in the corrosive environment, lost or damaged corrosion samples, or loss or failure of monitoring capability.

Comparing test results with the goals and objectives of the test is the clearest measure of the success of the test. In this way, opportunities to improve the test by revising its design, exploiting scientific and technological advances, and considering new or additional information can be achieved.

## SUMMARY

Corrosion tests provide information about materials and their applications that have an important effect on the economic vitality and quality of life. An overview of the key steps in planning and designing corrosion tests includes identifying goals and objectives, developing a test design using statistical and economic analysis, establishing the protocol for reliable and reproducible measurements, efficiently engineering the corrosion test with limited resources, and coping with modifications to the test plan.

# Types of Data

David C. Silverman<sup>1</sup>

CORROSION TESTS ARE performed to provide information on material degradation in specific environments, information that is not available from other sources. Corrosion testing can be divided into two broad categories, electrochemical and nonelectrochemical. Within these categories, test results are presented in a number of ways, ranging from numerical output to qualitative examination of the test specimen. Both types of data are represented in each category. A very complete listing of data formats for collection and compilation for computerized databases is presented in ASTM G 107, Guide for Formats for Collection and Compilation of Corrosion Data for Metals for Computerized Database Input. The information in that standard includes a significant portion of the type of test data that might be recorded during corrosion testing. Since required data are test-dependent, not every test would include all of the data listed, but the standard does provide a reasonable, first pass checklist and should be used to ensure that needed information is not overlooked.

The purpose of this chapter is to provide an overview of types of corrosion data for metals and alloys that might be obtained from or be relevant to different types of corrosion tests. The examples discussed are not meant to be all-inclusive. They are meant to provide a flavor of the types of data that might be recorded. The reader is strongly encouraged to refer to the references and cited standards for a more complete discussion of the types of data relevant to the test discussed.

## ELECTROCHEMICAL TEST DATA

The main variables that are measured in an electrochemical test are the voltage and the current. The goal is to translate this information into a corrosion rate or some other information that describes the corrosion process. ASTM G 3, Practice for Conventions Applicable to Electrochemical Measurements in Corrosion Testing, provides guidelines for conventions for reporting a myriad of electrochemical data for the more common tests.

### Potential

One very common electrochemical measurement is the corrosion potential. This potential is the voltage of the corroding

electrode measured at open circuit in an electrolyte. The voltage is measured relative to a reference electrode. For example, ASTM G 69, Practice for Measurement of Corrosion Potentials of Aluminum Alloys, describes how to measure the corrosion potential of aluminum alloys, and ASTM G 82, Guide for Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance, describes the development and use of a practical galvanic series for predicting relative corrosion performance. Very often, the attempt is made to relate the measured potential to potentials calculated from thermodynamic data, e.g., as presented in Pourbaix Diagrams [1], in order to understand better the corrosion mechanism. One reason this approach requires caution is that the measured corrosion potential is at best a steady state potential in which reactions are not at equilibrium and the potential on the Pourbaix diagram is a thermodynamic or equilibrium potential.

Confusion sometimes exists with the sign convention when reporting voltage with respect to the reference electrode. The thermodynamic electrochemical potential of a reaction written as oxidizing ( $M \rightarrow M^{n+} + ne^-$ , where  $M$  is the metal and  $e^-$  is the electron) has the opposite sign as when the same reaction is written as reducing ( $M^{n+} + ne^- \rightarrow M$ ). The recommended approach is to use the Stockholm sign invariant convention. In this convention, the positive direction (increasing potential) implies increasingly oxidizing conditions at the electrode surface (noble). The negative direction (decreasing potential) implies increasingly reducing conditions at the electrode surface (active). For example, the potential of the gold couple with its ion would be more positive than the couple of zinc with its ion. Care must be taken when recording the potential of a specimen in an electrolyte relative to a reference electrode so that the recorded potentials are consistent with this convention. One can always make sure that the connection is correct, i.e., the leads are hooked up properly, by checking against a known couple (see ASTM G 3).

### Current or Current Density

Measurement of current or current density is the most common output of electrochemical corrosion tests. This quantity is usually related either to the corrosion rate or to some features of the corrosion process, such as surface redox reactions that can change the corrosion characteristics. The relationship between the measured current and the corrosion rate or mechanism depends to some degree on

FIG. 1—Hypothetical polarization resistance or linear polarization plot (from ASTM G 3).

the technique used to obtain the current. The type of data obtained and the format by which the information is displayed depend on the test. Some tests display voltage versus current, others display voltage versus the logarithm of the current, others display information about the impedance (voltage divided by the current), and others examine fluctuations in the current around some average value. These different types of current data have different uses and may require additional types of data or analysis programs to translate the data into usable information.

Polarization resistance or linear polarization measurements are used to determine the polarization resistance, a quantity related to the corrosion rate. Current is measured as a function of voltage in the vicinity of the corrosion potential. The two values are plotted as voltage versus current. The polarization resistance is the slope of the curve at the corrosion potential. The importance of this quantity lies in the fact that it is (usually) inversely proportional to the corrosion current, the proportionality constant being related to the Tafel slopes. ASTM G 59, Practice for Conducting Potentiodynamic Polarization Resistance Measurements, describes a method by which these measurements are made and the polarization resistance is calculated. Figure 1 shows a hypothetical plot as a function of current. A very extensive discussion of the historical development, theory and assumptions, and pitfalls provides an excellent background to ASTM G 59 [2]. Additional experimental artifacts have also been discussed [3].

Data in addition to the slope as estimated from a curve, such as in Fig. 1, are required when calculating the corrosion rate from polarization resistance measurements. ASTM G 102, Practice for Calculation of Corrosion Rates and

Related Information from Electrochemical Measurements, provides the methodology and equations. The method is summarized as follows. The slope actually contains contributions from the polarization resistance (shown) and the uncompensated resistance. The latter term contains several contributions, two of which are the electrical resistance in the solution between the reference electrode sensing point and the working electrode and the electrical resistance of the leads and measuring circuit. This uncompensated solution resistance must be subtracted from the resistance calculated from the slope to obtain the actual polarization resistance. The corrosion current is estimated from this corrected value. The procedure is to divide the Stern Geary constant by the polarization resistance. ASTM G 102 and Refs 2 and 3 provide details on how the Stern Geary constant might be estimated. If the current measurement is in current, e.g., amp, and not current per unit area of working electrode, e.g., amp/cm<sup>2</sup>, the corrosion current density is estimated from the corrosion current by dividing it by the exposed specimen surface area. The specimen area must be measured. Finally, the corrosion rate as a mass loss is obtained from the corrosion current density. The corrosion current density is divided by the density of the alloy and is multiplied by the alloy equivalent weight and a constant to obtain the corrosion rate in the proper units. The alloy equivalent weight is the reciprocal of the sum taken over all of the elements in the alloy of the valence of the element times its mass fraction divided by its atomic weight. The reader is referred to ASTM G 102 for the details and justification of using the alloy equivalent weight. Thus, more information than that in Fig. 1 is needed for the corrosion rate to be estimated from polarization resistance measurements.

A second type of presentation of current is as the plot of voltage versus logarithm of the current density (current divided by the surface area). ASTM G 5, Standard Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements, and ASTM G 61, Test Method for Conducting Cyclic Potentiodynamic Polarization

FIG. 2—Representative cyclic potentiodynamic polarization curves (from ASTM G 61).

Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-based Alloys, show examples of these types of plots. They are generated by ramping the voltage at a preset rate in the anodic direction with respect to the corrosion potential. Sometimes, the voltage ramp is then reversed so that the potential is driven at a slow rate back to the corrosion potential. This procedure of using a forward and reverse ramp of voltage is called cyclic potentiodynamic polarization. Figure 2 shows an example of a cyclic potentiodynamic polarization scan. One of the purposes of performing this type of experiment and presenting the data in this manner is to estimate the susceptibility of an alloy to undergo localized corrosion in the form of crevice corrosion and pitting. Certain relationships among “characteristic” voltages, e.g., the difference between the “repassivation potential” and the corrosion potential and the difference between the “pitting potential” and the corrosion potential, as well as other features related to the current, can be used to make a judgment about corrosion [4]. Both quantitative and qualitative information constitute the data that are used to interpret the polarization scan.

The electrochemical reactivation technique provides a different way of presenting and using current (see ASTM G 108, Test Method for Electrochemical Reactivation (EPR) Test Method for Detecting Sensitization of AISI Type 304 and 304L Stainless Steels). This test, like the one above, involves a voltage ramp, but in this case, the voltage ramp is from the passive region of the alloy to the active region. The required test result is the integration of the current or the total charge passed. This charge is related to the degree of sensitization of the alloy. In this case, the charge is divided by both the surface area and often the average grain size so it, too, must be measured.

Coupling of dissimilar metals can create a current caused by the potential difference between the two alloys. Such galvanic currents are measured by a zero resistance ammeter placed in an external circuit that connects the two alloys immersed in an electrolyte (see ASTM G 71, Guide for Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes). Sometimes, the current when divided by the surface area can be used to calculate the corrosion rate from Faraday's law. Often when using this type of test the coupled specimens have different surface areas so the surface area of each specimen is a type of data. If corrosion is localized on the alloy surfaces, however, conversion of current to a mass-loss based corrosion rate may not be meaningful.

## Impedance

Measurement of impedance of a corroding electrode has become important in corrosion prediction for such diverse applications as coatings and corrosion rate estimation in low conductivity media. As most commonly practiced, an electrode is subjected to a small amplitude (e.g., 5–10 mV) sinusoidal variation in the voltage of varying frequency, usually about the corrosion potential. The current is measured. The applied voltage is divided by this measured current. Since both the voltage and current have a sinusoidal component with respect to time and are usually out-of-phase, the division results in the impedance, which itself has real and imaginary contributions. Often, the current is

divided by the surface area, and the impedance has the units of ohm-cm<sup>2</sup>. Details are provided in ASTM G 106, Standard Practice for Verification of Algorithm and Equipment for Electrochemical Impedance Measurements. The impedance is usually plotted in one of two ways, as the inverse of the imaginary component versus the real component, as in Fig. 3a, or as a pair of plots in which the magnitude of the impedance and the inverse of the phase angle are plotted as function of the logarithm of the frequency, as in Figs. 3b and 3c (see ASTM G 106 and G 107).

A plethora of literature exists that discusses how to relate the structure of the impedance spectrum to the corrosion mechanism and corrosion rate. In the limit of zero frequency, the impedance becomes equal to the polarization resistance discussed above. Situations arise in which this value is not inversely related to the corrosion rate [5]. The reader is referred to two recent symposia on electrochemical impedance spectroscopy that provide excellent “snapshots” of the state of the art in determining corrosion rates and mechanisms from the impedance spectra and provide information on the additional types of data needed to make the connection [6,7]. In addition, Ref 3 provides an overview of practical applications of this technology, as well as those mentioned previously [3].

## Electrochemical Noise

The technique that has been labeled as electrochemical noise is the measurement and analysis of fluctuations in potential or current that arise from uncontrolled variations in a corrosion process. This technique has received much attention both for laboratory studies and on-line monitoring for localized corrosion (pitting, crevice corrosion, and stress corrosion cracking), coating degradation, and general corrosion [8]. Though no ASTM standard yet exists with respect to measurement procedure or analysis algorithm, a brief discussion of types of data associated with this technique is warranted because of the attention that this technique has received. The recorded data themselves are current and voltage recorded at constant time intervals. The method used to analyze the data points is as important as the data points themselves.

The methods used for expressing the data fall into two categories, time domain techniques and frequency domain techniques. The two methods are related because frequency and time are the reciprocals of each other. The analysis technique influences the data requirements. Reference 9 provides a brief overview of the various mathematical methods and a multitude of additional references. Specialized transforms (Fourier) can be used to transfer information between the two domains. Time domain measures include the normal statistical measures such as mean, variance, third moment, skewness, fourth moment, kurtosis, standard deviation, coefficient of variance, and root mean square as well as an additional parameter, the ratio of the standard deviation to the root mean square value of the current (when measuring current noise) used in place of the coefficient of variance because the mean could be zero. An additional time domain measure that can describe the degree of randomness is the autocorrelation function of the voltage or current signal. The main frequency domain

FIG. 3—Plot of electrochemical impedance spectrum in: (a) Nyquist format, inverse of the imaginary impedance versus real impedance; (b) Bode format, logarithm of the impedance magnitude versus logarithm of the frequency; (c) Bode format, inverse of the phase angle versus logarithm of the frequency (from ASTM G 106).

measure is the power spectral density of the corrosion potential noise or the current noise. The power spectrum is the Fourier Transform of the autocorrelation function and is the distribution of power of the signal in the frequency domain. The power spectral density is usually estimated by the Fast Fourier Transform algorithm or the maximum entropy algorithm. Another transform that is presently being investigated but has not found widespread use is the wavelet transform [10]. This transform has been proposed to overcome some of the shortcomings of the more traditional Fourier transform by using a family of basis functions that are localized in both the time and frequency domains. Debate remains as to which measures provide the most information, so all are found in the literature.

The types of data mentioned in the previous paragraph pertain to the results from analyzing fluctuations in either the voltage or current signal individually. One additional analysis is to divide the standard deviation of the voltage signal by the standard deviation of the current signal to obtain the noise resistance [11]. This parameter can be equivalent to the polarization resistance discussed in the previous section.

## NONELECTROCHEMICAL TEST DATA

Though a significant fraction of metallic corrosion involves electrochemical processes, much of corrosion testing involves techniques that do not have as the main goal the measurement of current or voltage. These techniques are used to examine a number of different forms of corrosion. Sometimes the data that result from the tests are quantitative. Sometimes the data are qualitative. Pictures of either the actual corroded sample or magnified portions of the corroded sample are often very useful and must be considered as types of data.

## Corrosion Rate from Mass Loss

The most common method for estimating the corrosion rate is from the mass loss of a metal specimen of known dimensions immersed in a fluid for a known amount of time. The weight of the specimen is obtained before and after the exposure. The corrosion rate is obtained by dividing by the exposed area, the time, and the density. The procedure is outlined in ASTM G 31, Practice for Laboratory Immersion Corrosion Testing of Metals. An example of a typical vessel for conducting such a test is shown in that standard. Different units exist for expressing the corrosion rate (mils/year for penetration rate or  $\text{mg}/\text{dm}^2/\text{day}$  for mass loss rate). Though a number of assumptions are made about the test and specimen when making this estimate, reasonably reliable values can be obtained when corrosion is not localized but extends reasonably uniformly across the specimen. Guidelines have been presented as to the error associated with measurements of weight, time, and surface area when these are the only sources of error [12].

In the case of rectangular panels or coupons, the area may be calculated from the exposed flat sides plus the four edges. Many investigators have chosen not to include the edge area, though its inclusion is fairly easily done. In the

case of a wire specimen, the exposed area decreases as corrosion proceeds. In order to take this effect into account, a somewhat different approach must be used to calculate the mass loss per unit area.

*Flat panel:*

$$A = 2lw + 2lt + 2wt \quad (1)$$

where

$l$  = length,  
 $w$  = width,  
 $t$  = thickness,  
 $A$  = exposed specimen area.

*Wire specimen radius loss:*

$$\Delta r = \frac{d_i}{2} \left[ 1 - \sqrt{\frac{m_f}{m_i}} \right] = \frac{d_i}{2} \left[ 1 - \sqrt{1 - \frac{\Delta m}{m_i}} \right] \quad (2)$$

$\Delta r$  = radius reduction from corrosion loss,  
 $d_i$  = initial diameter before exposure,  
 $m_i$  = initial mass,  
 $m_f$  = final mass after exposure,  
 $\Delta m$  = mass loss.

The specimen must be cleaned after exposure in order to obtain mass loss results. In many cases weighing the panel before cleaning is desirable so that an estimate of the corrosion product thickness or mass can be obtained. In some cases, removal of the corrosion products should be done nondestructively from at least a small area on some of the panels so that chemical analyses of the corrosion products may be carried out. Such removal may be done by scraping the surface or by using replicating tape. Replicating tape is not very effective in removing rust from steel specimens. ASTM G 1, Standard Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens, provides additional information.

The laboratory immersion test in which a specimen is exposed for a period of time and then removed for examination assumes that the corrosion rate remains constant with time. This assumption is not completely valid, even if the environment remains static over the exposure time. The corrosion rate might decrease from a high rate during which passivation occurs or inhibitors adsorb, or the corrosion rate might increase as different kinetic processes establish themselves. When the amount of change is great, one might use a modified immersion test in which identical specimens are immersed for differing time periods in the same environment [13]. The mass loss, exposure time associated with that mass loss, and area are used to calculate the corrosion rate for each interval. By comparing the rates during the different time periods, one can judge if the corrosion rate is constant, increasing, or decreasing. Again, the types of data needed are time, mass, and dimensions, but the exposure intervals are shorter than the total time of the test.

## Localized Corrosion

Required data can sometimes be a mixture of qualitative observations and quantitative measurements that are combined to provide an overall picture of corrosion. As mentioned

above, certain features of the cyclic potentiodynamic polarization scan are used to estimate somewhat qualitatively the risk of localized corrosion in the form of pitting and crevice corrosion. Likewise, the results from coupon immersion tests used to estimate the risk of crevice corrosion and pitting also contain both types of information. In the case of crevice corrosion, a common procedure is to immerse a coupon upon which is mounted an artificial crevice former. ASTM G 78, Guide for Crevice Corrosion Testing of Iron-Base and Nickel-Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environments, describes a typical procedure. Typical observations include a recording of the general appearance of the specimen, its mass change, the maximum depth of corrosion in each crevice, the number of crevices that had attack under them, and the severity of that attack. A picture sometimes becomes part of the data. This information might be used to rank alloy performance in the environment either qualitatively or even semi-quantitatively.

Similar types of qualitative and quantitative data are also combined when examining pitting. When a specimen is exposed to an environment, the depths of pits are often measured. However, the relationship between such depth and a pitting growth rate is not straightforward because pits do not necessarily grow at a continuous rate. Sometimes a sample is sectioned near the pit to examine its structure. ASTM G 46, Guide for Examination and Evaluation of Pitting Corrosion, provides a standard rating chart for pits in which the density of pits on a surface is rated on a scale of 1–5 (1 being the fewest pits, shallowest attack), as well as diagrams of different types of pit shapes. Comparing actual appearance to that shown in the standard can provide important information about the resistance of the alloy, how it is being attacked, and possible ways to overcome the attack. The appearance of the specimen is a type of data. ASTM G 46 discusses a number of detection and analysis techniques that could be used for analyzing pitting and the types of data that each technique can supply. In addition, the standard provides a methodology by which a pitting probability might be estimated from an immersion test.

Pitting corrosion is a phenomenon that may or may not proceed at a constant rate. Pitting can initiate, propagate, stop, reinitiate, propagate, stop, etc., many times before the entire specimen is penetrated completely. The mere presence of pitting does not necessarily indicate failure. Only when the deepest pit has penetrated and a leak has occurred has the alloy actually failed. The time for such penetration to occur may be impossible to estimate. In the laboratory, test time and specimen surface area can be far different from the expected field exposure time and surface area of the equipment being used. One method that has been proposed to bridge the large differences in space and time is using the statistical theory of extreme values [14,15]. The test and actual environments are assumed to be the same. Pit depths are measured on the laboratory specimen. The values are fit to a probability distribution function. If the fit is good, then by introducing the concept of return period, which is the ratio of the surface area of the object to the surface area of the specimen, the maximum pit depth can, in principle, be estimated for the object. The technique still requires more validation to determine the extent of usefulness.

If valid, it could provide a quantitative methodology for relating measured pit depths to equipment life. In terms of required data, one needs to know the surface area of both the laboratory coupon and the object being examined by the coupon and the depths of the pits on the coupon.

Types of data recorded for detection of intergranular corrosion are both qualitative and quantitative. Qualitative data are visual. They are obtained by examining under magnification a mounted and polished specimen that is etched appropriately. The etched structure is usually compared to photographs of specimens suffering similar types of corrosion (see ASTM A 262, Practices for Detecting Susceptibility to Intergranular Attack in Austenitic Stainless Steels) to determine if intergranular corrosion is observed on the specimen under examination [16]. The observed surface structure becomes the data. Characteristic information that might be recorded are evidence of grains missing from the structure, pits in the grain ends, and ditches between the grains.

Quantitative data relating to intergranular corrosion are actually relative corrosion rates between different materials or the same material treated differently. For example, the alloy under examination is exposed to a strongly acidic solution (see ASTM G 28, Test Methods of Detecting Susceptibility to Intergranular Attack in Wrought, Nickel-Rich, Chromium Bearing Alloys) for a specified length of time [16]. The corrosion rate is calculated from the mass loss of the specimen, its area, and the time of exposure (see ASTM G 31). This rate is compared to that obtained for a properly annealed material. Large differences between the two corrosion rates can mean the presence of intergranular corrosion.

### Stress Corrosion Cracking

The most common form of evaluation is time to failure for stress corrosion specimens. Failure usually means observation of the first crack. In relatively brittle materials, small cracks propagate rapidly causing the material to break into pieces. For specimens with constant loads, the rate of crack propagation increases as cracking proceeds, and failure is usually manifested as breaking of the specimen. Most specimens, however, are stressed by means of a constant strain. In such cases, the rate of propagation decreases after the initial crack is formed and, consequently, the best measure of time to failure is the time to observation of the first crack.

A number of tests are available that are used to estimate the alloy most resistant to stress corrosion cracking in an environment or to estimate a relative ranking of resistance among alloys. These tests employ a number of different types of specimens including U-bends, C-bends, precracked (Fracture Mechanics) specimens, tuning fork specimens, tension specimens, etc. The type of data generated depends on the specimen and the test. The reader is encouraged to consult two reviews [17,18] and the considerable number of citations to which the articles refer. These references discuss the type of data obtainable in stress corrosion cracking tests in considerable detail, as well as the behavior of a number of alloys. One of the reviews also contains references to a number of the ASTM standards that discuss test methods for stress corrosion cracking [17].

### Velocity Sensitive Corrosion (Single Phase Flow)

Corrosion can be sensitive to fluid motion, and often, fluid motion is included when testing for corrosion susceptibility. When fluid motion becomes part of the experimental protocol, measurements not only have to be made under dynamic conditions, but the data recorded must characterize the fluid motion in addition to corrosion rate or other indications of corrosion. This brief discussion is provided only to point out the type of information that must be obtained and recorded to integrate fluid motion into the estimation of corrosion. Though ASTM standards for testing for velocity sensitive corrosion do not yet exist, a recent NACE International Report reviews several methods for making these measurements [19]. While the techniques described all have different geometries, certain types of data are common to all. Merely recording fluid velocity or agitation rate is not sufficient to characterize the relationship between fluid motion and corrosion. Fluid motion is often quantified in terms of the dimensionless group the Reynolds number ( $Re$ ). Quantities such as fluid shear stress at the wall and the friction factor used to characterize the relationships between fluid flow field and the geometry are functions of this dimensionless group. If mass transfer controls or influences corrosion, the Schmidt number ( $Sc$ ) and Sherwood number ( $Sh$ ) are included in the description. These dimensionless groups are:

$$Re = \frac{(\text{velocity})(\text{characteristic\_length})}{(\text{kinematic\_viscosity})} \quad (3)$$

$$Sc = \frac{(\text{kinematic\_viscosity})}{(\text{diffusivity})} \quad (4)$$

$$Sh = \frac{(\text{mass\_transfer\_coefficient})(\text{characteristic\_length})}{(\text{diffusivity})} \quad (5)$$

The dimensionless groups can usually be related by the following equation:

$$Sh = a Re^b Sc^c \quad (6)$$

where  $a$ ,  $b$ , and  $c$  are constants that depend on the geometry of the test apparatus.

Equation 6 is usually assumed to model the relationship among these dimensionless groups and the variables  $a$ ,  $b$ , and  $c$  are determined by curve-fitting to actual data for the geometry in question.

Finally, when the corrosion rate is under complete mass transfer control, the corrosion rate can be derived from an equation of the form:

$$\text{Corrosion Rate} = (\text{Mass Transfer Coefficient}) \times (\text{Concentration Gradient}) \quad (7)$$

In theory, one could estimate the mass transfer controlled corrosion rate from knowledge of velocity, the characteristic dimension, and certain physical properties. In practice, such a simplified approach would not be prudent though

differences between measured and calculated values might provide insight into the corrosion mechanism.

The background and methodology for using these parameters in real situations to relate the laboratory geometry to the field and estimate corrosion rates are presented in detail elsewhere [20,21]. The equations point to the information deficiency if only velocity is recorded. Such physical properties as the diffusivity, viscosity (kinematic viscosity = absolute viscosity/density), and density need to be included in the recorded data. The characteristic length is a parameter that scales the geometry to the flow field and is used as a scaling factor for distance from the wall. Examples are the diameter of a rotating cylinder or the diameter of a pipe. The concentration gradient between the corroding surface and the bulk fluid can often be approximated by the bulk concentration (e.g., oxygen diffusion controlling) or the saturation concentration (e.g., steel corroding in concentrated sulfuric acid). Either should be measurable. The reader should consult the references for more details.

## OTHER DATA

Though this brief discussion has focused on the various types of corrosion data that might be recorded during certain corrosion tests or upon the analysis of the data, there also are noncorrosion data that should be recorded. Temperature, alloy type, heat number, surface condition, and environment chemistry are a few examples. Many more exist and may be required to complete the analysis. ASTM G 107, and especially its Table 1, contains a reasonably comprehensive list of the type of data that might be recorded during a corrosion test. ASTM G 161, Standard Guide for Corrosion Related Failure and Analysis, and especially its Appendix X1, list the type of qualitative and quantitative data that should be considered when analyzing corrosion-related failures. Though not all of the data types listed are relevant to every test, the contents serve as a useful checklist. Experimenters are encouraged to consult these listings prior to setting up an experiment to help ensure that key data and observations are not omitted from the measurements or records during the testing. An important concept to keep in mind is that recording too much information is always better than not recording enough information.

# Metallographic Analysis

*Richard L. Colwell<sup>1</sup>*

A NEW DOOR opened into the study of materials in the late 19th century (1863) when a British geologist named Henry C. Sorby decided to polish a piece of steel, etch it with acid, and examine it under a microscope. Since that time, metallographic examinations have been performed on most every engineering material developed.

Metallographic examination is a valuable tool in providing an understanding of structure/property relationships in many engineering materials. The true value in these examinations cannot be obtained without an intimate knowledge of a materials thermodynamic phase equilibria, and the effects of environmental factors on that equilibria. While this knowledge can be gleaned from the numerous technical volumes available, first hand experience can be a far better teacher.

## SAMPLE SELECTION

The selection of samples can be very important to the outcome of metallographic analysis. If the component is very large, it may require sectioning to provide manageable metallographic samples. The location for removal of metallographic samples should be considered carefully. Samples should contain areas representative of the corroded or fractured component. Samples of unaffected areas can reveal contrasting structures, thus distinguishing damage. Sometimes multiple samples must be taken at different orientations to understand the true nature of failure mechanism.

When sectioning, care should be taken to keep the sample cool. Elevated temperatures can promote phase transformations and exfoliation of surface deposits and scales. Heat can also promote volatilization of chemical species on the surface. Keeping the sample cool may require slow cutting to avoid heat generation. If samples must be cut using a torch, make sure that large areas are removed, thus leaving enough unaffected area for later saw cuts. Recently, the plasma cutting torch has gained much acceptance for use in obtaining samples in steels. The plasma torch transfers very little heat to the steel, thus creating very small heat-affected areas.

Cutting may also require use of a coolant. One should be careful of liquid coolants, especially if chemical analysis of surface scales and deposits will be required. Introduction of cooling liquids can contaminate areas of interest. In addition,

chemical species responsible for damage may dissolve and be washed away.

## PROCEDURES FOR SAMPLE PREPARATION

### Fixturing and Mounting

Once a sample has been obtained, it can be prepared for metallographic examination. Preparation usually involves taking a representative sample of usable size and fixturing it for easy handling during grinding. The sample may be fixtured in a mechanical assembly by using a clamping load supplied by threaded fasteners. Most often the sample is sandwiched between two pieces of material of similar hardness. This sandwiching promotes good edge retention. One should be sure that the sandwich material is nonreactive with the sample, especially in the presence of water and other fluids. In order to prevent capillary draw of fluid into the crevices inherent to the clamping fixture, paraffin can be used to fill the voids and gaps.

Another fixturing technique involves the use of either thermoplastic, or thermosetting polymer granules and powders. These powders and granules have different values of wearability. Mounting resins with high wear resistance promote good edge retention, but slow the material removal rate. Mounting polymers can also be transparent and electrically conductive. Conductive mounts are required to keep the sample from charging when examination using a scanning electron microscope is required.

Mounting involves inserting a specimen, to-be-polished side down, into a heated cylindrical cavity of fixed diameter so that the area to be examined is flat against one end of the cylinder. The sample may require support, such as clip rings, to keep it in the desired position. Next, polymer granules or powder, or both, are carefully added to the cavity, care being taken to not disturb the sample. Once sufficient material has covered the sample, the other end of the cylinder is secured, and the cylinder is pressurized. Heat and pressure cause the polymer to liquify and then set, thus encapsulating the sample. Thermoplastic polymers should be allowed to cool to near room temperature before releasing pressure. At temperatures above their glass transition, flow will result, causing the polymer to pull away from the sample.

When encapsulating samples, it is advisable, if possible, to remove any sharp corners, sharp protrusions, and burrs

<sup>1</sup>Bechtel Corporation, Houston, TX.

from the sample edges. Their presence tends to concentrate stresses during polymer cool-down and can promote cracking. Once cool, the sample can be handled easily during grinding and polishing.

Another method of sample fixturing uses cold-set epoxy resins. This method is helpful when samples are large or when cutting affects the physical integrity of the sample. Samples can be mounted in mold release coated metal molds or bakelite preforms. Molds or preforms, or both, are then affixed (rubber cement, Seal-All™, etc.) to an aluminum foil or PTFE covered flat surface. The sample is then placed on the flat foil/PTFE surface, in the preform, side-to-side polished down. Mixed, bubble-free epoxy resin is then poured over the sample, filling the mold. When using epoxy resins, it is helpful to have access to a bell jar and vacuum pump. A few minutes under vacuum tends to draw any air and gas bubbles out of the sample. The best method using liquid resins involves introducing it to the sample while under vacuum. Upon venting to atmosphere, resin is actually forced into microcavities. The sample is then placed in the preform mold and resin is added to fill the mold.

For some resins, raising the temperature of reaction significantly reduces the time required for the resin to cure, but there are some drawbacks. If the temperature is too high, the resin can oxidize, causing discoloration, thus decreasing visibility of the sample. More important, the amount of shrinkage is significantly higher for resins cured at temperatures above room temperature. This shrinkage can lead to cracking of the epoxy glass. Curing at high temperatures can also cause the epoxy to pull away from the sample, which promotes staining during etching.

If metallographic examination of coatings, specifically oxide coatings, is required, the following special techniques are helpful in preserving the integrity of the coating. The basis of coating preservation involves minimizing shrinkage associated with the curing resin. Blank mounts are made by filling bubble-free liquid resin in 1.25 in. diameter bakelite preforms. After a 24 h cure, two parallel saw cuts are made (approximately 7/8 in. apart) through the sample, creating flats (Fig. 1). Next, a thin slot is cut normal to the flats, half-way through the mount thickness. The ends of the slot are dammed up using cellophane tape. The sample is vacuum impregnated and then placed in the slot. The sample is then shimmed up using thin stainless steel strips. "The strips minimize rounding and reduce the chance of separation at the specimen-resin interface by providing a preferential site for such separation, if any should occur" [1].

Other methods are available and the reader is advised to explore them. A good outline of additional mounting methods and materials is given in *Metallography Principles and Practice* by G. Vander Voort, Ref 2, section 2.4, and ASTM E 3, *Methods of Preparation of Metallographic Specimens*, sections 7 through 9.

## Grinding

Once the sample is fixtured properly, the surface should be ground smooth and flat. Grinding is traditionally performed using silicon carbide papers, but sometimes diamond impregnated grinding media are used. Grinding can be done manually with stationary abrasive papers, manually

FIG. 1—Mounting arrangement for preserving oxide scales.

using rotating abrasives, or automatically (usually encompassing rotating abrasives, a counterrotating sample platen, and downwards pressure of the sample onto the abrasive). The choice between these methods depends on the number of samples and economy.

Whatever method is used, the principle is still the same: material removal. Material is removed for two reasons. The first involves removal of gross scratches and deformities from the surface. The second, which is equally important, especially for softer materials, is to remove subsurface damage. During grinding, abrasive particles actually cut gouges in the sample surface. While cutting, the material just beneath the surface of the gouge is plastically deformed. This plastically deformed material has a higher dislocation density, and is therefore higher in internal strain energy than the material around it. During etching, these higher energy areas are preferentially attacked, thus leaving traces of scratches and etch pits. It is very important to not only remove the scratches you see, but remove subsurface damage you cannot see.

During grinding, the metallographer should keep in mind that increasing the pressure on the sample will result in greater material removal rates, but will not increase the amount of subsurface damage [3]. The maximum depth of subsurface damage is independent of pressure [4].

Traditionally, grinding starts at grits numbered 60 or 120, depending on the initial condition and flatness of the sample. Grinding should start with the finest grit capable of rendering a flat specimen and removing damage from sectioning. Coarse grinding should be minimized in order to limit subsurface deformation. Figure 2 shows the relationship between scratch

FIG. 2—Depth of scratches (roughness) and subsurface deformation in steels as a function of abrasive grit size.

depth (roughness) and depth of deformation in steels for various grit sizes [5]. Additional grinding is performed using successively finer abrasives, typically using 240, 400, and 600 grit abrasives sequentially.

During grinding, the sample surface should be kept cool. Cooling is usually provided by use of water, alcohol, or other organic compounds. Nonaqueous coolants are used to inhibit leaching of water soluble compounds from the sample or oxide scales.

Once grinding using 600 grit paper is completed, it is usually a good idea to chamfer the edges of the sample mount. This chamfer minimizes damage to the polishing cloth nap.

## Polishing

There are basically two types of polishing: electrolytic (electrochemical) and mechanical. Each will be discussed separately.

### Mechanical Polishing

Subsequent to grinding and prior to polishing, the metallographer's hands and the sample should be thoroughly washed. Washing keeps any residual grinding abrasives from contaminating the polishing cloth.

The polishing operation is very similar to grinding, but the size of the polishing abrasives is considerably smaller than the size of grinding abrasives. Again, the sample should be washed between each polishing step to inhibit abrasive carryover and contamination of the polishing cloths. Ultrasonic baths are highly recommended for cleaning during polishing. Ultrasonic waves promote superior cleaning by agitating small particles out of cracks and voids. However, metallographers beware: extended use can result in cavitation and pitting on the sample surfaces.

Typically, a sample will first be rough polished using 6  $\mu\text{m}$  or 3  $\mu\text{m}$  diamond compound, or similarly sized alumina slurries. Choice of polishing cloth is a function of sample material hardness, polishing rate, desired edge retention, and relief. A listing of various polishing cloths and their uses is presented in Table 1. It is a good idea to keep separate wheels for both soft and hard materials.

TABLE 1—Polishing cloth selection table.\*

Cloth	Recommended Uses
Canvas	Rough general polishing. Use with coarse grades of SiC and $\text{Al}_2\text{O}_3$ .
Billiard Cloth (Sheared Virgin Wool)	Rough general polishing of ferrous-based materials.
Red Felt (Plucked Virgin Wool Pile)	Rough or intermediate polishing.
Cotton-Medium Nap	Intermediate polishing. Commonly used with diamond, $\text{Al}_2\text{O}_3$ , and colloidal silica.
Cotton-Fine Nap	Rough diamond polishing of soft metals. Use with polishing grades of $\text{Al}_2\text{O}_3$ , $\text{Cr}_2\text{O}_3$ , and silica.
Nylon	Rough polishing with diamond. Helps maintain flatness.
Silk	Use with diamond in rough polishing of extremely friable materials and rough polishing of metals.
Woven Wool	Rough and intermediate polishing of hard materials.
Wool (Short Pile)	Use in all final polishing stages.
Rayon (Flock on Cotton Backing)	Final polishing with diamond, $\text{Al}_2\text{O}_3$ .
Rayon-Fine	Superior final polishing with diamond, $\text{Al}_2\text{O}_3$ , and colloidal silica.
Synthetic Velvet	Intermediate and final polishing. Minimizes relief and edge rounding.
Synthetic Velvet-Fine	Use in vibratory polisher, especially with soft materials.
Medium Napped Polyurethane Cloth on Polyester	Polishing oxide films. Use with cerium oxide.

\*Courtesy of South Bay Technology, Inc.

A diamond extender (i.e., fine cutting oil) is used during polishing. This oily compound allows diamond particles to adhere to the fibers of the polishing cloths, removes abraded material, and permits dissipation of heat during polishing.

For very soft materials, it is sometimes necessary to etch the sample and repeat the previous step before continuing. This repetition is required to remove subsurface damaged material.

Once the sample has been polished to 3  $\mu\text{m}$ , a final step (fine polishing) usually involving either an alumina slurry or colloidal silica slurry is used. The size of particles in these aqueous slurries can be as small as 0.02  $\mu\text{m}$ . Once finished with this step, the sample is ready for etching. If elemental analysis of the polished sample is to be performed using SEM/EDS or other X-ray techniques, extra care should be taken. Often times artifact silicon or aluminum peaks can be introduced by accumulation of polishing abrasives in cracks and pores, and sometimes, depending on the metal hardness, by intrusion into the sample surface.

### Vibratory Polishing

Vibratory polishing is another method commonly used. Mounted samples are weighted down and allowed to randomly circulate on a cloth covered vibrating platen. The platen holds an aggressive slurry of polishing abrasives and is usually covered to avoid evaporation and splashing. The downside of vibratory polishing is that it requires much more time than traditional mechanical or electrolytic polishing. Fortunately, this time is unattended. Vibratory polishing is very good at

Fig. 4—Simplistic representation of the principle of chemical etching.

Fig. 3—Diagram of a simple electrolytic polishing cell.

producing scratch-free samples for soft metals. After polishing, samples should be washed, rinsed in alcohol, and blown dry to avoid staining.

### Electrolytic Polishing

Electrolytic polishing is a convenient way to polish metallic samples in the fine grinded (600 grit) or machined surface states. This method requires formation of an electrical circuit in which the sample is the anode (Fig. 3). A suitable electrolyte flows across the surface of the sample. The current density is adjusted for the type of material and size of the polished sample to facilitate suitable dissolution of metal ions from the to-be-polished surface. As the electrolyte washes over the sample, any perturbations in the surface (high energy sites) are selectively dissolved. The result is a flat surface with no mechanical damage.

Although this method is easy to use, storage and use of potentially dangerous electrolytes limit its use. For example, some solutions of perchloric ( $\text{HClO}_4$ ) can become explosive if allowed to evaporate to concentrated solutions.

### Etching

Etching is performed in order to observe microstructural constituents, including grain boundaries, twin planes, slip lines, and second phase particles. In addition, etching can sometimes, as will be discussed later, reveal a material's propensity towards certain corrosion mechanisms.

Safe laboratory work practices are very important. A metallographer is useless without his or her eyes. Use proper protective equipment (gloves, safety glasses, etc.) when using laboratory chemicals.

There are three basic types of etching mechanisms: chemical etching, staining, and optical etching. Chemical etching uses the anisotropy in a material. The reaction rates of the chemical etchant on a polished sample's surface are dependent on the energy state of materials microstructure. The higher the energy state of one region, the faster it will react, and more etching (localized material removal) occurs.

In other words, some microstructural constituents are anodic to others. Grain boundaries and twin boundaries are more energetic (anodic) than the material in the center of a grain. Likewise, regions under elastic tensile strain, or regions that have undergone plastic deformation will etch faster than nonstrained, nondeformed material. In a multiphase material, one phase may be more reactive than another.

Similarly, grain orientation on polished surfaces can affect the degree of etching. Close packed orientations can etch slightly faster than lesser packed planes.

Under reflected light, etched material will appear darker than the unetched material. Indentations created by etching act as holes, reflecting light away at different angles. The "off-reflected" light cannot be reflected back to the objective lens, and therefore appears as regions of darkness (Fig. 4).

Some materials etch more easily than others. Grain boundary delineation in aluminum alloys is perhaps one of the most difficult tasks for a metallographer. In aluminum alloys, it is sometimes necessary to experiment with many etchants in order to obtain the desired grain boundary resolution.

Table 2 contains a number of chemical etchants that have proved useful for a limited number of the more popular engineering alloys. Included are the microstructural characteristics highlighted by the etch.

After chemical etching, samples should be rinsed in water, followed by alcohol and blown dry to avoid staining. Samples should be stored in desiccators to inhibit corrosion on the highly polished surfaces. If a desiccator is not available, use of commercial clear coat paints is recommended.

Electrolytic etching is similar to chemical etching, but the electrochemical reaction is forced by means of an externally applied potential. If the sample is embedded in a polymeric mounting material, provisions for making electrical contact must be made (i.e., prepared mount, drilling through the mount, removal from mount, etc.).

A family of chemical etchants known as deposit etchants works slightly different than chemical etchants. Like electrolytic etchants, deposit etchants promote dissolution of metal on the polished surface. However, the dissolved metal ions react with agents in the etchant solution, promoting

TABLE 2—A brief list of etchants for revealing microstructure in popular engineering alloys.

Alloy	Etchant	Uses
Aluminum and Al Alloys	0.5–25 g NaOH	General purpose etch.
	1 g zinc chloride	Grain boundary delineation.
	100 mL water	Immerse up to 2 min.
	1 mL HF (48 %)	Outlines microconstituents.
	200 mL water	Immerse for 30–40 s.
	12.5 mL HNO <sub>3</sub> (conc.)	General purpose etch.
	2.5 mL HF (48 %)	Grain boundary delineation.
	85 mL water	Immerse up to 1 min.
	2 mL HF (48 %)	Modified Keller's Rgnt.
	3 mL HCl (conc.)	General purpose etch for Al & Al alloys. Immerse 10–60 s.
	20 mL HNO <sub>3</sub> (conc.)	Wash in warm water, blow dry.
	175 mL water	
	10 mL NH <sub>4</sub> OH	General purpose etch.
Copper and Copper Alloys	10 mL H <sub>2</sub> O <sub>2</sub> (3 %)	Grain boundary delineation.
	Can dilute up to 20 mL water	Use fresh, swab, or immerse up to 1 min.
	10 g (NH <sub>4</sub> ) <sub>2</sub> S <sub>2</sub> O <sub>8</sub>	General purpose etch.
	90 mL water	Grain boundary delineation.
		Immerse up to 1 min.
	10 g Cr <sub>2</sub> O <sub>3</sub>	Swab or immerse up to 30 s.
	4 drops HCl	
Nickel and Nickel Alloys	75–100 mL water	
	20 mL HNO <sub>3</sub>	AquaRegia
	60 mL HCL	Grain boundary, carbide, and $\sigma$ contrast. Use fresh and under hood. Discard after use.
		Swab or immerse up to 1 min.
	3 parts glycerol	Glyceregia.
	2–3 parts HCl	Popular etch. Use fresh and under hood. Discard after use.
	1 part HNO <sub>3</sub>	Swab or immerse up to 1 min.
	10 g CuSO <sub>4</sub>	Marble's Reagent.
	50 mL HCl	Grain boundary delineation
	50 mL water	Swab or immerse up to 1 min.
Iron and Iron Alloys		A few drops of H <sub>2</sub> SO <sub>4</sub> increase etch activity.
	2 mL HNO <sub>3</sub>	Nital.
	98 mL ethanol	Gives good pearlite-ferrite-grain boundary contrast in carbon and low alloy steels.
		Swab or immerse up to 1 min.
	4 g picric acid	Picral. Promotes good resolution of pearlite, bainite, martensite, and carbides.
	100 mL ethanol	Swab or immerse up to 1 min.
	4–5 drops of zephiran chloride (wetting agent)	
Stainless Steel	100 mL picric acid (sat.)	Reveals prior austenitic grain boundaries in martensitic steels.
	1 g tridecylbenzene	
	1 part HNO <sub>3</sub>	General purpose etch for stainless steels.
	1 part HCl	Promotes grain boundary contrast.
	1 part water	Immerse in a gently stirred solution.
	1 g picric acid	Viella's Reagent.
	5 mL HCl	Outlines carbides, $\sigma$ , and $\delta$ .
	100 mL ethanol	Immerse up to 1 min.
	1 part glycerol	Glyceregia for SS's.
	3 parts HCl	Reveals grain structure.
	1 part HNO <sub>3</sub>	Outlines $\sigma$ and carbides.
		Use fresh and under hood. Discard after use.
		Swab or immerse up to 1 min.
	10 g oxalic acid	Electrolytic etch (sample is anode). Use at 1–6 V @ 0.1–1.0 A/cm <sup>2</sup> .
	100 mL water	Resolves $\sigma$ in 5–10 s. Resolves carbides in 15–30 s. Resolves grain boundaries in 45–60 s.

precipitation of insoluble compounds on the sample surface. The relative thickness of the coating is dependent on the reaction rate, which again is variant depending on microstructure and chemical composition.

Heat tinting is another type of deposit etch. Exposing a polished sample (not in a plastic mount!) to elevated temperatures in air causes oxidation to occur. On the microscopic level, oxidation rates of microstructural constituents vary according to their reactivity in a given environment.

The second type of etching is more of a staining operation than etching. Staining has been more involved with the

identification and differentiation of oxide films than in outlining microstructural constituents.

Optical etching is a nondestructive method. The term optical etching is a misnomer. Optical methods do not involve etching, but are useful in showing microstructural features in certain alloys. In this method, microstructural contrast, specifically crystallographic contrast of polished samples, is produced by using the "Kohler" principle of illumination (Fig. 5). Modes of illumination including polarized light, differential interference contrast (Nomarski), and dark field illumination can produce vivid and sometimes colorful contrast.

FIG. 5—The Kohler Principle of Illumination.

A comprehensive list of chemical etchants and etching procedures can be found in Refs 2, 6, and 7.

### Metallographic Interpretation

In the preparation of metallographic samples, not only are good hygiene and technique required, but also a good understanding of the sample material and its properties. Most metallographers have at least once been surprised by a structural anomaly that turned out to be an artifact. Experience and an inquisitive nature are necessary for good metallographic interpretation.

## METALLOGRAPHIC EXAMINATION AND EVALUATION OF CORROSION MECHANISMS

### Stress Corrosion Cracking (SCC)

The nature of stress corrosion cracking (SCC) can be directly observed by metallographic examination. The distinction between intergranular (IGSCC) and transgranular

cracking. TGSCC is best revealed by etching materials to reveal grain boundaries (Fig. 6). In addition, the magnitude of crack branching and crack initiation sites is best revealed by metallographic examination.

Susceptibility of SCC is highly dependent on the metals stress state. Tensile stresses, either applied or residual, above a threshold value (material dependent), are required for cracking to occur. Chemical etching of metals can sometimes provide clues into a material's thermomechanical history. Signs of plastic deformation (deformation twins, slip lines), and thus knowledge of exceeding of material yield strength, can be revealed through etching.

Some stainless steels can be made susceptible to IGSCC by exposure to elevated temperatures ( $823^{\circ}\text{K} < T < 1073^{\circ}\text{K}$ ). At these temperatures, carbon atoms migrate to grain boundaries where they combine with chromium atoms to produce chromium carbides. Since chromium atoms are tied up as carbides, they are not available for matrix corrosion resistance, and the near-grain boundary regions are locally depleted in chromium (Fig. 7). This depletion renders grain boundary regions susceptible to corrosion, and the alloy is then termed "sensitized." The degree of sensitization is a function of temperature and time at temperature. In many cases, a prediction of the susceptibility of austenitic stainless steels to IGSCC can be obtained by a simple electrolytic etch (ASTM A 262, Practices for Detecting Susceptibility to Intergranular Attack in Austenitic Stainless Steels, practice A).

### Pitting

Metallographic examination can be quite useful in determining severity of pitting, and can also be used to qualify materials for use in specific environments. A procedure for metallographic preparation of pitted samples is cited here, quoting ASTM G 46, Guide for Examination and Evaluation of Pitting Corrosion, section 5.1.5: "Select and cut out a representative portion of the metal surface containing pits and prepare a metallographic specimen in accordance to the recommended procedures in Methods E 3. Examine microscopically to determine whether there is a relation between pits and inclusions or microstructure, or whether

FIG. 6—Transgranular (left) and intergranular (right) stress corrosion cracking in type 304 stainless steel (magnification 200 $\times$ )

FIG. 7—Electron microprobe analysis showing depletion of chromium at and near grain boundaries of sensitized type 304 stainless steel [14].

the cavities are true pits or might have resulted from metal dropout caused by intergranular corrosion, dealloying, etc.”

Evaluation of the metallographic samples of pitted materials can be performed easily using charts A, B, and C in ASTM G 46, section 7.2.1. (Figs. 8 and 9). These charts characterize a sample's pit density, pit size, and pit depths. These data are convenient ways of relating and illustrating the severity of pitting to the lay person. It is sometimes helpful to reassess a sample after additional grinding and

FIG. 8—ASTM pitting chart for density, size, and depth (see ASTM G 46).

FIG. 9—ASTM pitting chart for pit shape (see ASTM G 46).

polishing. Material removal can eliminate overly conservative measurements caused by the three-dimensional (3-D) travel path of corrosion pits.

Another way to quantify the extent of pitting is to just examine the pitted surface of an unprepared sample under a laboratory microscope. By measuring the vertical difference, via micrometer measurements on focus knob, between the top of sample and bottom of pit, the pit depth can be measured. One should use this method with caution because pits are not always straight. Pits may travel a circuitous path, and measurement of the perceived pit bottom will result in an overly conservative depth.

## Dealloying

Dealloying is a corrosion mechanism where one element in a multielement system is selectively leached from the matrix by action of a fluid system. Two alloy systems that are widely known for dealloying are cast iron (graphitic corrosion) and copper zinc (Zn > 15 wt. %) brasses. In gray cast irons (in the presence of sulfate reducing bacteria, salt water, or weak acids), alpha iron is anodic to graphite and corrodes, leaving behind a porous mass of graphite and iron sulfates. In brasses, zinc is selectively leached from the matrix, leaving behind a porous mass of copper [8,9]. Dealloying severely reduces the mechanical properties of components made from them. Metallographic examination can confirm visual indications of dealloying (Fig. 10). Not only will the microstructure appear changed as one element is selectively leached from the matrix, but changes in microchemistry can also be observed. Dealloying can be observed optically or by analyzing the polished specimen in a scanning electron microscope (SEM). Back scatter electron images will show contrast in regions of varying atomic number. Another SEM method that graphically displays differences in microstructural elemental composition is the digital X-ray line scan or X-ray dot map. The line scan can

**FIG. 10—Photomicrograph showing selective dezincification of the continuous phase in an  $\alpha$ - $\beta$  brass (magnification 200  $\times$ ).**

show variations in elemental composition along a line (Fig. 11). The dot map shows compositional differences over the examined area. Depending on computer capabilities and software, some systems can map out the concentrations of up to 16 elements simultaneously.

### Corrosion Due to Phase Changes ( $\sigma$ Phase Formation in Cr-Ni-Fe and Fe-Cr Alloys)

Exposure of certain alloys to elevated temperatures can produce phase changes within the alloy. These phase changes can sometimes lead to corrosive attack of the alloy. Corrosion can occur if the phase change alters the formation of protective barriers on surface. Examples of this mechanism are sensitization of stainless steels (discussed earlier) and sigma phase ( $\sigma$ ) formation. Sigma phase formation occurs in nickel-chromium-iron and chromium-iron alloys containing a minimum of 16.5 %

**FIG. 11—EDS line scan showing a reduction in zinc concentration across a dezincified interface in an  $\alpha$ - $\beta$  brass alloy.**

**FIG. 12—Photomicrograph showing  $\sigma$  phase precipitation along austenitic grain boundaries in a type 310 stainless steel (magnification 500  $\times$ ).**

Cr exposed to temperatures between 1100° and 1700°F (593.3° and 926.7°C) over long periods of time [10]. Sigma phase is an iron chromium rich phase that precipitates along austenitic grain boundaries and delta ferrite precipitates (Fig. 12). Test results have shown that sigma phase stainless steels undergo significant intergranular corrosion in boiling 65 %  $\text{HNO}_3$  and in hot concentrated sulfuric acid solutions. Sigma phase formation also results in loss of room temperature base metal ductility.

Sigma phase formation can be easily assessed by metallographic examination. One of the easiest ways of determining the presence of sigma phase is by using a 45 % aqueous KOH solution as an electrolytic etch. Sigma grains are revealed as distinct reddish-brown islands in the austenitic matrix.

### General Corrosion

In conditions where general corrosion occurs, metallographic samples can be used to verify the extent of metal loss through microscopic measurements of sample thickness. Reduction of thickness coupled with weight loss information provides a checks and balances program into the analysis and reveals any corrosion rate differences due to anisotropy.

### Liquid Metal Embrittlement

Liquid metal embrittlement (LME) is not a very common mechanism. Only a small number of liquid metals can cause LME in any given alloy system. LME is an inter- and intragranular cracking mechanism produced by a liquid metal on the surface of a sensitive solid metal in the presence of a tensile stress, either applied or residual. The mechanism occurs only above a threshold stress value and has an incubation period. Table 3 shows a few of the solid and liquid systems exhibiting LME. More alloys systems exhibiting LME are tabulated in the ASM Metals Handbook, 9th edition, Vol. 11, p. 238.

**TABLE 3**—Solid and liquid systems exhibiting LME.

Solid Metal	Liquid Metals Promoting Embrittlement
Aluminum Alloys	Mercury, Gallium, Sodium, Indium, Tin
Brass (70/30-Cu/Zn)	Mercury, Lithium Bismuth
Iron or Steel	Lithium
Nickel Copper Alloys	Mercury, Lead
Stainless Steels	Zinc, Cadmium
Ni-Cr-Fe Alloys	Lead

Metallographic examination can assist in identifying LME. Liquid metal penetration can be observed readily, usually without use of an etchant (Fig. 13). However, etching for grain boundaries can distinguish between inter- and intra-granular cracking. In addition, SEM/EDS (energy dispersive spectroscopy) analysis, as discussed in the section covering Dealloying, can positively identify the presence of foreign metals at grain boundaries within a matrix. Care should be taken when trying to identify mercury using SEM/EDS. High vacuum and electron beams promote evaporation of mercury. Low kV settings should be used over wide areas to inhibit burning off highly volatile mercury. In addition, mercury X-ray energy peaks (M) and sulfur (K $\alpha$ ) peaks are easily mistaken for each other. Wet chemical spectroscopy is perhaps the best method for absolute identification of liquid metal species.

Radiography can be used as a check for LME in large structures. By virtue of the large difference in liquid and solid metal system densities, cracks can be revealed easily on X-ray film, even when they are not visible on the surface.

### High Temperature Corrosion—Metal Dusting

Metal dusting of heat-resistant alloys (Ni-Cr-Fe) occurs in carbonaceous atmospheres at temperatures above 800°F (426.7°C), with very high activity in the temperature range of 1450°F to 1550°F (787.7° to 843.3°C) and above 1700°F (926.6°C). In metal dusting environments, a black “sooty” residue (graphite) usually covers the surface in most of the wasted areas. The residual metal is usually thinned and contains multiple rounded pits. The originally austenitic matrix

transforms to a brittle ferromagnetic material and can be checked with a simple magnet.

Metallographic examination reveals an inward diffusion layer of gross carburization and grain “pop out”.

### Sulfidation

Metallographic examination of metals which have exhibited wastage due to sulfidation usually show a two-layer scale, the upper layer being red, the lower being black and shiny. A few drops of aqueous hydrochloric acid on the deposit can release a noticeable H<sub>2</sub>S odor and verify the presence of sulfides. In addition, creation of a “sulfur print” can verify sulfidation damage. A cross section sample of thinned metal with surface scale is sanded to a 120 grit finish. Next, wash a piece of black and white photographic paper in 2–3 % sulfuric acid. Wipe away excess acid with a clean sponge. The sample is placed on the photographic paper for a few seconds. The paper is then stopped and fixed as in normal circumstances. An image of the sulfide distribution on the tube will appear [11].

### Oxidation

Oxidation, perhaps the most visible of all corrosion mechanisms, is responsible for consuming a significant amount of maintenance dollars. Metallography of oxidized metals can provide information about the type of reaction. Types of oxidation reactions (general, internal, intergranular) can be differentiated by microexamination. Knowing the oxide scale thickness and composition can provide data on time-temperature exposure by knowing the oxidation rate laws of the material. In addition, knowledge of the mass ratio of oxide species in the scale can determine exposure temperature.

Metallographic examination of different phases within oxide scales has proven difficult, but some techniques are available. For example, in steels the scales formed at high temperature are generally composed of three layers: wüstite (FeO), hematite (Fe<sub>2</sub>O<sub>3</sub>), and magnetite (Fe<sub>3</sub>O<sub>4</sub>). The formation of these three oxides can be described by the following reactions:

The mineralogical names are used to emphasize their specific physical and chemical properties. Wüstite forms at high temperatures (>565°C) adjacent to the steel surface. Magnetite is an intermediate layer and hematite is the outer layer. Usually a layer of mixed hematite and magnetite is observed.

An etchant containing 0.5 % selenic acid (H<sub>2</sub>SeO<sub>4</sub>) and 4 % HCl in ethanol can produce a nice contrast between the oxide phases on polished samples after immersion at room temperature [12]. Selected dyes have also been used with various degrees of success. The reader is encouraged to read Ref 13 for further information on dying oxide scales.

# Surface Analysis

*Alfred G. Hopkins<sup>1</sup>*

BECAUSE CORROSION is fundamentally a surface phenomenon, those interested in the fundamental processes of corrosion have always been among the first to explore the utility of surface analysis techniques. These techniques have had, and will continue to have, great success in illuminating many facets of corrosion phenomena.

For those seeking a more detailed treatment of the application of surface analysis techniques to the study of corrosion than can be given here, there are a number of Symposium Proceedings from the Electrochemical Society and from ASTM that are of great utility [1–6]. For those interested in more depth on the subject of surface analysis in general or on particular surface techniques, the following are some useful references [7–13]. Systems that are particularly amenable to surface analysis include inhibitor films and protective coatings, stable oxide films, and corroded surfaces.

## LIMITATIONS

There are, however, a number of limitations that have prevented these techniques from being even more widely used. The first is that corrosion is inherently a dynamic process, while these techniques are essentially static in nature. They can only give a snapshot in time of the chemical state of the system. These techniques are obviously of more use in those systems that change slowly in time versus those that change rapidly.

The second limitation is that most of these techniques require that the sample be removed from the corrosive environment and placed into a high vacuum environment before analysis can be performed. This is a major problem for those systems that can change structure upon drying or loss of absorbed water.

The third major limitation is that the analysis process itself can change the composition of the surfaces to be analyzed. The two most common types of this problem are analysis beam-induced damage and inhomogeneities caused by the sputtering process, which is used often to probe past the topmost surface of the sample.

The final major limitation is cost/availability. Some of the techniques are not widely available, and even those that are easily available (XPS and Auger) are still quite expensive.

This limits the number of analysis points that can be obtained. All of the above limitations result in most studies being done on stable films on metals and making these techniques of lesser utility on unstable or rapidly changing systems.

## GENERAL PRINCIPLES

These techniques generally require the sample to be placed in an ultrahigh vacuum (on the order of  $10^{-7}$  Pa/  $10^{-9}$  torr) to prevent contamination from residual gases in the analysis chamber. A rule of thumb is that up to an atomic layer per second can be formed at pressures of  $10^{-4}$  Pa ( $10^{-6}$  torr) if each collision of a gas molecule results in its sticking to the surface. Fortunately, the sticking coefficients are often much less than unity, especially for oxidized samples such as often are of interest in corrosion studies. Some samples are especially prone to reacting with residual gases; this is often accelerated by electron beam-induced degradation at the sample surface with techniques such as Auger. In these cases, it may be necessary to bake the analysis system to reach vacuums in the low  $10^{-8}$  Pa range or better. With some techniques (such as Secondary Ion Mass Spectroscopy), the vacuum requirements can be relaxed since the surface that is actually being analyzed will only be exposed to the vacuum for a very short period of time.

Near surface techniques, in contrast to true surface techniques, do not require an ultrahigh vacuum. Secondary Electron Microscopy-Energy Dispersive X-ray Spectroscopy (SEM-EDS) is an example of a particularly useful near surface technique that will be discussed in a later section. Micro surface electrochemical techniques, such as the Scanning Kelvin probe, overcome these limitations and do give detailed electrochemical (rather than elemental) information about the system in question.

In classic surface analysis techniques, the surface is illuminated (interrogated) with high-energy electrons, photons, or ions. Depending on the illuminating species, any or all of these types of species will be generated from the ensuing collision. Elemental identification is then made based on characteristic energies or masses of the ejected species. One common way of characterizing surface analysis techniques is by tabulating the incoming and outgoing particles. Table 1 shows such a table, which was adapted from previously published ones [8–10]; this paper will concentrate on the most frequently used techniques. Because surface analysis

is an extremely specialized field, it has its own nomenclature; the reader is referred to ASTM E 673, Terminology Relating to Surface Analysis.

Surface analysis is mainly used in two separate modes. One is in surface science where the goal is to fundamentally understand the root causes and mechanisms that are occurring in a system. Usually a model system is picked to eliminate as many confounding variables as possible to get a system about which firm conclusions can be drawn. Often, many different techniques will be used on the same problem in order to illuminate as many facets of the problem as possible. The other mode is failure analysis. The goal here is to determine which of the failure modes (previously discovered by surface science) is the most important one for a particular failure. The samples are real, and hence, non-ideal. This analysis mode is often used to identify the elements present, their distribution pattern and their oxidation state.

The first and second most common of the true surface analysis techniques are Auger Electron Spectroscopy (AES) and X-ray Photoelectron Spectroscopy. They are electron spectroscopies that quantify the energy of electrons that are emitted by the surface during analysis. A good reference for those seeking more detail is "Uses of Auger Electron and Photoelectron Spectroscopes in Corrosion Science" by McIntyre and Chan in Practical Surface Analysis [12].

## AUGER ELECTRON SPECTROSCOPY (AES)

AES is the most commonly used surface technique on metal samples because of the following advantages:

- High-surface sensitivity.
- Acceptable detectability for many corrosion problems.
- Simultaneous detection of all elements (except hydrogen and helium).
- Very good small area analysis (mapping).
- Ability to probe deeper into the surface by sputter profiling.
- Analysis time not excessively long.
- Readily available instrumentation.

With AES, the sample is subjected to a high-energy (typically 2–20 KeV) electron beam that can cause ejection of a core electron from an atom to form an atomic inner shell vacancy. An outer-level electron will then fill the inner-level vacancy, which will induce an excited state. One of the ways that the atom can then relax is by emitting another electron to form a doubly ionized species. This electron is the Auger electron (named for Pierre Auger, who recognized the effect

in a Wilson Cloud Chamber and first described it in 1923) [14]. Because the emission of an Auger electron is, in reality, a three-electron process, Auger transitions are named for the energy levels of the three-electron orbitals involved, such as KLL.

The Auger process releases electrons of characteristic energy for each element, which are determined by the differences in energy of the orbitals involved. In addition to the Auger electrons, there are also much more plentiful secondary electrons with a broad energy distribution that overlay the characteristic peaks. To highlight the characteristic peaks, differentiation is performed on a plot of the number of electrons emitted by the sample versus the energy of those electrons. This results in a spectrum that ignores the more plentiful background (secondary) electrons and emphasizes the characteristic electrons that are used to identify the elements present. In some cases, the exact peak shape and energy can be used to identify the oxidation state of the elements present. To more clearly discern the peaks, the spectra are derivatized; such a spectrum is shown in Fig. 1.

One of the attractions of Auger analysis is that it is quite surface-sensitive since an Auger spectrum typically represents information about the composition of the top (0.5–2 nm) of the surface depending on the sample analyzed and the analysis conditions. Although Auger electrons can be generated at depths of several micrometers into the sample, in order to be detected, the Auger electrons must be able to escape to the surface without undergoing an inelastic collision. The presence of overlaying material exponentially decreases the probability of the electron reaching the detector unscathed. The exponential constant is the inelastic mean-free path of the electron, which depends on the kinetic energy of the Auger electron and the material it must

**FIG. 1**—Auger spectra of stainless steel surface.

traverse in order to reach the detector. Empirical graphs of the relationship between the electron kinetic energy and its mean-free path are often of use in understanding detectability issues. The effective depth of analysis varies from element to element, even varying between lines of a particular element. This results in high-energy Auger electrons being detectable from deeper in the surface than low-energy ones. For example, a thin, adsorbed carbon (organic) film will preferentially mask the low-energy (68 eV) peak of aluminum as compared to the high energy one (1396 eV). These same types of considerations are applicable to all related electron spectroscopies such as XPS.

Auger spectroscopy also offers acceptable detectability for many situations encountered in corrosion science. This can be as low as 0.01 %, although this is seldom realized in common practice since low detectability conflicts with other desirable qualities such as resolution, analysis time, and the need to minimize beam current to minimize beam damage.

Almost all Auger spectrometers have a scannable incident electron beam such as is used in a Scanning Electron Microscope (SEM). Such an instrument can also be called a Scanning Auger Microscope (SAM). This can provide spatial resolution as low as 15 nm. The ability to scan allows elemental concentration maps of the surface to be generated. This qualitative analysis of small areas is AES's greatest strong point. Its ability to determine element identity and distribution via mapping provides insights into many corrosion problems. In particular, the breakdown of passivity and the initiation of pitting corrosion are often associated with the presence of heterogeneous elements, which include both internal inclusions and corrosive species. Auger maps

are shown in Fig. 2. Variations in signal intensity caused by geometric effects can often be eliminated by ratioing the intensity of the peak of interest to that of adjoining background areas. Elemental mapping is also an important tool in techniques such as SIMS, SEM-EDS, Scanning Kelvin Probe and others.

As in most surface analysis techniques, qualitative identification of the elements present is the easiest type of analysis. Most elements have more than one Auger peak due to having either multiple transitions or fine structure within a transition. It is fairly easy to identify from an Auger spectrum what elements are present on the surface of the sample based on the following: peak position, peak intensity ratios for a particular element, and peak shape. Compilations of elemental spectra and charts of atomic number versus electron energy are available to help assign peaks. Modern data processing (background subtraction, peak fitting to standard spectra) has made it possible to correctly resolve many peak identification problems caused by peak overlap. The analyst should be familiar with ASTM E 827, Standard Practice for Identifying Elements In Auger Electron Spectroscopy. There have been some variations in peak electron energy between different systems and handbooks, but this should be minimized in the future as a result of standardization efforts of ASTM.

Both peak energy and peak shape can vary depending upon the chemical state of the element. This is particularly true for the low-energy transitions of valence electrons. It can also be seen in core-level transitions in those cases where the electrons experience strong energy losses in escaping from metallic surfaces but not from the oxide; for

FIG. 2—Auger elemental distribution maps.

instance; aluminum, magnesium, and silicon. A more detailed description can be found in ASTM E 984, Guide for Identifying Chemical Effects and Matrix Effects in Auger Electron Spectroscopy.

Auger spectrometers are normally equipped with ion-beam sputter guns that can slowly remove the surface while the sample is being analyzed in the vacuum chamber. This results in a depth profile that plots the composition of the freshly generated surface as it varies with depth into the surface. The following three basic issues must be faced when sputter profiling is employed: difficulties in determining the sputter rate, variations in depth resolution, and changes in the sample that are induced by the ion beam.

Sputter rates vary greatly depending on such factors as the identity of the ions (argon is most typical), the accelerating voltage, the angle of incidence, the chemical nature of the sample, and sample surface structure. Although published sputtering yields can be helpful, they cannot replace running known thickness standards on an individual instrument. Two standards that are easiest to accurately fabricate, and therefore are the most common, are tantalum oxide on tantalum and silicon oxide on silicon. Further complications are added by the dependence of sputter yield on depth and on surface roughness.

Depth resolution can be considered to be equal to the observed broadening of an originally atomically sharp interface. It is not constant; it worsens as one sputters into the material. Inert gas ion sputtering is used in the great majority of surface analysis techniques, either as a method of seeing deeper into the sample (Auger, XPS) or as a way of generating particles to be analyzed (SIMS). A discussion of some of the effects of the sputtering process is given in the SIMS section of this chapter. An important publication on the subject is ASTM E 1127, Guide for Depth Profiling in Auger Electron Spectroscopy. A review of sputtering is given in "Depth Profiling in Corrosion Research" in Ref 15. For Auger spectroscopy, a simplistic method of generating a sputter profile by plotting net peak heights works well if there are no problems such as: peak overlap, peak shape change, and peak shift. Modern data manipulation techniques such as factor analysis minimize the effects of these problems. An Auger sputter profile is shown in Fig. 3.

Absolute quantification of surface composition by electron-energy spectral techniques such as Auger and ESCA is a very difficult goal. Current efforts are concentrated in abstracting

quantifiable peaks from the spectra and in minimizing inter-instrument and inter-laboratory variations. ASTM Committee E-41 on Laboratory Apparatus has a number of subcommittees dealing with these issues for a number of surface analysis techniques including Auger, ESCA, and SIMS. A relevant publication is ASTM E 995, Guide to Background Subtraction Techniques in Auger Electron Spectroscopy. Auger analysis is subject to a number of possible artifacts due to effects such as sample charging, electron beam desorption, electron beam decomposition, and variations induced by sputter profiling. These are treated in ASTM E 983, Standard Guide for Minimizing Unwanted Electron Beam Effects in Auger Electron Spectroscopy. To prevent the analyst from adding contamination to the sample, he should be aware of ASTM E 1078, Guide for Specimen Handling in Auger Electron Spectroscopy, X-Ray Photoelectron Spectroscopy, and Secondary Ion Mass Spectrometry.

## X-RAY PHOTOELECTRON SPECTROSCOPY (XPS)

Einstein received the Nobel Prize for his explanation of the photoelectric effect in which atoms can be ionized by an incoming photon [16]. Siegbahn's [17] realization that the energy of the ejected photoelectron could be used to determine the chemical state of an atom caused him to coin the name ESCA (Electron Spectroscopy for Chemical Analysis). Because X-ray photons are necessary to generate appropriate electrons, the technique is also called X-ray Photoelectron Spectroscopy (XPS).

XPS shares the Auger characteristics of good surface sensitivity since this is driven by the same need for the electrons to be able to reach the detector unscathed. It is possible to vary the depth of analysis in both techniques by varying the tilt angle with regard to the detector. This technique is used more extensively in XPS where it is often called angle resolved depth profiling.

XPS also has the very important advantage of being able to obtain chemical state information on most atoms. It becomes easy to observe the effect of differing chemical environments in both the photoelectron peaks and in the Auger peaks, which are also generated by XPS's X-ray excitation. Often, the chemical shifts in the Auger peaks of an XPS spectrum are larger than the shifts in the photoelectron peaks. Another aid to assigning the proper oxidation state to a peak is the presence of satellite shake-up lines due to a simultaneous promotion of a valence electron to a higher orbital as the photoelectron is being ejected. Proper interpretation of the implications of peak shifts requires the knowledge of sample charging on the spectra. A useful reference is ASTM E 1523, Guide to Charge Control and Charge Referencing Techniques in X-Ray Photoelectron Spectroscopy. Another advantage of XPS is that peak identification is more easily done than in Auger because of the narrow line width, as well as the presence of both Auger peaks and photoelectron peaks in the spectra as is shown in Fig. 4.

XPS is also preferable in that it is able to analyze non-conducting samples and has a lesser tendency towards sample degradation than other techniques. XPS is not as preferable

FIG. 3—Auger sputter profile.

FIG. 4—Ultraviolet photon spectroscopy: uses of narrow scans for corrosion problem solving.

because it does not have Auger's very small spot size since it is much more difficult to focus X-ray beams than electron beams. Therefore, it is necessary to mask or abstract only a portion of the available analysis area which negatively impacts the signal to noise ratio. Relevant information is found in ASTM E 1217, Practice for Determination of Specimen Area Contributing to the Detected Signal in X-Ray Photoelectron Spectroscopy and Auger Electron Spectroscopy. However, 10–30  $\mu\text{m}$  size analysis is possible on a routine basis. The longer time necessary for an XPS spectrum often results in the analyst settling for a lower signal-to-noise ratio and, hence, poorer detectability than with Auger.

## SECONDARY ION MASS SPECTROSCOPY (SIMS)

Secondary Ion Mass Spectroscopy (SIMS) is the third of the three most common surface analysis techniques. A good reference to SIMS and other ion spectroscopies is Czanderna's and Hercules' "Ion Spectroscopies for Surface Analysis" in Ref 11. In SIMS, the sample is irradiated with a primary ion beam (normally argon), the impact of which sputters away the surface atoms, some as neutrals and others as ions. Those atoms that become ionized are then detected in a mass spectrometer where their masses are measured. The most common variant is Dynamic SIMS in which a high-energy ion beam is used that removes layers of the surface. The beam is so energetic that little chemical information is retained since the vast majority of any molecular species is fragmented. Although destroying the surface obviously prevents its re-examination, it is not a total disadvantage since it allows depth profiling to occur.

Some of the advantages of SIMS are that it has a very low detection limit (PPM to PPT) and it can detect all elements. These advantages make it able to address many problems that neither AES nor XPS are suitable for. Reasonably small (micrometer or smaller) spot sizes allow elemental mapping.

A major disadvantage of SIMS is that there is a very great range of ionization rates for different elements. Furthermore, the rates will vary depending on the other species present (matrix effects). Either a beam of positive or negative ions can be used as the exciting beam, although the response factors are much different between them. The biggest differences are found with the very electronegative halogens and the electropositive alkali metals. The variability in response factors makes quantification very difficult and closely matched standards critical. Of use is ASTM E 1505, Guide for Determining SIMS Relative Sensitivity Factors from Ion Implanted External Standards.

In SIMS, as in sputter profiling in Auger and XPS, there are other effects in addition to simply removing the surface atoms. For instance, there is implantation of the sputtering gas and a rearrangement or interfacial mixing of the surface layers. Also, compositional changes caused by preferential sputtering of one element versus another also occur. This is actually a bigger problem for Auger and XPS, which measure the surface, as compared to SIMS, which measures the elements ejected from the surface which soon reach an equilibrium with the actual composition.

Static SIMS uses a much less intense ion beam than Dynamic SIMS. This gives the advantage of not destroying all the molecular species on the surface, which results in one being able to obtain significant chemical information from the surface. It also maintains the integrity of the surface during analysis so that it is much more of a surface technique than Dynamic SIMS. Time of Flight (TOF) SIMS refers to the mode of analysis of the ionized particles rather than their generation process. It provides a very wide mass range plus very high sensitivity.

## OTHER SURFACE TECHNIQUES

The highly variable response factors that are the main limitation of SIMS are almost eliminated by Secondary Neutral

Mass Spectroscopies (SNMS), which provides relatively non-selective ionization of the sputtered species. Separating the sputtering and ionizing functions of SIMS not only eliminates matrix effects but also allows for much less aggressive sputtering conditions. The higher cost of the systems is an inevitable trade-off. There are three ways that the sputtered neutral species can be ionized. Surface Analysis by Laser Ionization (SALI) uses a high-power laser for photoionization, while Glow Discharge Mass Spectroscopy ionizes the neutrals in a glow discharge plasma. The third method is Electron Impact Ionization, and it is labeled by the name of the overall technique, SNMS. Both Electron Impact SNMS and SALI can give SIMS-type information on point defects without the quantification problems that SIMS is prone to. SALI is available with a time of flight (TOF) mass spectrometer which is desirable if higher mass range and resolution is needed than can be provided by standard mass spectrometers.

Rutherford Backscatter Spectroscopy (RBS) requires a monoenergetic beam of high-energy particles (helium ions) that is bounced off of the surface to be analyzed. By analyzing the energy of the backscattered particles, a standardless, nondestructive, quantitative depth profile of the top several micrometers of the surface can be obtained. A related technique is Ion Scattering Spectroscopy (ISS) in which a low-energy monoenergetic beam of ions is directed onto the surface and the energy of the scattered ions is measured. This technique is perhaps the most selective technique of all with regard to only analyzing the topmost layer of atoms. Its major limitations are that it is not able to detect elements at low concentration levels, and it has poor ability to discriminate between elements with similar atomic mass.

## NEAR SURFACE TECHNIQUES

Although not a true surface technique, SEM-EDS often provides useful information in regard to surface corrosion mechanism. The ubiquitous nature, low cost, and ease of use of this technique cause it to be used as a tool in many failure analyses involving corrosion. Because its analysis depth is much larger (approximately a micrometer) than the true surface techniques, it is not necessary to analyze samples that are high-vacuum compatible. This results in the necessity of almost no sample preparation for many different kinds of samples.

The sample is scanned with a high-energy (typically 5–30 KeV) electron beam in a raster pattern, which causes the ejection of a number of particles including secondary electrons, backscattered electrons, and X-rays. Secondary electrons (with energies less than 50 eV) are only detectable if they are generated in the top surface of a sample; this causes the secondary electron output to be responsive to topographical detail and therefore gives an image that is remarkably similar to that seen with an optical microscope. Added advantages are greater magnification and depth of field. The contrast in backscattered electron images is mainly dependent on atomic number, so these images provide rough elemental distribution information.

Element identification is provided by analysis of the characteristic X-rays that are emitted with an Energy Dispersive

Spectrometer (EDS). Quantification can be quite good if appropriate standards are used. The X-ray detector can be set to only detect and count X-rays that have energies within a narrow range. This output can then be used to generate elemental distribution maps, or line scans. Newer detectors with ultrathin windows can easily detect all elements with an atomic number of 5 (boron) or greater. Some applications of SEM-EDS analysis are given in the metallography chapter of this manual.

Particle Induced X-Ray Emission (PIXE) is similar to EDS analysis except that it uses high-energy particles instead of electrons to create the vacancies that lead to X-ray emission. It offers orders of magnitude better detection limits for trace elements than does EDS. Transmission Electron Microscopy (TEM) and Scanning Transmission Electron Microscopy (STEM) require extensive sample preparation. When coupled with another technique (EDS for example), they can be useful in determining the nature of surface films or in illuminating the microstructural causes of corrosion. Environmental Scanning Electron Microscopes (ESEM) that are equipped with EDS spectrometers allow SEM-EDS type data to be obtained from samples in the hydrated state.

Fourier Transform Infrared Spectroscopy (FTIR) and Laser Raman Spectroscopy (LRS) provide complementary views of chemical bonding in a sample by studying the vibrational energies of the bonds. Surface Enhanced Raman Spectroscopy (SERS) can give vibrational spectra of in situ films. A useful review of the application of these vibrational spectroscopies is available [19].

## IN SITU METHODS

Because of the changes that can occur in preparing and analyzing surfaces for high-vacuum techniques, there is great interest in techniques that can obtain information as to the chemical state of metal surfaces while they are in aqueous environments. Some of the most exciting research on the fundamentals of corrosion are using these new techniques. Scanning Tunneling Microscopy (STM) and especially Scanning Force Microscopy (SFM) were the first techniques to give an atomic scale and three-dimensional (3-D) image of a surface that would permit observation in aqueous environments. Since the first scanning probe microscope was invented in 1981 by Gerd Binnig and Heinrich Rohrer, a whole family of scanning probe microscopies have evolved. All of these Scanning Probe Microscopies operate by scanning a small probe tip over the surface to be imaged and creating distributional maps of the response. Two of the most useful for corrosion science are Scanning Kelvin Probe Atomic Force Microscopy (SKPAFM) and Scanning Electrochemical Microscopy (SECM). Two valuable resources on these and other techniques are the Electrochemical Society's *Proceedings on the Symposium on Localized In Situ Methods for Investigating Electrochemical Interfaces* [2] and *Scanning Electrochemical Microscopy*, which has been edited by Bair and Mirkin [20].

SECM is discussed elsewhere in this handbook. The Scanning Kelvin Probe is an updating and miniaturization of the classic method that was first postulated by Lord Kelvin in 1861. It is essentially a non-contact vibrating capacitor

formed between the sample and a vibrating electrode tip, which measures the work function of the sample. Since the work function is extremely dependent on surface condition, the SKP can be used to study such phenomena as oxide layer imperfections, surface and bulk contamination, surface charging, etc.

The availability of high intensity, synchronous X-ray sources at national synchrotron centers has allowed the development of a number of new tools that can study passive or corrosion films as they are forming in aqueous environments. Surface X-Ray Diffraction (SXRD) provides a direct determination of the crystal structure of the atoms of the surface. Surface Extended X-Ray Absorption Fine Structure (SEXAFS) can provide information on the geometric structure of atoms within a few angstroms around the absorbing atom.

These are truly exciting times for the application of surface analysis to corrosion problems.

# Statistical Treatment of Data, Data Interpretation, and Reliability

Fred H. Haynie<sup>1</sup>

MOST PHYSICAL AND CHEMICAL measurements, performed under nominally identical conditions, yield differing data. The results of corrosion tests are no exception. Sometimes the difference between values is less than the measurement accuracy and cannot be detected. At other times the difference approaches the magnitude of the values. Unfortunately, corrosion test data tend to be in the latter category more often than in the former.

Because of this variation in results it is necessary to apply some type of statistical treatment to the data (e.g., the arithmetic averaging of replicate values). When analyzing data, however, it helps to know some basics. Statistical techniques can be misused and give the researcher a false sense of security. One must be aware of limitations as well as advantages.

*Statistics in Research* by Bernard Ostle [1] is an excellent text that can be used as a handbook. In addition, Standard G 16 (Guide for Applying Statistics to Analysis of Corrosion Data) is a useful document. Statistical techniques are particularly useful in planning and designing experiments. This chapter describes some of the advantages and limitations of applying statistical techniques in corrosion research.

## BASICS

Three statistical methods that are often important in corrosion experiments are (1) probability distributions, (2) design of experiments, and (3) analysis of data. Most investigators use some kind of data analysis technique. Less attention is given to experimental design, and probability distribution is the most neglected of the three methods.

## Terminology

Certain words have specific meanings to the statisticians. These same words may have different meanings to those who are not familiar with statistics. In order to avoid confusion, a discussion of some of the basic terminology is presented.

### Error

Error is the amount by which a value is incorrect or inaccurate.

<sup>1</sup> Corrosion consultant, Cary, NC 27511, and updated and revised by S. W. Dean.

Unfortunately, all experiments have limitations and these limitations cause the existence of error. Whereas random error is acceptable, biased error is not. For example, if, when comparing the corrosion resistance of two alloys in a salt cabinet, the replicate samples of one alloy are placed at one end of the cabinet and the other alloy at the other end, it is possible that the results will be biased by the spray pattern. The within-sample error may be small, and the difference between samples may appear to be significant when the only true significance is a difference in spray pattern. The same type of biased error may be introduced when results obtained on a new alloy are compared to previously obtained results on an old alloy. Because such environmental conditions cannot be controlled exactly, it is necessary to compensate for them in the experimental designs by random exposure of sample replicates in both time and space. This procedure tends to counteract the effects of biased error but generally increases the within-sample error. Both effects reduce the probability of producing results from which erroneous conclusions are made.

### Population, Sample, and Replication

All units having a common set of conditions form a population described by those conditions. For example, if we wish to determine the corrosion behavior of an alloy in a particular type of chemical solution, the population consists of all heats of that alloy exposed to all solutions of the specified type. A much smaller population would be one particular heat of the alloy exposed to a single batch of the solution. It would be incorrect to assume that the smaller population is representative of the larger population.

A sample is some fraction, usually small, of the population. A good sample is representative of the population. Random selection of the proper number of units from a population should assure a good sample. In chapter 1 on *PLANNING AND DESIGN OF TESTS* both random selection and minimum sample size are discussed.

Replication is the repetition of a specified set of experimental conditions that describe the population. Repeated measurements on a single specimen constitute replication only if the population is the set of all such measurements on the specimen.

### Probability Distribution

If mass losses on a large number of replicate specimens are determined, it is often observed that there is one most frequently occurring value, and as other values deviate from

it, their frequencies of occurrence decrease. This peak is called the mode, and the shape of the curve produced by plotting frequency versus measured value is the probability distribution. Most such curves are symmetrical about the mode and have a bell-shaped normal distribution as shown in Fig. 1.

A normal distribution can be mathematically described with two terms: (a) the arithmetic mean ( $\bar{x}$ ) of all values in the population, and (b) the standard deviation ( $\sigma$ ). The mean, which is a measure of central tendency, is equal to the mode for a normal distribution. It is determined from the relationship

$$\bar{x} = \sum_{i=1}^n x_i / n \quad (1)$$

where  $n$  is the number of units in the population. The standard deviation ( $\sigma$ ) is the square root of the variance ( $\sigma^2$ ) and is a measure of the dispersion of values about the mean. The variance is the arithmetic average of all the squares of the deviations about the mean. Mathematically

$$\sigma^2 = \sum_{i=1}^n (x_i - \bar{x})^2 / n \quad (2)$$

Thus, 68.26 % of all the population will be contained within 1 standard deviation either side of the mean. Similarly, 95.46 % and 99.73 % will be contained within 2 and 3 standard deviations, respectively.

#### Best Estimate of Variance and Standard Deviation

The sample sizes in corrosion work are usually not large enough to establish either a true mean ( $\bar{x}$ ) or a true variance ( $\sigma^2$ ). Therefore, best estimates must be made. The number of bits of information that possibly can be obtained from a finite sample is restricted by the data collected. This restriction is known as the total degrees of freedom. As bits of information are obtained from the sample, the degrees of freedom are reduced. Thus, in order to estimate both a mean ( $\bar{x}$ ) and a variance ( $s^2$ ), which are two bits of information, we must have a minimum sample size of two. The best estimate of the mean ( $\bar{x}$ ) is calculated from the sample data using Eq 1. With any size sample ( $n$ ), 1 degree of freedom is said to be used in estimating the mean, thus leaving  $(\bar{n})$  1 degrees of freedom with which to calculate the best

estimate of variance ( $s^2$ ). Equation 2 is used to estimate variance by substituting  $(\bar{n})$  1 for  $n$ .

#### Confidence Limits for the Mean

In general the larger the sample size, the more closely the sample average ( $\bar{x}$ ) approaches the population mean since, if the entire population were measured, we could calculate the population mean. As the sample size decreases, however, the sample average probably deviates more from the population mean. We would like to know how the sample average deviates from the population mean in order to have confidence in the calculated average value.

Gossett [2] (who signed his article "Student") provided a relationship from which the confidence limits on the true mean can be estimated. The relationship is

$$\bar{x} - \bar{x} = \pm s_m \cdot t \quad (3)$$

where  $s_m$  is the square root of the best estimate of sample variance of the mean ( $s^2$ ) and  $t$  is the tabular value "Student's  $t$ " [which is a function of the degrees of freedom and probability ( $P$ )]. If, for example, a sample of five specimens is available and it is desired to establish 95 % confidence limits for the true mean ( $\bar{x}$ ) (i.e., it is desired to have some measure of assurance that 19 out of 20 times the true mean will lie within these limits), the table of " $t$ " values is consulted at 4 degrees of freedom ( $\bar{n}$ ) 1 and a probability  $P$  of 0.05, and a value of 2.776 for " $t$ " is found. If the best estimate of variance is 10,  $s_m$  is calculated to be  $\pm 1.414$ . Therefore, the 95 % confidence limits for the true mean  $\bar{x}$  are  $\bar{x} \pm 3.92$ .

## PROBABILITY DISTRIBUTION

Probability distribution was introduced in the section in this chapter on **Terminology**, and the components of a normal distribution and how to work with them were discussed. Some distributions are not normal because they are skewed to one side of the mode. Unless the values can be treated by some mathematical function to yield a new set of values that approximates a normal distribution, the use of normal statistical techniques could lead to erroneous conclusions. Sometimes the distribution is skewed in such a way that the logarithms of the values have a normal distribution. Fortunately, although the values are not amenable to standard statistical methods, their logarithms are. In contrast, maximum pit depths have an extreme value distribution and should be treated with extreme value statistics. We will discuss these three distributions.

#### Normal Distribution

The normal distribution has the familiar symmetrical bell shape as shown in Fig. 1 and is the basis for the most common statistical techniques of experimental design and data analysis. The characteristics of this distribution are described in the section on **Terminology**. Mass loss, mass gain, thickness loss, corrosion potential, corrosion rate, and pitting area may have a normal distribution. Although this may not be an established fact, in the past many researchers have assumed normal distributions for such data with apparent success.

FIG. 1—Normal distribution.

### Log-Normal Distribution

In some cases better results can be produced by assuming a log-normal distribution. A log-normal distribution is simply data that have a normal distribution after they are converted to logarithms. The data then can be analyzed using normal statistical techniques.

Some indicators that generally indicate a log-normal distribution are: (a) data values that physically cannot be negative, (b) normal standard deviations that are proportional to arithmetic means, (c) arithmetic means that are consistently greater than median values, and (d) dependent parameters whose logarithms are proportional to the values of independent parameters. Some types of corrosion data that are likely to be log-normally distributed are: (a) mass loss, (b) thickness loss, (c) time to initial stress corrosion cracks, (d) time to stress-corrosion cracking failures, and (e) polarization currents in the Tafel slope range.

### Extreme Value Distribution

The depths of deepest pits on specimens, the times to first leaks in pipe lengths, times to initial stress-corrosion cracking failures, and the number of cycles to first corrosion-fatigue failures are, by definition, extreme values. The depth of the deepest pit on a specimen is the upper tail of the distribution of depths of all pits on that specimen.

The Weibull distribution [3] often is used in analyzing extreme value data. Expressed in a linear form [4]

$$\ln[-\ln[1 - F(x)]] = c \ln(x - a) - c \ln(1/b) \quad (4)$$

where  $F(x)$  is cumulative probability,  $x$  is a ranked measured value equal to or greater than  $a$ ,  $a$  is the minimum value of  $x$  and is equal to or greater than 0,  $b$  is a scaling parameter, and  $c$  is a shape factor. When working with finite samples, the cumulative probability or plotting position is estimated by [5]

$$F(x_m) = m/(n + 1) \quad (5)$$

where  $m$  is the ordered rank of the measured value (1,2,3, . . . ,  $n$ ) and  $n$  is the total number of the sample.

### Data Distribution Evaluation

Corrosion scientists seldom have enough replicate data to analyze distributions using such techniques as histograms and tests of fit. Sometimes, however, enough data are available to order and plot as a function of linearized forms of the different kinds of probability distributions. Also, nonlinear least squares curve fitting may be used. The best approach is to choose the type of distribution that clearly produces the best approximation to a straight line. If an extreme value distribution is only slightly better than a normal distribution, a normal distribution may be assumed because the statistical techniques are easier to use and more universally understood.

## DESIGN OF EXPERIMENTS

The philosophy incorporated into the design of corrosion experiments is more encompassing than the application of

statistical methods. The purpose of any experimental design should be to efficiently provide a maximum amount of relevant information. In this optimization process, statistical methods, economic analysis, as well as knowledge of corrosion processes is normally employed. Therefore, the use of statistical techniques in design of experiments, is covered in more detail in the chapter on *PLANNING AND DESIGN OF TESTS*. It is discussed here to show how it subsequently affects the analysis of data.

### Types of Experiments

Corrosion scientists work with two basic types of experiments, (1) controlled and (2) uncontrolled. In controlled experiments, levels of independent variables (factors such as temperature and chemical composition) are controlled and the dependent variables (corrosion rate, pitting potential, etc.) are measured. In uncontrolled experiments such as atmospheric exposures, uncontrolled independent variables such as temperature and relative humidity are measured along with the dependent corrosion results. Properly designed controlled experiments are much more amenable to statistical analysis of variance than are properly designed uncontrolled experiments. Many scientists prefer some form of factorial design for controlled experiments.

#### Factorial Experiments

Each controlled variable with more than one controlled level is considered a factor in an experiment. The main advantage of a factorial design experiment is that interaction as well as direct effects can be studied with less replication than several one-way analyses of variances. An example of an interaction effect is a change of slope of a corrosion rate versus relative humidity curve with a change in temperature.

Researchers use two-level factorial experiments to determine which variables or factors cause direct or interaction (synergistic) effects on the measured parameter. Each new factor introduced, however, doubles the number of test conditions. Thus, the need to include a large number of factors in a complete experimental design often results in an impractical number of test conditions. To circumvent this problem, statisticians can design fractional experiments that produce nearly all of the information that researchers need by confounding some possible effects such as higher order interactions. At this point, corrosion researchers have the knowledge and background to assess which physical and chemical relations may control the corrosion process. Some high-order interaction effects may be physically impossible or very unlikely, and statisticians may be able to confound these with direct or lower-order interaction effects that may be possible. Without such guidance, statisticians normally will assume that the higher-order interactions will have little effect, and therefore will design a fractional factorial experiment accordingly.

The Greco-Latin square is a fractional, four-level, four-factor factorial experiment composed of a total of 16 sets of conditions. The complete factorial experiment requires 256 test conditions. It is a very efficient experiment when the data are commensurate with a model containing no interaction terms. Unfortunately, in corrosion experiments it is a

rare situation when a study of four variables does not involve some interaction effects.

### *Uncontrolled Experiments*

In the real world, metals are seldom exposed to controlled environments. Thus, the development of materials for use in the real world normally requires exposure studies in uncontrolled environments.

A properly designed uncontrolled experiment is one that considers all the possible effects of uncontrolled variables. The corrosion researcher's knowledge of physical and chemical processes is most valuable in this respect. Changes in variables that are believed to cause effects along with the resulting effects should be measured. If an important variable is missed, all of the other data become less meaningful.

For proper subsequent analysis, uncontrolled experiments require the collection of considerable data. For example, it is possible to collect ten sets of data involving nine uncontrolled variables and the measured corrosion results. The total is 100 bits of information that can be subjected to multiple regression analysis. If all of the variables are included in the analysis, a perfect mathematical fit can be obtained that is both physically and statistically meaningless. The experimental design does not consider the possibility of nonlinearity effects, interaction effects, nor error effects. One approach to assure that enough data sets are collected is to count all of the physically and chemically (not mathematically) possible direct and interaction effects of the measured variables and multiply by 4 or 5 to account for possible nonlinearity and error.

## ANALYSIS OF DATA

With the use of desktop computers and work stations now common, it is possible for corrosion researchers to put in their data and come out with analysis of variance tables for factorial experiments and multiple linear regression analysis tables for uncontrolled experiments. Most such tables include a statistical test of significance for observed effects. That test (such as a F test) is a measure of the probability that an observed effect either exists or is caused by random error.

Handbooks usually tabulate F values for 0.05 and 0.01 probability levels. If a proper probability distribution has been assumed and an experiment has been designed and executed properly, calculated F values exceeding tabulated values at the 0.05 probability level indicate that the observed effect is likely to be caused by random error only one in 20 or more times. Those are rather good odds involving relatively little risk. Such odds establish a relatively high degree of confidence in the decisions that are based on the corresponding experimental results. When complex tradeoff decisions are to be made, it may be necessary to assume a higher degree of risk. More complete F tables are available that include other probability levels; nothing is magical about 95 or 99 % confidence levels. Researchers should be able to weigh the involved risks in decisions and act accordingly.

### **Analysis Techniques**

A lot of sophisticated statistical software can be used to analyze data. These comprehensive packages can be expensive.

Most of the popular spreadsheet programs can perform multiple regression analysis, and most of the information that is needed can be obtained from this process. Regression analysis as well as other techniques that deal with normal statistics are based on two basic assumptions that are seldom completely accurate; these are (1) independent variables upon which dependent variables are regressed are truly independent, or not associated with each other in any way, and (2) the values of the independent variables are fixed (that is, each one is not just a sample of a distribution of values and thus is not subject to error). In the real world of corrosion research, it is extremely difficult to design or conduct an experiment where these criteria are met. Thus, it is necessary to evaluate how these assumptions might affect the data analysis. The different statistical techniques discussed in the following paragraphs consider the effects of these assumptions.

### *Simple Linear Regression*

This technique fits a straight line to data as dependent values related to a single set of values of an independent parameter. The set of equations that are used minimizes the sum of the squares of differences between the dependent values and the line.

This technique may be illustrated by the analysis of a conceptually simple experiment, galvanic current as a function of dewpoint-temperature and ambient-temperature differences. Assume the experiment was conducted in an environmental chamber that can control conditions uniformly within the measurement accuracy of temperature and dewpoint. We have spaced replicate specimens randomly in the chamber and have measured currents from each very accurately. Three tests were performed at each of three levels of dewpoint (28, 26, and 24°C) holding temperature constant at 30°C. For each new test, at each level, old specimens were retained while new specimens were added and measurements made on both. If three specimens were added for each test replication, there would be 18 current measurements at each level for a total of 54 measurements. That may seem like a lot of measurements just to establish two points that define a straight line. This approach has taken into consideration that both time and space may have an unexpected effect on our current responses, and that our environmental measurements and their resulting controls on chamber conditions truly may not be fixed. For example, although continuous temperature measurements may be within a tenth of a degree, dewpoint measurements may be accurate only within a degree.

Spreadsheet programs consider independent variables as in the  $x$  range and the dependent variable as the  $y$  range. The resulting statistics are placed in an output range in the form of a table. The primary results of interest are the intercept ( $a$ ), the slope ( $b$ ), the estimated standard deviation of the slope ( $s_b$ ), the square of the correlation coefficient ( $R^2$ ), and the number of degrees of freedom for error. In simple linear regression, only one independent value or one column for  $x$  is considered. In multiple regression, several variables ( $x_i$ ) may be included in a like number of columns and the results include a coefficient ( $b_i$ ) and estimated standard deviation ( $s_{bi}$ ) for each.

TABLE 1—Fractional factorial design and results.

	Natural Logarithm of Current in Microamps								
	28°C			26°C			24°C		
	1st Time	2nd Time	3rd Time	1st Time	2nd Time	3rd Time	1st Time	2nd Time	3rd Time
First Exposure	2.0656	...	...	1.4563	...	...	0.2700	...	...
	2.0656	...	...	1.5195	...	...	0.3075	...	...
	2.1294	...	...	1.4231	...	...	0.4055	...	...
Second Exposure	2.2905	2.3224	...	1.3762	1.2119	...	-0.3011	-0.3011	...
	2.3523	2.4105	...	1.2641	1.3762	...	-0.1744	-0.4463	...
	2.3523	2.2905	...	1.2119	1.1410	...	-0.4463	-0.2107	...
Third Exposure	1.8625	1.8991	1.8625	1.2613	1.1086	1.1725	0.0862	0.2390	0.0862
	2.0980	2.1564	2.0360	1.1725	0.9670	1.1410	0.1484	-0.0513	0.0198
	1.8991	2.1282	1.9359	1.0750	1.2326	1.0403	0.0198	0.1222	0.1823

The results of a simple linear regression of our data are:  $-a = 44.01$ ,  $b = 1.859$ ,  $s_b = 0.094$ , and  $R^2 = 0.882$  (the fraction of the variability explained by the regression). However, it is known that current is an exponential function of dewpoint, and the current values are log-normally distributed. One reason to think so is that current cannot be negative when the dewpoint is zero as is indicated by the intercept value. Regressing the natural logarithms of the current with dewpoint yields  $-a = 12.68$ ,  $b = 0.532$ ,  $s_b = 0.018$ , and  $R^2 = 0.943$ . The exponential model produces a better fit than the linear model.

How does dewpoint not being fixed affect these coefficients? If dewpoint is regressed with log-current and the resulting equation transposed, the coefficients  $a$  and  $-b$  are 13.52 and 0.563, respectively. This result shows that the inability to precisely measure and control the dewpoint results in an underestimate of the slope and an overestimate of the intercept.

#### Multiple Regression Analysis and Analysis of Variance

The hypothetical experiment described previously was performed considering the possibility that time and space effects could bias our results. This possibility can be tested using multiple linear regression and analysis of variance. The experimental design has included two variables (other than dewpoint) we will call time and exposure. Values for exposure are 1, 2, and 3 for the first, second, and third exposures at a set dewpoint, respectively. Values for time are 1, 2, and 3 for specimens exposed only to the first exposure, to the first and second exposures, and to the first, second, and third exposures, respectively. With three variables, four interaction effects are possible: (1) dewpoint X time, (2) dewpoint X exposure, (3) time X exposure, and (4) dewpoint X time X exposure. The values for these interactions are the products of the differences between the values and their means. For example, a value for dewpoint X exposure is  $(28 - 26) \times (-12.33) = -2.67$ . By using formulas in a spreadsheet it is possible to create an  $x$  matrix of 7 columns with 54 rows that can be regressed against the measured current data  $y$ . The data in this fractional factorial experiment are presented in Table 1.

Multiple regression of the data for this three-factor, three-level factorial experiment can produce an analysis of variance. Calculated values for  $F$  are used to determine statistical significance of direct and synergistic effects.  $F$  may be determined using the following relationship

$$F = (b/s_b)^2 \quad (6)$$

Each coefficient uses one degree of freedom ( $DF$ ). In this experiment with an intercept and 7 slopes the remaining

error degrees of freedom are 46. The  $F$  tables are entered with 1  $DF$  for the greater mean square and 46  $DF$  for the lesser mean square. The  $F$  values associated with better than 0.95 and 0.99 probabilities of statistical significance for these  $DF$ s are 4.05 and 7.21, respectively.

The results of regression analysis and analysis of variance are given in Table 2. Only those effects containing dewpoint are statistically significant at greater than 0.95 or 0.99 probability. A regression including only those terms yields the results in Table 3. Only the intercept is slightly different from that in Table 2. The best estimate of the functional relationship between current and dewpoint at a constant temperature of 30°C is  $\text{Current} = \exp [0.581(DP - 24.2)]$ .

#### Covariance of "Independent" Variables

In many corrosion experiments, exposure conditions are uncontrolled and the independent variables of interest are measured and recorded. Multiple regression analysis is very useful in analyzing these data. The results of multiple regression analysis of uncontrolled experiments do not within themselves prove cause-effect relationships. Possible correlations between supposedly independent variables are a serious problem. When two "independent" variables are perfectly correlated, it is impossible to determine which variable actually correlates with the dependent variable results. Thus, when such strong correlations exist, although one variable may appear to be statistically more significant than the other, it may be mathematically serving as the other variable's proxy or stand-in a cause-effect relationship. Such might be the case when the error of measurements for the proxy variable is much less than the error of measurements for the variable actually causing the effect.

Significant proxy variables may be used within limits with some success as predictors and still not have any real physical significance. A good example is corrosion rates that correlate with distance from a seashore when the actual cause is the amount of salt spray deposited on the specimens.

Simple linear regressions between each of the independent variables can be used to produce a correlation matrix. The values of  $R$  in this matrix can be used to identify possible covariance problems. Once statistical significance of various factors is established, the corrosion researcher should consider the corrosion processes and first principles in reaction kinetics to evaluate the consistency of the statistical model with a physical model. Best fits of data to physical models can yield valuable information such as activation energies that can point toward diffusion controlled or activation controlled processes.

## SUMMARY

Corrosion researchers can gain a greater degree of confidence in their experimental results if they have a basic understanding and use statistical techniques of experimental design and data analysis. Statisticians cannot properly design

an experiment nor analyze the resulting data without the help of corrosion researchers. Statistical techniques have both advantages and limitations related to the types of data to be collected. Overall, corrosion researchers should have a better feel for the physical constraints that may limit statistical models than do statisticians. The statistician will have a better feel for how these constraints can be incorporated into the layout of the design which predetermines the style of statistical analysis to be used. Statistical techniques should not control the research to the point that it becomes the "tail that wags the dog." The research objectives must be kept in sight, and statistics is one of many tools that can be valuable to reach them.

# Computer Based Data Organization and Computer Applications

Pierre R. Roberge<sup>1</sup>

## INTRODUCTION

COMPUTERS PLAY IMPORTANT roles in data acquisition in laboratory and field environments, data processing and analysis, data searching and data presentation in understandable and useful formats. The rapid development of accessible computing power since the 1980s has led to the use of computers and direct or indirect applications of machine intelligence in every sphere of science and engineering. As a modern science philosopher has written, "The emergence of machine intelligence during the second half of the twentieth century is the most important development in the evolution of this planet since the origin of life two to three thousand million years ago" [1]. Computers also assist engineers to transform data into usable and relevant information. The connectivity of computers to the outside world through the Internet and the Web has opened up tremendous channels of communication that never existed before.

## Compilation of Corrosion Data

Corrosion data for metals are measures of time dependent material/environment interactions that are manifested in many forms; for example, pitting, stress corrosion cracking, corrosion-fatigue, crevice corrosion, and fretting. If nonmetals are considered, swelling, property changes, and cracking are important manifestations. Data are available from many sources including standardized laboratory and field tests, industrial exposures, and the results of failure analyses, and are recorded in many formats that may or may not include sufficient information for independent understanding and reliability assessment. As with many other material property studies, the data often are developed for proprietary purposes by an individual or a small group of users who have a common understanding of unique terminology, algorithms, test methods, and data report formats and have no motivation to modify their data compilations for sharing with other potential users [2].

## Standardized Data Recording Formats

The need to develop standardized data recording formats was recognized by Committee G01 on Corrosion of Metals. The committee efforts addressed material identification and recording of test details along with guidelines for assessing data quality, data interchange formats, and consistent terminology

as it relates to computerization. ASTM G 107, Guide for Formats for Collection and Compilation of Corrosion Data for Metals for Computerized Database Input, serves as a master list with a total of 125 individual data entry fields, each defined with preferred units and category sets (acceptable entries) to assure consistency. Not all fields are required for any one data record, but an estimated 25–50 often are required to fully describe the material, environment, and test results for an individual test. Table 1 describes the eight basic data categories detailed in the standard as being considered essential for the complete documentation of corrosion data. Rarely is this detail provided in the published literature, a factor that compounds the difficulties in comparing published data from different sources [2].

ASTM G 135, Guide for Computerized Exchange of Corrosion Data for Metals, defines the techniques used to encode corrosion of metals test results for exchange between computer systems. The guide establishes formalism for transferring corrosion test data between computer systems in different laboratories and defines a generic approach to structuring data files. The guide is designed for standards developers to help them specify the format of files containing test results and create programs that read and write these files.

### Data Quality

Physical and mechanical property data are normally generated using established standard test procedures that permit direct comparisons of test results. However, the transformation of corrosion testing results into usable real life functions for service applications can be a rather difficult task, often generating unreliable or questionable data as illustrated in Fig. 1 [3]. In the best cases, laboratory tests can provide a relative scale of merit in support of the selection of materials exposed to specific corrosive conditions and environments. Data can be classified by a variety of schemes that reflect the extent of the data generated and the level to which the data have been processed [2]:

- Raw (unanalyzed) individual test results.
  - Analyzed individual test results.
  - Mathematically reduced (average or statistically based) values representative of sets (multiple replicates) or results.
  - Validated data, meeting the validity requirements of the appropriate test standards.
  - Evaluated data, representing parametric analysis of data sets, including in some cases judgmental interpretation by one or more experts.
  - Certified values, representing approval by some referee on certification groups for some specific application (for example, design).
- Several distinct steps should be taken to assess the quality of any material property or performance data. While the data evaluation and validation steps reflect more on the quality of the data generated, data verification reflects on the data search and retrieval system used to ensure the retrieved data are consistent with the original source [2].
1. Evaluation: The process of establishing the accuracy and integrity of data. Evaluation may involve examination and appraisal of the data presented, assessment of experimental technique and associated errors, consistency checks for allowed values and units, comparison with other experimental or theoretical values, reanalysis and recalculation of derived quantities as required, selection of best values, and assignment of probable error or reliability.
  2. Validation: The process of substantiating that the data have been generated according to standard methods and practices or other indices of quality, reliability, and precision.
  3. Verification: The process of substantiating the accuracy of the data transcription and manipulation within the data system.
- A number of corrosion data evaluation studies have described the scope of the effort required [4]. Unfortunately,

the complexities of corrosion data tend to discourage attempts to undertake this type of rigorous data analysis. A more accepted approach is to develop expert consensus, often through peer review or technical committee activities, resulting in publication of summary documents addressing specific environments or applications with judgmental appraisals of the quality, reliability, and adequacy of available data for the intended purpose or application.

### Overcoming Knowledge Gaps

Humans are used to working with imprecise information. They naturally accept vague use of language, making continuous interpretations of the information they receive based upon context. Computers are much less forgiving. This section introduces a generic framework linking mechanistic principles leading to corrosion damage with the observable signs of a corrosion attack.

Six important corrosion factors have been identified in a review of scientific and engineering work on SCC damage [5], generally regarded as the most complex corrosion mode. According to Staehle's materials degradation model, all engineering materials are reactive and their strength is quantifiable, if all the variables involved in a given situation are properly diagnosed and their interactions understood. For characterizing the intensity of SCC the factors were material, environment, stress, geometry, temperature and time. These factors represent independent variables affecting the intensity of SCC. Furthermore, a number of subfactors have been identified by Staehle for each of the six main factors, as shown in Table 2.

The term "form" of corrosion is generally well known from Fontana's popular corrosion engineering textbook [6]. The different forms of corrosion represent corrosion phenomena categorized according to their visual appearance. Dillon [7] considered Fontana's eight basic forms of corrosion and divided them into three groups, based on their ease of identification:

- Group 1—readily identifiable by ordinary visual examination
  - Uniform corrosion
  - Pitting
  - Crevice corrosion
  - Galvanic corrosion
- Group 2—may require supplementary means of examination
  - Erosion
  - Cavitation
  - Fretting
  - Intergranular
- Group 3—verification by microscopy is usually required
  - Exfoliation
  - Dealloying
  - Stress corrosion cracking
  - Corrosion fatigue

An empirical correlation was established between the factors listed in Table 2 and these forms of corrosion. Fifteen recognized corrosion experts agreed to complete an opinion poll listing the main subfactors and the common forms of corrosion. The responses were then analyzed and represented in a graphical way, such as illustrated in Fig. 2, for

the most important factors leading to different forms of corrosion failures. An obvious application of the results shown in Fig. 2 would be to help optimize the number of fields required for the development of an efficient knowledge based system.

Context sensitivity is fundamental to failure analysis. For one, the criticality of a specific failure is very much system dependent. While the general description of the corrosion types presented in Table 2 is sufficient to explain the general appearance of most specific problems, it can lead to great confusion when one tries to quantify the attributes associated with them. Pitting corrosion, which, for example, is almost a common denominator in all types of localized corrosion attack, may assume different shapes. Pitting corrosion can produce pits with their mouth open (uncovered) or covered with a semipermeable membrane of corrosion products. Pits can be either hemispherical or cup-shaped. In some cases, they are flat-walled, revealing the crystal structure of the metal, or they may have a completely irregular shape [8]. The severity associated with pitting corrosion can also vary greatly and is directly dependent on the criticality of the systems subjected to this form of damage.

A more detailed analysis of these survey results reveals some interesting features that relate to the terminology used in corrosion science and engineering. The results of interviews were analyzed with Box-and-Whisker plots. These plots divide the data for each sample into four areas of equal frequency. A box encloses the middle 50 %, and the median is drawn as a vertical

**FIG. 2—Results of an expert opinion poll indicating the most important factors causing different types of corrosion failures.**

line inside the box. Horizontal lines or whiskers extend on each side of the box to represent the smallest data point within 1.5 interquartile for the lower quartile (left) and the highest data point within 1.5 interquartile for the upper quartile (right). Individual points drawn outside of these ranges signify the presence of data values within three interquartile ranges (suspect outliers) or even farther apart as outliers.

Figure 3 presents the Box-and-Whisker plots of the results obtained with pitting corrosion, and Table 3 summarizes two features of the plot by prioritizing the importance associated with each subfactor included in the framework (the median) and the sharpness of the responses (inverse of the breadth of the whiskers). When presented in this fashion, such results provide a useful spectrum of factor and subfactor confidence levels. While the important and sharp subfactors can be used reliably to predict the occurrence of pitting corrosion, the least focused results provide a good indication of the ambiguities related to this form of corrosion.

## MODELING AND LIFE PREDICTION

Models of materials degradation processes have been developed for a multitude of situations using a great variety of methodologies. For scientists and engineers working at developing materials, models have become an essential benchmarking element for the selection and life prediction associated with the introduction of new materials or processes. For systems

managers the corrosion performance or under-performance of materials has a very different meaning. In the context of life cycle management, corrosion is only one element of the whole picture, and the main difficulty with corrosion knowledge is in incorporating it at the system management level.

### Bottom Up Approach

Scientific models can take many shapes and forms, but they all seek to characterize response variables through relationship with appropriate factors. Traditional models can be divided into two main categories: mathematical or theoretical models and statistical or empirical models [9]. Mathematical models have the common trait that the response and predictor variables are assumed to be free of specification error and measurement uncertainty [10]. Statistical models, on the other hand, are derived from data that are subject to various types of specification, observation, experimental and/or measurement errors. In general terms, mathematical models can guide investigations while statistical models are used to represent the results of these investigations.

### Mathematical Models

Some specific situations lend themselves to the development of useful mechanistic models that can account for the principal features governing corrosion processes. These models are most naturally expressed in terms of differential

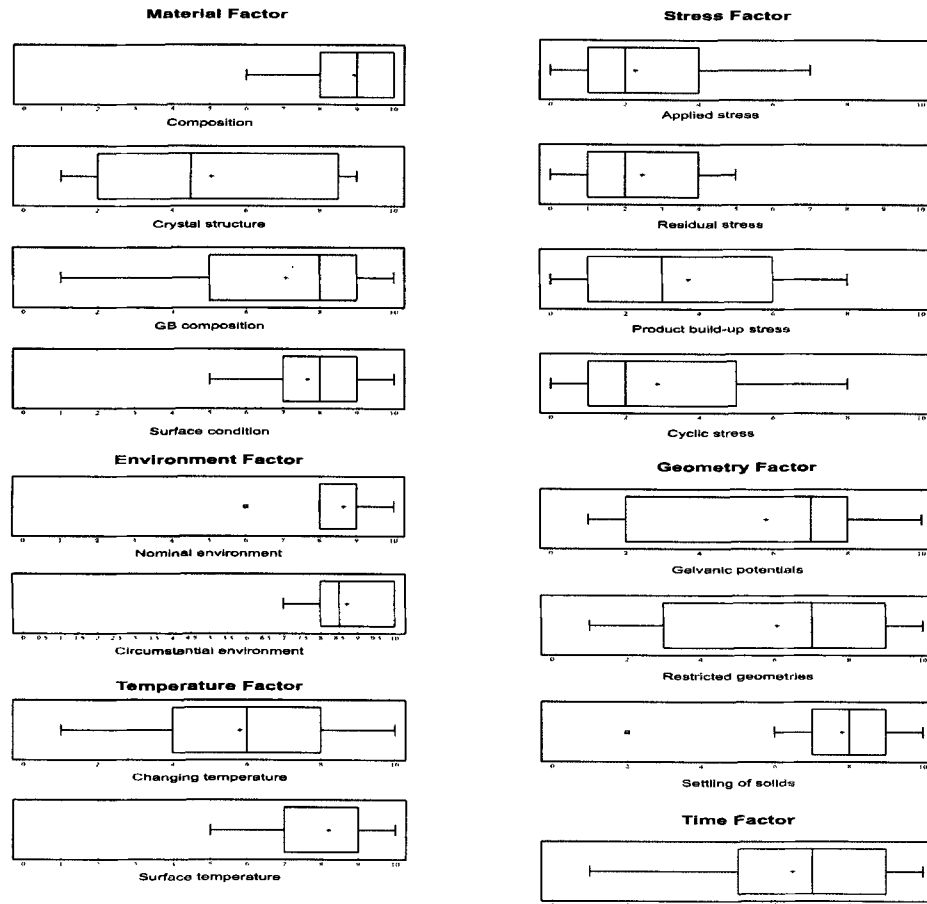

FIG. 3—Box-and-whisker plots of the survey results obtained for the factors and subfactors underlying the appearance of pitting corrosion.

equations or in another nonexplicit form of mathematics. However, modern developments in computing facilities and in mathematical theories of nonlinear and chaotic behaviors

have made it possible to cope with relatively complex problems. A mechanistic model has the following advantages [11]:

- It contributes to our understanding of the phenomenon under study;
- It usually provides a better basis for extrapolation;
- It tends to be parsimonious, i.e., frugal, in the use of parameters and to provide better estimates of the response.

The modern progress in understanding corrosion phenomena and controlling the impact of corrosion damage was greatly accelerated when the thermodynamic and kinetic behavior of metallic materials was made explicit in what became known as E-pH or Pourbaix diagrams (thermodynamics) and mixed potential or Evans diagrams (kinetics). These two models, both established in the 1950s, have become the basis for most of the mechanistic studies carried out since then. The multidisciplinary nature of corrosion science is reflected in the multitude of approaches that have been proposed to explain and model fundamental corrosion processes. The following list illustrates some scientific disciplines with examples of modeling efforts one can find in the literature:

- **Surface science:** atomistic model of passive films
- **Physical chemistry:** adsorption behavior of corrosion inhibitors

- **Quantum mechanics:** design tool for organic inhibitors
- **Solid state physics:** scaling properties associated with hot corrosion
- **Water chemistry:** control model of inhibitors and anti-scaling agents
- **Boundary element mathematics:** cathodic protection

### Statistical Models

Mechanisms underlying corrosion processes are frequently not understood sufficiently well or are simply too complicated to allow an exact model to be built from theory. In such cases empirical models may be useful. The degree of complexity that should be incorporated in an empirical model can seldom be assessed in the initial phase of designing such model. A most common approach is to first build a simple model based on a limited set of variables and increase its complexity with growing evidence and confidence.

Statistical assessment of time to failure is a basic topic in reliability engineering for which many mathematical tools have been developed. Evans, who also pioneered the mixed potential theory to explain basic corrosion kinetics, launched the concept of corrosion probability in relation to localized corrosion. According to Evans, an exact knowledge of corrosion rate was less important than the ascertainment of the statistical risk of its initiation [12]. The following examples illustrate the application of empirical modeling in two areas of high criticality.

### Extreme Value Statistics

A number of statistical transformations have been proposed to quantify the distributions in pitting variables. Gumbel is given the credit for the original development of extreme value statistics (EVS) for the characterization of pit depth distribution [13]. The EVS procedure is to measure maximum pit depths on several replicate specimens that have pitted, then arrange the pit depth values in order of increasing rank. The Gumbel distribution expressed in Eq 1, where  $\lambda$  and  $\alpha$  are the location and scale parameters, respectively, can then be used to characterize the dataset and estimate the extreme pit depth that possibly can affect the system from which the data was initially produced.

$$F(x) = \exp\left(-\exp\left[-\frac{x-\lambda}{\alpha}\right]\right) \quad (1)$$

In reality there are three types of extreme value distributions [14]:

- **Type 1:**  $\exp(-\exp[-x])$  or the Gumbel distribution
- **Type 2:**  $\exp(-x^{-k})$  Cauchy distribution
- **Type 3:**  $\exp(-[\omega - x]^k)$  Weibull distribution

where  $x$  is a random variable, and  $k$  and  $\omega$  are constants.

A goodness-of-fit test is required to verify which of these three distributions best fits a specific data set. The Chi square test or Kolmogorov-Smirnov test has often been used for this purpose. A simpler graphical procedure is also possible using a generalized extreme value distribution with a shape factor dependent on the type of distribution. There are two expressions for the generalized extreme value distribution, i.e., Eq 2 when  $kx \leq (\alpha + uk)$  and  $k \neq 0$ ,

$$F(x) = \exp\left(-1 - k \frac{x-u}{\alpha}\right)^{1/k} \quad (2)$$

and Eq 3 when  $x \geq u$  and  $k = 0$ .

$$F(x) = \exp\left(-\exp\left[-\frac{x-u}{\alpha}\right]\right) \quad (3)$$

EVS were put to work on real systems on several occasions in the oil and gas industries for two main reasons. The 1st reason was the critical nature of many operations associated with the transport of gas and other petroleum products, and the 2nd is the predictability of localized corrosion of steel, the main material used by the oil and gas industry. Meany has, for example, reported four detailed cases where extreme value distribution proved to be an adequate representation of corrosion problems in underground piping and power plant condenser tubing [15]. In another study, data from water injection pipeline systems and from the published literature were used to simulate the sample functions of pit growth on metal surfaces [16]. It was concluded that maximum pit depths were adequately characterized by extreme value distribution, that a Gaussian distribution could model corrosion rates for water injection systems, and that an exponential pipeline leak growth model was appropriate for all operation regimes.

## PROPAGATION OF PROBABILITY FUNCTIONS

The regulations pertaining to the geologic disposal of high-level nuclear waste, in the U.S. and Canada, require that the radionuclides remain substantially contained within the waste package for 300–1000 years after permanent closure of the repository. The current concept of a waste package involves the insertion of spent fuel bundles inside a container that is then placed in a deep borehole, either vertically or horizontally, with a small air-gap between the container and the borehole. For vitrified wastes, a pour canister inside the outer container acts as an additional barrier. Currently, no other barrier is being planned, making the successful performance of the container material crucial to fulfilling the containment requirements over long periods of time.

A model developed to predict the failure of Grade-2 titanium was published in which two major corrosion modes were included [17]: failure by crevice corrosion and failure by hydrogen induced cracking (HIC). A small number of containers were assumed to be defective and fail within 50 years of emplacement. The model was probabilistic in nature, and each modeling parameter was assigned a range of values resulting in a distribution of corrosion rates and failure times. The crevice corrosion rate was assumed to be only dependent on properties of the material and the temperature of the vault. Crevice corrosion was also assumed to initiate rapidly on all containers and subsequently propagate without repassivation. Failure by HIC was assumed to be inevitable once a container temperature fell below 30°C. However, the concentration of atomic hydrogen to render a container susceptible to HIC would occur only very slowly and might even be negligible if that container had never been subject to crevice corrosion.

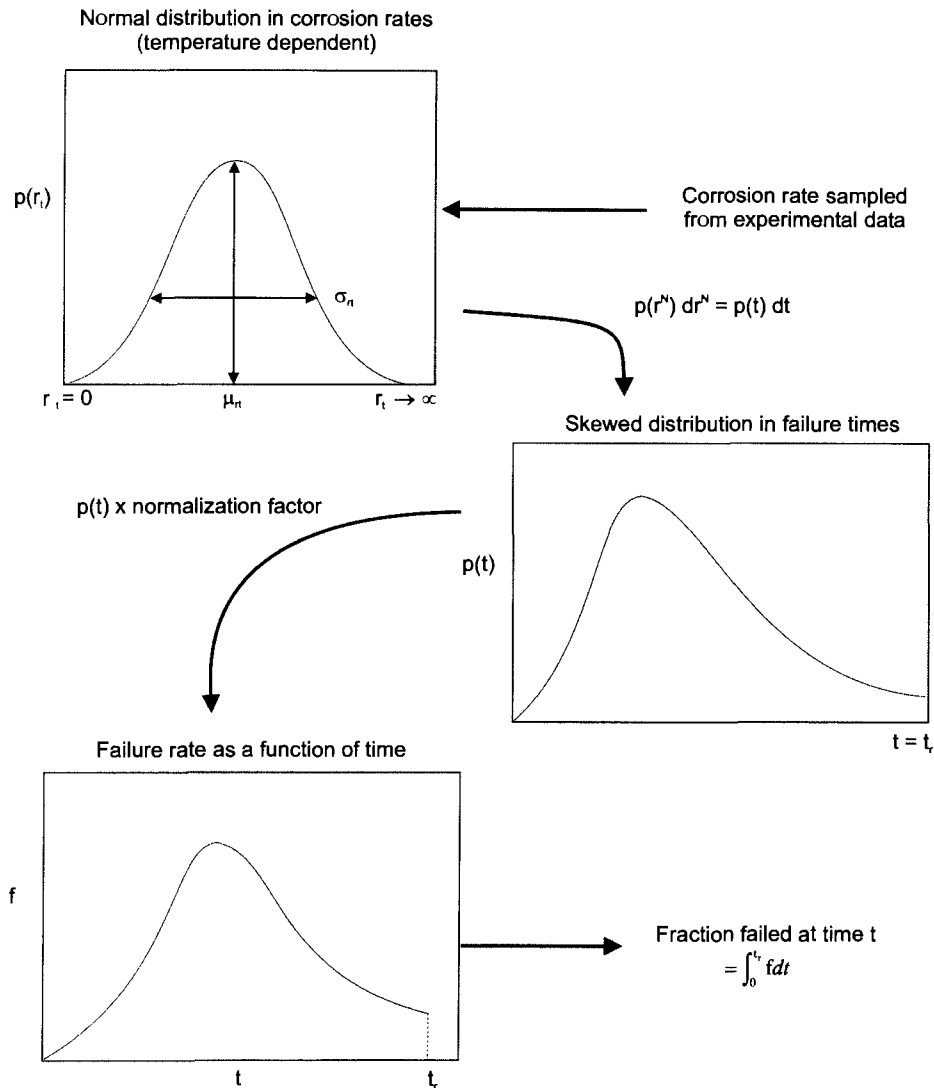

FIG. 4—Procedure used to determine the failure rate of hot containers as a function of time.

The mathematical procedure to combine various probability functions and arrive at a failure probability of a hot container due to crevice corrosion at a certain temperature is illustrated in Fig. 4. The failure rate due to HIC was arbitrarily assumed to have a triangular distribution in order to simplify the calculations, and knowing that HIC is only a predicted marginal failure mode in the considered burial conditions.

On the basis of these assumptions and the calculations described in the full paper, it was predicted that 96.7 % of all containers would fail by crevice corrosion and the remaining by HIC. However, only 0.137 % of the total number of containers were predicted to fail before 1000 years (0.1 % by crevice corrosion and 0.037 % by HIC) with the earliest failure after 300 years.

### Top Down Approach

Some of the issues involved in deciding on a cost-effective solution for combating corrosion are generic to sound system

management. Others are specifically related to the impact of corrosion damage on system integrity and operating costs. The following examples illustrate how these considerations are put into practice and integrated into efficient management systems.

### A Fault Tree for the Risk Assessment of Gas Pipeline

This first top-down model example briefly describes the fault tree analysis (FTA) methodology adopted by Nova Corporation for the risk assessment of its 18 000 km gas pipeline network [18]. FTA is a very efficient method for reviewing and analytically examining a system or equipment in its details to emphasize the lower level fault occurrences that directly or indirectly could contribute to a major fault or undesired event. By performing an FTA from lower-level failure mechanisms, a global overview of the system is achieved. Once completed, the fault tree allows the risk engineer to evaluate fully a system safety or reliability by altering the various lower-level attributes of the

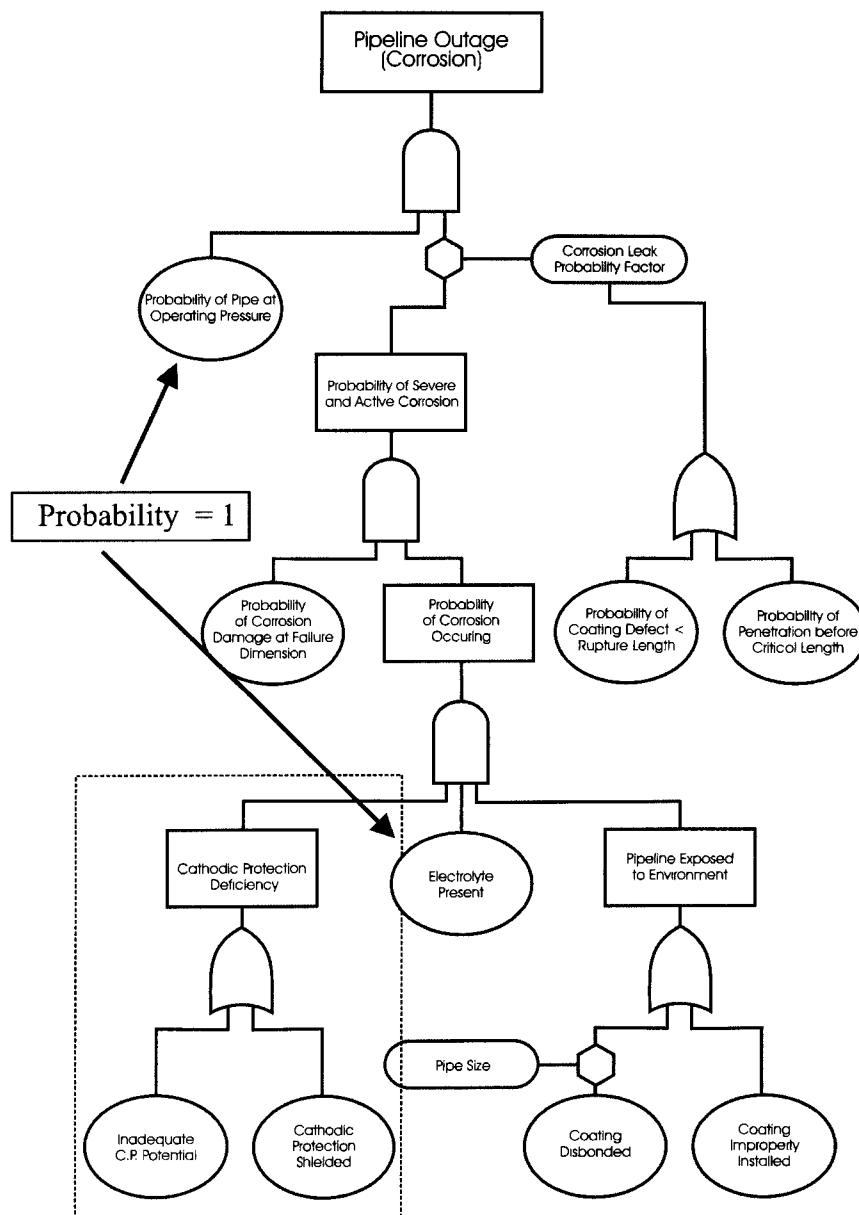

FIG. 5—Fault tree for natural gas pipeline outage due to general corrosion.

tree. Through this type of modeling, a number of variables may be visualized in a cost-effective manner.

The Nova rupture risk FTA is normally performed for the review and analytical examination of systems or equipment to emphasize the lower-level fault occurrences, and the results of the FTA calculations are regularly validated with inspection results. These results also serve to schedule maintenance operations, conduct surveys, and plan research and development efforts. Figure 5 presents the uniform corrosion branch pipeline outage FTA system. Each element of the branch in this figure contains numeric probability information related to technical and historical data for each segment of the 18 000 km pipeline. In some cases, it is simpler to assume some probability

values for an entire system. The probabilities of operating at maximum permitted pressure and the presence of electrolyte were both set at value unity in Fig. 5, therefore forcing the focus on worst case scenarios. Other more verifiable variables can be developed fully, as is shown in Fig 6 for the two basic events describing the probable impact of a cathodic protection deficiency on the pipeline network. As can be seen in this figure, the probability values used for fault-tree calculations are written directly in the database program.

#### Maintenance Steering Group (MSG) System

The aircraft industry and its controlling agencies have developed, over the past few decades, a top down system to

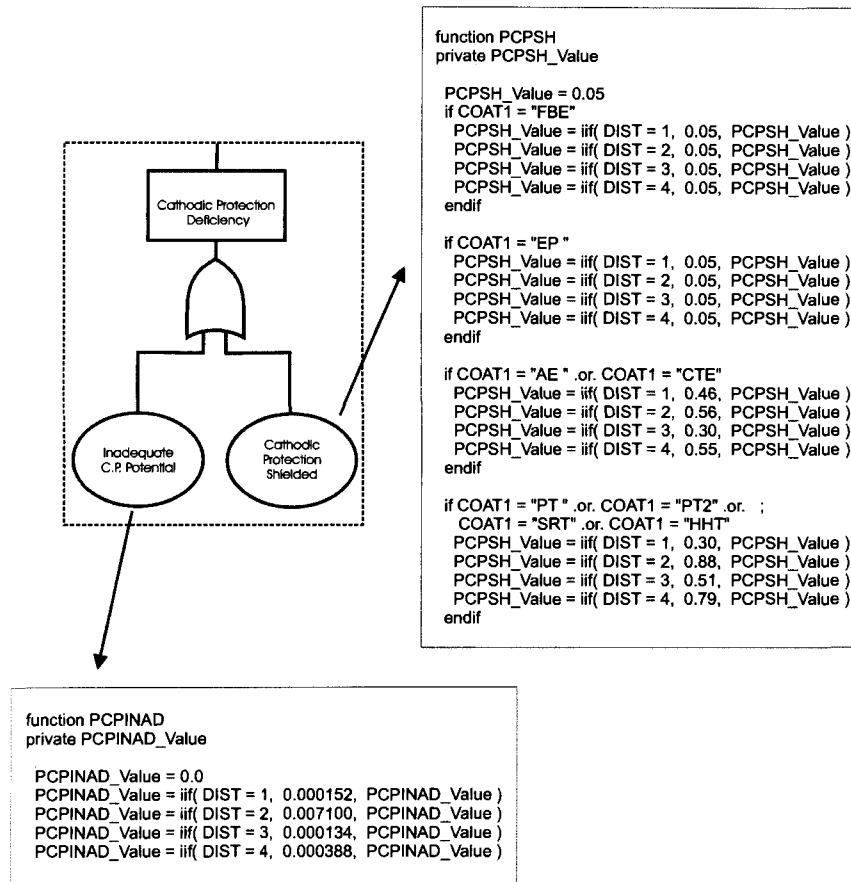

FIG. 6—Detailed code for the basic events leading to a cathodic protection deficiency.

represent potential failures of aircraft components, the Maintenance Steering Group (MSG). The first generation of formal air carrier maintenance programs was based on the belief that each part on an aircraft required periodic overhaul. As experience was gained, it became apparent that some components did not require as much attention as others and new methods of maintenance control were developed. Condition monitoring was, thus, introduced in the decision logic of the initial maintenance steering group document (MSG-1) and was applied to Boeing 747 aircraft.

The most recent major update to the system was initiated in 1980. The resultant MSG-3 system is based on the basic philosophies of MSG-1 and MSG-2, but prescribes a different approach in the assignment of maintenance requirements. In 1991, industry and regulatory authorities began working together to provide additional enhancements to MSG-3. As a result of these efforts, Revision 2 was submitted to the Federal Aviation Administration (FAA) in September 1993 and accepted a few weeks later. One particularly interesting addition in this revision is a procedure for incorporating corrosion damage in the MSG logic. The environmental deterioration analysis (EDA) involves the evaluation of the structure against probable exposure to adverse environments. The evaluation of deterioration is based on a series of steps supported by reference materials containing baseline data expressing the susceptibility of structural materials to various types of environmental damage.

The MSG-3 (Revision 2) structures analysis begins by developing a complete breakdown of the aircraft systems, down to the component level. All structural items are then either classified as Structure Significant Items (SSIs) or other structure. An item is classified as an SSI depending on consideration of consequences of failure and likelihood of failures as well as material, protection, and probable exposure to corrosive environments. All SSIs are then listed and categorized as damage tolerant or safe life items to which life limits are assigned [19]. Accidental damage, environmental deterioration corrosion prevention and control, and fatigue damage evaluation are then performed for these SSIs following the logic diagram illustrated in Fig. 7. Once the MSG-3 structure analysis is completed, each element of the structural analysis diagram (Fig. 7) can be expanded right to the individual components and associated inspection and maintenance tasks. The logic of the EDA, illustrated in Fig. 8, requires the input of a multitude of parameters such as component part number, location, material composition, and protective coating that can be actuated in practical templates.

#### *A Corrosion Index for Pipeline Risk Evaluation*

The third example of top down models is the pipeline risk assessment methodology that is described in much detail in the 2nd edition of a popular book on pipeline risk management [20]. Since this book was published, many systems

**FIG. 7—Overall MSG-3, Revision 2, structural analysis logic diagram.**

based on similar logic have been produced with much more data and complexity. Thus, the following description should serve more as an example than a state-of-the-art description of the technology.

The methodology proposed in that document is based on subjective risk assessment, a method particularly well adapted to situations where knowledge is incomplete and judgments are based on opinions, experience, and other nonquantifiable factors. The technique used for quantifying risk factors is described as a hybrid of several methods allowing the user to confide in scores obtained by combining statistical failure data with operator experience. The subjective scoring system

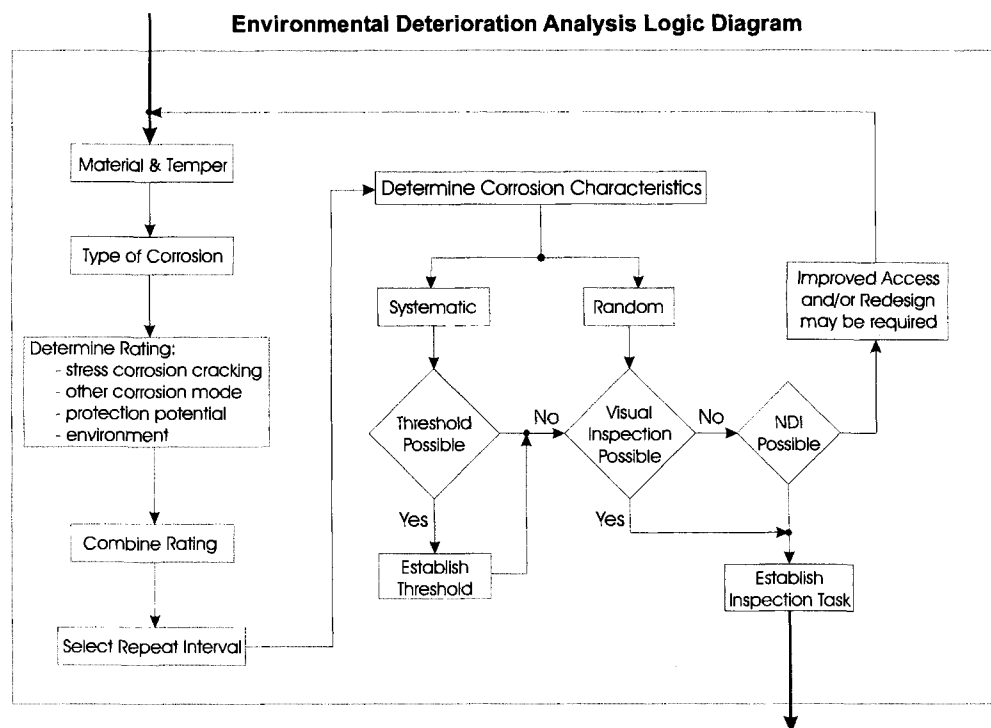

permits an assessment of the pipeline risk picture in two general parts:

**First Part:** In the first part, a detailed itemization and relative weighting of all reasonably foreseeable events that may lead to the failure of a pipeline are carried out. The itemization is further broken into the four indexes illustrated in Fig. 9, corresponding to typical categories of pipeline accident failures. By considering each item in each index, an expert evaluator arrives at a numerical value for that index. The four index values are then summed to obtain the total index value.

**Second Part:** The second part of the scoring system is a detailed analysis of potential consequences of each failure, considering product characteristics, pipeline operating conditions, and line location.

The risk of a pipeline failure caused by corrosion, directly or indirectly, is a common hazard associated with steel pipelines. The corrosion index was organized in three categories to reflect three types of environment to which pipelines are typically exposed, i.e., atmospheric corrosion, soil corrosion, and internal corrosion. Table 4 contains the elements contributing to each of the contributing type of environments and suggested weighting factors. Building the risk assessment tool is said to require the following four steps:

**1. Sectioning:** Dividing a system into smaller sections. The size of each section should reflect practical considerations

**FIG. 8—Environmental deterioration analysis logic diagram.**

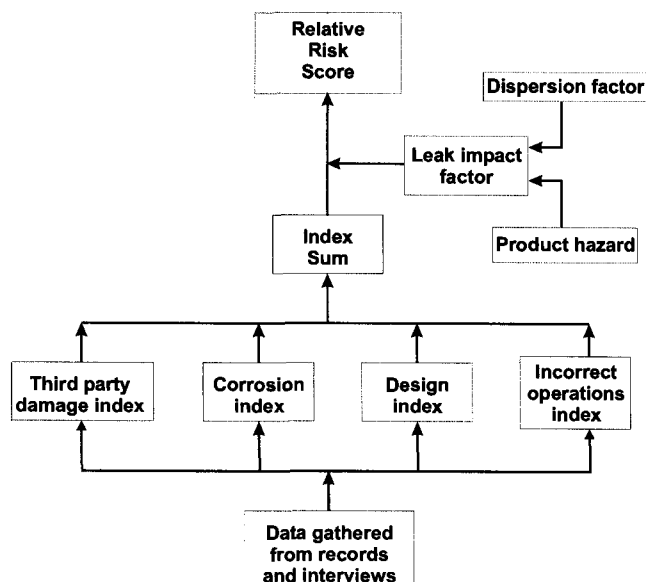

FIG. 9—Pipeline risk assessment model.

of operation, maintenance, and cost of data gathering versus the benefit of increased accuracy;

2. **Customizing:** Deciding on a list of risk contributors and risk reducers and their relative importance;
3. **Data Gathering:** Building the database by completing an expert evaluation for each section of the system;
4. **Maintenance:** Identifying when and how risk factors can change and updating these factors accordingly.

## APPLICATIONS OF ARTIFICIAL INTELLIGENCE

The modern world has produced an unprecedented level of technical information that merits being preserved and

managed. In an age of conservation and recycling, it is important to recognize the fact that the most valuable commodities are information as a vehicle and knowledge as the essence. It is surely sensible to preserve and reuse these most valuable commodities. The adequate transfer and reuse of information covering corrosion problems and solutions involve the development of information-processing strategies that can become very complex. Some of the artificial intelligence tools that have been developed recently in support of corrosion control and protection will be reviewed in the following sections.

### Expert Systems (ESs)

During the 1970s, research in Expert Systems (ES) was mostly a laboratory curiosity. The research focus then was really centered on developing ways of representing and reasoning about knowledge in a computer, and much less on designing actual systems [21]. In 1985 approximately 50 systems were deployed and reported, but the success of some of these captured the attention of many organizations and individuals. The corrosion community reacted with interest to the advent of these new information-processing technologies by establishing programs to foster and encourage the introduction of ES in the workplace. While some of these programs were relatively modest, others were quite ambitious and important both in scope and in funding. The advantages and limitations of using ES technology were analyzed in great detail in one of the first reported efforts on combating corrosion with ES [22]. The Stress Corrosion Cracking (SCC) ES (SCCES) had been created to calculate the risk of various factors involved in SCC, such as crack initiation, when the user supplied evidence. The main goal of this effort was to support the decision process of "general" materials engineers. The system would initially play the role of a consultant, but it was anticipated that SCCES had the potential to become:

- An intelligent checklist;
- A trainer;
- An expert sharpener;
- A communication medium;
- A demonstration vehicle.

The transfer of corrosion expertise into ES has been realized in a multitude of projects. The NACE Conference Proceedings, for example, regularly contain papers that illustrate the continuous interest in the application of knowledge engineering to corrosion. Unfortunately, many systems reported in the literature have never been commercialized. This has resulted in a lack of impartial and practical information concerning the performance and accuracy of these systems. It is, indeed, very difficult to believe everything that is said in a paper, or even more so when the information is some form of publicity. To remedy this situation, the European Federation of Corrosion (EFC) and Materials Technology Institute (MTI) have performed two surveys, between 1988 and 1990, requesting recognized developers of ES in corrosion-related areas to provide very specific information concerning the availability, scope, and performance of their systems [23]. A review of the information presented in these reports was summarized [24]

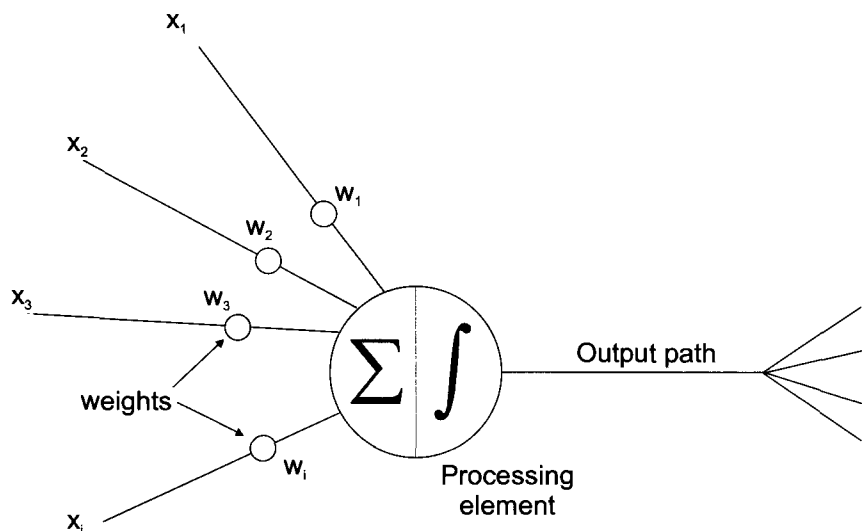

FIG. 10—Schematic of a single processor or neuron in an artificial neural network.

and other developments in expert systems for corrosion prevention and control reported subsequently [25].

### Neural Networks

An artificial neural network (ANN) is a network of many very simple processors or neurons (Fig. 10), each possibility having a small amount of local memory. The interaction of the neurons in the network is roughly based on the principles of neural science. Unidirectional channels that carry numeric data based on the weights of connections connect these neurons that operate only on their local data and on the inputs they receive via the connections. Most neural networks have some sort of training-rule. The training algorithm adjusts the weights on the basis of presented patterns. In other words, neural networks “learn” from examples. ANNs excel particularly at problems where pattern recognition is important and precise computational answers are not required. When ANNs inputs and/or outputs contain evolved parameters, their computational precision and extrapolation ability significantly increases and can even outperform more traditional modeling techniques. Only a few applications of ANN to solving corrosion problems have been reported so far. Some of these systems are briefly described here:

- **Predicting the SCC Risk of Stainless Steels:** The risk of encountering a stress corrosion cracking (SCC) situation was functionalized in terms of the main environment variables [26]. Case histories reflecting the influence of temperature, chloride concentration, and oxygen concentration have been analyzed by means of a back-propagation network. Three neural networks were developed. One was created to reveal the temperature and chloride concentration dependency (Fig. 11) and another to expose the combined effect of oxygen and chloride content in the environment. The third ANN was trained to explore the combined effect of all three parameters. ANNs were found to outperform, during this project, traditional mathematical regression

techniques where the functions have to be specified before performing the analysis.

- **Corrosion Prediction from Polarization Scans:** ANN was put to the task of recognizing certain relationships in potentiodynamic polarization scans in order to predict the occurrence of general or localized corrosion, such as pitting and crevice [27]. The initial data inputs were derived by carefully examining a number of polarization scans for a number of systems and recording those features that were used for the predictions. Table 5 lists the initial inputs used and how the features were digitized for computer input. The variables shown were chosen because they were thought to be the most significant in relation to the predictions (Table 5). The final ANN proved to be able to make appropriate predictions using scans outside the initial training set. The resulting ANN was imbedded in an ES to facilitate the input of data and the interpretation of the numerical output of the ANN.
- **Modeling CO<sub>2</sub> Corrosion:** A CO<sub>2</sub> corrosion “worst case” model based on an ANN approach was developed and the model validated against a large experimental database [28]. An experimental database was used to train and test the ANN. It consisted initially of six elemental descriptors (temperature, partial CO<sub>2</sub> pressure, ferrous and bicarbonate ion concentrations, pH, and flow velocity) and one output, i.e., the corrosion rate. The system demonstrated superior interpolation performance compared to two other well known semi-empirical models. The ANN model also demonstrated extrapolation capabilities comparable to a purely mechanistic electrochemical CO<sub>2</sub> corrosion model.
- **Predicting the Degradation of Nonmetallic Lining Materials:** An ANN was trained to recognize the pattern between results from a sequential immersion test for nonmetallic materials and behavior of the same material in field applications [29]. Eighty-nine cases were used for the supervised training of the network. Another 17 cases were held back for testing of the trained network. An effort was made to ensure that both sets had experimental data taken from the same test but using different samples. Appropriate

FIG. 11—Neural network architecture for the prediction of SCC risk of austenitic stainless steels in industrial processes.

choice of features enabled the ANN to mimic the expert with reasonable accuracy. The successful development of this ANN was another indication that ANNs could seriously aid in projecting laboratory results into field predictions.

- **Validation and Extrapolation of Electrochemical Impedance Data:** The ANN developed in this project had three independent input vectors, frequency, pH, and the applied potential [30]. The ANN was designed to learn from the invisible or hidden information at high and low frequencies and to predict in a lower frequency range than that used for training. Eight sets of impedance data acquired on nickel electrodes in phosphate solutions were used for this project. Five sets were used for training the ANN and three for its testing. ANN proved to be a powerful technique for generating diagnostics in these conditions.

### Case-Based Reasoning

Much of human reasoning is case-based rather than rule-based. When people solve problems, they frequently are

TABLE 5—Data inputs and outputs for predicting corrosion out of polarization scans with an Artificial Neural network.

Input parameter	Value of feature
Repassivation potential	$E_{\text{prot}} - E_{\text{corr}}$
Pitting potential	$E_{\text{pit}} - E_{\text{corr}}$
Hysteresis	+1 = Positive 0 = None -1 = Negative
Current density at scan reversal	$\mu\text{A cm}^{-2}$
Anodic nose	+1 = Yes 0 = No
Passive current density	$\mu\text{A cm}^{-2}$
Potential at anodic-cathodic transition	$E_{\text{A to C}} - E_{\text{corr}}$
Output parameter	Value of feature
Crevice corrosion predicted	+1 = Yes 0 = No
Pitting predicted	+1 = Yes 0 = No
Should general corrosion be considered	+1 = Yes 0 = No

reminded of previous problems they have faced. For many years, both law and business schools have used cases as the foundation for knowledge in their respective disciplines. Within AI, when one talks of learning, it usually means the learning of generalizations, either through inductive or through explanation-based methods. Case-Based Reasoning (CBR) is unique in making the learning little more than a byproduct of reasoning [31]. CBR has met with tangible success in such diverse human decision-making applications as banking, auto-clave loading, tactical decision-making, and foreign trade negotiations. The CBR approach is particularly valuable in cases containing ill-structured problems, uncertainty, ambiguity, and missing data. Dynamic environments can also be tackled, or when there are shifting, ill-defined, and competing objectives. Cases where there are action feedback loops, multiple human involvement, and multiple and potentially changing organizational goals and norms can also be tackled.

A critical issue for the successful development of such systems is the creation of a solid indexing system, since the success of a diagnosis depends heavily on the selection of the best stored case. Any misdirection can lead a query down a path of secondary symptoms and factors. Therefore, it is very important to establish an indexing system that will effectively indicate or counter-indicate the applicability of a stored case. Three issues are particularly important in deciding on the indices [32]:

- Indices must be truly relevant;
- Indices must be generalized, otherwise only an exact match will be the criterion for case applicability;
- But indices shall not be over-generalized.

Failure analysts and corrosion engineers also reason by analogy when faced with new situations or problems. Two CBR systems have been developed recently in support of corrosion engineering decisions. Both systems derived their reasoning from a combination of two industrial alloy performance databases. The general architecture of these two

FIG. 12—Case-based reasoning architecture for the prediction of materials behavior.

FIG. 13—Compilation of the results to the questions, “What is the most dependable information source you depend upon to carry your work?” and “What is the least dependable information source you depend upon to carry your work?”

CBR systems is presented in Fig. 12. The first, “M-BASE,” facilitates the process of retrieving materials according to a given set of desired properties and/or specifications. The second, “C-BASE,” helps the materials engineer in the difficult task of selecting materials for corrosion resistance in complex chemical environments.

## INTERNET AND THE WEB

The Internet has revolutionized both the computer and communication worlds like nothing before. The invention of the telegraph, telephone, radio, and computer set the stage for this unprecedented integration of capabilities. The

Internet is at once a world-wide broadcasting capability, a mechanism for information dissemination, and a medium for collaboration and interaction between individuals and their computers without regard for geographic location.

Besides being extremely efficient tools for transferring documents and data of all types, the Internet and the Web are also gigantic repositories of information. However, there are some doubts concerning the quality of that information. The confidence professionals have in the information currently available on the Web was verified during a survey carried out directly from a Web site. That survey was conducted by inviting the active participants of two well-known Internet corrosion discussion groups [33,34], totaling approximately 1200 active members, to reach a specific page of the Corrosion Doctors site and answer a set of both short and specific questions. In the survey designed to reveal the importance of different information sources used by corrosion engineers, the participants were asked to select among a series of optional answers the one that best fitted a specific question:

- Books
- Journals
- Conferences and their associated activities and publications
- Software systems (databases, CDs, etc.)
- Own network of friends and contacts
- Internet discussion groups such as UMIST, NACE, and others
- Internet sources others than above, e.g., Web sites
- Other

The questions themselves were semirepetitive, asking of the 52 participants that registered to this particular survey to identify which of the proposed information sources was either the most dependable, the least dependable, or a gradation of these questions. Fig. 13 shows the breakdown of answers to the question, "What is the most dependable information source you depend upon to carry your work?" and to the question, "What is the least dependable information source you depend upon to carry your work?" The information explaining the survey and the survey results have been edited and processed into a page of the site for further consultation. The histograms presented in Fig. 13 indicate rather clearly that the confidence level people have on the information displayed on the Web in general or shared in discussion lists is presently rather low. This situation will probably change as the technology matures into a credible repository of useful information.

## SUMMARY

The difficulties associated with recording corrosion information are many, ranging from the basic lack of details in failure analyses to the inherent complexity of the variables involved. The complexities associated with corrosion damage information are compounded by a general lack of standard schemes to represent materials in their operational environments. Data gathered in controlled laboratory environments can usually be obtained with more precision and for such data standards have been developed to stream-

line the exchange of information between organizations. However, it is evident that the progress made in recent years with communication tools and protocols has been much greater than the progress in the quality of data that are generated and cumulated. Improvement in this area has to precede the development of generalized models of corrosion failures and the subsequent reuse of the information by applying methodologies related to artificial intelligence.

## **Section III: Types of Tests**

*H.P. Hack, Editor*

# Electrochemical Tests

John R. Scully<sup>1</sup>

SEVERAL TEXTBOOKS AND SYMPOSIA proceedings cover the application of electrochemical methods in corrosion testing [1–16]. This chapter highlights many of the commonly used laboratory methods after presenting a brief review of thermodynamics and kinetic aspects of electrochemical reactions that describe corrosion processes. Techniques discussed include Tafel extrapolation, polarization resistance, electrochemical impedance spectroscopy, electrochemical noise resistance, use of rotating disks, and cylinders to study aspects of corrosion affected by solution flow, polarization methods for assessing susceptibility to localized corrosion, scratch repassivation, potential-step repassivation, electrochemical noise applied to pitting, potentiodynamic repassivation techniques for assessing sensitization, the barnacle electrode and permeation methods for hydrogen concentration analysis, and methods for evaluating anodized layers and coatings on metals.

## ELECTRODE REACTION THERMODYNAMICS AND KINETICS IN CORROSION

Metallic corrosion is usually an electrochemical process. Electrochemical processes require anodes and cathodes in electrical contact, as well as an ionic conduction path through an electrolyte. The electron flow between the anodic and cathodic areas quantifies the rates of the oxidation and reduction reactions. When anodes are physically separated from cathodes, the current can be readily measured by replacing direct electrical contact with a zero resistance ammeter. The conversion of the reaction rate per unit area,  $J$ , from units of mol/cm<sup>2</sup>-s to electrical current density,  $i$  (A/cm<sup>2</sup>) is accomplished with Faraday's constant,  $F$ , and knowledge of the number of electrons transferred to complete the electrochemical reaction a single time,  $n$

$$i = nFJ \quad (1)$$

where

$n$  = number of electrons transferred, equivalents/mol, and  
 $F$  = Faraday's constant, 96,484.6 coulombs/equivalent.

<sup>1</sup>Professor of Materials Science and Engineering, Co-director, Center for Electrochemical Science and Engineering, Department of Materials Science and Engineering, University of Virginia, Charlottesville, VA 22903-2442.

Monitoring this current provides the means of assessing the kinetics of the corrosion process, not just the thermodynamic tendencies for corrosion nor merely the mass of metal loss registered after the test. There are three typical half cell reactions by which a metal ( $M$ ) may be oxidized in water

or

In all cases, metal atoms in the solid ( $s$ ) metallic state (in the electronic conductor) are converted to an oxidized state. These species remain either on the metallic surface or are ejected into the aqueous ( $aq$ ) solution (the ionic conducting phase). Typical cathodic half-cell reactions in aqueous media involve the reduction of oxygen, protons, and water at the interface between the metallic and ionic conducting phases. This process involves consumption of electrons liberated during oxidation:

The Nernst equation describes the reversible electrode or equilibrium potential,  $E_{\text{redox}}$ , associated with the thermodynamic tendency for an electrochemical half-cell reaction to occur spontaneously. At potentials more positive than the equilibrium potential associated with a particular electrochemical half-cell reaction, oxidation proceeds spontaneously, while at potentials more negative, reduction occurs. The forms of the Nernst equation for the oxidation reactions given in Eqs 2 and 7 are, respectively,

$$E_{\text{redox}} = E_o + (2.303RT/nF) \log (M^{n+}) \quad (9)$$

and

$$E_{\text{redox}} = E_o - 2.303RTpH/F \quad (10)$$

where

$R$  = the ideal gas constant, cal/mol-K,  
 $T$  = temperature, K,

$n$  = the number of electrons to complete the half-cell reaction a single time, and

$E_0$  = the specific standard half-cell potential for the reaction cited at unity activity for dissolved species and 1 atmosphere fugacity for gaseous substances at 25°C. The standard half cell potential for the reaction  $2\text{H}^+ + 2\text{e}^- = \text{H}_2$  is defined as 0.0 V versus the normal hydrogen electrode (NHE) at 25°C.

Concerning corrosion in aqueous media, metal oxidation reactions (see Eqs 2-4) with Nernst or redox potentials more negative than the Nernst or redox potentials associated with typical cathodic reactions given by Eqs 5-8 will occur spontaneously [4-5].

The reaction rate for any single reduction-oxidation process is a function of overpotential  $E - E_{\text{redox}}$ , where  $E$  is the applied potential. For a single charge transfer controlled redox reaction,  $i_{\text{net}}$  is described by:

$$i_{\text{net}} = i_{\text{ex}} [\exp[\alpha_a F(E - E_{\text{redox}})/RT] - \exp[-\alpha_c F(E - E_{\text{redox}})/RT]] \quad (11)$$

where the exchange current density,  $i_{\text{ex}}$ , describes the non-zero rate at which the forward (oxidation) and reverse (reduction) reactions occur equally at  $E_{\text{redox}}$ . Since  $E_{\text{redox}}$  represents an equilibrium condition, the forward and reverse rates of the reaction must be equal.  $\alpha$  is known as the symmetry factor (such that  $\alpha_c = 1 - \alpha_a$ ) in the case of single step electron transfer processes representing a reduction oxidation process.  $\alpha$  represents a transfer coefficient for a multi-step reaction process (in this case,  $\alpha_c + \alpha_a \neq 1$ ). The factor  $2.303 RT/\alpha_a F$  is equal to the anodic Tafel slope,  $\beta_a$ . Similarly, the factor  $2.303 RT/\alpha_c F$  is equal to the cathodic Tafel slope,  $\beta_c$ . If  $E - E_{\text{redox}}$  is a large positive voltage (i.e., such that the term  $[\alpha_a F(E - E_{\text{redox}})/RT]$  is greater than about 2.303 or  $(E - E_{\text{redox}})/\beta_a > 1$ , then the following simplification known as the Tafel approximation applies for a charge transfer controlled process:

$$i_{\text{ox}} = i_{\text{ex}} \exp[\alpha_a F(E - E_{\text{redox}})/RT] \quad (12)$$

Similarly, when  $E - E_{\text{redox}}$  is a large negative number (i.e., such that  $(E - E_{\text{redox}})/\beta_c > 1$ ), another analogous simplification applies in the case of a single cathodic reaction:

$$i_{\text{red}} = i_{\text{ex}} \exp[-\alpha_c F(E - E_{\text{redox}})/RT] \quad (13)$$

Typical corrosion processes occurring under freely corroding conditions involve at least one cathodic and one anodic reaction. The thermodynamics discussed above dictate the circumstances where these reactions will proceed spontaneously. The current density measured during a polarization experiment,  $i_{\text{app}}$ , involving a single charge transfer controlled oxidation and single charge transfer controlled reduction reaction is

$$i_{\text{app}} = i_{\text{corr}} \left[ \exp\left(\frac{\alpha_a F(E - E_{\text{corr}})}{RT}\right) - \exp\left(\frac{\alpha_c F(E - E_{\text{corr}})}{RT}\right) \right] \quad (14)$$

The corrosion potential,  $E_{\text{corr}}$ , is a kinetically and thermodynamically determined "mixed" potential given by the interception of the lines describing the total anodic and cathodic reaction rates. At  $E_{\text{corr}}$ ,  $i_{\text{ox}} = i_{\text{red}}$  and  $i_{\text{corr}}$  is described by the magnitude of  $i_{\text{ox}}$  at  $E_{\text{corr}}$  as shown in Fig. 1. Either reaction

FIG. 1—Application of mixed potential theory showing the electrochemical potential-current relationship for a corroding system consisting of a single charge transfer controlled anodic reaction and single charge transfer controlled anodic electrochemical reaction.  $\beta_a$  and  $\beta_c$  are Tafel slopes.

rate may become mass transport limited under certain circumstances, in which case Eqs 12, 13, and 14 do not apply.

### Obtaining Corrosion Rates from Electrochemical Kinetic Data

According to mixed-potential theory, any overall electrochemical reaction can be algebraically divided into half-cell oxidation and reduction reactions, and there can be no net electrical charge accumulation [17]. For open-circuit corrosion in the absence of an applied potential, the oxidation of the metal and the reduction of some species in solution occur simultaneously at the metal/electrolyte interface, as described by Eq 14. Under these circumstances, the net measurable current density,  $i_{\text{app}}$ , is zero. However, a finite rate of corrosion defined by  $i_{\text{corr}}$  occurs at anodic sites on the metal surface, as indicated in Fig. 1. When the corrosion potential,  $E_{\text{corr}}$ , is located at a potential that is distinctly different from the reversible electrode potentials ( $E_{\text{redox}}$ ) of either the corroding metal or the species in solution that is cathodically reduced, the oxidation of cathodic reactants or the reduction of any metallic ions in solution becomes negligible. Because the magnitude of  $i_{\text{ox}}$  at  $E_{\text{corr}}$  is the quantity of interest in the corroding system, this parameter must be determined independently of the oxidation reaction rates of other adsorbed or dissolved reactants.

The information obtained in a polarization experiment is  $i_{\text{app}}$  as a function of the potential,  $E$ , as shown by the thick solid line in Fig. 1, where  $i_{\text{app}} = i_{\text{ox}} - i_{\text{red}}$ . To obtain  $i_{\text{app}}$  as a function of  $E$ , the applied potential between the reference electrode and working electrode is controlled and scanned

at constant rate (potentiodynamic), instantaneously increased a fixed amount (potentiostatic), or stepped at various times (potentiostaircase) [18].  $I_{app}$  is measured and normalized with respect to the surface area,  $A$  (i.e.,  $i_{app} = I_{app}/A$ ). Conversely,  $i_{app}$  can be supplied between the working and counter-electrodes under galvanostatic or galvanostaircase control, and the resulting potential between the working and reference electrodes is monitored. Several ASTM standards discuss methods for performing these experiments.<sup>2</sup> Several approaches are available to determine  $i_{corr}$  from such experimental information. These methods are discussed below.

### Conversion of Corrosion Rates to Mass Loss and Penetration Rate

Determination of  $I_{ox}$  at open circuit potential or other potential of interest, where  $I_{ox} = i_{ox} \times A$ , over a known period of time leads to direct determination of the mass loss

$$M = \frac{I_{ox}t(A.W.)}{nF} \quad (15)$$

where:

$M$  = the mass loss, g,

$I_{ox}t$  = the product of current and time, coulombs, and

$A.W.$  = the atomic weight of the electroactive species, g/mol.

This relation is known as Faraday's 1st Law. Rearrangement of Eq 15 leads to a straightforward determination of the penetration rate (applicable only when  $i_{ox}$  ( $\mu A/cm^2$ ) is uniformly distributed over the entire wetted surface area, or where the localized actively corroding area,  $A$ , is known), as follows

$$CR = \frac{K_1 i_{ox}(E.W.)}{\rho} \quad (16)$$

where

$CR$  = the corrosion rate, in mm/year,

$E.W.$  = the equivalent weight (considered dimensionless in this calculation), and

$\rho$  = the metal or alloy density, g/cm<sup>3</sup>.

The constant  $K_1 = 3.27 \times 10^{-3}$  when  $i_{ox}$  is expressed as  $\mu A/cm^2$ .  $K_1$  has units of mm-g/ $\mu A$ -cm-y when  $CR$  is desired in mm/yr. ASTM standard G 102<sup>3</sup> gives other values for this constant when  $CR$  is expressed in other units. Expressions are also available to calculate mass loss rate per unit area from knowledge of electrochemical corrosion rate. For instance,

$$MR = K_2 i_{ox}(E.W.) \quad (17)$$

where  $K_2 = 8.954 \times 10^{-3}$  g-cm<sup>2</sup>/ $\mu A$  m<sup>2</sup> d when  $MR$  is expressed as g/m<sup>2</sup> d. For alloys, the equivalent weight  $E.W.$  should be calculated as outlined in ASTM G 102<sup>3</sup>

$$E.W. = \frac{1}{\sum \left( \frac{n_i f_i}{A.W._i} \right)} \quad (18)$$

<sup>2</sup>ASTM G 5, Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements; and ASTM G 59, Practice for Conducting Potentiodynamic Polarization Resistance Measurements.

<sup>3</sup>ASTM Standard G 102, Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Measurements.

where

$f_i$  = the mass fraction of the  $i$ th component of the alloy (–),

$A.W._i$  = the atomic weight of the  $i$ th component element, g/mol

$n_i$  = the number of electrons transferred or lost when oxidizing the  $i$ th component element under the conditions of the corrosion process (equivalents/mol), and

$i$  = the number of component elements in the alloy.

$n$  is usually equal to the stable valence of the elements oxidized, or must be determined from either a Pourbaix (potential-pH) diagram or experimentally from an analysis of the ions in the corrosive solution. This expression assumes that all component elements oxidize when the alloy corrodes and that they are all oxidizing at essentially a uniform rate. In some situations, these assumptions are not valid and the calculated corrosion rate will be in error. For example, if an alloy is composed of two or more phases and one phase preferentially oxidizes, the calculation must take this into consideration.

### ELECTROCHEMICAL METHODS FOR THE STUDY OF UNIFORM CORROSION: POLARIZATION METHODS

One method for examining the corrosion behavior of a metal is to determine the  $E$ - $i_{app}$  relationship by conducting a polarization experiment. The following  $E$ - $i_{app}$  relationship is often experimentally observed between applied current and potential. The expression is applicable to charge transfer controlled corrosion processes, regardless of the exact number of charge transfer controlled reactions or reaction steps. It provides the basis for the electrochemical polarization technique [1,2,17,19].

$$i_{app} = i_{corr} \left[ \left( \exp \left\{ \frac{2.303(E - E_{corr})}{\beta_a} \right\} \right) - \exp \left\{ -\frac{2.303(E - E_{corr})}{\beta_c} \right\} \right] + C \frac{\partial E}{\partial t} \quad (19)$$

where

$C$  = the interfacial capacitance associated with the electrochemical doublelayer [1,2], and

$\beta_a$  and  $\beta_c$  = the anodic and cathodic Tafel slopes ( $\partial E / \partial \log i_{app}$ ) given by the slopes of the polarization curves in the anodic and cathodic Tafel regimes, respectively, and

$\partial E / \partial t$  = the time rate of change in applied potential, or voltage scan rate.

The second term of the expression ( $C \partial E / \partial t$ ) approaches 0 at low voltage scan rates  $dE/dt$ . Steady state is desirable, since the goal is to obtain  $i_{corr}$  at  $E_{corr}$ . Note that  $i_{app}$  becomes approximately equal to either  $i_{ox}$  or  $i_{red}$  at large  $\eta$ , where  $\eta = (E - E_{corr})$ . At very large anodic or cathodic overpotentials, Eq 19 can be rearranged in the form of the Tafel expression [1-3,5,7,18,19]

$$\begin{aligned} \eta_a &= \beta_a \log \left( \frac{i_{app}}{i_{corr}} \right) \\ \eta_c &= -\beta_c \log \left( \frac{i_{app}}{i_{corr}} \right) \end{aligned} \quad (20)$$

where:

$\eta_a$  and  $\eta_c$  = the anodic and cathodic overpotentials, respectively.

Equations 20 are only strictly valid for a single anodic or cathodic reaction, respectively, although approximately linear behavior can be observed despite several reactions. The linear portion of the solid line describing  $E-i_{app}$  in Fig. 1 above  $E_{corr}$  describes a single anodic reaction that can be described by Eq 20. Similarly, the linear portion of the solid line describing  $E-i_{app}$  in Fig. 1 below  $E_{corr}$  describes a single cathodic reaction that can be described by Eq 20.

### Tafel Extrapolation to Determine Corrosion Rate

In cases where Eq 20 is valid,  $\eta$  can be plotted versus  $\log(i_{app})$  over a sufficient range to obtain a linear relationship between the logarithm of current density and potential [1,5,7,19].  $i_{corr}$  can be determined from extrapolation of  $i_{app}$  from either the anodic or the cathodic Tafel region to the open-circuit potential (zero overpotential). Figure 1 illustrates this method. The method is potentially damaging to the corroding metal, since a large overpotential must be applied. This is particularly true in the case of anodic polarization, in which the surface is changing because of corrosion and or passivation of the metal. No ASTM standard currently exists for this method.

### Complications with the Polarization Method Involving Solution Resistance

Tafel extrapolation, as well as other polarization techniques, can be complicated by several factors. One such factor, ohmic resistance, arises from the resistivity of the solution, cell geometry, location of the reference electrode, and magnitude of applied current [2,6]. Ohmic resistance can contribute a voltage error to the measured potential. This error is summed algebraically with the true interfacial overpotential across the electrochemical interface (the potential usually sought in electrochemical measurements) measured with respect to a reference electrode. Placement of the reference electrode near the working electrode with a Luggin-Haber capillary is used to minimize the solution resistance error, which can be estimated from the product of the applied current density, the solution resistivity, and the perpendicular distance from the Luggin probe to the specimen surface in a planar electrode geometry. The error contributes to the measured overpotential  $\eta_{app}$ :

$$\eta_{app} = \eta_{true\ interfacial} + i_{app}R_s \quad (21)$$

$R_s$  ( $\Omega\text{-cm}^2$ ) is the uncompensated solution resistance between the working electrode and the position where the reference electrode senses the potential in solution (at the tip of the Luggin-Haber capillary). Thus,  $\eta_{app} > \eta_{true}$  at high anodic, current densities high  $R_s$  or high cathodic applied current density,  $E_{app} > E_{true}$  and the Tafel slope desired from a fit of Eq 19 or 20 to  $E$  versus  $i_{app}$  data cannot be obtained from  $E$ - $\log i$  data. When the dominant term in Eq 21 is the second term, a linear relationship between  $\eta$  ( $\eta = \eta_{app}$ ) and  $i_{app}$  is obtained instead of the semi-logarithmic relationship discussed above. The true scan rate in the potentiodynamic technique may also be altered, since the applied potential that contains the ohmic component

is controlled during the scan, not the true overpotential. Several excellent reviews are available on the subject of the voltage error introduced from solution resistance [20–23].

### Complications Involving Concentration Polarization Effects

The Tafel relationship established through Eqs 19 and 20 is valid for pure activation control, or charge transfer control. An additional consideration involves the concept of concentration polarization. In this case, the reaction rate is fast enough that the reacting specie is depleted (reduction reaction) or concentrated (oxidation) at the reacting surface. In order to maintain the reaction rate, diffusion through the electrolyte becomes the kinetic limitation. The reaction becomes completely diffusion controlled at the limiting current density,  $i_L$ . The deviation from activation control in the case of a cathodic reaction can result in an additional overpotential known as a mass transport overpotential,  $\eta_{conc}$ . This overpotential is described by [4,5]

$$\eta_{conc} = \left[ \frac{2.303RT}{nF} \right] \log \left[ 1 - \frac{i_{app}}{i_L} \right] \quad (22)$$

where

$i_L$  = the mass transfer limiting current density defined by Fick's first law at steady state.

As  $i_{app}$  approaches  $i_L$ , the concentration overpotential,  $\eta_{conc}$ , becomes very large. The cathodic reaction may be under mixed charged transfer-mass transport or mass transport control for many corrosion situations, particularly if the cathodic reaction is  $O_2$  reduction [5]. The cathodic polarization behavior associated with "mixed" charge transfer—mass transfer control can be described mathematically by the algebraic combination of Eqs 20 and 22. Tafel extrapolation of cathodic data becomes difficult under these conditions because the Tafel region may not be extensive.

For a completely mass transport limited corrosion process, the concentration of the cathodic reacting species  $C_b$  approaches zero at the electrode interface and  $i_{corr} = i_L$  (Fig. 2) [2]. The diffusional boundary layer thickness,  $\delta$ , is decreased by increasing solution stirring or rotation rate,  $\Omega$  (rad/s), in the case of a rotating cylinder or disk electrode [1]. The limiting current density  $i_L$  is a linear function of concentration gradient [15]. The concentration gradient ( $C_b/\delta$ ) increases as a function of  $\Omega^{0.5}$  or  $\Omega^{0.7}$  for the rotating disk and cylinder, respectively [2,15]. For a mass transport controlled cathodic reaction,  $i_{corr}$  is increased with flow as shown in Fig. 2. The governing equation for the rotating cylinder electrode is [15]

$$i_L = 0.079nFC_bD^{0.64}\nu^{-0.34}\Omega^{0.7}r^{0.4} \quad (23)$$

and for the rotating disk electrode is [2,15]

$$i_L = 0.621nFC_bD^{0.67}\nu^{-0.167}\Omega^{0.5} \quad (24)$$

where

$C_b$  = the reacting species concentration in the bulk solution, moles/cm<sup>3</sup>,

$D$  = the diffusion coefficient for the reacting specie, cm<sup>2</sup>/s,

$\nu$  = the kinematic viscosity of the solution, cm<sup>2</sup>/s, and

$r$  = cylinder or disk radius, cm.

FIG. 2—Application of mixed potential theory showing the electrochemical potential-current relationship for a corroding system consisting of a mass transport controlled cathodic reaction and a charge transfer controlled anodic reaction. As the fluid velocity increases from 1 to 4, the corrosion rate increases from A to D.

Corrosion engineers often favor the rotating cylinder to simulate flow in turbulent piping systems, since this flow regime is readily obtained [15]. In contrast, the rotating disk electrode operates in the laminar flow regime, even at high rotation rates, and does not accurately represent many corrosion situations [15]. No ASTM methods currently exist to examine mass transport controlled corrosion.

### Polarization Resistance Methods

Stern and Geary simplified the kinetic expression describing charge transfer controlled reaction kinetics (Eq 19) for the case of small overpotentials with respect to  $E_{corr}$  [24,25]. Equation 19 can be linearized when  $\eta/\beta < 0.1$ . This simplified relationship has the following form if the second term describing the capacitive current,  $C(dE/dt)$ , is negligible

$$i_{corr} = \left( \frac{\Delta i_{app}}{2.3 \Delta E} \right) \left( \frac{\beta_a \beta_c}{(\beta_a + \beta_c)} \right) \quad (25)$$

rearranging

$$i_{corr} = \left( \frac{1}{2.3 R_p} \right) \left( \frac{\beta_a \beta_c}{(\beta_a + \beta_c)} \right) = \frac{B}{R_p} \quad (26)$$

where  $R_p$  is the polarization resistance ( $\Omega\text{-cm}^2$ ) given by  $\partial E / \partial i$  at  $t = \infty$ ,  $\Delta E = 0$ , and  $B$  is a constant given by the constant terms shown in Eq 26.

$i_{app}$  is often approximately linear with potential within  $\pm 5\text{--}10$  mV of  $E_{corr}$ , as shown for AISI 430 stainless steel in  $\text{H}_2\text{SO}_4$  (Fig. 3). The slope of this plot,  $\Delta E / \Delta i$ , when determined at  $E_{corr}$  as shown in Fig. 3 defines the polarization resistance, which is inversely proportional to corrosion rate [26,27]. The surface area of the working electrode must be known. Knowledge of  $R_p$ ,  $\beta_a$ , and  $\beta_c$  permits direct determination of the corrosion rate at any instant in time using Eq 26 [24,25,27,28].

FIG. 3—ASTM G 59 polarization curves used for polarization resistance determinations based on the results from eight independent laboratories for AISI type 430 stainless steel in 1N  $\text{H}_2\text{SO}_4$ . Curve 1 is the mean result, with Curves 2 and 3 showing the 95 % confidence limits from the laboratory round robin.

ASTM standards G 59<sup>2</sup> and G 96<sup>4</sup> describe standard procedures for conducting polarization resistance measurements.<sup>a</sup>

Other techniques exploit nonlinearity at larger overpotentials that invalidates the approximation given by Eq 25 [29]. The Oldham-Mansfeld method calculates  $i_{corr}$  from nonlinear  $E$  versus  $i_{app}$  data obtained usually within  $\pm 30$  mV of  $E_{corr}$ , using tangent slopes and intercepts to calculate corrosion rate without high overpotential determination of  $\beta_a$  and  $\beta_c$  [30a]. Computerized curve fitting can exploit nonlinearity to calculate  $\beta_a$  and  $\beta_c$  from low overpotential data, avoiding the destructive nature of large overpotentials [30b]. The

<sup>4</sup>ASTM Standard G 96, Guide for On-line Monitoring of Corrosion in Plant Equipment (Electrical and Electrochemical Methods).

<sup>a</sup>This review focuses on corroding systems with different cathodic and anodic half-cell reactions. However, the concept of polarization resistance applies equally well to reduction-oxidation systems involving a single half-cell reaction. Here, the exchange current density,  $i_o$ , may be calculated from the polarization resistance, where  $R$  is the ideal gas constant,  $F$  is Faraday's constant,  $T$  is the temperature, and  $\alpha_a$  and  $\alpha_c$  are the anodic

$$R_n (\text{ohm-cm}^2) = \left[ \frac{\Delta E}{\Delta i} \right]_{(E-E_{corr}) \rightarrow 0} = \left( \frac{RT}{i_o F (\alpha_a + \alpha_c)} \right)$$

and cathodic multi-step electron transfer coefficients, respectively, for the reduction-oxidation process.

Mansfeld technique substitutes Eq 26 into Eq 19, eliminating  $i_{corr}$  [30b].  $\beta_a$  and  $\beta_c$  are determined from the best fit of the resulting expression containing  $\beta_a$  and  $\beta_c$  as unknowns to a nonlinear plot of  $\eta$  versus  $2.3i_{app}R_p$ .  $\eta$  versus  $i_{app}$  data are obtained within  $\pm 30$  mV of  $E_{corr}$ .  $R_p$  is determined from the linear slope of  $E$  versus  $i_{app}$  within  $\pm 5$  mV of  $E_{corr}$ .  $i_{corr}$  is subsequently determined from Eq 25 using  $R_p$ ,  $\beta_a$ , and  $\beta_c$ .

### Complications with Polarization Resistance Measurements

Complications related to the polarization resistance method and possible remedies are reported in the literature [29–34]. Three of the most common errors involve: (1) invalidation of the results through oxidation or reduction of some other electroactive species besides the corroding metal in question, (2) a change in the open-circuit or corrosion potential during the time taken to perform the measurement, and (3) use of a large  $\eta$ , invalidating the assumption of a linear relationship between  $i_{app}$  and  $E$  required by Eqs 25 and 26.

Another source of error involves cases in which both the anodic and cathodic reactions are not charge transfer controlled processes, as required for the derivation of Eq 25. Modifications to Eq 25 exist for cases in which pure activation control is not maintained, such as in the case of partial diffusion control or passivation [35]. Other researchers have attempted to calibrate the polarization resistance method with gravimetrically determined mass loss [36]. In fact, polarization resistance data for a number of alloy-electrolyte systems have been compared to the observed average corrosion currents determined from mass loss via Faraday's law [28]. A linear correspondence was obtained over six orders of magnitude in corrosion rates.

Two other frequently encountered complications are the need to correct polarization data for errors that arise from the contribution of solution resistance,  $R_s$ , and the addition of capacitive current,  $C dE/dt$ , which occurs with increasing scan rate [16]. Capacitive current gives rise to hysteresis in current-potential plots [37]. Solution resistance contributes to a voltage error as discussed above, as well as a scan rate error. Since the applied potential is increased by an ohmic voltage component, an apparent value of polarization resistance  $R_p'$  is obtained which overestimates  $R_p$  by an amount equal to  $R_s$ . Consequently, the corrosion rate is underestimated. Hysteresis in the current density-applied potential plot is brought about for combinations of high voltage scan rate and large interfacial capacitances, as well as large polarization resistances. Attempting to determine  $R_p$  at too fast of a scan rate underestimates its true value, leading to an overestimation of corrosion rate. This error can be minimized by determining the polarization resistance at a slow scan rate, or extrapolating the results at several slow scan rates to zero scan rate. Alternatively, one may take two or more current density measurements from potentiostatic data after long time periods near  $E_{corr}$  to minimize fast scan rate effects. These complications and others have been reviewed elsewhere [38].

Many treatments of this subject have used an electrical equivalent circuit model to simulate the corroding metal/electrolyte interface [1,38,39]. The simplest form of such a model is shown in Fig. 4. The three parameters discussed above

FIG. 4—Electrical equivalent circuit model simulating a simple corroding metal/electrolyte interface. See also Fig. 5.  $R_s$  is the solution resistance.  $R_p$  is the polarization resistance.  $C$  is the double layer capacitance.

( $R_p$ ,  $R_s$ , and  $C$ ) that approximate a corroding electrochemical interface are shown. The algebraic sum of  $R_s$  and  $R_p$  is measured when a d-c measurement is performed. The impedance associated with a capacitor approaches infinity as the voltage scan rate approaches zero, and parallel circuit elements are always dominated by the element with the smallest impedance. Therefore, the sum of  $R_s$  and  $R_p$  is measured and the true corrosion rate will be underestimated when  $R_s$  is appreciable. Conversely, any experiment conducted at a fast voltage scan rate causes the algebraic sum of the ohmic resistance and the resultant impedance of the parallel resistive-capacitive network to be measured. This value will be lower than the sum of  $R_p$  and  $R_s$  determined at an infinitely slow scan rate, as current leaks through the parallel capacitive element at higher scan rate due to its low impedance at high frequency. This will usually result in an overestimation of the true corrosion rate. These complications can be overcome by using the electrochemical impedance method.

### Electrochemical Impedance Methods

One approach for determining the polarization resistance of a metal involves the electrochemical impedance (sometimes known as a-c impedance) method [2,37–41]. ASTM Standard G 106,<sup>5</sup> Practice for Verification of Algorithm and Equipment for Electrochemical Impedance Measurements, contains an appendix reviewing the technique. In this technique, typically a small-amplitude sinusoidal potential perturbation is applied to the working electrode at a number of discrete frequencies,  $\omega$ . At each one of these frequencies, the resulting current waveform will exhibit a sinusoidal response that is out of phase with the applied potential signal by a certain amount ( $\Phi$ ) and has a current amplitude that is inversely proportional to the impedance of the interface. The electrochemical impedance,  $Z(\omega)$ , is the frequency-dependent proportionality factor that acts as a transfer function by establishing a relationship between the excitation voltage signal and the current response of the system

$$Z(\omega) = V(\omega)/i(\omega) \quad (27)$$

<sup>5</sup>ASTM G 106, Practice for Verification of Algorithm and Equipment for Electrochemical Impedance Measurements.

where

$V$  = the time varying voltage across the circuit,  $V = V_o \sin(\omega t)$ ,

$i$  = the time varying current density through the circuit,  $i = i_o \sin(\omega t + \Phi)$ ,

$Z(\omega)$  = the impedance,  $\Omega\text{-cm}^2$ , and

$t$  = time, s.

$Z(\omega)$  is a complex-valued vector quantity with real and imaginary components whose values are frequency-dependent

$$Z(\omega) = Z'(\omega) + jZ''(\omega) \quad (28)$$

where

$Z'(\omega)$  = the real component of impedance,  $Z'(\omega) = |Z(\omega)|\cos(\Phi)$ ,

$Z''(\omega)$  = the imaginary component of impedance,  $Z''(\omega) = |Z(\omega)|\sin(\Phi)$ ,

$j^2$  = the square of the imaginary number,  $-1$ ,

$|Z(\omega)|$  = the impedance magnitude, where  $|Z(\omega)| = (Z'(\omega)^2 + Z''(\omega)^2)^{1/2}$

The electrochemical impedance is a fundamental characteristic of the electrochemical system it describes. A knowledge of the frequency dependence of impedance for a corroding system enables a determination of an appropriate equivalent electrical circuit describing that system. Table 1 shows the transfer functions for resistors, capacitors, and inductors.

Figure 4 illustrates for a simple case the equivalent electrical circuit model for an actively corroding metal. The following expression describes the impedance for that system

$$Z(\omega) = R_s + R_p / (1 + \omega^2 R_p^2 C^2) - j\omega C R_p^2 / (1 + \omega^2 R_p^2 C^2) \quad (29)$$

where

$\omega$  = the frequency of the applied signal where  $\omega = 2\pi f$ , rad/s

$f$  = the frequency of the applied signal, Hz (cycles/sec),

$R_s$  = the solution resistance, and

$C$  = the interfacial capacitance,  $F/\text{cm}^2$ .

The Bode magnitude and phase information of Fig. 5 and Eq 29 show that at very low frequencies

$$Z\omega \rightarrow 0(\omega) = R_s + R_p \quad (30)$$

while at very high frequencies

$$Z\omega \rightarrow \infty(\omega) = R_s \quad (31)$$

Determination of  $R_p$  is attainable in media of high resistivity because  $R_p$  can be mathematically separated from  $R_s$  by taking the difference between  $Z(\omega)$  obtained at low and high  $\omega$  ( $R_p = Z(\omega \rightarrow 0) - Z(\omega \rightarrow \infty)$ ). Determination of the corrosion rate using Eq 25 also requires knowledge of  $\beta_a$ ,  $\beta_c$ , and electrode area,  $A$ , which are not obtained in the impedance experiment [42]. The minimum applied frequency required to obtain  $R_s + R_p$  can be approximated by

$$f_{min} < f_{bp} = \frac{1}{2\pi C(R_s + R_p)} \quad (32)$$

**TABLE 1**—Linear circuit elements commonly used in electrochemical impedance.

Circuit Element	Impedance
Resistor	$Z(\omega) = R$
Capacitor	$Z(\omega) = -j/\omega C$
Inductor	$Z(\omega) = j\omega L$

**FIG. 5**—Bode phase angle and magnitude plots demonstrating the frequency dependence of the electrochemical impedance for the circuit model shown in Fig. 4.

where

$f_{bp}$  = the lower breakpoint frequency approximated by the point on the  $\log |Z(\omega)|$  versus  $\log f$  plot where the low frequency plateau dominated by  $R_s + R_p$  and slope  $-1$  region dominated by capacitance produce equal values of  $Z(\omega)$ , Hz, and

$f_{min}$  = the minimum required test frequency required according to Eq 32, Hz.

Since the magnitudes of  $C$ ,  $R_s$ , and  $R_p$  are not known explicitly a priori, prudence dictates that  $f_{min}$  be selected as 0.1–0.5 of the estimated  $f_{bp}$ . Thus, large values of  $C$ ,  $R_s$ , or  $R_p$  dictate that a low  $f_{min}$  is required to accurately obtain  $R_p + R_s$  at  $Z(\omega) \rightarrow 0$ . One mHz is typically chosen as a reasonable initial choice of  $f_{min}$ , but it is obvious from Eq 32 that either a lower frequency may be required or a higher frequency permitted, depending on circumstances.

Either the anodic or cathodic half-cell reaction can become mass transport limited and restrict the rate of corrosion at  $E_{corr}$ . The presence of diffusion controlled corrosion processes does not invalid the EIS method, but does require extra precaution and a modification to the circuit model of Fig. 4. In this case, the finite diffusional impedance is added in series with the usual charge transfer parallel resistance shown in Fig. 4. The transfer function for the frequency dependent finite diffusional impedance,  $Z_D(\omega)$ , has been described [43]:

$$Z_D(\omega) = R_D \left[ \frac{\tanh \sqrt{(j\omega s)}}{\sqrt{(j\omega s)}} \right] \quad (33)$$

Here,  $s = l_{eff}^2/D$  where  $l_{eff}$  is the actual finite diffusion length and  $D$  is the diffusivity of the diffusing species that limits the interfacial reaction. The value of  $Z_D(\omega)$  approaches the real component of diffusional resistance,  $R_D$ , as  $\omega \rightarrow 0$ . The frequency required to obtain  $R_D$  depends on the value of  $s$ . The larger the value of  $s$ , such as when  $l_{eff}$  is large or  $D$  is small, the lower the frequency required.  $R_p$ , defined as  $[\partial E / \partial i_{app}]$  as  $\omega \rightarrow 0$ , is the sum of the charge transfer controlled,  $R_{ct}$  and diffusion controlled,  $R_D$ , contributions to the polarization resistance assuming that  $R_D + R_{ct} \gg R_s$ .

$$R_p = R_{ct} + R_D \quad (34)$$

A very low frequency or scan rate may be required to obtain  $R_p$  defined by Eq 34 under circumstances where reactions are mass transport limited, as indicated by Eq 32. Here, a  $l_{eff}$  of 0.1 cm and  $D = 10^{-5}$  cm<sup>2</sup>/sec requires that a frequency below 0.1 mHz be implemented to obtain  $R_p$  from  $|Z(\omega)|$  at the zero frequency limit. Hence, a common experimental problem in the case of diffusion controlled electrochemical reactions is that extremely low frequency (or scan rates) are required to complete the measurement of  $R_p$ . In the case where  $R_p$  is dominated by contributions from mass transport such that Eq 33 applies, the Stern approximation of Eqs 25 and 26 must be modified to account for a Tafel slope for either the anodic or cathodic reaction under diffusion controlled conditions (i.e.,  $\beta_a$  or  $\beta_c = \infty$ ). In fact, Eq 19 becomes invalid.

Similarly, a frequency above  $f_{max}$  must be applied to obtain  $R_s$ .

$$f > f_{max} = \frac{1}{2\pi C R_s} \quad (35)$$

where

$f_{max}$  = the frequency required such that  $Z(\omega)$  is dominated by  $R_s$ .

Typically,  $f_{app}$  must be in the kHz range to determine  $R_s$ . These issues equally plague time as well as frequency domain methods for obtaining  $R_p$ , since in the time domain measurement, the triangle waveform is simply the Fourier synthesis of a series of sinusoidal signal functions.

The capacitance is also determined from the impedance technique. In many corroding systems, an interfacial capacitance associated with the electrified double layer scales linearly with the true electrochemical surface area. An electrochemically based estimate of the surface area may be obtained if the area-specific capacitance is known or determined from the slope of a plot of  $C$  versus surface area [42].

A common issue in the use of impedance-derived capacitance concerns the use of constant phase elements (CPE). The impedance associated with a CPE has been given by the following expression [44]:

$$Z_{CPE}(\omega) = \left( \frac{1}{Y_o (j\omega)^n} \right) \quad (36)$$

$Y_o$  and  $n$  are usually assumed to be frequency independent parameters. The units for  $Y_o$  are s<sup>n</sup>/ohm, while those for capacitance ( $C$ ) are s/ohm. Hence, in the case of an ideal

capacitor or resistor,  $n = 1$  or 0, respectively, and either the magnitude of  $Y_o$  equals the magnitude of  $C$  with the dimensions s/ohms or  $1/Y_o = R$  (ohms). In the case of  $n = 0.5$ , an infinite diffusional impedance best describes the constant phase element. At issue is the task of extracting physically meaningful parameters conveyed by the capacitance in the case of impedance data that is best represented in an electrical circuit model by a constant phase element. Examples of such parameters extracted from ideal interfacial capacitance include electrode area in the case of a double layer capacitance, surface coverage in the case of an adsorption pseudo-capacitance, and dielectric constant or dielectric layer thickness in the case of a coating or oxide with dielectric properties. Other parameters may be extracted from capacitance associated with solid state impedance experiments, but these are beyond the scope of the present paper. In the case where  $n = 0.8-0.99$ , the CPE is often treated as a nonideal capacitance value, and attempts are made to extract physically meaningful parameters from the CPE data. One equation proposed to convert  $Y_o$  into  $C$  is [45]:

$$C = Y_o (\omega''_{max})^{n-1} \quad (37)$$

where  $\omega''_{max}$  is the frequency where the imaginary component of impedance,  $Z''$ , is maximized. This frequency is independent of  $n$ . In an earlier approach,  $C = Y_o (\omega)^{n-1} / \sin(n\pi/2)$  was suggested as a method for extracting capacitance,  $C$ , from  $Y_o$ , where  $\omega$  was taken as the frequency where the phase angle was maximized [46]. This method has the disadvantage that the exact value of  $\omega$  associated with the phase angle maximum changes with the value of  $n$ .

## Frequency Modulation Methods

Both harmonic and electrochemical frequency modulation (EFM) methods take advantage of nonlinearity in the E-I response of electrochemical interfaces to determine corrosion rate [47-50]. A special application of harmonic methods involves harmonic impedance spectroscopy [51]. The EFM method uses one or more a-c voltage perturbations in order to extract corrosion rate. The electrochemical frequency modulation method has been described in the literature [47-50] and has recently been reviewed [52]. In the most often used EFM method, a potential perturbation by two sine waves of different frequencies is applied across a corroding metal interface. The E-I behavior of corroding interfaces is typically nonlinear, so that such a potential perturbation in the form of a sine wave at one or more frequencies can result in a current response at the same and at other frequencies. The result of such a potential perturbation is various AC current responses at various frequencies such as zero, harmonic, and intermodulation. The magnitude of these current responses can be used to extract information on the corrosion rate of the electrochemical interface or conversely the reduction-oxidation rate of an interface dominated by redox reactions as well as the Tafel parameters. This is an advantage over LPR and EIS methods, which can provide the  $Z(\omega)$  and, at  $\omega = 0$ , the polarization resistance of the corroding interface, but do not uniquely determine Tafel parameters in the same set of data. Separate experiments must be used to define Tafel parameters. A special extension of the method involves

**TABLE 2**—Governing equations for extraction of  $i_{corr}$ , as well as  $b_a$  and  $b_c$ , from harmonic and intermodulation frequency data [52].

Reaction Type	Governing Equation	Determination of $i_{corr}$	Determination of Tafel Parameters
Charge transfer control Tafel behavior	Eq 19	$i_{corr} = \frac{i_{\omega_1\omega_2}^2}{2\sqrt{8i_{\omega_1\omega_2}i_{2\omega_2\pm\omega_1} - 3i_{\omega_2\pm\omega_1}^2}}$	$b_a = \frac{i_{\omega_1\omega_2}V_o}{i_{\omega_1\omega_2} + \sqrt{8i_{\omega_1\omega_2}i_{2\omega_2\pm\omega_1} - 3i_{\omega_2\pm\omega_1}^2}}$ similar expression for $b_c$
Passive or Anodic mass transport control	$i = i_{corr} \left[ 1 - \exp\left(\frac{-\eta}{b_c}\right) \right]$	$i_{corr} = \frac{i_{\omega_1\omega_2}^2}{2i_{\omega_2\pm\omega_1}}$	$b_c = \frac{i_{\omega_1\omega_2}}{2i_{\omega_2\pm\omega_1}} V_o$
Cathodic mass transport control	$i = i_{corr} \left[ \exp\left(\frac{\eta}{b_a}\right) - 1 \right]$	$i_{corr} = \frac{i_{\omega_1\omega_2}^2}{2i_{\omega_2\pm\omega_1}}$	$b_a = \frac{i_{\omega_1\omega_2}}{2i_{\omega_2\pm\omega_1}} V_o$

Note that  $b_a = \beta_a/\ln 10$ , and  $b_c = \beta_c/\ln 10$   
 $i_{2\omega_1\pm\omega_2}$  can be evaluated at  $i_{2\omega_1+\omega_2}$  or  $i_{2\omega_1-\omega_2}$   
 $i_{\omega_1\pm\omega_2}$  can be evaluated at  $i_{\omega_1+\omega_2}$  or  $i_{\omega_1-\omega_2}$   
 $i_{\omega_1\omega_2}$  can be evaluated at  $i_{\omega_1}$  or  $i_{\omega_2}$

harmonic impedance spectroscopy where the harmonic currents are converted to harmonic impedance values at various frequencies through knowledge of the magnitude of the a-c perturbation.

In the EFM method, an a-c voltage perturbation is applied at two frequencies,  $\omega_1$  and  $\omega_2$ . As an example, the voltage perturbation could be given as:

$$\eta = V_o [\sin(\omega_1 t) + \sin(\omega_2 t)] \quad (38)$$

where

$$\eta = E - E_{corr}$$

$V_o$  = the magnitude of the voltage amplitude applied.

Harmonic current responses occur at  $\omega_1$ ,  $2\omega_1$ ,  $3\omega_1$ , as well as at  $\omega_2$ ,  $2\omega_2$ , and  $3\omega_2$ , etc. Additionally, a current response can be seen at various intermodulation frequencies, such as  $2\omega_1\pm\omega_2$  and  $2\omega_2\pm\omega_1$ . Consider the application of this method to a charge transfer controlled corrosion process with an E-I response that behaves according to Eq 19. Under the assumption that  $\omega_2 > \omega_1$  and  $\beta_a < \beta_c$ , the corrosion current density,  $i_{corr}$ , and Tafel parameters,  $b_a$  (where  $b_a = \beta_a/\ln 10$ ) and  $b_c$ , can be determined from the equations summarized in Table 2. The current components at the angular frequency  $\omega_1$  or  $\omega_2$  can be measured at  $\omega_1$  or  $\omega_2$ . The intermodulation components  $\omega_1\pm\omega_2$  can be determined from the signal response at  $\omega_1+\omega_2$  or  $\omega_1-\omega_2$ , etc. The method is one of the few that enables extraction of corrosion rate and Tafel parameters directly from a single measurement (see Refs 29 and 30). Currently, there are no ASTM standards for this technique.

### Electrochemical Noise Resistance

Electrochemical noise analysis can provide a parameter called the electrochemical noise resistance,  $R_n$ , [53–59]. It is desirable to utilize this parameter in an analogous fashion as the polarization resistance. One electrode configuration that enables such a measurement involves connecting a zero resistance ammeter between two nominally identical corroding electrodes immersed in the same solution. A third, nominally identical electrode can be immersed in solution and connected to the first two using a high impedance voltmeter. This electrode serves as a “noisy” pseudoreference electrode. This approach is attractive in field applications due to the more rugged nature of the metallic electrode compared to laboratory electrodes, but complicates the analysis

because two uncorrelated potential sources (i.e., from the couple and the pseudoreference) are measured in the collection of potential noise,  $V_n$ . Since  $V_{n(meas)} = (V_{n(couple)} + V_{n(pseudo-ref)})^{1/2}$ ,  $V_{n(meas)}$  must be divided by 2 [60] to yield  $V_{n(couple)}$ . Another alternative is a four electrode arrangement where the first pair is coupled through a zero resistance ammeter to monitor current, and the second pair is connected with a high impedance voltmeter to sample an uncorrelated  $V_{n(couple)}$ . Alternatively, a less noisy, conventional reference electrode may be utilized in the three electrode arrangement. In this case  $V_{n(meas)}$  and  $I_{n(meas)}$  are correlated. The reference electrode noise can be separately defined as the electrochemical voltage noise between two nominally identical reference electrodes [61]. If the reference electrode noise is low, then the correction factor of 2 is not needed. In either case, the third electrode (reference electrode) is connected to the first two via a high impedance voltmeter. These arrangements enable simultaneous recording of the galvanic current with time and the galvanic couple potential versus time. The standard deviation of the voltage noise divided by the standard deviation of the current noise has been proposed to yield a statistical parameter called the noise resistance  $R_n$  [53–60,62]. Analysis of simulated noise data has led to the conclusion that the ratio of the standard deviations of the current and voltage noises measured between two identical electrodes can be normalized by surface area by multiplying by the square root of  $A_v A_i$  [59]:

$$R_n (\text{ohm-cm}^2) = \left[ \frac{\sigma_{V(meas)}}{\sigma_{I(meas)}} \right] \sqrt{A_v A_i} \quad (39)$$

where  $\sigma_{V(meas)}$  is the standard deviation of the voltage noise,  $\sigma_{I(meas)}$  is the standard deviation of the current noise, and  $A_v$  and  $A_i$  are the surface areas of the corroding electrodes used for voltage and current measurement, respectively. Correlations between this parameter and conventionally determined polarization resistance, as well as mass loss-based corrosion rates, have been obtained [54,60]. Unfortunately, experimental confirmation of the area normalization factor has not been extensively performed. Recall that in the case of a polarization resistance determined from  $E-i_{app}$  data or EIS data at the zero frequency limit, measured resistance can be multiplied by electrode area and will yield the same area-normalized polarization resistance over a broad range of electrode areas.

Moreover, the correlation has lacked a rigorous fundamental foundation for correlating  $R_n$  with corrosion rate, despite the intuitive connection between  $\sigma_V$  and  $\sigma_I$  given by the proportionality factor  $R_n$ . The surface of one freely corroding electrode could be divided into areas that experience fluctuations in interfacial resistance that produce changes in anodic and cathodic half-cell reaction rates in any one patch. The electrode potential must then change in each patch to drive the half-cell reactions, such that the sum of all the anodic half-cell currents from all patches equals the sum of all cathodic half-cell currents, regardless of whether the source of cathodic half-cell current is from capacitive discharge or electrochemical reaction [58]. Some global change in potential also occurs on the electrode. If the first electrode is now connected to a second electrode whose interfacial properties and global electrode potential don't change on their own at the same instant in time and by the same degree as on the first electrode, then a galvanic cell is momentarily created which induces a further difference in anodic and cathodic half-cell currents on the first electrode. Current now flows between the first and second electrode, such that the sum of anodic and cathodic half-cell currents over all patches on both electrodes is equal. When the interfacial resistances return to normal values over all patches, the potential difference between the two electrodes is eliminated and so is the measurable current between the two electrodes. Bertocci argued that the external current fluctuation measured between two identical electrodes is identical to the fluctuation in one electrode [58,59]. Others have argued using concepts of mixed potential theory that, at worst, the current sampled is only one half of the total for equal size electrodes.

Theoretical relationships establishing the connection between  $R_n$  and  $R_p$  have been sought by several researchers [59,63–66], but their validity has been questioned. A great concern has been that the largest current peaks would occur during the most rapid voltage fluctuations, since the electrode interface contains a capacitance through which current can be shorted [58,59]. Thus, when voltage fluctuations are rapid, the measured noise current will be shorted through the interfacial capacitance, assuming a simple electrical equivalent circuit model consisting of a two parallel resistor-capacitor network describing the interface for each electrode connected in series through  $R_s$ . This situation would lead to the lowest impedance between the two electrodes during the most rapid voltage fluctuations that, in turn, produce the greatest current fluctuations. The theoretical maximum measured current would be given by the voltage fluctuation divided by  $R_s$ . The outcome would be a statistical noise resistance parameter that is proportional to, or heavily influenced by, higher frequency data. Indeed,  $R_n$  was found to equal an absolute impedance at some frequency that depended on the frequency of the voltage fluctuations and the RC time constant of the electrode interface in one study of simulated noise [58]. Unfortunately, a  $R_n$  value obtained at high frequency would be smaller in magnitude than the  $R_p$  obtained at the zero frequency limit. Hence, it would not represent the desired zero frequency limit interfacial resistance,  $R_p$ . Indeed, such underestimations in the true value of  $R_p$  have been observed experimentally [60,62].

FIG. 6— $R_{sn}(\omega)$  versus frequency for iron in 1 M  $\text{Na}_2\text{SO}_4$  at pH 4 with a “noisy” iron reference electrode compared to two times the impedance  $|Z(\omega)|$  versus frequency using the EIS method. Impedance measurements were performed in a two electrode cell with two iron electrodes to produce  $2|Z(\omega)|$ . The value of  $R_{sn}(\omega)$  calculated is equal to  $\sqrt{3}|Z(\omega)|$  for the case of two iron electrodes coupled through a ZRA and a third iron electrode as reference electrode [71].

Recently, a more rigorous theoretical and experimental analysis has been made comparing the spectral noise resistance obtained at each frequency with both the polarization resistance obtained from the zero frequency limit of impedance data  $|Z(\omega=0)|$  as well as the frequency dependent impedance of two electrodes [67–71]. The spectral noise resistance  $R_{sn}(\omega)$  was determined by taking the square root of power spectral density of the voltage noise  $(V^2/\text{Hz})^{1/2}$  and dividing it by the square root of power spectral density of the current noise  $(A^2/\text{Hz})^{1/2}$  at each frequency using the same two-electrode arrangement as discussed above [70,71].

$$R_{sn}(\omega) = \frac{\sqrt{(V_{PSD})}}{\sqrt{(I_{PSD})}} \quad (40)$$

$R_{sn}(\omega)$  is proportional to the magnitude of the cell impedance,  $|Z(\omega)|$  in the two electrode arrangement [70,71]. The proportionality factor is unity in the case of identically-sized electrodes in a two electrode cell with identical impedances and a noise-less reference electrode [70,71]. Therefore, the spectral noise resistance at the zero frequency limit equals the interfacial impedance at the zero frequency limit  $|Z(\omega=0)|$  in the theoretical case of identical electrode impedances with negligible  $R_s$ . In this case  $R_{sn}(0) = R_p$ . Figure 6 illustrates data for identical Fe electrodes in 1 M  $\text{Na}_2\text{SO}_4$  with an iron reference electrode. Here  $R_{sn}(\omega) = \sqrt{3}|Z(\omega)|$  due to the noisy RE. Thus,  $2|Z(\omega)|$  and  $R_{sn}(\omega)$  appear to be similar. For a corroding system,  $|Z(\omega=0)|$  equals  $R_p$ . For a corroding system  $R_{sn}(0) = R_p$ . Even  $R_n$  may equal  $R_{sn}(\omega=0) = |Z(\omega=0)| = R_p$  if  $|Z(\omega)|$  equals  $R_p$  in the frequency regime dominating

the  $R_n$  value. The frequency range dominating the  $R_n$  value is determined by several factors, but this statement is more likely to be true if  $|Z(\omega)|$  and  $R_{sn}(\omega)$  both exhibit long low frequency plateaus over a broad frequency range that encompasses the  $f_{min}$  and  $f_s$  utilized in the  $R_n$  measurement. Here  $f_{min}$  is given by the total sampling time,  $T$ , where  $f_{min} = 1/T$  and  $f_s$  equals the data sampling rate.  $R_n$  typically varies with  $f_s$  and underestimates  $|Z(\omega = 0)|$ . Unfortunately,  $R_{sn}(\omega \rightarrow 0)$  does not equal  $R_p$  in the zero frequency limit under many other conditions, such as when  $\log(R_s/R_p) > 0$  or in the case of very noisy reference electrodes [70,71]. Moreover,  $R_{sn}(\omega)$  can be dominated by the properties of the high impedance electrode in the case of dissimilar electrode impedances that are equally noisy, but this is not always the case. For instance, the low impedance electrode in a two electrode cell with a third reference electrode can be sensed by  $R_{sn}(\omega)$  if the higher impedance electrode is much noisier than the low impedance electrode [70,71]. Recent attempts have been made to address circumstances where  $R_{sn}(\omega)$  lies in between  $|Z(\omega)|_1$  and  $|Z(\omega)|_2$  representing the high and low impedance electrodes. Methods have been suggested for sensing the current fluctuations on both electrodes [72]. The reader is referred to these articles for further information.

## ELECTROCHEMICAL METHODS FOR THE STUDY OF GALVANIC CORROSION

Galvanic corrosion is defined and described in Section IV of this manual on corrosion types.

### Methods Based on Mixed-Potential Theory

The thermodynamic tendency for galvanic corrosion may be determined from the electromotive series [5] or from the construction of a galvanic series as discussed in ASTM G 82,<sup>6</sup> Guide for Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance. Galvanic corrosion rates can also be determined from mixed-potential theory as schematically illustrated in Fig. 7. In the case of bimetal or multimetal galvanic attack in which two or more metals are electrically in contact with one another, there is in theory a minimum of two cathodic and two anodic reactions. One of each of these reactions is occurring on each metal. In this case, the more noble of the two metals is cathodically polarized, and its anodic reaction rate will thus be suppressed. Conversely, the less noble or anodic material is anodically polarized and the anodic reaction rate is accelerated. The mixed potential (the galvanic couple potential,  $E_{couple}$ ) of the galvanic couple and the resulting galvanic current can be uniquely determined from the sums of all of the individual anodic and cathodic currents obtained for each material at each potential when the following condition is met

$$\sum i_a A_a = \sum i_c A_c \text{ at } E_{couple} \quad (41)$$

where

$i_a, i_c$  = the anodic and cathodic current densities,  $\mu A/cm^2$ , and  
 $A_a, A_c$  = the anodic and cathodic areas,  $cm^2$ .

<sup>6</sup>ASTM Standard G 82, Guide for Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance.

FIG. 7—Potential-current relationships for the case of a galvanic couple between two corroding metals. Steel is the more noble metal, zinc is the less noble metal [5]. The corrosion rate of zinc is increased significantly when coupled while the corrosion rate of steel is decreased.

The galvanic couple potential is defined by the potential where the sum of the anodic currents equals the sum of the cathodic currents for all reactions on all of the metals in the couple. The galvanic couple potential can be determined either by direct measurement with a reference electrode or from polarization data if:

1. Polarization data are available for each material in the galvanic couple,
2. The area of each metal is known, and
3. The current distribution is uniform.

Once  $E_{couple}$  is determined, the galvanic corrosion rate may be estimated for the metal of interest in the couple if a relationship such as given in Eq 19 is known for that metal. In simple bimetal cases, direct superposition of polarization data (corrected for wetted surface area) can yield  $E_{couple}$  and the galvanic corrosion rate [73]. However, because applied currents instead of true anodic or cathodic currents are measured in any polarization experiment, the E-log(I) superposition technique will introduce the least error when the cathodic reduction reaction rate on the anode is negligible and the anodic oxidation reaction rate on the cathode is negligible at the galvanic couple potential. Obviously, when the OCPs of the anode and cathode are similar, error is more likely. Fortunately, galvanic corrosion may be less significant in these cases. In addition, special care must be taken in the procedures used to develop the polarization data [73], especially if time effects are to be taken into consideration when evaluating long-term galvanic corrosion behavior.

### Direct Measurement of Galvanic-Corrosion Rates

A more straightforward procedure involves immersing the two dissimilar metals in an electrolyte and electrically

connecting the materials together using a zero-resistance ammeter to measure the additional galvanic current [9, 74,75]. In this method, the galvanic current is directly determined as a function of time. The galvanic corrosion rate so determined is the additional corrosion created with the couple and will not equal the true corrosion rate. This is given by the sum of the galvanic corrosion rate and the corrosion rate under freely corroding conditions, unless the latter is negligible. Recall that the corrosion rate of the uncoupled anode is undetermined by this method, since an equal cathodic reaction rate is occurring on the same surface. A reference electrode connected to the galvanic couple can be used to determine the galvanic couple potential. ASTM standards do not exist for direct measurement of galvanic corrosion or scanning potential probe methods.

### Potential Probe Methods

Potential probe methods may be used to determine and map the local ionic currents associated with galvanic corrosion cells between dissimilar metals or heterogeneities on complex alloy surfaces [76–79]. In the most straightforward application, the local potential is mapped over a planar electrode oriented in the x-y plane to give an indication of local current. The basic concept is that the ionic current density in three dimensions can be mapped by either scanning an array of reference electrodes or by vibrating a single electrode. The following equation expresses the orthogonal ionic current flow in terms of solution conductivity and the gradient in potential in the solution above the galvanic couple,

$$i = -\kappa(\nabla E) \quad (42)$$

where  $\kappa$  is the solution conductivity and  $\nabla E = \delta_1 dE/dx + \delta_2 dE/dy + \delta_3 dE/dz$ , where  $x, y, z$ , define axes in a coordinate system and  $\delta_i$  are unity vectors. The advantage of the vibrating technique is that minor differences between the reference potential of separate electrodes is eliminated by using a single vibrating reference electrode. The ionic current density so recorded is the component of current density flowing perpendicular to iso-potential lines in solution established due to the galvanic couple and the established potential gradient. Therefore, a map of local current can be constructed by scanning over a planar electrode in the x-y plane, where  $z$  is the vertical distance in the solution above the electrode. Locations of high local current imply significant galvanic interactions.

## ELECTROCHEMICAL METHODS FOR THE STUDY OF PASSIVITY AND LOCALIZED CORROSION

Pitting and crevice corrosion are associated with the breakdown of passivity [80]. Electrochemical tests for evaluating the susceptibility of a material to pitting and to crevice corrosion include potentiodynamic, potentiostatic, scratch potentiostatic, potentiostaircase, tribo-ellipsometric methods, pit-propagation rate curves, galvanostatic, and electrochemical noise measurements [80–82].

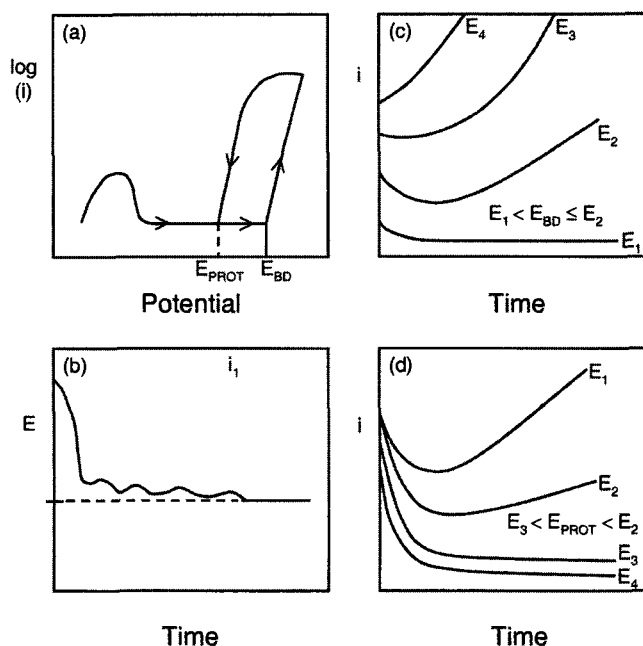

FIG. 8—Schematic representations of experimental data for (a) a cyclic potentiodynamic polarization curve; (b) galvanostatic potential-time curve for a material; (c) potentiostatic current-time curve for a previously passivated surface which pits at  $E_1 < E_{bd} < E_2$ ; and (d) potentiostatic current-time curve for active surface. The protection potential is found as  $E_3 < E_{prot} < E_2$  [80].

### Cyclic Potentiodynamic Polarization Methods to Determine $E_{bd}$ and $E_{prot}$

ASTM G 61<sup>7</sup> describes a procedure for conducting cyclic potentiodynamic polarization measurements to determine relative susceptibility to localized corrosion. The method is designed for use with iron- or nickel-based alloys in chloride environments. In this test, a cyclic anodic polarization scan is performed at a fixed voltage scan rate. Figure 8a shows a schematic of the cyclic potentiodynamic method. Particular attention is focused on two features of cyclic polarization behavior (Fig. 8a). The first is the potential at which the anodic current increases significantly with applied potential (the breakdown potential,  $E_{bd}$ ). In general, the more noble this potential, obtained at a fixed scan rate in this test, the less susceptible the alloy is to the initiation of localized attack. The second feature of great interest is the potential at which the hysteresis loop is completed during reverse polarization scan after localized corrosion propagation. This potential is often taken as the repassivation potential or protection potential,  $E_{prot}$ . In general, once initiated, localized corrosion sites can propagate only at some potential more positive than the potential at which the hysteresis loop is completed (when determined at a fixed scan

<sup>7</sup>ASTM Standard G 61, Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-Based Alloys.

rate). In other words, repassivation will occur at more negative potentials, even after localized corrosion initiation. Therefore, the more positive the potential at which the hysteresis loop is completed, the less likely that localized corrosion will propagate. Additionally, the difference in potential between  $E_{corr}$  and  $E_{prot}$  ( $E_{prot} - E_{corr}$ ) is often taken to indicate relative resistance to local corrosion. ASTM G 61 illustrates cyclic polarization behavior for Hastelloy C-276 and 304 stainless steel in 3.5 % sodium chloride solution. Based on this criterion, it is evident that Hastelloy C-276 is more resistant to localized corrosion in this environment than AISI 304 stainless steel.

### Complications with Cyclic Potentiodynamic Polarization Methods

Although the cyclic method is a reasonable method for screening variations in alloy composition and environments, the cyclic potentiodynamic polarization method has been found to have a number of shortcomings [80–85]. One major problem concerns the effect of the potential scan rate. The values of both  $E_{bd}$  and  $E_{prot}$  are a strong function of the manner in which the tests are performed, particularly the potential scan rate employed. Experimental values of  $E_{bd}$  are linked to the induction time required for pitting. Another complication arises from allowing too much pitting propagation to occur before reversing the scan direction. This either alters the localized chemistry in pits, affects pit depth, or both. Pit depth alters the diffusion length associated with the dilution of pit chemistry necessary for repassivation. This factor affects the polarization behavior after the reversal in the direction of scanning and influences  $E_{prot}$ . From an engineering standpoint, metal surfaces held at potentials below the repassivation potential of the deepest pits should be safe against stable pit propagation. That is to say, stable pits should not propagate. It has been found that  $E_{bd}$  observed after potentiostatic holds or the slowest scan rates approaches the protection potential found after minimal pit growth when pits are small [85]. This suggests the existence of a single critical potential,  $E_c$ , for pit initiation and growth in the absence of crevices or other occluded sites [85]. If the potential can be maintained below  $E_c$ , pitting does not occur.

### Potentiostatic and Galvanostatic Methods for Localized Corrosion

The shortcomings of the cyclic potentiodynamic polarization method have become the basis for several other electrochemical techniques. Other methods are schematically illustrated in Fig. 8. In the galvanostatic or galvanostaircase technique (Fig. 8b), potential is measured versus time at various constant applied currents that are incrementally increased in steps, then reversed and decreased. In the case of passive materials, a potential rise during galvanostatic testing indicates passive film growth, while a decline indicates breakdown and growth of local corrosion sites. In the galvanostaircase technique, the current is step increased. Potential measurements are made until the time rate of change in potential approaches zero. These forward and reverse potential-current density data are extrapolated to the zero current density to obtain  $E_{bd}$  and  $E_{prot}$ . The technique

is described by ASTM G 100<sup>8</sup> (Method of Conducting Cyclic Galvanostaircase Polarization) as a test method for aluminum alloys. Potentiostatic methods can overcome the inherent problems involving scan rate. A more conservative estimate of  $E_{bd}$  can be obtained by polarizing individual samples for long periods of time at potentials above and below the values of  $E_{prot}$  and  $E_{bd}$  previously determined from the potentiodynamic method (Fig. 8c). Eventual initiation is indicated by a current increase. In another approach (Fig. 8d), initiation of pits is intentionally induced by applying a “stimulation” potential well above  $E_{bd}$  and then quickly shifting to a preselected potential below that value. If this second applied potential is above  $E_{prot}$ , propagation of the existing pits will continue and the current will increase. However, at potentials less than  $E_{prot}$  the pits will eventually repassivate and the current will subsequently decrease with time. The critical potential for pitting is defined as the most noble potential at which pits repassivate after the stimulation step. This approach is covered in ASTM F 746<sup>9</sup> (Test Method for Pitting or Crevice Corrosion of Metallic Surgical Implant Materials).

### Determination of $E_{prot}$ by Potential Step-down or Scan-down Methods

As stated above,  $E_{bd}$  and  $E_{prot}$  often depend strongly on the method by which they are determined and, therefore, do not uniquely define intrinsic material properties. The  $E_{prot}$  values determined from the scanning method can be complicated by scan rate, pit size or depth, vertex potential/current, polarization curve shape, and specimen geometry [86,87]. Investigators have found more consistent  $E_{prot}$  values after a critical charge has passed, while others report a single critical potential [85]. Often this potential is difficult to choose from E-I data and has been taken at various points on the reverse scan of a cyclic potentiodynamic polarization curve [89].

What is needed is a method for determination of  $E_{prot}$  that defines a conservative value of this potential that likely reflects a true pit or crevice repassivation potential. Tsujikawa has developed a method for determination of  $E_{prot}$  from previously grown pits and crevices [90,91]. This method and its variations have been successfully used by several research groups and associates the critical potential for repassivation  $E_{prot}$  with the need to grow local corrosion sites to a critical minimum size [92]. The method is an enhancement of the determination of  $E_{prot}$  from potentiodynamic E-I scans that involve scan reversal to the point where pits are repassivated. In the potential step-down method, the potential is first set at a high enough value to induce and grow stable pits to the specified size. The potential can then be stepped down or scanned downward, while the pit propagation current is recorded. Subsequently, the potential may be held after a pit has been initiated in order to determine the time until repassivation [93]. Moreover, long potential holds at selected applied potentials enable confirmation of a true

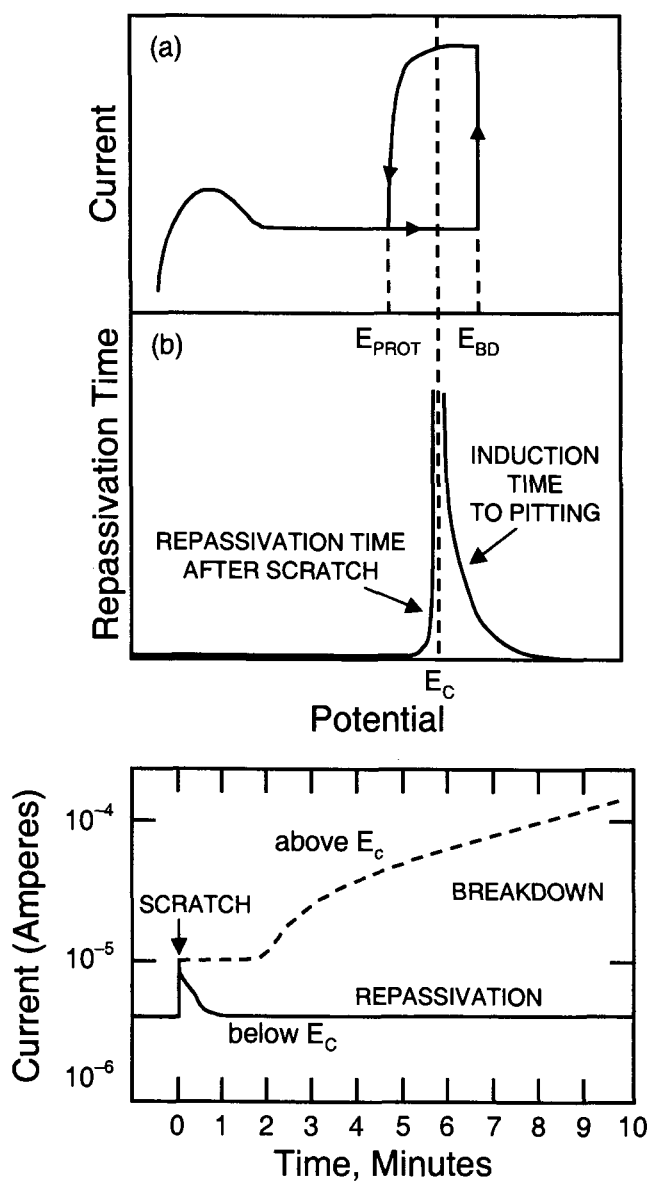

FIG. 9—(a)  $E$ -log( $i$ ) curve showing location of  $E_{bd}$  and  $E_{prot}$ . (b) Time versus applied potential plot from scratch test illustrating a possible location of the critical potential,  $E_c$ , as it relates to the induction time and the repassivation time [80]. (c) Current versus time plot for a scratched specimen when scratched above and below  $E_c$ .

repassivation potential, often indicated by an abrupt decrease in current density at the time when the chemical conditions favoring pit stability (often expressed as some fraction of the salt saturation concentration) are no longer maintained. Abrupt transitions in finite repassivation time towards infinity with increasing hold potential may indicate that conditions favorable to pit growth are sustained. Another benefit of determining  $E_{prot}$  from controlled growth of pits and crevices is that the repassivation potential can be determined from pits of preselected sizes that can be controlled by the duration of the potential holds. The method

has been successfully applied to nickel-base alloys, stainless steels, and Al-base alloys, and is being standardized by the committee for Japanese Industrial Standards. When a one-dimensional pit or pencil electrode is tested, the pit propagation kinetics can be recorded from a single pit [94]. Whether pit growth is ohmic, mass transport, or charge transfer controlled may also be determined. Moreover, the effects of various material and solution parameters (e.g., flow rate, conductivity, and solution composition) on pit propagation rates can be determined.

### The Scratch-Repassivation Method for Localized Corrosion

An additional potentiostatic technique to be mentioned in the area of localized corrosion involves the scratch method [95]. In this method, the alloy surface is scratched at a constant potential and the current is measured as a function of time. The potential dependencies of the induction time and the repassivation time are determined by monitoring the current change over a range of different potentials. This is illustrated in Fig. 9. From this information the critical pitting potential,  $E_c$ , thought to be more negative than  $E_{bd}$  determined by potentiodynamic scan, can be determined. Other methods of studying localized corrosion are also available [80]. An ASTM standard exists for the critical pitting temperature measurement method under the designation ASTM G 150.<sup>10</sup>

### Statistical Distributions in Critical Potentials

$E_{bd}$  is typically observed to be a significantly "statistically distributed" property compared to the repassivation potential. This is often observed when critical potentials are determined by potentiodynamic scanning, but also can be observed during potentiostatic tests where the pit incubation time and subsequent survival probabilities are also seen to be distributed.  $E_{prot}$  distributions are often attributed to distributions in pit size. However,  $E_{prot}$  is not distributed when pits are uniformly large [88] and may not depend on the depth of corrosion damage at all during crevice corrosion when a crevice former controls mass transport [96]. Statistical distributions in pitting potentials have been observed for AISI 304 [97], Fe-Cr-X (where  $x$ =Nb, Mo, or Ti) alloys [98], AISI 316 [99], Ti [100], high purity Al [101], AA 2024-T3 [102], and amorphous Al-base alloys [103]. These statistical distributions imply that significant variations exist when a number of specimens are tested under identical conditions. These distributions have been attributed to the stochastic nature of pitting [99], distributions in oxide film cation vacancy transport properties [104], the effects of potential on the nature of the eligible sites for the metastable pit nucleation process [97], and the population of fatal flaws or pit initiating defects on an electrode surface [105]. The possibility that oxide defects at densities exceeding millions of sites/cm<sup>3</sup> produces specimen-to-specimen variations appears unlikely for specimens with surface areas of the order of cm<sup>2</sup>. It appears to be more reasonable to expect that

<sup>10</sup>ASTM Standard G 150, Test Method for Electrochemical Critical Pitting Temperature Testing of Stainless Steels.

sample-to-sample variations are, instead, associated with distributions in the population of micrometer scale defects, such as sulfide inclusions in stainless steel [106] and constituent particles in Al alloys [105] that control the density of pit nucleation sites and produce micropit to micropit variations in growth rates and diffusive transport characteristics (e.g.,  $D_{eff}$ , pit shape) for a large population of metastable pits grown at a single potential. A statistical distribution of the product  $i_{pit} * r_{pit}$  (where  $i_{pit}$  is the pit current density and  $r$  is pit radius) was observed for a large population of pits at a fixed potential in high purity Al [101]. This product is linearly related to the acid pit chemistry. Although not rigorously proven, it is reasonable to argue that a slightly slower rate of pit transport or slightly larger  $i_{pit} * r_{pit}$  product for a given pit might lead to pit stabilization through achievement of the critical acid pit chemistry at different applied potentials on an electrode with a population of pits sites. Moreover, such behavior is likely controlled by micrometer scale defects spaced at tens of micrometer lateral separation distances across planar electrode surfaces. Investigators seeking information on critical potentials for engineering use should consider appropriate specimen sizes relative to critical defect densities and spacings. There are no ASTM standards that address these issues. However, the sizes of test specimens recommended in many ASTM standards are conservatively large so as to include many possible pit sites.

### Electrochemical Noise Methods

Electrochemical noise (EN) methods are used increasingly as a nondestructive tool for evaluating susceptibility to localized corrosion as well as stress-corrosion cracking (SCC), particularly in field or process plant applications [107–112]. EN is appealing because it may be conducted at open circuit without perturbing the corroding system. However, currently no consensus exists as to the most appropriate test procedure or analysis method, or how well results correlate with coupon exposures. The origins of EN current and potential signals are discussed in more detail in the chapter on Testing for Corrosion Types: Pitting. The transient development of bare metal at newly formed pit or cracking sites as a result of temporary propagation and repassivation can result in potential noise (open circuit EN), current noise (potentiostatic EN), or both. In the latter case, the current noise is measured with a zero resistance ammeter (ZRA) used to monitor a galvanic couple consisting of two identical electrodes, while the potential noise comes from the reference electrode (or, third metallic electrode) monitoring the couple potential. The noise signal, hereafter referred to as a potential or current time record, is caused by the galvanic couple formed between the very small anode sites corroding at current densities (c.d.) approaching 10 A/cm<sup>2</sup> in pitting corrosion and the much larger remaining cathode surface operating at lower cathodic current densities (c.d.) (e.g., 10 μA/cm<sup>2</sup>). Regarding pitting phenomena, a negative shift in measured potential is observed (OCP and galvanic couple EN), an increase in current is observed for potentiostatic EN, and current fluctuations of either polarity are observed for galvanic couple EN.

Several analysis methods exist, including electrochemical [113], statistical [111,112], spectral [107–110], and autocorrelation [109]. Some of the approaches for determination of spectral noise resistance during uniform corrosion are discussed above in the section on polarization resistance. Electrochemical analysis may also enable the determination of pit sizes from the charge associated with each pitting event [101], or from attempting to determine pit current densities. Statistical analyses include determining the root mean square (rms), variance, and standard deviations of the EN voltage or current time records, as well as a noise resistance,  $R_N$ , taken as the ratio of the rms or standard deviation of the potential and current time records acquired over various periods of time [111]. Spectral analysis consists of Fourier transformation of EN data acquired in the time domain to create a power spectral density plot [109, 110,112,114]. Qualitative assessment of the benefits of inhibitors, or the effects of process stream variations are made possible by comparing statistical or spectral results. Quantitative analysis and predictive capability still require further development.

### Use of Shot Noise Methods During Pitting

In the prepitting stage, multiple subcritical pitting events are often observed. The current time record shows exponential decaying or rising transients associated with discrete pitting events. In many systems these prepitting events occur at potentials far more negative than  $E_{bd}$  and sometimes  $E_{prot}$ . Numerous investigators have proposed that the ratio of peak pit current to pit radius during metastable pitting or product of pit current density times pit radius ( $I_{pit}/r_{pit}$  or  $i_{pit} * r_{pit}$ ) provides a insightful parameter that can be used to characterize the risk of stable pit propagation based on the critical acid pit chemistry theory of Galvele [115].

When anodic current is monitored near the pitting potential, multiple overlapping metastable pitting events are often detected as current spikes at potentials just below  $E_{bd}$ . EN analysis provides one method for extracting information on pitting from such complicated current time records. That is, the power spectrum for a population of spikes of similar amplitude and duration is the sum of the spectra for each spike and should have the same shape as an individual spike. The use of Shot noise analysis has been proposed to calculate the pit charge from power spectral density (PSD) analysis obtained from a current-time record [116–118]. According to this approach, pit charge,  $q_{pit}$ , and, through Faraday's Law the pit radius,  $r_{pit}$ , for the pit events that dominate the current-time record can be determined from the PSD of a pitting current noise spectrum. The following equation describes the theoretical power spectral density (PSD) of current fluctuations for the case of randomly occurring, exponentially decaying current spikes associated with metastable pitting events during the prepitting stage [115]:

$$\frac{I^2}{\Delta f} = \left[ \frac{2q_{pit}I_{mean}}{1 + (2\pi f\tau)^2} \right] \quad (43)$$

where  $f$  is the spectrum frequency,  $\Delta f$  is the frequency resolution given by the data acquisition frequency divided by the number of data points collected,  $q_{pit}$  is the pit charge,

$I_{mean}$  is the mean current from a  $I-t$  record containing multiple current fluctuations associated with pit events after subtraction of any background passive current,  $I$  is the amplitude of pit current fluctuations, and  $\tau$  is the time constant for individual exponentially decaying current transients that comprise the current fluctuations. Hence, the low frequency limit of a  $\log I^2/\Delta f$  versus  $\log f$  plot provides information on  $q_{pit}$  for known  $I_{mean}$ . The frequency of the intercept (or breakpoint frequency) of the sloping part of the high frequency PSD with the low frequency plateau,  $f_{bpt}$ , provides information on the time constant for exponentially decaying pitting events,  $\tau$ ;  $f_{bpt} = 1/2\pi\tau$ . Therefore,  $q_{pit}$  and  $\tau_{pit}$  may be extracted from current PSD plots constructed from current-time data containing many overlapping metastable pitting events. This analysis method has been successfully applied to Al alloys [119,120]. Unfortunately, the approach has its shortcomings. The parameters recovered are heavily biased towards smaller more numerous pitting events that dominate the current time record. The biggest and/or fastest growing pits that might readily form stable propagating pits may not be detected. However, the method does enable determination of pit sizes at various potentials and allows the comparison of one environment, temperature, or set of plant conditions to another. No ASTM standard currently exists on this topic.

## ENVIRONMENTALLY ASSISTED CRACKING

There are several electrochemical techniques for assessing susceptibility to environmental cracking. For alloys that are susceptible to SCC by a mechanism of slip induced passive film rupture and anodic dissolution, electrochemical measurement of dissolution rate has obvious practical advantages. In this case, the increment of crack growth is defined by the anodic charge associated with each film rupture event. The crack growth rate is defined by this repetitive process. In the case of hydrogen embrittlement (HE) phenomena, determination of the mobile hydrogen concentration in the metallic lattice is an important consideration. Such a determination is possible using an electrochemical approach. Several pertinent methods are discussed below.

### Scratch Repassivation

The scratch repassivation technique discussed above may be more useful for studying SCC than pitting [107]. This is because natural pitting is often initiated at defect sites in the passive film that are electronic or chemical in nature. Such sites are not necessarily probed by a mechanical scratch. Scratching can simulate SCC where mechanical film rupture processes are operative and anodic dissolution controls the SCC process. In general, once the passive film is mechanically disturbed at some potential, an electrochemical current can be measured that will decay back to a low level when repassivation has occurred. A measure of the crack growth rate,  $V$ , (cm/s) can be obtained from these data

$$V = \left( \frac{E.W.}{\rho F} \right) \left[ Q_f \frac{\epsilon_{ct}}{\epsilon_f} \right] \quad (44)$$

where  $E.W.$ ,  $\rho$ , and  $F$  have been defined previously, and

$$Q_f = \int i_{ox} dt$$

$Q_f$  = the anodic charge density (coulombs/cm<sup>2</sup>),

$\epsilon_f$  = the fracture strain of the film, and

$\epsilon_{ct}$  = the crack tip strain rate (s<sup>-1</sup>).

## Tribo-ellipsometric Methods

The tribo-ellipsometric method is an advancement of the scratch method and has been used to distinguish between cases where an alloy is susceptible to localized corrosion, such as pitting or SCC, as opposed to general dissolution. The total anodic current transient following film destabilization consists of the algebraic sum of the repassivation current and the current corresponding to dissolution of the exposed bare metal in lieu of film formation. The electrochemical current measurement is conducted in conjunction with the optical ellipsometric method to measure the rate of film growth and repassivation film thickness. This combination offers a method of separating the two currents (dissolution versus repassivation), assuming that the valence state and density of the oxide are known so that charge can be determined from its volume. Based on the ratio of the charge involved in dissolution and the charge associated with repassivation, a criterion for stress corrosion is established by the parameter  $R_{sc}$ :

$$R_{sc} = 1 + Q_d/Q_r \quad (45)$$

where

$Q_d$  = the charge involved in dissolution, and

$Q_r$  = the charge associated with repassivation.

For example, a low-carbon steel was not found to be susceptible to SCC in a solution in which  $R_{sc}$  was 2.8. In this case, repassivation occurred very rapidly. However, the steel was found to be susceptible when that ratio was 26, and it was not susceptible again in a solution in which  $R_{sc}$  was 75 [121]. In the latter case, widespread pitting occurred instead. Hence, a balance between repassivation and widespread dissolution is required for anodically controlled SCC. Only under intermediate conditions is SCC possible.

## Potentiodynamic Methods

Parkins has devised a slow and rapid potentiodynamic scanning method to determine both the relative susceptibility to slip-film rupture-repassivation SCC susceptibility, as well as possible ranges of potential where SCC might occur [60]. The method applies to metals and alloys whose oxide films can initially be cathodically reduced. The validity of the method relies on the notion that SCC only occurs when crack walls are readily passivated while the crack tip dissolves at a high rate due to continual destabilization of the passive film. In this method, the rapid scan anodic polarization curve provides a measure of the bare dissolution kinetics over a range of anodic potentials. A slow anodic potentiodynamic scan provides a measure of the passive crack flank dissolution kinetics over the same range of potential. Alloy-electrolyte combinations that produce potential

ranges where a difference in dissolution rate of 100–1000 is observed for the two scan rates are more SCC susceptible. Caution is warranted, however, over concern that the differences in current do not merely reflect capacitive current as indicated in Eq 19. All of the techniques mentioned in this section suffer from the need to perform testing in solutions that simulate the relevant crack tip chemistry and at the potentials actually experienced by the crack tip. No ASTM standard exists for these methods.

### The Barnacle Electrode Technique for Determination of Diffusible Hydrogen Concentration

The degradation of fracture toughness below levels obtained in dry air or vacuum is a strong function of the internal diffusible hydrogen concentration for alloys prone to HE. Therefore, it is often important to determine this concentration, hereafter referred to as  $C_H$ .  $C_H$  can be determined by measuring the anodic current density associated with the oxidation of mobile hydrogen, which has diffused to the surface. Of course, precaution must be taken to ensure that  $i_{ox}$  is associated only with the reactions given by Eqs 7 or 8 and does not include a contribution from other oxidation processes, such as metal oxidation. The source of the adsorbed hydrogen is internal hydrogen in a precharged specimen that diffuses to the surface across the concentration gradient created when the surface concentration is lowered to zero as a consequence of hydrogen oxidation and extraction. In the Barnacle Electrode method, a hydrogen-containing steel part with initial uniform diffusible hydrogen concentration,  $C_H$ , is galvanically coupled to a nickel/nickel oxide electrode in an alkaline electrolyte [123,124]. This couple polarizes the steel to a potential at which the hydrogen is oxidized as it diffuses out while metal oxidation is minimized.  $i_{ox}$  is related to mobile hydrogen concentration in the metal by the first term solution to Fick's second law [123]. The appropriate boundary conditions for this equation are:  $\partial C_H / \partial x = 0$ ,  $x = 0$ ,  $t \geq 0$ ;  $C_H = 0$ ,  $x = L$ ,  $t > 0$ ;  $C = C_H$ ,  $0 \leq x \leq L$ ,  $t \leq 0$ .

$$\frac{i_{ox}}{nF} = C_H \left( \frac{D_H}{\pi t} \right)^{1/2} \quad (46)$$

where

- $C_H$  = the mobile or diffusible hydrogen concentration (1 gram-mole  $H/cm^3$  Fe  $\equiv 1.3 \times 10^5$  wt. ppm),
- $D_H$  = the apparent diffusion coefficient for  $H$  ( $cm^2/s$ ),
- $t$  = time, s, and
- $L$  = one-half the sample thickness so that  $x = L$  at the extraction surface and  $x = 0$  is the center of the specimen, cm.
- $i_{ox}$  = the current density associated with hydrogen oxidation ( $A/cm^2$ ).

The first term solution given in Eq 46 is valid if  $L^2/Dt \geq 4$ . The slope of a plot of  $\log(i_{ox})$  versus  $\log(t)$  should be  $-0.5$ .  $C_H$  is determined from measured values of  $i_{ox}$  and  $t$  if  $D_H$  is known and the data fit Eq 46. If  $D_H$  is not known, then the product  $C_H D_H^{1/2}$  is obtained.

### The Permeation Method for Determination of Diffusible Hydrogen Concentration

In this method, an electrochemical technique is used to measure the diffusion coefficient,  $D$ , and the solubility,  $C_o$ , of

hydrogen in iron or other metallic foil, under a variety of experimental conditions [125,126]. The advantages of the electrochemical technique are twofold. First, as noted above, by adjusting the potential one can apply a wide range of equivalent hydrogen pressures to the charging side of the metal membrane without resorting to high-pressure or high-vacuum techniques. Secondly, the hydrogen forced through a thin metal foil can be transformed to  $H^+$  ions ( $H \rightarrow H^+ + e^-$ ) when it reaches the solution on the other side of the permeation foil, and thus, the permeation rate will be proportional to the oxidation current required on the exit side of the membrane. Very accurate and sensitive measurements of the permeation rate to be made, can be seen from the fact that a current density of  $1 \mu A/cm^2$  corresponds to a permeation rate of  $H_2$  of about  $10^{-7} mL/cm^2 sec^{-1}$  at STP in palladium.

The diffusion equation given by Fick's second law where  $C_H(x, t)$  is the position dependent diffusible hydrogen concentration,  $t$  is time,  $D$  is the diffusion coefficient, and  $x$  is distance through the foil has been solved for the initial conditions  $C_H(x, t = 0) = 0$  and for the boundary conditions  $C_H(0, t = \infty) = C_o$ ,  $C_H(L, t = \infty) = 0$ . In other words, the conditions are that before the experiment is started, the foil contains no hydrogen and, at any time after the start of the experiment, the concentration,  $C_H$ , on one side ( $x = 0$ ) is a constant,  $C_o$ , and on the other side ( $x = L$ ) it is equal to zero. The time  $t = 0$ , in this case, corresponds to the time at which the concentration is switched from 0 to  $C_o$ . The solution of Eq 47 with the above initial and boundary conditions yields a series, which, to a good approximation,\* can be given by its first term:

$$\frac{i(t)}{i(\infty)} = \left( \frac{2}{\pi} \right) \left( \frac{1}{\tau^{1/2}} \right) \exp \left( -\frac{1}{4} \right) \quad (47)$$

in which  $i(t)$  and  $i(\infty)$  are the measured currents (proportional to the permeation rate of hydrogen) at a time  $t$  and at steady state, respectively, and  $\tau$  is a dimensionless parameter given by  $\tau = Dt/L^2$  where  $L$  is the thickness of the membrane. Figure 10 depicts the relation between  $i(t)/i(\infty)$  and  $\tau$ . The values of  $\tau$  corresponding to some selected values of  $\gamma$  are given in Table 3.

The diffusion coefficient may be determined from the transient permeation current density at various times  $t\gamma$  for  $\tau\gamma$  and selected foil thickness,

$$D = \tau\gamma L^2/t\gamma \quad (48)$$

where  $t\gamma$  is the time required to reach a current  $i(t) = \gamma i(\infty)$  and  $\tau\gamma$  is the corresponding value of  $\tau$ . This forms the basis of the lag time and breakthrough time methods discussed in ASTM standard G 148.<sup>11</sup> A test of the validity of the assumptions leading to Eq 47 is to calculate  $D$  from Eq 48 for different values of  $\gamma$  and show that it is independent of  $\gamma$ . An alternative approach facilitates determination of  $D$  from a linear regression of many data points, instead of relying on a single data point on the rise transient. Here, the solution given by McBreen for the rise transient is used based on a rearrangement of Eq 47:

\* This approximation is valid for  $i(t)/i(\infty) < 0.96$ .

<sup>11</sup>ASTM Standard G 148, Practice for Evaluation of Hydrogen Uptake, Permeation, and Transport in Metals by an Electrochemical Technique.

FIG. 10—Plot of permeation rise transient  $H$  oxidation current density expressed as the ratio of the transient current density to the steady state current density ( $\gamma = i(t)/i(\infty)$ ) versus  $\tau = (D/L^2)t$ . The constants associated from the breakthrough and lag time methods can be obtained from this plot. Selected values are given in Table 3.

TABLE 3—Selected values of  $\gamma$  and  $\tau$ .

$\gamma = i(t)/i(\infty)$	$\tau = Dt/L^2$
0.10	0.066
0.30	0.101
0.50	0.138
0.63	0.167
0.70	0.192
0.90	0.304

$$\text{Log}(i(t)\sqrt{t}) = \text{Log}\left(\frac{2FC_0\sqrt{D}}{\sqrt{\pi}}\right) - \frac{L^2\text{Log}(e)}{4D} \cdot \frac{1}{t} \quad (49)$$

such that a plot of  $\log(i(t)\sqrt{t})$  vs.  $1/t$  is linear and has a slope of:

$$\frac{-L^2\text{Log}(e)}{4D} \quad (50)$$

where  $t$  is time after start of charging in seconds,  $i(t)$  is the time dependent permeation flux in amps/cm<sup>2</sup>,  $L$  is foil thickness in cm, and  $D$  is the diffusion coefficient in cm<sup>2</sup>/sec. This solution assumes that the initial subsurface hydrogen concentration ( $C_0$ ) is zero. This solution is valid for  $0.02 < \tau < 0.9$ . This method has been used to determine the effective diffusion coefficient in high strength steels [127].

For steady-state conditions we have

$$i(\infty) = \frac{nFDC_0}{L} \quad (51)$$

and knowing the value of  $D$  from the transient, the concentration  $C_0 = C(0, t)$  at  $t = \infty$  can be calculated. This is the diffusible

hydrogen concentration under the conditions of interest. Hydrogen embrittlement severity is often proportional to this steady state diffusible hydrogen concentration when specimens are charged at the same hydrogen overpotential as used in the permeation experiment. ASTM Standard G 148, Standard Practice for Evaluation of Hydrogen Uptake, Permeation, and Transport in Metals by an Electrochemical Technique,<sup>11</sup> describes this method.

### Evaluation of Alloy Sensitization

Measurement of the coulombs generated during the electrochemical polarization of a material from the passive range to the active corrosion potential can be used to quantify the susceptibility to intergranular attack associated with the precipitation of chromium carbides and chromium nitrides at grain boundaries [128–130]. The method is described by ASTM G 108.<sup>12</sup> A modification of this procedure, called the double loop electrokinetic repassivation test [131, 132], involves a potentiodynamic polarization of the metal surface initially from the open-circuit potential in the active region to a potential in the passive range. This is immediately followed by reverse polarization in the opposite direction back to the open-circuit potential. The second method is less dependent on surface finish and precise knowledge of the grain size. Both variations of the method are illustrated in Fig. 11. In the latter method, the degree of sensitization is determined by the ratio, ( $I_r/I_a$ ), of the maximum current generated in the reactivation,  $I_r$ , or reverse scan compared to that generated in the initial anodic scan,  $I_a$ . The procedure is contingent on the presence of anodic current during the reactivation scan that results mainly from incomplete passivation of the zone adjacent to the grain boundaries that is depleted of chromium due to carbide precipitation at grain boundaries. For nonsensitized material, the passive film remains essentially intact during the reverse scan and the magnitude of the reactivation polarization peak remains small. For the same reasons, the charge,  $Q$ , obtained from integration of current versus potential for a known voltage scan rate in the single loop method is small for nonsensitized material. As a refinement to the method, the charge is normalized by the grain-boundary area (GBA) because this is the area from which most of the current arises in the single reactivation scan [130]

$$P = Q/GBA \quad (52)$$

$$GBA = A_s [5.09544 \times 10^{-3} \times \exp(0.34696 \times GS)] \quad (53)$$

where

$P$  = the reaction charge density associated with the sensitized area, coulombs/cm<sup>2</sup>,

$A_s$  = the wetted specimen surface area,

$GBA$  = grain boundary area, and

$GS$  = the ASTM grain size in accordance with ASTM E 112, Test Methods for Determining the Average Grain Size.

The same procedure can be used to normalize the ratio  $I_r/I_a$  [132]. The current peak,  $I_r$ , for the reactivation scan is normalized

<sup>12</sup>ASTM Standard G 108, Test Method for Electrochemical Reactivation (EPR) for Detecting Sensitization of AISI Type 304 and 304L Stainless Steels.

FIG. 11—Schematics of two procedures for anodic reactivation polarization testing. (a) The Clarke method involves a downward reactivation scan [129–130]; (b) The Akashi method involves an upward scan to the passive state followed by a reverse scan [131,132].

for the grain boundary area, while the initial anodic current peak remains normalized to  $A_s$ .

$$\frac{i_r}{i_a} = \left[ \frac{I_r}{I_a \times [5.09544 \times 10^{-3} \exp(0.34696 \times GS)]} \right] \quad (54)$$

$I_r/I_a$  ratios approaching 1 imply sensitization. A number of investigators have correlated this electrochemically derived ratio with optical metallographic evaluations of the degree of material sensitization, such as those outlined in ASTM A 262.<sup>13</sup> This has been accomplished for several different iron-nickel-chromium alloys [133–135]. The technique is nondestructive to the underlying metal and can be applied in the field.

## ELECTROCHEMICAL EVALUATION OF PROTECTIVE COATINGS AND FILMS

Numerous ac and dc electrochemical methods have been used to study the performance and the quality of protective

coatings, which include passive films on metallic substrates, and to evaluate the effectiveness of various surface pre-treatments. Several are discussed below.

### Anodized Aluminum Corrosion Test

The Ford anodized aluminum corrosion test (FACT) [136] involves the cathodic polarization of the anodized aluminum surface by using a small cylindrical glass clamp-on cell and a special 5 % NaCl solution containing cupric chloride ( $\text{CuCl}_2$ ) acidified with acetic acid. A large voltage is applied across the cell by using a platinum auxiliary electrode. The alkaline conditions created by the cathodic polarization promote dissolution at small defects in the anodized aluminum. As the coating resistance is decreased, more current begins to flow, and the voltage decreases. The cell voltage (auxiliary electrode to test specimen voltage) is monitored for 3 min and the cell voltage multiplied by time is recorded. The former standard ASTM B 538<sup>14</sup> described this method. This standard has been withdrawn because some aluminum alloys failed the test but still performed well in service. A similar test, known as the cathodic breakdown test, involves cathodic polarization to  $-1.6$  V versus saturated calomel electrode (SCE) for a period of 3 min in acidified NaCl [137]. Again, the test was designed for anodized aluminum alloys because the alkali created at the large applied currents will promote the formation of corrosion spots at defects in the anodized film. Today, impedance spectroscopy provides a more informative approach to examining anodized aluminum (see below).

### The Electrolytic Corrosion Test

This test was designed for electrodeposits of nickel and chromium on less noble metals, such as zinc or steel [138–140]. Special solutions are used, and the metal is polarized to  $+0.3$  V versus the standard calomel electrode. The metal is taken through cycles of 1 min anodically polarized and 2 min unpolarized. An indicator solution is then used to detect the presence of pits that penetrate to the substrate. Each exposure cycle attempts to simulate one year of exposure under atmospheric-corrosion conditions. The former standard ASTM B 627,<sup>15</sup> Test Method of Electrolytic Corrosion Testing (EC Test), described the method but has been withdrawn.

### The Paint Adhesion on a Scribed Surface Test

This involves the cathodic polarization of a small portion of painted metal. The area exposed contains a scribed line that exposes a line of underlying bare metal. The sample is cathodically polarized for 15 min in 5 % NaCl. At the end of this period, the amount of delaminated coating is determined from an adhesive tape pulling procedure.

<sup>15</sup>ASTM Standard B 627, Test Method for Electrolytic Corrosion Testing (EC Test) (Withdrawn 1998).

<sup>13</sup>ASTM Standard A 262-01, Practices for Detecting Susceptibility to Intergranular Attack in Austenitic Stainless Steels.

FIG. 12—Electrical equivalent circuit to simulate a coated steel panel with a defect [146,147,149].  $R_D$  is the coating defect resistance,  $R_T$  is a charge transfer resistance (similar to  $R_p$ ) at the metal interface where water has penetrated.  $C_c$  is the coating capacitance.

### The Single Frequency Impedance Test for Anodized Aluminum

The method described by ASTM B 457,<sup>16</sup> Test Method for Measurement of Impedance of Anodic Coatings on Aluminum, is used to study the seal performance of anodized aluminum [141,142]. This method uses a 1-V rms 1-kHz signal source from an impedance bridge to determine the sealed anodized aluminum impedance. The test area is again defined with a portable cell, and a platinum or stainless steel auxiliary electrode is typically used. The sample is immersed in 3.5 % NaCl (see ASTM B 457).

### Electrochemical Impedance Spectroscopy (EIS) Methods

The electrochemical impedance technique offers an advanced method of evaluating the performance of metallic-based coatings (passive film forming and/or conversion coatings) and the barrier properties of organic coatings and corrosion rates under paints [143–151]. The method does not accelerate the corrosion reaction and is non-destructive. The technique is quite sensitive to changes in the resistive-capacitive nature of coatings as well as the electrochemical interface. It is possible to monitor the polarization resistance of the corroding interface under the coating with this technique. In this respect, the electrochemical impedance technique offers several advantages over d-c electrochemical techniques in that resistances related to

the corrosion rate can be separated from the high d-c resistance of the dielectric coating. This is not possible with the d-c methods. Because a large frequency bandwidth is used for the applied signal (usually from the mHz range to the kHz range), the electrochemical impedance technique is “spectroscopic” and surpasses the capabilities of single-frequency impedance methods. The reason for this lies in the capability of the electrochemical impedance technique to discriminate between the resistive properties of the coating or passive film because of its ionic and/or electronic conductivity and the capacitive nature of the passive film or coating due to its dielectric constant, area, and thickness. Although impedance circuit models for coatings (Fig. 12) contain more elements than the model shown in Fig. 4 for bare metals, frequency regimes in which impedance information is primarily due to the coating capacitance or coating resistance can be separated from one another and analyzed independently by using a broad frequency bandwidth. If the coating or passive film capacitance can be determined by impedance analysis and if the dielectric constant is known, then the film thickness can be estimated for a given exposed area:

$$C = \frac{\epsilon \epsilon_0 A}{d} \quad (55)$$

where

$A$  = the surface area,  $\text{cm}^2$ ,

$d$  = the dielectric thickness,  $\text{cm}$ ,

$\epsilon_0$  = the electric permittivity of a vacuum ( $8.854 \times 10^{-12} \text{ F/m}$ ), and

$\epsilon$  = the dielectric constant for the passive film or coating.

In addition to this relationship between thickness and area of dielectric and capacitance, the uptake of water in an organic coating can be monitored because the dielectric constant for water is over an order of magnitude greater than the dielectric constant for the dry organic coating. The quantity of water absorbed in the organic coating can be estimated as follows [144,146]:

$$\text{vol.\%H}_2\text{O} = \left[ \frac{100 \log \left( \frac{C_t}{C_0} \right)}{\log(79)} \right] \quad (56)$$

where

$C_t$  = the coating capacitance after some exposure time, and  
 $C_0$  = the initial coating capacitance at time zero when the exposure begins.

The coating resistance can also be monitored as a function of exposure time. Large decreases signify permeation of ionic species through the coating or the presence of defects in the coating [150,151]. The breakpoint frequency is a useful method for estimating the area fraction of physical defects in an organic coating [149–152]. The following expression describes the dependency between the high-frequency breakpoint frequency and defect area:

$$f_{bpt} = \left( \frac{1}{2\pi\epsilon\epsilon_0\rho} \right) \left( \frac{A_d}{A} \right) \quad (57)$$

<sup>16</sup>ASTM Standard B 457, Test Method for Measurement of Impedance of Anodic Coatings on Aluminum.

A 2) Effect of Defect Area Percentage on Impedance Magnitude Behavior of a Coated Steel Equivalent Circuit. Total Cell Area Assumed is 10 cm<sup>2</sup>.

B 3) Effect of Defect Area Percentage on Impedance Phase Behavior of a Coated Steel Equivalent Circuit. Total Cell Area Assumed is 10 cm<sup>2</sup>.

**FIG. 13—Theoretical Bode Magnitude and Phase Angle Plots for various known electrochemically active defect areas for a coating containing a cylindrical defect penetrating to the metal substrate and no delaminated regions. (a) Bode magnitude, (b) Bode Phase Angle. ASTM visual ratings with the % of area damaged as blisters or rust spots according to standards D 610 and D 714 are included for comparison [152].**

where

$A_d$  = the defect area where electrochemical reactions operate,  
 $A$  = the total painted surface area, and  
 $\rho$  = the resistivity of the coating at defects.

Thus,  $f_{bpt}$  can track with change in defect area provided that decreases in  $\rho$  over time and increase in  $\epsilon$  with electrolyte uptake do not dominate. Under such circumstances, the term preceding the ratio ( $A_d/A$ ) remains constant. In this case, increases in  $f_{bpt}$  occur mainly as a function of the increases in the defective area. However, circumstances may exist where small increases  $A_d$  in  $\epsilon$  and very large decreases in  $\rho$  occur so that  $f_{bpt}$  does not relate linearly to defect area.

Moreover, bare metal under delaminated coating regions may not be detected under all circumstances, especially if the coating resistivity over the delaminated area and dielectric constant are identical to those in regions where the coating is not delaminated. The hypothetical relationship between  $f_{bpt}$  and open defect area is shown in Fig. 13 [152]. No ASTM standard currently exists for conducting impedance measurements on coated metals.

### Electrochemical Noise Methods for Organic Coating Evaluation

Electrochemical noise (EN) methods have also been explored as a method to analyze the degradation of polymer coated metals [153–157]. A variety of methods have been used. A common method involves the use of a cell with two identical working electrodes connected through a zero resistance ammeter. The entire galvanic couple is coupled through a high impedance voltmeter to an ideally noiseless reference electrode. Two samples often experience drastically different behavior; for instance, if one electrode has a coating defect and the other does not, then asymmetrical electrode behavior results. The spectral noise impedance obtained is equivalent to the geometric mean of the moduli of individual electrode impedances. Instrument noise should be carefully considered when this approach is used to analyze high resistance coatings. No ASTM standard currently exists for conducting EN tests on coated metals.

### CHARACTERIZATION OF ANODIZED SURFACES AND CONVERSION COATINGS ON METALS

The impedance technique also provides a useful approach for characterizing anodization [158–160], conversion coatings, sealing of anodized layers, and passivity [161]. ASTM STP 1188, *Electrochemical Impedance: Analysis and Interpretation*, covers some of these applications [162]. EIS methods have also been applied to the study of conversion coatings [163–165]. In the case of conversion coatings, an impedance modulus of 1–2 megaohm-cm<sup>2</sup> at the DC limit is a threshold value required in order for the conversion coating to pass an ASTM B 117<sup>17</sup> salt spray test [166]. This value must be passed after a 24 h exposure to aerated 0.5 M NaCl solution [167]. EIS studies of synthesized bulk Cu-based intermetallic compounds have improved insight on the role of conversion coatings in affecting the electrochemical properties of intermetallic compounds [168]. Such phases are often responsible for microgalvanic corrosion of Al-base alloys.

# Cabinet Tests

Cynthia L. Meade<sup>1</sup>

CABINET CORROSION TESTS have been used since the early 1900s as a means of evaluating the performance of coatings as a quality control tool for monitoring processes, and in some cases, as a method for accelerating corrosive activity.

A cabinet corrosion test is one in which a test chamber (or cabinet) is used to produce an environment that will cause the occurrence of a corrosion product on a test sample. Some common corrosive environments produced in a test chamber are salt fog, humidity, hot and cold temperatures, ultraviolet exposure, and corrosive gases. These environments may be used individually or in combination with each other.

Corrosion test cabinets have evolved from homemade water-and-spray tanks that operated at fixed or ambient temperatures and humidity to computer-controlled, multi-environmental laboratory apparatus that are not only functional, but are also an attractive addition to the laboratory. Sizes range from small benchtop units to large walk-in and drive-in chambers capable of testing full vehicles or other large specimens. ISO requirements have led to the use of NIST traceable devices for measurement of temperature, humidity, and/or other critical conditions to enhance the accuracy and repeatability of the test conditions. A list of commonly used cabinet tests is shown in Table 1.

## SALT SPRAY (FOG) TEST

The most commonly used cabinet corrosion test is the Salt Spray (Fog) Test. Although originally adopted as a test method, ASTM B 117 is actually a practice—Standard Practice for Operating Salt Spray (Fog) Apparatus [1].

The salt spray test was adopted by ASTM in 1939 after considerable developmental work by the National Bureau of Standards [2]. It has widespread use in many industries, including automotive, aerospace, paints and coatings, etc. ASTM B 117 can be found as a reference in many material and performance standards as a stand-alone test or as part of other environmental conditions to which a specimen is subjected prior to acceptance.

While typically called a salt 'spray' test, it actually consists of a fog produced by air atomization of a 5 % sodium chloride solution. The cabinet temperature is maintained at 35°C. Variations of the test, using a 20 % salt solution or

higher temperatures, exist within specific industries. Historically, salt fog chambers were heated via a water jacket, which surrounded the sides and bottom. Newer designs utilize heated air jackets and alternative heater configurations. Figure 1 illustrates typical salt fog chamber designs as depicted in ASTM B 117 [1].

Salt fog testing is performed by placing samples in a test cabinet that has been designed and operated in accordance with Paragraph 4, Apparatus, of B 117. A 5 % salt solution, prepared by dissolving sodium chloride into water that meets the requirements of ASTM D 1193, Specification for Reagent Water, Type IV, is supplied to the chamber. At the time the samples are placed into test, the cabinet should be preconditioned to the operating temperature of 35°C and fogging a 5 % salt solution at the specified rate of 1–2 mL/h. The fog collection rate is determined by placing a minimum of two 80 cm<sup>2</sup> funnels inserted into two 100 mL graduated cylinders inside the chamber. One collection device is located nearest the nozzle, and one in the farthest corner.

Unless otherwise agreed upon, the samples are placed at a 15–30° angle from vertical. (Automotive components, however, are often tested in 'in-car' position.) This orientation allows the condensation to run down the specimens and minimize condensation pooling. Overcrowding should be avoided. An important aspect of the test is utilization of a free-falling mist, which uniformly settles on the test samples. Samples should be placed in the chamber so that condensation does not drip from one to another. Test durations are typically in 24-h increments and can range from 24–5000 h. (Where salt fog exposure is a part of a more complex test method, exposure time can be as little as 15 min.) Except for sample rotation and daily monitoring of collection rates, the cabinet should remain closed for the duration of the test.

In 1987, Appendix X.3 was added to B 117 to suggest the use of mass loss panels as a means for checking the corrosive conditions in a given salt spray chamber. The procedure calls for SAE 1008 commercial grade cold-rolled carbon steel panels, measuring 76 × 127 × 0.8 mm, to be cleaned, weighed, and placed in the chamber in the proximity of the collector funnels. After an exposure time of 48, 96, or 168 h, the panels are removed, cleaned, and reweighed. When conducted on a regular basis, the final mass loss number can be used as a tool for monitoring consistent corrosive conditions within the chamber. The frequency of conducting this test should be determined by the user, but common practice suggests the test be conducted monthly,

Note: Thanks to Harold Hilton, Atlas Electric Devices, for his assistance in compiling this list.

or whenever any change occurs which might affect the cabinet—change of location, salt, water, operators, etc.

Whether due to the lack of an alternative test method or other reasons, the salt spray test has endured in spite of clear data that, in some cases, it is misapplied and misused, thereby providing erroneous information. As indicated in paragraph 3.2, 'Prediction of performance in natural environments has seldom been correlated with salt spray results when used as stand alone data.' Significance and Use, a modification made to ASTM B 117 in 1985, paragraph X2.2 specifically states, 'It should be noted that there is usually not a direct relation between salt (fog) resistance and resistance to corrosion in other media because the chemistry of the reactions, including the formation of films and their protective value, frequently varies greatly with the precise conditions encountered.'

The salt spray test is a useful process control tool. For example, if a given product, when plated, coated, or painted

properly, passes X number of hours of salt spray exposure, any failure prior to that target number would be a good indication that the **process** is out of specification. As evidence of its continuing popularity, B 117 is one of the top ten best-selling standards published by ASTM [3].

## MODIFIED SALT FOG TESTS

### Acetic Acid Salt Spray (Fog) Tests

A compilation of modified salt fog tests, ASTM G 85, includes five annexes. The first, Acetic Acid Salt Spray (Fog) Testing, was originally published as ASTM B 287. In this annex, the salt solution is prepared in accordance with B 117, then adjusted to a pH in the 3.1–3.3 range with the acetic acid. The acetic acid salt spray test is used for decorative chromium plating on steel [4]. The test duration is typically 144–240 h.

NOTE 1— $\theta$ —Angle of lid, 90 to 125°

- 1—Thermometer and thermostat for controlling heater (Item No. 8) in base
- 2—Automatic water leveling device
- 3—Humidifying tower
- 4—Automatic temperature regulator for controlling heater (Item No. 5)
- 5—Immersion heater, nonrusting
- 6—Air inlet, multiple openings
- 7—Air tube to spray nozzle
- 8—Heater in base
- 9—Hinged top, hydraulically operated, or counterbalanced
- 10—Brackets for rods supporting specimens, or test table
- 11—Internal reservoir
- 12—Spray nozzle above reservoir, suitably designed, located, and baffled
- 12A—Spray nozzle housed in dispersion tower located preferably in center of cabinet (typical examples)
- 13—Water seal
- 14—Combination drain and exhaust. Exhaust at opposite side of test space from spray nozzle (Item 12), but preferably in combination with drain, waste trap, and forced draft waste pipe (Items 16, 17, and 19).
- 16—Complete separation between forced draft waste pipe (Item 17) and combination drain and exhaust (Items 14 and 19) to avoid undesirable suction or back pressure.
- 17—Forced draft waste pipe
- 18—Automatic leveling device for reservoir
- 19—Waste trap
- 20—Air space or water jacket
- 21—Test table or rack, well below roof area

NOTE 2—This figure shows the various components including alternate arrangements of the spray nozzles and solution reservoir.

FIG. 1—Typical Salt Spray Cabinet.

### Cyclic Acidified Salt Fog Test

The second annex, Cyclic Acidified Salt Fog Testing, originally ASTM G 43, was used for exfoliation testing on certain aluminum alloys [4]. It is often referred to as the

MASTMAASIS test and is used for exfoliation testing of aluminum. Annex 2 uses a 5 % sodium chloride solution that has been adjusted to a pH between 2.8 and 3.0 with acetic acid [4]. The test cycle is a 6-h cycle of  $\frac{3}{4}$ -h spray, 2-h dry air purge, and  $\frac{3}{4}$ -h soak at high humidity. The

chamber exposure temperature is held at a constant 49°C, and the humidifying tower is operated at 57°C. An important aspect of this test is that the specimens dry during the purge cycle, leaving a white corrosion product. Note: Both ASTM B 287 and G 43 were discontinued in 1988 and incorporated into G 85 [5].

### Acidified Synthetic Sea Water (Fog) Test

Annex 3, Acidified Synthetic Sea Water (Fog) Testing, is commonly referred to as the SWAAT test and is often used to test aluminum alloys. Rather than a 5 % salt solution, a synthetic seawater solution is used with the pH adjusted to 2.8–3.0. This annex includes recommendations regarding the chamber operating temperature for different substrates. The chamber must be equipped with a device to conduct the following cycle: 30-min seawater spray (fog), followed by a 90-min period at a relative humidity greater than 98 %. The high relative humidity is achieved by maintaining approximately 1 in. of water in the bottom of the chamber [4].

### Salt/SO<sub>2</sub> Spray (Fog) Test

Annex 4, Salt/SO<sub>2</sub> Spray (Fog) Testing, may be performed using either a 5 % salt solution or synthetic seawater solution. Like the salt spray test, it is conducted at 35°C. The fog may be continuous or intermittent. Depending upon the chosen cycle, the sulfur dioxide is injected into the chamber four times a day for 1 h or within a cycle of ½-h salt fog, ½-h SO<sub>2</sub> injection, and 2-h soak [4]. The test was developed by the Navy to simulate exfoliation corrosion on aircraft carriers [6].

### Dilute Electrolyte Cyclic Fog/Dry Test

The latest addition to G 85 is Annex 5, Dilute Electrolyte Cyclic Fog/Dry Test. This test, often referred to as the Prohesion test, was developed by F. D. Timmins with Mebon Paints in the 1970s [7]. This test utilizes a wet/dry cycling operation. The wet cycle is conducted at room temperature, while the dry cycle is at 35°C. This method causes the specimens to be visibly wet, then dry, thereby creating a concentrated corrosive agent on the specimens [7]. This annex has widespread use in the industrial protective coatings market. It has recently become a performance requirement by the United States Postal Service for curbside mailboxes as part of 39CFS Part 111 [8].

The equipment needed to conduct any of the above tests is typically a traditional salt spray chamber that meets the requirements of B 117, with additional electronic control packages for cycling air, solution, and/or corrosive gas flow, while monitoring time and temperature.

### Cyclic Salt Fog/UV Exposure

ASTM D 5894, Standard Practice for Cyclic Salt Fog/UV Exposure of Painted Metal, was adopted in 1996 and incorporates a UV exposure cycle following G 85 Annex 5 exposure [9]. The addition of the UV exposure cycle added a weathering effect to the test conditions and produced results that more closely resembled field exposure. Due to the alternating Salt Fog/UV exposure, two separate test chambers are required.

The Steel Structures Paint Council and the Cleveland Society of Coatings Technology Technical Committee have done extensive studies and published and presented numerous papers on the virtues of this procedure, as well as G 85 Annex 5 [10,11].

### CASS Test

The Copper-Accelerated Salt Spray Test, ASTM B 368, commonly known as the CASS test, is typically used for testing copper-nickel chrome products. It was developed by the American Electroplaters Society as AES Research Project 15 [12], along with the Corrodokote Test (ASTM B 380) and incorporated into ASTM in 1965.

The CASS test is conducted at an exposure zone temperature of 120°F. The electrolyte solution is a 5 % salt solution, with the addition of copper chloride and glacial acetic acid. The sodium chloride used *must be* reagent grade in order to produce the mass loss specified on the nickel panels. Similar to B 117, collection rates should be at 1–2 mL/h.

Nickel panels are used to calibrate and monitor CASS test chamber conditions. The panels must be 7.5 × 10 × 0.09 cm and made from higher grade carbon as described in ASTM B 162. The panels are weighed and placed in each of the four corners of the chamber. After a 22-h exposure period, the panels are removed, cleaned, and reweighed. ASTM B 368 identifies the target weight loss as 0.45–0.85 mg/cm<sup>2</sup> [13].

Although a salt spray (fog) chamber and CASS test chamber may be structurally identical, users are discouraged from using a chamber that has previously been used for CASS testing as a salt fog chamber.

## HUMIDITY TESTS

Humidity tests generally fall into two categories: controlled humidity that targets a specific relative humidity range such as 85 %, or high humidity conducted at humidity levels in excess of 95 %. A list of commonly used humidity tests is included in Table 1.

A number of tests exist within ASTM, SAE, ISO, and automotive standards that include a controlled humidity cycle as part of a total test procedure.

### Corrodokote Test

The Corrodokote test, ASTM B 380 [14], was developed by the American Electroplaters Society to improve the performance of decorative plating used on automobiles. The original test protocol used actual Detroit city road slush consisting of dirt, road salt, and water [12]. The Corrodokote test uses a slurry consisting of kaolin, cupric nitrate (Cu(NO<sub>3</sub>)<sub>2</sub> · 3H<sub>2</sub>O), ferric chloride (FeCl<sub>3</sub> · 6H<sub>2</sub>O), and ammonium chloride (NH<sub>4</sub>Cl) in deionized water [14]. The slurry is applied to the samples being tested. They are then placed in the humidity chamber maintained at 38 ± 2°C and a relative humidity between 80 and 90 %, with no condensation on the parts. Twenty hours is considered one cycle [20]. Upon completion of the test, the specimens shall be cleaned with a mild abrasive and fresh running water. Additional

FIG. 2—Humidity Cabinet.

exposure to salt fog or humidity may be necessary after cleaning to provide evidence of corrosion products [14].

### Filiform Test

ASTM D 2803, Standard Guide for Testing Filiform Corrosion Resistance of Organic Coatings on Metal, was originally published in 1969 [15]. The test typically begins with a salt spray exposure according to ASTM B 117, followed by humidity exposure at 70–90 % relative humidity. Variations of the test exist that vary the length of the salt spray exposure and percent of relative humidity. General Motors Engineering Standard GM9682P, Filiform Corrosion Test Procedure for Painted Aluminum Wheels and Painted Aluminum Wheel Trim, incorporates a CASS Test exposure for 6 h, prior to the humidity cycle [16]. Care must be taken to maintain the proper humidity, as filiform corrosion only occurs at humidities between 70 and 95 %.

Filiform corrosion, identified by threadlike strands, is formed under finishes such as powder-clear-coated aluminum [17].

### High Humidity Tests

ASTM D 2247, Standard Practice for Testing Water Resistance of Coatings in 100% Relative Humidity, was originally published in 1966. As the title implies, it is primarily used to test the water resistance of coated specimens. The apparatus as depicted in D 2247 is shown in Fig. 2.

The chamber and humidifying tower temperatures are maintained at 38°C. As described in Annex A1.1, the apparatus may be a water tank with an immersion heater or test chamber with an air dispersion pipe assembly. The key design feature is that condensation is formed on the speci-

mens. A modified salt fog chamber as described in ASTM B 117 is commonly used for this type of test. (Note: The fogging apparatus must be removed and replaced with a water tank or air dispersion pipe assembly. The water level in the heated water jacket must be reduced to a level above the inside humidified water.)

### CORROSIVE GAS TESTS

Corrosive gas tests are often a combination of a gas introduced into a high humidity atmosphere and typically used as a porosity test. A few examples of these tests are:

- ASTM G 87, Standard Practice for Moist SO<sub>2</sub> Testing
- ASTM B 827, Mixed Flowing Gas Test
- DIN 50018, Testing in Saturated Atmospheres in the Presence of Sulfur Dioxide
- ISO 3231, Determination of Resistance to Humid Atmospheres Containing Sulfur Dioxide

### ASTM G 87

ASTM G 87, Standard Practice for Conducting Moist SO<sub>2</sub> Tests, was modeled after the German standard DIN 50018, and is commonly referred to as the Kesternich test. The test incorporates low volumes of sulphur dioxide gas (usually 2 liters or less) into a 100 % humid atmosphere. The test is conducted at a temperature of 40°C. A typical chamber design is shown in Fig. 3a as depicted in G 87.

G 87 and DIN 50018 are used in the electronics industry, as well as on roofing materials and fasteners (ASTM D 6294) [18]. A recent ASTM Guide for Coil Coatings

FIG. 3a—Typical Moist SO<sub>2</sub> Test Chamber.

(D 3794) [19] references G 87 as a performance standard. Variations of the test exist that incorporate other gases, such as carbon dioxide.

### Mixed Flowing Gas

The Mixed Flowing Gas Test, ASTM B 827, is used extensively in the electronics industry. As the name implies, the test method uses a combination of various gases at controlled temperatures and humidities to produce the desired conditions. The MFG test requires equipment of a more complex nature than other corrosive gas tests. A schematic of a typical chamber is shown in Fig. 3b, as depicted in ASTM B 827.

## CYCLIC CORROSION TESTS

Typical cyclic corrosion tests include one or more steps of salt solution exposure, humidity, drying, and/or ambient conditions. A list of commonly used cyclic tests is included in Table 1.

### SAE J2334

The automotive industry has taken a lead role in the development of cyclic corrosion tests that can produce results that better correlate with field exposure. In 1984, a joint effort, Automotive Corrosion and Prevention Committee, began between the Corrosion Task Force of the American Iron and Steel Institute and the Society of Automotive Engineers. Nearly 20 years later, and after considering over 130 available laboratory, proving ground, and outdoor corrosion tests, SAE Surface Vehicle Standard, J2334, Cosmetic Corrosion Lab Test, was published in June 1998 [20].

The development of SAE J2334 was arduous, but thorough. Ten materials were used to provide a wide range of anticipated results. At least two substrates were chosen because of proven corrosion testing results, to assure the consistency of the test. Canadian on-vehicle tests were conducted at Montreal, Quebec, and St. John's, Newfoundland for five years. The panels were placed in horizontal and vertical orientations. The corrosion mechanisms of on-vehicle tests were

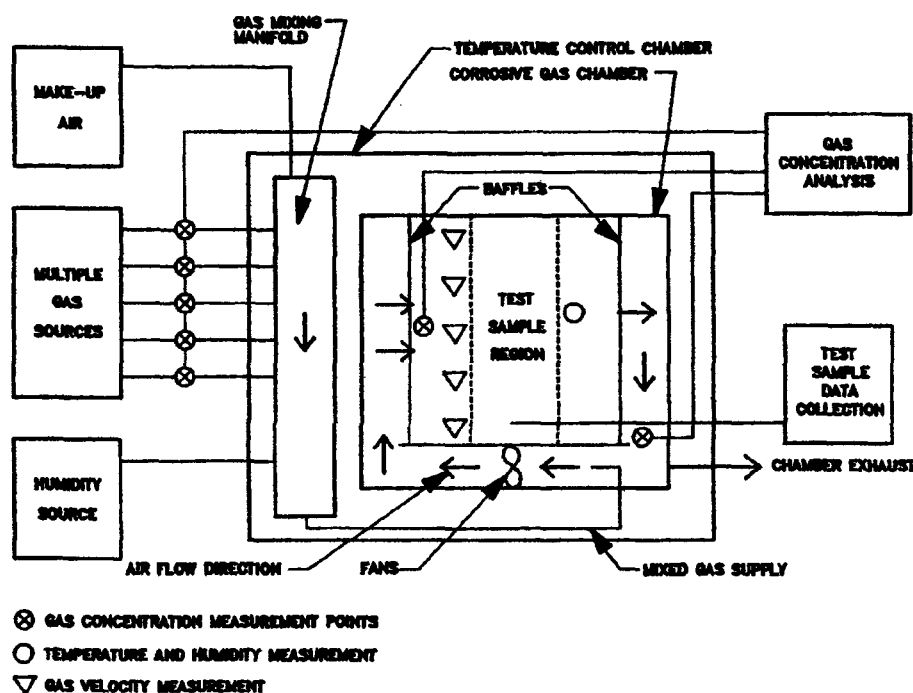

FIG. 3b—MFG Chamber.

studied by Lehigh University, where it was determined that similar corrosion products and modes were found when compared to those found after conducting J2334 [21].

The test procedure is:

1. Humid stage at 50°C and 100 % humidity for 6 h,
2. Salt application stage for 15 min at ambient conditions,
3. Dry stage at 60°C and 50 % humidity for 17 h and 45 min.

A typical test duration is 60 cycles, although longer cycles are commonly used for heavier coating systems.

The use of corrosion coupons is included in the test procedure as a means for monitoring corrosive activity within a given chamber. A minimum of six corrosion coupons, made of 25.4 × 50.8 mm AISI 1006-1010 steel, are used. The coupons are cleaned and weighed in accordance with the procedure described in J2334 and mounted in a nonmetallic rack. One coupon from each end of the rack is removed, cleaned, and reweighed every 20 cycles. At the present writing, no target mass loss numbers for each cycle or end-of-test mass loss have been published.

Efforts to improve the correlation and repeatability are underway as of this writing.

### General Motors GM9540P

Another commonly used cyclic corrosion laboratory test is GM9540P, Accelerated Corrosion Test [22]. The operating conditions are as follows:

Condition	Temperature	Humidity
Fog Humidity (GM4465P)	49 ± 2°C	100 %
Salt Solution Spray*	Ambient	Ambient
Dry Off	60 ± 2°C	< 30 %
Ambient	25 ± 2°C	40–50°C

\* The solution consists of 0.9 % sodium chloride, 0.1 % calcium chloride, and 0.25 % sodium bicarbonate mixed with ASTM D 1193 Type IV water.

The test cycle consists of four applications of salt solution every 90 min, 8 h of exposure in the humidity cabinet, and 8 h in the ambient environment.

The use of mild steel corrosion coupons is required and GM9540P provides end-of-test target mass loss numbers depending upon the number of cycles performed and coupon thickness.

### Typical Cyclic Corrosion Test Chamber

### Other Cyclic Tests

The number of available cyclic corrosion tests are too many to outline. ASTM Subcommittee D 01.27, Accelerated Test Methods, has formalized a document on laboratory corrosion tests that is published as ASTM D 6899.

### Evaluation of Cabinet Corrosion Test Results

Cabinet corrosion tests can be a useful tool in determining the production quality or suitability of given material.

**TABLE 2**—Commonly-used evaluation standards.

Standard Designation	Description
ASTM B537	Standard Practice for Rating of Electroplated Panels Subjected to Atmospheric Exposure
ASTM D610	Standard Test Method for Evaluating Degree of Rusting on Painted Steel Surfaces
ASTM D714	Standard Test Method for Evaluating Degree of Blistering on Paints
ASTM D1654	Standard Test Method for Evaluation of Painted or Coated Specimens Subjected to Corrosive Environments
ASTM G1	Preparing, Cleaning and Evaluating Corrosion Test Specimens
ASTM G46	Standard Guide for Examination and Evaluation of Pitting Corrosion
GM9102P	Corrosion Creepback Test Method

However, the results of cabinet tests should be considered in conjunction with field performance data.

Performance criteria are found in material and engineering standards. ASTM standards offer a scope, significance and use paragraphs, and precision and bias statements to assist the user of test methods and practices in defining the validity of the results. Common evaluation criteria include blistering, corrosion creepback, rust spots, etc.

A list of commonly used evaluation standards is shown in Table 2.

# Immersion Testing

*Richard A. Corbett<sup>1</sup>*

MOST CHEMICAL PLANT processes are complex. Materials of construction for process equipment and piping must be selected with care to assure corrosion-free operation of those plants. In a well designed plant, materials selection is based on a number of factors: prior service history, field in-plant corrosion tests, pilot plant corrosion tests and laboratory corrosion tests, in that relative order of usefulness. <sup>1</sup>Often, actual service history regarding materials performance is not available because plants kept poor records, plant personnel were not trained to evaluate corrosion failures, or, in the case of new processes, because there is no service history. The same can be said for field in-plant corrosion tests. Pilot plant testing is usually the best alternative in such cases, but such facilities are typically operated only for short runs and are not well suited for gathering long-term corrosion performance data.

For all of these reasons, laboratory corrosion tests are frequently the best available source of data for materials selection. If these tests are well planned, they can provide the information necessary for intelligent plant design and proper selection of materials of construction. Laboratory tests also offer unique advantages over in-plant tests: acceleration of results through variation of parameters or use of electrochemical methods, ability to vary process conditions at will to develop safe "windows" of operation for selected materials, plus the ability to look at a limitless number of candidate materials quickly and at relatively low cost. If poorly designed or improperly run and interpreted, all corrosion tests can give misleading information likely to lead to costly materials selection errors.

## BASIC PRINCIPLES

For any given chemical process it is not always possible to predict which forms of corrosion will occur, or even which chemical or parameter will dominate the corrosion scenario. Process flowcharts define certain chemicals and "normal" operating conditions, but frequently overlook trace elements (impurities), transient conditions, or chemical intermediates. Such factors can have a major effect on corrosion in that process. Subtle changes in pH, for example, can shift electrochemical potentials from, say, a passive range into a pitting range. Certain ionic species, while having little effect in the bulk environment, can act as accelerating charge carriers

when concentrated inside a pit or crevice. Such factors must be considered when designing a laboratory corrosion test.

Laboratory corrosion test parameters are usually separated into two groups: chemical and physical. Chemical parameters include not only the concentration of various compounds, but also such factors as dissociation, pH, phase equilibrium (especially vapor phase chemistry), dissolved gases, conductivity, and degradation reactions caused by the construction materials themselves. Relevant physical parameters include temperature (including temperature gradients and heat transfer), pressure, flow velocity, surface area effects (such as ratio of volume-to-surface area), and time (test duration). Also important are cyclical changes in these parameters. It is often impractical to study effects of all these variables, so educated decisions must be made as to which variables might be important in a particular process and how many variations of each shall be included in the corrosion test program.

Depending upon the expected mechanism of corrosion (i.e., general or localized pitting, crevice, cracking or galvanic attack), different tests can be designed to detect the susceptibility to attack. Table 1 summarizes some of the more common forms of corrosion and the appropriate laboratory tests used to evaluate the susceptibility of a material to a specific mode of attack [1]. Many of these tests are accelerated rather than simulated service (e.g., an accelerated test used to detect susceptibility to a form of corrosion), and are routinely performed to provide information for use in:

- fundamental corrosion evaluation
- failure analysis
- corrosion prevention or control
- acceptance of quality assurance
- environmental issues involving corrosion
- new alloy/nonmetallic or product process development

Custom and unique test set-ups to evaluate heat transfer, thermal shock, velocity, fatigue, or abrasion/wear effects are also used to determine the susceptibility of a material to a specific environment or process.

## Test Conditions

The selection of the conditions for a laboratory corrosion test should be determined by the expected results and the purpose of the test. If the test is to be a guide for the selection of a material for a particular application, then the limits of the controlling factors under service conditions must

be determined. Normally these factors include, but are not limited to, service temperature ranges, process fluid flow rates, atmosphere (i.e., air, nitrogen, argon, etc.), aqueous/organic phases, and other characteristics of the bulk solution (e.g., impurities or contaminants). There should be an effort to ensure duplication of the service conditions in the laboratory corrosion test, with conditions adequately controlled during the entire test duration to ensure reproducible results.

Experience shows that at least duplicate test specimens should be exposed in each test. Under laboratory tests, corrosion rates of duplicate specimens are usually within  $\pm 10\%$  of each other, when the attack is uniform. Occasional exceptions, in which a large difference is observed, can occur under conditions of borderline passivity of alloys that depend on a passive film for their resistance to corrosion. If the rate difference exceeds  $10\%$ , re-testing should be considered, unless it is observed that localized attack is predominant. Corrosion rates are calculated assuming a uniform loss of metal, and therefore when specimens are attacked non-uniformly, the calculated corrosion rates indicate only the relative severity of attack and should not be used to predict the performance of an alloy to the test solution. In such cases, weight loss per unit of surface area may be used to avoid implying a uniform penetration rate.

Ideally, laboratory tests should use actual solutions from plant processes, which is often impractical. Therefore, test

solutions are prepared from reagent chemicals and water. No matter what the source of the test solution, its composition should be controlled accurately and should be described in the test report as completely as possible. Minor constituents should not be overlooked because they often affect the corrosion rate. Chemical content should be reported as percentage by weight, molarity, or normality. If percentage is given, the solution density should also be provided so that molarity can be calculated. The composition of the test solution should be checked before and after testing by analysis to determine the extent of change in composition. Evaporation losses should be controlled by a constant level device, or by frequent additions of the evaporating solution, to maintain the original volume within  $\pm 1\%$ .

In some situations, the composition of the test solution may change as a result of the build-up of corrosion products in the solution, catalytic decomposition, or by reaction with the test specimens. If possible, these changes should be determined, and where required, the consumed constituents should be replenished or a fresh solution provided periodically.

Experience has shown that wherever possible, only one type of alloy or family of nonmetallics should be exposed in a given test apparatus. If several alloys or nonmetallics are exposed in the same apparatus the corrosion products from one material may affect the corrosion rate on another material. For example, copper corrosion products can inhibit corrosion of stainless steel but accelerate corrosion of aluminum.

If different alloys are coupled in a particular process, these couples must be reproduced in the laboratory test. For example, in ASTM Standards D 1384, D 2570, or D 2758, copper, brass and solder, found in the radiator and heaters in automobiles, are electrically connected and tested in the same laboratory apparatus.

## Physical Parameters

### *Temperature*

The temperature of the test solution should be controlled within  $\pm 1^\circ\text{C}$  and should be stated as such in the report of test results. If no specific temperature, such as boiling, is required or if a temperature range is selected, this should also be reported. For processes that are conducted under ambient conditions, the laboratory tests should be conducted at the highest temperature anticipated for stagnant storage during the summer months. This temperature may be as high as  $55^\circ\text{C}$ . Laboratory tests conducted at the temperature of a process solution may provide misleading results if heat transfer occurs as the metal heats the process stream.

### *Aeration/Deaeration*

Unless specified, the test solution should not be aerated or deaerated. Most laboratory tests used to replicate process equipment should be controlled with the natural atmosphere inherent under process conditions, such as the vapors of the boiling solution. If aeration or deaeration is used, the test specimens should not be located in the direct stream of the gas sparge tube. Undesirable effects can be encountered if the gas stream impinges on the test specimens.

### *Solution Velocity*

The effect of process solution velocity is not usually determined in normal laboratory tests, although specific tests have been designed for this purpose. Tests under boiling conditions should be conducted with minimal heat input, and inert material boiling chips should be used to avoid excessive turbulence and bubble impingement. For tests conducted below the boiling point, thermal convection generally is the only source of liquid velocity in the laboratory test. For test solutions with high viscosities or multiple phases, supplemental controlled stirring may be recommended.

### *Test Solution Volume*

The volume of the test solution should be large enough to avoid any appreciable change in its corrosiveness either through depletion of the corrodant or accumulations of corrosion products that may affect further corrosion. The preferred minimum solution volume-to-specimen surface area ratio is  $20 \text{ mL/cm}^2$ .

### *Methods of Supporting Test Specimens*

It is important that the supporting device and the test apparatus should not be affected by or cause contamination of the test solution. The method of supporting test specimens will vary with the apparatus used for conducting the test, but should be designed to insulate the specimen from

each other physically and electrically, and to insulate the specimens from any metallic container or supporting device used with the apparatus. The shape and form of the specimen support should assure free contact of the specimen with the test solution, the liquid/vapor interface or the vapor phase, whichever is applicable.

Common supports include glass or ceramic rods or hooks, glass cradles, fluorocarbon plastic thread or string, and various insulated or coated metallic supports.

## Test Duration

The duration of any laboratory test should be determined by the nature and purpose of the experiment. The amount of corrosion attack under any given test condition will be directly dependent on the duration of the test. Often it is assumed that corrosion is a linear function of time, and often this is incorrect. Yet this assumption is implied when a corrosion rate is stated.

Since corrosion may not be linear, it is important that tests be made with specimens exposed for an increasing increment of time, with some durations as long as possible to enable reliable extrapolation of performance. Under such test parameters, it is recommended to expose several identical specimens in the corrodant and remove them individually at different times over an extended duration. This technique is called the "Planned Interval Test" [2], and the procedure and evaluation of the results are presented in Table 2.

Materials that experience severe corrosion usually do not require long duration exposure to obtain accurate corrosion rates, and common testing periods are 24–240 h. Although this assumption is valid in many cases, there are situations where it is not valid. For example, aluminum exposed to solutions of sodium hydroxide corrodes at an extremely high rate, often in excess of an inch per year, while it is building a protective corrosion product film; then the rate decreases dramatically so that further corrosion is almost negligible, provided the film is not damaged. Likewise, stainless steels that form passive films may have that film broken down under prolonged exposure and subsequently experience rapid attack. Experience suggests that laboratory tests of long periods are considerably more realistic than those conducted for short duration. However, this must be qualified because corrosion should not proceed to where the original specimen size or the exposed area is drastically reduced or where the material is perforated or dissolved.

## TYPES OF TESTS

The type of laboratory immersion test to be used will be determined mostly by the environmental conditions that are to be simulated. For example, if the equipment is immersed in service, then the test specimens should be immersed in the laboratory test; if the exposure is alternating immersion and atmospheric exposure, then a cyclic exposure test to wet/dry conditions should be used. Another determining factor is the duration of exposure for arriving at the desired results, which is associated with the degree of acceleration that will be required of the test method.

TABLE 2—Planned interval test.

Specimen #	0	1	Time	t	t+1
1	←	→			
2	←	→			
3	←	→			
4				←	→
5				←	→

Calculated Specimen #3 - #2

The test specimens are placed in the same test vessel which contains the corrosive solution. The test conditions are kept constant during the duration of the test program. The parameter being measured is the penetration<sup>a</sup>, as defined below.

Interpretation	Criteria
Liquid Corrosiveness	—Unchanged if 1 = 4 —Decreases if 1 > 4 —Increases if 1 < 4
Metal Corrodibility	—Unchanged if 4 = 5 —Decreases if 4 > 5 —Increases if 4 < 5

Other Combinations of Interpretation:

Liquid Corrosiveness	Metal Corrodibility	Criteria
1. unchanged	unchanged	1 = 4 = 5
2. unchanged	decreases	1 = 4 > 5
3. unchanged	increases	1 = 4 < 5
4. decreases	unchanged	1 > 4 = 5
5. decreases	decreases	1 > 4 > 5
6. decreases	increases	1 > 4 < 5
7. increases	unchanged	1 < 4 = 5
8. increases	decreases	1 < 4 > 5
9. increases	increases	1 < 4 < 5

## Example of Planned Interval Corrosion Test Program

Exposure: Test specimens were of AISI Type 316L (UNS S31603) stainless steel (density 7.98 g/cm<sup>3</sup>), with dimensions of 25 × 50 × 3 mm (1 × 2 × 1/8 in.), immersed in 500 mL of 15 % methylsulfonic acid + 5 % sulfuric acid, balance water, at atmospheric pressure and 45°C.

Specimen Number	Duration Days	Mass Loss, mg	Penetration <sup>a</sup>		Apparent Corrosion Rate <sup>b</sup>	
			mm	mils	mm/y	mpy
1	0-1	1495	0.064	2.4	23	880
2	0-4	2240	0.095	3.6	8.7	330
3	0-5	2280	0.097	3.7	7.1	270
4	4-5	95	0.004	0.15	1.5	55
5	calc. 3-2	40	0.002	0.06	0.7	22

$$^a \text{Penetration} = \frac{(\text{mass loss in mg})(C\text{-factor})}{(\text{area in mm}^2 \text{ or in.}^2)(\text{density in g/cm}^3)}$$

where C = 1 for mm; or C = 0.061 for mils

$$^b \text{Apparent Corrosion Rate} = \frac{(\text{Penetration in mm or mils})365}{\text{time in days}}$$

From penetration information: Specimen 1 > 4 > 5

Based on the interpretation criteria, the liquid has decreased its corrosiveness during the test, and suggests the formation of a protective film owing to a decrease in metal corrodibility.

The principal reason for accelerated testing is the need to obtain results sooner than can be obtained under field conditions. Acceleration is achieved by lengthening the exposure to the critical conditions, or by intensifying the conditions so that the corrosion rate is increased. The former may be achieved by exposing a test specimen to a process condition an order of magnitude longer than actual practice. For example, if a vessel is to be batch processed with a chemical for 24 h, then a laboratory corrosion exposure of 240 h should be considered. Intensifying the test conditions may be achieved by increasing the solution acidity, salt concentration, temperature, or other parameters. In some cases, the physical parameters may be changed, such as the amount of stress or the degree of fatigue.

Once the service conditions of the test have been determined, and evaluation tests for all forms of corrosion that

might occur have been designed, then they should be repeated a sufficient number of times to determine whether it meets the desired reliability standard for reproducibility. Changes in the test procedure may be required if the reliability is not satisfactory.

If the test procedure is to be used by other laboratories, either to qualify on the basis of a specification or simply to compare results among laboratories, then it is important that reproducibility of results be determined. This is accomplished through round-robin tests that are conducted among interested laboratories to develop standard test procedures, such as those that are developed by ASTM International, Comité European Normalization (CEN), International Organization for Standardization (ISO), Japanese Standards Association (JSA), Materials Technology Institute (MTI) of the Chemical Process Industries, and NACE International.

MTI 4	Laboratory Testing of Wrought Iron and Nickel Based Alloys for Relative Resistance to Crevice Corrosion in Sodium Chloride Solutions
MTI 5	Laboratory Testing of Wrought Iron and Nickel Based Alloys for Relative Resistance to Stress Corrosion Cracking in a Sodium Chloride Drop Evaporation System

It is not unusual to use a laboratory test procedure for which there is no direct correlation with service or field results. Sometimes correlation cannot be obtained immediately because service results are either not available or are not practical to obtain in a reasonable time. For example,

suppose a company wishes to offer a lifetime warranty of a coating exposed to an industrial environment but needs data to back up their claim. Humidity chamber tests plus ultraviolet light exposure can give "best guess" results in a matter of weeks rather than years of actual exposure to the elements.

Because the laboratory test is designed around a synthesized or contrived environment, it is important that the results provide reliable information that can be used to make decisions on candidate materials of construction.

### Simple Immersion Tests

There are many variations in a laboratory immersion test. ASTM G 31 and NACE International Standard Test Method TM-01-69 are general guides on how these tests may be performed (see Table 3 for these and other standard corrosion test procedures). Basically, small pieces (i.e., 2.5-cm by 5-cm by 0.3-cm thickness) of the candidate material are exposed to the test medium, and the loss of weight of the material is measured for a given period of time. Immersion testing remains the best method for screening and eliminating from further consideration those materials that obviously should not be considered as useable materials. This technique is frequently the quickest and most economical means for providing a preliminary selection of the best candidate materials. Probably the most serious disadvantage of this method of corrosion study is the assumed average-time weight loss. The corrosion rate could be high initially and then decrease with time. In other cases, the rate of corrosion might increase very gradually with time, it could cycle, or it could be some combination of these things. Remember, "corrosion is not an exact science," and no written information can take the place of a corrosion consultant.

Besides the full immersion test, there are several variations that could be used to accentuate certain types of exposure conditions. For example, the test specimen can be partially immersed in an electrolyte (liquid or solid) to create an oxygen concentration cell at the vapor-liquid/solid interface (as opposed to an occluded cell).

### Alternate Immersion Testing

Another variation of the immersion test is the cyclic test procedure where a test specimen is immersed for a period of time in the test environment, then removed and dried (either air dry or use of heat lamps), then re-immersed to continue the cycle. Normally hundreds of these cycles are completed during the course of the test program. In ASTM G 60, test specimens are dipped in a test solution before being exposed to atmospheres varying in relative humidity. The intent of the test is to develop a layered corrosion product similar to that found on sheltered outdoor exposure test specimens. These tests can be either manually performed or conducted in apparatus equipped for automatic cycling.

### Simulation and Acceptance Testing

The laboratory test should try to simulate actual service conditions. Occasionally, this may be accomplished simply by building a scaled-down model of a particular operation. If the service operation is not too large, actual parts of the system can be modified to a laboratory bench-top to permit a better simulation of the actual process.

There are many examples where this approach has been applied. An excellent example is depicted in Fig. 1 of a circulating brine cooling/heating heat exchanger system. The effect

FIG. 1—Scaled-down model, circulating brine cooling/heating heat exchanger system.

of brine corrosion, and use of inhibitors, in the piping system is simulated by the use of full-sized pipe spool pieces of different alloy composition. The test model further incorporates the use of small test specimens and electrochemical monitoring probes.

Acceptance tests attempt to use actual service conditions and environments to control the quality of the material being supplied as material of construction. A classic example is the use of acceptance testing for susceptibility of alloys to intergranular corrosion under boiling nitric acid service using the ASTM A 262, Method C test procedure. Another example is to simulate down-hole sour gas or sour oil piping environments by use of the NACE International TM-01-77 procedure for hydrogen induced cracking susceptibility exposure to aqueous hydrogen sulfide.

## TEST SPECIMEN PREPARATION, CLEANING, AND EVALUATION

### Preparation

One of the most important parts of corrosion testing is the preparation of the specimen or part to be tested. Although it is desirable to use the same surface conditions for the tests as those found in service, this is not always possible because of the variability of the material's surface in service, but it should always be a desirable objective.

Test specimens should have many of the characteristics of the material that will be used for the service application, which typically includes composition (elemental chemistry), mechanical properties (strength, hardness, etc.), form (sheet, plate, bar, etc.), size and shape (surface area-to-corrodant volume ratio, flat-stock, end-grain exposure, etc.), metallurgical treatment (heat treatment, welding, hot or cold working, etc.), surface finish (dye-cut, sheared, saw-cut, mill scale, ground and polished, electropolished, etc.), identification procedures (stamped, engraved, etc.), and cleaning procedures (passivated, degreased, water washed, etc.).

Although the size and shape of the specimen will depend on the purpose of the test, rectangular specimens of the dimensions 2.5 cm by 5 cm by 0.3 cm thick are common. A typical variation is found when a corrosion test requires the specimen to be mechanically stressed as part of the evaluation procedure. It would be normal in this case to use a standard tensile test specimen for the corrosion test. Other examples are the use of disk-shaped specimens for rotational erosion tests, or special configurations for stress corrosion, exfoliation, or crevice tests.

A reproducible surface finish is desirable for repetitive testing. A common final surface finish for test specimens is No. 120 grit abrasive paper or cloth, or their equivalent. Whenever possible or known, the same metallurgical treatment should be used for the test specimen as used for the service part, because heat treatment or cold work can change the surface composition, grain size and structure, and residual stresses. Mechanical operations can affect the materials surface. Cutting, shearing, grinding, and polishing operations should be performed to avoid excessive work-hardening or stresses.

There are many ways to identify test specimens, such as marking with ink or paint, incise marking, or stamping numbers or letters with a tool that leaves an impression in the surface. Precautions should be observed with the use of any system to avoid excessive stresses, the creation of sites for pit initiation, or the use of materials that will be reactive with the metal. It is important that the identification endures the duration of the test, so some of these problems may have to be tolerated.

### Cleaning Specimens Before Testing

After the test specimen has been prepared for testing, it must be cleaned to remove oil, soil, and fingerprints. Either chemical or electrochemical means can be used for the final cleaning, but the effects of cleaning on surface topography must be considered. A recommended procedure involves scrubbing with a toothbrush and a bleach-free scouring powder, followed by thorough rinsing in water and a suitable solvent (such as acetone or methanol) and warm air-drying. For relatively soft metals (such as aluminum, magnesium and copper) scrubbing with abrasive powder is not always desirable as it can mar the surface of the specimen. Ultrasonic techniques may be used, as necessary.

If coatings are to be evaluated, it is important that the metal surface be cleaned and the coating applied in a similar manner to that used in the service application. This step may involve using regular production facilities.

After cleaning, the test specimens are weighed on an analytical balance to an accuracy of  $\pm 0.5$  mg, and dimensional measurements are made to  $\pm 0.001$  cm to permit accurate calculation of the exposed surface area.

### Cleaning Specimens After Testing

The effect that corrosion and the resulting corrosion products have on the test specimen should be determined in order to evaluate the severity of the attack. Locations of deposits or corrosion products are important in evaluating localized attack such as pitting, crevice attack or cracking.

Therefore before cleaning the exposed specimens should be observed and their appearance recorded. Although this method is qualitative it is helpful in assessing the nature and extent of corrosion.

Corrosion rates are based on weight loss (consumption of the base material) during the duration of exposure. Therefore cleaning the specimens of their corrosion products is a vital step in the corrosion test protocol. Generally, the cleaning procedure should remove all corrosion products from the specimen with a minimum removal of sound material. Set procedures for specimen cleaning vary depending on the type of the material being cleaned, and on the degree of adherence of corrosion products. Cleaning methods are divided into three general categories: mechanical, chemical, and electrolytic. Detailed procedures are described in ASTM G 1.

After cleaning, the specimens are re-weighed. The weight loss during the test duration is used as the principal measure of corrosion: the corrosion rate.

### Evaluation of Results

Even though each step of the corrosion test procedure is important, if not properly evaluated the results can be misused or can lead to erroneous conclusions. It is important to remember that the corrosion rate is based on the extrapolation of results from short-term tests. For example, corrosion rates may be reported in the terms of millimeters per year (mmpy) on the basis of results obtained from exposure of one month, one week, or one day. The degree of extrapolation ranges from a multiple of 12 to 365. Since corrosion is rarely linear, with initial rates being extremely high, it is important that the extent of extrapolation be considered in the evaluation phase of the test program.

After the specimens have been re-weighed, they should be carefully examined visually and under low-power magnification for the presence of localized attack. If there are pits or creviced areas, the extent of the depth of attack can be measured with a pit gauge or a calibrated microscope which is first focused on the bottom of the pit and then the specimen surface edge (see ASTM G 46 for details).

If the test material is suspected of being subject to dealloying (such as dezincification) or intergranular corrosion, a cross section of the specimen should be microscopically examined. If embrittlement is suspect, simply bending the specimen may determine this susceptibility.

### PRECAUTIONS AND VALIDITY OF RESULTS

Most metals and alloys are thermodynamically unstable and will therefore attempt to revert back to their native stable state (e.g., red rust or ferric oxide). The rate at which this reversion (corrosion) occurs varies with the particular alloy and the environment to which it is exposed. The purpose of the laboratory corrosion test is to best simulate these conditions, determine corrosion rates, and predict the various modes of attack. Although each data point is important, the results can be misinterpreted and lead to the wrong conclusion if they are not properly evaluated. Therefore, a laboratory corrosion test can be most useful only if the test results can be compared with actual plant or process service experience.

The precautions mentioned throughout this section focus on the planning and execution of the laboratory test and particularly in the interpretation of results. These cautions are not intended to provide a false impression that corrosion tests are unreliable. Rather, they are intended to emphasize that when corrosion test procedures are executed carefully and interpreted intelligently our knowledge of corrosion may be enhanced. That this is true is evident by the few number of cases of unexpected failures by corrosion or gross misapplication of corrosion resistant materials.

## STANDARDS

Reference is made throughout this section to standards and test methods issued regularly by technical societies such as

ASTM International and NACE International. Other organizations, which also issue standards for the many types of corrosion tests, are CEN, ISO, JSA, and MTI. These professional organizations have produced industry accepted recommended practices and test procedures (see Table 3), which allow comparison with others through direct interaction or published data.

# High-Temperature and High-Pressure Corrosion Testing

Russell D. Kane<sup>1</sup>

AUTOCLAVE CORROSION TESTS are a convenient means for laboratory simulation of many service environments for the purpose of evaluating the corrosion resistance of materials and for determining the effects of metallurgical, processing, and environmental variables on corrosion processes. The reason for such tests is to more closely recreate the high temperatures and pressures commonly occurring in commercial or industrial processes.

In many of these cases, the factors affecting corrosion behavior are intimately linked to the conditions of total system pressure, partial pressures of various soluble gaseous constituents and temperature. Table 1 provides a listing of several HT/HP environments of commercial interest. Therefore, corrosion tests conducted at room temperature or ambient pressure, or both, simply cannot produce conditions which allow simple glassware experiments to be totally adequate for the purpose of determining corrosion behavior. In these situations, greater effort must be taken to carefully reproduce conditions of high temperature and pressure in laboratory test vessels in which corrosion coupon, electrochemical, or environmentally assisted cracking (EAC) experiments can be conducted.

## BASIC PRINCIPLES

HT/HP corrosion tests by their nature have special requirements not common to conventional corrosion experiments

conducted in laboratory glassware. There are basic considerations that are necessary when these conditions are used for laboratory corrosion tests. There are several standards documents that have been developed for specific purposes which describe equipment and experimental methods for HT/HP corrosion testing. However, in many situations, the procedures used by laboratory personnel for conducting such tests are not always found in accepted standards documents, but have been developed through years of experience. In general, the degree of difficulty and amount of expense required for HT/HP corrosion tests increases with increasing test pressure and temperature.

## Pressurized Corrosion Tests

### Equipment

The simplest type of HT/HP corrosion test is that which is conducted in a sealed, static, pressurized test vessel as shown schematically in Fig. 1. The test vessel contains a solution and a vapor space above the solution. The liquid and gas phases will be determined by the amount and vapor pressures of the constituents in the test vessel as well as by the test temperature. Corrosion coupons can be placed in the aqueous phase, vapor space, or at phase interfaces depending on the specific interest involved. Additionally, it is also possible to conduct electrochemical tests (i.e., linear polarization resistance (LPR), polarization curve generation

TABLE 1—Typical high temperature/high pressure test conditions.

No.	Application	Environment	Temp, C	Pressure, MPa (bar)
1	Nuclear Power	high-purity water/steam/H <sub>2</sub>	280 to 500	≤ 7 (170)
2	Fluidized Bed Combustion	air, gas, coal	600 to 750	1 (10)
3	Deep Sea	seawater, Cl <sup>-</sup>	0 to 70*	<5 (50)
4	Oil and Gas Production	brine, H <sub>2</sub> S, CO <sub>2</sub> , S <sup>o</sup> , Cl <sup>-</sup>	20 to 250	≤130 (1300)
5	Aerospace Propulsion	hydrogen	-200 to 900	0.1 to 67 (1 to 670)
		oxygen	-200 to 480	≤8 (80)
6	Petroleum Refining	H <sub>2</sub> , H <sub>2</sub> S, hydrocarbons, CO	350 to 650	≤10 (100)
7	Compressed Natural Gas Storage	methane w/trace H <sub>2</sub> S	0 to 100	≤8 (80)
8	Ammonia Storage	NH <sub>3</sub> , H <sub>2</sub> O	0 to 70	≤4 (40)
9	Thermodynamic Power Generation	NH <sub>3</sub> , H <sub>2</sub> O	100 to 650	1.5 to 11 (15 to 110)

FIG. 1—Simple static HT/HP test vessel configuration.

and cyclic polarization, electrochemical noise (ECN), harmonic distortion analysis (HDA). In these cases, it is often necessary to modify the simple static test vessels with additional electrical feed-throughs to accommodate the electrodes required for electrochemical testing while maintaining a pressure containment.

### Static Tests

In the simplest case of HT/HP corrosion tests conducted under static conditions, it is common to use a single liquid medium. However, in some cases, exposure to a single gaseous phase is required as found in studies of the compatibility of materials to environments containing high-pressure hydrogen gas, oxygen, or other chemical environments. In most situations involving aqueous corrosion, this involves a water-based solution containing various dissolved salts such as chlorides, carbonates, bicarbonates, alkali salts, acids, and various mixtures of these and other constituents. In many cases, the aim is to simulate a particular service environment rather than a simple test environment commonly found in many standardized test methods.

HT/HP corrosion tests can use many of the same test procedures and similar specimens commonly found in conventional aqueous corrosion testing as per ASTM G 31, Practice for Laboratory Immersion Corrosion Testing of Metals. However, in general, somewhat smaller corrosion coupons and stressed EAC specimens are used for HT/HP testing than those used in glassware experiments. The reason for this is that vessels for HP/HT experiments often are of limited internal volume. Volume generally decreases with increasing pressure rating of the equipment due to the increasing wall thickness required to contain the pressure and the high costs associated with particularly larger test vessels. Most laboratory test vessels have an internal volume of between 500 mL and 5 L. In some special cases, however, this type of equipment may have an internal volume in excess of 120 L. To minimize the wall thickness and associated equipment costs, most large test vessels tend to be long

so that volume can be maximized while minimizing the vessel diameter. In most cases, the equipment is designed to specification given in the ASME Boiler and Pressure Vessel Code.

### Agitated Tests

In static corrosion tests, the only form of agitation of the test environment is convection produced by heating of the solution. However, if multiple liquid phases are present (e.g., aqueous along with liquid hydrocarbon phases) it is often necessary to stir or agitate the media or test vessel to produce mixing and conditions whereby the corrosion test specimens are contacted by all of the phases present. Special magnetic and mechanical stirrers and flow loops are available that can be used (see Fig. 2a–c) to produce movement of the fluid to produce a mixing of the phases. In some cases where contact of the specimens with both liquid and gaseous phases is important in the corrosion process, it may be necessary to slowly rotate, rock or shake the test vessel to produce the intended results.

Magnetic or mechanical stirring equipment can also be employed to spin the specimens in the test environment as commonly used in spinning disk or spinning cylinder tests. To study the effects of velocity, it is usually more practical to spin the specimens while minimizing fluid movement by placing baffles in the test vessel. In some applications, turbulent or high-velocity flow is a critical factor in materials performance and must be simulated under temperature and pressure. Test systems can use jet impingement techniques to simulate such conditions using a pressurized flow system up to 350°C. In these tests, it is necessary to not simulate service conditions based on linear flow velocity. A more important and relevant parameter used when assessing field, plant and laboratory test environments is the wall shear stress, which is a measure of the mechanical action (and frictional force) produced at the interface between the flowing media and the metal surface.

### Refreshed and Recirculating Tests

The limited volume of corrosive environment in HT/HP tests makes issues such as solution volume to specimen surface area ratio a critical factor. In most cases, it is advantageous to limit this ratio to no less than 30 mL/cm<sup>2</sup>.

$$\text{Solution volume to surface area ratio} = V / (N \times A_s)$$

where:

$A_s$  = Exposed surface area of an individual test specimen  
(area calculation depends on size and shape)

$N$  = Number of test specimens in experiment

$V$  = Volume of corrosive solution used in test vessel

In any event, care should be taken to prevent depletion of critical corrosive species or contamination of the test solution with unacceptably high levels of metal ions produced by corrosion. Such conditions may require periodic changes in the test constituents after a certain period of testing time (e.g., 3 days, 7 days, 1 month, etc.) depending on their rate of consumption or contamination by corroding specimens.

In particularly critical situations, it is possible to minimize such concerns by using constant or periodic replenishment of either the gaseous or liquid phases in the autoclave

**FIG. 2—HT/HP test vessel with stirring attachment; (a) vessel schematic, (b) High pressure test vessel, (c) High pressure flow loop.**

while under pressurized conditions. An example of a pressurized liquid phase replenishment system used in HT/HP corrosion testing is shown in Fig. 3. These include systems that can refresh the liquid or gas phases with continuous or periodic additions by simply flowing through the test cell while at pressure. In other cases it may be possible to recirculate the solution after it has been recharged with particular corrosive species or been regenerated to attain certain compositional requirements.

### Factors Affecting HT/HP Test Environments

For simple HT/HP exposure tests involving either aqueous or nonaqueous phases with a gas cap over the solution, the total pressure is usually determined by the sum of the partial pressures of the constituents of the test environment, which will vary with temperature. Where liquid constituents are being used for the test environment, the partial pressure is usually taken to be the vapor pressure of the liquid at the intended test temperature (see Table 2 for steam pressure versus temperature). Vapor pressures for several other volatile compounds used in HT/HP corrosion testing can usually

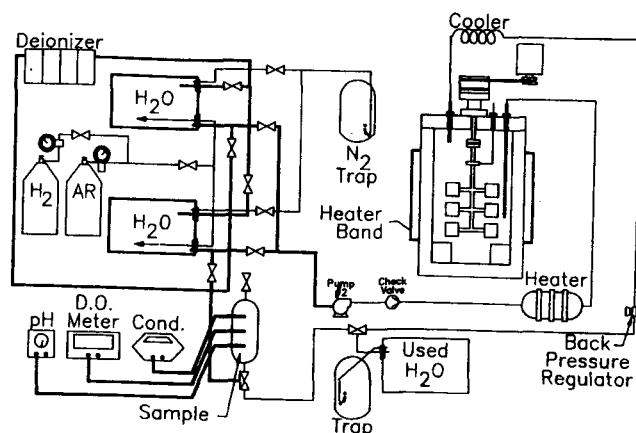

FIG. 3—HT/HP test vessel with recirculation loop and environmental monitoring.

be found in the chemistry literature. In some cases, higher test pressures can be obtained by pumping additional gas (either inert or corrosive) into the test vessel using a special gas pump depending on the situation being simulated. Alternately, hydrostatic pressurization may be employed to increase test pressure whereby there is no gas phase in the test vessel and the pressure is increased by pumping additional liquid into the test vessel in a controlled manner. However, this requires very careful techniques as the hydrostatic pressure increases very rapidly due to the incompressibility of the most liquids.

For mixed gases, the partial pressure of the constituents are usually represented as the product of their respective mol fractions (in the gas phase) times the total pressure (see below):

$$P_g = P_t \times X_g$$

where:

$P_g$  = partial pressure of gaseous constituent

$P_t$  = total system pressure, and

$X_g$  = is the mole fraction of the constituent in the test gas

For example, if a sealed, 2-L test vessel containing 75 % water was heated to 200°C, then the total pressure would be expected to be approximately 1.5 MPa. This is based on the vapor pressure of water as given in steam tables (Table 2). However, if a 10:90 mixture of carbon dioxide and nitrogen was added to the vessel to increase its pressure by 1.5 MPa to 3.0 MPa, then after saturation of the solution, the partial

pressure of the constituents would be estimated to be as follows: (1)  $PCO_2 = 0.15$  MPa; (2)  $PN_2 = 1.35$  MPa;  $PH_2O = 1.5$  MPa. Other liquid and gaseous constituents usually act similarly to the cases given. However, in cases where the gas phase is extremely soluble in the liquid gas more complicated ionic models can be used to predict the total and partial pressures of the constituents in the test vessel and their solubility in the liquid phases. Prior to initiating HT/HP corrosion tests, it is usually prudent to consult various sources of solubility and vapor pressure for the specific test constituents. This will usually prevent unintentional over-pressurization of the test cell.

The importance of partial pressure in HT/HP corrosion testing is that the solubility of the gaseous constituents in the liquid phase is usually determined by its partial pressure. For a particular mol fraction of gas in the vapor phase, its concentration in the liquid will usually increase with increasing total pressure. This is why the effects of low-level (ppm) corrosive impurities such as oxygen, hydrogen,  $H_2S$ , and many other species on corrosion and cracking are often found to be magnified at high pressure and exhibit corrosive effects not commonly found in conventional low-pressure corrosion tests.

### Special HT/HP Corrosion Test Conditions

HT/HP testing has been used to simulate corrosive environments commonly found in many industrial and commercial processes. Those which have been highly studied and which highlight some of the important effects and considerations of HT/HP corrosion testing are discussed briefly in this section.

#### Oxygen

In many cases, the effects of oxygen (or aeration) in solution are important due to its effect on the corrosion potential of materials, particularly alloys, which exhibit active/passive corrosion behavior. One example of the effects of oxygen on corrosion behavior is the combined effect of oxygen and chloride concentrations on the stress corrosion cracking (SCC) of stainless steel in HT/HP water systems [1]. Such conditions represent a wide range of aqueous applications. In general, the severity of SCC in stainless steel increases with both dissolved oxygen and chloride concentrations in an aqueous solution at elevated temperature. Additionally, if the oxygen concentration can be reduced to very low levels (0.1 ppm) through extensive deaeration procedures, this material can be used in systems with a reduced tendency for SCC compared to systems where the dissolved oxygen level is high.

Figure 4 shows a laboratory test vessel specially designed to examine the effects of oxygen on engineering materials. In such systems, it is very important to design the test equipment to (1) contain minimum volume of reactive constituents, and (2) to resist rapid oxidation or even burning of materials of construction. ASTM G 88, Guide for Designing Systems for Oxygen Service, gives guidelines that can be used for the design of such systems. The particular system shown includes the use of copper or copper/nickel alloys for test cells. In this case, alloy N04400 was used as the material of construction for the vessel. However, in some cases stainless or nickel-base alloys will provide sufficient oxidation

TABLE 2—Pressure of dry saturated steam versus temperature.\*

Temperature, °C	Absolute Pressure, MPa (bar)
100	0.1 (1.0)
150	0.5 (5.0)
200	1.5 (15.0)
250	4.0 (40.0)
300	8.5 (85.0)
350	16.5 (165.0)

\*In closed container with liquid phase present.

FIG. 4—Schematic of HT/HP oxygen test cell.

resistance in less severe environments. It is also important to carefully select all polymeric materials used in the system to resist deterioration and combustion in oxygen environments. This requires attention to both the partial pressure of oxygen in mixed gas environments as well as the maximum operating temperature of the system when selecting materials for the test vessel and ancillary equipment.

### Hydrogen

Another chemical species whose chemical behavior impacts corrosion resistance and materials performance is hydrogen. It has been known for decades that atomic hydrogen can produce embrittlement in many metallic materials to varying degrees, particularly under conditions of high-pressure hydrogen. Under high hydrogen environment pressure or electrochemical reaction, or both, hydrogen atoms can enter the material where it can react by one of the following mechanisms:

1. Recombination to form pressurized molecular hydrogen blisters at internal sites in the metal.
2. Chemical reaction with metal atoms to form brittle metallic hydrides.
3. Solid state interaction with metal atoms to produce a loss of ductility and cracks.

There has been much interest in conducting hydrogen embrittlement cracking (HEC) tests in aqueous media which can produce atomic hydrogen on the surface of materials as a result of corrosion or cathodic charging. In most cases, these tests can be conducted at ambient pressure and at

temperatures from ambient to elevated depending on the application. When aqueous hydrogen charging is involved, pressure is usually not a major factor. However, as in the case of steels exposed to aqueous hydrogen sulfide containing environments, the atomic hydrogen is produced as a result of sulfide corrosion. The severity of the mass-loss corrosion and hydrogen charging is directly dependent on the amount of hydrogen sulfide dissolved in the aqueous solution. In applications involving petroleum production and refining, compressed natural gas storage, chemical, processing and heavy water production such effects are compounded by exposure to HT and/or HP conditions. Additionally, variations in pH which control the type and amount of dissolved sulfide species and the severity of corrosion and hydrogen charging can be affected by hydrogen sulfide pressure.

The hydrogen flux produced by exposure to aqueous hydrogen sulfide containing environments can be categorized based on the hydrogen sulfide partial pressure. The effect of solution pH produced by the combined effect of certain soluble corrosive gases (i.e., hydrogen sulfide and carbon dioxide) is also important.

Service environments that contain a high partial pressure of gaseous hydrogen as found in hydrogen-fueled aerospace or transportation vehicles can only be simulated using HT/HP test methods. The environments involved in hydrogen storage, active cooling systems, and hydrogen combustion can vary in hydrogen partial pressure from less than 0.1 MPa to over 70 MPa (10 000 psi) and temperatures that range from cryogenic to over 925°C. In these situations, the concerns for absorption of atomic hydrogen lead to the need for laboratory HT/HP testing of engineering materials which include high-strength steels as well as advanced materials such as nickel-base and titanium alloys, intermetallic compounds and composites, high-conductivity microcomposites, and nonmetallic structural materials and composites [2].

### Other Dissolved Gas Systems

In other systems, similar effects of dissolved gaseous species can be important and may require the use of HT/HP corrosion test procedures to give accurate simulation of service environments. Examples of such conditions are those that contain carbon dioxide, sulfur dioxide, and  $\text{NO}_x$ , which can determine the pH of the aqueous phase and affect the severity of corrosion reactions.

To simulate dissolved gas conditions in the laboratory it is important to simulate their partial pressures in the gas phase over the test solution since this, in turn, will determine the amount of dissolved species present. If low (generally <1 %) levels of these constituents or high reaction rates are present, then some form of continuous or periodic replenishment of these species during testing may be necessary. For very low (ppm) levels of these constituents in pressurized systems, such procedures are usually always required to provide for valid test conditions to be maintained.

### Test Variations

The HT/HP corrosion test methods described previously require many specialized procedures, evaluation techniques and test equipment. In this section, four variations of common

HT/HP test methods that have been found to be useful in materials evaluation involving corrosion phenomena will be briefly described. These include:

1. Windowed test vessels.
2. Electrochemical measurements.
3. Hydrogen permeation measurements.
4. Mechanical property testing.

Typically, the major differences between these types of tests conducted at high pressure and in conventional low-pressure glassware are the special requirements and limitations imposed by the test vessel, vessel feed-throughs, and the high-pressure environment. However, these types of evaluations can be accomplished through careful planning and test vessel design.

#### Windowed Test Vessels

It may be necessary to make visual measurements or observations within the confines of the test vessel. Additionally, it may be necessary to introduce radiation into the test vessel to produce reactions on metal surfaces as in the case of photo-assisted chemical or electrochemical reactions or for conducting analytical techniques such as Raman Spectroscopy.

To accomplish direct visual contact with specimens in laboratory test vessels, it is common to use special transparent windows and fixtures which can withstand the pressures, temperatures, and corrosive environments commonly used in these experiments. An example of such a test cell is shown in Fig. 5. In this case, it is necessary to provide energy from an external light source to provide stimulation of a corroding metal surface. The transparent port is provided by a special connection in the end of the test vessel containing a sealed sapphire window which allows transmission of the light to the specimen surface. The specimen is also being monitored using electrochemical methods for its potential/current response under varying conditions of light stimulus [3].

Other types of specimen monitoring that can be performed by this technique are (1) visual observation of the development of localized corrosion phenomena with time, (2) monitoring of environmental crack initiation, and (3) crack growth rate measurements. In these cases, it is important to be able to provide for incoming light and for reflection of light from the specimen in order to visually observe the test specimen. Therefore, such measurements often require somewhat larger transparent ports and are usually limited to lower pressure systems.

FIG. 5—Schematic of HT/HP optical test vessel.

FIG. 6—HT/HP electrochemical test cell with electrical feed-throughs for working electrodes.

It is also possible to use fiber optics to provide an optical conduit into pressurized systems. In either case, it is possible to use photographic or video techniques to magnify, supplement, and record the direct visual monitoring and examination of corrosion processes first-hand. The main concern for such systems is that they be constructed of materials that are compatible with the test environment and have adequate pressure ratings. This is possible in lower pressure and less aggressive systems, but may prevent the use of such methods in some highly corrosive or ultrahigh-pressure applications.

#### Electrochemical Measurements

Electrochemical corrosion measurements can be conducted in HT/HP environments with modification of conventional test vessels and by using few special techniques. In general, most all of the conventional electrochemical techniques performed in glassware have also been conducted inside of HP test equipment. Figure 6 shows a test system that uses cylindrical electrodes where only the lower portion of the electrode is exposed to the liquid phase of the test environment and where the electrical connections are made externally to the test vessel.

In general, the most critical portion of any electrochemical system is the reference electrode. The design and construction of the reference electrode for HT/HP corrosion testing is particularly important as it must provide a stable

reference potential (relatable to other common reference electrodes) to which the working electrode (i.e., test specimen) can be compared. It must also give a reasonable service life to remain functional throughout the intended test period.

In many applications, a test vessel modified with an external reference electrode cell has become the most common system to minimize effects of temperature, pressure, or contamination, or a combination thereof, from the corrosive environment. This approach helps to prolong the usable life of the reference electrode. One of the most common reference electrode systems used in HT/HP corrosion testing is Ag/AgCl [4]. However, other reference systems have been developed and are used for application in specific environments [5]. The external reference electrode is usually contained in a separate pressurized compartment. The reference electrode is then connected to the test vessel using a bridge or conductive solution conduit.

To minimize penetrations into the test vessel for HT/HP electrochemical tests, it is possible to use the test vessel directly as the counter-electrode. This requires special selection of materials of test vessel construction so that it will be effectively inert to the test environment.

In systems that contain impurities which will contaminate common reference electrode systems and degrade their performance, it is possible to pressure balance the electrode [6] and to even provide a reverse flow into the test vessel to minimize ingress of the contaminant species into the reference electrode.

Another type of reference system that can be employed effectively in HT/HP systems where conventional stable reference electrodes are not usable is the use of an inert (i.e., graphite or platinum) or a corroding metal to produce a stable potential [7]. Such electrodes are considered “pseudo-reference” systems since they may tend to exhibit a drift in potential with time. However, in environments where no other convenient reference electrodes are available, they can provide at least a measurement of relative potential between materials in the environment even if their reference potentials cannot be considered truly constant.

### *Hydrogen Permeation Measurement*

In some environments that produce hydrogen charging in metals, it is necessary to measure hydrogen permeation rates and diffusion constants in order to predict hydrogen attack rates or time-to-failure by HEC. It may also be important to determine the effects of additions of inhibitors into the environment and surface barriers which may act to reduce the level of hydrogen flux. At ambient temperatures and pressures, such measurements are easily obtained through the use of various forms of the standard glass permeation cell reported in the literature [8,9]. Such procedures and equipment are generally limited to ambient pressure and to the atmospheric boiling point of the aqueous solutions in the permeation cell. For higher temperatures and pressures, further modifications must be made which involve adaptation of this system along with incorporation of a high pressure test vessel [10].

As shown in Fig. 7a and b, HT/HP systems have been used for both laboratory and field measurements of hydrogen flux commonly called a “patch probe” or “barnacle cell” [11]. They have typically been used for the monitoring of

**FIG. 7—Hydrogen permeation cell for conducting tests on HT/HP system with external electrochemical hydrogen patch probe.**

hydrogen permeation in steel refinery plant vessels and piping or pipelines exposed to corrosive wet H<sub>2</sub>S environments. For hydrogen permeation measurements in higher temperature systems, it is necessary to use solid state methods since systems involving liquids in the measurement compartment will be subject to evaporation or breakdown with increasing temperature. These systems depend on monitoring of either the pumping rate of a vacuum pump or the pressure

buildup rate in an evacuated compartment to determine the hydrogen flux through a membrane in contact with the hydrogen environment.

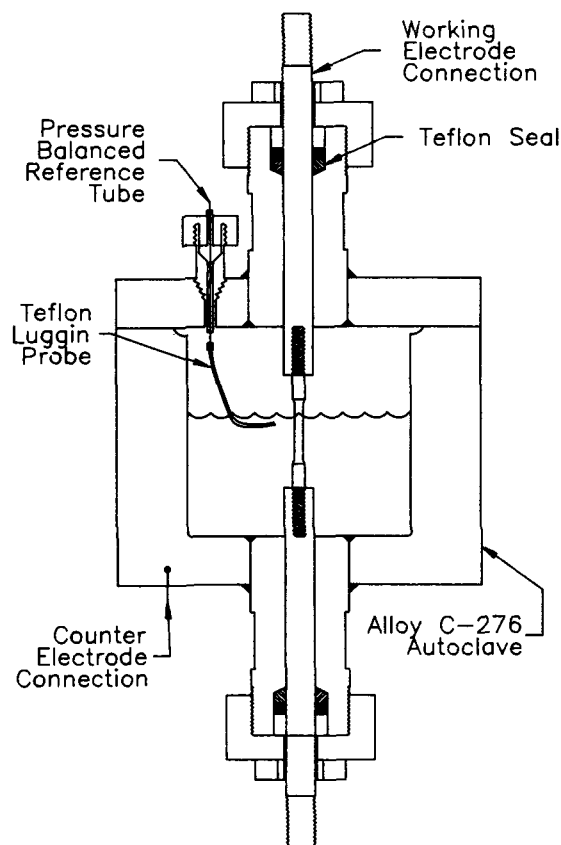

#### *Mechanical Property Testing in HT/HP Corrosive Environments*

In cases where susceptibility to HEC, SCC, liquid metal embrittlement (LME), or other EAC mechanism may be suspected, it is common to evaluate the actual mechanical behavior of the alloys under consideration in the corrosive environment of interest. For decades, these techniques were developed and conducted in low-pressure aqueous environments and are referred to as slow strain rate (SSR) testing or constant extension rate testing (CERT) [12]. The important aspect of such techniques is the requirement for these tests to be conducted in a range of strain rate or cross-head extension rate in which the material under evaluation is going to experience cracking if it is susceptible.

In general, it is necessary to conduct such tests slow enough so that the environment has adequate time to affect the material and produce cracking. These strain rates are typically in the range of  $10^{-4}$  to  $10^{-7}$  s $^{-1}$  for SCC in many common metals/environment systems. For HEC, the critical strain rate is somewhat higher (i.e.,  $10^{-2}$  to  $10^{-4}$  s $^{-1}$ ) in most susceptible iron, nickel, and titanium alloys. SSR tests are particularly adapted to HT/HP in simulated environments. Since the test is accelerated mechanically by the application of the dynamic straining, it is possible to use simulated test environments rather than the overly aggressive chemical environments commonly used in conventional standardized tests.

Figure 8a and b shows a vessel used to conduct SSR tests at HT/HP conditions. In aqueous environments, the heating is accomplished from the outside of the vessel to uniformly heat the entire test solution surrounding the specimen. For high-temperature gaseous environments it may be possible to heat the specimen within the pressurized test vessel. If not, the configuration of the test cell should be changed to reduce the radial distance between the internal diameter (I.D.) of the vessel and the specimen to minimize gas volume required and to reduce heat transfer problems. In either case, it is important to monitor the temperature of the gage section of the test specimen to obtain accurate measurement of test temperature.

In some cases, it may be possible to use the similarly designed HT/HP test vessels to conduct fracture or fatigue loading, or both. For such tests, accommodations must be made to be able to handle the generally larger specimen configuration of fracture mechanics specimens. Additionally, there is the need to closely monitor crack opening displacement or crack growth, or both, directly using various methods including (1) pressure and environmentally compatible clip gages, (2) mechanical fixtures which exit the pressure vessel, or (3) potential drop across the specimen. In the case of potential drop techniques, as the specimen cross section is reduced due to crack growth, the electrical resistance measured across the cracked region increases and can be monitored as a measure of crack growth. Alternately, in some cases, direct measurements of crack opening displacement can be conducted using special mechanical feed-throughs in the test vessel. This technique, while

**FIG. 8—HT/HP test vessel for slow strain rate tension testing.**

cumbersome, is preferred where the test environment is particularly corrosive and may attack clip gages and interfere with electrical feed-throughs for use with potential drop techniques.

#### **Safety**

HT/HP corrosion tests require attention to safety on many levels since this type of testing involves handling high pressures, high temperatures, and exposure to corrosive and potentially hazardous and/or toxic chemical test constituents. Special care should be taken to obtain properly designed and constructed test equipment and facilities, and to develop safe test procedures. Additionally, safety planning should be carried out well in advance of the initiation of testing and it should include training of technical personnel in the aspects of safely handling chemical environments at HT and HP as well as the development of contingency and emergency procedures in the event of problems.

#### *Pressure*

To safely handle high pressure environments, it is critical that all equipment including test vessels, piping, fittings, gages, and other ancillary components be properly designed and constructed to withstand the intended test pressure.

It is common to design test vessels and piping per methods given in Section VIII of the ASME Boiler Code even though in many cases compliance with this specification may not be mandatory [13]. Additionally, all test equipment and pressure vessels should be fabricated from materials that are highly resistant to the corrosive environments that they are going to contain. This is needed both from the standpoint of safety and to prevent depletion of reactive constituents from the test environment. Consideration should also be given to the full range of chemical environments that the test equipment will be exposed to during its useful service life. Major emphasis should be placed on selecting material(s) that are resistant to not just mass-loss corrosion but to localized corrosion and EAC. It is recommended that many sources of information be consulted in the process of materials selection along with any relevant service experience which can be obtained from field/plant operations and from manufacturers experienced in providing pressurized test equipment.

It is common for most corrosion test vessels to be designed to be periodically hydrostatically tested at pressures from 1.25 to 1.5 times their maximum working pressure depending on the nature of the service. It is also a good practice to limit the test conditions in the test vessel to less than the maximum working pressure limits. This will prolong the service life of fittings and seals. Also, prior to each use, a leak check of all fittings and seals with an inert gas will minimize problems later when the vessel contains corrosive and potentially hazardous test environments. Vessels can also be used with liners which are made from corrosion resistant metallic materials or nonmetallic materials such as TFE or glass depending on the nature of the test environment. This technique can prolong the useful life of a test vessel; however, it is important not to totally rely on liners to protect the test vessel. Situations can occur that result in breakage or leakage from the liner, thus exposing the test vessel to direct contact with the corrosive environment.

In some cases, chemical reactions in the test environment or interactions between the test environment and the specimens can produce unexpected increases in pressure or temperature, or both. Conditions that can result in large or rapid pressure increase inside of the test vessel should be carefully studied prior to testing and eliminated unless adequate safety precautions and/or pressure relief methods can be provided.

### *Temperature*

For tests conducted at high temperature, there are several concerns regarding safety that should be taken into account. The first is that HT corrosion tests may involve test conditions that are above the atmospheric boiling point of the aqueous solution or even above the flash point of various combustible constituents in the test environment. Therefore, all precautions to prevent leakage from the test vessel should be taken prior to the initiation of testing. This usually includes a pressure test of all fittings and seals with an inert gas prior to introduction of the corrosive environment.

In some cases, bolted closure vessels that are being used to conduct tests which involve very high temperatures (>250°C) may experience thermal expansion of the bolts in the closure. This situation can result in a relaxation of the

sealing force and can produce leakage from the test vessel at high temperature even though the vessel was leak-tight at low temperature. Similarly, when using test vessels that have elastomeric seals, it is important to limit the test temperature to conditions that will not produce either mechanical or chemical deterioration or thermal decomposition of the elastomeric seals. This situation can also result in leakage from the test vessel when it is hot.

Second, in most HT/HP corrosion tests, heating of the test environment is used to produce at least a portion of the total test pressure. Therefore, overheating as a result of loss of temperature control can lead to overpressurization of the test vessel and associated equipment. Unexpected pressure increases can be obtained during heating through volume expansion of test fluids. It is normal to take into account such conditions when determining the amounts of constituents to be added to the test vessel. Adequate precautions need to be taken to prevent temperature excursions through failure of temperature control equipment with the use of overtemperature controllers or thermostats. The exact needs in any particular test should be carefully considered.

### **Simulation of Service Environments**

In many situations, actual service environment samples are retrieved and brought to the laboratory to provide the most representative media in which to conduct such tests. In these cases, sampling techniques play a major role in determining the successful usage of simulated environment corrosion tests.

In some cases, the actual service environment may not be readily available or accessible for laboratory evaluation. Such cases include situations where the effects of changes in environment composition on corrosion behavior are being examined. Additionally, simulated service environment tests are used to select materials that are resistant to new processes that are not yet commercial. This necessitates the formulation of a simulated service environment from reagent grade chemicals. Judgments must be made concerning the effects of impurities found in process equipment which are not commonly found in reagent grade chemicals. In some cases, these impurities may act as inhibitors and in others they may act to promote corrosion or SCC. These judgments require a basic knowledge of alloy sensitivities to environment species and test parameters obtained through both service and testing experience and through review of the published literature and available corrosion databases.

### *Temperature Effects*

The service temperature is normally duplicated exactly in laboratory simulations. Unlike glassware experiments, HT/HP corrosion tests can be conducted at temperatures above the atmospheric boiling point of the test environment. This is an important benefit of HT/HP testing which normally results in better simulation of actual service conditions. However, problems may arise when the corroding system is not isothermal as in the case under heat transfer conditions commonly found in many types of industrial process equipment such as heat exchangers and dynamic process vessels. Temperature can also be used to accelerate reactions in the laboratory. This can have its drawbacks which

**FIG. 9—Test assembly for prototype component test with internal HT/HP hydrogen gas exposure.**

mainly arise when elevating the test temperature over the service temperature changes the operating corrosion mechanisms. Therefore, care must be taken to choose the test temperature that best typifies the service condition including normal operation and upset conditions.

#### *Pressure Effects*

Pressure stresses can be duplicated allowing simulation of actual components exposed to corrosive environments [14]. In the actual vessel tests, the environment is often pressurized hydrostatically. This testing arrangement allows for nondestructive inspection using techniques such as ultrasonics and acoustic emission to be used from the outside while the test is being conducted. It also provides for evaluation of complex situations involving fabrication, welding, stress relief, etc. It should be mentioned that, under such test configurations, careful test control and containment must be used. The consequences of failure can be minimized through the use of fully hydrostatic pressure conditions. Another example is shown in Fig. 9, which represents the evaluation of an actual component prototype pressurized with high-pressure hydrogen. Each chamber was monitored for internal hydrogen pressure versus exposure time so that time-to-failure from hydrogen attack could be determined [15].

In other cases, total system pressure may be of less importance in laboratory simulations. Usually, simulation of partial pressure of soluble gaseous constituents is the important parameter which affects the corrosion test results.

However, total pressure can be a major effect under conditions where total pressure affects phase behavior or flow conditions or where it may be a driving force in a particular chemical reaction or in diffusion of a particular species in the test environment. In these cases (e.g., where volatile inhibitors or polymeric coatings or seals are being evaluated), it is important to simulate the total pressure so that the proper relationships between liquid and gaseous phases or permeation of corrosive media can be obtained. An example of the effect of total pressure is the performance of sacrificial anodes under simulated conditions of varying depths of water.

### **STANDARDS: SCOPE, SIGNIFICANCE, AND USE**

The number of standards involving HT/HP corrosion testing is somewhat limited. In general, the procedures used for HT/HP corrosion tests have been highly specialized to the particular nature of the corrosion test and the test environment. Those that have been identified are described in this section.

#### **NACE Standards**

NACE has developed several standards involving HT/HP corrosion testing. These have involved the laboratory simulation of two types of corrosive environments: (1) Aqueous oilfield production environments containing corrosive acid gases (i.e., hydrogen sulfide and carbon dioxide) and water, and (2) nuclear reactor high-purity water environments.

#### *Oilfield Corrosion Test Environments*

NACE Standard Test Method TM0185 (Evaluation of Internal Plastic Coatings for Corrosion Control of Tubular Goods by Autoclave Testing) was developed to provide manufacturers, applicators, and users of internal pipe coatings with a method of comparing the performance of these coatings for corrosion control. The test method establishes a laboratory method for evaluation of plastic coatings for downhole tubulars in specific HT/HP environments for the purpose of corrosion control. The intent was to standardize existing laboratory methods used by various laboratories.

NACE TM0185 was not developed to provide results that correlate directly with any particular set of field conditions, but solely for the purpose of comparing materials under uniform laboratory test procedures. Controls are given for specimen size, test environment, test duration, and depressurization rate. It allows for post-test evaluation of the coating performance based on visual examination and various physical and mechanical evaluations.

NACE has standardized test methods (TM0177 and TM0198) for the evaluation of environmentally assisted cracking—EAC—(sulfide stress cracking of steels and SCC of stainless and nickel-base alloys exposed to simulated aqueous environments containing hydrogen sulfide. TM0177 involves exposure of tensile, bent beam, C-ring, and fracture mechanics specimens and TM0198 involves smooth and notched tensile and pre-cracked specimens using the slow strain rate testing technique. The purpose of these

specimens and test methods are to provide a basis to screen materials for EAC in environments containing both sulfide and chloride species in an aqueous environment. These tests are not meant to simulate service behavior directly, but to provide a reproducible method of comparing alloy performance, thus aiding the determination of the effects of various metallurgical and environment parameters. Suggested environmental conditions for testing are provided in these standards and may include HP/HT exposures in some cases. The standards provide meaningful information relative to specimen preparation and various methods that can be used to attain HT/HP test environments containing various partial pressures of hydrogen sulfide.

### *Corrosion Tests in High-Purity Water*

NACE has standardized two test methods that deal specifically with conducting corrosion tests in high-purity water for nuclear applications. These are NACE Standards TM0171 (Autoclave Corrosion Testing of Metals in High Temperature Water) and TM0274 (Dynamic Corrosion Testing of Metals in High Temperature Water). The two test methods discuss corrosion testing in high-purity water under dynamically replenished and recirculated conditions, respectively.

NACE TM0171 establishes suggested laboratory procedures for determining the extent and the rate of uniform corrosion of metals in high-temperature water or aqueous solutions at temperatures in the range 100°C to 360°C. This is to aid in the standardization of laboratory procedures and in the evaluation of corrosion test specimens exposed to HT/HP aqueous conditions. The standard is not applicable to the testing of cladding fissionable materials or neutron absorbing materials, which are the subject of ASTM G 2 (see next subsection). It is not intended that the data be used to determine the release rate of metallic elements to the test medium or to determine the effects of velocity on corrosion.

This method provides for the descriptions of test apparatus for the purification, storage, heating, pumping, and replenishment of a high-purity water environment and the exposure of test specimens in this environment. Techniques are provided for cleaning the test equipment and specimens, fixturing, solution purity levels, flow rates and testing procedures. Procedures are also given for the evaluation of the corrosion specimens and the corrosion films produced on them and for determination of corrosion rate. A critical part of the test method is the maintenance of the test environment within specific environmental limits.

NACE TM0274 appears to be an outgrowth of the previously mentioned TM0171 test method. It is similar in many aspects. The major difference is the use of a dynamic recirculation loop which accommodates both a high temperature test station and a low temperature test station in which corrosion coupons can be placed. This method can be used for (1) the quantitative measurement of the general corrosion rates of metallic materials for consideration for use in high-purity water, (2) the determination of the effects of flow velocity, and (3) the estimation of the release rate of metallic elements to the aqueous medium. No provisions

are made for simulation of heat transfer conditions or steam/water environments.

### **ASTM Standards**

There are also several ASTM standards that describe testing techniques for the evaluation of corrosion and materials compatibility which involve HT/HP conditions. These are:

- G 2M Test Method for Corrosion Testing of Products of Zirconium, Hafnium, and Their Alloys in Water at 633K or in Steam at 673K
- G 4 Method for Conducting Corrosion Coupon Tests in Plant Equipment
- G 72 Standard Test Method for Autogenous Ignition Temperature of Liquids and Solids in a High-Pressure Oxygen-Enriched Environment
- G 86 Test Method for Determining the Ignition Sensitivity of Materials to Mechanical Impact in Pressurized Oxygen Environments
- G 94 Guide for Evaluating Metals for Oxygen Service
- G 111 Standard Guide for Corrosion Tests in High Temperature or High Pressure Environment, or Both
- G 124 Standard Test Method for Determining the Combustion Behavior of Metallic Materials in Oxygen-Enriched Atmospheres
- G 129 Standard Practice for Slow Strain Rate Testing to Evaluate the Susceptibility of Metallic Materials to Environmentally Assisted Cracking
- G 142 Standard Test Method for Determination of Susceptibility of Metals to Embrittlement in Hydrogen Containing Environments at High Pressure, High Temperature, or Both
- G 146 Standard Practice for Evaluation of Disbonding of Bimetallic Stainless Alloy/Steel Plate for Use in High-Pressure, High-Temperature Refinery Hydrogen Service
- G 170 Standard Guide for Evaluating and Qualifying Oil-field and Refinery Corrosion Inhibitors in the Laboratory

Example of other ASTM standards which high pressure methods for evaluation of materials and corrosion apply include:

- D 572 Standard Test Method for Rubber-Deterioration by Heat and Oxygen
- D 3632 Standard Test Method for Accelerated Aging of Adhesive Joints by the Oxygen-Pressure Method
- D 6396 Standard Test Method for Testing of Pipe Thread Sealants on Pipe Tees
- E 712 Standard Practice for Laboratory Screening of Metallic Containment Materials for Use With Liquids in Solar Heating and Cooling Systems

These standards involve a variety of test conditions and environmental parameters. The ASTM standards listed provide specialized information on specific combinations of environments and materials and give guidelines for test procedures, equipment, and evaluation techniques required to measure or monitor corrosion resistance and material compatibility. ASTM G 111 is a standard guide that is directed at providing general guidelines for a broad range of tests that can be conducted under HT/HP conditions involving corrosion, environmentally assisted cracking, and electrochemical measurements.

# Atmospheric

*Sheldon W. Dean, Jr.*<sup>1</sup>

EXTENSIVE EXPERIENCE, TOGETHER with many exposure programs, has shown that atmospheric corrosion is a phenomenon that varies greatly from location to location [1]. Studies throughout the world have revealed that the rate of atmospheric corrosion is a function of the metal being tested, the location, the climate, the proximity to pollutants, and a variety of other factors. Most people understand that atmospheric corrosion can occur in outdoor exposures, but more recent experience has shown that corrosion can occur from indoor atmospheres under certain circumstances [2].

Outdoor atmospheric exposure tests have been carried out for a variety of purposes [3]. Alloy producers have used this type of testing to evaluate the performance of new alloys in a variety of atmospheric conditions. Atmospheric corrosion testing has also been used to test both metallic and nonmetallic coatings to demonstrate their performance in atmospheric conditions [4]. Manufacturers of items designed to be used in outdoor conditions sometimes expose components to various atmospheres to demonstrate their performance and develop data on the service life that may be expected from such components. In some cases, atmospheric exposure programs are run to evaluate the corrosivity of specific atmospheres. This type of information can be helpful in selecting coatings or other corrosion protection systems to be used at specific sites.

## BASIC PRINCIPLES

### Types of Exposures

Probably the most common type of atmospheric exposure is conducted in a static location; that is, racks or holding devices are fixed in a location and specimens are exposed for a test period at that site. This type of exposure can be carried out in sheltered sites or boldly exposed sites. A wide variety of different types of specimens may be employed in long-term tests.

Another type of test is the dynamic or mobile test where panels are mounted on vehicles to simulate the service conditions of cars or trucks. Vehicles are exposed to significant amounts of spray and splash from the road surface and, as a consequence, this environment is significantly different from that normally seen in the static exposures. In some

cases, panels have been mounted on the sides of trucks to allow a larger number of panels to be mounted in approximately the same type of environment [5]. Panels mounted on automobiles are generally mounted in locations where they are not visible, although in some cases bumper-mounted panels have been used [6]. Variability in dynamic tests is substantial because no two vehicles see exactly the same environment. A similar situation exists for ocean-going vessels. The atmospheric corrosion that occurs on aircraft carriers, for example, is unique because it incorporates both marine spray from the ocean and flue gases from the engines.

Because of the rather substantial variability in dynamic tests, coupled with the problem of having very limited numbers of panels on each vehicle, some investigators have employed an approach of spraying static panels with simulated road splash solutions, for example, mixtures of sodium and calcium chloride. This is, of course, a much more severe environment than normal static atmospheric exposure. However, it does have the advantage of being more reproducible than a vehicular exposure while allowing many panels to be exposed at the same time under the same conditions. Such an approach also allows for the natural wetting and drying that is normally seen in atmospheric exposures. These conditions are difficult to simulate in cabinet-type tests.

### Monitoring Atmospheric Variables

A conventional weather station approach has often been used to monitor atmospheric variables regarding atmospheric corrosion [7]. Temperature and relative humidity may be recorded continuously, and these data are used to produce average temperatures for periods of time such as days, weeks, or months. Electrical monitoring sensors have been developed to measure when wetness exists on the surface by means of detecting a potential difference between dissimilar metals [8]. A standard device is shown in ASTM G 84, Practice for Measurement of Time of Wetness on Surfaces Exposed to Wetting Conditions as in Atmospheric Corrosion Testing. The information on time of wetness is usually reduced to a percentage or fraction of time a surface is wet in a month or in a year.

Atmospheric sulfur, usually in the form of sulfur dioxide, is measured by means of a volumetric sampling approach in which samples of the air are passed through a detector that directly measures the sulfur dioxide concentration. Another

<sup>1</sup>President, Dean Corrosion Technology, Inc., 1316 Highland Ct., Allentown, PA 18103.

approach is to use a sulfation plate or sulfation candle [9] (Fig. 1). These devices rely on lead dioxide to react with the sulfur compounds in the atmosphere to form lead sulfate. At the conclusion of a fixed exposure period, usually 30 days, the sulfation plate or candle is removed from exposure and analyzed for the presence of lead sulfate. ASTM G 91, Practice for Monitoring Atmospheric  $\text{SO}_2$  Using the Sulfation Plate Technique, describes the sulfation plate method. Sulfation plates are exposed in a horizontal downward-facing position so that the lead dioxide reagent is not exposed to rainwater. ASTM D 2010, Test Methods for Evaluation of Total Sulfation Activity in the Atmosphere by the Lead Dioxide Technique, describes the sulfation candle, which is a similar type of collector except that it employs a vertical cylinder rather than a flat disk. Again, the sulfation candle must be protected from exposure to rain or snow. Neither the sulfation plate nor the sulfation candle is specific for sulfur dioxide. They will respond to reduced sulfur species such as hydrogen sulfide and carbonyl sulfide. However, the presence of these gases is relatively rare, and usually a source of such reduced species would be very apparent to investigators at the site. These gases dramatically enhance the corrosion of some alloys but are not equivalent to sulfur dioxide.

It should be noted that the volumetric measurement and the deposition rate measurement measure different phenomena. The transfer from the gas phase to the solid surface requires both convective diffusion and surface adsorption steps [10]. Air movement assists the convection process while the adsorption step is accelerated by the presence of

condensed moisture. As a result, correlations between volumetric concentration and deposition rate are approximate and may not necessarily apply from site to site. For corrosion correlation purposes, the deposition rate is a more relevant phenomenon. However, as a practical matter, the mass transfer rate that occurs on a sulfation plate or candle is probably not equivalent to what would occur on a flat surface or a wire. Therefore, the results obtained from devices such as sulfation plates provide a reasonable measure of the concentration of sulfur in the atmosphere but not an accurate measure of what deposits are on test samples or structures. The volumetric concentration monitoring instruments are clearly the preferred technique because they require less labor to expose and retrieve samples and can provide much more detailed information on how the sulfur dioxide concentration varies with time.

Sulfur dioxide deposition and chloride deposition have been designated dry depositions in studies concerned with the effects of acid precipitation in spite of the fact that these processes do occur when the specimen is physically wet with dew or rain. The term *wet deposition* refers to acidity delivered to the specimen during periods of rain or snow [11]. The reason for this distinction is that the source of acidity in precipitation is probably different from the source of either atmospheric sulfur dioxide or chloride. In order to monitor wet deposition, it is necessary to collect and analyze precipitation samples. In general, the damage to metals from acid precipitation is relatively small as compared to damage caused by significant levels of sulfur dioxide or chloride on most engineering metals.

Several techniques have been used to monitor chloride in the atmosphere. The wet candle method, ASTM G 140, Method for Determining Atmospheric Chloride Deposition Rate by Wet Candle Method, has been used in marine sites and consists of a fabric-wrapped tube in which the fabric is kept wet with water [12] (Fig. 2). The wet fabric acts as a collector for chloride particulates or droplets. Exposure periods of one week or up to one month have been used. The longer time periods can be a problem because the water source must not be allowed to dry. It is important to protect the wet candle from rain exposure so that wet candle assemblies are usually mounted with a cover over them. With the

FIG. 1—Sulfation plate in holder (see ASTM G 91).

FIG. 2—Wet candle apparatus with holder (see ISO 9225).

**FIG. 3—Comparison of wet candle and dry plate results for atmospheric deposition at two sites. Reference ISO/TC156/WG4/N236.**

wet candle method it is necessary to employ an antifreeze solution in cold climates when freezing can occur. Glycerine has been used for this purpose, but if glycerine is used, it is necessary to add an inhibitor to prevent biological growth in the solution. Another technique that has been used is the dry plate method. In this case, a vertical assembly is used with fabric stretched over a frame. Chloride-containing particles adhere to the dry fabric and are extracted from the fabric and analyzed at the end of the exposure period. Figure 3 shows the relationship between chloride deposition rates measured by both methods at two sites.

Atmospheric chlorides generally originate from marine sources. Surf is a major contributor to atmospheric chlorides. The spray from surf is entrained in the air and carried inland by the wind. As a result, spray droplets tend to settle out and dry out as they move inland, becoming smaller and more concentrated in an almost exponential decay as they move. Chloride particles are very water soluble so that areas washed by rain tend to retain much less chloride than protected areas. Large smooth surfaces are much poorer collectors of salt particles than small diameter wires. As a result, devices such as the chloride candle or dry plate collector give only rough approximations of actual chloride depositions on test samples or structures exposed to the atmosphere.

Chlorine and hydrogen chloride are sometimes found in industrial atmospheres. These compounds can cause serious corrosion, but are not covered by the ISO standards.

### Classification of the Atmosphere—ISO Approach

The International Organization for Standardization Technical Committee on Corrosion of Metals and Alloys, ISO/TC156, has developed a systematic approach to classification of atmospheric corrosivity [13]. This approach is based on two different methods. The first method involves exposure of standard coupons of steel, zinc, copper, or aluminum to the atmosphere at the site where the classification is to be made. The selection of which metal is to be used will depend on the purpose of the test. Panels are

exposed for a one-year period, at which time they are retrieved and a mass loss per unit area obtained. This mass loss value can then be used to determine the corrosivity of the atmosphere at that location. Table 1 shows the corrosivity classes based on mass loss results.

The second method involves measurement of the temperature, time of wetness, amount of sulfur in the atmosphere, and the amount of chloride in the atmosphere. Temperature and humidity information can be used to estimate the time of wetness. This estimation is based on the percentage of time that the temperature is above freezing, 0°C, and the relative humidity is at the same time above 80 %. Once the time of wetness is known, it is then possible to determine a time of wetness class (Table 2). Sulfur dioxide content of the atmosphere can be estimated either by measurement of the concentration in the atmosphere over some period of time or by means of the sulfation plate or candle. This information is then used to develop a sulfur dioxide class or P class (Table 3). The chloride dry plate or wet candle method is used to obtain the chloride deposition rate of the atmosphere that is then converted to a chloride class or S class (Table 3). The corrosion class or C class can be obtained for the time of wetness, chloride, and sulfur dioxide classes (Table 4). Once the corrosion class is known, it is possible to estimate the corrosion damage that will occur in either short-term or long-term exposures for the five metals, steel, weathering steel, aluminum, copper, and zinc (Table 5). The detailed information on this method is discussed in Tables 2–5.

**TABLE 6—Gaseous and solid materials affecting indoor atmospheric corrosion.**

Substance	Concentration µg/m <sup>3</sup>	Comments
SO <sub>2</sub>	1-100	30-50% lower than outdoors
NO <sub>2</sub>	2-150	Similar to outdoors
H <sub>2</sub> S	1-3	Higher in some situations
Cl <sub>2</sub>	<0.1	
HCl	0.1-20	Usually very low
NH <sub>3</sub>	20	
Soot	5	Higher when fires are used
O <sub>3</sub>	2-25	Usually lower than outdoors

This system of atmospheric classification is now being revised to create a new approach based on dose-response functions for steel, copper, and zinc. Because the corrosion of aluminum occurs by a pitting or localized mechanism, the traditional approach of using mass loss to determine severity of attack is often misleading. Atmospheric corrosion problems with aluminum alloys are most frequently a result of metallurgical conditions rather than environmental conditions, and the behavior of aluminum may be excluded in the upcoming revision of the ISO 9223-6 documents.

### Indoor Atmospheres

Although the ISO approach to classification of the atmosphere was envisioned to cover both indoor and outdoor atmospheres, the classification range on indoor atmospheres was too broad to be useful for many applications. The corrosion concerns for indoor atmospheres covered three different categories. One major area of concern was storage of metallic parts and components in warehouses. The concern

here is that the storage conditions do not stain or damage the parts. The second area of concern is the use of metallic materials in indoor atmospheres where corrosive conditions can occur, for example, plumbing fixtures in humid environments such as kitchens and bathrooms. A third area of concern is for electronic components [14]. There have been serious problems with failures of measuring devices, computers, and related equipment in control rooms, and even in offices, that have been attributed to corrosion. The ISO system is adequate to deal with the concerns of warehouse storage but has not been adequate to deal with the concerns of electronic materials degradation. The reason for this is that the mechanism of corrosion that causes problems in electronic circuitry is quite different from that encountered by engineering materials in atmospheric outdoor exposure. The problems that occur in electronics are development of resistive films that interfere with switch operation and the migration of corrosion products causing short circuits or related problems. Two specific problems have been noted. One is the development of pore corrosion. This phenomenon has been observed on gold surfaces in the form of black spots distributed over the gold surface. The second problem is film creep that refers to a rapid diffusion of corrosion products across the gold surface. Other problems have also been noted.

In the case of corrosion in storage areas and the protection of materials in humid indoor atmospheres, conventional techniques that apply to outdoor corrosion are suitable. The primary mechanism seems to be the development of moisture films on the metallic surfaces that then promote corrosion. In the case of electronic components corrosion, the critical moisture contents are at substantially

lower values than are normally seen in outdoor corrosion. In addition, the critical pollutants seem to be reduced sulfur species such as  $\text{H}_2\text{S}$ , and also acid chloride species such as hydrogen chloride. These species are present in indoor atmosphere at very low levels, typically 0.1–10 ppb (Table 6).

## ATMOSPHERIC TESTING

### Program Development

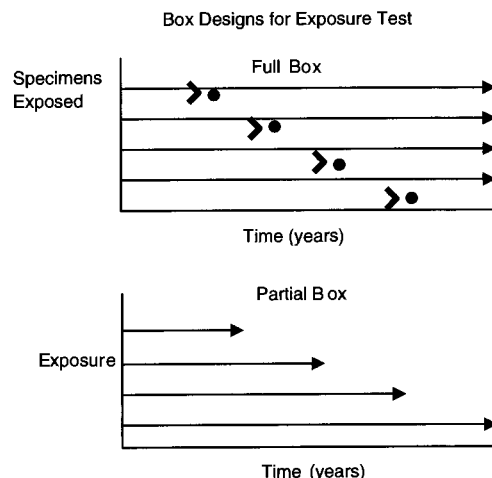

The first step in an atmospheric testing program is to develop a program that will provide answers to the question: What is the purpose of this program [15]? If the purpose of the program is to characterize the atmospheric performance of a new material, it is important to determine what time interval is relevant and what reference materials should be included so that a definite comparison can be made. It is also important to determine what type of exposure will be used and what the specimens should look like. Further, it is important to determine at this time how the results of the program will be evaluated. Understanding these issues at the beginning of the process is very helpful in determining later how many specimens are needed and what types of materials are required and, ultimately, what the cost of the exposure program will be. Table 7 supplies a list of the key issues that need to be decided at the beginning of any atmospheric testing program.

### Exposure Program

The simplest type of exposure program is a fixed material program in which a set of specimens is exposed for a fixed time period. At the conclusion of this period, the specimens are retrieved and evaluated. A variation on this approach is to inspect the specimens at the exposure site at intervals during the exposure period and report results.

A somewhat different approach is to expose a group of specimens initially and then retrieve portions of the group at intervals, e.g., 1 year, 3 years, 5 years, 10 years, and 20 years. This approach allows the investigator to estimate the kinetics of the process if an assumption can be made about the constancy of the environment. A variation of this approach is to replace each specimen removed with an unexposed specimen to be retrieved at the conclusion of the test. This approach allows variations in the environment to be averaged out or at least acknowledged (Fig. 4).

An important issue in exposure tests is the question of replication. It is desirable to use at least duplicate specimens in corrosion tests. However, in atmospheric tests it is good

Specimens exposed at dots and retrieved for evaluation at arrow head  
Full box allows atmospheric corrosivity change estimate as well as specimen corrodibility estimate Partial box estimates only specimen changes

**FIG. 4—Example of exposure program designs [15]. (Reprinted from Materials Performance. © Copyright 1988 by NACE International. All Rights Reserved by NACE; reprinted with permission.)**

practice to use a larger degree of replication, preferably five specimens for statistical analysis. Three specimens are generally considered the minimum acceptable in most cases to avoid problems from damage, loss, and unexpected events.

In general, indoor exposures are usually made for relatively short periods. In most cases, 30 days and 90 days are typical, although occasionally a 1-year exposure is used. Because the purpose of these exposures is generally to evaluate the environment, it is usually necessary to obtain results rapidly to determine what protective measures are necessary.

### Specimen Types

Once the purpose of the program is decided, the next question is: What type of specimen should be used? Some typical specimen types are listed in Table 8. Probably the most widely used specimen in atmospheric exposure programs is a 100 by 150 mm panel. This type of panel is very suitable for mass loss measurements. It is also used for evaluating coatings and is convenient to handle. For nonferrous metals, investigators have preferred to use larger panels, for example, 100 by 200 mm [16]. Larger sizes do lose some convenience and ability to fit on some balances.

Wire helix specimens have been used to monitor atmospheric corrosivity [17]. It should be noted that this type of specimen tends to show higher corrosion rates than flat panels of the same material. For this reason, it is likely that helix specimens will be dropped for the purpose of site monitoring. The reason that wire samples show higher corrosion rates seems to be related to the increased collection efficiency of small diameter cylinders in gathering other gaseous or solid particles and these materials tend to stimulate the corrosion process [18].

Coated Specimen	ASTM D 1654
Fabricated Items	

Atmospheric stress corrosion tests are frequently run with U-bend specimens or two-point loaded specimens. U-bend specimens are used when the stress level is not a variable, but it is desired to determine if an alloy is susceptible to cracking (Fig. 5). Two-point loaded specimens have the advantage of being held at points of low stress and at locations where a crevice will do the least damage. It is relatively simple to construct racks to hold two-point loaded specimens. A two-point loaded specimen can be designed to cover a wide range of maximum stresses [19]. Other types of standard stress specimens may also be used, for example, direct tension specimens, C-ring specimens, and other bent beam configurations (Fig. 6). Table 8 has a list of standard stressed specimens that may be used in atmospheric corrosion.

It is occasionally desirable to evaluate galvanic corrosion effects from atmospheric exposures (see ASTM G 116, Conducting Wire-on-Bolt Test for Atmospheric Galvanic Corrosion and ASTM G 149, Conducting the Washer Test for Atmospheric Galvanic Corrosion). Several different types of specimens have been used for this purpose. One approach is

FIG. 5—U-bend specimen designs (see ASTM G 30).

to use washers bolted together as shown in Fig. 7 [20]. At the end of the test, it is possible to measure the depth of corrosive attack associated with the region of galvanic corrosion by means of mass loss measurements. Other types of galvanic exposure specimens that have been used have included plates of different metals bolted together. The third type that has been used is the helix wire on bolt type of specimen [21] (see ASTM G 116), and in this case the test specimen is usually a wire that is wrapped around a bolt of a different material to evaluate the galvanic corrosion that may occur from this couple. Mass loss measurements are usually used to evaluate the loss of metal from the wire specimen.

Atmospheric exposure programs are often run to evaluate coating performance. This is true for both organic coatings and for inorganic coatings including metallic coatings such as electroplated coatings [22], flame-sprayed coatings [23], and hot-dipped coatings [24]. The key issue in the case of organic coatings is the adhesion of the coating and particularly the ability of the coating to maintain adhesion and protection even in the face of mechanical damage. Consequently, it is often desirable to scribe an x-shaped mark on the surface of the panel after the coating process. The scribe should penetrate to the basis metal. At various times during the exposure, the panel is evaluated by noting how far the corrosion of the basis metal has proceeded under the

FIG. 6—Bent beam specimen designs (see ASTM G 39).

FIG. 7—Cross section of washer bimetal assembly (ASTM G 149).

paint or coating. In the case of metallic coatings, visual examinations are usually conducted during the life of the exposure to look for penetration of rust through the coating, spalling, or other degradation of the coating itself.

It is often desirable to expose fabricated items such as roofing panels, automotive trim parts, wire ropes, wire specimens, and a host of other hardware items. This type of program allows the performance of a finished product to be evaluated in a controlled exposure program. It is especially good for evaluating differences in finishes to determine if the difference in the finishing process has caused a change in the coating performance.

### Specimen Preparation

The type of preparation that a specimen will require depends very much on purposes of the exposure program [3]. In cases where bare metals are to be exposed to the atmosphere, a somewhat arbitrary decision must be made on what type of surface finish will be tested. Typical steps in an atmospheric exposure program are given in Table 9.

Characteristically for ferrous metals, it is generally desirable to employ a mechanical finishing technique that removes the mill scale. Surface grinding with 120-grit abrasive is a typical finish. Such finishes are rather active, and consequently panels must be wrapped with an inhibiting paper or protected by other means so that the surface rust does not develop during shipment. In this case, it is necessary

TABLE 9—Specimen preparation steps.

to remove any traces of inhibitor that might have transferred to the metal surface. A solvent cleaning step immediately before exposure is frequently used.

It is also necessary to place an identifying mark on the panels before exposure (Table 10). In the case of ferrous metals where heavy corrosion occurs, it is necessary to use techniques such as drilling holes in the panels in specific locations or milling notches in the side of the panel so that it will be possible to identify the panel even after extensive corrosion has occurred [16]. In the case of materials that do not suffer such extensive corrosion in atmospheric exposures, techniques such as stencil stamping may be used. It is desirable to use clean, sharp stencils and to avoid transferring foreign metals from the stencil stamps to the metal surface. In the case of coated samples, stencil stamping may not be acceptable. Other approaches may be used such as writing the panel identification on the back of the panel with a weather-resistant paint or attaching a tag to the panel with the panel identification stamped on it.

The panels should be carefully weighed and measured before exposure. This should be the last step before the panel leaves the laboratory. In the case of coated samples, an important issue is the edge protection. In some cases, specimens are sheared from larger sheets and, consequently, the edges are left uncoated. In this case, it is essential that measures be applied to edges to prevent edge damage from confusing the results. For short-term exposures, vinyl tape is sometimes used to protect the edges. It may also be necessary to carry out preliminary evaluations of the surface of coated samples, including reflectivity measurements, color measurements, or related optical measurements before placing them on exposure.

For indoor exposures, the metals used are usually copper, silver, or steel. Typical exposure panels are 10 by 50 mm by 0.5 mm thick. These panels are usually abraded with a fine silicon carbide abrasive paper; 1200 grit for copper and silver and 500 for steel. After polishing, the specimens should be cleaned in ethanol in an ultrasonic bath before exposure. Occasionally, nickel or zinc specimens may be used in special circumstances where these metals are to be used.

### Outdoor Exposure

Most outdoor exposures are carried out in static situations with the specimens mounted on racks. A standard system has been developed whereby racks are mounted on stands with the panels exposed, in the United States at an angle of 30° to the horizontal [16]. In Europe the exposure angle is generally 45° to the horizontal [25] (Fig. 8). Exposure racks have been designed so that panels can be placed in the rack without disturbing adjacent panels. It is general

TABLE 10—Specimen identifying systems.

Type of Panel	Appropriate System

FIG. 8—Atmospheric exposure test rack support design (see ASTM G 50).

practice to have the panel racks facing south in the northern hemisphere. In the case of panels with organic coatings, the top surface will receive the greatest sun exposure if the panel is mounted at an angle to the horizontal equal to the latitude of the site. When panels are mounted in locations where sources of atmospheric-borne corrodants are present, generally it is desirable to have the racks face the source of the corrodant species. For example, at seacoast locations panels should face the surf. In cases where there are adjacent industrial sites, it may be desirable to orient the panels so that they face the source of the pollutants from the industrial source [3].

At the time panels are exposed, the weather should be recorded. It is also important to record the location of each panel on the rack and the rack identification and location at the site. Plans should also be made at this time for retrieving the panels or specimens. For short-term exposures this may not be a problem. However, for programs that go for many years, maintenance of the site can be a problem.

In the case of exposure programs where visual examination of the specimens is to be made at intervals during the program at the exposure site, it is important to set up an evaluation form so that the information desired is recorded along with the specimen identification (see ASTM G 33, Practice for Recording Data from Atmospheric Corrosion Tests of Metallic-Coated Steel Specimens). In the case of tests on stress corrosion specimens, it is desirable to remove specimens at regular intervals during the exposure period so that they may be examined for cracking. This is especially true for specimens that develop thick corrosion product films on their surface because such films often obscure the cracks. It is also desirable to retrieve broken specimens in stress corrosion programs so that the specimen may be evaluated for mode of cracking and presence of secondary cracks. For two-point loaded specimens, it is desirable to wire both ends to the holder in case the specimen fails by total fracture.

### Indoor Exposure

Indoor exposure sites generally employ vertical panels hung from hooks or wires through a hole near the top of the

specimen. In some cases, a plastic enclosure is used to protect the specimens from direct exposure to air currents and to shield the specimens from falling dust. In general, it is desirable to avoid locating the panels near walls and corners where unusual air currents may circulate. It is important that the site location be chosen to be representative of the conditions in question, but more importantly, that they not be damaged or disturbed by the activities in the area.

Indoor specimens may be evaluated by several techniques including mass gain, mass loss, electrochemical reduction, (coulometric measurement), and electrical resistance increase. Microbalance measurements on mass gain after removal of particulates is probably the most popular method because it requires the least specimen handling. However, it will detect dust and particulates on the surface that adhere strongly and may overestimate the corrosion damage in cases where this condition occurs.

Another approach to the microbalance concept is to deposit a thin layer of the metal in question on a quartz crystal and monitor the mass change due to oxidation by means of the change in resonance frequency of the crystal. Applying an AC potential across the thickness of the crystal and detecting the resonance frequency in the shear direction can activate the quartz crystal. By selecting a crystal orientation that has minimal temperature dependence on the resonance frequency, it is possible to obtain a device that can monitor mass changes on a continuous basis [26]. This technique can detect mass changes as low as  $10^{-6}$  g/cm<sup>2</sup>. The metal chosen for the test is typically deposited by vacuum evaporation onto the quartz surface.

### Site Monitoring/Evaluation of Environment

One of the distinguishing characteristics of atmospheric exposure programs is that the environment is not under the investigator's control. Sites may be selected to have specific properties or characteristics; however, unpredictable variations occur in weather patterns in both short- and long-term exposures. Furthermore, the presence of corrosive materials in the environment is often the function of activities that go on at some distance from the exposure site and, as such, are

entirely outside the control of the investigator. Consequently, it has long been a desire of investigators to develop techniques for evaluating the corrosivity of sites where exposure programs are taking place. One approach to measuring site corrosivity is to expose a set of standard panels of a known material that can be used as a control. Steel panels have been widely used for this purpose (see ASTM G 92, Practice for Characterization of Atmospheric Test Sites); however, zinc, copper, and aluminum have also been used [17]. The test material performance can be compared to the standard panel material performance and conclusions drawn from that. This is a very important approach and should be practiced as much as possible because we may never be able to measure all the variables that affect atmospheric corrosion.

The standard panel approach, however, does not provide information as to what caused corrosivity of the environment. In order to understand the factors that contribute to corrosivity, it is desirable to obtain data on the temperature, relative humidity, time of wetness, time during which precipitation occurred, and wind velocities [16]. It is also desirable to obtain samples of precipitation at various times during the exposure period and have it evaluated for acidity and the presence of ionic species. Another factor is the presence of sulfur species in the air, especially sulfur dioxide. The sulfation plate or actual volumetric sampling may be used. In addition, in marine locations it is desirable to have some estimate of the airborne salinity, either through a chloride candle or dry plate method [27]. Another variable that is very important, but seldom measured, is the temperature during the period which panels are wet. Corrosion occurs mainly during periods of wetness, so that the temperature during this period is most important in terms of determining the corrosion kinetics. Table 11 contains a list of atmospheric variables that are often monitored.

In the case of indoor corrosion, there are several parameters that can be measured to determine the corrosivity of the atmosphere. Unfortunately, there are no standards currently available that relate the corrosivity of the atmosphere to the concentrations of corrosive components, but the measurement of such components may be helpful in determining

what is causing problems with an indoor environment. For gaseous components, there are two types of measurements that can be used: active sampling and passive sampling. Active sampling requires a pump to draw a specific quantity of air into a measurement chamber. The gaseous components are measured by a specific method, e.g., IR absorption, and recorded. Passive samplers use either a diffusion cell or a direct deposition method. The diffusion cell employs a stagnant tube through which the components must diffuse and then be absorbed and measured. The deposition method eliminates the stagnant tube and relies solely on natural convection to transport the species in question to the reactive surface. The following gases have been monitored using diffusion cells: SO<sub>2</sub>, NO<sub>2</sub>, H<sub>2</sub>S, NH<sub>3</sub>, and O<sub>3</sub>. Particulates are more difficult to monitor and require different methods. Again, active sampling requires a pump to draw a specific volume of air through a filter or onto impingement plates that is then analyzed. Collection plates may also be used together with microscopic methods of analysis and evaluation. Temperature and humidity measurements are also important to measure for evaluation of the environment.

The corrosivity of indoor atmospheres must be determined by standard panel exposures. Currently ISO/TC 156 is developing standards on indoor corrosivity classification. These standards have not yet been adopted.

## ATMOSPHERIC EXPOSURE STANDARDS

ASTM Committee G01 has written a number of atmospheric exposure standards, which are listed in Table 12. ASTM G 50 provides a recommended practice for atmospheric corrosion test programs. ASTM G 33 covers visual

**TABLE 11**—Atmospheric variables for exposure program.

Variable	Measurement Frequency	Report	Typical Units
Temperature	Hourly	30 day A&R	°C
Temperature when wet	Hourly	30 day A	°C

TM0175-75	Visual Standard for Surfaces of New Steel Centrifugally Blast Cleaned with Steel Grit and Shot—Item #21209-P

examination of panels with metallic coatings such as galvanized or aluminized panels. There are several standards written by Committee G01 on stress corrosion specimens shown in this table. In addition, there are descriptions of galvanic specimen design, sulfation plate, time of wetness, and characterization of atmospheric test sites. ASTM Committee B08 has a standard on evaluating electroplated samples and atmospheric exposures. This standard, ASTM B 537, Practice for Rating of Electroplated Panels Subjected to Atmospheric Pressure, includes charts showing pit densities.

The International Organization for Standardization, ISO Technical Committee 156, has written six standards that

apply to atmospheric exposures, which are shown in Table 13. One standard covers galvanic corrosion specimens, one is a general procedure for atmospheric exposures, and four cover the subject of classification of atmospheres for corrosivity. ISO/TC156 is now considering the question of indoor atmospheric corrosivity classification and will be preparing standards in this area.

The National Association of Corrosion Engineers International (NACE) has several standards related to atmospheric corrosion, which are shown in Table 14. These standards apply mainly to coating systems to protect from corrosion.

The Instrument Society of America (ISA) has established a classification system for indoor corrosivity [28] that applies mainly to electronic devices.

# Seawater

James F. Jenkins<sup>1</sup>

## BASICS

AS IN OTHER NATURAL environments, corrosion testing in seawater is dependent upon the actual environmental conditions experienced by the exposed materials during the entire duration of exposure. These environmental conditions can vary widely in any specific location. Normal seasonal variations as well as variations from year to year and temporary natural or manmade conditions can dramatically affect the conditions of exposure that control overall corrosion behavior of materials. Seasonal variations include changes in temperature, dissolved oxygen content, and the type and extent of biological fouling. Significant year-to-year variations such as those caused by the aperiodic general ocean surface water warming in the eastern Pacific Ocean, called El Niño, also affect the seawater environment over a wide area. Temporary natural conditions may include natural proliferation of microorganisms such as the "red tide" blooms of algae that can significantly reduce dissolved oxygen availability. Temporary manmade conditions such as spills of oil, chemicals, and sewage can also have a dramatic effect on the local environment that can affect corrosion.

A further complication is that these variations may not affect the deterioration of materials in a simple manner. In many cases, metal corrosion is dependent upon surface films that form upon exposure to seawater. Variations of initial exposure conditions can affect the protective nature of these films, which can affect the further corrosion behavior of the material. Thus, a sample first exposed under conditions conducive to the formation of a protective film may perform very differently than the same material exposed for an identical period, but was first exposed to conditions that resulted in the formation of a film that was less protective. In other cases, short-term variations in environment may be sufficient to initiate attack that would not occur during typical conditions and that, once initiated, can continue over extended exposures.

The interaction between biological activity and material performance is very significant in seawater. Macrofouling such as barnacles and mussels can be either protective or can result in accelerated corrosion depending on the material exposed and the extent of the accumulation of fouling. Anaerobic conditions are frequently found at the base of extensive fouling accumulation and this can dramatically affect corrosion of many materials. Seasonal variations and

temporary upsets can also result in the death and sloughing off of specific types of fouling organisms, which can cause temporary upsets of conditions at the surface of the material.

Because of the highly variable nature of the seawater environment, the results of corrosion testing in seawater are subject to significant variability. Reference 1 describes several test programs that demonstrate this variability. Considerable variability in the corrosion behavior of steel, aluminum and copper-nickel was also demonstrated in a worldwide seawater corrosivity test program described in Ref 3. To properly interpret the results of such tests, it is important to include control samples in the testing program. These control samples should include materials whose corrosion performance in the environment is well established. One control should be a material such as mild steel, which corrodes significantly in the environment so that corrosion rates for the control can be established. Another control should be a material that has marginal resistance to the environment so that upset conditions that may cause unusual initiation of corrosion can be detected. Additional control materials with compositions and characteristics similar to those being tested should also be included. For example, if performance of a newly developed stainless steel is being evaluated, samples of previously tested stainless steels should be included as controls.

## SPECIMEN CONFIGURATION

There are no specific standards for the configuration of samples for seawater testing. A few general guidelines should be considered when determining the appropriate specimen configuration and size. As metallurgical condition is an important variable in the performance of many metals, specimens with metallurgical condition similar to that of the material of interest should be included in the test. For example, if plate material is of primary interest, plate material should be selected for testing. If the metallurgical condition of interest is not defined, or several conditions are of interest, specimens of the material with different metallurgical conditions should be exposed.

ASTM G 52 (see section on standards at the end of this chapter) recommends a nominal sample size of 100 by 300 mm. In general, larger specimens are preferred over smaller specimens. First, larger specimens will expose a greater amount of surface area which will increase the probability of initiation of localized attack such as pitting.

<sup>1</sup>329 Drake Street, Cambria, CA 93428.

Second, where measurement of corrosion rate by mass loss is important, mass losses for larger specimens will be greater, thus requiring lower precision in weighing for equivalent precision in mass loss per unit area. Third, for many sheet and plate materials, exposed edges may corrode differently than exposed faces. Corrosion potential differences resulting from these differences may accelerate the corrosion of either the edges or faces. This effect is minimized in larger samples because the ratio of face area to edge area is minimized. Increasing the sample size beyond approximately 300 by 300 mm, however, has little further effect in minimizing the influence of the edges on face behavior of most materials. Unlike laboratory tests where the volume of solution must be adjusted for sample size, this is not a factor in natural seawater exposures.

### Duration of Exposure

Because long-term durability is required for most marine applications, corrosion test exposures for periods of less than six months usually are not sufficient for engineering purposes. Exposures of 0.5, 1, 2, 5, 10, and 20 years are recommended in ASTM G 52. For control specimens, information on environmental variability can be obtained by exposing specimens for periods of one-fourth of a year where the specimens are initially exposed one-fourth of a year, a half-year, and three-quarters of a year after the start of the test. Year-to-year variability can be evaluated by exposing a series of specimens that are initially exposed at one-year intervals after the start of the test and removed after one year of exposure.

Testing for shorter periods may be appropriate when the test sample configuration intentionally provides more severe conditions than anticipated in service. Crevice corrosion tests using severe artificial crevice geometries may only require 30–90 days of exposure to establish relative crevice corrosion resistance.

### Number of Test Specimens

The number of replicate test specimens depends upon the desired reliability of the results of the test. ASTM G 16 gives guidance for establishing the required number of replicate specimens. In general, as recommended in ASTM G 52, triplicate specimens for each exposure period are sufficient for many seawater corrosion tests.

## TESTS FOR SPECIFIC TYPES OF CORROSION

If susceptibility to specific types of corrosion is of interest, specialized sample configurations can be used. If the corrosion performance of the material in seawater is completely unknown, at a minimum it should be evaluated for general corrosion and pitting, galvanic corrosion, crevice corrosion, and stress corrosion.

### General Corrosion and Pitting

Evaluation of general corrosion and pitting does not require any special specimen configuration. Mass loss and pit depths

can be measured on specimens of nearly any configuration. Specimen size, however, may dictate the type of instrumentation that is utilized in these measurements.

### Galvanic Corrosion

Galvanic corrosion tendencies can be evaluated by developing a galvanic series for the materials of interest as described in ASTM G 82. Galvanic corrosion rates can be established by exposure of galvanic couples as described in ASTM G 71.

### Crevice Corrosion

For many alloys such as stainless steels that rely on passivity for corrosion resistance, crevice corrosion can be a limiting factor in their seawater corrosion resistance. For a specific alloy, resistance to crevice corrosion in seawater is predominantly dependent upon the tightness and depth of the crevice formed and on the ratio of exposed surface inside and outside the crevice. Many crevice corrosion tests have been developed that attempt to control these three primary factors in crevice corrosion. ASTM G 78 describes a variety of crevice-forming assemblies and other test considerations. Both flat and cylindrical specimens are described in the latest version of ASTM G 78. It should, however, be remembered that even simple immersion tests include crevice testing because natural crevices form where the specimens are held in the test racks and may also be present at such features as sheared edges and drilled holes as well as under fouling organisms such as barnacles. Therefore, when specimens specifically configured for crevice corrosion evaluation are not included in a test program, special attention should be given to inspection of the specimens at these inherent crevice sites for indications of susceptibility to crevice attack. When artificial crevice formers are used, other crevices can be avoided by using the crevice former fastener to hold the specimen.

### Stress Corrosion

While many laboratory tests for resistance of metals to stress corrosion cracking have been developed, only a few tests are amenable to actual in-situ testing in seawater. These primarily consist of the exposure of statically stressed type test specimens such as described in ASTM G 30, G 38, G 39, and ISO 7539-2, ISO 7539-3, and ISO 7539-5. In addition, welded specimens such as described in ASTM G 58 are excellent for evaluation of the stress corrosion resistance of weldments in simple immersion tests. Evaluation of corrosion fatigue is usually limited to laboratory testing.

## SPECIMEN PREPARATION

Because multiple samples will normally be exposed in a seawater test program, specimens should be labeled in a manner whereby the sample can be easily identified during sample preparation and evaluation. ASTM G 52 recommends several methods of such specimen labeling including the use of coded drilled holes, edge notches, corrosion-resistant tags, and stamped numerals. In some cases, the use of stamped

numerals may introduce significant local residual stress in the sample which may cause cracking in susceptible materials. In addition, location of the specimens on the exposure racks should be recorded as a backup identification method.

To develop quantitative and reproducible corrosion performance data in any corrosion test program it is important to properly prepare the specimens for exposure. ASTM G 1, Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens, gives guidelines for specimen preparation for exposure. This standard includes guidelines for cleaning, measuring, and weighing the samples prior to exposure. In many marine corrosion studies, multiple samples will be placed on racks before exposure and a considerable period of time may elapse between specimen cleaning and exposure. In these cases, it may be necessary to store the specimens and racks in a low-humidity environment prior to exposure. In addition, care must be taken in handling the specimens to prevent contamination of the specimens with oils, salts, or other contaminants on people's hands.

## SPECIMEN EXPOSURE AND RETRIEVAL

An obvious but not trivial consideration in seawater corrosion testing is that the samples must not become lost prior to the end of the exposure period. The test racks and suspension systems must be resistant to corrosion failures during the exposure period. In-surface exposures, storms, mechanical damage by floating debris, vandalism, and many others may result in specimen loss. Frequent inspection of the exposure site is necessary to identify potential problems before specimen loss occurs. In deep ocean exposures, storm damage is less of a problem, but methods for locating and handling the racks requires considerable planning and ocean engineering experience in order to expose and retrieve the specimens without loss or damage.

### Static Testing in Surface Environments

Several test rack designs are described in Ref 3. For surface exposures where fouling accumulations are likely to be extensive, test racks that boldly expose the specimen surfaces such as shown in Fig. 3-3 and 3-6 of Ref 3 are preferred over basket-type racks such as shown in Fig. 3-7, where the spaces between the faces of the specimens can become completely clogged with fouling organisms and potentially affect the test results. As described in ASTM G 52, test racks should be fabricated from materials that are reasonably corrosion resistant. Wooden racks are usually limited to a one-year life. Aluminum alloy 5086 test racks may be suitable for exposures of up to five years. Welded nickel-copper alloy 400 racks have essentially indefinite life in surface seawater, but are expensive and heavy. Nickel-copper alloy 400 is subject to crevice attack in seawater and this may be significant on fasteners. Reinforced plastic structural shapes, fastened with corrosion-resistant fasteners such as titanium, are relatively inexpensive, lightweight, and durable for long exposure periods.

In designing test racks and exposure facilities, consideration must be given to handling of the test racks. In many cases, material handling equipment will not be provided and the racks will be handled by hand. The total weight of the rack plus

specimens should be limited to about 50 kg for manual handling by two persons. Allowance should also be made for the fouling that will accumulate on the test specimens and racks.

To identify problems such as frayed suspension ropes and rack entanglement, inspection of the exposure site at weekly intervals as a minimum with additional inspections during stormy periods is recommended. In most cases, specimens that become detached can be replaced in the test racks without serious effect on the test results if the samples are retrieved and replaced in the racks within a few days.

### Velocity Testing

Testing of materials for resistance to seawater under velocity conditions such as testing for resistance to erosion-corrosion, cavitation, and direct impingement can be performed in the ocean but are more commonly performed in water pumped into tanks and troughs. Velocity can be achieved by moving the specimen through the water, but is more commonly accomplished by moving the seawater past fixed specimens. Flow troughs can be designed to give flow velocities up to 2 m/s. Tests at higher velocities are essentially laboratory tests performed in continuously or intermittently refreshed seawater. There are several testing procedures that have been developed to perform these tests under standardized conditions. ASTM G 32 and G 73 are standard methods for vibratory cavitation erosion and liquid impingement erosion testing, respectively, and can be performed using refreshed seawater. Jet impingement testing usually requires filtration of the incoming seawater to avoid clogging of the jet orifices. Tests using spinning disk samples are described in Ref 3. Other tests at very high velocities have been developed as described in Ref 5. For testing at extreme velocities, such as those encountered by hydrofoils, special test apparatus using spinning circular water troughs have been developed.

Other nonstandard velocity tests can be performed using subscale or even full-scale systems. An example of such tests is the evaluation of condenser tubing using pumped seawater. While these tests provide results useful for the development of specific systems, the results may not be readily applicable to systems of different design or using different materials. Where water is pumped, such as in testing of condenser tubes and pipes, particular attention must be paid to the effects of turbulence and surface shear stress. The hydrodynamics at the test sample surface must be similar to the hydrodynamics anticipated in service.

### Deep Ocean Testing

Deep ocean testing is performed to determine the effect of depth-related environmental variables on material performance. To determine the relative effects of variation in environment, tests sites with significant variation in environment should be selected. For example, where oxygen content is the major variable of interest, sites with high, minimum, and intermediate oxygen content should be used. To compare deep ocean test results with results from surface seawater, testing of replicate specimens in the deep ocean and in surface seawater is often performed.

The emplacement and retrieval of deep ocean test samples is expensive and involves the coordinated efforts of

various ocean engineering disciplines such as navigation, ship handling, rigging, oceanography, and marine geotechnology. As in all ocean operations, considerable planning is required for successful emplacement and retrieval of deep ocean corrosion test samples. Sample configuration and preparation for deep ocean testing is similar to that for surface seawater exposures. For deep ocean exposures it is common to emplace and retrieve large assemblies of multiple racks containing individual samples. The test samples should be protected from atmospheric and salt spray corrosion during transit to the test site. This can be accomplished by transporting the racks below deck for small racks or by covering larger racks with plastic sheeting.

The test rack assembly design is dependent on the deployment and retrieval method selected. One test rack assembly design and the method for emplacement and retrieval of the test rack is described in Ref 6. In deep ocean testing, the accumulation of fouling organisms is much less than in near surface waters and basket-type racks can be used as the spaces between the sample faces will not become clogged with fouling organisms. Contamination of samples by corrosion products from other test samples can be minimized by grouping samples of similar types in separate racks. Particular attention should be given to vertical location of test samples. For example, aluminum samples should be located above copper alloys as copper corrosion products falling onto the aluminum alloys can cause contamination of the aluminum alloys, whereas the aluminum corrosion products have little effect on the copper alloys. Painted carbon steel, 5083 and 5086 aluminum alloys, and reinforced plastic test racks and rack assemblies have all been successfully used for deep ocean testing.

To provide different removal times, replicate rack assemblies can be emplaced and retrieved separately. As an alternative to removal of replicate racks, it is possible to design a rack assembly such that individual racks or even individual samples can be removed by remote operated vehicles or manned submersibles. Although not proven, autonomous systems that release racks or individual specimens at intervals for surface retrieval are within the capability of modern ocean engineering technology. Once these racks reached the surface they could report their location through satellite systems for location and recovery by a surface vessel.

## SPECIMEN EVALUATION

The evaluation of the specimens in any corrosion test must be appropriate for the type of corrosion that actually occurs on the samples. In many cases, the actual sample evaluation requirements will not be known until the samples are retrieved and examined visually. This can complicate the administration of the testing program as the cost of specimen evaluation and the time to perform the evaluation cannot be planned in advance. For example, if general corrosion is the only form of corrosion experienced, the cost of sample evaluation by mass loss measurement is relatively inexpensive, whereas a form of corrosion such as stress corrosion cracking may require a high cost evaluation.

Upon removal from exposure, the specimens should be examined visually as soon as possible after retrieval. If more than a few hours will elapse between the removal of the specimens

and this initial examination, the samples should be rinsed with fresh water after removal. For deep ocean tests, this will usually be performed at sea and sufficient fresh water for this purpose must be provided. Whenever possible, the samples should be photographed to record their appearance upon retrieval.

After initial visual examination, the specimens should be cleaned. ASTM G 52 gives guidelines for evaluation of specimens after exposure to surface seawater. In surface seawater exposures, the accumulation of fouling organisms may be removed using wooden or plastic scrapers and bristle brushes prior to chemical cleaning. In deep ocean and velocity tests, the accumulation of fouling organisms is usually very limited and scraping is usually not required. It may be appropriate to visually re-examine the samples and rephotograph them at this stage of the evaluation.

The specimens should be cleaned in accordance with the methods recommended in ASTM G 1 or ISO 8407. The samples should then be remeasured to determine geometric changes and reweighed to determine mass loss. Nonuniform attack must be evaluated using methods appropriate for the type of attack experienced.

Pitting corrosion should be evaluated using the methods described in ASTM G 46. Pitting evaluation of aluminum alloys can also be performed using the practices recommended in ISO 8993 and 8994. As crevice corrosion often results in pitting attack, crevice attack is frequently evaluated using techniques outlined in ASTM G 46. Due to the effect of material and surface condition on pitting, statistical analysis methods described in ASTM G 16 should be applied to estimating the confidence interval of the pitting. In addition, the statistical analysis methods described in ASTM G 16 can be applied to crevice corrosion data where not only the material and surface condition, but also the inevitable variability in crevice tightness may influence susceptibility.

Other forms of attack such as exfoliation of aluminum alloys and dezincification of brasses require specialized evaluation and interpretation. Methods and standards for evaluation of exfoliation of aluminum alloys which are given in ASTM G 34 and G 66 are for materials exposed to artificial environments but may be used for evaluation of materials exposed to natural environments such as seawater. Many forms of attack can be best evaluated by microscopic or mechanical tests. ASTM E 3 gives standard methods for preparation of metallographic specimens, but does not provide specific guidelines for use of metallographic analysis in evaluation of corrosion. There are many standards for mechanical testing, such as ASTM A 370 for mechanical testing of steel products, that can be used in evaluating corrosion damage.

## STANDARDS

Standards applicable to field testing in natural seawater are given below:

### ASTM

- E 3 Methods of Preparation of Metallographic Specimens
- G 1 Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens

- G 15 Terminology Relating to Corrosion and Corrosion Testing
- G 16 Guide for Applying Statistics to Analysis of Corrosion Data
- G 30 Practice for Making and Using U-Bend Stress-Corrosion Test Specimens
- G 32 Test Method for Cavitation Erosion Using of Vibratory Apparatus
- G 34 Test Method for Exfoliation Corrosion Susceptibility in 2XXX and 7XXX Series Aluminum Alloys (EXCO Test)
- G 38 Practices for Making and Using C-Ring Stress-Corrosion Test Specimens
- G 39 Practice for Preparation and Use of Bent-Beam Stress-Corrosion Test Specimens
- G 46 Practice for Examination and Evaluation of Pitting Corrosion
- G 52 Practice for Exposing and Evaluating Metals and Alloys in Surface Seawater
- G 58 Practice for the Preparation of Stress-Corrosion Test Specimens for Weldments
- G 66 Method for Visual Assessment of Exfoliation Corrosion Susceptibility of 5XXX Series Aluminum Alloys (Asset Test)
- G 71 Guide for Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes
- G 73 Practice for Liquid Impingement Erosion Testing
- G 78 Guide for Crevice Corrosion Testing of Iron-Base and Nickel-Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environments
- G 82 Guide for Development of a Galvanic Series for Predicting Galvanic Corrosion Performance

### International Standards Organization (ISO)

- 7539-1 Corrosion of Metals and Alloys-Stress Corrosion Testing-Part 1: General Guidance on Testing Procedures

- 7539-2 Corrosion of Metals and Alloys-Stress Corrosion Testing-Part 1: Preparation and Use of Bent-Beam Specimens
- 7539-3 Corrosion of Metals and Alloys-Stress Corrosion Testing-Part 3: Preparation and Use of U-Bend Specimens
- 7539-5 Corrosion of Metals and Alloys-Stress Corrosion Testing-Part 5: Preparation and Use of C-Ring Specimens
- 8407 Metals and Alloys-Procedures for Removal of Corrosion Products from Corrosion Test Specimens
- 8993 Anodized Aluminum and Aluminum Alloys-Rating System for the Evaluation of Pitting Corrosion-Chart Method
- 8994 Anodized Aluminum and Aluminum Alloys-Rating System for the Evaluation of Pitting Corrosion-Grid Method

# Freshwater

Walter T. Young<sup>1</sup> and Philippa Fairer<sup>1</sup>

THIS CHAPTER PROVIDES an overview of standard corrosion testing procedures for freshwater systems. Additional information is provided in Chapter 31—Freshwater. Freshwater can be defined simply as water that is not salty; brackish water as defined by the dictionary is water having a somewhat salty taste. A more quantitative definition of brackish water is water with a salinity between 0.5 and 17 parts per thousand [1]. Then freshwater can be further defined as water with a salinity of less than 0.5 parts per thousand. For the purposes of this chapter, freshwater systems include potable water, heating/cooling, steam, condensate, rivers, streams, lakes, and wastewater.

Corrosion studies are beneficial for both ensuring a safe operating system and containing costs associated with maintenance, downtime, and replacement parts. Testing aids in selecting a material, designing the physical and operating parameters of a system, selecting a water treatment program to mitigate corrosion, and monitoring the effectiveness of water treatment. These studies are especially useful when a system is in the design stage; however, existing systems also benefit from corrosion testing.

## FACTORS AFFECTING CORROSION

The environment must be considered when designing any testing program. Environmental factors that affect the corrosion rates of materials in freshwater systems can be divided into two categories. The first category, water chemistry, includes: pH, electrical resistivity, scaling ability, concentration of corrosives, suspended matter, and water treatment additives. Factors such as temperature, pressure, metallurgy, redox potential, biological effects, velocity, and galvanic effects comprise the second category. These factors must be identified for freshwater systems so that corrosive conditions may be simulated during testing. A full description of these factors is beyond the scope of this paper. The reader is referred to texts on corrosion [2–7].

### Water Chemistry

Factors that influence water corrosivity include pH, electrical resistivity, scaling ability, concentration of corrosive

species, and water treatment additives. Corrosive species include chlorides, sulfates, suspended matter, and dissolved gases.

In general, if the pH only is altered between pH 4 and 10, the corrosion rate of steel, copper, or stainless steel is not altered significantly. However, most common materials of construction for freshwater systems are adversely affected by waters with a pH less than 4. Zinc and aluminum will freely corrode in waters with a pH lower than 6 and higher than 9.

The electrical resistivity of water is a function of the concentration of electrically conductive ions it contains. Low resistivity waters are more corrosive generally because of the availability of ionic species to transport charge between anodic and cathodic sites. However, the magnitude of the resistivity is not the only determining factor for a water's corrosivity; waters with high resistivity may be corrosive due to the presence of corrosion-causing bacteria.

Some flowing waters have the ability to form protective scales (primarily calcium carbonates) on the surface of metals. This tendency is a function of the pH, temperature, alkalinity, and amount of total dissolved solids. Excessive amounts (above 100-ppm total) of ions such as chlorides or sulfates may inhibit the formation of protective scales. The Langelier and Ryznar Indices quantify the tendency of water to form a scale [1,8].

Chlorides and sulfates are common ions known to be aggressive towards metals. In general, environments with excessive amounts of chlorides or sulfates are considered to be aggressive towards most common materials of construction for freshwater systems.

The concentrations of dissolved gases in a freshwater system should also be determined to simulate corrosive conditions in a test. Of concern are oxygen, carbon dioxide, hydrogen sulfide, chlorine, and ammonia. Freshwater systems with at least 2 ppm of dissolved oxygen are considered to be corrosive. Oxygen is a necessary component for most corrosion reactions. However, oxygen is necessary for some metals, such as stainless steels and aluminum, to form a protective oxide film. This oxide is responsible for the corrosion resistance of these metals to many environments. Carbon dioxide and hydrogen sulfide in sufficient quantities may cause the pH of a freshwater system to decrease. Hydrogen sulfide is aggressive to copper, ferrous, and galvanized steel [9,10]. Chlorine and water form hypochlorous acid (HOCl) and the hypochlorite ion (OCl<sup>-</sup>). These are oxidizing agents and reduce pH and alkalinity, which can

<sup>1</sup>Principal Engineer and Former Engineer, respectively, Corropro Companies, Inc., 610 Brandywine Parkway, West Chester, PA 19380.

increase corrosion [2,11]. Ammonia causes corrosion of copper and copper alloys [4,11].

### Other

The second category of factors that affect corrosion includes: temperature, pressure, metallurgy, redox potential, biological effects, velocity, and galvanic effects [4,5]. In general, corrosion rates increase with increasing temperature or pressure. Both temperature and pressure affect reaction rates and gas solubility. Temperature will also affect the formation of protective scales.

Higher flow rates may have a beneficial or an adverse effect in freshwater systems. In many cases, the corrosion rate will increase with increased flow rates. This is mostly due to the removal of oxides or protective films that may form on the metal surface and the increased availability of oxygen to the surface. Erosion corrosion may occur on some alloys if critical velocities are exceeded. Critical velocities may be lowered by the presence of entrained solids or gases, which have the tendency to scour metal surfaces. One benefit of a higher velocity is the cleaning action, which makes it more difficult for biological organisms to attach to the walls of a system and form colonies. In addition, stainless steels benefit from higher flow rates because of the tendency to clean debris from surfaces and mitigate crevice corrosion and the increased oxygen availability to maintain the passive film.

The metallurgy of a system may have an impact on the type or magnitude of corrosion. In particular, the presence of inclusions or voids may lead to premature corrosion induced failures. In addition, grain boundaries that are formed during the manufacturing process may be different in composition from the rest of the material. This difference in composition may cause a form of galvanic corrosion commonly referred to as intergranular corrosion. Elements in an alloy may selectively corrode under certain conditions. This process, dealloying, is common in brass alloys containing more than 15 % zinc in certain waters. In addition, cast irons may preferentially corrode and an embrittled graphitic matrix will remain. The mechanical properties of the structure or piping will change, although the dimensions of the cast iron will be the same. Stainless steels and various copper alloys when subjected to (a minimum of 10 % yield strength) tensile stress, may fail prematurely due to stress corrosion cracking in water. Stainless steel may fail depending on the chlorine content. Avoiding manganese bronzes, leaded red brass and austenitic stainless steels that are not solution heat-treated may eliminate these problems.

Several types of bacteria are known to be corrosive to metals. Acid producing, sulfate reducing, thiobacillus, slime forming, and gallowella are among the most common forms of these bacteria. Acid producing bacteria (APB) may produce acids by their metabolic process. These acids will attack the base metal in very localized areas, usually beneath their colonies. Other organisms, not directly involved with redox reactions, may benefit from the corrosion process. Although some forms of bacteria thrive in deaerated systems, they may also be found in aerated systems underneath deposits of corrosion products or colonies of aerobic bacteria. For more information regarding

microbiologically influenced corrosion, the reader is referred to Refs 12 and 13.

Galvanic corrosion occurs when two dissimilar metals in the same environment are electrically connected. This type of corrosion may also exist in localized areas on the same metal. For example, a galvanic corrosion cell is formed if an area of piping is at a higher temperature than adjacent piping. In this case, the metal in the hotter zone is more active and will corrode. As another example, galvanic corrosion may occur if a new section of piping is welded into a system that contains older piping containing deposits. The new section (with its clean surface) will be more active than the older section of piping. Crevice corrosion occurs due to the formation of a differential oxygen cell that leads to galvanic corrosion. The crevice area is at a more active potential than the surrounding metal that has better access to oxygen. This form of corrosion is typically expected with materials (such as stainless steels or aluminum) that depend on a naturally occurring oxide film for their corrosion protection. However, crevice corrosion may also occur on steel and copper.

### Corrosion Considerations

The system's layout, operating conditions, maintenance procedures, and materials of construction should be defined so that corrosion tests can be designed to simulate conditions that exist or will exist in the system. For piping systems, the presence of elbows, tees, valves, placement of pumps, and presence of insulating joints should be known. For cooling water systems, the degree of cycling or concentrating before blowdown should be known.

## BASIC CORROSION TESTING TECHNIQUES

### Methods of Exposure

Corrosion testing may be conducted in the laboratory, pilot plant, or field. Systems that are either in the design phase or operating, benefit from laboratory and pilot plant testing. In-situ testing is useful for pilot plant testing and for providing information for systems that are currently operating [7].

Laboratory tests should simulate the water chemistry and operating conditions of the freshwater system. A sample of water from the system may be used if it is available. Immersion testing and electrochemical testing are commonly used for laboratory tests. Laboratory tests are often used to simulate a process in order to confirm a failure mode.

In-situ testing is commonly conducted in pilot plants. This testing is useful in evaluating or monitoring a water treatment system or the effects of varying operating parameters, such as flow rate and temperature. In addition, the performance of different alloys in a system may be studied by in-situ testing. In-situ testing provides information on uniform corrosion rate, types of corrosion, and pitting tendencies. In the case of utilities or others testing water treatment procedures to comply with the maximum permissible lead-copper concentrations in potable water, pilot testing is performed using corrosion specimens arranged in

loops with the various metals used in the system included in the loop. Copper/lead concentrations in the recirculating water are tested under various treatment protocols [14].

In-situ testing is also performed in the field to determine the effectiveness of a water treatment system, the performance of difference alloys, and the effects of varying operating parameters such as flow rate and temperature. Uniform corrosion rates, types of corrosion, and pitting tendencies are identified with in-situ testing.

## Design

The expected forms of corrosion can be anticipated once the water chemistry, operating conditions, materials of construction, and system layout are defined. A corrosion test matrix can be designed by determining the expected forms of corrosion. Some of the common forms of corrosion found in freshwater systems are described in the chapter on Freshwater Testing in Section V of this manual. A list of test methods is presented in this chapter. The following section describes the applicability and significance of these standardized tests.

## Uniform Corrosion

Uniform corrosion rates may be determined by weight loss or electrochemical methods. Both methods average a specimen's corrosion rate over its surface area. Corrosion rates calculated from weight loss data also average the loss over the exposure period. Electrochemical methods may yield instantaneous or time averaged corrosion rates. Weight loss testing is performed by immersing a coupon in a test solution either in the laboratory or in-situ.

The following standardized test methods are relevant for determining a uniform corrosion rate of a material in a specific test environment:

*ASTM G 31, Practice for Laboratory Immersion Corrosion Testing of Metals*—This method describes typical test vessels, metal specimens (coupons), process controls, aeration techniques, coupon placement and supports, exposure times, and corrosion rate calculations.

*ASTM G 1, Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens*—Methods for preparing, cleaning, and evaluating corrosion test specimens are discussed in this standard. Coupon preparation procedures include surface finish, specimen identification, degreasing, weighing, and dimensional measurement. After testing, several cleaning procedures are recommended that will remove common corrosion products for each type of alloy without causing significant additional corrosion to the specimen. The formula for calculating corrosion rates by weight loss testing is also presented in this standard.

*ASTM G 3, Practice for Conventions Applicable to Electrochemical Measurements in Corrosion Testing*—Conventions used for electrochemical corrosion testing are presented in this standard. Sign conventions for electrode potential, electrode potential temperature coefficients, and current and current density are discussed.

*ASTM D 2688, Test Method for Corrosivity of Water in the Absence of Heat Transfer (Weight Loss Methods)*—This standard contains two methods for performing corrosion rate

testing. The first method (Method A) uses flat, rectangular-shaped metal coupons that are mounted on pipe plugs and exposed to water flowing in metal piping such as in municipal, building, or industrial water systems. The corrosive and scaling tendencies of cooling waters can be evaluated by subjecting the coupons to the water in a bypass piping arrangement. Coupons are evaluated by measuring weight loss or gain (ASTM G 1), determining the characteristics of foreign matter on the coupon, measuring the depth and distribution of pits, and examining the coupon for other forms of localized corrosion. The second method (Method B) determines the weight loss or gain of metal pipe inserts that are installed in a plastic bypass assembly tailored to provide the same surface and flow conditions as in the normal metal piping system. Dimensions are selected so that water flow (distorted or no distortion) is the same as in the metal piping system. In both methods, meaningful data might require months or years to obtain depending on the corrosiveness of the water. Less corrosive waters require more exposure time. It should also be noted that several coupons might be needed in order to evaluate pitting since pits might not develop on a small coupon.

*ASTM G 4, Method for Conducting Corrosion Coupon Tests in Plant Equipment*—This standard outlines the procedures for performing immersion testing in an operating system. Typical mounting apparatus are described and illustrated. This standard discusses test specimen size, shape, preparation before testing, identification procedures, installation, exposure time, retrieval, cleaning, weighing, and examination.

*ASTM G 59, Practice for Conducting Potentiodynamic Polarization Resistance Measurements*—The technique of polarization resistance testing is described. This standard conducts electrochemical testing in 1.0 N H<sub>2</sub>SO<sub>4</sub>. The apparatus, specimen preparation, and test environment are described. In addition, the equipment, electrochemical test procedure, and standard reference plots are presented.

*ASTM G 96, Practice for On-Line Monitoring of Corrosion in Plant Equipment (Electrical and Electrochemical Methods)*—This standard outlines procedures for online corrosion monitoring in operating systems. The test methods described in this standard are used to determine the cumulative metal loss (electrical resistance method) or instantaneous corrosion rates (electrochemical method). Reference 15 provides a summary of electrical resistance and polarization resistance theory.

*ASTM G 102, Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Measurements*—Corrosion rate equations and sample calculations are included. In this standard, corrosion rates are calculated from galvanic cell currents, polarization corrosion data (including Tafel extrapolations), and polarization resistance data.

*NACE TM0171, Autoclave Corrosion Testing of Metals in High Temperature Water*—A material's resistance to systems operating at high temperatures and high pressures may be evaluated by this method. In general, tests performed by this standard are conducted between 212°F and 680°F (100°C and 360°C). Weight loss and metallographic examinations are performed after test specimens are exposed in the test solution at the high temperature and pressure for a selected period of time. This test method contains

a description of the test apparatus, test specimens, test solution, test duration, and methods of specimens evaluation and reporting results.

*NACE TM0274, Dynamic Corrosion Testing of Metals in High Temperature Water*—This standard presents a method for evaluating a material's behavior with respect to corrosion in high temperature, high pressure, recirculating aqueous environments. Since this method is conducted in the pilot plant, it may be used to determine the effects of water velocity unlike NACE TM0171. This method is used to determine the uniform corrosion rate and is not designed to evaluate localized corrosion. In general, test specimens are placed in a test loop and exposed to the environment at select operating conditions. After exposure, the specimens are evaluated by visual, weight loss, and metallographic inspection. This method suggests test apparatus, test specimens, operating conditions, test duration, methods of evaluation, and reporting results.

*NACE TM0169, Laboratory Corrosion Testing of Metals for the Process Industries*—A method for laboratory immersion testing is presented. This method involves immersing test specimens in an environment and performing weight loss analysis after exposure. Specimen preparation, test equipment, test conditions and solution, methods of supporting specimens, test duration, cleaning methods, and evaluation of results are covered in this standard.

*NACE RP-0775-87, Preparation and Installation of Corrosion Coupons and Interpretation of Test Data in Oilfield Operations*—This practice is typically used for determining corrosion rates of materials in oil field operations; however, NACE RP0775 may be adapted for fresh water systems. This standard describes the preparation, handling, cleaning and weighing of corrosion coupons that will be installed in the environment of interest. In addition, methods for installation and calculating corrosion and pitting rate are presented in this guideline.

## Pitting and Crevice Corrosion

Pitting and crevice corrosion tendencies of a material in a select environment may be determined by immersion testing or by electrochemical techniques. Immersion testing generally involves visual examination and dimensional analysis after exposure of a test specimen to a select environment. Electrochemical methods usually involve exposure of a test specimen to a select environment and graphical interpretation of data.

The following standardized test methods describe relevant test procedures or practices for evaluating the pitting and crevice corrosion tendency of a material in a select environment:

*ASTM G 4, Method for Conducting Corrosion Coupon Tests in Plant Equipment*—This test method is described under uniform corrosion.

*ASTM G 16, Guide for Applying Statistics to Analysis of Corrosion Data*—Statistical analysis methods are presented. The methods discussed in this standard allow investigators to determine the significance of their results with the inherent variation observed in corrosion testing. This method includes error analysis, variability measures, standard statistical tests, curve fitting methods, and sample calculations.

*ASTM G 46, Practice for Examination and Evaluation of Pitting Corrosion*—This standard is used for evaluating and quantifying pitting corrosion. It presents guidelines for visual examination, nondestructive inspection (including radiographic, electromagnetic, sonics, and dye penetrants), and quantifying the extent of pitting. Methods for measuring pit depth, pit density, and pit size are included in this practice. A chart is provided for rating pit data. In addition, ASTM G 46 presents a procedure for determining the metal penetration rates.

*ASTM G 61, Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-Based Alloys*—This standard presents a procedure for performing cyclic potentiodynamic polarization testing to determine the relative susceptibility of iron-, nickel-, and cobalt-based alloys to localized corrosion (pitting or crevice corrosion). It illustrates and presents test apparatus, reagents, and materials, test procedures, and interpretation of results.

*ASTM F 746, Test Method for Pitting or Crevice Corrosion of Metallic Surgical Implant Materials*—The susceptibility of an alloy to localized corrosion (pitting or crevice corrosion) may be determined using this standard. This procedure may be used to test alloys that have susceptibility to crevice corrosion in electrolytes of relatively low salt concentration although its intended purpose is to evaluate surgical implant alloys. In this standard, a specimen is allowed to stabilize in a test solution for approximately 1 h. After this time the potential is shifted to stimulate localized corrosion. The current is recorded with respect to time. A graphical analysis is then performed. ASTM F 746 describes test apparatus, reagents, preparation of specimens, test procedures, and report techniques typically used.

*ASTM G 78, Guide for Crevice Corrosion Testing of Iron-Base and Nickel-Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environments*—The tendency of an alloy to undergo crevice corrosion in chloride containing environments may be evaluated by using this standard. Specimens are prepared and intentional crevices are formed on the surface. These specimens are then immersed in a test environment and evaluated by visual means and depth of crevice areas. This guide lists suggestions for specimens dimensions, specimen preparation, crevice formers, specimen supports, test apparatus, test duration, and evaluation methods.

## Galvanic Corrosion

Galvanic corrosion is an electrochemical reaction that occurs between two different metals. This phenomenon may be studied by electrically connecting dissimilar metals in the same environment. Electrochemical analysis is typically used to evaluate the performance of two dissimilar metals when electrically connected in a select environment. The following standards and practices present methods for evaluating galvanic corrosion:

*ASTM G 82, Guide for Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance*—This standard contains a method for predicting the galvanic effect when two metals are electrically connected in a given electrolyte. It outlines the procedures for creating a galvanic

series for materials in a select environment. This standard covers the precautions in the use of a galvanic series, test condition considerations in developing a galvanic series, and the theory of galvanic corrosion.

*ASTM G 71, Practice for Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes*—The galvanic effects of materials in a select environment may be predicted by using this practice. Its method may be used in laboratory or field-testing. Two dissimilar metal specimens are electrically connected and immersed in an electrolyte. Galvanic current and potential measurements are recorded. The specimens are visually examined after exposure. This method covers test specimens dimensions, identification, the test environment, test procedures, evaluation of test specimens, and methods of reporting the results.

### Electrolyte Flow Effects

Movement of the electrolyte over a metal surface can cause erosion corrosion, impingement, or cavitation. The corrosiveness of the environment will accelerate the degree of corrosion. Standardized methods for evaluating erosion corrosion and cavitation involve immersion testing in the laboratory or operating system. Analysis is typically performed by visual examination and weight loss data. The following standards are commonly used to evaluate susceptibility to erosion corrosion and cavitation:

*ASTM G 40, Terminology Relating to Wear and Erosion*—This contains terms and their definitions relating erosion corrosion and cavitation of materials.

*ASTM G 73, Practice for Liquid Impingement Erosion Testing*—The behavior of solid specimens that are exposed to discrete impacts of liquid may be evaluated by conducting studies according to this standard. Specimens are subjected to liquid sprays or jets and the weight loss (or other metal loss data) is recorded with exposure time. This method presents test apparatus, test specimens, test procedures, and calculations and analysis of erosion resistance.

*ASTM G 32, Method for Vibratory Cavitation Erosion Test*—This standard presents a test method for determining the susceptibility of an alloy in an electrolyte to cavitation damage using high-frequency vibration. In general, the rate of erosion is determined by weight loss of the specimen. The method contains terminology definitions, a description of the apparatus, test specimen dimensions and preparation, test conditions, test procedures, interpretation of results, and report considerations.

### Stress-Corrosion Cracking

Stress-corrosion cracking (SCC) occurs on certain materials when exposed in select corrosive environments. Standards applicable for measuring the tendency of a material to undergo SCC involve immersion testing of stressed specimens and tension and slow strain rate testing. The following standards are applicable for evaluating a material's tendency for SCC in a select environment:

*ASTM G 30, Practice for Making and Using U-Bend Stress-Corrosion Test Specimens*—This describes methods for constructing specimens for evaluating SCC of metals. This standard includes specimen orientation, dimensions,

surface finish, and procedures for stressing. These coupons may be used for field or laboratory testing and evaluated by visual and microscopic methods.

*ASTM G 38, Practices for Making and Using C-Ring Stress-Corrosion Test Specimens*—This standard presents the design, machining, and procedures for stressing, exposing, and inspecting C-ring type stress-corrosion specimens. These coupons may be used for field or laboratory exposure and evaluated by microscopic methods.

*ASTM G 39, Practice for Preparation and Use of Bent-Beam Stress-Corrosion Test Specimens*—This describes methods for design, preparation, and use of bent-beam stress-corrosion specimens. This standard covers apparatus for supporting specimens, basic design of a specimen, stress calculations, test conditions, exposure, and inspection techniques.

*ASTM G 47, Test Method for Determining Susceptibility to Stress-Corrosion Cracking of High-Strength Aluminum Alloy Products*—Generalized procedures for characterizing the resistance to SCC of high-strength aluminum alloy wrought products are discussed. Test specimens are alternately exposed to wet and dry cycles in prepared solutions for ten to forty days. The specimens are then examined by microscopic and metallographic procedures. The major sections of this standard describe test specimen, test environment, loading procedure, examination, interpretation of results, and report considerations.

*ASTM G 49, Recommended Practice for Preparation and Use of Direct Tension Stress-Corrosion Test Specimens*—This presents the design, preparation, and use of ASTM standard tension test specimens for investigating susceptibility to SCC. Specimens are generally tested in a selected environment under axial load conditions until fracture occurs. This standard describes the apparatus for providing the load to the stressed specimens along with exposure considerations and inspection methods.

*ASTM G 58, Practice for Preparation of Stress Corrosion Test Specimens for Weldments*—This covers the manufacture and application of welded test specimens in stress corrosion testing. This practice is used to evaluate a total weldment, weld metal, or presence of notches and stress risers in weldments with respect to SCC in an environment. In addition, ASTM G 58 contains a method for evaluating the critical stress levels that will produce SCC in a weldment. The specimens are evaluated after exposure to an environment by microscopic methods. This standard includes typical specimens (stressed and tension), welding considerations, test specimen preparation, and inspection after exposure.

*ASTM E 3, Methods of Preparation of Metallographic Specimens*—This standard presents guidelines for proper selection and preparation of metallographic specimens. Recommendations for specimen size, cutting procedures, cleaning methods, various mounting techniques, and grinding and polishing practices are included.

*ASTM E 807, Practice for Metallographic Laboratory Evaluation*—This provides recommended practices for evaluating agencies that perform metallographic analysis. This guideline includes definitions of related terms, and recommended responsibilities, capabilities, and duties of the agency. In addition, ASTM E 807 recommends that an agency disclose a description of its staff, organization,

facilities, resources, and information relating to its procedural systems that directly affects the quality of services offered.

### Intergranular Corrosion

Intergranular corrosion is the preferential corrosion of a material at or along the grain boundaries. The standards commonly used for measuring a material's tendency to intergranular corrosion involve immersion testing followed by a visual and microscopic examination. The following standards predict a material's susceptibility to intergranular corrosion:

*ASTM G 108, Test Method for Electrochemical Reactivation (EPR) for Detecting Sensitization of AISI Type 304 and 304L Stainless Steels*—This method presents techniques for evaluating the susceptibility of 304 stainless steel, 304L stainless steel, other stainless steels and nickel alloys to intergranular corrosion and intergranular stress corrosion cracking caused by heat sensitization. Test specimens are subjected to anodic potentiodynamic testing from the passive to active regions of electrochemical potentials (from  $E_{corr}$  to  $E_{corr} + 200$  mV, back to  $E_{corr} - 50$  mV.) The test specimens are then metallurgically analyzed and the test data graphically analyzed. This method discusses apparatus, test specimens, test procedures, test solutions, metallographic inspection, graphical analysis, and calculations. This will provide meaningful results since as little as 10 ppm chlorides, which is present in most water, can make sensitized 304 and 316 stainless steels subject to SCC.

*ASTM G 1, E 3, and E 807*—ASTM G 1 is presented in the Uniform Corrosion section of this chapter; ASTM E 3 and E 807 are discussed in the Stress-Corrosion Cracking section.

## INTRODUCTION

MUCH OF THE underground infrastructure in the United States was constructed after World War II in the 1950s and '60s, and many of these structures, such as pipelines, utilities, and storage tanks, are approaching the end of their useful life. Thus, there is an increased need for data on the underground corrosion performance of materials used in these structures. The ideal measurement would nondestructively provide information on how much a structure has deteriorated and how rapidly this deterioration is occurring. With this information, engineers can predict the expected lifetime of a structure. With present day techniques, we can measure the rate of corrosion of an underground structure, but we lack a nonintrusive method that provides information on the extent of accumulated damage. Controlled tests are one way that data on accumulated damage can be obtained, and it is for this reason that this type of test is useful. This section on field measurements will concentrate on the types of underground corrosion measurements that can be made in controlled and uncontrolled conditions, with an emphasis on controlled site testing.

At a controlled exposure site, metal samples are intentionally exposed so that control of variables such as specimen surface area and size, depth of burial, minimum electrical and mechanical interference, and site accessibility are maximized. The design of this type of site allows retrieval of specimens from the ground without interrupting services as may be the case with a real structure. In an uncontrolled exposure site, the above variables may be in question, and this situation usually applies to any real underground structure. For example, the surface area of an underground pipeline is difficult to determine because from the standpoint of electrochemical polarization measurements, the pipeline is of infinite length. In addition, electrical isolation from other structures or services may not be possible with an underground system in use. In general, techniques for measuring corrosion are the same for controlled and uncontrolled sites, but some precautions and limitations must be kept in mind when these techniques are applied to real structures, and these will be discussed where appropriate. Assessing the corrosion of buried steel tanks is complicated by the presence of internal corrosion as well as external wall deterioration. This special case is addressed in ASTM G 158 [1].

## SPECIMEN AND SITE ACCOUNT

### Maintaining Records

Determining corrosion performance of metals in underground environments generally requires long-term testing, sometimes exposures of several years. Such long-term studies make it imperative that information be maintained in a readable, accessible, permanent system. Experience has shown that a bound notebook with numbered pages is one format that has proven successful for keeping these records. Today, computerized media such as CD ROMs provide other useful storage options. These data must include the exact location of the test site and its configuration. Identifying the location of the site with reference to survey markers or other reliable, long-term features may be warranted, and becomes more important as the length of exposure is increased. Using global positioning satellite (GPS) technology, a point on the surface of the earth can be identified with an error of less than  $\pm 1$  m, making it a very attractive means of identifying the location of buried specimens. One test site out of the direct control of this author was paved over for parking motorized equipment, and survey information allowed successful retrieval of the specimens. Specimen surface treatment, heat treatment, and identification marks must be carefully described in these records. Photographic records during all phases of preparation and burial are useful for future site and specimen evaluation. Finally, computer files on hard or floppy disks are invaluable for organizing and examining data, but they are a poor format for long-term storage of data. Changes in computer equipment or damage to magnetic disks may make it difficult or impossible to access old data files. CD ROMs, however, are not affected by magnetic fields, making them a good alternative storage media for data. The importance of maintaining good records cannot be overemphasized.

### Specimen Design

The design of specimens is determined by several factors, such as the form of corrosion expected (uniform corrosion, pitting, etc.), the type of structure in question (pipe, tank, etc.), and the measurements necessary for obtaining the data. Measurement requirements for determining the loss in cross section of a structural H-pile are different from measurements designed to examine pitting of a pipeline material. In general, the larger the sample exposed, the better the data,

but there may be a size limitation imposed by the measurements. Weight loss data requires weighing a specimen before and after exposure, and for this type of data, the size and weight of a sample is limited by the capabilities of the weighing equipment. Surface preparation of a sample must be considered. If the sample is a simulation of a real structure, then care should be taken to ensure that the specimen surface is representative of that structure. Thus, chemical cleaning, abrading, and polishing of the specimen surface may be undesirable if the real structure is not subjected to the same surface treatment.

For evaluation of pipeline materials, a segment of the pipe with endcaps to protect the interior may be the most suitable design for a test specimen. It is also common practice to use sheet material for specimens, where sheet metal is used for producing containers such as holding tanks. Where welds are encountered, it is valuable to include specimens with welded sections in the burial test. Coated panels and coated panels with intentional breaks in the coating may be desirable. Galvanic coupling of specimens is also a consideration, where two unlike metals are expected to be in contact. Stressed U-bend or C-ring type specimens are used for studies of stress corrosion failures. Specimen identification marks stamped or scribed must be easy to read, and in the case of large specimens, such as H-piles, identification marks can be applied with a welding torch. Thus, the design of the specimen is tailored to meet the needs of the study.

### Considerations for Physical Measurements

Weight loss, pit depth, or wall thickness determinations are physical measurements used as a reference to non-destructive electrochemical techniques. Physical measurements are considered destructive because, generally, the specimen must be removed from the site and cleaned. The process of extraction and preparation for examination changes the surface condition of the specimen, effectively destroying the possibility of continuing the exposure test with that particular specimen. Nevertheless, to rely solely on electrochemical measurements can result in misleading information, and it is strongly recommended that the test design include some form of physical verification of non-destructive measurements. To obtain corrosion data from physical measurements during long-term exposures, it is common practice to place enough samples in the ground to allow removals at intervals of time. The most meaningful data are obtained when duplicate samples are used for each removal, allowing averaging of data and providing a better representation of material performance.

### Burial Site

Choosing the correct burial site is important, since the environment will have a direct effect on the performance of buried materials. This choice must take into account more than just characteristics of a soil, and must include consideration of local conditions of temperature, rainfall, and location. For example, a soil located in a valley near a stream provides a different environment to the same soil on a nearby hill. In general, the best test site is near the structure

in question. Such a site has the added advantage that measurements can be made on the real structure, which can then be compared to data obtained from controlled specimens nearby. Where a variety of soils are encountered, several soil sites may be needed. If only one site is chosen, then the site with the "worst case" conditions will provide the most conservative data. Where anaerobic bacterial corrosion is of concern, redox potential measurements of the soil can identify the sites where these bacteria are most likely to be present [2]. Soil characterization is discussed in another section of this manual, but it is worth mentioning that the ASTM G01 committee on Corrosion of Metals has published useful techniques for measuring soil resistivity and soil pH [3,4].

### Specimen Emplacement

The manner in which a sample is buried is influenced by the configuration of the specimens. For example, steel piling specimens are driven into the ground with pile drivers, while small specimens will most likely be buried in trenches dug with a back hoe. A typical steel pile test site involves the placement of five pilings in a 2 m radius circle around a sixth centrally located pile, as illustrated in Fig. 1 [5]. The central pile was used as a counter electrode during electrochemical polarization measurements of the other piles as will be explained later. The top of each pile was 0.6 m below ground level, and to the top of each pile was welded a steel rod that extended to just below the surface of the ground. A removable concrete marker, extending above ground, was placed over the rod to help locate the steel rod. Since the study included examining the effect of disturbed soil, a seventh pile was buried horizontally in a nearby trench.

Small specimens can be buried in a long, narrow excavation made by a backhoe. Such a trench is typically 1 m deep, 0.6 m wide, and as long as necessary to accommodate all specimens, which are generally placed about 30 cm apart along the length of the trench. Where electrical wires from specimens extend above ground, wood posts are commonly used to serve as markers and hold the wires. Untreated wood is recommended, because leaching of chemicals from treated wood will modify the surrounding soil and possibly affect the results of the corrosion test. It is especially important to avoid placing wood treated with copper salts near aluminum specimens, since it is known that copper ions

FIG. 1—Typical view of steel pile placement at an underground test site.

accelerate the corrosion of aluminum. Retrieval of specimens is simplified by tying specimens together with a small diameter plastic cord and attaching the cord to wood posts. In this way, finding the cord or one specimen allows retrieval of all other specimens in a group. Where several retrievals are to be made over a period of time, specimens for a given removal can be grouped together in one section of the trench, so that when a group is retrieved, those remaining are not disturbed during digging. Wooden posts can be used as trench markers to delineate groups of specimens, or metal markers located just below the ground surface will serve the same purpose and can later be found using a metal detector.

More than one system of specimen identification must be incorporated in the test. For example, stamping identification characters on the specimen and on an attached plastic label reduces problems of identification in the future. In addition, specimens can be buried in a known sequence for further verification of identity.

### Specimen Retrieval

Immediately after excavation, a rapid superficial cleaning of specimens with a scrubbing brush and water allows easy removal of oxides and soil/oxide conglomerates that harden as they dry, making later cleaning difficult. An immediate cursory examination of specimens on initial removal, coupled with photographic documentation, has several advantages. This examination can become important in those unfortunate cases where specimens are lost or damaged in transit. Furthermore, although identification of a specimen may be obvious on removal, later it may be difficult where tags are separated or lost, and documentation with photographs or notes becomes crucial for identification. Where specimens have corroded to the point of separation, it is important to tag the parts for later identification, and this may include placing specimens in envelopes or bags. In some cases metal specimens undergo surface changes after retrieval, especially if there is a long period of time between removal and final examination, and photographs help identify those instances where this happens, allowing the examiner to differentiate between burial damage and damage from subsequent handling. This can be especially important in cases where coatings are involved in the test. Thus, the employment of some precautions and documentation on initial removal of specimens will save time and effort in subsequent examination procedures.

Some information can be obtained from the soil at the time of sample extraction. For example, soil conditions may vary along the length of a trench, resulting in a variation in the corrosion performance of similar samples, and these soil differences should be noted. In some cases, where warranted, local measurements of soil pH or soil resistivity at the depth of the specimens, can provide insight to material performance. The use of pH paper is an excellent method of obtaining a rapid reading on a soil. Unusual conditions of pH found with pH paper can be verified with more traditional pH electrodes. The resistivity of small samples of soil can be measured using a soil cup or soil box. The use of these techniques is an excellent way of getting information on localized soil conditions in the vicinity of the specimens.

Always be aware that local, small soil sample readings can change dramatically from place to place in the same trench, and these readings must not be assumed as representative of the soil as a whole. Other techniques for measuring large soil samples must be used and are described in the ASTM Annual Book of Standards [4].

### Cleaning and Examination of Specimens

Examination of specimens at the time of excavation is a critical step in the process of obtaining information from underground exposure studies. As has already been suggested, it is instructive to examine and characterize the condition of specimens before the final cleaning process. The presence or absence of an oxide on a corroded surface, the color of an oxide, and its location on the metal surface provide clues to the mechanism of attack. This initial examination is followed by removal of all corrosion products from the specimen. Fortunately, information on this difficult process, removal of oxide layers with minimum substrate attack, has been published by the ASTM G01 Committee on Corrosion of Metals [6]. This publication describes reagents and detailed chemical and electrochemical methods for cleaning ferrous and nonferrous metallic specimens.

## PHYSICAL MEASUREMENTS

### Weight Loss

Determining weight loss resulting from exposure to soil is a common technique used to measure corrosion rate. This type of data is most meaningful when corrosion is uniform over the surface of the specimen, since normally the entire exposed surface area of the specimen is used for calculating corrosion rate. If corrosion attack is localized and the total exposed surface area is used for the corrosion rate calculation, then the result will underestimate penetration. One possible way around this problem is to measure the area where the localized attack has occurred and use this corrected area in the calculation of corrosion rate. Possible sources of error in weight loss determinations are a) excessive removal of metal during cleaning, b) inadequate cleaning of specimen, and c) using the total surface area for calculating corrosion rate when the attack is localized.

A typical approach that has been used to determine weight loss of specimens through physical measurements is as follows. Small steel coupons, weighing approximately 200 g, were exposed to a soil environment. The samples were weighed before and after exposure. Prior to the "after exposure" weighing, the samples were cleaned using the ASTM solution designation C.3.1, which is an inhibited hydrochloric acid solution described in detail in the ASTM G 1 Standard Practice [6]. To determine the immersion time necessary for removal of the oxide, the specimens were cleaned and weighed repeatedly, until weight loss stabilized, indicating that the cleaning reaction had gone to completion. Figure 2 is an example of these data. Note that specimen 9 required immersion of only 30 s to remove the oxide, while specimen 7 took approximately 2.5 min to clean. This cleaning and weighing procedure allows monitoring of the chemical cleaning

FIG. 2—A plot of weight loss versus time for three steel coupons in inhibited hydrochloric acid, showing the initial rapid oxide removal and the slower dissolution of metal as a function of time.

process, and reduces the likelihood of error from removing too much base metal. The ASTM publication also provides information on the mathematical procedure for calculating corrosion rate from weight loss in terms of a variety of units, both English and Metric.

### Pit Depth

Obtaining information of the degree of pitting involves some form of visual inspection, so that the shape, depth, and density of pitting can be determined. Large shallow pits are relatively easy to evaluate, compared to small, narrow, deep pits. The degree of pit penetration of wide pits can be measured with a pit depth micrometer or by the use of a microscope that allows measuring the change in movement of the stage when focusing between the bottom of the pit and the surface of the metal. Determining the shape and depth of a narrow, deep pit is more challenging and may involve a metallographic cross-sectional examination of the pitted area. This same metallographic technique may be the most effective way of examining pits that get wider with depth. A crude but effective way of measuring the depth of relatively straight line pits is to insert a small diameter wire into the pit and measuring the length of penetration by the wire. In some cases, the rate of wall penetration is critical, as for pipeline material, and identifying and measuring the deepest pit is important, along with information on the average penetration of the ten deepest pits. Density of pitting can be obtained by counting pits in a known area or by comparing the pitted surface to standard charts as described in the ASTM G 46 Standard Practice for Examination and Evaluation of Pitting Corrosion [7].

### Stress Induced Failure

Determining susceptibility of a material to stress corrosion cracking or hydrogen embrittlement in a soil environment has been studied using buried U-bend specimens [8].

This approach provides information on whether or not a specimen failed, but will not reveal when, during the exposure period, the failure occurred. One novel method for application of stress allows monitoring the condition of the specimen from the surface, using a steel ring located above ground level to apply the stress to a tubular tensile specimen in the soil via a steel rod [9]. By monitoring the load on the steel ring, the failure of the tensile specimen is detected. Another technique that provides a remote indication of failure is the above ground monitoring of gas pressure used to apply a hoop stress to small containers buried in the ground. The ASTM committee on the corrosion of metals has developed and published standard methods for the use of U-bend and C-ring specimens for the application of stress [10,11].

## ELECTROCHEMICAL MEASUREMENTS

### Polarization

The technique of electrochemical polarization is a useful tool for obtaining corrosion rate data nondestructively during exposure, with a minimum of disruption to the test. The polarization resistance measurement is especially attractive because its use is well documented, and it requires a minimal amount of equipment, some of which is commercially available. The measurement involves applying current to a specimen from a second electrode, changing the potential of the specimen by approximately 10 mV versus a reference electrode, and noting the amount of current needed to make that change. The slope of the change in potential versus the applied current is inversely related to the corrosion current of the specimen [12]. With information on the Tafel slope of the material in that environment, the corrosion current can be determined. This approach uses: 1) a specimen as the working electrode (WE), 2) a reference potential electrode (REF), and a counter electrode (CE) used to apply the polarizing current. Additional information is available in ASTM Standard Practice G 59 [13].

Corrosion current density, and corrosion rate, can be calculated when the entire specimen is polarized and its surface area is known. This is the case for finite area specimens, as illustrated in Fig. 1 for steel piling. The reference electrode is located at the soil surface approximately 30 m from the WE. For these measurements, each of the seven piles was polarized using the centrally located pile as the CE with the REF at a fixed location. In this way, measurements could be duplicated from year to year and the results compared [5]. From this corrosion current measured over a period of time, in this case 14 years, an estimate of weight loss can be calculated.

There are situations where the polarized area of the specimen is not known, as is the case where the WE is a long structure such as a pipeline or electric power utility. In this situation, the WE is essentially infinitely long and the CE can only supply current to a portion of the structure. An estimate of how much of the structure is polarized when current is applied can be made by measuring the potential of the structure in the vicinity of the CE, as illustrated in Fig. 3 [14]. In this example, polarization region extends from the 4 m mark to the 18 m mark. From this information, the approximate polarized area can be calculated.

FIG. 3—A plot of overpotential versus distance, illustrating the distribution of current on an underground cable when 1.5 mA is applied from a rod placed 1 m to the side of the cable.

Special probes with associated measuring equipment that provide a means of determining the corrosion rate of a material in soil are commercially available. Generally, the probe and a specimen, built into the probe, are bought as a unit. An attractive feature of this equipment is that the data reads out directly in terms of corrosion rate. The biggest concern is that the specimen in the probe may not be representative of the structure of interest because of the small size of the probe specimen or its isolation from the structure. One type of probe system uses the change in electrical resistance of the coupon in the probe as an indicator of reduction in cross section due to corrosion attack. This reading is then converted to corrosion rate. Other types of probes use electrochemical polarization techniques and two or three electrodes to measure the corrosion rate of the WE in the probe [15,16]. Details on calculating corrosion rate from electrochemical data are discussed in ASTM G 102 [17].

In the laboratory, the technique of ac impedance is superseding polarization resistance, because it provides additional information on mechanisms of the processes involved. Guidance on performing corrosion tests in the laboratory in liquids or in soils is provided in ASTM G 31 and ASTM G 162 [18,19]. Ac impedance systems are now commercially available, but these units are limited to low polarization currents of 1 A or less, making them unsuitable for most field applications where larger current capabilities (>1 A) are needed.

### Galvanic Corrosion

The galvanic coupling of unlike metals in soil is an all too common occurrence, and the need to obtain information on the consequences of this condition is recognized. Copper ground rods and copper mesh ground beds are typically connected to steel piling supported structures and underground telephone, water, and fuel utilities to the detriment

FIG. 4—A plot of potential over a pipeline and to the side of the pipeline versus distance, illustrating the presence of cathodic regions where "over the pipe" potentials are more positive than "beside the pipe" potentials.

of the less noble steel. Burial of galvanically coupled metals in soil provides information on the degree of corrosion and the possibility of hydrogen embrittlement. The effect of relative surface area of the coupled metals and the spacing between them are important [20].

Measuring the galvanic current of the coupled metals during the exposure period allows monitoring of changes in the magnitude of the current and direction of current flow. This can be accomplished by attaching insulated wire conductors that extend above the surface of the soil where they are connected together. Periodically, an ammeter is inserted in the circuit and the current is measured. To reduce the possibility of affecting the current during the measurement, which may involve currents in the milliamp range or less, the use of a zero-resistance ammeter is recommended [8].

### Potential Mapping

Measured potentials at the soil surface above a utility, such as a pipeline, are often used to evaluate the effectiveness of cathodic protection systems and coatings.

One technique that has been applied for many years uses two sets of measurements where one of the electrodes is positioned over the pipeline and the second electrode is placed several meters to the side. The data from this approach provide a comparison of the local potential to the more distant potential made to the side of the pipeline, as illustrated in Fig. 4. Regions where the "Over Pipe" potential are more positive than the "25 ft From Pipe" potential are cathodic to other sections of the pipe line. Potential effects of stray currents, galvanic currents, and cathodic protection interference are identified from this information [21].

A more recent technique relies on a set of potential measurements between the pipeline and a reference electrode, where the electrode is positioned directly over the pipeline, and measurements are made along its length at intervals. Computerized data logging permits a detailed analysis of

discontinuities in potentials that reveal areas of active corrosion [22]. Recent improvements in programming and equipment permit elimination of iR error from cathodic protection potential measurements and also incorporate use of "over the pipe" and "beside the pipe" potential data [23].

## SUMMARY

Underground corrosion is particularly insidious in that, generally, we are not aware of its progress until a failure occurs. However, there are physical and electrochemical techniques available that will provide information on corrosion processes. Physical measurements furnish cumulative corrosion information obtained at the final removal stage, while electrochemical measurements supply data during the period of exposure to soil.

# Industrial Applications

Allan Perkins<sup>1</sup>

## PURPOSE AND IMPORTANCE OF IN-PLANT TESTING

THERE ARE A CONSIDERABLE number of sources of material testing data that have been accumulated over the years and are available to process plant designers to assess the most suitable materials selection for a particular plant and operating conditions. However, many of the factors involved in the selection of an optimum choice are subject to variability, and this makes the selection process more complex.

The ranking of the most valuable corrosion data for plant designers is generally understood to be as follows:

1. Operating experience on full-scale equipment under the actual process environment.
2. Operating experience on a pilot plant with similar feed-stock and operating conditions.
3. Sample tests in the field, corrosion test specimens, electrical resistance (ER) probes, or stressed samples exposed to the process environment.
4. Laboratory evaluations in "actual" plant fluids, or simulated environments.
5. Materials and Corrosion Database.

It should also be recognized that the economics of the various material selection choices is not constant. A decision that makes economic sense at the design time, or at the materials selection time, may not make sense by the time the plant is actually built or operating. In addition, the economics of plant shutdowns due to failure can depend on the market for the product being generated by the plant, although these costs are generally ever upward.

The choice must be made between the use of more expensive corrosion-resistant alloys, and the use of a less expensive, less corrosion-resistant alloys protected by chemical treatment. Changes in the raw material costs of chromium, nickel, and other constituents in corrosion-resistant alloys affect the initial construction costs. A less expensive material, that would otherwise be unacceptable due to low corrosion resistance, can still be the best choice when used with chemical corrosion inhibitors, or other protection methods such as anodic or cathodic protection.

In some process applications, the material selection may have been the optimum choice for the specified operating conditions.

However, unintended minor changes in the operating conditions may have a major influence on corrosion rates.

For these reasons, periodic and continuous in-plant corrosion monitoring is frequently used for materials evaluation. The main uses for corrosion monitoring are summarized in Table 1.

A range of material evaluation tools is available for in-plant use. Some of these may be classified as inspection methods, and some of them as on-line continuous corrosion monitoring methods. The difference between the two is the sensitivity and, consequently, the frequency with which measurements are taken. The lower-sensitivity measurement methods may be useful for long-term life prediction. Short-term continuous online methods may be used more for corrosion prevention, by allowing changes to the inhibitor injection rates or operating conditions before significant damage occurs.

## MEASUREMENT TECHNOLOGIES

There is a considerable number of technologies available for assessment of material degradation, each with its own benefits and limitations. Corrosion is rarely uniform throughout a plant, or even in a localized area, and it is preferable to use more than one method of assessment. An alternate measurement technology will improve confidence levels in the results obtained and avoid unrepresentative results.

The various types of measurement technologies for assessment of corrosion may be summarized as shown in Tables 2 to 5. These techniques cover both laboratory and field use. However, many of the direct methods, particularly the electrochemical methods of potentiodynamic polarization and electrochemical impedance spectroscopy (EIS) are generally more suited to laboratory evaluation. In the laboratory, test conditions are clean and more controlled. Consequently, more sophisticated measurement electrode systems can be used that take advantage of their more sophisticated measurements technologies. In the field, practicalities of changing process conditions, high flow rates, debris, electrical noise, and electrical safety limit their use.

**TABLE 1**—Main objectives of in-plant monitoring.

- Predict behavior of materials in full scale plant from a pilot plant.
- Assess choices of materials for plant replacement in an operating plant.
- Assess the corrosion penalty of uprating the maximum process capacity, or otherwise increase operating parameters.
- Assess the effectiveness and to optimize the costs of various corrosion inhibitors, or modified operating conditions.

--

In general, the most widely used field technologies for inspection are ultrasonic thickness measurement, while for online methods they are corrosion test specimens, electrical resistance, and linear polarization probes. Both of the inspection methods and the first two online methods measure metal loss. The last method measures corrosion rate, but only in a sufficiently conductive process environment, normally water.

Measurement sensitivity divides the metal loss methods. Ultrasonics and radiography are usually considered as inspection methods. Typically, ultrasonics has a measurement resolution of around 50  $\mu\text{m}$  (0.002 in.), and radiography 250  $\mu\text{m}$  (0.010 in.). Consequently, these types of measurements are typically made annually. Corrosion test specimens (coupons) assess metal loss typically over a one to three month interval. Electrical resistance probes, as an "automatic coupon," assess metal loss typically over a few hours to a few weeks.

It should also be noted that there is a difference between measurements made directly on the plant material compared to measurements made on a test specimen. The methods for the former are generally less sensitive than the latter. Hence, to be effective, overall inspection methods on the plant material should be as comprehensive as possible to

ensure location of severely corroded areas. Correspondingly, measurements on a test specimen to determine the corrosiveness of the process should be taken at representative locations, namely at the points of most severe corrosion.

## INSTALLATION OF MONITORING DEVICES

Ultrasonic and radiographic inspection techniques are used for long-term evaluations because of their lower sensitivity. The advantages of these techniques are that they are nonintrusive and do not normally require special mounting equipment or access to the process. The common intrusive techniques of corrosion test specimens, electrical resistance, and linear polarization probes require exposure to the process.

Corrosion test specimens in particular, and electrical resistance or linear polarization probes to a lesser extent, need to be removed and replaced, or inspected at intervals. These intervals most probably will not coincide with plant shutdowns.

Probes and corrosion test specimens that are mounted rigidly in the process by some form of fixed mounting do not allow removal online. This may suit some applications but may be inconvenient where shutdowns are not made except for emergencies or major planned overhauls at one, two, or even five year intervals. For these applications, removal of probes and corrosion test specimens under operating conditions may be achieved by various insertion and retrieval systems.

Evaluation of alternate materials of construction is often undertaken in operating plants with multiple corrosion test specimen holders of various types, typically over months or years. This type of test is useful for assessing alternate alloys that may be used for replacement of those already used. The tests may comprise simple unstressed immersion tests of various alloys, or specially strained or notched specimens to evaluate stress corrosion cracking (SCC) properties. Since a relatively large number of specimens are frequently used, with multiple specimens of each alloy that permit successive removal of the corrosion test specimens, these racks and fixtures can be quite bulky. Consequently, these racks are most commonly installed within vessels or sometimes in large pipe sections. Care must be taken in the latter case to avoid excessive restriction due to the bulk of the corrosion test specimen rack or assembly. Because of the size of the test rack, these assemblies are generally only removable at plant shutdown. The key features of corrosion test specimens support structures are strength and durability of the corrosion test specimen support structure and electrical isolation of the corrosion test specimens from the rack and each other.

Positioning of the rack is also critical to make the corrosion test specimens a good representation of the required test conditions. This should consider the phases that are present, the separation of phases, the velocity of the phase or phases in multiphase flow, and the velocity changes due to the test rack itself. Even greater care is required with mounting and construction of stressed specimens to ensure that the applied stresses are held constant by the stressing mechanism. The other more common aspect of material evaluation is to monitor the ongoing performance of the existing plant alloys, or a few alternate materials, through changes in feedstock, operating conditions, various inhibitors, and inhibitor feed rates.

Retractable corrosion test specimen holders allow removal under process operating conditions without process shut-down. The requirement for assessing only one or possibly two alloys permits a more compact construction. This assists the design of the retractable mechanism and permits more flexibility in positioning the corrosion test specimen correctly, to pick up the corrosive water phase in the bottom of an oil/water pipeline, for example.

Electrical resistance and linear polarization probes generally monitor a single alloy at a time, but permit much more rapid responses to dynamic corrosion rate changes that occur. Most commonly the probes are retrievable to allow replacement at required intervals or for inspection of probe elements.

## SPECIMENS

Any specimen used in a plant evaluation, whether it is a test specimen or a probe, has certain limitations that must be recognized:

1. It is a small sample compared to the plant equipment.
2. The sample may differ from the actual plant material in composition, preparation, orientation to the process, previous history, and exposure to the process.

Where corrosion test specimens are used, care is required in the preparation, identification, cleaning, and evaluation to ensure reasonable reliability and accuracy of the data. These requirements are well detailed in ASTM G 4, Guide for Conducting Corrosion Tests in Field Applications.

Corrosion test specimens are used to evaluate average corrosion rate over the exposure period and are also useful for assessment of crevice corrosion, pitting, and end grain attack, and may be used for metallographic examination of the corrosion test specimen or analysis of any deposits. Special corrosion test specimens may be prepared with welds to assess corrosion problems particular to weld material or heat affected zones. SCC may be monitored with specially mounted and loaded corrosion test specimens.

Identification of the corrosion test specimens is achieved by using low-stress stamping of an identification number directly on the corrosion test specimen surface. Signs of preferential attack on the stamped area can indicate susceptibility to corrosion when cold worked, and it may also be possible to detect stress corrosion cracking. However, tests for such problems of corrosion on cold worked areas and stress corrosion cracking should be made on specimens designed specifically for this purpose. On electrical resistance probe elements and linear polarization probe electrodes, the element alloy is identified on the probe body, thereby avoiding any stressing or damaging of the element material.

## TESTING APPROACHES

### Corrosion Test Specimens (Coupons)

Corrosion test specimens are convenient for determining average corrosion rates over periods of typically one to three months. They are also a relatively economical way of comparing various alloys for extended periods. Corrosion test

specimens are not suitable for determining the timing or magnitude of corrosion upsets within the exposure period.

### Electrical Resistance Probes

Electrical resistance probes are essentially "automatic" coupons, since they may be measured without removal from the system. The physical loss of material is measured by the increase in electrical resistance that is created in the test specimen as it corrodes. The resistance of the test specimen is compared to a reference specimen of the same material that does not corrode, since it is protected from the corrosive environment. This method of measurement compensates to a first order for resistance changes due to temperature. This technique is the most widely used system for automatic monitoring on a continuous basis. It is the only method of this type capable of use in virtually all environments—gases, liquids, or solids—whether conductive or nonconductive. It is not dependent on the variability of factors that apply to electrochemical methods. Changing the thickness of the element varies the sensitivity of the measurement. Probe span is typically half of the measurement element thickness. Measurement resolution of electrical resistance systems is typically 1 part in 1000 of the probe element span when using conventional electronic systems. With more recently developed high-resolution probes and electronic systems, this resolution has been increased to as much as 1 part in 262,144 (18 bit). Corrosion rate changes are detected by changes in the slope of the graph of metal loss against time [see Fig. 1, taken from ASTM G 96, Guide for On-Line Monitoring of Corrosion in Plant Equipment (Electrical and Electrochemical Methods)]. Changes in corrosion rate are detected typically in a period of a few hours to a few days with conventional electrical resistance systems, and in minutes to an hour or two for high-resolution systems. The response time to detect corrosion rate changes is inversely proportional to the probe element thickness. Temperature transients can cause second order noise on the measurement that can increase the time required to detect a corrosion upset. The sensitivity of electrical resistance systems is well-suited to detect quickly the loss of corrosion inhibitor, changes in corrosion caused by changes in operating conditions, or for adjustment of inhibitor treatment frequency.

FIG. 1—Typical plot of metal loss versus time (reprinted from ASTM G 96).

In the same way as mass loss on corrosion test specimens, resistance measurements on electrical resistance probes indicate metal loss by general corrosion. Pitting is generally not noticeable until near the end of probe life, where the effect of pitting becomes "runaway" on the resistance measurement.

The measured resistance of these elements is very low so that noise interference can be significant from thermal effects, and electrical noise if the probes are not well designed. Some deposits such as iron sulfide are sufficiently conductive to provide some apparent reduction in the corrosion rate, and a few molten ionic salts may have sufficient bulk conductivity to prevent the use of these probes.

## Electrochemical Probes

Any electrochemical method of corrosion measurement has the advantage of determining corrosion rates generally over a few minutes. For field methods, the primary electrochemical method is linear polarization resistance (LPR). Electrochemical methods can only be used in sufficiently conductive media. This essentially means sufficiently conductive

water systems. They cannot be applied to gases and solids unless the water phase completely covers and connects the measurement electrodes. For a practical guide on the operating range of such probes see Fig. 2, taken from ASTM G 96.

In addition, electrochemical measurements require a critical conversion factor between the measured electrical current and the corrosion rate of the alloy. These conversion factors are variable. The factor depends on the valency of the corrosion reaction, on how each element that makes up an alloy corrodes individually in the environment, and on the empirically determined Tafel slope for the corrosion mechanism (see ASTM G 102, Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Measurements).

For a given situation, such as a controlled laboratory environment, these factors may be more constant and more easily measured. In the laboratory, electrical noise can be minimized and a higher sensitivity achieved with short leads, special reference electrodes, and clean solutions. In the real world of operating plant conditions, damage of electrodes, screening of the electrodes by oil or other nonconductive

NOTE 1—See Appendix X1 for derivation of curves and Table X1.1 for description of points A, B, C and D.

NOTE 2—Operating limits are based on 20 % error in measurement of polarization resistance equivalent circuit (see Fig. 1).

NOTE 3—In the Stern-Geary equations, an empirical value of  $B = 27.5$  mV has been used on the ordinate axis of the graph for "typical corrosion rate of carbon steel".

NOTE 4—Conductivity  $\frac{\mu\text{mhos}}{\text{cm}} = \frac{1}{\text{Resistivity (ohm} \cdot \text{cm)}}$

NOTE 5—Effects of solution resistance are based on a probe geometry with cylindrical test and auxiliary electrodes of 4.75 mm (0.187 in.) diameter, 31.7 mm (1.25 ft) long with their axes spaced 9.53 mm (0.375 in.) apart. Empirical data shows that solution resistance (ohms  $\cdot$  cm<sup>2</sup>) for this geometry = 0.55  $\times$  resistivity (ohms  $\cdot$  cm<sup>2</sup>).

NOTE 6—A two-electrode probe, or three-electrode probe with the reference electrode equidistant from the test and auxiliary electrode, includes 50 % of solution resistance between working and auxiliary electrodes in its measurement of  $R_p$ .

NOTE 7—A close-space reference electrode on a three electrode probe is assumed to be one that measures 5 % of solution resistance.

NOTE 8—In the method for Curve 1, basic polarization resistance measurement determines  $2R_p + R_s$  (see Fig. 1). High frequency measurement short circuits  $C_{dl}$  to measure  $R_s$ . By subtraction polarization resistance,  $R_p$  is determined. The curve is based on high frequency measurement at 834 Hz with  $C_{dl}$  of 40  $\mu\text{F}/\text{cm}^2$  on above electrodes and  $\pm 1.5$  % accuracy of each of the two measurements.

NOTE 9—Curve 1 is limited at high conductivity to approximately 700 mpy by error due to impedance of  $C_{dl}$  at frequency 834 Hz. At low conductivity it is limited by the error in subtraction of two measurements where difference is small and the measurements large.

NOTE 10—Errors increase rapidly beyond the 20 % error line (see Appendix X1, Table X1.1).

FIG. 2—Guidelines on operating range for polarization resistance (reprinted from ASTM G 96).

deposits, physical bridging, and dynamic conditions are much more of a practical problem. Careful design of probes, cabling, and electronic equipment manages some of the inevitable compromises, and provides very effective dynamic corrosion monitoring so that the electrochemical methods have become the standard for the cooling water treatment industry.

For field use, linear polarization is the most commonly used technique for water-based process streams. For conductive waters, above about 2500 microsiemens the LPR technique may be used in its simplest form with an error of less than 20 % (see Fig 2). For a wider range of operation, the error due to solution resistance may be reduced with a close-space reference electrode, or with high-frequency measurements, which are modifications or components of the EIS laboratory technique.

Galvanic probes to monitor the effects of galvanic corrosion are much less common. Special care must be taken to consider the effect of relative areas of the different alloys in the plant as compared to those on the probe elements.

The other techniques of potentiodynamic scanning, EIS, harmonic impedance spectroscopy (HIS), and pure electrochemical current and potential noise are primarily laboratory methods that are used only in a limited way in field investigations. This is because of their relative expense, requirement for a low noise measurement environment, and clean and stable process conditions. However, simple qualitative electrochemical noise or pitting indications are used in a simple way in field applications to look at uniform versus nonuniform corrosion. Greater fluctuations and instability in the noise measurements are generally indicative of conditions leading to nonuniform or pitting corrosion.

## Other Corrosion Measurements

### *Hydrogen Probes*

Hydrogen probes may be used to assess susceptibility to hydrogen induced damage. Nascent (or atomic) hydrogen is generated from the cathodic part of the corrosion reaction in acid to neutral solution. This nascent hydrogen can permeate the steel and cause hydrogen embrittlement, hydrogen-induced cracking, and hydrogen blistering. Various types of hydrogen probes are available for detection of the hydrogen from simple pressure types to electrochemical types. While the cause of the hydrogen is the corrosion process, the method is not necessarily a good measure of corrosion rate, since hydrogen is not evolved from the cathode in alkaline environments. In addition, the proportion of evolved hydrogen that passes into the process and into the steel varies depending on contaminants in the process such as hydrogen sulfide, cyanide, or arsenic. Hydrogen measurements must generally be used in a rather qualitative empirical form since even the same grades of steel can behave differently to the same hydrogen flow rates. Separate laboratory tests on the actual plant material are best used to measure susceptibility to hydrogen damage.

### *Crevice Corrosion*

Crevice corrosion sites may be inherent with specimen mounting and may also be intentionally created at specimen or probe element locations. For example, a corrosion test

specimen mounting insulation normally provides a suitable crevice against the corrosion test specimen, and crevices may be measured at the time of removal. Some corrosion test specimens are specifically designed for crevice corrosion by having insulators with a variety of crevice gaps. On electrical resistance probes, multiple crevice-forming beads or insulations may be added to create multiple crevice corrosion sites and increase the total metal loss from crevice corrosion so that it can be detected by this "average metal loss" measurement method.

Some linear polarization probes incorporate a zero resistance ammeter to compare identical electrodes. O-rings may be added to one electrode to form crevices. Localized attack from crevice corrosion shows as an increase in the current measured between the electrodes in a zero resistance ammeter mode.

### *Galvanic Corrosion*

Galvanic corrosion may be monitored in-situ by placing a zero resistance ammeter in the electrical circuit between the electrodes of the galvanic couple under test. This may be useful as a qualitative measurement to monitor comparative corrosion inhibition treatments against galvanic corrosion. It is difficult to estimate representative plant galvanic corrosion rates. The relative areas of the two alloys in the plant, their geometry, the conductivity of the solution, and the connection path all affect the galvanic current and its consequential metal loss. Metal loss from galvanic corrosion depends on the magnitude of the galvanic current density. Consequently, the metal loss due to the galvanic current on a large area produces a much smaller metal loss per unit area than if the same galvanic current is concentrated in a small area.

### *Stress Corrosion Cracking*

This is a difficult phenomenon to monitor online. Mostly investigations are carried out over relatively long-term exposure of stressed corrosion test specimens. Slow strain rate tests that are carried out in laboratory evaluations are difficult to reproduce in the field environment. Techniques such as acoustic emission have been used on-line to detect process conditions that produce SCC, but the data analysis is still relatively lengthy, complex, and in the developmental stage.

## Online Monitoring

Online monitoring is most commonly employed to provide feedback for the control and regulation of corrosion within acceptable limits in the dynamic environment of real plant conditions. The use of inhibitors and modification of operating conditions can then be used to achieve control of corrosion. In many batch process systems, online monitoring is used to identify the part of the process causing corrosion problems. This narrows down the field of investigation for laboratory testing or simulations. In some instances, automatic samples are triggered by the measurement of high corrosion rates, for subsequent chemical analysis of the process corresponding to these excessive corrosion rates.

To be effective the specimens under test must be representative of the worst or most severe operating conditions from a corrosion viewpoint. This means positioning of the probe element or corrosion test specimen in the correct location

where the corrosion is occurring. This may be more difficult where no previous experience exists. If process simulators or side-streams are used, care must be taken to simulate accurately the process conditions that give rise to the corrosion. This can involve producing the appropriate phase (such as in condensation areas) correct temperatures and pressures, correct flow velocities, and so on.

## TESTING PRECAUTIONS

Corrosion by its very nature is rarely uniform, even over one area of a plant or even the area of a single test piece, corrosion test specimen, or probe. Considerable care needs to be exercised to ensure that monitoring is carried out effectively in order to measure the most severe conditions. The most effective or appropriate location to monitor the most severe corrosion conditions with probes or corrosion test specimens may not be the most convenient or accessible. However, priority should be given to monitoring at the correct location.

"Where should we monitor?" is probably the often most commonly asked question. This is where previous plant experience of corrosion problems is extremely important. On an existing plant this can usually be ascertained from experienced maintenance staff. On a new plant, previous experience on a similar plant is usually most helpful. Since the monitoring is being done on a test specimen rather than the actual plant, the probe or corrosion test specimen must be in a "representative" location. General location of probes and corrosion test specimens are listed in Table 6.

The combined effects of corrosion and erosion can be particularly severe and special care is required to capture its effect. In processes such as oil production, where sand may be present, erosion along the outside of bends and high velocity areas can be very high, necessitating careful probe or corrosion test specimen location to capture these most critical areas. When corrosion-resistant alloys and their durable passive films are present, this aggravates the difficulty of making accurate measurements. Erosion or cavitation may remove the protective film and then expose the base metal which corrodes at a comparatively high rate as it reforms its protective film. In such situations, small changes in the velocity can produce a very rapid change in metal loss due to this double effect.

In these cases, flow around the probe or corrosion test specimen should be carefully considered to ensure a representative measurement. Frequently in such situations, a flush mounting probe or corrosion test specimen will be most effective.

Thermal effects may also be a factor in the method of monitoring and the location of monitoring. Higher temperatures can produce a marked increase in corrosion rates. Location of a probe or corrosion test specimen in the highest temperature area with everything else being equal will generally show the higher corrosion rates. For example, on a cooling water system it is normal to measure corrosion rates at the high temperature outlet return to the cooling tower. However, it should be recognized that since the probe or corrosion test specimen is rarely heated to the surface temperature of the heat exchanger, the probe or corrosion test

TABLE 6—Probe locations.

Single Phase Flows	<ul style="list-style-type: none"> <li>• High flow rate (erosion or cavitation) areas</li> <li>• High temperature/low alloy areas</li> </ul>
Multiphase Flows	<ul style="list-style-type: none"> <li>• Usually monitor the water phase (bottom of line)</li> <li>• Points of condensation</li> <li>• Where acid gases pass into solution or organic acids are present</li> </ul>

specimen may not corrode at the same rate as the heat exchanger surfaces. Also, since scale will tend to occur at the hot end of the cooling water side of the heat exchanger, this may provide more corrosion protection that may not exist at lower temperatures where scale is not occurring.

The most suitable type of corrosion monitoring is dependent on the type of corrosion occurring. For general or localized corrosion, the choices are relatively easy. For cracking, online methods are currently very difficult and experimental.

## SUMMARY

Making measurements of corrosion rates and corrosion mechanisms in plant equipment is more complex than is often appreciated. There are many aspects to designing an effective in-plant monitoring program, which we have briefly covered here. A badly designed program, or even one compromised for practical difficulties, such as the correct monitoring location, can render measurements totally unrepresentative and thereby useless. However, dealing with the inherent variability of corrosion in real world application makes the use of in-plant measurements a vital requirement. A well designed corrosion monitoring program operated by skilled personnel can make an exceptionally good return on investment, when integrated into a complete process analysis. Although it sometimes seems difficult to obtain all of the corrosion management data we would like, the existing technologies are well able to make a major contribution to the reduction of the enormous annual worldwide costs of corrosion, when correctly applied. It is regrettable that in many situations, there is a lack of knowledge, or even the existence, of some of these corrosion measurement techniques by management. Automated monitoring systems using these existing techniques can make a major contribution to better asset and risk management with a relatively small investment of time and money.

# High-Temperature

Gaylord D. Smith<sup>1</sup>

SERVICE TESTS CHARACTERIZE the performance of materials in specific applications and should mimic the environment of the actual application as much as possible. This includes simulating the chemical composition of the atmosphere, the temperature and thermal cycle profiles, stress states, fatigue conditions, and design. These tests may be accomplished by exposing test racks to actual service conditions or through the use of prototype apparatus designed and constructed to duplicate the end-use application. Additionally, laboratory service tests designed to evaluate the effect of one or more critical aspects of the exposure conditions may be employed. Service test data enable one to determine failure mechanisms, component or material life, or to screen materials for an application.

Focus here is on service tests that evaluate materials in applications that involve both high-temperature and corrosive conditions. Basic chemical, thermodynamic, and physical principles are discussed. Specimen preparation, environment synthesis and evaluation are briefly reviewed and, where appropriate, reference is made to more detailed information and studies available in the technical literature.

## CORROSION BASICS

Kinetics, chemical, thermodynamic, and physical principles will all be operating in high-temperature service test environments, requiring each investigator to have an adequate familiarity of basic mechanisms and corrosion phenomena. A brief introduction to these aspects of service testing is presented here.

### Kinetics of High-Temperature Corrosion

Reaction kinetics is the study of the speed of chemical reactions. The factors driving these reactions are a complex interaction between the test material and the environment of the service test. Environmental issues include:

- temperature
- time/thermal cycle conditions
- corrosive species and their concentration
- chemisorption and dissociation characteristics
- stress states and cyclic strains

An incomplete list of material characteristics affecting high-temperature corrosion are:

- scale integrity
- the free energy of formation of oxides of the alloying elements
- alloy composition
- alloy substructure
- alloy interdiffusion coefficients in the material and in the scale
- coefficient of expansion differences in the scale and substrate
- specimen size and shape
- solubility of gaseous components of the atmosphere in the scale and substrate
- scale adhesion
- oxide formation during different stages of the service test

Materials frequently undergo changes in corrosion mechanisms that confound elucidation of reaction kinetics. For example, the corrosion of an alloy may initially follow parabolic kinetics (see below for a description of kinetic behavior) during scale formation, then enter a stage of linear behavior as another rate-limiting mechanism controls scale growth and, finally, upon depletion of scale-forming elements, catastrophic corrosion conditions occur and the rate of corrosion changes dramatically.

Reactions depicting high-temperature corrosion can be most commonly classified as one of three types: linear, parabolic, or logarithmic [1].

### Linear Reaction Kinetics

Linear rate kinetics are most often associated with materials that do not form protective scales or whose scales are highly porous, crack-prone, or poorly adherent, thus experiencing a relatively constant surface area to the corrosive environment.

Integrated, the rate equation that describes linear reaction kinetics (Fig. 1) is

$$x = k_1 t \quad (1)$$

where  $x$  is the scale thickness or mass gain per unit area and  $k_1$  is the linear rate constant. The units of  $k_1$  depend upon the manner in which the equation is used. Where oxide scale thickness is measured, then  $k_1$  has the units  $\text{cm s}^{-1}$ ; if mass gain measurements are used, then the rate constant has the units  $\text{g cm}^{-2} \text{s}^{-1}$ .

<sup>1</sup>Technical Manager, Product Development, Special Metals Corporation, Huntington, WV 25705.

FIG. 1—Linear reaction kinetics [6].

FIG. 2—Parabolic reaction kinetics [6].

### Parabolic Reaction Kinetics

Parabolic reaction kinetics describe high-temperature corrosion where the rate determining step is diffusion. This is often associated with protective scales and with internal penetration by such corrosive species as oxygen, carbon, or sulfur in certain materials.

Integrated, the rate equation describing parabolic reaction kinetics (Fig. 2) is

$$x^2 = k_2 t \quad (2)$$

where  $x$  is the scale thickness or mass gain per unit area,  $k_2$  is the parabolic rate constant with the units  $\text{cm}^2 \text{s}^{-1}$  for scale thickness measurements and the units  $\text{g}^2 \text{cm}^{-4} \text{s}^{-1}$  for mass gain measurements. The high-temperature corrosion resistance of most chromia ( $\text{Cr}_2\text{O}_3$ ) and alumina ( $\text{Al}_2\text{O}_3$ ) scale-forming materials follow parabolic reaction kinetics.

Internal penetration or attack can also be defined by parabolic rate equation. This term describes the formation of precipitates (both inter- and intragranular) by the interaction of one or more constituents of the atmosphere with the substrate. The reactive species of the atmosphere dissolves in the substrate if the gas pressure is below the dissociation pressure of the compounds formed by the reactive species with components of the substrate. The reactive species of the atmosphere diffuse into the substrate and form the most stable precipitate possible. Internal penetration

occurs only if the reactive component of the substrate diffuses outwardly more slowly than the gaseous species diffuses inwardly. Wagner developed a simplified equation to approximate internal attack [2].

$$X = \left[ \frac{2N^s D t}{v N_B^i} \right]^{1/2} \quad (3)$$

where

$X$  = depth of internal penetration at time  $t$ ,

$N^s$  = mole fraction of reactive gaseous species in the substrate at the surface,

$D$  = diffusion coefficient of the reactive species in the substrate,

$t$  = time,

$v$  = ratio of reactive gaseous species atoms to substrate reactive component atoms in the precipitate, and

$N_B^i$  = mole fraction of reactive component initially in the substrate.

### Logarithmic Reaction Kinetics

Logarithmic reaction kinetics are most often associated with low-temperature service tests, the initial stages of oxidation of certain materials, and with thick scale behavior where internal scale cavities or precipitates interfere with diffusion mechanisms [3]. The rate equation describing logarithmic reaction kinetics (Fig. 3) is

$$x = k_{\log}(t + t_0) + A \text{ (direct log law)} \quad (4)$$

$$1/x = B - k_{il} \log t \text{ (inverse log law)} \quad (5)$$

where  $A$ ,  $B$ ,  $t_0$ ,  $k_{\log}$ , and  $k_{il}$  are constants at constant temperature.

Logarithmic rate behavior can occur when the diffusion paths for ions or vacancies are reduced as a function of time. For example, this can occur when vacancies collect at the metal/scale interface and result in cavity formation or partial scale detachment, which, in turn, inhibits pre-existing scale growth mechanisms. It can also occur in alloys when particles of a very stable but slow growing precipitate form within the scale or at the metal/scale interface and restrict the growth of a much faster growing scale component. Growth stresses within the scale may also result in logarithmic rate kinetics if they cause the scale to develop short cracks parallel to the substrate interface. Inverse logarithmic rates have been associated with copper, aluminum, and iron at temperatures near room temperature.

FIG. 3—Logarithmic reaction kinetics [6].

Two not uncommon forms of high-temperature corrosion that do not lend themselves to mathematical modeling are (1) breakaway corrosion and (2) catastrophic corrosion.

#### Breakaway Corrosion

Breakaway corrosion (Fig. 4) commonly occurs if numerous cracks continuously form and extend rapidly through the scale. It can also occur for alloys that have had one component (principally the most stable scale former) either effectively depleted from the alloy through repeated scale formation and spallation or through selective internal compound formation. Breakaway corrosion leaves bare substrate continuously exposed. Mass change measurements are meaningless during breakaway corrosion as scales rapidly form and break away from the substrate. Efforts to predict the onset of breakaway corrosion have been attempted for iron-base oxide dispersion alloys [4].

#### Catastrophic Corrosion

Catastrophic corrosion refers to the unique situation where a liquid phase is formed as a consequence of the corrosion process. This can occur either when the metal is exposed to the vapors of a low melting point compound or during corrosion of a substrate having a component that

forms a low melting point compound with one or more of the corrosive species of the service test atmosphere. Table 1 lists a few common oxides, sulfides, and chlorides known to initiate catastrophic corrosion.

While the exact mechanism of catastrophic corrosion is debated, it is clear that a liquid phase is essential and that it initiates at the scale/atmosphere interface and penetrates the scale along grain boundaries and pores to reach the substrate. Once at the scale/substrate interface, the liquid phase spreads out by capillary action destroying scale adhesion. Predictable corrosion rates under conditions of catastrophic corrosion are unlikely as different areas of the substrate undergo ever changing corrosive attack. Catastrophic corrosion can be unpredictably temperature-dependent as observed in waste incinerator simulation testing [5]. Iron-base heat-resistant alloys are subject to chlorine attack that forms  $\text{FeCl}_2$  at 676°C and above. For example, this attack is initially quite high upon formation of the liquid  $\text{FeCl}_2$  phase, then decreases somewhat as the sublimation rate increases only to begin increasing mass loss rates once again as a result of further increasing temperature.

#### Determining Kinetic Effects

Each investigator is encouraged to graphically plot the test results (mass change, scale thickness, etc.) as a function of time at constant temperature and pressure and as a function of temperature at constant time and pressure or if pressure is of prime importance as a function of pressure at constant time and temperature. These plots will permit the investigator to gain an insight into the form of the kinetics operating in the service test. Caution is offered not to extrapolate short time data into life predictions or to necessarily assume a smooth change in corrosion rates over a wide range of temperatures.

### CHEMICAL, THERMODYNAMIC, AND PHYSICAL PRINCIPLES OF HIGH-TEMPERATURE CORROSION

Chemical, thermodynamic, and physical principles underpin the corrosion mechanisms and their rates, which occur in any given service test. Each investigator must address the relevant principles operating in the test environment to fully understand the factors influencing performance.

Due to extensive data on crystal structures (both scales and substrates) and their properties, including melting points, boiling or sublimation temperatures, vapor and dissociation pressures, coefficients of expansion, molar volumes, free energy of reaction, and phase stability, it is left to each investigator to consult with the appropriate sources for the necessary data. One excellent source describing the fundamentals of high-temperature corrosion with accompanying tables of data is found in Ref 6.

Of particular importance to high-temperature corrosion investigators are isothermal phase stability diagrams. These diagrams fix temperature and plot the other variables of gas pressures or alloy composition against each other. These diagrams show the species that will be most stable for a given set of conditions. Stability diagrams for selected metal-carbon-oxygen, metal-chlorine-oxygen, and

metal-sulfur-oxygen systems are found in Ref 7, and for coal gasification/combustion atmospheres in Ref 8. An example of a stability diagram for the Fe-Cr-Ni-S-O<sub>2</sub> system is given in Fig. 5 [9].

Investigators can derive their own stability phase diagrams from standard free energy diagrams. The relative stability of the compounds of gas-metal reactions is usually shown on a Gibbs energy-temperature diagram. Gibbs energy-temperature diagrams for numerous elements and bromine, chlorine, fluorine, iodine, nitrogen, and sulfur are available [10]. The standard Gibbs energies of formation of selected oxides as a function of temperature are shown in Fig. 6 [11]. For an explanation of how to interpret a Gibbs energy-temperature diagram, the reader is referred to Ref 6.

Knowledge of the diffusion coefficients in the scale and substrate are important in relating performance to fundamentals. The diffusion coefficient  $D$  increases exponentially with temperature according to the Arrhenius equation:

$$D = D_0 \exp - Q/RT \quad (6)$$

$D_0$  = constant that is a function of the diffusing species and the medium,

$Q$  = activation energy for diffusion,

$R$  = gas constant, and

$T$  = absolute temperature.

The activation energy  $Q$  is a measure of the temperature dependence of a diffusion process. The higher the value of  $Q$ , the more rapid is the diffusion at high temperature and the slower it is at low temperatures. Activation energies for interstitial diffusion are much lower than for vacancy diffusion.

Epitaphial effects of a scale can influence diffusivity as does any defect such as porosity, grain boundaries, cracks, dislocation substructures, etc. Impurity cations can have a great effect on diffusivity in the oxide depending on the valence of the impurity ion and the semiconducting properties of the scale. Common scales formed from oxides, sulfides, and nitrides can be classified as  $p$ -type,  $n$ -type, or amphoteric semiconductors. The  $p$ -type, metal-deficit scales are nonstoichiometric with cation vacancies present. Impurity ions with valencies greater than the  $p$ -type semiconductor will tend to increase the concentration of cation vacancies and, hence, diffusivity. Lower vacancy ions will have the opposite effect. Impurity ions with the same valence should have little effect on diffusion. The  $n$ -type semiconductors

have negatively charged free electrons as the major charge carriers;  $n$ -type semiconductors have either excess cations or deficient anions. The effect of impurities on diffusivity is the opposite of that which occurs in  $p$ -type semiconductors.

Physical factors can play a major role in service, and each investigator should be alert to the significance of these factors. Included here are such factors as the volume of scale to the volume of substrate from which it is produced, the so-called Pilling-Bedworth ratio [12], the coefficient of expansion differences between the scale and substrate, the effect of the relative scale thicknesses, scale transformation stresses, thermal stresses, imposed stresses, plasticity of the scale, and the physical condition of the scale (porosity, presence and nature of any cracking, decohesion, and number of layers). Specimen size and shape can influence test results. Edges and corners behave differently than planar surfaces.

## BASIC MODES OF HIGH-TEMPERATURE CORROSION

The principal forms of high temperature corrosion can be classified as:

- oxidation
- carburization
- metal dusting
- nitridation
- halogen corrosion
- sulfidation
- ash/salt deposit corrosion
- molten salt corrosion
- molten metal corrosion

The first six modes of corrosion are the result of interaction between reactive gaseous species and the material of the substrate. Testing in gaseous environments is discussed in detail in the chapter on **Testing in Environments**. Ash/salt deposit corrosion is generally associated with gas turbines, fossil fuel power generation, coal gasification, waste incineration, and certain molten metal corrosion with metallurgical processing. Special service tests can be found in the literature that mimic molten metal, salt, and glass industry environments. Especially helpful is the text by Lai, *High Temperature Corrosion of Engineering Alloys* (1990).

## TESTING IN ENVIRONMENTS

Oxidation is the most commonly encountered high-temperature corrosion reaction. It is likely found as one of the constituents in most mixed oxidant environments and serves to either aggravate or ameliorate sulfidation, carburization, halogen corrosion, nitridation, and ash/salt deposit corrosion. Oxidation environments may be classified on the basis of their oxygen activity being either "oxidizing" (excess free oxygen) or "reducing" (no free oxygen) at equilibrium for the gas mixture. Mixed oxidant environments with low oxygen activities are generally more corrosive.

As with oxygen, sulfur-containing environments are quantified on the basis of their sulfur activity. Solid sulfide scales

FIG. 5—M-S-O stability diagram for the Fe-Cr-Ni system at 870°C [9].

FIG. 6—Standard Gibbs energies of formation of selected oxides as a function of temperature [17].

generally grow at faster rates than their corresponding oxides. Liquid sulfide phases are especially damaging and can be troublesome for alloys containing more than 20 % nickel as the nickel-sulfide eutectic melts at about 645°C. Ash and slag from combustion products may aggravate sulfidation by shielding the substrate from oxygen or fluxing protective scales.

Carburization is typically controlled by both carbon and oxygen activities. Generally, the lower the oxygen activity, the greater the tendency for carburization to occur. While carbide scales do form, it is more frequently observed that inward diffusion of carbon has occurred. This inward diffusion can create a number of material problems, notably embrittlement, distortion, and reduction in oxidation resistance.

Nitridation characteristics are similar in behavior to that of carburization, although not as industrially common in occurrence. It is frequently observed in materials exposed in air at relatively high homologous substrate temperatures, in ammonia production, and in nitrogen-based atmospheres. As with carburization atmospheres, increasing oxidation activity decreases nitridation at a given temperature.

Service testing to simulate ash/salt deposit corrosion is of importance to a number of industries. The fossil-fired power generation industry must deal with what is called "fuel ash corrosion" from sulfur- and vanadium-containing fuels and alkali, chlorine, and sulfur in coal. The gas turbine industry must deal with "hot corrosion" problems arising from sulfur in fuel and sodium salts from ingested air. Waste incineration environments can become even more complex with refuse containing sulfur, chlorine, phosphorus, and numerous metallic elements.

## SERVICE TESTING

### Specimen Preparation

The subject of specimen selection and preparation is given thorough treatment in ASTM G 1, Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens and each investigator is encouraged to review this information. Attention to detail is critical to successful service testing

and it begins with a complete metallurgical profile on the material to be tested. Included here is the chemical composition, fabrication history, and a knowledge of the microstructure. Positive identification of all specimens is essential. Stamping numbers on all specimens is frequently used for identification purposes. Brittle materials can be notched. Setting up a pedigree reference material to be used over and over again in order to "calibrate" each run of the service test is strongly recommended. Duplicate samples will aid in assuring a certain accuracy of the data.

If the ultimate purpose of the service test is to evaluate wrought materials for a particular application, then the majority of the materials tested should reflect the selection of appropriate wrought materials. Similarly, cast components should have a bias toward cast substitutes. This is because costs, physical properties, and available forms lend themselves to either wrought or cast alloy construction. If welded construction is involved in the end-use, welded specimens should be part of the service test series. Again, the investigator must know the welding products and welding conditions used. Size and shape of service test specimens can vary widely but must be large enough to obtain meaningful quantitative data. In testing where internal penetration occurs, such as in carburization, it is important to have a specimen large enough to not become saturated prior to completion of the test. Edges and corners do not behave the same as planar surfaces. The investigator should consider which to emphasize through test specimen geometry. For wrought specimens, large surface to edge area is desirable to more accurately reflect typical equipment. If the effects of service conditions on mechanical properties are sought, machined test specimens should be exposed.

Although clean, uniform, and defect-free surfaces are rarely found in plant equipment, it is important to strive for a clean, uniform surface condition in order to assure meaningful and reproducible results. A common surface finish is produced by dry polishing with nominally #120 abrasive cloth or paper. The sample is polished until the surface is of uniform condition. Machining may be necessary to remove scale or other defects prior to polishing. Carburized or decarburized layers should be removed. Sheared metal may have a cold-worked layer that requires removal although this could be less important in high-temperature test environments. Certain materials may require special handling or safety procedures that can be obtained from the manufacturer.

After surface preparation, the sample must be carefully measured to permit an accurate calculation of surface area. The sample is then thoroughly cleaned in a solvent, dried, and weighed as precisely as possible. Typically, small specimens should be weighed to within 0.1 mg. Changes in mass and dimensions will occur during service testing and the precision of the results will be no better than those of the "before and after" mass and dimensions. Once weighed, the samples should be inserted into the test environment or stored in a desiccator.

### Service Test Atmospheres

Simulating the environment of an industrial process or application is a compromise in most situations. Most

atmospheres consist of mixed oxidants of varying partial pressures (activities), temperature gradient profiles, and, in some cases, velocity and erosion parameters as well. Key application variables should be identified and care should be taken to see that these variables are suitably simulated in the service test. Characterization of gas composition is as essential as the control of temperature and gas flow rate. This will assure that the system is at equilibrium and is free of extraneous components. If accurate and dependable atmospheres are to be maintained, care must be paid to flow stability and to maintaining calibrations. Atmosphere synthesis may require a stream of apparatus consisting of such units as an inlet saturator, exhaust condensers, gas preheater beds, catalyst beds, heat shields, bubblers, mass flow meters, and analytical instrumentation. It is helpful to fix flow meter inlet pressure at a constant, uniform level and meter the gaseous components with electronic mass flow controllers of the proper capacity range. Simple flow meter-needle valve controls should be limited to single component gases or for purge streams. Mass flow controllers will maintain uniform flow rates until a back pressure of 36 kPa is reached. Any service test environment that could cause system blockage through condensation, sulfate formation, coking, or line corrosion should be constantly monitored and relief valving provided. Corrosive gases such as sulfur trioxide will require corrosion-resistant materials of construction. Polyethylene is a convenient tubing material and does not appear to affect gas dewpoints as low as  $-73^{\circ}\text{C}$  (approximately 2 ppm). If the system is to be monitored using a gas chromatograph, septums must be appropriately located in the gas stream, preferably both immediately before and after the specimen reaction chamber. For more information on atmosphere simulation and analysis, the reader is referred to Refs 13 and 14. References to methods for purifying elemental gas streams are described in Ref 1.

### Service Testing Techniques

Data collection depends on the purpose of the service test. Measuring techniques include mass and dimensional changes, volumetric measurement of reactive gas consumption, changes in mechanical and physical properties, metallography, and radiographic analysis. These techniques are described in detail throughout this text, and it is the intent here to only caution a new investigator of several common mistakes that can occur in high-temperature corrosion testing. Any determination method that measures film formation during the initial period of scale growth can be highly misleading (and usually is) when it comes to extrapolating the results to long-term service. Only in the few instances where linear oxidation kinetics prevail over time would gravimetric data be valid for predicating service life. Care must be taken to assure that corrosion behavior has been measured over the entire range of temperature and pressure expected in actual service. For example, liquid phase formation is a function of temperature and can quite suddenly alter corrosion behavior in sulfur-containing atmospheres. Dependence on mass change data can be deceptive. Use of metallography to measure loss of metal and depth of internal penetration by the reactive gaseous species is essential to assess potential material degradation not

necessarily apparent by mass change data. For example, a net zero mass change effect for chromia-forming alloys can be observed at elevated temperatures in mixed oxidant environments where simultaneous mass loss of chromium by evaporation (as  $\text{CrO}_3$ ) occurs while internal attack by one or more of the oxidants (mass gain) is occurring.

## SERVICE TEST EXAMPLES

Service tests are meant to bridge the gap between fundamental data and end-use applications. These tests are used to evaluate existing materials or to screen candidate compositions for their suitability for a given application. In selected industries, service testing has become "semi-standard." Design of any given service test is a practical compromise of the critical aspects of the service conditions and a means of obtaining engineering data that in some way have their origins in fundamental data. It is assumed that at least some readers intend to design and construct a service test for their particular application and wish to assess the typical degree of test complexity found in established service tests.

It is not uncommon to find test methods in the literature used by companies or individuals to investigate specific service applications. Readers should be cautioned about using these types of tests. While they may be valid service tests, most have not been through any formal "standardization process," including peer review and interlaboratory testing. Thus no data are available to assess precision issues of the procedure such as "repeatability" (precision issues of the procedure) and "reproducibility" (precision between different laboratories). When possible, each investigator is encouraged to follow ASTM, ASME, or NACE standards in their service testing.

Examples of specific service tests for selected applications are cited below that have achieved a high degree of acceptability. Additional discussion on high temperature corrosion testing in specific laboratory and field environments can be found in the chapter on **Testing in Environments**.

### Electric Heater Wire Tests

Two service tests have been reported in the literature for life testing electric heater wire. The first test is described by ASTM B 76, Method for Accelerated Life Test of Nickel-Chromium and Nickel-Chromium Iron Alloys for Electrical Heating. The useful life of a material is determined by electrically heating a section of wire in air to a given temperature where it is held for 2 min, followed by 2 min of cooling. This cycling is repeated until a 10 % increase in electrical resistance is noted and reported as the useful life of the material. This testing can take about one week.

A faster technique has been proposed [15]. Based on analysis of the mechanisms of electrical heater wire failure, these authors derived a test incorporating a 2 % plastic strain in the wire after a preset degree of oxidation. A microbalance was used to obtain the parabolic rate constants before and after straining. A reduced parabolic rate constant after prestraining correlated well with the ASTM B 76

Life Test results. This service test could be accomplished in a few hours.

### Residual Fuel Oil Corrosion Tests

Because residual fuel oils contain sulfur, vanadium, and sodium, these fuels for power generation can be highly corrosive as a result of combustion. Consequently, a number of investigators have described test methods for evaluating residual fuel oil corrosivity, its inhibition, and the resistance of materials to it [16–21]. In these tests, specimens are partially or completely immersed in actual or synthetic ash and heated in air, followed by mass change measurement and metallographic evaluation of internal depth of penetration. Crucible tests gain increased credibility where their results can be correlated with test rack data obtained from an operating boiler using the same fuel. Viswanathan and Spengler have devised a laboratory test method for exposing specimens to synthetic or real combustion gases [22].

### Sulfur Corrosion Tests

Sulfur-bearing gases are found in many processes in numerous industries. The petroleum and petrochemical industries are particularly plagued by sulfur-bearing, elevated temperature process streams and, consequently, have been active in test method development and material evaluation [23–25]. A pilot plant size test reactor is described in Ref 23. In sulfur-bearing environments, metal loss and total depth of penetration are the principal measurement techniques. Numerous investigators have compared their service test data with actual operating conditions. A synthetic gas environment test was formulated to evaluate the effect of heating during the manufacture of heat-resistant alloys using sulfur-bearing fuels [26]. When sodium, usually from sea salt, reacts with any residual sulfur in a combustion gas stream, sodium sulfate ( $\text{Na}_2\text{SO}_4$ ) is formed, which is a particularly aggressive corrosion accelerator of nickel- and cobalt-base superalloys. This form of attack is called "hot corrosion." Seybolt has compared sodium sulfate crucible testing to  $\text{H}_2\text{S}/\text{H}_2$  gas mixture testing at 1000°C [27]. Sulfur dioxide ( $\text{SO}_2$ ) plus air mixtures have been used [28] and saturated solutions of sodium sulfate have been sprayed on alloys at 120°C and subsequently exposed to oxygen in a heated furnace and evaluated using a thermobalance [29]. More common and also much more elaborate and expensive is "hot corrosion" testing in a burner rig apparatus. A schematic of a G. E. Lynn burner rig is shown in Fig. 7. The typical burner rig meters fuel (usually JP-4 or JP-5 aviation fuel) to the fuel nozzle where it is atomized and combusted with an excess of air, usually at an air-to-fuel ratio ranging from 15:1 to 60:1. Sea salt and any other soluble component, such as additional sulfur, can also be injected through additional nozzles. The combustion tube is usually made from ceramic and electrically heated to assure a uniform, constant temperature in the specimen test zone of the rig. The sample holder is rotated at speeds to 200 r/min and the cycle between time in the combustion zone and time in a blast of room temperature air is programmable. A typical cycle is 58 min in the combustion zone and 2 min in the air blast.

FIG. 7—Schematic cross-sectional view of a hot corrosion rig.

The test specimens are evaluated for dimensional and mass change effects, the types of scale formed, and metallographically, for metal loss and depth of attack. Evaluation methods are further described in the section of this text on **Testing in High Temperature Gases**. Just, et al. have developed a test in which a synthetic ash, similar in composition to that found on blades of gas turbines used in industrial processes, covers the test specimens and a gas atmosphere containing sulfur dioxide is passed over the sample and ash [30].

### Molten Salt Corrosion Tests

Molten salt technology is employed in a number of industries including metal heat-treating, nuclear and solar energy systems, reactive metal extraction, high-temperature batteries, and fuel cells. Because molten salts tend to flux the inherent scales that form on heat-resistant alloys, the intrinsic resistance of the metal or alloy to the molten salt is of paramount importance. Oxygen and water vapor tend to accelerate molten salt corrosion that can either be uniform thinning, pitting, or internal or intergranular attack. Testing is often done in quartz crucibles either in air or in a controlled atmosphere. Molten salts can cause significant mass transport due to thermal gradients within the system. This form of corrosion involves dissolution of an alloying element in the higher temperature regions and subsequent deposition of the element in the cooler parts of the system. This can result in system fouling as shown in studies by Adamson in thermal convection loop [31] and by Misra and Whittenberger for a heat-storage medium in an advanced solar space power system [32]. A high temperature test to evaluate candidate automotive exhaust system materials for resistance to road salts has been developed by Crum, et al. [33].

### Carburization Corrosion Tests

Carburization atmospheres are extensively found in the metal fabrication and heat-treating industries where furnaces

are heated and the atmospheres maintained by hydrocarbon fuels. The petrochemical industry operates a great number of high-temperature hydrocarbon processes where carburization is the major degradation mechanism. Mason, et al. describe a pack carburization test method that is common for evaluating the resistance of materials to carburizing environments in the heat-treating industry [34]. More common are gaseous carburization test methods that use gaseous environments with varying carbon activity and various oxygen potentials [35]. Lai has a similar technique and controls the partial pressure of oxygen to dictate the type of protective scale that forms [36]. ASTM G 79, Practice for Evaluation of Metals Exposed to Carburization Environments, describes various methods of measuring the degree of carburization of a material. One test method to evaluate the resistance of alloys to metal dusting has been described by Baker et al. [37].

## SERVICE TEST STANDARDS

High-temperature service test standards are available from ASTM. No other technical organization has yet published any standards pertaining to high-temperature corrosion service.

### ASTM G 54, Practice for Simple Static Oxidation Testing

This service test practice covers determination of preliminary information on the relative growth, scaling, and microstructural characteristics of an oxide on the surface of a pure metal or alloy under isothermal conditions in still air.

### ASTM B 76, Method for Accelerated Life Test of Nickel-Chromium and Nickel-Chromium-Iron Alloys for Electrical Heating

This service test method covers the determination of the resistance to oxidation of nickel-chromium-iron electrical heating alloys at elevated temperatures under intermittent heating using a constant temperature cycle test. This test is used for internal comparative purposes only.

### ASTM B 78, Method for Accelerated Life Test of Iron-Chromium-Aluminum Alloys for Electrical Heating

This practice covers the determination of the resistance to oxidation of iron-chromium-aluminum alloys for electrical heating alloys at elevated temperatures under intermittent heating using a constant temperature cycle test. This test is used for internal comparative purposes only.

### ASTM G 79, Practice for Evaluation of Metals Exposed to Carburization Environments

This practice covers procedures for the identification and measurement of the extent of carburization in a metal sample and for the interpretation and evaluation of the effects of carburization. It applies mainly to iron- and nickel-based alloys for high temperature applications.

Four methods are described:

- Method A: Total Mass Gain
- Method B: Metallographic Evaluation
- Method C: Carbon Diffusion Profile
- Method D: Change in Mechanical Properties

These methods are intended, within the limitations as noted for each, to evaluate either laboratory or commercial product samples that have been exposed in carburizing environments.

*J. R. Scully, Editor*

# Uniform Corrosion

James A. Ellor<sup>1</sup> and John Repp<sup>2</sup>

TESTING FOR UNIFORM corrosion is one of the most common corrosion tests employed to determine material suitability in a wide variety of applications. The following is intended to be an introduction into the subject of testing for uniform corrosion, its applications, basic methodology, and limitations. The reader is referred to applicable standards fully detailing the procedures.

ASTM G 15, Terminology Relating to Corrosion and Corrosion Testing, defines uniform corrosion as: "corrosion that proceeds at about the same rate over a metal surface." The standard does not define the term "about." This discussion defines uniform corrosion as equivalent material loss across the continuous surface of a material. This very rarely occurs in practice. The degree to which the loss is indeed identical across a surface, as opposed to localized at some material feature, is a direct indication of compliance with this definition of uniform corrosion. The analyses described are not applicable to test specimens that show significant localized corrosion—for example, if only 20 % of the surface area appears attacked, or if certain sections have areas of metal loss ten times that of other areas. Should the corrosion pattern show such characteristics of nonuniformity, the researchers will need to consider these factors in their final analysis. Often, this might be addressed by running and reporting on both uniform and nonuniform corrosion tests.

## BACKGROUND AND THEORY

An appreciation of the basic principles guiding uniform corrosion aids in discussion of test methods. In general, corrosion is the net result of chemical or electrochemical reactions occurring at the surface of a metal. An example is red-rust occurring on iron exposed to the atmosphere. In most atmospheres, bright iron or steel surfaces are not favored by nature—nature instead favors iron oxide or "rust."

Most simply, uniform corrosion results when no single region or area of a metallic surface is favored over another. Over an exposure period, the active corrosion areas are evenly distributed over a surface. In localized corrosion, some feature of the material, a local crevice, defect, or surface metallurgy, acts to promote one particular site as the most active region of corrosion.

Two aspects of corrosion should be introduced: one is the tendency for a corrosion reaction and the second is the rate at which the reaction will occur. Often, one of these principles is considered without regard for the other, leading to improper conclusions.

In uniform corrosion on a metallic surface, the tendency for a corrosion reaction results from the magnitude of the electromotive force of the corrosion cells comprising the corrosion process [1]. In some materials, the corrosion cell may arise from the heterogeneous nature of the surface, the often discussed "local cell." Conceptually the local cell is similar to a battery, often used to discuss corrosion reactions, where oxidation occurs at an anode and reduction at a cathode. Yet unlike a battery, which is comprised of different materials immersed in a common electrolyte, a local cell on an otherwise uniform piece of material can be related to, among other factors, surface impurities, alloy phases, or nonuniform stress distributions. On a pure, homogeneous surface, corrosion may still occur. Practically, the corrosion rate of a pure material is often lower than a nonhomogeneous material. Corrosion is believed to occur through simultaneous oxidation and reduction reactions taking place at a common point [2]. In either case, the tendency for the reaction can be determined by inspection of the thermodynamic equilibrium potentials of the anodic and cathodic reactions.

Consider the corrosion of iron in an acidic environment. The anodic reaction is  $\text{Fe} = \text{Fe}^{+2} + 2\text{e}^-$ . The cathodic reaction is  $2\text{H}^+ + 2\text{e}^- + \frac{1}{2}\text{O}_2 = \text{H}_2\text{O}$ . The standard thermodynamic equilibrium potential at unity  $\text{Fe}^{+2}$  concentration for the anodic reaction is  $-0.44\text{V}$  versus the normal hydrogen electrode (NHE). The thermodynamic equilibrium potential for the cathodic reaction at unit activity for  $\text{H}^+$  is  $1.229\text{V}$  versus NHE [3]. The overall cell electromotive force (EMF) is  $1.669\text{V}$ . If  $V > 0$ , then the reaction has a tendency to proceed as written. In this case, iron would go into solution and oxygen would be reduced. Similar calculations can be made for different metals in solutions with varying cathodic reactions to determine the tendency for corrosion. For instance, iron would still corrode in an oxygen-free acid. Here  $2\text{H}^+ + 2\text{e}^- = \text{H}_2$  at  $0.0\text{V}$  (NHE) and  $\text{Fe} = \text{Fe}^{+2} + 2\text{e}^-$  at  $-0.44\text{V}$  (NHE) results in a cell potential of  $0.44\text{V}$ . Fontana and Greene, among many others, provide a good description of this type of analysis [4].

While such calculations can be made to investigate the tendency for corrosion, they do not indicate the rate of corrosion. Greater cell EMF values do not necessarily indicate

<sup>1</sup>P.E., Vice President, Corpro, Ocean City, NJ 08226.

<sup>2</sup>Manager, Corpro/Ocean City Research Corporation, Ocean City, NJ 08226.

higher corrosion rates. The corrosion rate is the parameter of concern in most practical problems. The corrosion reaction itself is complex, consisting of numerous steps. The overall reaction rate, and thus, the corrosion rate, can be no faster than the slowest of these steps (the rate determining step). Each portion of the reaction sequence imparts a resistance to the corrosion reaction, i.e., limits the corrosion current resulting from the thermodynamically favored anodic and cathodic reactions.

The key rate-controlling steps are commonly referred to as concentration control and activation control [4]. Concentration control implies that the rate determining step is the rate at which reactants or products move to or from the corroding surface. Concentration control is also referred to as mass transfer or diffusion control. Common illustrations of concentration control include the ability of a reactant, e.g., dissolved oxygen, to diffuse to a steel surface in an aqueous electrolyte or the ability of a reaction product, e.g., hydroxide, to diffuse from a steel surface. High supply rates of reactants favor a higher corrosion rate; low diffusion rates of products from a surface hinder corrosion rate.

Activation control refers to the rate of oxidation and reduction that takes place at a metallic surface. Activation control is also referred to as charge transfer control. For zinc in an acid environment, one reaction product is typically hydrogen gas. Given that the solution is sufficiently acidic, there is a large abundance of hydrogen ions in the solution; thus, mass transfer of hydrogen ions to the zinc surface is not usually the rate-controlling step. The rate-controlling step can be the transfer of electrons from the zinc to the hydrogen ions to form adsorbed atomic hydrogen on the zinc surface. Charge transfer rates can vary as material properties in different chemical environments (e.g., catalytic properties).

Other factors may influence uniform corrosion rates, such as the development of oxide layers on a metallic surface. In reality, such layers limit the corrosion rate by affecting diffusion and imparting concentration control.

## UNIFORM CORROSION TESTS

The uniform corrosion test methodologies outlined below are intended to provide the user with an overview to the process. They are centered on tests in aqueous applications, but can also be adopted to monitor uniform corrosion concerns in an atmospheric exposure. Uniform corrosion tests are only useful if the test results demonstrate that the corrosion was indeed uniform. The tests described below discuss the general procedures and areas of concern. The test results will be valid to the extent that the test simulates the potential material in-service application.

Factors that affect the in-service corrosion rate by influencing the controlling thermodynamic and/or kinetic parameters that are not accounted for by the experimental design limit the usefulness of the test. Typical operational parameters of concern include, but are not limited to, exact material composition and forming techniques, service temperature, electrolyte chemistry, electrolyte velocity, time-of-wetness (wet/dry cycles), exposure duration, and mechanical forces (e.g., abrasion or stress). Often, neglect of the key

operational parameters for testing convenience provides for erroneous results. Any testing method should attempt to determine which of these parameters is key and to simulate that parameter as closely as possible during the test.

It should be noted that there is often a desire to accelerate corrosion tests by increasing the corrosive stress factors, e.g., temperature or chemical concentrations. Before accepting the results from such tests, it is wise to confirm their validity, especially in light of the importance discussed above of matching the key operational conditions. In accelerated tests, it is suggested that one confirm (1) the acceleration factor and (2) that novel or unnatural corrosion processes do not result. Running a series of tests where the stress factors are incrementally increased and the resultant corrosion rate determined can assess acceleration factors. Severe discontinuities in this relationship or the formation of novel corrosion products or corrosion morphologies can be indications that novel or unnatural corrosion processes are occurring. In such cases, the acceleration factors should be decreased.

## MASS LOSS TESTS

The simplest uniform corrosion tests are those based on coupon immersion and mass loss tests. The tests provide data on the uniform metallic corrosion rate most often expressed in English units as mils per year (mpy) or in metric units as millimeters per year (mm/y). While there are various standards for such tests, the predominant methods are those prescribed by ASTM G 1, "Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens." This standard contains a comprehensive reference list of other ASTM standards that also apply, depending on the type of tests of interest to the investigator.

These mass loss tests consist of preparing metallic coupons, cleaning them before testing, weighing them before exposure, exposing them to the corrosive media, post-test removal of visible corrosion products, and reweighing. The corrosion rate is calculated from the mass loss measured, converted to a volume of metal loss by the material density, and finally to a corrosion rate by dividing this volume by the material surface area and the test time.

The reader is directed to ASTM G 1 for the procedure details. The following comments apply to these standard procedures and should be considered. The test coupon size selected should be large enough to minimize the ratio of edges to general surface area. On some sensitive materials, corrosion often preferentially takes place at an edge, thereby limiting the measurement of "uniform" corrosion. There are no advantages to using small coupon sizes other than the size of the test equipment. Specimens should be as large as practically possible considering the size of the test chamber, material cost, and capacity of an analytical balance for coupon mass measurements. This author has used samples as small as 2.5-cm by 5-cm by 0.3-cm, and as large as 15-cm by 10-cm by 0.6-cm.

The volume of the test media should be sufficient to ensure that the corrosion products formed or dissolved within the media do not significantly affect its properties. One may make an estimate of the required volume by estimating the

total volume of material possibly dissolved into the media based on an approximate corrosion rate and the size of the test coupon. ASTM G 31, "Practice for Laboratory Immersion Corrosion Testing of Metals" also addresses this same issue.

The exposure test(s) should be designed such that the expected mass loss of coupons is within detection limits of the measurement instrumentation. Variations to coupon dimensions and/or test duration can accomplish this. Coupons should always be large enough so that the mass loss expected over the test duration is resolvable above minimum, but does not exceed maximum detection limits. With low corrosion rates, larger coupons are necessary. Alternatively, the duration of exposure may also be changed to obtain detectable mass loss. However, this method is typically not favored, since significantly increased test durations may result.

Coupons must be identifiable before and after testing. Most simply, the coupons can be identified by a mark made directly onto the sample. However, with some notch-sensitive materials such as stainless steels that may have a tendency to favor localized corrosion over uniform corrosion, such a mark can modify the sample corrosion behavior. For the most sensitive materials, even a tag attached to the sample can affect the corrosion. In these cases, the materials should be identified by location within a test environment. Of course, the larger the test sample, the less of an influence some small mark will have on the overall results.

The material surface should be representative of the finish expected in-service. If the exact service finish is not known, the test surface finish should be noted. For stainless steel or aluminum alloys, where corrosion phenomena can attack specific elements of the metallic structure preferentially, the coupon forming process should also be noted (e.g., annealed, heat-treated, cold-rolled, cast, etc.).

ASTM G 1 provides specific details on the accuracy of the coupon weighing procedures before and after testing. Data to the fifth significant digit are suggested. While this is good practice, the practitioner should also consider the expected corrosion rate. Often in situations where the corrosion rate is expected to be quite high, data are not required to the fifth significant digit. This can be a significant time-saver if many coupons are to be tested and must be weighed on an analytical balance. The precision of electronic digital scales often makes this an unnecessary consideration.

Removal of visible corrosion products, after testing, is accomplished by cleaning of the coupon surface. Cleaning is accomplished by chemical stripping, mechanical removal (i.e., abrasive blasting or brushing), and electrolytic methods to remove corrosion products. This author's experience suggests that the best methods are abrasive blasting and chemical stripping. These techniques are more likely to remove all of the visible corrosion products without harming the metallic surface.

With respect to the chemical procedures described by ASTM G 1, the immersion time suggested for coupons in the alternative chemical baths should be used as a guideline only. There are many times when tenacious corrosion products can take significantly longer to remove than that expressed by the standard. All corrosion products must be removed without resulting in additional corrosion of the metallic substrate for an accurate mass loss measurement.

Furthermore, the standard does not describe a correction procedure for mass loss of the base metal. The standard suggests that the mass loss be plotted as a function of the number of cleaning cycles. The breakpoint in this curve is regarded as the corrosion mass loss; further mass losses are suggested to be the mass loss of base material. The standard urges that a cleaning procedure be selected such that the slope of this latter curve is "zero," i.e., the cleaning procedure is having no effect on the base metal. This is not always possible.

It is suggested that the cleaning cycle time be standardized and the number of cleaning cycles recorded. After cleaning, a clean coupon of the same base material should be subject to the same cleaning procedure and cleaning cycle. The mass loss of this material should be recorded as a function of cleaning cycles. For each cleaning cycle of the corroded specimens, an adjustment should be made for the mass loss of the base metal as a result of the cleaning procedure.

Some may argue that the base material mass loss per cleaning cycle is not the same for an already clean sample and a sample covered with corrosion products. This is a valid point; yet, if the base material is significantly affected by the cleaning solution, a correction should be attempted and the procedure described is appropriate. If the base material is not significantly affected, application of this correction factor will have no effect on the test results.

Abrasive grit blast methods for removal of corrosion products have increased in popularity in recent years. Some test specifications specifically list this as the preferred cleaning method [5]. Fine abrasive grit (the author has used 120 grit glass bead) is used in an air-powered blast cabinet. The surface of the coupon is blasted until removal of all visible corrosion products is observed. Mass loss and corrosion rates are then determined by standard methods.

The use of abrasive grit blasting has several advantages over chemical stripping. This cleaning method eliminates the use and disposal of hazardous chemicals during the cleaning processes. Eliminating hazardous chemicals also reduces the need for personal protective equipment (PPE) and reduces potential worker health and safety issues. This method also reduces the amount of time necessary to remove all corrosion products both during the cleaning and disposal operations.

The author has used this method to clean carbon steel coupons following exposure tests. Similar results were obtained from samples using this and the chemical stripping cleaning methods. Use of this method on uncorroded test samples resulted in negligible mass loss of sound base metal. Before using this method on other materials, similar comparisons between cleaning methods and removal of base metal are suggested.

The duration of the test can have a significant effect on the test data. Most materials will corrode most rapidly in the early stages of exposure to an environment—before oxide films are developed that may inhibit the corrosion rate by limiting the diffusion rate of reacting species to and from the metallic surface. Thus, tests of 24-h duration extrapolated to 30-day or 1-year behavior may be extremely conservative. Where time allows, multiple test durations may be evaluated to determine the actual effect of exposure time on uniform corrosion.

One last factor that should be considered in the design of mass loss tests is metallic plated specimens, e.g., galvanized steel. It is often difficult to distinguish between the corrosion of the zinc-galvanizing and the base steel and difficult to clean the zinc corrosion products without damaging the steel. For this example, it is suggested that the test design include both bare steel and solid zinc coupons as additional materials. Coupons of the base metal and plating materials should be evaluated for other samples, e.g., aluminum and nickel for nickel-plated aluminum samples. The corrosion rates of the homogeneous materials can aid in distinguishing the corrosion of the base metal and plating materials.

After completion of the test, the corrosion rate may be calculated from the mass loss as follows:

$$\text{Corrosion Rate} = (K \times W) / (A \times T \times D)$$

where

$K$  = constant,  
 $T$  = time of exposure, h,  
 $A$  = area,  $\text{cm}^2$ ,  
 $W$  = mass loss, g, and  
 $D$  = density,  $\text{g/cm}^3$ .

$K = 3.45 \times 10^6$  for a corrosion rate in mpy. Other constants include  $K = 8.76 \times 10^4$  for a corrosion rate in mm/y. Refer to ASTM G 1 for a complete listing of constants. Common material densities include about  $7.9 \text{ g/cm}^3$  for most steels and many stainless steels,  $8.9 \text{ g/cm}^3$  for copper alloys, and  $2.7 \text{ g/cm}^3$  for aluminum. Refer to ASTM G 1 for a detailed listing of material densities.

It should be realized that the utility of the tests is limited if the corrosion is not uniform. If there is extensive localized corrosion, the mass loss data will greatly underestimate the maximum corrosion rate, as it will distribute the corrosion over the entire surface of the coupon. Where localized corrosion may be a concern, the investigator may use a micrometer or other type of sensitive instrument to measure the coupon thickness before and after test. Multiple measurements should be made to ensure that the coupon surface is well-characterized. The thickness loss in mils divided by the test duration in years should be compared to the corrosion rates calculated by the above formula. The degree to which the two results agree indicates the degree to which the coupon did indeed undergo uniform corrosion.

## ELECTROCHEMICAL TESTS

Electrochemical tests are often preferred to mass loss studies as a method of measuring uniform corrosion. Such tests are preferred because in theory they: (1) provide a real-time measurement of the metallic corrosion rate, (2) can provide time-corrosion rate data on a single coupon, and (3) are rapid to perform. Disadvantages of the electrochemical tests include the requirements for comparatively expensive equipment (versus mass loss tests) and higher levels of technical expertise for data analysis. Furthermore, the data reduction requires the use of conversion-“constants,” factors applied to the results of the electrical measurements to convert the data to a corrosion rate. These “constants”

are usually developed from theoretical behavior of metals in an environment and are checked through actual mass-loss data for materials in the test environment. However, when evaluating a material in a new environment or novel operating condition, the assumption that similar conversion-“constants” apply can be misleading and result in erroneous conclusions. In such cases, a limited number of mass loss tests (or other physical tests) should be run in parallel to the electrochemical tests to confirm the validity of the conversion-“constants.” Often, if the test is only intended to develop the relative order of magnitude of corrosion, as opposed to an exacting value, this is not necessary and historical “constants” may be used.

With the advent of advanced electronics and computerization, electrochemical techniques have evolved rapidly. The most common technologies today are the polarization resistance technique, electrochemical impedance, and Tafel extrapolation. Regardless of the technique used, each relies on the same basic principles: in each test, a metallic coupon in an electrolyte is subject to an electrical perturbation. This perturbation is the application of a current from an external source (power supply). This current stimulates the surface corrosion reactions. The voltage (potential) response of the coupon is measured and correlated with the current applied—a galvanodynamic test. Conversely, the coupon potential is controlled and correlated with the requisite current—a potentiodynamic test. In either case, the resultant current is representative of the rate determining mass transfer or charge transfer rate. This may be related to the corrosion rate.

Standard test procedures are defined within ASTM standards: ASTM G 59, “Practice for Conducting Potentiodynamic Polarization Resistance Measurements”; G 5, “Standard Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements”; G 106, “Practice for Verification of Algorithm and Equipment for Electrochemical Impedance Measurements”; and G 102, “Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Measurements.” Each of these methods describes a standard procedure or practice for the test method. A complete discussion of the technologies is beyond the scope of the current text. For the current text, the focus is on the application of the most simple and most widely used of these techniques, the polarization resistance measurement, ASTM G 59. The parameters discussed are, however, applicable concerns for all electrochemical tests.

The ASTM G 59 standard experiment described determines the uniform corrosion rate of 430 stainless steel in  $1.0 \text{ N H}_2\text{SO}_4$  solution, purged with oxygen-free hydrogen. The procedure described is adequate for learning the basic polarization resistance techniques, equipment calibration, and operator training. However, as acknowledged by the standard, the techniques are not applicable to all material and environment combinations. The reader should consider the following modifications to the standard procedure when dealing with materials other than the calibration standards.

Consider a metal in a flowing natural water. The standard procedure suggests establishing a coupon in a standard “polarization cell.” This exposure is valid to the extent that the in-service application of the material is similar to a

polarization cell. If the electrolyte is expected to flow past the metallic surface, this will influence the local mass transfer rate, and data from a polarization cell will be of little utility if either the anodic or cathodic reaction is affected by mass transport. Agitation in the polarization cell by a stirring mechanism is perhaps better than testing under completely quiescent conditions, yet is no guarantee that the data will be representative of the actual field conditions. Experience and correlation of the test data with field results provide the best confirmation of the test setup. The test setup concerns are not limited to electrolyte flow but include electrolyte chemistry, temperature, material preparation, etc. As with mass loss tests, the closer one comes to duplicating the in-service conditions, the more confidence can be placed in the resultant data. For a more complete discussion of uniform corrosion testing under mass transport controlled conditions, the reader is referred to the chapter on electrochemical testing in this manual.

The standard procedure suggests that sample potential be monitored through 55 min of exposure before initiating the scan. This is not always an adequate time for coupon stabilization. The coupon potential versus time should be monitored for a sufficient time (even greater than 24 h if necessary) to ensure stability before beginning the scan. Stability is a relative term. However, consider that the testing will polarize (perturb) the material only a few millivolts (10–20) around its corrosion potential in a period of a few minutes. This suggests that stability is a variation of  $\pm 1$ –2 mV (less than 10 %) per the anticipated polarization resistance test period. While some may argue that the requirement for a long stabilization period eliminates the ability to get rapid data early in the exposure, it should be recalled that the procedure relies on measuring the coupon response from an external perturbation. If the natural perturbations are of the same magnitude as those imposed on the sample (external), the test data are difficult to interpret. In some cases, if the natural perturbation can be documented to be a consistent factor, this input can be subtracted from the effects of the external perturbation, and polarization resistance tests can be run before complete stabilization. Such data interpretation is beyond the current discussion.

The standard procedure suggests that the polarization scan be initiated by polarizing the material 30 mV active. The scan is then run through the corrosion potential (previously measured stabilized potential) to 30 mV noble to this value. This range may be appropriate for the standard test, but can be significantly too much for many materials in a natural environment. In many natural environments, the actual external perturbation should be limited to  $\pm 10$  mV about the corrosion potential.

It is also interesting to note that the standard procedure suggests that the scan be initiated by shifting the coupon potential 30 mV active and then scanning in a noble direction at 0.6 V/h. The standard prescribes the scan rate from the cathodic to the anodic side of the corrosion potential but not a time for polarizing the material 30 mV active. This appears contradictory. Scan rate is very important in these experiments. If the sample is “immediately” driven to a potential 30 mV active with a potentiostatic input, the sample surface can be strongly influenced. In many “real-life” experiments the procedures described are not adequate. It is

suggested that the scan be started from the corrosion potential at a standard scan rate in the active direction until the sample is polarized 10 mV active (versus 30 mV). At this point, the scan should be reversed in polarity, and the material polarized until it is 10 mV noble to the initial corrosion potential. At all times the scan rate is kept the same. The polarization resistance value is obtained as described by ASTM G 59.

With respect to the actual value of scan rate, the ASTM standard suggests a value of 0.6 V/h. Again, this is adequate for the standard test but may not be for a wider variety of materials. The primary objective of the scan rate is to perturb the sample yet minimize any “capacitive” effects at each point along the scan. If a potentiodynamic scan is run too fast, the amount of current required to “hold” the indicated potential is too high. Thus, the calculated polarization resistance value is too low.

One simple way of determining an appropriate scan rate is to use a scan rate slow enough so that if the scan is stopped (and the applied potential or current is maintained constant), the current does not decrease with time under a potential controlled scan, nor does the potential continue to shift under a current controlled scan. A little trial and error will determine the optimal scan rate. Often times it can be much faster than 0.6 V/h, especially in well-aerated, flowing solutions. Under quiescent conditions with oxidized materials, the necessary scan rate is much slower than 0.6 V/h. A detailed discussion on effects of scan rate, ohmic voltage error, choice of over-potential, and other factors appears in the chapter on electrochemical test methods in this manual.

Under any conditions, the choices of scan rate and magnitude of the potential scans about the corrosion potential dictate the individual test duration. With multiple samples and frequent testing, a significant amount of labor and time can be consumed in the testing. The test designer must balance the alternatives of the test matrix with the available testing time and budget.

Following acquisition of the polarization resistance value, a corrosion rate can be calculated by ASTM G 102. Briefly,

$$\text{Corrosion rate} = (K \times i_{\text{corr}} \times EW)/(D)$$

where

Corrosion rate = mm/y,

$i_{\text{corr}}$  = corrosion current density,  $\mu\text{A}/\text{cm}^2$ ,

$K = 3.27 \times 10^{-3}$ , mm g/ $\mu\text{A cm yr}$ ,

$EW$  = equivalent weight = atomic weight of the primary alloy element/number of electrons involved in the oxidation process,

$D$  = material density, g/cm<sup>3</sup>,

$i_{\text{corr}} = B/R_p$  where  $B$  = Stern-Geary constant, mV, and  $R_p$  = polarization resistance,  $\Omega\text{-cm}^2$ .

The derivation of the value for the term  $B$  is a central focus of ASTM G 102 and need not be repeated within the current text. As an approximate value for quick calculation only,  $B$  often is about 20 mV.  $EW$  values include 9 for aluminum alloys, 50 for copper alloys, and 27 for carbon steel.

Refer to ASTM G 102 for more precise values and determination methods for multi-element alloys. Yet these data can be used to estimate the corrosion rate predicted by the  $R_p$  value obtained.

It is also noted that Scully provides an excellent summary of electrochemical tests in Section III: Type of Tests in this text.

## OTHER TECHNIQUES

There are many other techniques for measuring corrosion. Some of these may rely on chemical solution analysis or physical measurement of metal loss. One widely used additional technique is provided by ASTM G 96, Practice for On-Line Monitoring of Corrosion in Plant Equipment (Electrical and Electrochemical Methods). This guide covers two basic procedures. In one, a sample of the material, usually in the form of a continuous wire, is immersed into the environment of interest (liquid, air, solid, or multiphase). The electrical resistance through the wire is determined. As corrosion consumes the cross section of the wire, the resistance increases proportionately. The second procedure uses the polarization resistance technique described in ASTM G 59 to determine the corrosion rate in the environment.

Both of these techniques have their utility and drawbacks. The resistance probe is limited because it is difficult to determine if the electrical resistance increases being monitored are the result of localized or uniform corrosion without visual inspection of the probe. However, the resistance probe is of great use in that it may be used in multiphase environments, whereas the polarization resistance probe is mostly limited to use in conductive aqueous

environments. The primary advantage of the polarization resistance probes is that they can provide a rapid indication of the corrosion rate on a real-time basis. As with any polarization resistance technique, the procedure assumes that the predominant corrosion mode is uniform attack and not pitting. Polarization resistance-type probes are not suited for monitoring where pitting corrosion is of concern. On both types of probes, one additional concern has to be the presentation of the probes to the environment being monitored. In typical installations, the probes are used as through wall fittings in process piping. The flow characteristics imparted on the probes is not the same as that observed on the pipe walls, and therefore, the corrosion rates may not be similar. This is less of a problem in process vessels, yet is always a concern. ASTM G 96 describes additional precautions in the use of the probes.

# Pitting

Robert G. Kelly<sup>1</sup>

## INTRODUCTION

PITTING CORROSION occurs when discrete areas of a material undergo rapid attack, although the vast majority of the surface remains virtually unaffected. This morphology is in sharp contrast to uniform corrosion in which all parts of the exposed surface recede at approximately the same rate. Essentially, all metals and alloys undergo pitting corrosion under some set of experimental conditions, although the relative susceptibility varies widely. The basic requirement for pitting is the existence of a passive state for the material in the environment of interest. Pitting occurs when portions of the metal surface lose their passivity and dissolve rapidly. This loss of passivity often occurs at heterogeneities in the surface (either physical or chemical). Pitting of a given material depends strongly on the presence of an aggressive species in the environment and a sufficiently oxidizing potential (e.g.,  $\text{Cl}^-$  ion in neutral, aerated aqueous solution for Type 304 stainless steel). There are many metal/environment combinations that can lead to pitting, as extensively reviewed by Szlarska-Smialowska [1] and more recently by Frankel [2]. In many situations, pitting can severely limit the performance of the material.

Testing for localized corrosion resistance usually aims at meeting one (or more) of four general goals: (a) alloy ranking for selection or development; (b) failure analysis; (c) determination of the effects of changes in process parameters; and (d) prediction of penetration rates. Of the four, the last is by far the most difficult to accomplish, but also the most important in many cases. This chapter discusses the different types of tests that have been developed for pitting corrosion. The physical and chemical basis for each test is described, as are some of the practical applications and limitations. The first section describes coupon exposure testing, while the second describes electrochemical testing.

## COUPON TESTING

The exposure of test coupons to the corrosive solutions to evaluate localized corrosion resistance has a long and successful history. The materials of interest are typically machined into coupon form before being measured, cleaned, weighed, and exposed to the corrosive medium. After a set

period of time, the coupons are removed; the surfaces are carefully cleaned and evaluated for attack. General requirements and information on coupon testing can be found elsewhere in this manual as well as in other sources [3,4]. ASTM G 1, Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens, describes the details of the preparation of test coupons. ASTM G 4, Method for Conducting Corrosion Coupon Tests in Plant Equipment, details related information on the performance of such tests in plant equipment under operating conditions. The advantages of properly conducted coupon testing include the fact that actual process streams can be used, a large number of coupons can be exposed simultaneously, and various forms of corrosion can be detected. Disadvantages include the inability to monitor the time dependence of the corrosion process and the long exposure times usually required to characterize both the initiation period and the propagation rate.

## Coupon Preparation and Analyses

Because detailed information on coupon testing is available elsewhere, this section will focus on the aspects of such testing that are specific to the evaluation of pitting corrosion. When performing coupon exposures, it is important to include alloys whose corrosion behavior in the environment of interest is well characterized and reproducible to serve as an internal standard. This protocol is of particular importance when localized corrosion is studied. Because pitting has a stochastic nature, the use of these "controls" increases the confidence with which final material selection choices are made. If the control materials behave as expected, it is probable that the results for the other materials reflect typical behavior for the environment of interest.

Whereas mass loss characterizes the rate of uniform corrosion well, such measurements can be extremely misleading for pitting corrosion. Badly pitted specimens can exhibit negligible weight loss if the attack is extremely localized. In fact, the more a given amount of attack is localized, the more severe the pitting problem. ASTM G 46, Practice for the Examination and Evaluation of Pitting Corrosion, describes different methodologies for evaluating pitting corrosion attack. Visual attack of both cross sections and plan views of pitted specimens can be ranked as shown in the standard. Whereas pit density (number/cm<sup>2</sup>) is important, pit depth measurement is often the most directly applicable measurement. Values for both average pit size and for the deepest pit observed are useful. To quantitatively evaluate the depth of attack, a variety

<sup>1</sup>Associate Professor, Department of Materials Science and Engineering, University of Virginia, P.O. Box 400745, 116 Engineer's Way, Charlottesville, VA 22904.

of measurement methods can be used including depth gages, metallographic examination of cross sections, or change in the focus plane on a metallurgical microscope, depending on the size of the pits. Direct measurement of pit depth using confocal laser scanning microscopy is attractive in that pit depths and distributions can be obtained rapidly. All line-of-sight methods are unable to detect and characterize undercutting pits (i.e., those with “ink-bottle” shapes or those with lacy covers [6]). The pitting factor (PF) is the ratio of the average of the ten deepest observed pits to the average metal penetration by uniform dissolution, with higher values indicating a greater susceptibility to pitting. Statistical methods have also been applied to the evaluation of pitting corrosion (see ASTM G 16, Guide for Applying Statistics to Analyses of Corrosion Data, and Refs 7 and 8). In terms of predictive capability, the use of extreme value statistics is attractive [8]. Plotting the measured maximum pit depths for a large number of small samples has been used to estimate the probability that a pit of a specific depth will occur under the same conditions for a larger area [8].

### Exposure Environments

There are two general types of environments used in coupon testing for pitting corrosion: those that simulate service conditions and those that seek to accelerate the pitting process. Tests in simulated (or actual) service solutions are extremely valuable due to their direct applicability. However, because time is often of the essence, the long exposure times required usually limit the use of such tests to (a) confirmation of decisions made on the basis of accelerated laboratory tests, and (b) corrosion monitoring. The aim of testing in accelerating environments is usually alloy ranking or screening. Thus, little information is gained on the expected rate of attack in the actual application. However, the relative susceptibility of different alloy compositions or the effects of heat treatments, welding, or other processing can be assessed rapidly and quantitatively.

There is a variety of accelerated exposure tests that have been developed to aid engineers in material selection for corrosion resistance. This section will review some of those that are useful for localized corrosion resistance. Besides a brief description of the test, the scientific reasoning behind it is presented, along with comments concerning the limits of its applicability, and alterations one can make to improve the utility of the test for a specific application. An experimenter should not feel bound by the strictures of the ASTM standards if he or she can justify that by changing the procedure, more relevant information can be gained. However, it should be noted that these ASTM tests are probably the most widely used tests for localized corrosion resistance. Thus, an understanding of them can be of great importance in analyzing the results of testing performed in other labs or by manufacturers.

#### *ASTM G 48, Test Method for Pitting and Crevice Corrosion Resistance of Stainless Steels and Related Alloys by the Use of Ferric Chloride Solution*

This test involves exposure of the material to a highly oxidizing, highly acidic, concentrated metal chloride solution. In essence, it is an attempt to simulate very roughly the composition of the environment within a localized corrosion

site in a stainless steel. Briefly, a material is exposed to a 10 wt%  $\text{FeCl}_3$  solution for a relatively short time (24–72 h) at either ambient or elevated (usually 50°C) temperature. At the end of the test, the sample is examined for weight loss and localized attack (see ASTM G 46 for a recommended practice for evaluating the extent of pitting corrosion). If pitting and crevice corrosion are of concern, artificial crevices can be applied by the use of Teflon® blocks held tightly to the sample surface by rubber bands (see ASTM G 48).

The basic concept behind this test is the application of a high potential using a chemical potentiostat in an acidic, concentrated chloride solution. The ferric salt forms a  $\text{Fe}^{3+}/\text{Fe}^{2+}$  redox couple with a potential of approximately +0.45 V(SCE). The high concentration of ferric ion allows the couple to provide a large current without an appreciable change in potential (approaching an ideally nonpolarizable electrode). The cathodic reaction (reduction of ferric to ferrous ion) occurs on the boldly exposed passive surface of the material under test. Thus the redox couple serves the role of the *chemical* potentiostat. The high potential in turn nearly guarantees that the pitting potential will be exceeded, especially in such a concentrated  $\text{Cl}^-$  solution (and even more so if the test temperature is raised to 50°C). The low pH of the solution (typically about 1.3) inhibits repassivation and lowers the stability of the passive film. Thus, the ferric chloride test is a test of the resistance of an alloy to propagation of localized corrosion for most alloys, because their pitting potentials are well below +0.45 V(SCE). However, more highly alloyed materials can resist initiation in this solution, and thus the time of the test can be extended to a period of many days or the temperature increased.

This very popular test does have a number of limitations. Very few industries operate in 10 wt%  $\text{FeCl}_3$ . Thus, the relation of the results of this test to material performance in real service environments that are profoundly different is questionable, and in fact, reversals in alloy ranking can occur. For nickel-base materials, the use of a ferric ion solution is also of questionable value. Despite these limitations, the  $\text{FeCl}_3$  test will continue to be an important tool in alloy development and screening for historical, if for no other reasons.

The ferric chloride test details can be modified and still fall within the spirit of the requirements of the published method. The exposure time and temperature can be altered, as can the surface finish. As mentioned above, surface finish can have important impact on the localized corrosion behavior. For example, it can affect the geometry of occluded sites and, in some cases, it can alter the surface area for cathodic reactions. Thus, it is important that the surface finish be chosen with care to simulate the expected conditions of the application.

#### *B 117 Standard Practice for Operating Salt Spray (Fog) Apparatus and G 85 Standard Practice for Modified Salt Spray (Fog) Testing*

Probably the most widely used test for pitting resistance is salt spray. B 117 describes the experimental arrangements to be used and mandates the use of 5 wt.% NaCl at slightly elevated temperature (35°C). The test chamber allows the solution to be sprayed within its confines, creating a salt fog environment around the coupons. Such a constantly moist, salty environment is quite aggressive.

G 85 describes modifications to B 117 involving a variety of solution chemistries and exposure regimens that can be used, including acetic acid-NaCl solution, acidified synthetic sea water, NaCl solution with SO<sub>2</sub> gas added and a 0.05 % NaCl +0.35 % (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> solution. In addition, a variety of cycles (wet/dry) are described that have been found to be more aggressive than the constant moisture of B 117. In general, a spraying period is followed by a longer time at high relative humidity during which the sample can partially dry.

This cyclic type of exposure represents a more aggressive condition for most alloys than does constant, full immersion. Although still the subject of some debate, the generally accepted explanation involves the increased kinetics for oxygen reduction within the thin electrolyte layer that is present. Due to its limited solubility in water, oxygen reduction is usually under mixed or fully diffusion control for most alloys, particularly those undergoing stable pitting. The thin electrolyte layer present during wet/dry cycling increases the rate of delivery of oxygen to the surface by reducing the diffusion boundary layer thickness from ca. 0.05 cm characteristic of stagnant solution to the thickness of the solution layer (often between 25 and 100 microns [9]). In addition, the concentration of aggressive ionic species increases dramatically during drying periods to the point of saturation.

Although reams of salt spray data exist, their use must be approached with care. As with ferric chloride, few industries actually operate in continuous salt spray (coastal regions and ships being notable exceptions). A number of industries have found that the standard salt spray testing not only does not reproduce the damage observed in service, but also is not particularly accelerating. Thus, the auto industry has developed a more complicated cyclic test known as GM 9540 [10]. The reasons for the discrepancies between service experience and these laboratory tests are not clear, and users of the test should bear them in mind.

#### *G 69 Standard Test Method for Measurement of Corrosion Potentials of Aluminum Alloys*

Aluminum alloys are highly susceptible to localized corrosion, including pitting. For many years, G 69 has been used to determine the so-called "solution potential" of Al alloys. The test solution described in G 69 is a strongly oxidizing, near-neutral pH chloride solution. The oxidizing power originates in the 3 g/L (0.09 M) hydrogen peroxide that is added. In the 1 M NaCl, virtually all precipitation-hardened Al alloys will undergo stable pitting. The solution potential measurement is made over a period of 1 h. It represents a mixed potential between the passive portions of the surface on which peroxide reduction is occurring and the pitting sites. Thus, the potential depends on (a) the cathodic kinetics of peroxide reduction, (b) the pit dissolution kinetics, and (c) the number and size of the pits. As these characteristics vary from alloy to alloy as well as with time, quantitative interpretation of the solution potential is challenging. Mixed potential theory can be used to demonstrate that the solution potential cannot be used to rank the resistance of Al alloys to stable pitting. Nonetheless, it has been used as a type of quality control test to probe batch-to-batch variations within a given alloy. This solution is also specified in G 110, a standard practice for evaluating intergranular corrosion of heat treatable aluminum alloys.

### **Alteration of Test Methods**

When considering how to accelerate a test, the two most commonly applied methods are to increase the temperature and/or increase the concentration of aggressive species (e.g., Cl<sup>-</sup> or H<sup>+</sup>). Either can be effective, and some of the electrochemical tests described below use the strong temperature dependence of pit stabilization as a parameter to quantify pitting resistance. That said, such changes must be introduced with care to ensure that the mechanism of attack in the accelerated test is the same as that in the actual service environment. Decreased time required for the testing should be balanced against the decreasing relevance of the results, and the consequential increase in the uncertainty in their interpretation. In addition, results from accelerated tests are useful for material selection, but not life prediction, as there is no means currently to connect the rates of pitting corrosion observed in these tests to other environments. This situation can be contrasted with crack growth testing where the similitude of the stress intensity factor, *K*, has been repeatedly demonstrated. This similitude allows results from laboratory scale test samples to be applied to service structures if the stress and flaw size and shape are known.

### **ELECTROCHEMICAL TESTS**

The main advantage of electrochemical testing is the opportunity to investigate corrosion phenomena in the solution of interest rather than in a (possibly) more aggressive and (probably) less relevant environment. In addition, a great deal of information can be gained about the dependence of the phenomena on external variables in a short time. Finally, the determination of critical potentials for initiation and propagation of localized corrosion can be useful in design decisions. For example, the use of mixed potential theory can allow prediction of the protection (either anodic or cathodic) criteria, as well as information on the galvanic couples to avoid.

#### **Specimen Mounting**

Probably the main problem associated with electrochemical testing for localized corrosion resistance is sample mounting. It can be extremely difficult to mount a sample with an insulated electrical contact and a controlled exposed surface area without introducing a crevice at the sample/mount interface. Because crevice corrosion will occur at lower potentials than pitting, the sample invariably begins to be attacked at the crevice, leading to an underestimation of the resistance of the sample to pitting. Some may argue that for the same reason, this type of testing is not overly conservative, as in service, one wants to know the potential at which any localized corrosion can occur, not just pitting. The flaw in this argument is that most crevices formed during sample preparation are not reproducible either in position or geometry, making comparisons extremely difficult. In addition, there may be applications where crevice corrosion is not the failure mode of concern, but pitting is. Such testing with crevices present would lead one to choose a more resistant (and therefore more expensive) alloy than one would actually need.

**FIG. 1—Stern-Makrides electrode assembly. (A) glass tube that protects threaded steel rod from solution, (B) PTFE gasket, (C) specimen. For more details, see ASTM G 5.**

A number of suggested solutions have been made for sample mounting, including the use of “knife-edge” Teflon washers [11], various mounting compounds and procedures [12], the use of wire loops [13], and flag geometries [14]. One experimental design even includes a crevice area that is continually washed with deionized water [15]. All of these have their limitations, and one must choose the most appropriate for the particular alloy/environment combination. The knife-edge PTFE washer, in combination with what has been known as the Stern-Makrides assembly (Fig. 1), has been used successfully in a number of applications in which a tight seal can be formed, which (a) prevents ingress of any electrolyte, and/or (b) causes the IR drop into the crevice to be so high as to prevent any polarization of the creviced surface away from  $E_{\text{corr}}$ . Because the latter of these is unlikely to occur, the prevention of ingress is critical. This prevention of solution ingress is closely related to the quality of the surface finish both in terms of its fineness (i.e., final polishing step particle size) and its uniformity. One large scratch can allow capillary action to draw electrolyte into an otherwise impervious crevice and start the crevice corrosion initiation process. This is the prime reason for the failings of this type of approach. In addition, due to the cost of the PTFE washers, many experimenters tend to try to reuse them. However, after the knife edge is deformed once, it will not form a watertight seal again, thus allowing crevice corrosion to occur.

The cell designed by Quarfort [15,16] uses a slow flow (4 mL/min) of deionized water into the creviced area to prevent the accumulation of dissolution products inside the occluded area, the hydrolysis of which leads to crevice corrosion. The design has been successfully applied to the study

of the pitting of a wide variety of stainless steels at both ambient and elevated temperature [15,16]. However, this cell can only be used for flat samples. In addition, one must be careful to ensure that the deionized water flow is uniform throughout the crevice. If a dead spot were to develop, crevice corrosion will very likely be initiated. Details of the cell can be found in Annex X2 of G 150.

One example of the effect of crevices is shown in Fig. 2 for a 18Cr-8Ni stainless steel in a solution in which propagating crevice corrosion will not occur (1 N  $\text{H}_2\text{SO}_4$ ) [12]. In this case, the higher passive current densities are observed for the insulating materials that perform poorly. In a  $\text{Cl}^-$ -containing solution, this would translate into a lower  $E_{\text{bd}}$ . As can be seen from Fig. 2, some mounting materials perform well in this solution, though it should be pointed out that these results cannot be extrapolated to other solutions. For example, the alkyd varnish is used in electroplating to mask off areas that should not be plated. Although it works well in acid solutions, it performs very poorly in neutral or basic solutions, especially on materials with passive films such as stainless steel.

If mounting cannot be accomplished, three other approaches can be used. The first is the use of a wire loop electrode, as shown in Fig. 3a. Stockert et al. [13] have used this approach to study pitting without the complications of crevice corrosion. This approach works extremely well if one can get the material in wire form, though there is always the concern of metallurgical differences between material in wire form and that in plate or tube form, which are more likely to be used in engineering applications. A related approach is the use of a flag electrode configuration, as shown in Fig. 3b. This works well with plate material by minimizing the shaft size and thereby minimizing any effects of the waterline. If localized corrosion at the waterline continues to be a problem, deaeration of the solution and the air space above it can be of help as well. When deaerating, a baffle should be placed between the sample and the bubbler in

**FIG. 2—Polarization curves of stainless steel in 1 N sulfuric acid using different specimen mounting methods: (1) Stern-Makrides compression gasket, (2) heat-cured epoxy, (3) alkyd-varnish, (4) phenol-formaldehyde, (5) polymethyl methacrylate, (6) cold-cured epoxy [12].**

FIG. 3—(a) Wire loop configuration for electrochemical testing, (b) flag electrode configuration for electrochemical testing.

order to prevent oscillations of the waterline. It should be noted that flag electrodes can suffer edge attack that is not indicative of the behavior of the flat surface. Thus, post-test inspection of the location of the attack and careful interpretation of the results are important, as is the case for all electrochemical testing.

Suter [17] developed a third approach to delineation of the surface area of interest. By using a microcapillary attached to a conventional optical microscope, Suter was able to define small areas of stainless steel surfaces and generate polarization curves. The area probed is defined by the diameter of the capillary with results demonstrated for capillaries between 2 and 1000 microns [18]. The cell is of particular use when the behavior a particular microstructural feature is of interest [19–21], as the design allows the matrix contribution to be minimized.

### Cyclic Polarization

By far the most common electrochemical test for localized corrosion resistance is cyclic polarization. ASTM G 61, Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-based Alloys, has been developed to allow experimenters to test their equipment and procedures on systems that are well characterized. The potential is scanned from  $E_{\text{corr}}$  (or slightly below it) in the anodic direction until localized corrosion initiates as indicated by a large increase in the applied current. At this point, the direction of the scan is reversed, and the current decreases until it changes polarity (i.e., becomes cathodic). Representative scans are shown in Fig. 4 for Type 304 SS and Hastelloy C-276. Conventional wisdom states that  $E_{\text{bd}}$  (the breakdown potential) is the potential above which pits are initiated, while  $E_{\text{rp}}$  (the repassivation potential) is the potential below which pits repassivate. The breakdown potential is usually defined as the potential at which there is a large increase in the applied current, whereas the repassivation potential is the potential on the reverse scan at which the applied anodic current becomes zero (i.e., the current changes polarity). Thus, the higher the value of  $E_{\text{bd}}$ , the more resistant is the alloy to the initiation of localized attack. The higher  $E_{\text{rp}}$ , the more easily the alloy can repassivate. At potentials between  $E_{\text{bd}}$  and  $E_{\text{rp}}$ , sites that have initiated can propagate. Based upon this argument, one would favor an alloy that had both a high  $E_{\text{bd}}$  and a high  $E_{\text{rp}}$ .

Examples of the range of data that can be expected are shown in the standard. The scatter in the data is apparent, especially in the forward scan. This scatter points out the statistical nature of the nucleation of pitting. The average  $E_{\text{bd}}$  of Type 304SS was found to be approximately +0.15 V(SCE), while the average  $E_{\text{rp}}$  was found to be approximately -0.21 V(SCE). The reverse scans are much more reproducible, because the local chemistry controls the repassivation. Another

FIG. 4—Representative cyclic potentiodynamic polarization curves (ASTM G 61). The average  $E_{\text{bd}}$  for Type 304SS was approximately +0.15 V(SCE), while the average  $E_{\text{rp}}$  was approximately -0.21 V(SCE).

example of the inherent scatter in  $E_{bd}$  is shown in Fig. 5 [22] for three variants of Type 304SS in 1000 ppm NaCl. The large variation in  $E_{bd}$  arises despite the fact that all of the samples of each type were from the same heat of material and were tested under identical conditions.

There have been numerous attempts to use the amount of hysteresis in the cyclic scan as a measure of localized corrosion susceptibility, with varying degrees of success. In this approach, the larger the hysteresis, the more likely a localized corrosion site will propagate once initiated. In the presence of a well-defined crevice, a good correlation has been found and the relative crevice corrosion susceptibility of alloys can be obtained. Wilde [23] demonstrated this for Hastelloy C, Incoloy 825 and Carpenter 20Cb3 in seawater where the amount of hysteresis correlated well with the amount of weight loss (due to crevice corrosion) in a two-year exposure to seawater. There is not a linear correlation, however, so local penetration rates cannot be predicted, but the test has been used successfully for alloy selection. However, in studies that have attempted to study the relative pitting susceptibility of alloys, it has been found that comparisons are valid only if no crevices are present on any of the specimens tested. An example of the differences that one can observe is shown in Fig. 6. In the absence of crevices, the Fe-30Cr-3Mo alloy performs well in 1 M NaCl, with a high  $E_{bd}$  and a small hysteresis. Microscopic examination showed the attack occurred only at the grain boundaries. However, when a crevice was intentionally applied, the alloy performed poorly. The possible problems in comparing one specimen that had a crevice with another that did not are obvious; incorrect conclusions concerning the relative resistance of two materials could easily be reached. Independent of the mounting method used, one should always examine the specimen for localized attack after the test is completed. At a minimum, microscopic examination of likely creviced areas should be performed. Some samples should be broken out of their mounts for more thorough examination.

While the interpretation of breakdown and repassivation potentials remains controversial, progress towards a consensus

FIG. 5—Cumulative probability distributions of pitting breakdown potentials for three Type 304 stainless steels in 1000 ppm NaCl with different sulfur contents: high sulfur (□), commercial purity (△), and high purity (○) [22].

FIG. 6—Cyclic polarization curve for Fe-30Cr-3Mo alloy in deaerated 1 M NaCl for specimens (a) without a crevice (●) and (b) with a crevice (▲) [23].

is being made. The large scatter in the breakdown potential is thought to be due to the sensitivity of pit initiation to the initial conditions. Its dependence on scan rate is most likely the result of the time dependence of the localized corrosion site chemistry development. In addition, it is now generally accepted that corrosion-resistant designs should not use  $E_{bd}$  as the important parameter, but the appropriate value of  $E_{rp}$ , because this is the potential below which pits should repassivate. Under these circumstances, the determination of the proper value of  $E_{rp}$  becomes the focus.

Thompson and Syrett [24] attempted to address the problem of the proper pitting potential by performing a variety of electrochemical tests on Type 317L and Alloy 825 in simulated flue gas desulfurization environments to determine  $E_{bd}$  and  $E_{rp}$  as a function of the extent of pitting damage, characterized in terms of the time during which localized attack was allowed to occur. In terms of cyclic polarization, this time would be inversely proportional to the sweep rate on the reverse portion of the scan, with lower sweep rates leading to greater attack. As shown in Fig. 7 for Type 317L, their results indicate the convergence of  $E_{bd}$  and  $E_{rp}$  at a single potential of +0.2 V(SCE). This "unique potential" can be interpreted as the potential below which the smallest pit will neither initiate nor grow. Quantifying the size of the "smallest" pit remains an important task. However, the work is important support for the hope of eventually developing quantitative, engineering-relevant criteria for material selection against pitting.

One of the historical controversies with regard to  $E_{rp}$  as a "material property" are the results of Wilde [23] in which the repassivation potential was shown to depend to some extent on the amount of localized dissolution that has been allowed to occur, and therefore depends on both the scan rate and the current at which the scan is reversed. The more attack that has been allowed to occur, the more negative is the  $E_{rp}$ . However, there are other data on stainless steels that show a limiting value for large pits (0.05–0.5 mm deep) [25,26], complementing the work of Thompson and Syrett [24], where a limiting value is also found for small pits.

**FIG. 7—Critical potentials ( $E_{bd}$  and  $E_{rp}$ ) for Type 317L stainless steel exposed to a simulated flue gas desulfurization environment as a function of the time during which localized corrosion was allowed to propagate before repassivation occurred. Symbols denote different methods used to determine values: cyclic polarization (filled and open squares and triangles); constant potential tests (filled and open circles and diamonds) [24].**

Despite the problems, polarization testing is useful for comparing alloys with respect to propagation of localized corrosion, though its use gives little information on the initiation time that is necessary for accurate lifetime prediction. One alloy may have superior resistance to propagation, but have much inferior resistance to initiation, and thus result in a shorter application lifetime.

### Galvanostatic Measurements

Controlled current tests for pitting are seeing increased popularity. Galvanostatic measurements involve the application of a series of small, step changes in the applied current. The potential is followed as the current is increased as described in ASTM G 100, Method for Conducting Cyclic Galvanostaircase Polarization. In some cases, more reproducible values for  $E_{rp}$  can be obtained galvanostatically in some systems, notably aluminum in inhibited water [27]. However, potential oscillations at constant current can sometimes occur, which, while of scientific interest, can make interpretation of the results difficult, as the choice of potential becomes almost arbitrary.

### Potentiostatic Measurements

By far the most common electrochemical tests used is cyclic polarization. Nonetheless, potentiostatic measurements can be powerful tools in evaluating pitting behavior. Ideally, potentiostatic tests would be conducted over long time periods to avoid being fooled by long initiation times. Potentiostaircase tests can be performed in lieu of potentiodynamic tests, though, at equivalent potential scan rates, the results should be identical. Unfortunately, long-term potentiostatic testing is extremely time-consuming and expensive.

In addition, the time frames involved are usually still very short compared to the projected life. Thus, a number of approaches have been developed for accelerating the process of initiation.

Mechanical scratching is favored by some as a means by which a bare surface can be created. In this technique, one is ascribing no importance to initiation time. The surface is held at a constant potential and then a portion of it is scratched, usually with a diamond-tipped stylus. The current is monitored with time. For potentials below  $E_{rp}$ , the surface will repassivate rather rapidly, as shown in Fig. 8. Just above  $E_{rp}$ , the surface will try to repassivate, but will fail, and the current will eventually increase. The closer the potential to  $E_{rp}$ , the longer is the time before the current increases. Thus, in most cases, the  $E_{rp}$  measured by this method is not conservative, as usually no more than 10 min is spent at any one potential. If one had waited long enough at the potential used just before the measured  $E_{rp}$ , localized corrosion might have occurred. However, this does not denigrate its utility as a screening test. One problem with scratching tests of this type is the dependence on the weight of the scratch. For scratching by hand, the  $E_{rp}$  decreases with increasing damage. A mechanical system improves the reproducibility. A more difficult problem concerns the site of pitting. In many cases, pitting occurs at inclusions or second-phase particles of one type or another. Such inclusions are usually present at small volume fractions, so the probability of scratching across one (or more) with a fine diamond tip is extremely small. This paucity of sites can lead to erroneously high values of  $E_{rp}$ , which reflect the pitting susceptibility of the matrix material, but ignore the susceptibility of the weakest link, the inclusions.

There are also purely electrochemical methods that can be used to produce a bared surface. In one technique, the entire exposed surface is activated by a large positive voltage excursion, which is followed by a voltage step back to (or towards)  $E_{corr}$ . In this way, any potential pitting sites are initiated, and the test measures the ability of the material to resist propagation and to repassivate. One version of this test (Fig. 9) involves a step to +2 V for 3 s followed by a step back to  $E_{corr}$ , during which time the current is monitored. The potential is held there for 5 min before it is again

**FIG. 8—Scratch test current-time curves for a specimen held potentiostatically above the repassivation potential ( $E_{rp}$ ) and below  $E_{bd}$ .**

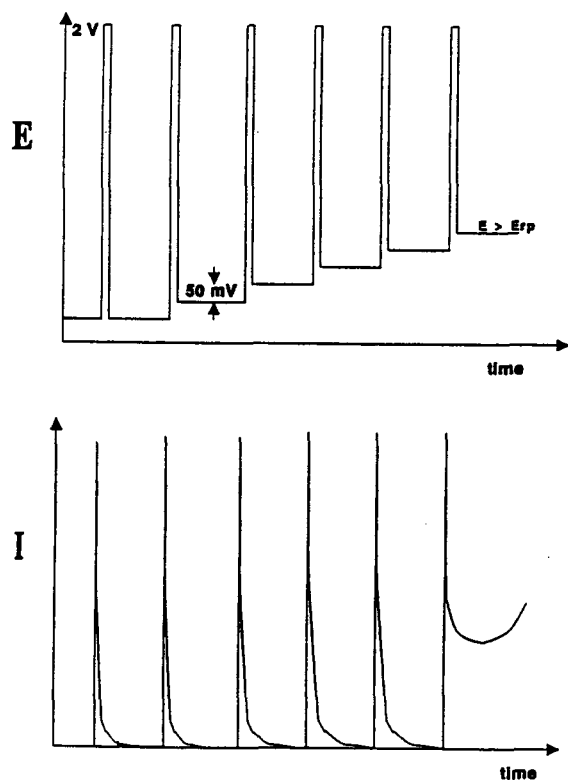

FIG. 9—Schematic  $E(t)$  and  $I(t)$  for electrochemical scratch method for determining the repassivation potential.

stepped to +2 V for 3 s to reinitiate localized corrosion. At this point, the potential is stepped back to a potential 50 mV above  $E_{\text{corr}}$  and the current is monitored for 5 min. The process is repeated until the current does not decay upon the step in the negative direction. In this way, an estimate of  $E_{\text{rp}}$  can be made, with better estimates resulting from the use of smaller increments in the test potential (e.g., 25 mV instead of 50 mV). This method is essentially using the potentiostat to “electrochemically scratch” the specimen surface. A related method is described in ASTM F 746, Test Method for Pitting or Crevice Corrosion of Metallic Surgical Implant Materials, for determining the pitting and crevice corrosion susceptibility of materials used in medical implants.

In another electrochemical test that focuses on pit propagation, the potential is scanned at 10 mV/s to a potential  $E_1$  between  $E_{\text{bd}}$  and  $E_{\text{rp}}$  where it is held to determine the background passive current density. After 10 min, the potential is scanned anodically past  $E_{\text{bd}}$  until the current density is 10 mA/cm<sup>2</sup>, at which time the potential is stepped back to  $E_1$ . The current is then monitored for 10 min, after which the potential is held at  $E_{\text{corr}}$  for 5 min to repassivate the pits. Finally, the potential is stepped back to  $E_1$  and the current is monitored to ensure that the background current has not changed appreciably. The amount of charge passed during the propagation stage is compared to the pitted area (determined by optical microscopy) to determine an average pit penetration rate. This test is known as the Pit Propagation Rate (PPR) Test [28].

Frankel [29,30] has developed a means of testing pit propagation using thin foils. The geometry of the foil restricts the dissolution to two spatial dimensions, allowing optical measurements of changes in diameter to be related to the measured current, thereby establishing an accurate rate of pit propagation as well as conditions under which such pits repassivate. The method has been applied to sputtered Al thin films [30] as well as Al alloys [29]. The primary experimental challenge is the creation of foils that are sufficiently thin to produce a stable, two-dimensional pit. While sputter deposition is an excellent method, the production of thin foils of engineering alloys provides more of a challenge, although not always an insurmountable one.

### Critical Temperature Tests

Although ASTM tests use temperature to accelerate attack during exposures, temperature can also be used in combination with electrochemical techniques. One example of this is the determination of critical pitting temperatures (CPT) [16,31,32] for alloy development or selection, or both. An anodic potential is applied to an electrode at low temperature (room or below) in the solution of interest and the temperature slowly increases in order to determine the temperature at which initiation of localized corrosion occurs, as signified by an increase in the current above some criterion. Such a method allows a quantitative ranking of materials in terms of resistance to pitting.

ASTM G 150 (Standard Test Method for Electrochemical Critical Pitting Temperature Testing of Stainless Steels) describes in detail how to perform such experiments. The solution prescribed is 1 M NaCl, the suggested applied potential is +700 mV(SCE) and the starting temperature is deemed to be 0°C, with the temperature being increased at 1°C/min. The CPT is defined as the temperature at which the current exceeds 100  $\mu\text{A}/\text{cm}^2$  and remains so for greater than 1 min. The test method clearly states that alternative potentials can be used if they are within the range for which the CPT is potential independent.

Salinas-Bravo and Newman [33] developed variation on the critical pitting temperature test for welded stainless steels in which a large, unwelded specimen was coupled to a welded sample via a zero resistance ammeter (ZRA). The unwelded specimen polarizes the welded sample to a positive potential. As the temperature is raised, the galvanic current between the two remains low until the CPT is reached. At that point, the welded sample undergoes stable pitting and a large current is observed. The attractiveness of this test is that it probes the inherent galvanic couple that is the essence of localized corrosion: the large, passive cathode, and the small, active pit.

### Electrochemical Noise

Recently, electrochemical noise has seen increased interest as a tool for both corrosion science and corrosion engineering. By monitoring the galvanic current between two nominally identical electrodes or the corrosion potential of a single electrode carefully, metastable pitting can be detected. The localization of the dissolution inherent in localized corrosion implies a separation of the anodic and cathodic reactions that

constitute the corrosion couple. This physical separation of reactions distinguishes localized corrosion from uniform corrosion in which it is traditionally thought that the anodic and cathodic sites are in very close proximity to one another. The majority of the anodic (oxidative dissolution) reaction occurs inside the localized corrosion site, while the majority of the cathodic (reduction) reaction occurs on the boldly exposed surface. Thus, a galvanic couple is created. The spatial separation of the processes necessitates the passage of current between the two sites. This passage of current leads to the various electrochemical noise signals measured.

Under open circuit conditions, bursts of dissolution at localized corrosion sites require the generation of bursts of cathodic current from the surrounding boldly exposed surface. This increased demand typically causes a decrease in the measured open circuit potential. Localized corrosion sites are typically very small ( $<100\text{ }\mu\text{m}$  diameter). However, the current densities inside these cavities during transient bursts can be on the order of  $1\text{ A/cm}^2$ . These rates are possible because of the extremely aggressive environments that develop inside localized corrosion sites. Thus, even though the sites are geometrically small, they can influence the electrochemical potential of the much larger boldly exposed surface on which the electrode kinetics are far slower. This difference in relative current densities on separated anodes and cathodes is what accounts for the ability to detect the electrochemical noise associated with localized corrosion. When the potential of the surface is controlled with an external device, the same burst of dissolution requires the device to supply a burst of current, which can be recorded. Usually, these bursts are transient, with temporary repassivation of the localized corrosion site occurring and allowing the system to return to the previous steady-state condition. On a metal surface of appreciable size ( $>1\text{ cm}^2$ ), there can be many localized corrosion sites. They will usually propagate independently, so that a series of current (or potential) fluctuations is observed due to the summation of the signals from the individual sites. These fluctuations are referred to as "electrochemical noise." Because electrochemical noise can be observed often under open circuit conditions, it has been hailed as the only truly noninvasive electrochemical method.

Changes in the noise signal are often taken as an indication that conditions are favorable for pit initiation to occur. Thus, if one is monitoring a process stream, corrective action can be taken. The disadvantage of noise monitoring is that it does not give sufficient information about what level of this metastable pitting is acceptable. For example, there may be literally millions of metastable pits forming and repassivating in a vessel wall, but only one needs to penetrate completely for a leak to develop. It may not be possible to differentiate between conditions that will allow that and those in which the extent of pitting is negligible. Experience and correlations with coupon exposures are critical factors in the use of noise for localized corrosion monitoring. No ASTM standard currently exists for noise measurements.

## PREDICTIVE CAPABILITIES

With the caveats mentioned previously in mind, the study of metastable pitting can be used to assist in lifetime prediction studies. If pitting is truly a stochastic phenomenon, then one

can apply statistics to allow prediction of the likelihood of pit propagation, given sufficient information. The information needed is (a) the probability that a pit will nucleate under a given set of conditions, and (b) the probability that once a pit nucleates, it will survive (i.e., become stable). Such information could be used to estimate component lifetimes, which could then be used to make design decisions based on the consequences of a failure. For example, a 3 % chance of perforation may be acceptable for an easily shutdown and repaired vessel if it allows a cheaper alloy to be used, but such a probability would not be acceptable for a critical component in an inaccessible submersible.

Analyses of these current and potential transients due to metastable pits can provide information regarding the controlling factors and their dependence on environmental, metallurgical, and applied potential conditions. For example, Pride et al. [34] characterized the metastable pitting behavior of high-purity Al and aged Al-2%Cu. They found that the frequency of pitting events was proportional to both the applied potential and the chloride concentration. The rate of pitting was also found to decrease with increasing exposure time. These kinds of analyses can serve as the basis for the pitting prediction methodologies described below.

Shibata et al. [7] and Williams et al. [35] have applied such statistical arguments to pitting of stainless steel. To develop these models, a large amount of data that can be treated as an ensemble must be gathered. In other words, variations in results from test to test are expected, even for nominally identical tests. This variation is used to develop the cumulative probability curve for pitting under a certain set of conditions. Both groups used multiple specimen testing apparatus to gather up to 12 data points for critical potentials and metastable pit nucleation rates simultaneously. The results for one set of 30 tests are shown in Fig. 5 [22]. This shows that the breakdown potential  $E_{bd}$  follows a distribution. Thus, there is a 20 % chance that the breakdown potential of commercial 304 SS will be below +160 mV(SCE) in 1000 ppm NaCl. The argument is that there was nothing "wrong" with those tests whose  $E_{bd}$  was less than +160 mV(SCE), but that the variation reflects the stochastic nature of the pitting process. Qualitatively similar data have been developed for Al alloys and their constituent second phase particles [36].

The development of commercially available multipotentiostats has made measurements of pitting conditions and the underlying factors more tractable. Lunt et al. [37] used an array of nominally identical electrodes to characterize the strengths and extent of the types of interactions that occur among active pits. In addition, such instrumentation makes the determination of the statistical distribution of pitting potentials via the testing of a large number of specimens much less time intensive, as multiple electrodes (up to 100) [38] can be independently tested simultaneously.

## CONCLUDING REMARKS

The goals of this chapter were to give a brief overview of the exposure tests used to determine localized corrosion susceptibility, and to introduce a variety of electrochemical techniques that can provide important information concerning localized corrosion susceptibility. Although none of the

methods is perfect or a panacea, when used judiciously and in combination, a better picture of the localized corrosion process can be gained, even in complicated solutions. This allows for more informed decisions on alloy selection, process alteration, or failure analysis. While prediction of localized penetration rate remains a goal of electrochemical testing, applications of statistics to the process appear promising.

# Crevice Corrosion

Narasi Sridhar,<sup>1</sup> Darrell S. Dunn,<sup>1</sup> C. S. Brossia,<sup>1</sup>  
Gustavo A. Cragnolino,<sup>1</sup> and Jeffery R. Kearns<sup>2</sup>

CREVICE CORROSION OCCURS IN regions of a metal that are not directly exposed to an environment such as flanged joints, lap joints, and under corrosion deposits. The metals that undergo crevice corrosion are otherwise protected by a surface film. Alloys that are not protected by a surface film tend to corrode outside the crevice region where there is greater access to cathodic reduction reactions. In this regard, there are many similarities between pitting and crevice corrosion. Indeed, for some classes of materials, a case can be made that the same mechanism operates both phenomena. It must be emphasized that the crevice corrosion tendency is not the property of a particular alloy class; rather it is a function of the alloy's response to a given environmental condition. For example, carbon steels do not suffer crevice corrosion in acidic solutions because of the absence of a passive film, but do suffer crevice corrosion in alkaline solutions when there is a passive film. Similarly, some alloys suffer crevice corrosion in the presence of a corrosion inhibitor, whereas corrosion occurs outside the crevice in the absence of the inhibitor.

Several tests have been developed over the years to determine the crevice corrosion resistance of alloys. The objectives of these tests include comparison of alloys, qualification of alloys for a given service, evaluation of the effects of fabrication processes on crevice corrosion resistance, quality control, and life prediction. This chapter will briefly describe the types of tests, and their applicability and limitations, with a focus on tests that have been or are now being considered by ASTM Committee G-1 on Corrosion of Metals. While these test principles are applicable to a wide variety of alloys, the information presented is focused on stainless and nickel-base alloys.

## THE MECHANISMS OF CREVICE CORROSION

It was realized early on that crevice corrosion occurs because the protective film on the metal is somehow removed or made less protective. Mears and Evans [1] and Uhlig [2] suggested that oxygen depletion inside the crevice was responsible for the destabilization of the protective passive film.

However, Rosenfeld and Marshakov [3] in the late 1950s conducted a detailed examination of processes occurring in the crevice that was a precursor to many experimental studies that are being conducted even today. They suggested that crevice corrosion occurs through a combination of reduction in oxygen or a corrosion inhibitor in the crevice, a reduction in pH, and shift in the potential within the crevice to a more negative value such that the potential is in the active regime. Since these early ideas, many conceptual models of crevice corrosion have been developed [4–39] that have elaborated one or more aspects of this model. Quantitative modeling of crevice corrosion was first performed by Crolet and Defraux [11], who considered only the effect of passive dissolution rate on pH reduction within the crevice and ignored the effect of transport of species in and out of the crevice. This was further improved by Galvele [12] and Oldfield and Sutton [14,15], who considered transport of species in and out of the crevice. These early models have since been improved considerably both in terms of the conceptual models and the numerical solutions [13,16–21].

The crevice corrosion process can be described in four stages: (1) deoxygenation, (2) increase of the salt and acid concentrations, (3) depassivation, and (4) propagation, as illustrated in Fig. 1. Crevice corrosion begins when discrete areas on a passive surface are physically isolated or occluded. Convection between the solution entrapped within an occluded area on a passive surface and the bulk environment is slow, so the dissolved oxygen in a crevice solution is rapidly depleted (Fig. 1, stage [a]). A localized galvanic cell is established due to the difference in the oxygen concentrations of the solutions within a crevice (anode) and the surrounding surface (cathode). The depletion of oxygen in the crevice solution shifts the corrosion potential for a passive surface in the active direction. Although “differential aeration” [1] is sufficient to induce crevice corrosion of certain metals and alloys, it only provides the initial driving force for the crevice corrosion of stainless alloys.

As metallic dissolution continues within a crevice, the metal cations (e.g., Fe<sup>2+</sup>, Cr<sup>3+</sup>, Al<sup>3+</sup>, etc.) are concentrated in the stagnant solution within a crevice. They also react with water (called hydrolysis reaction) to generate acidity.

Mobile anionic species (e.g., Cl<sup>−</sup>) are attracted to the crevice and charge neutrality is maintained. The crevice solution

**FIG. 1—Processes leading to crevice corrosion.**

becomes concentrated in metallic chlorides even when only small quantities of chloride anions are present in the bulk environment (Fig. 1, stage [b]). Active metallic dissolution occurs when the pH of the crevice solution is sufficiently low and the concentration of chlorides is high enough to break down the passive film. The development of a critical crevice solution is controlled by alloy composition, crevice geometry, and bulk solution chemistry [35,36]. The length of time (or incubation period) required to develop a critical crevice solution with a particular crevice geometry determines the effective crevice corrosion resistance of a stainless alloy. The critical crevice solution criterion has proven to be useful for ranking alloy performance [15,35,36].

Following Karlberg and Wranglen [8], many investigators [22–29] have shown that a small potential gradient in the crevice can result in the shift of the electrochemical behavior from passive to active (Fig. 1, stage [c]) and thus result in high corrosion at an intermediate distance into the crevice. Once corrosion has been initiated, the reaction can proceed rapidly due to the unfavorable area ratio of the small, anodic crevice to the large, cathodic surrounding surface. For corrosion resistant alloys that do not exhibit a large active-passive slope at near-neutral pH, stages [b] and [c] are both required because an active-passive peak is not observed unless low pH values are attained [22,23,29].

Pits in crevices were reported early on by Karlberg and Wranglen [8]. An alternative mechanism was originally proposed by Stockert and Bohni [30] and later enhanced by Laycock et al. [37]. This suggests that pit nucleation occurs

in the crevice even at small applied potentials leading to current noise (Fig. 1, stage [d]), but above a critical potential, the dissolution rate increases steadily as pit stabilization occurs. The pit stabilization, in turn, is linked to formation of metal-chloride salt films [38,39].

## REVIEW OF TEST METHODS FOR CREVICE CORROSION RESISTANCE

The tests can be classified into three general categories: (i) non-electrochemical tests, (ii) electrochemical tests under open-circuit conditions, and (iii) electrochemical tests under controlled potential or current conditions. Brief descriptions of the more established methods for evaluating crevice corrosion appear in Table 1 along with comments concerning limits of applicability. Details of each method can be found in the literature cited. The reader is also advised to consider one or more of the excellent reviews on test techniques for crevice corrosion [40–45,76,114].

## NON-ELECTROCHEMICAL TESTS

In these tests, specimens fitted with crevice-forming devices (artificial crevices) are exposed for varying lengths of time to environments containing an anionic species that promotes crevice corrosion (e.g., chloride) and an oxidizing agent to accelerate initiation of crevice corrosion (e.g., ferric ions). The crevice corrosion resistance is then measured by mass-loss and visual methods. ASTM G 48<sup>3</sup> (2000 version) involves four test methods. Methods A and C apply to pitting corrosion. Method B measures the crevice corrosion resistance at two fixed temperatures, whereas Method D measures the crevice corrosion resistance in terms of a critical crevice temperature. These two methods will be described in greater detail below, but the standards provide a comprehensive description of the methods.

### ASTM G-48, Method B

Method B employs a 6 weight percent  $\text{FeCl}_3$  solution (equivalent to 10 %  $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ ), with an exposure period of 72 h at either  $22 \pm 2$  or  $50 \pm 2^\circ\text{C}$ , or both. It involves the use of crevice formers (i.e., cylindrical TFE-fluorocarbon blocks) that are held tightly against the sample surface by two rubber bands. These methods produce localized corrosion of type 304L stainless steel at ambient temperature and can be used to rank other materials with respect to this stainless steel and to a lesser extent with respect to each other. The limited ability of Method B to rank a wide range of alloys stems from the limited temperatures used and the fact that the extent of localized corrosion at a given temperature, even if it can be measured accurately, is not often as important in materials selection as the initiation of localized corrosion. Method B employs two tetrafluoro ethylene (TFE)

<sup>3</sup>Standard Test Methods for Pitting and Crevice Corrosion Resistance of Stainless Steels and Related Alloys by Use of Ferric Chloride Solution.

**TABLE 1**—Comparison of tests for resistance to crevice corrosion.

Test	Summary
(a) Non-Electrochemical Test	
FeCl <sub>3</sub> Test, ASTM G 48, Method B [78,79]	Maximum corrosion depth perpendicular to the crevice plane and/or mass-loss are measured after exposure of creviced specimens to 22°C, 50°C, or both. Crevice device is a TFE block without serrations. The test can provide qualitative ranking of an alloy's resistance with respect to type 304L SS, but is not adequate in ranking a number of corrosion resistant alloys. The rubber band holding the crevice blocks provide additional, uncontrolled crevice sites.
FeCl <sub>3</sub> + HCl Test, ASTM G 48, Method D [47,48,72,77]	A serrated TFE crevice block is used and critical crevice temperature is determined through a series of tests at 5°C increments. The test can be used to rank alloys. Test is limited to 85°C because of instability of FeCl <sub>3</sub> . The pitting resistance equivalents used to determine starting temperature can be misleading because they do not consider synergism between alloying elements. Critical crevice temperature is dependent on specimen preparation, test time, and solution composition.
Other solutions	A procedure similar to ASTM G 48 or ASTM G 78 should be followed.
(b) Electrochemical Open-Circuit Potential Tests	
Remote Crevice Assembly Test [87–89] ASTM G 71 can be used for guidance	A sample with crevice block is electrically coupled to a larger open sample through a zero-resistance ammeter. The current flowing in the external circuit is an indicator of crevice activation and growth. It provides a more sensitive and continuous record of crevice initiation and growth processes. It simulates a real crevice condition. At present, there is no standard test procedure for this. Test time, area ratio of open to creviced sample are important factors.
(c) Electrochemical Applied Potential/Current Tests	
Critical Temperature Tests [48,50,64,73–75,79,90–93]	The temperature is varied in steps or continuously while the potential is held at a constant value. The temperature at which a sustained increase in current is observed is noted as the critical temperature. While phenomenologically equivalent to ASTM G 48D, it provides greater freedom in choice of potential and sensitivity in current measurements.
Critical Potential Tests (ASTM G 61 and variants)	The potential can be scanned continuously or varied in a stepwise manner. The potential at which current increases during the upward scan or stepping of potential is called the initiation potential, $E_{\text{crev}}$ or $E_p$ . The potential at which current decreases to a low value during downward scan or stepping of potential is called repassivation potential, $E_{\text{rcrev}}$ or $E_{\text{tp}}$ . The value of $E_{\text{rcrev}}$ is independent of prior growth of crevice corrosion provided a sufficient extent of growth is maintained. For corrosion resistant alloys, too high an initial potential at which crevice corrosion is initiated can result in erroneous measurement of $E_{\text{rcrev}}$ .

fluoropolymer blocks and either rubber band or o-rings to fasten the blocks to a flat specimen and create crevices (Fig. 2, top). The rubber-band crevice assembly is inexpensive, easy, and fast to assemble, and produces useful results in a reasonably short period of time. However, the rubber band crevice assembly has certain drawbacks:

1. The test is invalid if either rubber band breaks.
2. The compressive pressure associated with the rubber band is not uniform.
3. The ratio of the creviced area to the bold exposed area ratio cannot be accurately measured [66].
4. The surface finish of the TFE-block is not specified.
5. Crevice attack often initiates on the edges of the specimen in contact with rubber bands rather than under the TFE blocks. The edge attack may be related to a combination of crevice geometry as well as metallurgical condition (e.g., inclusion stringers). This may lead to uncertainties about correlating the test results to service conditions where edges of plates/sheets may not be exposed. At the end of the test, the sample is evaluated visually for signs of attack. ASTM G 46,<sup>4</sup> Practice for Examination and Evaluation of Pitting Corrosion, can provide guidelines for evaluating the extent of crevice corrosion after the sample has been removed from the test solution. A mass loss measurement is also recommended, but no acceptance criteria or test data for visual or gravimetric evaluations are presented in the standard. Criteria such

as a maximum of 0.038 mm depth of penetration and maximum of 0.2 mg/cm<sup>2</sup> mass loss have been commercially accepted by certain metals producers and users. As previously stated, many important aspects of the test that influence the result, such as the method of examination and evaluation criteria, must be agreed to by the vendor and user of the product to be tested.

### ASTM G 48, Method D

To overcome these limitations, Method D measures the critical crevice corrosion temperature, using a multiple crevice assembly (MCA). The test solution is 6 wt. percent FeCl<sub>3</sub> acidified with 1 wt. percent HCl. This test method is also referenced in ASTM G 157<sup>5</sup> for evaluating the corrosion properties of wrought iron- and nickel-based corrosion resistant alloys for the chemical process industries.

The multiple crevice assembly (MCA) consists of two “serrated” washers made of TFE-fluorocarbon bolted together through a hole drilled in the specimen, as illustrated in Fig. 2(b). The bolts, made of a highly corrosion resistant alloy, are electrically isolated from the specimen. The MCA eliminates the crevices created where the rubber band contacts the specimen and facilitates the measurement of the crevice area to boldly exposed area ratio. The advantage of the MCA is that the crevice geometry can be made very severe by

<sup>5</sup>Standard Guide for Evaluating the Corrosion Properties of Wrought Iron- and Nickel-Based Corrosion Resistant Alloys for the Chemical Process Industries.

<sup>4</sup>Standard Guide for Examination and Evaluation of Pitting Corrosion.

FIG. 2—Standardized crevice corrosion test specimen assemblies described in ASTM G 48 B (top) [25,44] and ASTM G 78 (bottom) [78,79], commonly referred to as the rubber band assembly and multiple crevice assembly (MCA), respectively.

applying greater torque to the bolt and the multiple small contact points. A torque of 0.28 Nm is recommended by ASTM G 48, based on interlaboratory testing. Higher torque may be used, but creep of the crevice washer is an important concern. The depth and number of crevice sites attacked under the washer are reported and can be statistically analyzed if desired, although statistical analysis is not required by ASTM G 48, Method D. Also shown in Fig. 2(c) is the multiple crevice assembly specified in ASTM G-78<sup>6</sup>. Although the design and material of the crevice device are different, the underlying principle is the same in these crevice designs.

The test consists of exposing the MCA in the  $\text{FeCl}_3$  solutions at different temperatures to determine the temperature at which crevice corrosion can be observed when examined at a magnification of 20X. As a guidance to estimating the starting temperature, two multiple regression equations are suggested by ASTM G 48:

For Ni-base alloys:

$$\text{CCT} (^{\circ}\text{C}) = (1.5 \times \% \text{Cr}) + (1.9 \times \% \text{Mo}) + (4.9 \times \% \text{Nb}) + (8.6 \times \% \text{W}) - 36.2 \quad (\text{Eq. 1})$$

For Iron-base alloys:

$$\text{CCT} (^{\circ}\text{C}) = (3.2 \times \% \text{Cr}) + (7.6 \times \% \text{Mo}) + (10.5 \times \% \text{N}) - 81.0 \quad (\text{Eq. 2})$$

ASTM G 48 recommends that tests shall be started within 5°C of the critical temperature estimated by the above equation. The minimum and maximum test temperatures are recommended to be 0°C and 85°C, respectively. Separate samples are to be used for each temperature and a test duration of 72 h is recommended. The main limitation of Eqs 1 and 2 is that they do not recognize the interactive effects of some alloying elements and are regression estimates based on a limited number of commercial alloys. For example, according to Eq 1, alloy C-276 (Ni-15.5%Cr-16%Mo-4%W) would have a CCT of 52°C, whereas alloy C-22 (Ni-22%Cr-13%Mo-3%W) would have a CCT of 47°C. However, the observed CCT of alloy C-276 is significantly lower than that of alloy C-22.

Critical temperature test values determined by various methods have been used for ranking and comparing the localized corrosion resistance of a large number of commercial alloys and to develop new alloys [41,43,46–69]. Critical crevice temperature has been used as a convenient and quantitative measure of the relative ranking of various alloys. However, it must be used with caution in predicting the performance of an alloy in a given service. This is because the localized corrosion dependence on temperature is a function of the test technique, corrosion potential of the alloy in a given environment, and the concentration of chloride or other anionic species. For example, higher corrosion potentials, longer exposure time, and higher chloride concentrations have a tendency to lower the critical crevice temperature. However, the presence of inhibitive species such as nitrate can increase the critical crevice temperature.

The Immersion Critical Pitting Temperature (ICPT) and Immersion Critical Crevice-Corrosion Temperature (ICCT) tests produce results that follow similar trends relative to alloy composition, as demonstrated by the well-known work of Garner (Fig. 3). Garner found that the ICPT values were approximately 20°C higher than the ICCT values for a broad range of alloy compositions [47,70,71]. Crevice corrosion typically occurs at lower temperatures and in less time than pitting [71,73]. Consequently, a pitting test will typically take longer than a crevice test in the same test environment. However, since the problems associated with the geometry of the gap created by the crevice former are avoided, ICPT tests are more sensitive to differences in alloy composition [50,74,75] and are more reproducible (+2.5°C for ICPT versus ±10°C for ICCT) than are ICCT values [50,57]. The scatter in ICCT can be reduced by extending the test exposure period (e.g., from 24 to 72 h [76]) or testing more samples.

### Precision in Critical Temperature Tests

The variability of critical crevice temperature measurement was originally addressed by Brigham [63]. The round

<sup>6</sup>Standard Guide for Crevice Corrosion Testing of Iron-Base and Nickel-Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environments.

FIG. 3—Immersion Critical Pitting Temperature (CPT) and Immersion Critical Crevice Corrosion Temperature (CCT) curves for molybdenum-bearing austenitic alloys. The dots represent, from left to right: UNS S31600, S31700, N08904, S31254, and N08366. Data are replotted from Refs 45,47,70.

robin test program using G 48, Method D is given in Table 2. The interlaboratory test program found that the pooled repeatability standard deviation and the 95 % confidence limit for Method D were 2°C and 6°C, respectively. The pooled reproducibility standard deviation and 95 % confidence interval for Method D were 6°C and 16°C, respectively. Previous studies [48,70,71] have established  $\pm 10^\circ\text{C}$  as the variation for immersion ICPT values above 40°C.

One significant difference in the results of ICPT and ICCT tests that use acidified ferric chloride (Table 2) versus straight ferric chloride is that the values obtained are significantly lower in the acidified solution. For example, the AL-6XN<sup>®4</sup> alloy (UNS N08367) has an ICCT of 43°C when tested in conventional ferric chloride but, as shown in Table 2, it has a value of 30°C in acidified ferric chloride. Although it is an apparently insignificant part of ASTM G 48, the preparation of 2.5 by 5 cm (1 by 2 in.) corrosion specimens from sheet, strip, and, particularly, plate is a time-consuming and costly part of product testing. Many corrosion-resistant alloys are nonmagnetic, very tough, and, therefore expensive to machine into corrosion specimens. Even properly machined/polished coupon edges are subject to preferential attack because either (a) the rubber bands holding the crevice-former on the sample surface form a very tight crevice on the sample edges, or (b) a subsurface microstructural constituent is exposed and

suffers preferential attack. The bias of test results by edge attack is unacceptable because, in general, product corrosion performance is determined by the surface, not the through-thickness microstructure.

### Applications of ASTM G 48 Tests

As noted in Table 3 [77], the results of multiple alloy tests in seawater are correlated to the Pitting Resistance Equivalence (PRE) number [47,48,72,77], which also correlates to alloy performance in  $\text{FeCl}_3$ . Anderson [78] and Streicher [79] used MCA in seawater tests to compare alloy performance. More recently, a simple, flat, plastic (specifically, polymethylmethacrylate, which is often referred to as “perspex”) washer has been successfully used to evaluate a series of alloys in seawater [77]. One application of the ASTM G 48 test has been in simulating leaking tube-to-tube sheet joints in seawater heat exchangers and condensers [81]. When certain highly corrosion-resistant alloys were paired in a dissimilar metal crevice (DMC) with alloys that would be expected to suffer crevice corrosion in the particular test solution, the more corrosion-resistant alloy was found to corrode due to the accelerating effects of the corrosion products from the less resistant alloy. The results of DMC tests in ferric chloride were confirmed by long-term DMC exposures in seawater [82].

TABLE 2—Results of interlaboratory test program

### ASTM G 78 Test

ASTM G 78 describes crevice corrosion testing using a number of specimen geometries. While the standard is primarily devoted to seawater testing, it can be adopted for other applications. In addition to variations of multiple crevice assembly, ASTM G 78 describes other geometries, including cylindrical pipe geometries with flexible polymeric sheaths as a crevice-forming device. The test method involves exposing the specimens to the applicable environment and evaluating the crevice corrosion susceptibility through mass-loss, measurement of the area of corrosion, and depth of penetration.

### Other Non-Electrochemical Tests

Immersion tests have also been conducted in other environments, notably seawater. The test procedures for preparing the crevice samples can be similar to that in G 48, Method D. The results from seawater tests are shown in Table 3 [79]. It must be emphasized that natural seawater behaves quite differently than synthetic seawater in that the corrosion potential is often much higher in natural seawater [83]. The  $\text{FeCl}_3$  solution is not stable above about 85°C, necessitating use of more aggressive environments for highly corrosion resistant alloys. On the other hand, the  $\text{FeCl}_3$  solution can be too aggressive for some alloys, making it difficult to differentiate between alloys. Crevice corrosion tests in other oxidizing, chloride solutions have been reported in the literature [84]. Caution should be exercised in ranking alloys for their localized corrosion resistance in one oxidizing chloride solution based on their ranking in another chloride environment. For example, the ranking of alloys in  $\text{FeCl}_3$  solution has been found to be in variance with that in chlorine dioxide-containing solutions [85,86]. The localized corrosion resistance in chloride containing solutions may also not be an accurate indicator of their resistance to non-chloride environments.

### ELECTROCHEMICAL TESTS UNDER OPEN-CIRCUIT CONDITIONS

Electrochemical tests are the most rapid way of detecting localized corrosion and measuring corrosion rates. With proper calibration and control, corrosion can be detected and quantified online and in real-time. Electrochemical tests can be conducted at open-circuit potential conditions by galvanically coupling a creviced specimen to an open (non-creviced) specimen and measuring the current flow using a zero-resistance ammeter [87–90]. Such an arrangement is called the remote crevice assembly. The area ratio between the creviced and non-creviced specimens can be varied depending upon the specific application. The advantage of this technique is the sensitivity with which early stages of crevice corrosion and later growth and repassivation can be measured, without perturbing the system away from its open-circuit potential. Care should be taken to minimize exposed (non-crevice) area in the anodic member of the remote crevice assembly. The test specimen geometry can be designed to reproduce anticipated macroscopic crevice geometries in many applications.

The crevice can be formed in the same manner as for G 48, Method D. Care must be taken in exposing only the crevice with controlled gap. The crevice where electrical contact is made with the specimen is uncontrolled. This crevice area can be designed to be above the solution level. The choice of area ratio between cathode (non-creviced specimen) and anode (creviced specimen) depends upon the application. For example, in a low conductivity solution or an environment where a condensed water film controls corrosion, the cathode to anode area ratio is expected to be relatively small (less than 2:1). In flowing seawater systems, this ratio can be quite large. For example a ratio of 300:1 has been used [90]. Visual examination at the end of the test is essential in correlating the observed galvanic currents with degree of crevice corrosion. The open-circuit potential can be changed as in the non-electrochemical tests by changing the redox species or concentration. At present, there is no specific ASTM standard for his test. However, ASTM G 71<sup>7</sup> can be used as guidance.

### ELECTROCHEMICAL TESTS UNDER APPLIED POTENTIAL/CURRENT

These techniques for evaluating crevice corrosion resistance involve holding (static) or incrementally changing (step or scan) the potential or current. Some of the more frequently used techniques for evaluating crevice corrosion resistance are listed below, following the definitions given in ASTM G 15:

1. Potentiostatic technique—Changes in current density are monitored for a sample maintained at a constant potential. The potential can be varied from sample to sample.
2. Galvanostatic technique—changes in potential are monitored for a sample maintained at a constant current in a test solution.
3. Potentiostep or potentiostaircase technique—Changes in current density are monitored for a sample that is polarized in a series of potential increments or decrements. Typically, the time duration or potential steps in a crevice corrosion tests are not equal.
4. Potentiodynamic technique—The potential is changed scanned continuously at a predetermined rate (ASTM G 5).
5. Cyclic potentiodynamic technique—The potential is scanned forward from some low value to a high value and scanned backward to a predetermined potential or current value (ASTM G 61).
6. Galvanostep or galvanostaircase technique—Changes in potential are monitored for a sample that is polarized in a series of current increments or decrements. (For more information the reader is referred to a related standard, ASTM G 100, Method for Conducting Cyclic Galvanostaircase Polarization.)

<sup>7</sup>Standard Guide for Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes. The work of Qvarfort [51] represents a different approach to critical temperature testing that is intended to study pitting rather than crevice corrosion. See the previous chapter, Pitting, for a discussion of this approach.

These four basic techniques are used alone, combined, or in combination with other corrosion-accelerating factors such as increased temperature or chloride concentration. For example, ASTM F 746, Test Method for Pitting or Crevice Corrosion of Metallic Surgical Implant Materials, test involves alternatively controlling the potential until a specified current density is achieved and then following the current until a specified potential is achieved. One way of determining the critical crevice corrosion temperature is with a series of potentiostatic tests conducted at uniform increments of increasing temperature until a limit in current density is exceeded. In the electrochemical tests, it should be noted that some of the measured parameters are sensitive to crevice geometry.

### Measurement of Critical Temperature

Electrochemical critical temperature (ECT) testing has been evolving for more than two decades [48,50,64,73–75,79,91–94,101].<sup>7</sup> The programmed changes in applied potential and temperature that constitute the ECT method are schematically illustrated in Fig. 4. (Note that the corresponding changes in current density are not illustrated in Fig. 4.)

The periodic decreases in the applied potential and current density shown in Fig. 4 are due to the fact that the potential is not applied during the rise in temperature. Several workers have found that the continuous application of potential while temperature is increased continuously at a constant rate to be a more efficient and less complex method of testing [102]. The primary reason for preferring the intermittent or step method (the latter is illustrated in Fig. 4) over the continuous method of ECT testing is that the step method better simulates the conditions of the conventional immersion-type test, in which samples are removed from the test solution after exposure at each temperature and inspected, then reimmersed.

Under some combination of elevated temperature and applied potential, localized corrosion will initiate and result

in a rapid increase in current density. Eventually, the change in current density is sustained at a level two or more orders of magnitude higher than the passive current level. The temperature at which this occurs is taken to be the electrochemical critical crevice corrosion temperature (ECCT) or electrochemical critical pitting temperature (ECPT), depending on whether a crevice-former was used. The transient surges of current density that occur below the ECT are usually ignored since such changes represent the initiation and rapid repassivation of pits.

The results achieved by using the ECT technique have very good correlation with long-term exposure tests in brine as well as the same ranking as found in cyclic polarization work [55]. ECT test methods have been found to be very effective in detecting rather subtle differences in the composition and microstructure of stainless steels [95,96,103].

The most important aspect of ECT testing is that a wide range of alloys can be ranked by a single parameter. Another advantage of ECT testing over immersion testing is that different degrees of polarization can be used to simulate the corrosion potentials that are characteristic of various environments. If the corrosion potential ( $E_{\text{corr}}$ ) of an alloy in a service environment is known, a specimen of that alloy can be polarized to that potential in a simulated solution or to a value typically 200–600 mV more anodic than  $E_{\text{corr}}$  in order to accelerate pitting or crevice corrosion.

An extension of the ECT method described above that has been used to evaluate alloys for service on North Sea oil platforms [97,98] has been referred to as cyclic thermammetry [99]. The technique involves exposing a coupon fitted with an MCA to a test solution under an applied potential that simulates a process environment. The current density of the crevice specimen is monitored as the temperature of the test solution is slowly changed (e.g., 4°C/24 h) in a cyclic manner up to a critical value and then back toward room temperature. The test results are in the form of a curve (Fig. 5) that looks very much like a conventional anodic polarization curve [97] with the exception that temperature rather than applied potential is the independent variable. Values for a critical crevice corrosion

FIG. 4—Schematic illustration of changes in test variables in the course of an intermittent type of ECT test [93].

FIG. 5—Cyclic thermammetry plot for N08367 alloy exposed in a crevice assembly to aerated 3 wt% NaCl under an applied potential of 600 mV (SCE). The temperature was changed by 4°C/24 h; data from Ref 97.

temperature (CCT) and a repassivation temperature ( $T_R$ ) can be determined from a cyclic thermammety curve, as indicated in Fig. 5 [98].

### Bias in ECT Tests

The current limit for the ECT, like mass loss or crevice depth, is crucial in establishing a value for the ECT. No criteria for ECT have yet been established by any internationally recognized standards writing organization. A limited survey of the literature yielded test parameter values ranging from 0.01–1.8 mA/cm<sup>2</sup>, depending on test environment and sample configuration. One method for establishing the current limit for an ECT test that has been used by several workers involves conducting a series of cyclic potentiodynamic polarization tests (after ASTM G 61<sup>5</sup>) at various temperatures to determine the current density associated with the pitting potential. The influence of the rate of temperature increase in an ECT is analogous to that of potential scan rate in cyclic potentiodynamic polarization test. Figure 6 shows that lower rates of temperature increase result in lower ECCT values.

With regard to intermittent versus continuous ECT test, intermittent tests generally produce higher ECT values than do continuous tests. The reason is that metastable pits are more likely to stabilize and propagate in a continuous test; intermittent tests pits or crevices can repassivate during the intervals when the specimen is allowed to return to open circuit potential.

### Measurement of Critical Potentials

Critical potentials are important in determining the resistance of a metal to localized corrosion because they have a mechanistic underpinning and they are rapid measurements. Two potentials have been used as a measure of the crevice corrosion resistance—crevice/pit initiation potential ( $E_{crev}$  or  $E_p$ ) and crevice/pit repassivation potential ( $E_{rcrev}$  or  $E_{rp}$ ). The  $E_{crev}$  or  $E_p$  is the potential at which the current

increases significantly when the potential is raised from a lower value either in a stepwise or continuous fashion. The  $E_{rcrev}$  or  $E_{rp}$  is the potential at which the current decreases to a low value when the potential is decreased (Fig. 7).

However, there has been considerable debate about the validity of these parameters for determining the long-term performance of a given alloy and their dependence on measurement techniques [39,103–107]. It is well known that the  $E_p$  and  $E_{rcrev}$ , the potential at which the current increases from a low passive value to a high active value, depends on the scan rate [104], among other factors. Another reason cited against the use of critical potential as a measure of the localized corrosion resistance is the observation made by Wilde and Wilde and Williams [106,107] that the  $E_{rp}$  decreased with the extent of prior pit growth. Since then, a number of studies [39,108–110] have shown that the  $E_{rcrev}$  and  $E_{rp}$  attain a lower bound value beyond a certain pit or crevice corrosion depth (Fig. 8). Longer-term, potentiostatic tests have also shown that the  $E_{rp}$  measured for deep pits is a reasonable parameter to predict long-term localized corrosion occurrence [39,108].

The techniques for measuring the repassivation potential have not been standardized, although existing methods can be adapted. For alloys that exhibit low to moderate resistance to localized corrosion, the ASTM G 61 method is adequate in defining the repassivation potential, provided sufficient growth in crevice corrosion is assured. For highly corrosion resistant alloys, the use of cyclic, potentiodynamic polarization method (ASTM G 61) can lead to misleading results. For example, hysteresis between the forward and backward scans has traditionally been used as an indicator of localized corrosion. In highly corrosion resistant alloys, such a hysteresis can be observed without any visual appearance of crevice corrosion (Fig. 9a and b). This is because the initiation of crevice corrosion in the forward scan is monitored by the magnitude of current density. In highly corrosion resistant alloys high currents can be attained during continuous scanning by polarizing to high potentials (above 1 V SCE) where transpassive dissolution takes place. The fact that this is not crevice corrosion is

FIG. 6—Effect of the rate of temperature increase on the anodic current density for welded S31254 in natural seawater at an applied potential of +400 mV (SCE). The solution temperature was increased continuously at the cited rates. Data from Ref 99.

FIG. 7—Cyclic potentiodynamic polarization curve for type 316L SS showing hysteresis and crevice corrosion.

FIG. 8—The repassivation potential as a function of prior crevice corrosion and pit depth showing a bounding value less sensitive to penetration depth [39].

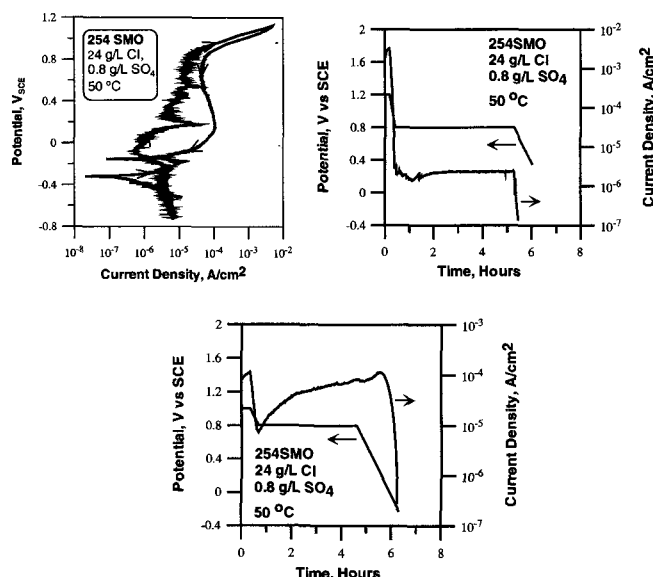

FIG. 9—Cyclic potentiodynamic polarization curve for alloy 254 SMO showing a large hysteresis, but no crevice corrosion (a). If potentiostep tests were performed with the initial potential value at 1.2 V SCE, no crevice corrosion is initiated upon subsequent growth at 0.8 V SCE, as noted by lack of current increase (b). If the initial potential was held at 1.0 V SCE, then crevice corrosion growth occurred at 0.8 V SCE subsequently as noted by the current increase (c).

seen in Fig. 9b, where the potential is held at 0.8 V SCE after initiating corrosion at 1.2 V SCE. The current in this case does not increase even after relatively long time periods. In such a case, backward scanning will indicate a misleading value for repassivation potential. On the other hand, if the corrosion is initiated at a lower potential, the current increases and crevice corrosion is observed visually. Therefore, a combination of cyclic polarization test to determine

the overall characteristics of the polarization curve, followed by potentiostep technique is recommended for highly corrosion resistant alloys.

### Precision in Measuring Critical Potentials

ASTM G 61 shows the precision in these measurements. The scatter in the  $E_p$  and  $E_{crev}$  is much larger than the scatter in  $E_{tp}$  or  $E_{tcrev}$  [39,108–110]. Limited experimental data [108] indicate a scatter in the  $E_{tcrev}$  values of about 100 mV.

### Measurement of Depassivation pH

Following a number of crevice corrosion modeling approaches [11,12,14], another measure of the crevice corrosion resistance of an alloy was established in terms of the depassivation pH,  $pH_d$ . This is the pH below which an alloy does not exhibit any passivity and thus represents the conditions at an active crevice corrosion site. It must be noted that in some of the experimental investigations criteria are adopted that may not always result in complete depassivation. For example, Oldfield and Sutton [14] assume a certain current density under potentiostatic conditions as the criterion for depassivation. The  $pH_d$  values have been measured for a number of alloys [36,113]. The  $pH_d$  can be measured either by generating polarization curves in various simulated crevice solutions with decreasing pH using ASTM G 5 or G 61 method or by monitoring the potential of a specimen under galvanostatic conditions while simultaneously decreasing the pH by the addition of HCl. There is no standard procedure established for this measurement.

# Galvanic

Harvey P. Hack<sup>1</sup>

## BASIC PRINCIPLES

### Electrochemical Reactions

IN ORDER TO BE able to properly design and interpret the results from galvanic corrosion tests, it is necessary to have some appreciation of the electrochemical theory behind galvanic corrosion. Metal corrosion consists of at least two reactions. The first is the metal going into solution in the electrolyte

For iron in steel corroding in water at room temperature, this reaction would be

Since the metal is transformed from an atom with no net charge to an ion in solution with a net positive charge, this type of reaction is called an oxidation reaction, and generates electrons. Oxygen need not be involved in an oxidation reaction, only a net increase in charge of the metal. The oxidation reaction involved in the corrosion process is also called the anodic reaction.

Since electrons are generated by the oxidation reaction, and since there can be no net accumulation of charge in these reactions, there must be another reaction occurring that uses up these electrons. This is the cathodic or reduction reaction, and it will always result in some species reducing its charge as it gains electrons. The three common reduction reactions in water are hydrogen reduction, occurring primarily in acids

oxygen reduction occurring primarily in acids

and oxygen reduction occurring primarily in bases or neutral water

The first of these cathodic reactions generates hydrogen gas and is readily observed when zinc or iron are placed in certain strong acids. The last two cathodic reactions use

oxygen molecules that are dissolved in the water. Other reduction reactions not illustrated include metal ion reduction and plating.

All of these reactions generate or use up electrons and, therefore, involve the flow of a current. For this reason, they are called electrochemical reactions, and their rates are influenced by externally applied currents and potentials. For example, if electrons are forcibly removed from the anodic corrosion reaction, the reaction will occur more rapidly. Removing electrons also causes the potential of the corroding metal, as measured relative to a device with a very stable potential called a reference electrode, to become more positive. This is plotted in Fig. 1. The relationship is illustrated as a straight line where potential is plotted against the log of the reaction rate. This straight-line relationship was first noted by Tafel [1], and the slope of the line honors him by being called the Tafel slope. Anodic reactions usually have a positive Tafel slope. Ideal reactions frequently yield these straight lines, but in practice it is common to see curved lines. The process of changing potential by applying a current is called polarization.

The cathodic reactions can also be plotted on the same type of graph. Adding electrons to the hydrogen reduction reaction (or to any cathodic reaction) will speed up that reaction and shift the potential more negative. This is shown in Fig. 1 as another straight line with a negative Tafel slope. Electrochemical reactions generate or use up electrons, and therefore, the rate of a reaction is equivalent to the electron current generated or used up by that reaction.

FIG. 1—Evans diagram for iron in an acid.

<sup>1</sup>Northrop Grumman Corporation, Oceanic Systems, Annapolis, MD 21404.

## Galvanic Series

Since no charge can accumulate on any metal surface, the electrons generated by the anodic reaction must all be used up by the cathodic reaction. This can only occur in Fig. 1 where the anodic and cathodic reaction lines cross. At this point, the rate of the anodic reaction, the corrosion rate, equals the rate of the cathodic reaction—in this case, hydrogen generation. This rate is called the open-circuit corrosion rate, abbreviated  $i_{\text{corr}}$ . The potential at which the lines cross is called the open-circuit corrosion potential, abbreviated  $E_{\text{corr}}$ . This type of plot is called an Evans Diagram, after U. R. Evans, a pioneer in corrosion electrochemistry. Any corroding metal should, under open-circuit conditions, exist at  $E_{\text{corr}}$  corroding at a rate  $i_{\text{corr}}$ , which can be predicted from the Evans Diagram. The value of  $E_{\text{corr}}$  will depend on the position of the curves. The anodic curve is a function of the type of metal and the charge it receives when it goes into solution. The cathodic curve is a function of the type of cathodic reaction, the type of surface on which that reaction takes place, the concentration of reacting species, and other factors, most of which are dependent on the environment in which the metal sits.

FIG. 2—Galvanic series of various metals in flowing seawater at 2.4–4.0 m/s for 5–15 days at 5–30°C (redrawn from original in Ref 21; taken from ASTM G 82).

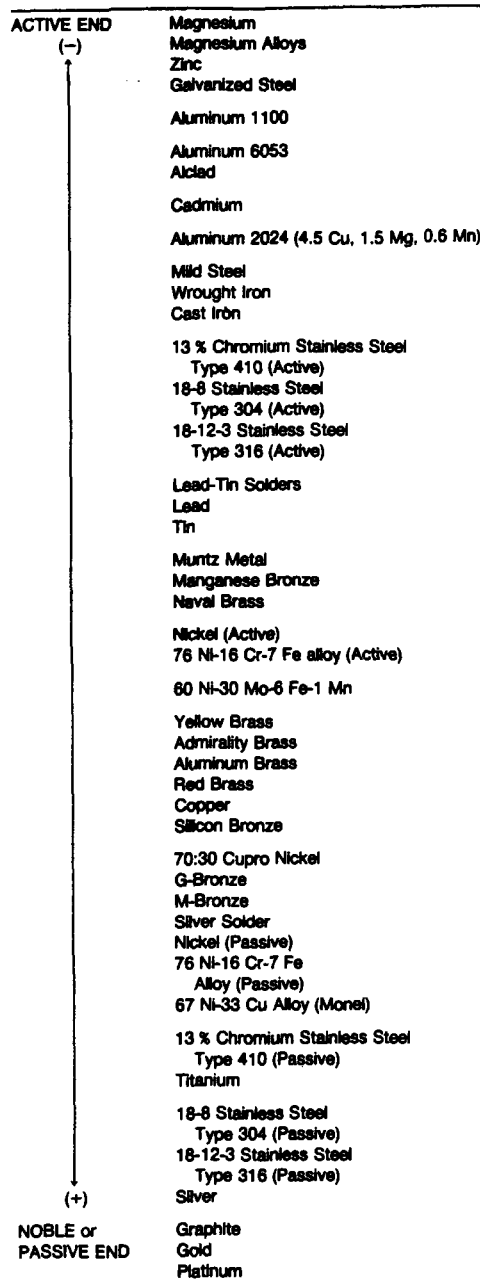

FIG. 3—Galvanic series of various metals exposed to seawater (taken from ASTM G 82).

Each metal/environment combination, therefore, exists at a unique potential. For a given environment, the potentials of various materials can be listed in a form called a galvanic series. Galvanic series can be expressed either as a graph giving the numerical values of the potentials of the materials in the given environment, as in Fig. 2, or as a list in order of increasing or decreasing potential without the specific values, as in Fig. 3. The galvanic series is important because it helps to predict what happens when two metals are placed in electrical contact in that environment. The metal that is more negative in the galvanic series will have

a driving force to lose electrons to a metal in electrical contact that is more positive in the series. This will cause the corrosion rate of the more negative metal to increase when the electrical connection is made. It is this increase in corrosion of the more negative metal upon contact with a more positive metal that is called galvanic corrosion. The galvanic series allows prediction of which of the metals in contact, the galvanic couple, will suffer increased corrosion.

### Mixed Potential Theory

It is tempting to say that the farther apart two metals are in the galvanic series, the more corrosion will occur on the more negative material, or anode. Unfortunately, this is not the case. In order to predict the rate of galvanic corrosion, an Evans Diagram of both metals involved must be considered. This approach is called Mixed Potential Theory.

In Fig. 4, Evans Diagrams are shown for two materials of equal surface area that have different potentials on the galvanic series in an acid: iron and zinc. The anodic material, zinc with the more negative  $E_{\text{corr,Zn}}$ , corrodes uncoupled at a rate of  $I_{\text{corr,Zn}}$ . The cathodic material, iron with the more positive  $E_{\text{corr,Fe}}$ , corrodes uncoupled at a rate of  $I_{\text{corr,Fe}}$ . When these metals are electrically connected, electrons can flow between them, upsetting their individual balances. Since there are four reactions to consider, and since electrons can now flow freely between all four reactions, the charge balance must be handled differently than for the individual metals. All of the electrons generated by the anodic reactions must still be consumed by the cathodic reactions. Therefore, the sum of the anodic reactions is plotted as a dashed line with a positive Tafel slope, and the sum of the cathodic reactions is plotted as a dashed line with a negative Tafel slope. The intersection of these two sum lines is where all charges balance, and the potential so defined is called the mixed potential of the galvanic couple, or coupled potential,  $E_{\text{couple}}$ . The mixed potential of the couple is shown as a dotted line in Fig. 4. The points where the individual reaction lines cross the mixed potential define the rates of

FIG. 4—Evans diagram for iron and zinc in acid.

those reactions. The zinc corrosion rate has increased from  $I_{\text{corr,Zn}}$  to  $I_{\text{coupled,Zn}}$ . This increase is the galvanic corrosion rate. The iron corrosion rate has decreased from  $I_{\text{corr,Fe}}$  to  $I_{\text{coupled,Fe}}$ . This decrease is called cathodic protection.

### Effects of Anode/Cathode Area Ratio

There was a shift in axis labeling between Figs. 4 and 1. Figure 1 expressed reaction rate as lower case  $i$ , the reaction current per unit area, which is appropriate for considering single metals. Figure 4 was forced to switch to total reaction current  $I$ , because it is the total current from each metal that must be considered in the summation. The effect of changing the relative areas of the anode and cathode is illustrated in Fig. 5. If the cathode is small, the original Evans diagram for the cathodic material must have the current densities multiplied by a small area to obtain total currents. This makes the lines appear far to the left in Fig. 5, and results in only a small increase in anodic corrosion rate,  $I_{\text{coupled,anode,small cathode}}$  over  $I_{\text{corr,anode}}$ . If the cathode is large, the original Evans diagram for the cathodic material must have the current densities multiplied by a large area to obtain total currents. This makes the lines appear far to the right in Fig. 5, and results in a large increase in anodic corrosion rate,  $I_{\text{coupled,anode,large cathode}}$  over  $I_{\text{corr,anode}}$ . This illustrates the area ratio effect in galvanic corrosion. A small anode and large cathode result in a large anodic corrosion rate, whereas a large anode and small cathode are far more desirable.

### Flow Rate

Changing the electrolyte flow rate can have significant effects on the curves in the Evans diagram, and therefore, can dramatically influence galvanic corrosion rate. The direction of the effect can only be predicted using Evans diagrams, however.

If the cathodic reaction is oxygen reduction rather than hydrogen reduction, oxygen must be supplied to the metal surface by diffusion in order to react. Diffusion can be a slow process relative to the electron exchange, and this can make the cathodic line in the Evans diagram deviate from

FIG. 5—Effect of cathodic area on couple current.

a straight line. Oxygen diffusion occurs through a relatively stationary boundary layer, which becomes thinner as flow increases. Diffusion rate therefore increases with flow, and the maximum rate of the oxygen reduction reaction,  $i_L$ , increases with flow. This is shown in Fig. 6. When the diffusion-limited cathodic curve is present in a galvanic couple, the total cathodic current will increase with increasing flow, causing corrosion rate of the anode to increase with increasing flow.

Flow can also have an effect on the anodic reaction. Many materials exhibit passivity, which causes the anodic reaction to deviate dramatically from a straight line. This is caused by the corrosion products formed during the anodic reaction becoming firmly attached to the metal surface, blocking the reaction from proceeding further. The anodic line in the Evans diagram will be straight until the corrosion product forms, after which the current will rapidly drop even though potential is still increasing. The low current will persist until the potential becomes sufficiently positive to break down the corrosion product or to produce oxygen directly from water by electrolysis. In either event,

FIG. 6—Effect of flow on diffusion-limited current density.

the current will then rise sharply. This is shown in Fig. 7. Some of the most protective passivating corrosion products are on stainless steels. These films form more readily in the presence of oxygen, and so are enhanced by flow. This leads to the situation shown in Fig. 8 where increasing flow increases oxygen delivery, which increases the amount of protective corrosion products, lowering the anodic currents. This can cause corrosion rates in a galvanic couple to decrease with increasing flow, opposite to the oxygen effect on the cathodic reaction discussed above.

### Measured Currents

Much of the current that flows between reactions in a galvanic couple will flow between the anodic and cathodic metals, but some also flows within these metals. Internal current is not directly measurable, although it can be inferred from other test methods that use external current that can be measured. Measurable external currents can be predicted from the Evans diagrams as follows. When a metal is corroding by itself, as in Fig. 9, the corrosion current is  $i_{corr}$ , which flows entirely between anodic and cathodic sites in the metal and cannot be measured. All

FIG. 8—Effect of flow on passivity.

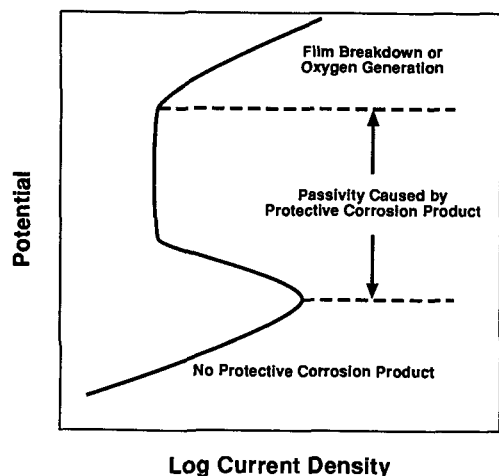

FIG. 7—Effect of passivity on anodic polarization curve.

FIG. 9—Creating polarization curves from Evans diagrams.

electrons produced by the anodic reaction are consumed by the cathodic reaction. If an external source, such as a power supply or another metal electrically connected to the first, removes electrons, the anodic reaction will increase to supply more electrons and the cathodic reaction will decrease to use up less electrons. The externally applied anodic current will be the difference between the anodic and cathodic reaction currents. At very positive potentials, the cathodic current will be negligible, and the applied current will roughly equal the anodic corrosion rate. At very negative potentials, the anodic current will be negligible, and the applied current will roughly equal the cathodic current. At  $E_{\text{corr}}$  the external current will be zero. The externally applied current will follow a shape called a polarization curve, shown in Fig. 9.

Galvanic corrosion rate can be roughly predicted by superimposing the polarization curves of the anodic and cathodic materials. This is shown in Fig. 10. When the open-circuit potentials of the anode and cathode are relatively far apart, more than roughly 120 mV depending on the slopes of the curves, this prediction is fairly accurate. The polarization curves for the anodic and cathodic materials are multiplied by their respective wetted surface areas and placed on the diagram. The intersection of the anodic curve for the anodic material with the cathodic curve for the cathodic material provides an indication of the galvanic corrosion rate,  $I_{\text{galvanic}}$ , and the exact coupled potential,  $E_{\text{couple}}$ .

### Current and Potential Distributions

For galvanic corrosion to occur, there must exist at least two metals with different corrosion potentials, a metal path for electrons to flow between them, and an ionic path through the electrolyte to complete the electronic circuit. The latter is sometimes not considered, but contributes to nonuniformity of galvanic current and potential on large structures.

Figure 11 shows two metals electrically connected in an electrolyte that has a significant resistivity, such as tap water. Current  $I_1$  must travel through some small electrolyte resistance  $R_1$  to go the short distance from the anode to the cathode, and undergoes a voltage drop according to Ohm's

law of  $I_1 R_1$ . Current  $I_2$  must travel farther, through an increased resistance  $R_2$ , and will therefore be smaller than  $I_1$ . The voltage drop here is  $I_2 R_2$ . The largest distance is traversed by current  $I_4$ , through the largest resistance  $R_4$ , and will therefore be the smallest current and undergo a voltage drop of  $I_4 R_4$ . The falloff of current (and corrosion rate) as distance from the second metal increases is a common method for recognizing galvanic corrosion. Although current decreases with distance, the product of current times resistance will increase with distance. The largest voltage drop in this example would be  $I_4 R_4$  and the smallest would be  $I_1 R_1$ . The voltage drops are shown in Fig. 11. The presence of an IR drop not only decreases the current on the anodic and cathodic materials, but also allows the anode to be at a different potential than the cathode. The potentials will be closest to  $E_{\text{couple}}$  where the anode and cathode are closest, and will shift towards  $E_{\text{corr}}$  for each material as separation distance increases. This creates a potential distribution over the structure that can be measured.

### Factors Controlling Galvanic Corrosion

Any factor that controls corrosion of a single metal may control galvanic corrosion by its effect on one or more of the reaction lines on the Evans diagram. Besides flow and pH, these factors include temperature, electrolyte composition, surface condition of the metals, thermomechanical and potential history of the surfaces, and many more too numerous to mention. Factors unique to galvanic corrosion include anode/cathode area ratio, electrolyte resistivity, and geometry. Sometimes it is important to know which reactions control or limit galvanic corrosion rates. The polarization curves in Fig. 12a illustrate how a diffusion-limited cathodic reaction will control the rate of galvanic corrosion. Changing the shape of the anodic polarization curve, for example, by the use of an anodic inhibitor, has no effect on galvanic corrosion rate determined by the curve intersection, whereas changes in the cathodic diffusion-limited current result in equivalent changes in galvanic corrosion rate. Similarly, galvanic corrosion of passive materials, as

FIG. 10—Rough prediction of galvanic current from overlapping polarization curves.

FIG. 11—Effect of distance on IR drop and current density.

FIG. 12—Type of control of galvanic corrosion reactions: (a) cathodic control; (b) anodic control; (c) mixed control.

shown in Fig. 12b, is frequently under anodic control, with the shape of the cathodic polarization curve making little difference. Mixed control as in Fig. 12c is also possible.

## TESTING TECHNIQUES

### Exposure of Galvanic Couples

The most obvious method of testing for galvanic corrosion is to construct a couple between the materials of interest and place it in the environment of interest. Material condition, environment, and geometry should simulate the application as closely as possible. Care should be taken during assembly to ensure adequate electrical connection, and this connection should be checked before, after, and occasionally during the exposure using an appropriate ohmmeter. In some cases, it may be possible to electrically isolate the individual metals from each other and connect them through an external wire, which can be used to measure galvanic current during exposure. For small specimens it is permissible to use a 1- $\Omega$  resistor in the line to measure voltage drop and calculate current. Where currents are larger or where corrosion potentials are close for the materials involved, use of a zero-resistance ammeter may be more appropriate for current measurement. The potential of the couple can also usually be monitored during the exposure using a suitable reference electrode. More detail on galvanic corrosion testing in electrolytes can be found in ASTM G 71, Guide for Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes.

Important material factors to consider when simulating a galvanic corrosion situation include chemical composition, thermal history, and surface condition. Changes in these parameters may change the corrosion behavior of a material when it is not in a galvanic couple without affecting its galvanic corrosion behavior, or may affect its galvanic corrosion behavior without a significant effect on its corrosion properties when it is used alone.

Any environmental factor that can influence corrosion can also affect galvanic corrosion. Environmental factors to consider when designing a test include major chemical components, dissolved gases, minor constituents, organic materials, biological organisms and activity, temperature, flow, and electrical conductivity. In atmospheric galvanic couples, atmospheric factors such as time-of-wetness, orientation relative to prevailing winds, sunlight exposure, height above ground, and other unique atmospheric conditions should also be considered. Some important atmospheric

factors affecting corrosion are discussed in ASTM G 33, G 50, G 84, and G 92.<sup>2</sup>

The relative geometry of the parts of interest in the galvanic couple can also influence corrosion behavior. In low conductivity environments, the distance of separation of the dissimilar metals will affect galvanic corrosion rate. Even in high conductivity environments, it is difficult for galvanic current to travel into long narrow crevices or down the insides of tubes. The relative wetted surface areas of the dissimilar metals will dramatically influence galvanic corrosion rate. In atmospheric exposures, geometry can control water trapping and drainage, and thermal mass, which controls dew retention.

Ensuring adequate electrical contact between the dissimilar metals in a galvanic couple can be difficult. Pressure contact, such as between two plates bolted together, is subject to corrosion products forming between the plates and wedging them apart. Attachment of wires by soldering or brazing will work with some materials, but the use of drilled and tapped holes for screw attachment or through holes for bolting may be required for others. In some cases, spot welding can be used for electrical attachment. Finally, a wire may be inserted into a drilled hole and the hole peened closed around the wire, although this method is not reliable over long exposure periods. Whatever connection method is used, the connection area and wire are subject to corrosion, which can affect both the electrical contact and the performance of the galvanic couple being tested. For this reason, coatings are frequently used on the connection area. When electrical contact is maintained by physical contact of the dissimilar metals, periodic measurement is desirable to ensure that electrical continuity is maintained. If continuity is checked frequently relative to the length of the exposure, it will be possible to adjust the materials to regain this continuity without significantly affecting the results. This should be done without disassembly or gross movement, such as by tightening tensioning bolts.

Mounting of galvanic couples for testing should be done carefully using insulator materials to avoid the possibility of establishing electrical continuity with the mounting device or test chamber. Mounting techniques include gasketed seals, rod mounting, epoxy mounting, press-fit, partial immersion, full immersion, and others. The mounting technique chosen is related to the type of corrosion expected, the electrical connection method, the type of exposure desired, presence or absence of water-line effects, and the materials chosen.

Duration of exposure is extremely important in galvanic corrosion testing. In many galvanic couples, the amount of corrosion is highly variable with time. Initial high corrosion rates may fall dramatically, initial low rates may suddenly increase, and the relationship between anodic and cathodic materials can even reverse with time. For these reasons, the duration of the test exposure should be of sufficient length to ensure that the corrosion processes have reached steady

<sup>2</sup>ASTM G 33, Practice for Recording Data from Atmospheric Corrosion Tests of Metallic-Coated Steel Specimens; G 50, Practice for Conducting Atmospheric Corrosion Tests on Metals; G 84, Practice for Measurement of Time-of-Wetness on Surfaces Exposed to Wetting Conditions as in Atmospheric Corrosion Testing; G 92, Practice for Characterization of Atmospheric Test Sites.

state if long-term performance is being evaluated. Test duration should be similar to service duration for short-term service. In atmospheric testing, the season of the year when exposure is initiated may influence the test. Multiple exposures of different time periods may be used to give corrosion rate information as a function of time.

Exposures can be conducted on full-scale components or on scaled down or simplified geometries. Full-scale components have a number of advantages, including not needing to consider details of geometry and ease of relating the results to service performance. However, full-scale component testing may be impractical or too expensive, in which case scale modeled components may have to be used. If scale modeling is used, details of scaling laws must be understood before designing the test. For example, when galvanic corrosion current distribution is important, the conductivity of the electrolyte may need to be scaled by the same factor as the physical size. This procedure, called Dimension and Conductivity Scaling (DACS), would involve the use of an electrolyte of one-tenth conductivity for a one-tenth-scale model. DACS scales only primary current distribution, which is controlled by IR drop in the electrolyte. Secondary and tertiary current distribution are influenced by polarization behavior of the material involved, and are best approximated by the use of full-conductivity electrolytes. Both types of current distributions cannot be modeled simultaneously, so a decision must be made as to which is most important. Small structures in highly conductive electrolytes should generally be tested in full-conductivity electrolytes, whereas DACS should be used primarily for large structures in low-conductivity electrolytes. To date, DACS has been used primarily for ship cathodic protection system design. More information on scaling can be found in Refs 2 through 5.

## Electrochemical Tests

Accelerated testing to get a result in a shorter time period than would be possible naturally should be avoided whenever possible, because the mechanism of galvanic corrosion can change if the rate is altered significantly. For this reason, electrochemical tests are frequently chosen to evaluate galvanic corrosion performance. The sensitivity of these tests allows for obtaining results fairly quickly without accelerating the corrosion process.

Electrochemical galvanic corrosion tests can be placed into three categories: sensitive galvanic current measurement, galvanic series determination, and polarization curve measurement. Sensitive current measurement involves an ordinary galvanic couple exposure, but with current between the dissimilar metals forced to flow through an external wire where it can be measured with a zero-resistance ammeter or by voltage drop across a 1- $\Omega$  shunt resistor. This type of testing is described in ASTM G 71.

Determination of a galvanic series involves placing the materials of interest from the galvanic couple individually in the environment of interest and monitoring their electrochemical potential over time. The material with the more electronegative potential will become the anode and suffer accelerated corrosion when placed in a galvanic couple. Galvanic series are extremely useful during the materials

selection process to make sure that the anodic areas are large compared to the cathodic areas in complex structures. The galvanic series is influenced by all of the environmental variables described earlier, so the series should only be used if it is developed in the environment in which the galvanic couple will see service. One disadvantage of the galvanic series is that it is frequently misapplied. A series developed in one environment is used to predict performance in another environment. A second disadvantage of the galvanic series is that it does not predict rate. Separation in potential between dissimilar materials does not relate to the rate of corrosion in a couple. More details of the development and use of galvanic series are given in ASTM G 82, Guide for Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance.

Galvanic corrosion can be predicted by overlaying polarization curves, as described earlier. The determination of polarization curves is, therefore, an important method for galvanic corrosion testing. These curves can be obtained galvanostatically, potentiostatically, or potentiodynamically. Galvanostatic testing is typically used for determining the efficiency of sacrificial anodic materials, such as is done in ASTM G 97, Test Method for Laboratory Evaluation of Magnesium Sacrificial Anode Test Specimens for Underground Applications, or NACE Standard RP0387, Metallurgical and Inspection Requirements for Cast Sacrificial Anodes for Offshore Applications.

The most common method of obtaining polarization curves is potentiodynamically. Potentiodynamic testing is described in an earlier section of this manual. For galvanic corrosion, the scan rate for these tests should be as slow as possible, since long-term polarization behavior is usually what is sought in predicting long-term galvanic corrosion behavior.

Potentiostatic polarization curve generation is advantageous for situations where polarization is time-dependent and prediction of long-term galvanic corrosion performance is desired. This involves exposing a series of individual specimens of each material at a variety of different potentials for a duration sufficient to ensure steady-state behavior. The steady-state current at each potential is obtained, and polarization curves constructed from the potential/current data pairs.

Using electrochemical tests to predict galvanic corrosion performance has the same caveats as in any other type of predictive testing. Conditions must be as close as possible to those being modeled. This includes not only solution chemistry and flow, but also the surface condition of the samples. Polished samples can behave quite differently from samples with more representative surface conditions and corrosion products developed by pre-exposure.

More detail on using electrochemical tests for galvanic corrosion can be found in Refs 6 and 7.

## Computer Modeling

Although not a laboratory testing technique, computer modeling is still an important tool in understanding and predicting galvanic corrosion performance. As mentioned above, exposure of scaled components of a galvanic couple leads to scaling problems in that the primary current

distribution cannot be scaled at the same time as the secondary and tertiary current distributions. Computer modeling is usually best for making accurate predictions of the distribution of galvanic corrosion over a structure in which both solution IR drop and polarization behavior both control current distribution. Computer models require the geometry of the structure to be input. Additional inputs include the electrolyte conductivity and the polarization behavior of the surfaces of all materials, usually obtained from laboratory testing. Although finite element analysis and finite difference analysis have both been used to predict distribution of galvanic currents on structures, the boundary element technique is becoming the computer tool of choice. This technique requires only that the surfaces of the structure be defined, whereas the other methods require that the volume of the electrolyte be divided into a three-dimensional grid, a time-consuming and difficult process for complex structures. The disadvantage of the boundary element method is that at present the commercially available software for performing this analysis is not very user-friendly.

### Atmospheric Tests

Unlike galvanic corrosion testing in electrolytes, galvanic corrosion testing in the atmosphere can be standardized because special circumstances exist that limit the number of test variables.

Three factors that are different in atmospheric testing from most other galvanic corrosion testing are the presence of a limited amount of electrolyte, the need for a very long duration of exposure, and the importance of specimen

orientation. Since rainwater and dew are fairly poor electrical conductors, and since they are usually present only as thin layers on the surfaces of materials exposed to the atmosphere, there is a large IR drop between the anode and the cathode in any atmospheric corrosion exposure. This limits the effective distance over which galvanic interactions take place to about 0.5 cm, which in turn means that the effective area ratio of anode to cathode in an atmospheric exposure is almost always about 1:1. The limited electrolyte also makes electrochemical measurements impractical.

Atmospheric corrosion typically occurs only during a small percentage of the total exposure time, typically when the surfaces are wet from precipitation, dew, fog, or when hygroscopic compounds on the surface absorb moisture during periods of high humidity. For this reason, atmospheric corrosion occurs slowly, and long exposure durations are usually necessary. Most tests typically involve minimum durations of 1 to 3 years, with 20 years maximum exposure not unusual. Tests of shorter duration than one year not only have so little corrosion as to make evaluation of mass loss difficult, but also suffer from the effects of seasonal variation of corrosion rate.

Finally, the time that a specimen is wet depends on sunlight heating, prevailing winds, and specimen geometry. Specimen orientation is, therefore, much more critical in atmospheric galvanic corrosion testing. Standard orientations are specified in ASTM G 50 as 30° to the horizontal facing south or the nearest source of corrodent (the sea).

Three standardized atmospheric galvanic corrosion tests are the plate test, the wire-on-bolt test, and the disk test. The plate test, described in ISO Standard ISO7441, Determination

FIG. 13—Plate test assembly for galvanic corrosion testing (redrawn and simplified from ISO 7441).

of Bimetallic Corrosion in Outdoor Exposure Corrosion Tests, consists of a large plate of the anodic material sandwiched between two small plates of the cathodic material and held together with nonmetallic or insulated bolts. Sometimes the crevice area between the plates is coated with an organic material. The two possible configurations are shown in Fig. 13. Typical exposure durations are 1 to 20 years. At the end of this time, the anodic plate may be evaluated metallographically, visually, by mass loss, or by material property loss (typically using tension testing). The advantages of this test are that materials are usually available in plate form, and a wide range of analyses can be used on the exposed panels. The disadvantages include the need to know which material is the anodic beforehand, the long exposure duration, the difficulty of maintaining electrical continuity between panels, and the possibility of confusing crevice effects with galvanic effects. At one time, ASTM also had a standard for this test method, but dropped this standard due to these disadvantages and lack of use.

The wire-on-bolt test, described in ASTM G 116 (Practice for Conducting the Wire-on-Bolt Test for Atmospheric Galvanic Corrosion), has been used with standard materials as an atmospheric corrosivity test under the names of the CLIMAT and ATCORR tests. This test consists of wrapping a 1.0-m length of wire of the anodic material around a threaded bolt or rod of the cathodic material. Post-test evaluation is typically done by mass loss only. Since the wire diameter is much smaller than the 0.5-cm galvanic interaction distance in the atmosphere, the effective anode-to-cathode area ratio is well below 1:1, making this a fast test. A typical exposure duration is 90 days. The short duration is

FIG. 14—Components for making wire-on-bolt atmospheric exposure assemblies (taken from ASTM G 116).

FIG. 15—Schematic of completed wire-on-bolt assemblies mounted for exposure (taken from ASTM G 116).

FIG. 16—Cross section of disk test assembly for atmospheric galvanic corrosion.

a significant advantage to this test. The disadvantages include materials needing to be in wire and threaded rod form, the beforehand knowledge of which material is the anode, and the seasonal variations in exposures of such short duration. A diagram of the sizes and forms of the components needed to construct an assembly is given as Fig. 14, and a completed assembly is shown as Fig. 15.

The disk test, described in Refs 8 and 9 and in ASTM G 149, Practice for Conducting the Washer Test for Atmospheric Galvanic Corrosion, consists of a set of four washers of alternating anodic and cathodic materials of graduated sizes bolted together with an insulated bolt. Only the center two washers are used for the analysis. A cross-sectional assembly view is shown in Fig. 16. The duration of this test is usually 1 to 20 years. Post-test evaluation usually consists only of mass loss. Advantages to this test are that material is usually easy to find, the anodic material need not be known beforehand, and it is easy to set up and evaluate. The disadvantages include the long test duration and the lack of information on corrosion morphology or mechanical property degradation.

## EVALUATION OF TEST RESULTS

### Exposure of Galvanic Couples

If the different materials can be disassembled after testing, mass loss measurements can be performed. In some

cases, loss of strength may also be of interest. If disassembly is not possible, the specimens may still be examined for pitting, cracking, color and extent of corrosion products, and, in some geometries, thickness loss. Mass loss of an assembly may still be useful if corrosion of the cathode was minimal. After exposure, destructive techniques such as metallographic examination may also provide information about the extent and morphology of corrosion. Useful standards for cleaning samples after immersion and evaluating mass loss, pitting, and degradation in properties are ASTM G 1, G 46,<sup>3</sup> and G 71. Applying the results of a set of measurements designed to generate a galvanic series is described in ASTM G 82.

### Electrochemical Tests

When the potentials of two materials in a galvanic couple are widely separated, Faraday's Law can be used to calculate the galvanic corrosion rate from the galvanic current measured between them. This calculation can be done by the procedures in ASTM G 102.

Overlaying of polarization curves of the different materials in a galvanic couple must be done by first converting the current densities into total currents by multiplying the polarization curves by the exposed wetted surface area for each material. The curves then may be overlaid, and if IR drop is not important, the couple current and potential may be predicted. If the coupled potential deviates by 50–100 mV from the open-circuit potential of the anode, then the current may be converted by Faraday's Law into a corrosion rate. If the coupled potential deviates by less than 50–100 mV from the open-circuit potential of the anode, then it is conservative to add the open-circuit corrosion rate of the anode to the corrosion rate calculated from Faraday's Law to get the total anodic corrosion rate. Neither of these methods is exactly accurate, but both will give a reasonable approximation to the true corrosion rate of the anode in the couple.

If the polarization curve for the anode is known, the coupled potential may be measured to predict corrosion performance. The couple current is the current on the anodic material polarization curve at the measured coupled potential. Corrosion rate may be calculated from the couple current determined in the same way as in the previous paragraph.

### Computer Modeling

Interpretation of results from computer models is straightforward, since the results are usually potential maps that can be related back to current density maps by using the polarization curves of the appropriate materials, or the current density maps, themselves. Faraday's Law can be applied to the current densities to determine the corrosion rates over the various surfaces. The results of this type of analysis always look good intuitively, with the potential

profiles deviating in the right places in the right directions. This does not mean that the answer is correct, however. Discontinuities in potentials between adjacent areas could be caused by discretization error, resulting from the selection of boundary elements that are too big. The analysis should always be checked to ensure that the total anodic and cathodic currents are equal. Inequality could mean a lack of mathematical convergence of the model. The most important check on the results of a computer model occurs before the model is ever run. The input polarization curves must be accurate in order for the model predictions to be meaningful. Model results should be spot-checked against the real structure whenever possible.

### Atmospheric Tests

Only mass loss information is obtained from the standard atmospheric galvanic corrosion tests, with the exception of the plate test. The plate test specimens can also be evaluated by metallography, visual examination, probe-type attack depth gages, or mechanical tests such as tensile strength.

## STANDARDS

Laboratory testing for galvanic corrosion involves so many variables that it is difficult to write a single standardized test. For this reason, there are no standardized laboratory testing procedures specifically for galvanic corrosion. If another form of corrosion is being studied, then a slight modification to a standardized test for that corrosion form may be used. For example, to study galvanically accelerated stress corrosion testing, ASTM G 30, Practice for Making and Using U-Bend Stress-Corrosion Test Specimens, may be used, adding only a wire between the specimen and a second material to create the galvanic couple. To study the breaking strength of a piece of metal, a standard mechanical pull test such as that found in ASTM E 8, Test Methods for Tension Testing of Metallic Materials, may be used. To study the effect of galvanic corrosion on breaking strength, the same test may be used on pieces of metal after exposure to the environment of interest, both with and without galvanic coupling to a second material. Subtracting the strength of the metal with galvanic coupling from that without it will give the effect due to galvanic corrosion. There are two guidelines for galvanic corrosion testing published by ASTM: ASTM G 71 and G 82. Specific test standards for atmospheric galvanic corrosion can be found in ASTM G 116 and G 149, and ISO 7441, as described above.

## ADDITIONAL INFORMATION

Additional information and details of galvanic corrosion testing are available in the standards referred to above and in Refs 10 and 11. Additional information on the theory of galvanic corrosion is available in Refs 12 to 22. A good series of articles summarizing galvanic corrosion theory and application in various industries is available in Ref 23. Galvanic corrosion testing descriptions are written at the level of a corrosion technician in Ref 11.

# Intergranular

Michael A. Streicher<sup>1</sup>

THERMAL EXPOSURES, such as during welding, fabrication, and faulty heat treatment, can change the composition of grain boundaries of metals and alloys by equilibrium segregation of impurities and/or alloying elements and, most frequently, by the formation of precipitates, such as chromium carbides in stainless steels. These changes can make the grain boundaries susceptible to rapid, preferential attack (sensitization) in many, mostly acid, environments in which the materials are otherwise considered to have an acceptable degree of corrosion resistance for industrial purposes. The materials of construction most widely used for severely corrosive applications and which may also be subject to sensitization are the numerous iron-base austenitic and ferritic stainless steels and certain nickel-rich alloys with chromium or chromium and molybdenum.

Since 1926, a large variety of tests has been developed to detect susceptibility to intergranular attack in these materials and thereby to investigate this phenomenon, monitor production procedures, screen for plant use as acceptance tests, analyze plant failures, and develop improved and new alloy compositions. The first of these tests to be incorporated in the ASTM Book of Standards for detecting and quantitatively measuring susceptibility to intergranular attack in some austenitic and ferritic stainless steels was the boiling, 65 % nitric acid test, ASTM A 262<sup>2</sup>, in 1943. Five other standard practices have since then been added to ASTM A 262, and one of them has been removed. Thus, there are now five tests deployed for testing 19 wrought and cast austenitic stainless steel compositions. In 1971, the boiling 50 % sulfuric acid-ferric sulfate test, which was one of the five tests added to ASTM A 262, was also specified for application to 13 Ni-Cr and Ni-Cr-Mo alloys in a new standard, ASTM G 28<sup>3</sup>, along with a second test for three of these alloys. In 1979, a separate standard with four test methods was devised for a group of twelve old and new ferritic stainless steels, ASTM A 763<sup>4</sup>. Most recently, a standard

for an electrochemical method for detecting quantitatively mild degrees of sensitization in Types 304 and 304L has been developed, ASTM G 108<sup>5</sup>.

The following discussion on testing for detecting susceptibility to intergranular attack is limited to the tests included in the above four ASTM standards for stainless alloys. The only other ASTM standards on intergranular corrosion testing, ASTM G 67<sup>6</sup> and G 110<sup>7</sup>, are for certain aluminum alloys. These two tests are discussed in the chapter by Lifka in this manual.

## BASIC PRINCIPLES [1]<sup>8</sup>

Metals and alloys generally consist of agglomerations of variously oriented, individual crystals or grains. At the boundaries between these crystals, lattices of different orientations meet and zones of less perfect structure are formed whose properties depend, in part, on the relative orientations of the adjacent grains. Two properties of these boundary zones are of particular importance in corrosion. Small amounts of impurities in solid solution in metals and alloys may segregate at grain boundaries while remaining in solid solution, defined as equilibrium segregation [2]. In addition, precipitates, which form during heat treatments in some alloys, frequently nucleate more readily at or within the boundaries. Thus, as a result of structural imperfections, the chemical composition and, consequently, the electrochemical properties and the corrosion resistance of grain boundaries may be appreciably different from those of the interior of grains. It is apparent that the surfaces of metals consist of a two-dimensional network of such grain-boundary zones which surrounds cross sections through variously oriented grain interiors of greater structural perfection.

<sup>8</sup>Text by the author within this section is reprinted with permission from Van Nostrand Reinhold, New York, NY.

Intergranular attack on these surfaces may range from light etching of grain boundaries, which merely outlines the granular structure, to rapid penetration, which may lead to loss of mechanical strength or even a residue of completely separated grains, "sugaring." Whether corrosion is predominantly by intergranular or by general attack depends on the difference between the rate of corrosion of the grain-boundary zones and that of the grain faces. This difference in rates is determined not only by the metallurgical structure and composition of the boundary but also by the characteristics of the corroding solution.

Surprisingly, even in cases of pronounced intergranular attack, the rate of grain-face corrosion plays an important role. The grain-boundary zone along which there is rapid intergranular penetration is usually very narrow. As a result, even though grain boundaries have all been dissolved, the grains tend to remain linked together and do not drop out of the surface of the metal. However, if there is also some appreciable grain-face corrosion, the narrow groove formed by intergranular penetration is gradually widened by corrosion of the grain faces making up the walls of the grooves and grains drop out readily. In addition, the size of the grains determines how much time is required to undermine and dislodge a grain. Small (and in the first layer, sectioned) grains drop out sooner than large grains. Because of these factors—the ratio of intergranular to grain-face corrosion and the grain size—the results of quantitative measurements of intergranular corrosion depend not only on the type of solution that causes intergranular attack, but also on the method used for the measurement.

Measurements of changes in electrical resistance clearly show the reduction in effective cross section of the corroding metal, even when the undermined grains remain in place. In contrast, weight-loss determinations depend on undermining and dropping-out of grains. Therefore, the two methods provide identical results only on metals corroding in solutions in which there is sufficient grain-face corrosion to lead to ready removal of undermined grains. Specific examples of various types of intergranular corrosion and of different techniques of measurement are described below.

The effect of grain-boundary imperfections on intergranular attack is illustrated by the attack of hydrochloric acid on high-purity (99.998 %) aluminum (Fig. 1). Corrosion varies with the curvature of the boundary. Corrosion may be intensified by equilibrium segregation of traces of iron and/or copper impurity in zones at the boundary with high concentrations of imperfections. For example, corrosion of aluminum in hydrochloric acid is increased by a factor of 1000 in the presence of 0.03 % iron [3].

Intergranular corrosion associated with precipitates is clearly observed on 18Cr-8Ni stainless steels. Upon heating in the range of 1000–1700°F (538–927°C), a precipitate of chromium carbide forms preferentially at grain boundaries in steels containing about 0.02 %, or more, carbon (sensitization). Its presence can be readily detected by metallographic examination. Because of the industrial importance of these steels, their susceptibility to intergranular corrosion has been investigated extensively, and a number of rapid methods for detecting susceptibility to intergranular attack has been developed [4–6].

**FIG. 1—Intergranular attack on pure aluminum (250×). Attack of 20 % solution of hydrochloric acid on 99.9998 % aluminum specimen at 25°C.**

A solution of boiling 50 % sulfuric acid containing ferric sulfate as a passivating inhibitor is used for one of these evaluation tests. Typical weight-loss data obtained on two specimens of the same 18Cr-8Ni steel are plotted in Fig. 2. One of these specimens is free of chromium carbides and has a low, constant rate of corrosion. In contrast, the corrosion rate (slope of the curve) of the other specimen, which had been previously heated to produce profuse precipitation of chromium carbides at grain boundaries, increases rapidly because of intensive dropping of grains. An early phase of this intergranular attack is shown in Fig. 3.

**FIG. 2—Corrosion of stainless steel in ferric sulfate-sulfuric acid solution. Effect of carbide precipitation in 18Cr-8Ni steel on corrosion in boiling 50 % sulfuric acid containing ferric sulfate inhibitor. Sensitized: chromium carbide precipitate at grain boundaries. Annealed: no intergranular precipitate, all carbides dissolved in solid solution.**

FIG. 3—Intergranular attack on stainless steel (500 $\times$ ). Initial stages of corrosion in boiling 50 % sulfuric acid containing ferric sulfate. Steel was sensitized and shows some grain face corrosion and rapid intergranular attack which has undermined and dislodged several grains.

Differences in the type of intergranular corrosion produced on identical, sensitized specimens of 18Cr-8Ni steel in various acid solutions are shown in Fig. 4. Measurements of weight loss and of the corresponding increase in electrical resistance are plotted for intergranular corrosion in three boiling solutions: (1) sulfuric acid containing ferric sulfate inhibitor, (2) sulfuric acid containing copper sulfate inhibitor, and (3) nitric acid. The dotted line shows the relationship of weight loss and change of resistance on a specimen corroding uniformly (no intergranular attack). For a given change in resistance (i.e., penetration of intergranular attack) the weight loss is lowest in the copper sulfate-sulfuric

FIG. 4—Comparison of intergranular corrosion in various acid solutions. Measurement of weight-loss and change in electrical resistance on sensitized stainless steel corroding in boiling 65 % nitric acid, and boiling sulfuric acid solutions containing cupric or ferric sulfate. Specimen: 0.15 by 0.60 cm in cross section.

FIG. 5—Local cell polarization on grain faces and boundaries of corroding stainless steel. In ferric sulfate-sulfuric acid solutions grain faces and grain boundaries are both polarized to the oxidation-reduction potential of the solution. The corrosion current at corroding boundaries is greater than that on grain faces.

acid solution and highest in the nitric acid solution. As expected, in all cases the weight loss is lower than on a uniformly corroding metal because some of the grains adhere even though they have been undermined. The reason for these differences is that the ratio of intergranular penetration to grain-face corrosion is different for each solution. It is highest for the copper sulfate-sulfuric acid solution because of the very low rate of grain-face corrosion and lowest in the nitric acid because of the high rate of grain-face corrosion.

Electrochemical measurements [6] show that in nitric acid and in sulfuric acid solutions inhibited with cupric or ferric salts the grain faces and the grain boundaries containing chromium carbide precipitate are both passive. This passive state is a dynamic condition in which there is continual dissolution (breakdown) and re-formation (repair) of a protective, passive film by a reaction between the dissolving metal and the corroding solution. The weight loss of stainless steel actually dissolved in sulfuric acid-ferric sulfate solutions is electrochemically equivalent to the weight of ferric ions reduced. There is no evolution of hydrogen gas, even on rapidly corroding grain boundaries. However, at these boundaries the corrosion current (metal dissolution) required to keep the film in repair, and, thereby, to polarize the boundaries to the same passive potential as the grain faces, is much greater (Fig. 5). The reason for this is that precipitation of chromium carbides (Cr<sub>23</sub>C<sub>6</sub>) at boundaries greatly depletes adjacent metal in chromium.

Variations in the composition of grain boundaries of 18Cr-8Ni stainless steel containing 2-3 % molybdenum may also be caused by precipitation of sigma phase, a chromium- and molybdenum-rich constituent. This precipitate forms during heating in the range of 1000-1600°F (538-871°C). In some cases there may merely be a form of "equilibrium segregation," which is not visible in the microstructure when examined by light or electron microscopy [7]. Nevertheless, such steels are rapidly attacked at grain boundaries by nitric acid, even in the absence of any

chromium carbides. Because sigma phase may not be visible in the microstructure, exposure to nitric acid solution provides a simple method whereby this change in metallurgical structure may be detected.

## DETECTING SUSCEPTIBILITY TO INTERGRANULAR ATTACK IN STAINLESS ALLOYS<sup>9</sup>

A large group of these iron-base alloys (Tables 1 and 2) has been found to be susceptible to rapid intergranular attack in a wide range of plant environments when the compositions at the grain boundaries have been changed by equilibrium segregation of alloying elements and especially by the precipitation of chromium carbides and nitrides, the formation of separate intermetallic phases (e.g., sigma or mu-phase), and molybdenum carbides. These changes are a result of exposures of the alloys during production of mill forms (rods, plates, sheet, tubes) to temperatures at which solid state reactions occur preferentially at grain boundaries. Because welding operations are used in the production of tubes from sheet and during shop fabrication and field

erection, there are further opportunities for the exposure of alloys in the range of temperatures which may result in the formation of deleterious phases at grain boundaries.

An example of weld effects is shown in Fig. 6. Four different 18Cr-8Ni stainless steel panels were joined by welding and were then immersed in a solution of nitric-hydrofluoric acids. This solution produces rapid attack on grain boundaries containing chromium-rich carbide precipitates, which are surrounded by chromium-depleted zones. The attack is similar to that shown in Fig. 3. Dislodgement of grains in the weld-decay zones leads to the formation of grooves on both sides of the panel of Type 304 (about 0.06 % C) steel that are parallel, but not adjacent to the weld bead. If immersion had been continued, the panel would have dropped off from the assembly.

The absence of intergranular attack on the rest of the Type 304 panel shows that the original sheet had been properly annealed (1066°C, 1950°F) at the mill and had been rapidly cooled (quenched) from the annealing temperature through the range of 871–427°C (1600–800°F). This is the range of temperatures in which chromium carbides might form most readily. During welding, the temperatures of the metal in the zone adjacent to the molten zones were raised well above the chromium carbide precipitation range and were cooled rapidly enough to prevent carbide precipitation. But in the weld-decay zone, the base-metal was exposed long enough in the precipitation range, with a maximum rate of precipitation near 677°C (1250°F), so that there was profuse formation of carbides which made this zone susceptible to rapid intergranular attack.

<sup>9</sup>The term *stainless alloys* includes the austenitic and ferritic stainless steels with 12 % or more chromium and certain austenitic nickel-rich chromium-bearing alloys. From this section through the discussion on the oxalic acid etch test, the text is an update and condensation of material in Ref 9. <sup>a</sup>Types 430, 434, 436, and 446 are nonstabilized grades that are generally not used in the as-welded or sensitized condition in other than mildly corrosive environments. In the annealed condition, they are not subject to intergranular corrosion. For any studies of IGA on Types 430, 434, 436, or 446, the indicated test methods are suggested.

<sup>b</sup>Nickel plus copper.

<sup>c</sup>Carbon plus nitrogen = 0.025 max.

**FIG. 6—Weld decay and methods for its prevention. The four different panels were joined by welding and then exposed to a hot solution of nitric-hydrofluoric acids. The weld decay, such as shown in Type 304 steel, is prevented by reduction of the carbon content (Type 304L) or stabilization of carbon with titanium (Type 304L) or niobium (Type 347).**

Weld-decay zones can be prevented by reducing the carbon content to less than 0.03 % (Type 304L)<sup>10</sup> or by addition of “stabilizing” elements, titanium or niobium. By heating such stabilized alloys near 900°C (1650°F), most of the carbon reacts to form “harmless” titanium and niobium carbides, and, as a result, the formation of chromium carbides is prevented during exposure in the range of 871–427°C (1600–800°F).

In ferritic stainless steels, such as Types 430 and 446 (Table 2), diffusion rates of carbon and chromium are much higher than in the nickel-bearing, austenitic alloys, e.g., Type 304. As a result, the precipitation of chromium carbides is so rapid that it cannot be prevented even during water-quenching of small specimens in water from annealing temperatures. Such specimens have extensive amounts of precipitates at grain boundaries and are, therefore, sensitized. However, because of the high rate of diffusion of chromium, a heat treatment at 1500°F (816°C) will diffuse chromium into the depleted zones around the chromium-rich carbide precipitates and will thereby eliminate sensitization, i.e., make the material resistant to intergranular attack even though the grain boundaries still contain chromium carbides. (Because of the much lower rate of diffusion in the austenitic alloys, and, consequently, the long heat treatments required, elimination of sensitization by rediffusion of chromium into depleted zones is not practical.)

<sup>10</sup>By argon-oxygen decarburization (AOD) the carbon content of commercial heats of 304L can now be reduced consistently to 0.01 %. AOD and vacuum induction melting are used to produce the new high-purity Fe-Cr-Mo ferritic stainless steels in Table 2.

All of the alloys listed in Tables 1 and 2 may become sensitized; that is, form various precipitates at grain boundaries when exposed to certain temperatures and thereby become subject to intergranular attack. Chromium-rich carbides are the most common precipitates in the alloys of Tables 1 and 2, except in the Ni-Cr-Mo alloys in which molybdenum carbide is formed. All of the evaluation tests discussed below detect susceptibility to intergranular attack associated with chromium and molybdenum carbide precipitates.

The stainless steels in Table 1 containing molybdenum (Types 316, 317, 316L, and 317L) may also contain molybdenum-rich sigma phase. Furthermore, the nickel-rich alloys with molybdenum in Table 1 may form an intermetallic, molybdenum-rich compound, mu-phase. When these phases are present at grain boundaries, even in some cases as a preprecipitation form (i.e., not visible in the microstructure, see above in the previous section), they may also lead to intergranular attack, but only in certain oxidizing solutions, for example, boiling 65 % nitric acid in which the redox potential (the potential of a platinized platinum electrode) is about +1.0 V versus SCE. In the 50 % sulfuric acid test with ferric sulfate (redox potential +0.6 V versus SCE) only mu-phase, which may be present in Ni-Cr-Mo alloys (C, C-276, and C-4) causes susceptibility to intergranular attack, but not sigma-phase in Types 316, 316L, 317, and 317L stainless steels. Alloys 625 and 825 also contain molybdenum that can in some cases lead to phases that increase corrosion rates in oxidizing (especially nitric acid) solutions.

Precipitates at grain boundaries may make the costly alloys of Tables 1 and 2 subject to intergranular corrosion in a very wide range of mostly acid plant environments in the chemical process industries, as well as pulp and paper, food processing, and petroleum refining plants. A number of solutions that have resulted in intergranular attack on sensitized austenitic stainless steels is given in Table 3. These solutions range from highly reducing (−0.6 V versus SCE) redox potentials, e.g., in sulfuric acid, to highly oxidizing (+1.0 V versus SCE) in nitric acid. Under severe conditions, i.e., higher concentrations and temperatures, many of these solutions may also produce intergranular attack in the nickel-rich, chromium-bearing alloys of Table 1, e.g., sulfuric, hydrochloric, chromic, and nitric acids.

Chromium and molybdenum carbide precipitates have also been found to result in susceptibility to other forms of corrosion. Some examples are stress accelerated intergranular attack on Type 304 and alloy 600 in polythionic acid and stress corrosion cracking (SCC) of ferritic stainless steels, such as Type 446 in boiling sodium chloride with 50 ppm Cl<sup>−</sup>. Molybdenum carbide precipitates make alloys C and C-276 subject to stress corrosion in boiling 45 % magnesium chloride solution, and to crevice attack in ferric chloride. Finally, sensitization of Type 304 stainless steel during circumferential welding to join pipe segments has made the heat affected zones, which run parallel to these welds, subject to intergranular stress corrosion cracking (IGSCC) on boiling water nuclear plants. The pipes contain water at 289°C and crack when the concentration of oxygen is in the range of 0.2–8 ppm. Cracks have been found in pipes from 4 to over 30 in. (10.2 to over 76.2 cm) diameter on many plants, which has necessitated costly replacement operations [9].

## ORIGIN OF EVALUATION TESTS

The first laboratory tests for detecting susceptibility to intergranular attack were simulated service tests. In 1926, Hatfield [10] observed intergranular attack on an austenitic stainless steel used for a pickling tank containing sulfuric acid and some copper sulfate. To prevent the selection of material that might be susceptible to intergranular corrosion for this service, he used an 8 % sulfuric acid solution containing copper sulfate to evaluate steels before use. By 1930, Hatfield's test solution was being used to investigate intergranular corrosion and to develop methods for overcoming this problem. Strauss et al. [11] and Aborn and Bain [12] established that the cause of intergranular attack is the precipitation of chromium carbides,  $(\text{Cr,Fe})_{23}\text{C}_6$ , at grain boundaries. Because these chromium-rich precipitates are surrounded by metal that is depleted in chromium, there is more rapid attack at these zones than on undepleted metal surfaces.

## 65 % NITRIC ACID TEST

In 1930, Huey [4] described another simulated service test used at the Du Pont Co. since 1927 to quantitatively detect variations in the performance of iron-12 to 18 % chromium alloys intended for service in nitric acid plants. For rapid results, he selected a concentrated solution of 65 % nitric acid, which is near the constant boiling concentration of 68.5 %. Five 48-h periods, each with fresh acid solution, were proposed. Fresh solutions are needed to minimize the effect of corrosion products as described below. The weight

loss was converted to a corrosion rate. A glass flask fitted with a reflux condenser via a ground glass joint was specified. Later, the less costly cold finger condenser (Fig. 7) was used at many laboratories, apparently without recognition that this change in condensers lowers corrosion rates, by keeping the concentration of hexavalent corrosion products at relatively low levels [13,14].

Hexavalent chromium greatly increases both general and intergranular corrosion. It is formed when stainless steel dissolves in hot, concentrated nitric acid as divalent chromium ions (blue), which are then oxidized by nitrate ions to the trivalent (green) and then the hexavalent (orange) state. Concurrently, nitric oxide gas (NO) is formed. When this is absorbed in the cold condensate on the surfaces of the condensers and thereby recirculated into the boiling nitric acid solution it reduces the hexavalent ions to the tri- and divalent states. The cold finger condenser provides a more efficient method for recirculating nitric oxide than the Allihn or drip-tip condenser. (Contact of nitric oxide gas (colorless) with air (oxygen) results in nitrogen dioxide ( $\text{NO}_2$ , brown.) The latter also reduces hexavalent chromium ions) [14].

It was soon found that among the variables affecting corrosion rates were certain heat treatments that made not only the ferritic stainless steels subject to intergranular attack, but also the austenitic, 18Cr-8Ni alloys. From this simulated service test in boiling 65 % nitric acid, there evolved Practice C of ASTM A 262. Its large-scale use by one

of the first and largest purchasers of stainless steels, the Du Pont Co., made it the leading method for acceptance testing of stainless steels for many years in the United States.

## COPPER SULFATE-SULFURIC ACID TESTS

In England and Germany, the copper sulfate test with sulfuric acid has been the most frequently used. Evaluation in this test is qualitative by examination for fissures (cracks) on the test specimen, which is bent after exposure to the test solution. In the United States, this test was not standardized by ASTM until 1955. ASTM A 393, which later became A 708, Practice for Detection of Susceptibility to Intergranular Corrosion in Severely Sensitized Austenitic Stainless Steel, specified a solution of 6 % anhydrous copper sulfate and 16 % sulfuric acid, by weight. Evaluation of results after only 72 h of testing was also done by bending the tested specimen over a mandrel and examining the outer surface for fissures. In this short form, the test was useful only for detecting very severe cases of sensitization. This limitation, along with the qualitative nature of evaluation, greatly limited the usefulness of this form of the copper sulfate-sulfuric acid test. It eventually resulted in the removal of ASTM A 708 from the ASTM Book of Standards because several other tests can detect severe cases of sensitization as well as mild and medium conditions of sensitization.

In Germany, the rate of intergranular attack in this solution has been greatly increased by Rocha [15] since 1950. He added zinc dust to precipitate metallic copper and later simply embedded the stainless steel specimens in metallic copper chips or shot. This has the effect of changing the corrosion potential of the test specimen in the less noble direction to that of the metallic copper and thereby reducing the testing time from 200 to less than 48 h.

Quantitative measurements of the effect of metallic copper in the copper sulfate-sulfuric acid solution on intergranular attack were reported in 1959 [6]. Three types of tests were made in flasks with cold finger or pine cone condensers (Fig. 7): (a) without metallic copper, (b) with a specimen of copper not in contact with the stainless steel specimen, and (c) with copper (turnings) in contact with the stainless steel specimen. Results are shown in Fig. 8. Simultaneous immersion of a copper specimen increased the rate of corrosion on a sensitized Type 316 specimen by a factor of 8 in a 200-h test period. Contact of the stainless steel with the copper increased this factor to 34.

The three electrode potentials plotted in Fig. 9 provide data on the changes taking place in the cupric sulfate-sulfuric acid solutions during these tests in a flask with a finger condenser. As in the case of ferric ions, cupric ions make stainless steels passive in sulfuric acid. Measurements on the platinized platinum electrode give the oxidation-reduction potential of the solution. The potentials on the stainless steel and the copper specimens are the corrosion potentials of these materials. In the presence of the stainless steel specimen whose corrosion potential is constant, there is a gradual decrease (change in the active direction) in the redox potential of the solution resulting from the formation of cuprous ions on the surface of the specimen.

FIG. 8—Corrosion of sensitized Type 316 steel in boiling copper sulfate-sulfuric acid solution. Specimen: 17.4 Cr; 12.7 Ni; 1.89 Mo; 0.053 C. Heated 1 h at 677°C. Solution: 15.7 % sulfuric acid with 5.7 % anhydrous copper sulfate.

This produces a change in the relative concentrations of cupric and cuprous ions. The rate of this change is greatly increased by the addition of metallic copper (40 cm<sup>2</sup> surface area in 600 mL) whose dissolution is governed by the rate of the cathodic reaction:

Within an hour in boiling solutions, the potentials of the stainless steel and of the platinized platinum electrode become constant at +0.13 V versus SCE; that is, the stainless steel assumes the redox potential which remains constant at a relatively low potential. However, the corrosion potential of the copper specimen is even lower, and when contact is made between the stainless steel specimen and the copper, the steel assumes the potential of the copper. The redox

Z	Copper Sulfate 16% Sulfuric Acid with metallic copper	boiling	24 h	17–18% Cr	Check for fissures in bend test

potential (platinum electrode) remains unchanged. Reversing these steps, that is, breaking contact and removing the metallic copper, reverses the potential changes. The potentials of the platinized platinum and the stainless steel move in the noble direction. Thus, in tests with finger condensers there must be contact between the copper and the stainless steel test specimen to obtain reproducible and maximum corrosion rates.

In contrast, when a flask with an Allihn condenser (Fig. 7) is used, it is unnecessary to have physical (electrical) contact

between the copper and the stainless steel specimen. The corrosion rate is the same for the "no contact" and the "contact" tests [9]. This difference in the performance of the two condenser systems is caused by the greater concentration of oxygen from air in the condensate from the cold finger condenser as compared with that coming from the Allihn condenser [9].

Two versions of the copper sulfate test are now included in the ASTM standards (Tables 4–6). For both versions, Allihn condensers and the addition of metallic copper are

specified. In ASTM A 262, Practice E, the 6 % copper sulfate–16 % sulfuric acid test is specified for austenitic stainless steels. The specimen is to be embedded in copper shot or turnings. (However, as mentioned above, with the Allihn condenser it is not really necessary to make contact between the stainless steel specimen and the copper metal.) Evaluation of results after 24 h is by examination for fissures on a bent specimen. The same test method is also specified for certain ferritic stainless steels in ASTM A 763 as Practice Z. (This method is favored by the petroleum industry where the concern is IGSCC in polythionic acid.)

ASTM A 763 also includes a copper sulfate 50 % sulfuric acid test with metallic copper and an Allihn condenser, Practice Y. In place of copper shot or turnings, a copper specimen (2.5 by 2.5 cm) is immersed in a second glass cradle. Thus, there is no contact between it and the specimen. The use of 50 % sulfuric acid for the 120-h test on higher chromium (25–29 %) ferritic stainless steels increases the rate on sensitized specimens so that weight-loss can be used as a quantitative method of evaluation in addition to bending for fissures and microscopic examination for evidence of dropped grains (Table 4). The use of 50 % sulfuric acid was taken over from the boiling 50 % sulfuric acid ferric sulfate test [16].

## FERRIC SULFATE-50 % SULFURIC ACID TEST

This test solution was introduced in 1958 [17] to reduce the 240-h testing time of the boiling 65 % nitric acid test to 120 h and to limit intergranular attack to grain boundaries containing chromium carbides. As mentioned above, the nitric acid test also causes intergranular attack on austenitic, molybdenum-bearing stainless steels containing sigma-phase in Types 316, 316L, 317, and 317L. The ferric sulfate test was the first test that was not derived from a plant service problem. The oxalic acid etch test (described below), which is used as a screening test, had already established the concept (1953) that all of the evaluation tests were simply a means for determining the presence and degree of sensitization, i.e., whether or not a given stainless alloy had been made susceptible to intergranular attack in certain chemical solutions by faulty heat treatments or welding. They do not predict service life in the way that the results of a simulated service test might be used. Although the nitric acid and the copper sulfate tests were originally derived from simulated service tests, they became tools for providing information on the presence and extent of damaging precipitates at grain boundaries [13].

Allihn condensers are specified for the ferric sulfate test (Figs. 7 and 10). However, this is not an essential requirement. Other condensers can be used. Also, because corrosion products do not affect the rate of corrosion, there is no need to change the solution during the 120-h test period and several specimens may be tested in the same flask. The only requirement is that the ferric sulfate inhibitor, which is consumed during the inhibition process, must be replenished in proportion to the total amount of metal dissolved from the test specimen. This is in contrast to the 240-h 65 % nitric acid test in flasks for which the solution must be changed

FIG. 10—Apparatus for ferric sulfate-sulfuric acid test.

every 48 h to avoid the buildup of chromium ion corrosion product for reasons described above. The ferric sulfate-50 % sulfuric acid test has been standardized for use on austenitic (Table 5) and ferritic (Table 6) stainless steels, as well as Ni-base alloys (Table 7).

Table 8 provides a summary of the redox potentials of various tests for austenitic and ferritic stainless steels. Because both carbides and molybdenum-rich sigma-phase may result in intergranular attack in highly oxidizing solutions, the nitric acid test should be specified for materials to be used in nitric acid or other highly oxidizing environments.

## OXALIC ACID ETCH TEST

The gradual introduction of various new stainless steels, as well as a variety of evaluation tests, has resulted in a relatively large numbers of ASTM test methods, and, consequently, a rather involved set of choices to be made for a specific evaluation procedure. Sometimes a short testing time is a prime requirement. The original 65 % nitric acid

<sup>a</sup>The potential of the specimen in the oxalic acid etch test while being anodically etched at 1A/cm<sup>2</sup> is 1.7 V vs calomel scale. In austenitic stainless steels only chromium carbides are detected and sigma phase when present as a second phase; also in stabilized ferritic stainless steels.

<sup>b</sup>There is some effect of sigma phase in Type 321 steel.

<sup>c</sup>In unstabilized Fe-Cr-Mo alloys (29Cr-4Mo and 29Cr-4Mo-2Ni) sigma- and chi-phases do not cause intergranular attack.

test took 240 h of actual testing time, plus the preparation of fresh solutions for each of the five 48 h test periods. In addition, specimen preparation, shipping, and calculations resulted in a total delay of as much as three weeks for test results. This provided the motivation for the introduction and acceptance of the oxalic acid etch test for screening specimens by classifying microstructures [18]. These are obtained simply by making a polished surface anodic in 10 % oxalic acid solution for 1.5 min with a current density of 1.0 amp/cm<sup>2</sup>. This results in an "over etch" which facilitates interpretation. On specimens that are free of chromium carbides at grain boundaries the different rates of dissolution of variously oriented metal grains results in steps between grain (Fig. 11, Step Structure). When the boundaries contain enough carbides to surround completely at least one grain there can be expected to be undermining of grains in the boiling acid tests and an increase in the corrosion rate with testing time (Fig. 12, Ditch Structure). When the ditching does not surround grains completely the classification is Dual Structure (Fig. 13).

Specimens with step and dual structures do not drop grains in boiling acid tests, and therefore have acceptable or "passing" corrosion rates in weight-loss tests. Materials represented by such specimens can therefore be accepted for plant use on the basis of the 1.5 min oxalic acid etch test. Only those materials that have a ditch structure must be submitted for testing in the hot acid tests to determine whether or not their corrosion rates fall below or above the acceptance rate for the given alloy.

Type 304 and especially Type 304L are now by far the steels produced in the largest quantity. During the last 15 years all producers have switched to argon-oxygen refining. This makes it possible to keep the carbon content of Type 304L in the range of 0.01–0.02 %. Low carbon grades are used specifically for materials that will be welded (tubes, shop and field fabrication). To anticipate welding effects, specimens of Types 304L and 316L are heated for 1 h at 677°C (1250°F) before corrosion testing. Before the introduction of argon-oxygen refining, low-carbon alloys had carbon contents between 0.02 and 0.03 %, and in these the

FIG. 11—Oxalic acid etch (500 $\times$ ). Step structure. Etched 1 A/cm<sup>2</sup> for 1.5 min.

FIG. 12—Oxalic acid etch (500 $\times$ ). Ditch structure. Etched 1 A/cm<sup>2</sup> for 1.5 min.

FIG. 13—Oxalic acid etch (250 $\times$ ). Dual structure. Etched 1 A/cm<sup>2</sup> for 1.5 min.

heat treatment at 677°C resulted in more carbides than the newer heats with 0.01 to 0.02 % carbon. The result is that an ever larger proportion of low-carbon heats can now be

screened by the oxalic acid etch test from the hot acid tests after the heat treatment of 1 h at 677°C (1250°F).

The oxalic acid etch test has been incorporated as Practice A in ASTM A 262 for screening a large number of wrought and cast austenitic stainless steels. It has also been included in ASTM A 763 for screening of stabilized ferritic stainless steels, Practice W (Table 6).

## NITRIC-HYDROFLUORIC ACID TEST

The 10 % nitric-3 % hydrofluoric acid test at 70°C (Practice D in ASTM A 262) was developed into a quantitative, 4 h method specifically for Types 316 and 316L material to detect sensitization associated only with chromium carbide precipitates, and not with that caused by sigma phase (Table 5) [19]. Because hydrofluoric acid attacks glassware, special apparatus is required made of polyvinyl chloride. For this reason and because of the unique hazards involved in handling hydrofluoric acid, this test has never been used widely. It was found recently that it was not being used at all and was, therefore, removed from ASTM A 262 in 1993. There are several other tests that accomplish the same objectives: the ferric and the cooper sulfate tests with the oxalic acid etch test as a screening method. A large percentage of Types 316 and 316L can be "accepted" without further testing in boiling acid tests, even after heating Type 316L specimens for 1 h at 677°C (1250°F) in the case of material to be welded. This percentage is even higher for 316L than for 304L because the 2.5 % molybdenum in Type 316L retards formation of chromium carbides.

## EPR TESTS

### Single Loop (SL)

The failures by SCC of welded Type 304 piping exposed to water at 289°C with 0.2–8 ppm of oxygen on boiling water nuclear power plants created a demand for a nondestructive method for detecting quantitatively the degrees of sensitization in these pipes. A nondestructive method was needed so that measurements could be made directly on the heat-affected zones of pipes on the plants. For this purpose, Clarke et al. [20] selected and applied the electrochemical potentiokinetic reactivation (EPR) technique. A cell was designed that could be attached to pipes.

This EPR method has now been incorporated in the ASTM Book of Standards as a laboratory test, ASTM G 1085. A mounted and highly polished specimen of Type 304 or 304L material is polarized in a special cell from its corrosion potential of about -400 mV versus SCE to a passive potential of +200 mV versus SCE and then reactivated to the corrosion potential at rates of 6 V per h (Fig. 14). During this sweep the total charge (area under the curve) passing through the cell (coulombs) is measured. The counter-electrode is a graphite rod and the solution consists of 0.5M sulfuric acid with 0.01M potassium thiocyanide. The temperature must be controlled at  $30 \pm 1^\circ\text{C}$  and the solution must be freshly prepared. Automatic scanning, data recording, and plotting are carried out with computerized instrumentation. The

FIG. 14—Schematic diagram of electrochemical potentiokinetic reactivation, (SL-EPR), method for AISI 304 and 304L stainless steels [27]. ©NACE International. All Rights Reserved by NACE; reprinted with permission.)

results,  $P_a$ , are calculated as coulombs,  $Q$ , per  $\text{cm}^2$  of grain boundary area, GBA

$$P_a = \frac{Q}{\text{GBA}}$$

$\text{GBA} = A_s [5.09544 \times 10^{-3} \exp(0.34696 X)]$  where  $A_s$  = the specimen area and  $X$  = the ASTM grain size in accordance with ASTM E 112, Test Methods for Determining Average Grain Size.

The assumption in this procedure is that dissolution takes place uniformly at all grain boundaries and that there is no increment of current coming from other areas in the surface, such as pits. However,  $P_a$  values should not be pictured too literally because there are many specimens for which this is not the case, because only segments of the boundaries are attacked (dual structures) and there are pits at nonmetallic inclusions [21].

For comparisons, data from the EPR, ferric sulfate, and oxalic acid etch tests have been plotted on log-log scales in Fig. 15, along with information on pitting in the EPR structures. It has been observed that  $P_a$  values on nonsensitized (step structure) AISI 304 or 304L material exceeding 0.10 coulomb/ $\text{cm}^2$  are evidence of significant amounts of pitting in the EPR etch structures.

The line at 2.0 coulomb/ $\text{cm}^2$  has been drawn because Clarke et al. [20] selected it as the upper limit for acceptance testing of incoming stainless steel to ensure a "lack of discernible intergranular carbide precipitation." This is in agreement with our findings as shown in Fig. 15, i.e., the limit of 2.0 coulomb/ $\text{cm}^2$  essentially covers the range of step structures in the oxalic acid etch test. However, any  $P_a$  value in excess of 0.10 coulomb/ $\text{cm}^2$  denotes the presence of some random pitting in the microstructure.

Figure 15 also shows that for certain values of  $P_a$  there is an overlap of step and dual structures in the oxalic acid etch. Dual structures extend down to  $P_a$  values of about 0.4 coulomb/ $\text{cm}^2$ . Thus, in the case of  $P_a$  values in the range of 0.4 to 2.0 coulomb/ $\text{cm}^2$ , it is essential to look at the microstructure produced by the EPR test to establish whether it is a result of pitting in a step structure or of a mild case of sensitization (dual structure). The cause for the second overlap between dual and ditch structures is also pitting.

FIG. 15—Correlation of SL-EPR, oxalic acid etch, and ferric sulfate tests for AISI 304 and 304L stainless steels [27]. ©NACE International. All Rights Reserved by NACE; reprinted with permission.)

The curves in Fig. 15 can be divided into three ranges [21]:

1. In the range of  $P_a$  values from 0.01–5.0 coulomb/ $\text{cm}^2$ , there is essentially no effect on the rate in the ferric sulfate test. The EPR test can provide a sensitive measure of sensitization in this range in which the weight-loss, boiling acid tests are insensitive because there are no grain droppings. This is the range of step and dual structures in the oxalic acid etch test.
2. From a  $P_a$  of 5.0–20 coulomb/ $\text{cm}^2$ , there is a transition region in which there is an increase in corrosion in the ferric sulfate test as  $P_a$  values increase. (The small overlap between dual and ditch structures falls in this range.)
3. Above about 20 coulomb/ $\text{cm}^2$ , the EPR test almost saturates; i.e., even though corrosion rates in the ferric sulfate test increase, there is essentially no increase in  $P_a$  values.

In terms of the data in Fig. 15, the requirement as mentioned above for freedom of sensitization corresponds to a requirement for a step structure in the oxalic acid etch test. Even though the oxalic acid etch is not a quantitative test, the step microstructure can be readily identified and has been used for laboratory acceptance testing in industry for more than 40 years to identify and screen acceptable material which needs no further testing in one of the boiling tests that provide quantitative data. The much simpler oxalic acid etch test also has been used as a nondestructive test on equipment in chemical plants.

### Double Loop (DL)

It has been found [22] that the problem of pitting mentioned above for the single loop EPR test can be eliminated by the use of a double loop test. This test was proposed by Akashi et al. [23] to reduce the amount of polishing

required in the field on the surface to be tested from a 1  $\mu\text{m}$  surface for the SL test to 100 grit (140  $\mu\text{m}$ ) finish for the DL test. Otherwise, the requirements for the DL test are the same as those for the SL test except for the polarization procedure and the criteria for evaluation of the results. The polarization sequence is shown in Fig. 16. The specimen is polarized anodically from the corrosion potential of about  $-400$  mV versus SCE to a potential of  $+300$  mV versus SCE at a rate of  $6$  V/h. As soon as this potential is reached, the scanning direction is reversed and the potential is decreased at the same rate to the corrosion potential. The maximum current for each loop is measured:  $I_a$  for the large anodic loop, which was generated first, and  $I_r$  for the smaller loop generated during reactivation. The measure of sensitization is the ratio of  $I_r/I_a$ .

DL data have been plotted in Fig. 17 as a function of corrosion rates in the ASTM standard ferric sulfate test and the classifications obtained in the oxalic acid etch test. They show that the current ratio is very sensitive for detecting the absence of sensitization and for differentiating mild degrees of sensitization for which the oxalic acid test shows step or dual structures. Current ratios are in the range of  $0.0001$ – $0.001$  for step structures and between  $0.001$ – $0.05$  for dual structures. Corrosion rates in the ferric sulfate test do not differentiate between these small levels of sensitization. However, for severely sensitized materials with ditch structures, current ratios become less effective in making distinctions between medium and severe levels of sensitization, while the corrosion rates vary over a wide range. These specimens have DL ratios in a wide band extending from  $0.05$ – $0.3$ .

Note that there are no overlaps in oxalic acid etch structures for any values of current ratios (Fig. 17). In contrast, two overlaps were found for the SL test (Fig. 15). The absence of an overlap in Fig. 17 indicates that nonmetallic inclusions do not affect values of current ratios in the DL test and that it is, therefore, unnecessary to examine the microstructure after the DL test. (The same specimens were used for the data in Figs. 15 and 17.)

FIG. 16—Schematic diagram of the double loop EPR test. Evaluation is by the ratio  $I_r/I_a$  [22]. (©NACE International. All Rights Reserved by NACE; reprinted with permission.)

FIG. 17—Correlation of the DL test with the ferric sulfate and oxalic acid etch tests on AISI 304 stainless steels [22]. (©NACE International. All Rights Reserved by NACE; reprinted with permission.)

The advantages [22] of the DL over the SL EPR test are its relative independence not only of the surface finish, but also of the presence of nonmetallic inclusions that cause pitting in the SL test. It is more reproducible than the SL test and less sensitive to variations in scan rate and solution composition. It provides a quantitative, nondestructive method for detecting relatively mild degrees of sensitization which match the metallographic classifications obtained in the oxalic acid etch test.

Test procedures for the DL test are being considered for inclusion in ASTM G 108 as Method B, along with those for the SL test, Method A (Table 9).

## NICKEL-RICH, CHROMIUM-BEARING ALLOYS

It was known that alloy C (Table 1) could also become susceptible to intergranular attack as a result of exposure to a range of elevated temperatures. However, there was no reliable quantitative method available for detecting this condition until the publication in 1963 [24] of the results shown in Fig. 18. To demonstrate the applicability of the ferric sulfate-50 % sulfuric acid test, specimens were heat-treated for 1 h at temperatures between  $900$  and  $2450^{\circ}\text{F}$  ( $482$ – $1343^{\circ}\text{C}$ ), and tested for 24 h. (This is much shorter than the 120-h period used for Type 304 because of the 2 % lower chromium content and the 16 % molybdenum in alloy C.) It was found in the ferric sulfate test that there are two maxima in corrosion rates: one at  $1300^{\circ}\text{F}$  ( $704^{\circ}\text{C}$ ), which is

**TABLE 9**—Test methods for electrochemical reactivation (EPR) for detecting sensitization of AISI 304 and 304L stainless steels.

Designation	Test	Temperature	Testing Time	Applicability	Evaluation Method
Method A G 108	EPR-SL (Single Loop)	$30^{\circ} \pm 1^{\circ}\text{C}$	10 min	Chromium carbides in 304 and 304L	Coulombs per $\text{cm}^2$ of grain boundary area, $P_p$ . $P_p$ values $>2.0$ coulombs per $\text{cm}^2$ denote onset of sensitization. (Equivalent to Dual Structure in Oxalic Acid Etch.)
"Method B" (proposed)	EPR-DL (Double Loop)	$30^{\circ} \pm 1^{\circ}\text{C}$	15 min	Chromium carbides in 304 and 304L	Ratio of currents; $I_p/I_a$ . Values $>0.001$ denote onset of sensitization. (Equivalent to Dual Structure in Oxalic Acid Etch.)

associated with the formation of a molybdenum-rich carbide at grain boundaries, and another at 1900°F (1038°C), which is associated with a molybdenum-rich intermetallic compound, mu-phase. It is apparent from Fig. 18 that reducing acids, such as hydrochloric acid, result in high rates near 1300°F, and highly oxidizing acids, such as chromic acid, near 1900°F.

These results on the effect of heat treatments on corrosion resistance of the original (Hastelloy) alloy C are discussed here because they show clearly the different effects of molybdenum-rich carbides and molybdenum-rich mu-phase on corrosion in reducing and oxidizing acids. This alloy has been replaced during the past 30 years by a series of compositions that were designed to minimize the formation of second phases and to enhance

the general corrosion resistance in oxidizing acids, as well as the resistance to intergranular stress corrosion in chloride solutions.

The first improvements by Haynes International resulted from a reduction of the carbon (0.02 % max) and silicon (0.05 % max) contents in alloy C-276. These improvements in properties were facilitated by the application of the ferric sulfate test [25]. Reductions of the carbon and silicon contents greatly reduced the formation of both types of precipitates (Fig. 19) [26,27]. Further improvements are represented by Hastelloy alloys C-4 [25] and C-22 [28], Inconel Alloy 686 [29] and VDM Alloy 59 [30] (Table 1). At present, all but alloy 686 of this class of alloys are included in ASTM G 28 (Table 7), as well as alloys G-3, G-30, and A.L.6XN.

**FIG. 18**—Effect of heat treatment on corrosion and etch structures of Hastelloy alloy C. Solutions: boiling 50 % sulfuric acid with 42 g/L ferric sulfate; boiling 10 % hydrochloric acid; boiling 10 % chromic ( $\text{CrO}_3$ ) acid; specimens: 0.06 % carbon [24]. (©NACE International. All Rights Reserved by NACE; reprinted with permission.)

**FIG. 19**—Effect of carbon content in Ni-Cr-Mo alloys on corrosion in the ferric sulfate-50 % sulfuric acid test [25]. (©NACE International. All Rights Reserved by NACE; reprinted with permission.)

Generally, evaluation in the 50 % sulfuric acid ferric sulfate test is by weight-loss. However, on alloys C and C-276 the relatively low chromium content of about 15 % (i.e., 3 % less than in Type 304 steel) results in a somewhat high rate of general corrosion that tends to mask low rates of intergranular attack. Therefore, to establish evidence of intergranular attack, microscopic examination is recommended in ASTM G 28 to supplement the corrosion rate (weight-loss) data. The newer C-type alloys (Table 1) have 20 to 23 % chromium, and therefore do not pose this problem.

In 1974, the ferric sulfate test was applied by Brown [31] to other nickel-rich, chromium-bearing alloys and found to be applicable for detecting susceptibility to intergranular attack in alloys G, 20 Cb-3, 600, 625, 800, and 825 (Table 1). All of these alloys have been incorporated in ASTM G 28, Practice A (Table 7).

In 1985, Manning [32] proposed the use of a boiling solution of 23 % sulfuric acid, 1.2 % hydrochloric acid, 1 % cupric chloride, and 1 % ferric chloride for a 24-h test in order to provide a more sensitive measure of the presence of molybdenum-rich precipitates at grain boundaries of alloy C-276. When such precipitates are present there is severe pitting attack at grain boundaries that results in a large increase in corrosion rates. This test, which was first applicable only to wrought alloy C-276, has been incorporated in ASTM G 28 as Method B and is now also being applied to C-22 and 59 alloys. Weldments can be tested only when the welds have been annealed after welding. The test is not applicable to as-welded specimens because weld metal is severely attacked by this solution probably because of segregation of alloying elements in the dendritic structure of weld metal.

Because there are many successful applications of alloy C-276 for which weldments cannot be annealed after welding, e.g., in shop fabrication and field erection, it seems that this test may be too severe in detecting mild forms of sensitization. This is also suggested by the results with 14 different solution compositions [32]. Only two of the 14 resulted in a large increase in rates on mildly sensitized alloy C-276. The two were the Method B solution and a second version of this solution with 2.4 % hydrochloric acid in place of the 1.2 % specified for Method B. This is now used on sheets of alloy C-276 for sulfuric acid coolers to monitor the success of final annealing heat treatments. These solution-annealing treatments require heating of large objects to a relatively high temperature [2050°F (1121°C)] to dissolve precipitates and rapid enough cooling to prevent their reformation during cooling through the range of 2000° to 1000°F (1093 to 538°C).

For recent results and discussion on alloys C-276, C-22, and 682 weld metals, see item 7 in Future Developments section.

## WHEN TO EVALUATE FOR SUSCEPTIBILITY TO INTERGRANULAR ATTACK

All the stainless steels and nickel-rich alloys to which the various evaluation tests are applied (Tables 1 and 2) are relatively costly. However, for critical applications in the process and power industries, the replacement cost of alloys may be only a relatively small part of the total cost of corrosion

failures. The loss in production due to plant shutdowns can greatly exceed the costs of new equipment. For such critical applications, it is essential that the alloys be in their optimum metallurgical condition for resisting intergranular attack and other forms of corrosion associated with precipitates at grain boundaries. The laboratory equipment and apparatus required for the boiling acid tests and the oxalic acid etch test are generally available in metallurgical laboratories. Only the EPR tests require relatively costly computerized electronic equipment.

Sensitized alloys, i.e., materials containing potentially damaging precipitates at grain boundaries, may come into use on plants inadvertently when:

- (a) regular carbon Types 304 or 316 are used unknowingly in place of Types 304L and 316L for fabrication involving welding;
- (b) the final mill annealing heat treatments and quenching operations are not effective, e.g., on regular carbon grades of Type 304 and alloy 600, in dissolving chromium carbides and nitrides and intermetallic phases and keeping them in solution during cooling;
- (c) there is incomplete stabilization of titanium- or niobium-bearing alloys (Types 321, 347, alloys 625, 825, 18Cr-2Mo-Ti, and 26Cr-1Mo-Ti) either because of inadequate amounts of these elements or because of ineffective stabilizing heat treatments;
- (d) heat is applied for unscheduled forming operations during fabrication or installation of equipment;
- (e) there is interior carburization of tubes resulting from decomposition during annealing heat treatments of incompletely removed drawing lubricants;
- (f) the carbon and/or nitrogen contents of any of the extra low-carbon austenitic stainless steels, of the new high-purity ferritic iron-chromium-molybdenum alloys or of alloys C-276, C-22, 59, 686, 6XN, and G-30 exceeds the specified limits; and
- (g) in a very few certain cases, sensitized material is accepted knowingly to reduce costs or even is specified to minimize failures by stress corrosion in certain caustic environments. When it is known that there will be no intergranular attack on sensitized material by the process stream during the life of the equipment, such material may be used. It can reduce costs in three ways: (1) the regular carbon grades cost less than the extra low-carbon grades; (2) they have somewhat higher yield strengths which permit the design of smaller sections; and (3) solution-annealing treatments can be omitted.

## Testing Strategy

1. When available plant experience shows clearly that there will be intergranular or other localized attack on sensitized material, the alloy intended for such service must obviously be free of damaging grain-boundary precipitates and should, therefore, be resistant to intergranular attack in an appropriate evaluation test.
2. Only when available data from plant service or long-time plant tests show definitely that a certain plant environment does not cause intergranular attack on sensitized alloys and when it is known that the process conditions

**TABLE 10**—Corrosion rates indicating susceptibility to intergranular attack. Corrosion rates higher than those listed indicate grain dropping in unwelded specimens.

Alloy (AISI Type)	Condition	Test Practice	Time, h	Corrosion Rate	
				mil/year	mm/year
304	as-received	Nitric Acid Practice C ASTM A 262	240	12 (18) <sup>a</sup>	0.30 (0.46)
304L	20 min, 677°C		240	12 <sup>a</sup>	0.30

<sup>a</sup>Used as acceptance rates by the du Pont de Nemours Co. When two rates are listed, the rate in parentheses is the acceptance rate.

will not change, there is no need to specify an evaluation test, or even to specify costly low-carbon grades.

But, because service life may range from ten to 40 years, the degree of sensitization that can be tolerated can be decisive. Therefore, the knowledge that sensitized material has been found to be free of intergranular attack for five to ten years in plant service can be used as a guide for future action only when there is information on the severity and type, carbide or sigma, of sensitization involved and on the effect of time on the rate of intergranular attack over the length of the expected service life.

Another example is a process in which stainless steels are used to prevent product contamination by corrosion products. In such cases, even carbon steel may have the necessary corrosion resistance from an engineering standpoint, but the corrosion products formed by the small amount of corrosion of carbon steel are not acceptable, and for this reason a stainless steel is used, e.g., to prevent discoloration of polymers on certain textile fiber plants. Finally, sensitization may not be a problem when stainless steel is used for appearance or ease of maintenance.

3. This leaves new environments for which there are no actual or even comparable data on their effects on sensitized alloys. Even when such a new environment is thought to be harmless, evaluation tests should, nevertheless, be applied to assure optimum metallurgical conditions. There have been a number of costly corrosion failures on material sensitized by welding when exposed

to previously unknown factors, such as oxygen in water at elevated temperatures. Also, when the original environment is known not to cause intergranular attack on sensitized alloys, there may be changes later in process conditions which may cause such attack.

Information on "acceptable" and "nonacceptable" corrosion test results has been given for the two EPR tests in the section above on these tests. Acceptable etch structures (step, and in some cases, dual) are also identified for the oxalic acid etch test. The absence of fissures in bends after certain copper sulfate tests is considered an indication of acceptable results. However, in the case of weight-loss tests (nitric acid, ferric sulfate, and certain copper sulfate tests) the standard ASTM test methods merely show how corrosion rates are calculated without identification of rates which are evidence of the onset of susceptibility to intergranular attack.

Data on corrosion rates in the nitric acid and the ferric sulfate-sulfuric acid tests that are indicative of the onset of enough intergranular attack to dislodge grains from the surface (sugaring) during the specified testing times are given in Table 10 for a group of alloys. Most of these rates are being used as a cut-off for acceptance of material for use on plant equipment. However, for some of these alloys these rates have proven to be unnecessarily low. In these cases it has been found that considerably higher rates can safely be used for industrial applications. These rates are also shown in Table 10.

The following references provide some examples of major applications of evaluation tests and of problems associated with sensitization. The uses of evaluation tests for the study of the effects of complex microstructures on corrosion have been illustrated in a detailed investigation of titanium stabilized, Type 321 stainless steel [33]. Industrial experience at Du Pont with the application of evaluation tests to more than 10 000 specimens of Type 300 series steels has been reported by Brown [34]. On the subject of IGSCC at weldments of Type 304 stainless steel piping on boiling water nuclear plants, a detailed report is available from the U.S. Nuclear Regulatory Commission [35], which provides information on the origin and extent of the problem, remedial procedures, and the selection of replacement alloys.

## FUTURE DEVELOPMENTS

The numerous tests in ASTM A 262, A 763, and G 28 are the results of the introduction of a great number of commercial stainless alloys over a period of about 80 years and the development of a great variety of methods for determining susceptibility to intergranular attack in these alloys. (The accidental discovery of both the ferritic and austenitic stainless steels in 1912 and the subsequent evolution of various stainless alloy compositions have been described in Ref 36.) The result has been considerable overlap in tests; e.g., Types 304 and 304L stainless steels, which are produced in the largest tonnage of all of the alloys listed in Tables 1 and 2, can be evaluated in the nitric acid, oxalic acid, ferric sulfate-sulfuric acid, and copper sulfate tests, and even the EPR tests. Simplifications in the test programs could be made by removing alloys that are no longer of commercial importance from the lists and by removing tests that are rarely or no longer used. Also, changes in production of alloys, such as the introduction of argon-oxygen refining for reducing the carbon contents to the range of 0.01 to 0.02 %, can and have resulted in greater "resistance to sensitization" in Type 304L and other alloys. As a result, a greater proportion of test specimens are found acceptable in the simple and rapid oxalic acid etch test, and therefore do not have to be tested in the boiling acid or EPR tests.

The following are some initial steps that would further simplify the test program:

1. Remove the Nitric Acid Test from ASTM A 262 and establish it as a separate ASTM Test: At present, the boiling 65 % nitric acid test (Practice C) is specified for materials to be used in nitric acid service. Only this test is sensitive to sigma-phase in molybdenum-bearing austenitic stainless steels. Also, problems such as end-grain corrosion associated with hexavalent chromium derived from corrosion products are unique to this solution. While this test also detects susceptibility to intergranular attack associated with chromium carbide precipitates, there are other tests that perform this function in less time and with greater simplicity.

Thus, the nitric acid test should be used primarily as a kind of simulated service test for alloys to be used in nitric acid environments. This is a return to its original function as defined by Huey [4]. When used in this way, it will be

essential to specify the test apparatus, including the condenser, the ratio of surface area of test specimens to solution volume, and the number of changes of solution to provide a close simulation of the severity of the hexavalent chromium problem which the material being tested is to encounter in plant service. In ASTM A 262, Practice C, a wide-mouth Erlenmeyer Flask with a cold finger condenser (Fig. 7) is recommended for the nitric acid test.

It has been shown [14] that this condenser results in lower corrosion rates than the Allihn condenser. The lowest rates are obtained with (glass) apparatus in which there is continuous flushing of (chromium) corrosion products [6,14]. A design for such conditions has also been provided by Corbett [38]. In this apparatus, up to 100 specimens can be tested simultaneously with corrosion products kept so low that the test simulates a "once through" industrial application.

2. Drop the Single Loop EPR Test: If and when the double loop version of the EPR test is approved for inclusion in ASTM G 108, the single loop version can be dropped due to the greater clarity of the results and simpler test procedures for the double loop as compared to the single loop (see section, EPR Tests).
3. Apply EPR Tests to Castings in ASTM G 108: Because of the relatively large grains in castings, it takes longer to undermine grains (and register corrosion as weight-loss) on sensitized castings than on the small-grained, wrought stainless steels. Therefore, much longer testing times are needed for castings in the ferric sulfate-50 % sulfuric acid test, perhaps two or three times 120 h; or two or three times the 240 h used for the 65 % nitric acid test [9].

To reduce greatly the time required for testing of castings, consider the inclusion in ASTM G 108 of the double loop practice to cast alloy CF-8 as described by Reichert and Stoner [39] and Sydow et al. [40]. By applying the double loop EPR test to cast alloys such as CF-8 and CF-3 (the cast equivalents of Types 304 and 316), quantitative data on sensitization may be obtained in less than an hour.

The application of an EPR test to castings to provide rapid, quantitative data on sensitization may prove to be the main use of the EPR technique.

4. Consider the Use of a Simplified EPR Test: Such a test has been proposed in Ref 41. It is based on the maximum current measured for the reactivation loop (Fig. 14) which is proportional to the area within the loop, and therefore to  $Q$ , the total charge.

Attempts to assess sensitization in Type 304 alloy by means of 5–15 min potentiostatic electrochemical tests in solutions that simulated exactly the plant conditions have been shown to be invalid [42]. This testing period is much too short for testing in simulated service conditions, i.e., the electrode potential applied to the specimen in the laboratory test, the solution compositions, and temperature were the same as those to be used in plant service. Thus, there was no accelerating factor in the laboratory test and it would have had to be just as long as a plant test, perhaps 3–12 months, to determine whether or not the material would be subject to intergranular attack in plant service.

**FIG. 20—Schematic diagram of components of weldments in austenitic stainless steels. Diagram based on findings of W. F. Savage [43].**

5. Eliminate the Two Copper Sulfate Tests with 6 % Sulfuric Acid, Practice E in A 262 and Practice Z in ASTM A 763 (Tables 5 and 6): Similar results can be obtained with the 50 % sulfuric acid-copper sulfate tests, Practice F in ASTM A 262 and Practice Y in ASTM A 763.

At present, the copper sulfate test with 50 % acid is specified in ASTM A 763 only for ferritic alloys with 25 % or more chromium. Tests on Type 430 (14–18 % chromium) [37] and on Type 321 (17–19 % chromium) steels [33] show that the 50 % acid test is also applicable to these alloys. Thus, Practices Z in ASTM A 763 and E in ASTM A 263 could be eliminated. All remaining copper sulfate tests (Practices F and Y) would then be in 50 % acid solution.

6. Establish criteria for evaluation of weldments. The various components of weldments are shown in Fig. 20, which is based on the classification scheme of W. F. Savage [43]. The weld nugget or the composite region contains the bulk of filler metal which is somewhat diluted with material melted from surrounding base metal. Adjacent to the nugget is a zone of base metal that melted and solidified during welding without experiencing mechanical mixing with the filler metal, the unmixed zone. In these two regions, there is complete melting, resulting in a cast structure. Beyond this weld interface, there is a partially melted zone within which the proportion melted ranges from 100–0 %. The heat-affected zone is that portion of the base metal within which all microstructural changes produced by welding occur in the solid state. The maximum temperature reached in the heat-affected zone is highest near the molten zone and decreases with distance from this interface.

As shown in Fig. 6, the weld decay zone which contains chromium carbide precipitate is not adjacent to the cast metal, but at some distance from it, in austenitic stainless steels. The reason for this is that the temperature of the metal in the zone adjacent to the molten zones has been

raised above the chromium carbide precipitation range. During cooling, the precipitation range is traversed from above. It has been shown [25] that carbide precipitation is much slower when the sensitizing range is entered from above. Thus, both because of this factor and because the total time in the precipitation range is relatively short, there is no carbide precipitate in the zone adjacent to the partially melted zone. In the weld decay zone, the metal is heated into the carbide precipitation range, and the time in this range is longer than that of the zone adjacent to the partially melted zone [44]. Beyond the weld decay zone, the temperature remains below the sensitizing range during the welding operation.

In effectively stabilized austenitic stainless steels (Types 321 and 347), there is no weld decay zone (Fig. 6). However, immediately adjacent to the partially melted zone, the temperature is so high that the titanium or niobium carbides are dissolved in the solid solution before rapid cooling through the sensitizing range. As in the case of unstabilized steels, cooling from above the sensitizing range is rapid enough to keep the carbon in solid solution and is too rapid to form titanium or columbium carbides. However, when weldments in stabilized steels are later heated into the sensitizing range, for example, during a stress-relieving treatment or another weld pass, chromium carbides form, and this zone becomes sensitized. Exposure to certain acid solutions results in intergranular attack in a narrow zone next to the partially melted zone, knife-line corrosion [45]. It can be prevented by heating the weldment at 900°C to react the stabilizing element with carbon to form niobium or titanium carbides. As a result, there is no carbon available to form chromium carbides during subsequent exposure in the carbide precipitation range, 430–870°C.

Figure 21 illustrates intergranular attack on an autogenous weldment (made with tungsten electrode without filler metal) in a ferritic, 29Cr-4Mo, alloy with a nitrogen content that greatly exceeds the maximum permissible concentration of 200 ppm. Intergranular attack takes place in the melted metal and in a narrow zone immediately adjacent to it. Apparently, the high temperatures in these zones resulted in the slowest rates of cooling through the sensitizing range (Fig. 22) and the precipitation of chromium nitrides at grain boundaries.

When weldments are made to simulate fabrication welds or when they are part of the tube producing process, they then contain the very components that will be exposed in service, the same compositions, structures, and thermal cycles. Any evidence of intergranular attack in any of the components of the weldments will, therefore, be an indication of susceptibility during long time exposure in those service environments that are known to cause such attack on sensitized material. Because of this, assessment of weldments after exposure in laboratory evaluation tests must be based on very strict criteria for the onset of intergranular attack. Such criteria include the appearance of fissures on specimens bent after testing and evidence of dropped grains. Weight loss measurements are generally too insensitive to detect intergranular attack confined to narrow zones of a weldment. To implement this method of assessing corrosion on weldments, tests are needed in nitric, ferric sulfate, and cupric sulfate solutions on weldments prepared

**FIG. 21—Intergranular attack on weldment in ferritic stainless steel caused by high nitrogen content (5 $\times$ ). Autogenous weld in 28.5 %Cr-4.2 %Mo alloy with 22 ppm carbon and 388 ppm nitrogen after exposure in ferric sulfate-50 % sulfuric acid test.**

by the various methods applicable to each alloy for which the new assessment criteria are to be established. In addition, where applicable, the results should be compared with the oxalic acid etch structure of the weldment on cross sections perpendicular to the weld bead.

In some cases, there is preferential attack on weld filler metal in austenitic stainless steels related to its ferrite content.

**FIG. 22—Effect of heat treatment on intergranular corrosion of Fe-29 %Cr-4 %Mo alloy. Specimens: heat treatment 1 h as shown, water-quenched. 2.5 by 2.5 by 0.2 cm. Q-738: 40 ppm nitrogen; Q-742: 120 ppm carbon. Solution: boiling ferric sulfate-50 % sulfuric acid.**

R. W. Gurry et al. [46] have found that chloride-containing acids, strong organic acids, and sulfuric acid preferentially attack weld metal containing more than about 5 % ferrite, whereas the oxidizing acids, nitric and ferric sulfate-sulfuric acid, used in evaluation tests do not cause preferential attack on ferrite-bearing weldments. Removal of the ferrite by cold-working and annealing eliminates this form of preferential attack. Thus it may be possible to screen weldments for service in reducing acids by microscopic (oxalic acid etch) testing for the presence of ferrite. To establish a series of standard etch structures for evaluation, comparisons are needed between etch structures containing various amounts of ferrite and the corrosion in reducing acids of these same weldments.

7. Testing Weld Metal of Alloys C-276, C-22, and 686: In the previous section, Nickel-Rich, Chromium-Bearing Alloys, tests with Practice B in ASTM G 28 are discussed. Twenty-four hour tests in a boiling mixture of sulfuric and hydrochloric acids with cupric and ferric chloride are used as a very sensitive method for detecting the presence of molybdenum-rich precipitates in wrought alloys C-276, C-22, and 686. Practice B is considered too severe for as-welded material because it fails by pitting in the dendritically segregated, cast structure of the weld deposit. High-temperature annealing treatments (2050°F, 1121°C) eliminate this problem [32].

In a recent investigation of the corrosion resistance of as-welded C-276, C-22, and alloy 686 specimens, Saldanha [47] has shown that such weld metal is also susceptible to rapid and severe pitting in a simulated plant solution, boiling 80 % acetic acid with 1000–5000 ppm ferric chloride. There was severe pitting on all three alloy weldments; see Fig. 23 for pitting in C-276 weld metal in only five days of testing. There was no attack in the heat-affected zones or in the base-plate. Thus, there are plant environments in which

**FIG. 23—Alloy C-276 plate with C-276 weld metal (7 $\times$ ). Pitting attack in weld deposit after exposure of five days in boiling 80 % acetic acid with 1000 ppm ferric chloride. No attack in heat-affected zones or on base plate [47].**

as-welded C-276, C-22, and alloy 686 may be susceptible to rapid localized attack in service. For such applications welded equipment must be annealed. Practice B tests on weldments provide a needed tool for acceptance testing in addition to the process control application on wrought sheet as described in the above-mentioned section.

Additional investigations are needed to establish the limits of use of as-welded C-276, C-22, and alloy 686 and the extent to which Practice B should be specified as a requirement for acceptance testing of weldments. Practice B may also serve as a tool for the development of new weld-rod compositions which result in welds that can be used without post-weld annealing treatments for use in environments that are known to cause pitting of alloys C-276, C-22, and 686 weld-deposits. Such new compositions are needed especially for field welding of equipment that cannot be annealed.

## Acknowledgments

The author would like to thank F. Galen Hodge and Stephen Corey, Haynes International, Inc., Kokomo, Indiana; Robert F. Steigerwald, Bechtel, San Francisco, California; and John R. Scully, University of Virginia, Charlottesville, Virginia, for information on current developments. He also expresses his appreciation and thanks to Brian J. Saldanha, E. I. DuPont Co., Wilmington, Delaware, for making the results of his recent tests on alloys C-276, C-22, and 686 weldments available for inclusion in this chapter.

# Exfoliation

Donald O. Sprowls;<sup>1</sup> revised by Kevin R. Cooper<sup>2</sup>

## EVALUATION OF EXFOLIATION CORROSION

HISTORICALLY, exfoliation corrosion problems have been associated principally with high-strength aluminum alloys used in aircraft construction and by the U.S. Department of Defense. This chapter, therefore, will deal mainly with test procedures developed for alloys of aluminum.

### Basic Principles

Exfoliation is defined in ASTM G 15, Terminology Relating to Corrosion and Corrosion Testing, as a form of “corrosion that proceeds laterally from the sites of initiation along planes parallel to the surface, generally at grain boundaries, forming corrosion products that force metal away from the body of the material, giving rise to a layered appearance.” An example is shown in Fig. 1.

For a metal to exfoliate, a highly directional grain structure is necessary along with electrochemically active corrosion paths parallel to the metal surface. The severity of exfoliation in susceptible materials is influenced to a marked degree by environmental conditions [1]. Figure 2 shows the broad range of behavior of a particular material in different types of atmospheres [2]. Taking an example from service, it is recognized that forged motor truck wheels made of an aluminum copper alloy (AA2024-T4) give corrosion-free performance for many years in the warm dry climates of the southern and western United States, but they exfoliate severely in only one or two years in the northern states where deicing salts are used on the highways during the winter months [3].

### Susceptible Metal Alloy Systems

#### Aluminum

Exfoliation corrosion of aluminum is an industrial problem chiefly with the higher strength AA2XXX, AA5XXX, and AA7XXX alloy wrought products in which the grains of metal are elongated during manufacture. The alloy typically is in a temper that is susceptible to dominant intergranular corrosion. The severity of the exfoliation will depend not

**FIG. 1—Three degrees of resistance to exfoliation produced by variations in heat treatment of a AA2024 alloy extruded 13-mm thick bar. T/10 and T/2 are designations for the interior machined test surfaces (refer to the subsection, Test Specimens, in this chapter). The stepped specimens were exposed for 55–61 months in an industrial environment at Brookfield, IL [3]. (Reprinted with permission from EMAS, Ltd., U.K.)**

only on the extent to which the grains have been elongated, but also to the continuity of the anodically active paths and to the environmental conditions. These materials also have a low resistance to environment-assisted cracking when stressed in the short transverse direction, and the two phenomena may be mutually accelerating when short transverse tension stresses are involved [3,4]. A more detailed discussion of the importance of the macrostructure of the exfoliation test specimens is given in Refs 3–4 and in the ASTM G 112, Standard Guide for Conducting Exfoliation Corrosion Tests in Aluminum Alloys.

Exfoliation also can occur in the directional fragmented grain structure of severely cold-rolled products of certain lower strength strain-hardening alloys of the AA3XXX and

FIG. 2—Influence of environmental conditions on the exfoliation corrosion of a material with a low resistance to exfoliation. AA2124-T351 rolled 51-mm thick plate rated ED in the standard EXCO test, ASTM G 34 [2].

AA5XXX families. The anodic corrosion path in these materials is not in the grain boundaries, but rather it is in deformation bands of aluminum or Al-Mg solid solutions interspersed between relatively cathodic strata of Al-Mn and/or Al-Cr phases depending on the composition of the alloy and the thermal history during processing. Although this form of intragranular exfoliation corrosion rarely presents industrial problems, it is possible, however, as a result of inappropriate ingot homogenizing thermal treatments, to encounter exfoliation susceptibility of severely cold-rolled products in aggressive environments [3].

Severe exfoliation has been reported with graphite/aluminum metal matrix composites in marine environments [5]. Localized corrosion along wire-wire and wire-foil diffusion bonds resulted in disbondment of the precursor wires and aluminum foils. See also the discussion by Hihara on corrosion of metal-matrix composites in Section VI of this manual.

### Other Metals

Although exfoliation corrosion has been reported in a few other metal systems, incidents of this form of corrosion are few and presumably not of practical importance. Therefore, no attempts have been made to develop and standardize specific tests for detecting susceptibility to exfoliation for these other metals. The following notes from published literature may be of interest to some readers.

"A peculiar form of attack (exfoliation) has been reported with 80/20 or 70/30 cupro-nickel tubes in high-pressure feed-water heaters. A severe form of general corrosion on the steam side consists of an exfoliating scale mainly of a mixture of metal oxides in the same proportions as the metals present in the alloy. The attack has only been observed on tubes heated intermittently and the mechanism is obscure . . . materials which are immune are copper or 90/10 cupro-nickel" [6].

Wrought iron, produced by piling several plates on top of one another, subjected to heat, and passed through a rolling mill, develops zones that behave differently from one another when subjected to corrosive conditions. Evans considers this zonal corrosion of wrought iron to have much in common with the layer corrosion (exfoliation) of light alloys [7].

An experimental magnesium-base alloy sheet containing 14 % lithium and 2 % aluminum was reported to have experienced intergranular layer attack similar to the exfoliation of aluminum-copper alloys [8].

## Test Procedures for Aluminum Alloys

### Relation to Service Conditions

Laboratory corrosion tests for exfoliation corrosion susceptibility are a necessary tool for research and quality control engineers; however, the validity of such accelerated tests depends on their relationship to realistic service conditions and their sensitivity to various degrees of susceptibility. The tests must be discriminating and yet not so severe as to be unrealistic. For the majority of engineered structures, exposure to outdoor atmospheres provides a baseline that is representative of many service conditions, except for structures that are subjected to unusual chemical environments. Experience has shown that seacoast conditions are more corrosive to aluminum alloys than inland urban and industrial conditions (see Fig. 2), and seacoast atmospheric exposure tests have been particularly useful for the validation of accelerated exfoliation tests [9].

Accelerated tests do not precisely predict long-term corrosion behavior; however, answers are needed quickly in the development of new materials. For this reason, accelerated tests are used to screen candidate alloys before conducting atmospheric exposures or other field tests. They also are used for production control of exfoliation-resistant heat treatments for the AA2XXX, AA5XXX, and AA7XXX aluminum alloys. ASTM has standardized several laboratory tests for susceptibility to exfoliation corrosion in recent years.

### Selection of Appropriate Test Procedures

Selection of the most appropriate test procedure(s) depends on the type of alloy to be tested, the anticipated service environment, and the purpose of the test.

When testing an experimental alloy or product form, one would normally select a procedure known to be applicable to a similar commercial alloy. The investigator is cautioned, however, that even a small difference in alloy chemistry or changes in processing method can markedly affect the resistance to exfoliation of the new material and the appropriateness of a specific test method. Therefore, when investigating a new type of material, it is advisable to initially use more than one laboratory test procedure and compare the test results. If they do not agree, determine which procedure is the most applicable by conducting a seacoast atmospheric exposure. It is unrealistic to expect a single laboratory test to be applicable to all materials and purposes [2]. The known applicability of each of the standardized test procedures is discussed below.

These several tests, developed by the producers of aluminum alloys and U.S. Government laboratories, have been used mainly for research and alloy development. Certain test procedures are also used for production control of exfoliation-resistant materials. If they are considered for quality assurance purposes, however, limits of acceptable performance should be the subject of an agreement between concerned parties.

**Salt Spray (Fog) Tests**—Three different cyclic acidified salt spray tests have been widely used for exfoliation testing in the aluminum and aircraft industries. These are described in Annexes A2, A3, and A4 in ASTM G 85, Practice for Modified Salt Spray (Fog) Testing. The three practices are not equivalent, and the user should determine which one is best suited for the alloy and application under investigation. The following notes were taken from the ASTM G 112, which contains additional details regarding their usage:

- Annex A2 describes a cyclic salt spray test (MAST-MAASIS) that uses a 5 % sodium chloride solution acidified to pH 3 with acetic acid in a spray chamber at a temperature of 49°C (120°F). This test is applicable for exfoliation testing of AA2XXX (dry-bottom operation) and AA7XXX (wet-bottom operation, that is, with approximately 25 mm (1 in.) of solution present in the bottom of the test chamber) aluminum alloys with test duration of 1–2 weeks. Results with AA7075 and AA7178 alloys in various metallurgical conditions have been shown to correlate well with results obtained in a seacoast atmosphere (four-year exposure at Point Judith, RI) [9]. The exfoliation behavior of lithium-containing aluminum alloys AA2090-T8, AA2091-T3 and T8 and AA8090-T8 obtained with dry bottom MASTMAASIS agree with marine environments [10–12]. There is no record of this test being unrealistically aggressive, that is, causing exfoliation of a material that did not exfoliate at the seacoast.
- Annex A3 describes a cyclic salt spray test (SWAAT) that uses a different exposure cycle and a 5 % synthetic sea salt solution acidified to pH 3 with acetic acid in a spray chamber at a temperature of 49°C (120°F). This test is applicable to the production control of exfoliation-resistant tempers of the AA2XXX, AA5XXX, and AA7XXX aluminum alloys. Wet-bottom operating conditions are recommended with test durations of 1–2 weeks [13,14].
- Annex A4 describes a salt-sulfur dioxide (SO<sub>2</sub>) spray test that uses either 5 % sodium chloride or 5 % synthetic sea salt solution in a spray chamber at a temperature of 35°C (95°F). The spray may be either cyclic or continuous, which, along with the type of salt solution and test duration, is subject to agreement between the purchaser and the seller. This test, which was developed to simulate the hostile environment on the deck of an aircraft carrier, reproduces in two weeks the exfoliation attack on susceptible AA2XXX and AA7XXX aluminum alloys that occurs on a carrier in about eight months [2]. However, the sulfur dioxide salt spray does not well reproduce the exfoliation behavior of aluminum lithium alloys AA2020, AA2090 and AA8090 observed when exposed to the environment encountered on aircraft carriers [15,16].

**Immersion Tests**—Continuous total immersion tests were developed more recently to provide simpler, rapid, and more reproducible test methods than the salt spray tests. Although plain sodium chloride solutions do not cause exfoliation during the desirable short periods of immersion, formulations of chloride-nitrate solutions were found that produced severe exfoliation of highly susceptible alloys of various types in only one to four days. Optimum test conditions differed for separate alloy families [1].

ASTM G 66, Method for Visual Assessment of Exfoliation Corrosion Susceptibility of AA5XXX Series Aluminum Alloys (ASSET Test), describes a procedure for the continuous immersion exfoliation testing of AA5XXX alloys containing 2.0 % or more magnesium. Specimens are immersed for 24 h at 65°C (150°F) in a solution containing 1.0 M ammonium chloride, 0.25 M ammonium nitrate, 0.01 M ammonium tartrate, and 0.09 M hydrogen peroxide. This method provides a reliable prediction of the exfoliation corrosion behavior of AA5XXX alloys in marine environments including seawater [17,18]. This test is useful for alloy development studies and quality control of mill products such as sheet and plate.

ASTM G 34, Method for Exfoliation Corrosion Susceptibility in 2XXX and 7XXX Series Aluminum Alloys (EXCO Test), provides an accelerated test for AA2XXX and AA7XXX aluminum alloys by continuous immersion of test materials in an aqueous solution containing 4 M sodium chloride, 0.5 M potassium nitrate, and 0.1 M nitric acid at 25°C (77°F) (with a starting pH of 0.4 rising to 3.2 during the first 7–20 h of exposure) for periods of 24–48 h. “This test method is primarily used for research and development and should not be construed as a method for quality acceptance.” Seacoast atmospheric exposures of six to twelve years have proven the EXCO test to be a reliable indicator of service performance for the following alloys used in an interlaboratory testing program: AA2024 and AA2124 in T351 and T851 tempers; AA7075 in T651, T7351, and T7651 tempers; and AA7178 in T651 and T7651 tempers [14,15,19].

The EXCO test has been reported as being too aggressive and not representative of outdoor atmospheres for more recently developed alloys, such as AA2219, AA2419, and AA2519 in the T851 tempers [20], for aluminum-lithium alloys AA2020, AA2090, AA2091, and AA8090 in both as-quenched and artificially aged tempers [10,11,15,21] and for AA7050 and AA7150 in the T7XX type tempers [21]. The problem is that EXCO test specimens of these materials quickly become covered with corrosion products from general attack making it difficult to visually distinguish the general attack from genuine exfoliation. The result is that test specimens frequently have been rated as being overly susceptible to exfoliation (EA or EB) whereas little or no exfoliation occurred in extended seacoast exposures. Metallographic examination is often required to establish a true rating for these relatively resistant materials. Similar problems related to the severity of the EXCO test have also been experienced with copper-free AA7XXX alloys and wrought products of powder metallurgy AA7XXX alloys. This sort of difficulty contributes to variability in the assessment of the exfoliation.

Modified EXCO test solutions not yet standardized that cause less general corrosion have been investigated with promising results in that the reduced general attack favored positive identification of the exfoliation and more accurate estimation of the intensity of it without the necessity of metallographic examination. One approach was to reduce the acidity to pH 3.2 and to add a small amount of aluminum ion while keeping the molarities of chloride and nitrate the same. A 96 h exposure to this modified EXCO solution appears more capable of reliably predicting exfoliation performance in seacoast environments and of distinguishing

between various commercial tempers of AA7075, AA7050, and AA7150 alloys. With a 48 h exposure at a slightly elevated temperature of 52°C (125°F) this modified solution also reflected accurately the performance in a seacoast atmosphere of alloys AA2024 and aluminum-lithium AA2090, in both the T3 and T8 type tempers [21].

Another approach involved the addition of a corrosion inhibitor. Sinyavsky et al. [4], using an addition of 10 g/L potassium dichromate to the standard EXCO solution, reported that the exfoliation trends were the same as in the standard solution for all of the alloys examined (AA2124-T3, T8; AA2618-T6; and AA7175-T6, T76, T73), and because of less general corrosion the exfoliation was easier to identify and to assess in the inhibited solution.

Additional testing of these and other possible modifications, including interlaboratory comparisons, is needed to verify the promising results noted. An ideal modification would hopefully work well with a variety of alloys and be shown to have good reproducibility before it is proposed as a new standard test method.

Historically, various investigators in Europe have used hydrochloric acid-potassium dichromate solutions for testing the exfoliation susceptibility of all types of aluminum alloys. An example is the Russian Standard GOST 9.904-82, Aluminum Alloys: Methods of Accelerated Exfoliation Corrosion Testing [22]. It should be noted, however, that hexavalent chromium ( $\text{Cr}^{6+}$ ) solutions are considered undesirable for health and environmental considerations and have been prohibited in some countries.

*Electrochemical and Conductivity Tests*—These are useful techniques that indicate expected exfoliation corrosion performance but do not actually produce corrosion. Both the electrochemical corrosion potentials and the electrical conductivity are secondary characteristics that relate to the metallurgical condition of the metal and must be correlated to actual exfoliation corrosion tests.

Several researchers experimented with electrochemically driven techniques. Budd and Booth used a potentiostatic approach [23]. Others have tried impressed current tests. Although both appeared promising, these procedures did not lend themselves to the multiple testing required for production control of heat treatment. Neither type of test has been standardized to date.

A useful measure of the degree of improvement in exfoliation resistance of the overaged T7X tempers for AA7075 and similar copper-containing AA7XXX alloys is available from a correlation of the decrease in yield strength combined with the increase in electrical conductivity as the alloy is overaged [3]. Such lot acceptance criteria are included in certain specifications for the T7X temper products of these alloys.

### Test Specimens

Specimens may be of any practical size or shape. However, it is advisable not to use too small a specimen since visual examination is the key evaluation method. It is recommended that flat specimens at least 50 mm by 75 mm in size and full section thickness be used with the specimen length oriented in the direction of principal deformation of the mill product. Larger sized panel specimens are desirable for salt spray testing or outdoor exposures.

The test surface is either the as-fabricated surface or some other specified plane(s). Interior planes typically used are: (a) T/10 = 10 % of the thickness removed (this is representative of a minimal cut to obtain a flat surface free of traffic marks), (b) T/4 = quarter plane, 25 % of the thickness removed, or (c) T/2 = midplane, 50 % of the thickness removed. These interior planes are representative of many of the exposed surfaces of parts machined for aircraft components and they also may expose regions in the grain structure with the highest likelihood of exfoliation susceptibility. When removing test specimens from extrusions and die forgings, locations where the grain structure is variable, such as underneath flanges and ribs, should be avoided. The roughness parameter of machined test surfaces,  $R_a$ , should not exceed 2.5  $\mu\text{m}$ , unless it is required to simulate an as-manufactured surface condition.

Edges of the test specimens should preferably be sawed or machined. If specimens are obtained by shearing, the plastically deformed edges should be dressed by machining, sanding, or filing to a depth equal to the specimen thickness to remove residual short transverse tensile stresses. With very susceptible materials stress-corrosion cracks parallel to the surface may initiate in the edges.

### Test Duration

The length of time to develop exfoliation in a susceptible material can vary appreciably depending on the degree of directionality of the grain structure and the heat treatment of the test specimen. Therefore, it can be helpful when the purpose is to compare various items in a series to examine and assign exfoliation ratings after increasing periods of exposure during the test.

*Accelerated Tests*—Standard tests generally are conducted for the recommended exposure period. However, if no appreciable exfoliation is observed on a new alloy or temper, the period may be doubled. If this still does not produce significant exfoliation it generally can be concluded that the material is not susceptible to exfoliation in that test medium.

*Outdoor Tests*—Past experience has shown that materials that are very prone to exfoliation in service conditions will show marked exfoliation within four years of exposure at severe outdoor sites, such as seacoast and certain highly industrialized urban areas. If test space is limited, specimens surviving this length of exposure at outdoor sites known to cause exfoliation can be terminated and considered “not highly susceptible.” However, some investigators now have programs of 20 or more years duration showing that exposures exceeding four years still may discriminate between materials with the “better and best” resistance.

### Evaluation of Test Results

One of the problems with evaluating exfoliation corrosion is the lack of a generally accepted numerical measure of the corrosion damage. Mass loss is a poor indicator of exfoliation behavior because the degree of attack can be spatially nonuniform. Delaminated layers that are not completely detached from the specimen also complicate accurate mass loss determination. Cross-sectional metallographic examination can add valuable information on the degree and mode of attack, but is time consuming and no relative ranking system has been devised.

Therefore, the usual practice is to inspect the specimens and to assign visual ratings with reference to standard photographs illustrating four degrees of severity as in ASTM G 34 and G 66. To choose a rating, the inspector must make a judgment, and herein lies the main source of variability in the test results from the relatively uncomplicated immersion tests. It is often desired for the record to make photographs of the exposed test specimens as well as to rate them using the standard photographs.

*Classification of Exfoliation*—The following classifications (Table 1) are recommended when reporting the visual ratings of corroded test specimens by comparison with standard photographs in Figs. 3–8 (after ASTM G 34, G 66, and G 112):

TABLE 1—Classifications for corroded test specimens.	
Classification	Rating
No appreciable attack	N
Pitting	P
General	G
Exfoliation	EA, EB, EC, ED

(a) N—No appreciable attack: surface may be discolored or superficially etched.

**FIG. 3—Metallographic sections illustrating two different types of attack (reprinted from ASTM G 34): (a) undermining pitting that may from the surface give the appearance of the beginning of exfoliation (Keller's Etch: 100×); (b) exfoliation resulting from rapid lateral attack of selective grain boundaries or strata forming wedges of corrosion product that force layers of metal upward giving rise to a layered appearance (Keller's Etch: 100×).**

**FIG. 4—Examples of exfoliation rating EA (superficial): tiny blisters, thin slivers, flakes, or powder, with only slight penetration into the metal (reprinted from ASTM G 34).**

- (b) P—Pitting: discrete pits, sometimes with a tendency for undercutting and slight lifting of metal at the pit edges (Fig. 3a).
- (c) G—General: fairly uniform corrosion with accumulation of powdery corrosion products; the basic type of attack may be either pitting or intergranular.
- (d) EA to ED—Exfoliation: visible separation of the metal into layers manifested in various forms such as blisters, slivers, flakes, fairly continuous sheets, and sometimes granular particles resulting from disintegration of thin layers of metal; attack may be wide-spread or localized. Various degrees of exfoliation with increasing area, penetration, and loss of metal are shown in Figs. 4–8.

*Inspection of Specimens*—After discontinuation of the exposure, performance should be rated while the specimens are still moist, taking into account all corrosion products adhering to the metal surface or lying on the bottom of the test container. Photographs may be advisable at this stage. If in some cases it is impossible to positively distinguish mild forms of exfoliation from general corrosion it may be helpful to chemically clean the specimens by soaking them in concentrated nitric acid (70 % HNO<sub>3</sub>, specific gravity 1.19) at room temperature for only a few minutes, just long enough to dissolve corrosion products without dislodging layers or flakes of true exfoliation, followed by gently rinsing again with tap water. When the presence of exfoliation is still questionable because of remaining powdery deposits or if real exfoliation actually was removed, metallographic examination of a cross section of the corrosion will be required to determine the correct rating (Fig. 3). The purpose is to avoid giving a specimen an unrealistic visual rating of EA or EB when there is no microscopic evidence of actual delamination or conversely giving an erroneous visual rating of P or G when the evidence of real exfoliation was destroyed. Experience has shown that material that is roughened and exhibiting a loosely adherent powdery deposit in the standard EXCO test does not exfoliate during exposure of five years in the seacoast atmosphere at Point Judith, RI [24].

FIG. 5—Examples of exfoliation rating EB (moderate): notable layering and penetration into the metal (reprinted from ASTM G 34).

FIG. 7—Examples of exfoliation rating ED (very severe): similar to EC except for much greater penetration and loss of metal (reprinted from ASTM G 34).

FIG. 6—Examples of exfoliation rating EC (severe): penetration to a considerable depth into the metal (reprinted from ASTM G 34).

When a test specimen appears to be borderline, choose the rating indicating higher susceptibility. And when exfoliation occurs at isolated sites, rate the worse condition observed.

Care must be taken not to over interpret the inherently subjective ratings. As an example, the difference in the amount of attack between samples rated on the severe end of the EA range and mild end of the EB range is small such that samples receiving those designations may not in fact have different exfoliation susceptibilities. In addition, material with exfoliation resistance between highly susceptible and highly resistant can be difficult to rate visually, as highlighted in an interlaboratory test program that used two non-commercial heat treatments of AA7075 with different levels of resistance (see ASTM G 34-01 section 14). Results from this round-robin test program indicate that the visual rating system gives consistent classification designation for highly susceptible samples but may produce a large amount of variation for moderately resistant tempers. Experience also suggests that the visual rating system produces more consistent results for highly resistant material than it does for aging conditions of moderate to low resistance.

FIG. 8—Examples of four degrees of exfoliation corrosion, EA-ED of several AA5XXX alloys (reprinted from ASTM G 66).

Another approach based on visual examination has been used in the former Soviet Union [4,22]. Three rating criteria are used to express the degree of damage on a scale of 1–10:

- (a) Percent area of swelling and exfoliation of test surface,
- (b) Maximum diameter in mm of swellings (blisters) on test surface, and
- (c) Percent length of cracking in specimen perimeter (edges).

The material is evaluated by calculating the arithmetic mean of these three criteria. Although a numerical result is generated, it is calculated from subjective visual estimates and is more complicated.

A classification system for exfoliation attack based on an objective and quantitative rating method and criteria would be a beneficial alternative to the existing subjective visual rating method.

#### *Test Procedures for Other Metals*

Exploratory investigations of the possible susceptibility to exfoliation corrosion of alloys of other metals would be advisable if wrought mill products have highly directional grain structures and if it is known that they may be susceptible to intergranular

or lamellar corrosion. It is recommended that, if practicable, exposure tests be conducted under environmental conditions of anticipated service applications. Otherwise, consider a severe seacoast atmosphere, one of the cyclic salt spray tests described in ASTM G 85, or one of the immersion type tests.

### Test Controls

It is always advisable to include control specimens from known materials representing both high and low resistance to exfoliation. This is recommended for both accelerated and outdoor tests. Such controls verify the validity of a particular test environment and permit the investigator to make some assessment of the normalcy of a particular test run. For example, one cannot conclude that a new material is resistant to exfoliation if the susceptible control specimen did not exfoliate to the usual degree. In outdoor tests, the condition of the susceptible control serves as an indicator of when a meaningful length of exposure has been reached. Control specimens are especially advisable in outdoor environments that encounter variable conditions of temperature, precipitation, airborne pollutants, and the like.

# Erosion, Cavitation, and Fretting

W. A. Glaeser<sup>1</sup>

## BASIC PRINCIPLES

### Review of Mechanisms

#### Erosion

SOLID PARTICLE and liquid drop erosion are surface removal processes caused by impingement of solid particles or droplets carried in a moving gas or liquid stream against a surface. Erosion can also occur when the surface is the moving body impacting suspended particles or drops, as happens on a helicopter blade moving through rain.

The mechanism of erosion differs for various materials. For ductile materials, impacting particles produce craters that have material extruded from the surface, as shown in Fig. 1.

FIG. 1—Crater formed in the surface of a ductile material by an impacting particle.

FIG. 2—Particle erosion of brittle material: (A) subsurface crack formed by impacting particle; (B) the result of multiple impacts causing fracture linkage and chipping out of material.

The arrow in Fig. 1 shows the direction of travel by the impacting particle. The crater formed is shaped by the particle and by the angle of impact. A lip of material has been thrown up on one side of the crater. Population density of craters increases with time until the entire surface is covered. The time to develop this condition is called the induction period. During the induction period, surface removal is small. After the induction period, erosion rate increases as the crater lips are broken off by impacting particles.

For brittle materials such as glass, the surface removal mechanism is different. Impact by particles causes micro fractures in the surface and as fractures increase in numbers they grow together and produce chips, as shown in Fig. 2.

### Factors Controlling Particle Erosion

- **Impingement angle:** Ductile materials show the highest erosion rate at low impingement angles. Brittle materials show highest erosion rates at impingement angles around 90° to the surface. These effects are shown in Fig. 3. The dashed line shows ductile material erosion characteristics while the solid line represents ceramics. The dashed line is shown to vary with the impingement angle  $\alpha$  by theory. However, in practice, erosion of metals departs from the dashed line at about 40° as shown. It can be seen that for ductile materials a maximum volume of removal occurs at an impingement angle of about 28°. For brittle materials, minimum removal occurs at low impingement angles, while the maximum removal occurs from 70 to 90°. Concentration of particles in the gas or liquid stream can influence the erosion. When concentration becomes heavy, erosion rate decreases owing to the interference among particles.
- **Velocity:** Particle velocity has a significant effect on erosion rate. Erosion is generally given as mass loss per unit mass of particles impinging.

For a given impingement angle, the erosion rate can be expressed as follows:

$$E = kv^n$$

where:

$E$  = erosion rate

$v$  = velocity

$n$  = exponent that ranges between 2 and 2.5 for metals and 2.5 and 3 for ceramics.

<sup>1</sup>Research Leader, Battelle Laboratories, 505 King Ave., Columbus, OH 43201.

FIG. 3—Chart showing the effect of impingement angle on erosion weight loss for metals and ceramics. Aluminum characteristics (typical for ductile metals) are shown in the dashed line. Aluminum oxide (ceramics) is represented by the solid line. The dashed line follows theory while the solid line deviation at about 40° represents practical experience (from Ref 1).

- Particle size: Erosion rates for metals decrease significantly when particle size drops below 100  $\mu\text{m}$ . For ceramics, erosion rate increases to the two-thirds power of particle diameter.
- Material hardness: For steels, hardening by working or by heat-treating has little effect on erosion resistance. For pure face centered cubic metals, erosion resistance increases with hardness. Thus, tantalum has twice the erosion resistance of aluminum. (Hardness for pure aluminum is 37 DPH, for tantalum the hardness is 70 DPH.)

Liquid drop erosion is a different process from solid particle impingement. When a droplet impacts a solid surface, the contact stress distribution is maximum at the edges of the drop and minimum at the center of the contact. This is the opposite of a Hertzian concentrated contact for a solid point pressed against a flat surface. The droplet rapidly spreads radially at very high velocity and causes a roughening of the periphery of the circular contact. Thus, the deformation left by the impacting drop is a ring indentation with a little depression in the center of the circle. The circular indentation is roughly the diameter of the impinging drop. As the surface roughens with accumulation of drop impacts, the indentations deepen and fill with liquid. The presence of liquid in the pits tends to cushion the drop impacts and reduces the rate of erosion.

The appearance of the eroded surface impacted by liquid drops is different from solid particle erosion. Liquid drop

impacts leave roughly circular pits while solid particle impacts leave irregular pits with shapes that show the angle of impingement.

- Droplet velocity influences erosion rate. Heyman [1] suggests that maximum erosion rate varies as the fourth or fifth power of impact velocity.
- Impact angle also influences erosion rate. Rate is maximum around 90°.
- Erosion rate increases with droplet size increase.

## EROSION-CORROSION

Titanium alloys are being used in increasing quantities in the aerospace industry because of their high corrosion resistance. The reduction in the passivating films caused by particle erosion as observed in stainless steel has been investigated for titanium and titanium alloys [2].

Solid particle erosion in salt water was found to increase anodic passivation in titanium. The rate of erosion for pure titanium was compared with the same for titanium alloys. It was found that titanium alloys like Ti-6Al-4V showed significant increased resistance to erosion-corrosion. The addition of 0.1 % Ru to Ti-6Al-4V further increased the erosion-corrosion resistance of the alloy.

## Cavitation

The most familiar is cavitation of ship propellers. At the periphery of the rotating propeller, the moving velocity is highest. Fluid dynamic effects cause the formation and collapse of gas bubbles near the tips. The collapse of the gas bubbles is so rapid that it causes violent pressure impulses that are audible. These pressure pulses shock the solid surfaces and cause localized pitting. The origin of the bubbles can be trapped air bubbles, dissolved air coming out of solution or water vapor.

Cavitation in a liquid medium requires a rapidly changing pressure distribution. This can happen in oil-lubricated journal bearings around a discontinuity like an oil inlet hole. The shear rates in the thin oil film supporting the bearing load are very high. Thus, when the moving oil encounters a hole or slot, flow rate and local pressures change abruptly. Bubbles in the vicinity collapse. The bubble collapse is much like a violent implosion and the shock wave will deform and pit the bearing material. Cavitation in oil can be more damaging than in water [2].

## Fretting

One definition of fretting is "Wear phenomena occurring between two contacting surfaces having oscillatory relative motion of small amplitude." **Note:** *Fretting* is a term frequently used to include fretting corrosion. This usage is not recommended.

Another is the "Small amplitude oscillatory motion, usually tangential, between two solid surfaces in contact." **Note:** Here the term fretting refers only to the nature of the motion without reference to wear, corrosion or other damage that may follow. The term *fretting* is often used to denote fretting corrosion and other forms of fretting wear.

Usage in this sense is discouraged due to the ambiguity that may arise.

### Fretting Corrosion

"A form of fretting in which chemical or electrochemical reaction predominates. Note: Fretting corrosion is often characterized by the removal of particles and subsequent formation of oxides, which are often abrasive and so increase the wear. Fretting corrosion can involve other chemical reaction products that may not be abrasive."

The above quote is from the Tribology Volume of the Metals Handbook [3] and serves to point out the confusion that can exist in defining fretting.

The term *fretting* means removal of material from between two contacting surfaces when one oscillates against the other at a very small amplitude (sometimes from vibration). Godfrey [4] showed that for iron and steel, metal particles are removed and pushed to the edge of the contact where they oxidize. He demonstrated that oxidation did not start within the contact region. He also showed that inert metals like platinum and gold will produce fretting debris under the same conditions.

### Factors Controlling Fretting [5]

- Number of cycles: Volume removed is about proportional to number of fretting cycles.
- Load: Damage increases linearly with increasing normal load.
- Amplitude: Fretting wear volume increases with amplitude. Above about 100  $\mu\text{m}$  the rate increases owing to a change in the wear mode. Wear rate can go to zero at very low amplitudes if motion is purely elastic.
- Frequency: Fretting wear per cycle increases at low frequency in oxidizing environment or corrosive conditions. Frequency has little effect when inert environment exists.
- Temperature: The nature of oxide chemistry influenced by temperature will affect fretting. Some oxides become quite refractory at elevated temperatures and inhibit fretting.

R. C. Bill [6], discussing high-temperature fretting, suggests three conditions: (1) adhesive asperity contact and removal of metal in the absence of an oxide film, (2) removal of oxide film as it grows, and (3) oxidative attack of fretting pit walls causing weakening and removal of wall surfaces.

### Fretting Fatigue

Fretting of clamped joints will reduce the fatigue strength of the joint significantly. In fact just fretting a joint reduces its inherent fatigue strength. Figure 4 shows a fatigue S-N curve for both classic fatigue and for fretting fatigue (where S is stress and N is number of fatigue cycles).

Waterhouse [7], using Mindlin's state of stress for fretting contacts, found that the action of fretting was to increase the areas of real contact and to increase the coefficient of friction until a sufficient volume of material is subjected to sufficiently high stress field to enable a crack (or cracks) to

FIG. 4—S-N curve showing the reduction in fatigue strength caused by fretting.

be generated. Coefficient of friction can reach values of 0.8 during fretting.

Hills and Nowell [8] propose that the contact stress state (assuming a ball-on-flat configuration) involves a maximum shear stress oriented at 45° to the surface which produces slip and eventual persistent slip bands. Cracks are then generated in these bands.

More recent experimental work in fretting fatigue [9] has shown that fretting alone can develop cracks. These cracks are oriented at approximately 45° to the surface and are likely shear induced. An example is shown in Fig. 5. This is a photomicrograph of a right section through a titanium alloy test bar showing several fretting generated cracks that did not propagate to failure.

## TESTING TECHNIQUES

ASTM International has a number of standard test methods for erosion, cavitation, and fretting wear.

### Particle Erosion

The ASTM standard for conducting erosion tests by solid particle impingement is ASTM G 76-95 (2000) [10]. ASTM scope: "This practice covers the determination of material loss by gas-entrained solid particle impingement erosion with a jet - nozzle type erosion equipment. This practice may be used in the laboratory to measure the solid particle erosion of different materials and has been used as a screening test for ranking solid particle erosion rates of materials in simulated service environments. Actual erosion service involves particle size, velocities, attack angles, environments, etc., that will vary over a wide range. Hence, any single laboratory test may not be sufficient to evaluate expected service for solid particle impingement erosion measurement for which interlaboratory test results are available."

Since particle velocity has a strong influence on erosion rate, accurate results require knowledge of this parameter.

**FIG. 5—Photomicrograph showing fretting caused surface cracks in a metallographic section through a Ti-6Al-4V fretting fatigue specimen.**

The particles in a pressurized gas jet do not necessarily move at the gas velocity. Measurement of gas entrained particle velocities is difficult. Therefore, another test method, involving moving the specimen through a suspended column of particles can also be used. The specimen or specimens are mounted on a rotating arm or wheel with set approach angles and rotated through a stream of particles dropped in their path or suspended in a fluidized bed. There is no ASTM standard for this; however, recommended practice does exist for liquid particle impingement (see below).

### Liquid Impingement Erosion

The same methods used in particle erosion tests can be used in liquid impingement tests. Liquid gun devices in which a small quantity of liquid is ejected through a nozzle are used in the study of drop impact effects on materials [11]. The rotating arm method, carrying specimens through suspended drops, is often used for testing aircraft leading edges and helicopter rotor blades erosion characteristics in rain fields. ASTM G73-98, Practice for Liquid Impingement Erosion Testing, gives recommendations for setting up a liquid drop impingement test [12].

### Cavitation Erosion

ASTM G 32-98, Test Method for Cavitation Erosion Using Vibratory Apparatus [13], describes a standard method for performing cavitation tests. Its scope is listed as follows: "This test method produces cavitation damage on the face of a specimen vibrated at high frequency while immersed in a liquid. The vibration induces the formation and collapse of cavities in the liquid, and the collapsing cavities produce the damage to and erosion (material loss) of the specimen."

"Although the mechanism for generating fluid cavitation in this method differs from that occurring in flowing systems and hydraulic machines, the nature of the material damage mechanism is believed to be basically similar. The method therefore offers a small-scale, relatively simple and

controllable test that can be used to compare the cavitation erosion resistance of different materials, to study in detail the nature and progress of damage in a given material, or by varying some of the test conditions to study the effect of test variables on the damage produced."

### Fretting Wear

A number of test methods are used to evaluate the fretting resistance of various materials and lubricants. The object of the tests is to bring two surfaces into contact under a known load and contact geometry and to move one surface relative to the other under an oscillating motion with a very small amplitude.

Conventional wear test configurations can be adapted to fretting. Ball-on-flat, block-on-ring, and crossed cylinders can be modified so that the sliding motion can be made oscillatory and the amplitude small (less than 100  $\mu\text{m}$ ).

Fretting fatigue configurations are generally adaptations of standard bending fatigue machines. By clamping metal pads to the fatigue bar in the maximum bending strain region, the relative motion developed between the pads and the bar surface as it flexes produces fretting in the bending fatigue zone. This will cause acceleration of the fatigue process.

ASTM Method D 4170, Test Method for Fretting Wear Protection by Lubricating Greases [14], evaluates the fretting wear protection to rolling contact bearings afforded by various greases. This test was developed in response to a fretting problem found in long distance transportation of automobiles. Fretting of the wheel bearings (sometimes called "false brinelling") is caused by small oscillations cause by swaying movements of the transporters (barges and automobile truck transports). This test can be used for ball bearings under small amplitude oscillatory movement.

The above test methods do not exactly simulate the actual fretting conditions. The surface damage produced by the test should be compared to the damage on parts damaged in service. If there is significant difference between scar morphologies, the wear mode may not be correctly simulated in the test. Corrections can be made in contact geometry, contact stress, and amplitude and velocities of movement.

### Fretting Fatigue

Currently, there is no recognized standardized test for fretting fatigue. A number of tests have been developed. Most involve either bearing balls or cylindrical bars clamped on either side of a fatigue "dog bone" specimen. The dog bone is either subjected to push pull tensile loading or reversed bending. Both cause elastic deformation in the bar contact zone on the order of 10 to 100  $\mu\text{m}$  providing relative motion between the contacting surfaces. Some tests involve fretting alone and then subjecting the fretted specimen to classic fatigue conditions. A variety of contact geometries have been tried for fretting fatigue testing including "bridges," or flat specimens with a channel cut in the contact surface or the flat end of chamfered rectangular coupon. Descriptions of these various test configurations can be found in Ref 8, Chapter 7.

# Dealloying

*Ann Chidester Van Orden*<sup>1</sup>

DEALLOYING HAS BEEN KNOWN for many years, in many alloy systems, under many different conditions. A number of mechanisms have been proposed and examined over time. Six specific mechanisms are reviewed here with information regarding systems wherein they have been observed, temperature regime, solutions, microstructural features, and the evidence that was cited for their origination. The literature regarding these mechanistic models is outlined along with possible problems not addressed by each model. Methods used for examination of dealloying are mentioned along with evaluation methods for considering the results of the examination. Although few standards exist dealing with dealloying, the lack of standards is discussed along with the few standards in existence. Test methods such as those used in examining stress corrosion cracking (SCC), which may be influenced by dealloying, are outlined and the effect of dealloying on these test methods is discussed.

## FUNDAMENTALS

ASTM International defines dealloying, or parting, as “the selective corrosion of one or more of the components of a solid solution alloy” [1]. This preferential removal or parting has been known for as long as alloys have been exposed to corrosive environments. An early study by Calvert and Johnson [2] discussed the action of acids on metals and alloys, specifically 50Cu-50Zn submerged in concentrated HCl for several days. The authors stated that, over the duration of the experiment, the zinc was totally removed from the alloy, rendering the specimen copper-colored and quite soft. This explanation of the preferential removal of the zinc is one of the earliest discussions of a mechanism for dealloying.

Dealloying is known to occur in many alloy systems at ambient and high temperatures, in aqueous and vapor environments, and in mild-to-severe acids or bases [3–10]. Examples of systems that show dealloying include removal of zinc from copper-zinc [10–13], nickel from copper-nickel and Cu or Ni from monels [7,14–16], aluminum from aluminum-bronzes [5,14,15], manganese from copper-manganese [17], tin from copper-tin [18], copper from copper-gold [19–24], and from Al-Cu-Li [25,26]. Nickel can be dissolved preferentially from steels [27]. At high temperatures, chromium will dissolve preferentially from steels [28] as well. Cobalt

is known to dissolve from Co-Ni-Cr [29,30], chromium and iron can be removed from Fe-Ni-Cr [31,32], and iron will dissolve preferentially from gray cast iron [33]; carbon (graphite) can also be preferentially removed from cast iron [34] and from steels [35,36]. In high-temperature hydrogen environments and certain oxidizing atmospheres as early as 1917, the preferential removal of iron from Fe-Cu alloys was reported [37]. In addition to the much studied removal of copper from Cu-Au [32–38], gold can be removed from Pt-Au [38–40], silver from Ag-Pd [41] and from Ag-Au [42–51], and lead from Pt-Pb [52]. Several authors have surveyed the literature on dealloying and summarized the information up to the time of their published work [8,35,51,53].

Dealloying is characterized by the formation of a porous microstructure, much like that of a microscopic sponge. The pores are interconnected and open to the environment. Selective dissolution and preferential leaching are other terms for dealloying. Dezincification is the specific term given to preferential removal of zinc from brasses. Other words have developed that are similar to dezincification (such as denickelification) and refer to dealloying in specific cases. The term “dealloying” is universally acceptable and is preferred by ASTM [54]. Alloys in which a specific phase is susceptible to dealloying include some of the systems mentioned earlier, such as gray cast iron, stainless steels, and copper-zinc alloys [55].

In alloys that form solid solutions, the microstructure formed by dealloying is characterized by islands of the more noble material, with open channels between the islands. This unique microstructure is one of the characteristic features of dealloying. Figure 1 shows an example of this microstructure in a 90Ag-10Au alloy, dealloyed electrochemically in perchloric acid. Although the dimensions of the microstructure may vary with alloy composition [19], and dealloying conditions such as solution, temperature, and time [49], the dimensions of the islands and channels are approximately equal and are characteristic of the specific set of dealloying conditions applied. In some cases, the microstructure can be viewed without magnification or with low-power light microscopy [3]; under other circumstances, the microstructure is of small enough dimensions that it can only be viewed with transmission electron microscopy (TEM) [51] or high resolution scanning electron microscopy (HRSEM) [56].

Many of the alloys that undergo selective dissolution (or dealloying) are also prone to stress corrosion cracking (SCC).

<sup>1</sup>Formerly, Mechanical Engineering Department, Old Dominion University, Norfolk, VA 23529. Now deceased.

**FIG. 1—The microstructure of silver-gold anodically polarized in perchloric acid. The microstructure consists of islands of the more noble material (the dark areas) and empty channels (the light areas), which are of equal dimensions. The islands and channels are interconnected and cover the entire specimen following the electrochemical polarization treatment to produce dealloying. (160 000  $\times$ .)**

From the ASTM definition, stress corrosion cracking is “the simultaneous action of a corrosive environment and a sustained tensile stress promoting rupture” [54]. Both SCC and dealloying often occur in the same environment. By the 1940s, dealloying was considered to be involved in the initiation of SCC [57].

Examining the relationship of dealloying to initiation of SCC involves, first, exposing susceptible alloys to environments that promote dealloying. A mechanically weak, porous layer forms, either on the surface or at pre-existing crack tips, and with addition of stress, ductile fracture occurs in this corroded material and may propagate into the surrounding uncorroded region leading to failure. The study of the initiation of SCC by dealloying is of continuing technological importance [58–60]. Recent studies have focused attention on crack initiation in dealloyed material [22,61–64].

Biological activity has been found to cause the dealloying of Cu-Ni alloys under some conditions [65]. Dealloying may also be a problem in copper-gold and silver-gold alloys used for connections on printed circuit boards [66–68]. Since the vapor-deposited layers of silver-gold on printed circuit boards are very thin, even mild environments may cause enough dealloying to be of serious consequence and result in failure. A new class of aerospace alloys based on the aluminum-lithium system may also be affected by dealloying [25,26]. The removal of zinc from brasses (dezincification) has been of concern for many years [69], especially since it

occurs under ambient conditions in seawater and does not require application of a potential to initiate the dealloying.

In some cases, dealloying may have beneficial applications; for example, in the Raney process, patented in 1925 [70,71], dealloying produces a high-surface-area of nickel for applications such as catalysis, by the preferential removal of aluminum from Al-Ni alloys, leaving “active” nickel behind. This is a beneficial use for the porous metal resulting from dealloying. Another example of a beneficial use of dealloying is a recent one. Novel work by Verink and coworkers showed that the inner surfaces of faucets can be dealloyed to preferentially remove the lead from the surfaces and eliminate lead contamination to the drinking water coming into contact with the interiors of the faucets [72]. These examples show that dealloying continues to be of commercial interest and benefits of the microstructure and composition of dealloying can be found.

## MECHANISTIC MODELS AND MECHANISMS OF DEALLOYING

In order to exercise control over the process, the mechanism by which an alloy is parted (or dealloyed) needs to be understood. Mechanisms of dealloying have been discussed as long as the phenomenon has been known [2,69]. The specific example of dealloying in silver-gold alloys will be used to help explain and demonstrate features of the models outlined here. Six separate mechanistic models have developed for describing how dealloying takes place. The mechanistic models may be designated: Volume diffusion, vacancy diffusion, surface diffusion, oxide formation, percolation, and dissolution and reprecipitation. With these six models and the amount of experimental work that has gone into their creation, varying opinions on the results of experimental work exist and can be used to reinforce more than one of the models.

Preceding the discussion of the six proposed models for dealloying is Table 1, which summarizes the basic features of each model, along with information such as the temperature regime and the alloy systems to which each has been applied.

### Volume Diffusion Model

As the less noble component is removed by ionization and diffusion away from the metal surface, a constant supply of the less noble metal must be maintained by its diffusion toward the corroding interface from the bulk or diffusion of the more noble components away from the interface, or both (interdiffusion). At high temperatures, diffusion may be fast enough in some alloys to account for the constant supply of ionizable metal [73–75]. It was in this high-temperature regime where this model was first proposed by Wagner [73]. Since diffusion measurements are most often made at high temperatures, extrapolations of diffusivities to lower temperatures are often used in dealloying studies performed at room temperature. These extrapolations show that diffusion is too slow under steady state conditions to account for the extent of dealloying. Diffusion at ambient temperatures may be faster than extrapolations show, due to effects of grain boundaries, dislocations, or enhanced numbers of vacancies.

**TABLE 1**—Representation of the six mechanistic models for dealloying with information on temperature regimes, microstructural features, and evidence for the existence of the specific models.

Mechanism	Temp.	Features	Evidence	Alloys
Volume Diffusion	HT	Bulk diffusion accounts for all atoms ionized at interface	Intermediate composition phases found by X-ray diffraction	Au-Ag, Au-Cu, Cu-Ni, Co-Pt,
Vacancy Diffusion	RT	di- and trivacancies create pipeline diffusion	Mathematical model and X-ray diffraction data	Au-Cu, Co-Pt, others
Surface Diffusion	RT	High Energy Sites (Kinks and Jogs) allow dissolution of less noble metal	Mathematical simulation	Au-Cu, Au-Ag, Cu-Zn, others
Oxide Formation	RT	Noble metal oxide is metastable phase oxide rearranges to noble metal islands	Electron diffraction pattern shows extra spots	Au-Ag only
Percolation	RT	Inner-connectedness of lattice allows less noble metal to be removed	Mathematical simulation of structure	Au-Ag, Fe-Cr, Ni-Co, others
Dissolution and Reprecipitation	RT	Dissolution of both components, reprecipitation of more noble component, as islands	Solution chemistry crystals of pure metals electron diffraction shows rings	Au-Ag, Cu-Zn, Fe-Ni, others

A mathematical explanation for the severity of the room temperature diffusion problem, exemplified by silver-gold, can be summarized as follows: Data [76,77] demonstrate that interdiffusion at room temperature is too slow to account for dealloying. Diffusion coefficients previously used were extrapolated from values taken above 600°C. Data taken nearer room temperature cast doubt on earlier extrapolations and allow much more reliable values for diffusion coefficients to be obtained. These values could not account for diffusion of the silver to the solution interface, which would require diffusion of many orders of magnitude faster for removal of all of the silver from the alloy. Since, in some alloy compositions at room temperature, all of the silver can be ionized and removed from the alloy within a few minutes, bulk diffusion cannot be the means for moving the silver to the surface for ionization. There must be a much faster method by which the less noble metal can reach the solution metal interface, because volume diffusion can only account for a fraction of the movement required to ionize all of the less noble metal at the alloy-solution interface.

### Enhanced Diffusion Models

Mechanisms seeking to explain dealloying by enhanced diffusion have been considered by many authors. Vacancy Diffusion, where atoms associated with vacancies are transported rapidly through the lattice, is known to be faster than equilibrium bulk diffusion. This atomic diffusion coupled to vacancy diffusion is at the center of a model proposed by Pickering [78]. The model involves the formation of a large number of di- and trivacancies on the surface as a result of the dealloying process. Monovacancies have been shown to be too slow to account for the diffusion and so are not considered in Pickering's model [78]. In a later article, Pickering showed that with a divacancy concentration of approximately 10<sup>-2</sup>, his model can account for the diffusion of the less noble metal to the surface [79]. This is several orders of magnitude higher than the equilibrium vacancy content in well-annealed samples [77], and di- and trivacancies are generally at concentrations lower than the equilibrium monovacancy concentrations. This suggests that any model that relies on large numbers of vacancies to enhance diffusion must account for the energy required to form these vacancies in the dealloyed material, and this energy of formation is not included in Pickering's model.

Recent work by Jones et al. [80] has shown an enhancement of diffusion due to vacancies formed by anodic polarization. He has once again suggested that vacancies formed at room temperature by anodic dissolution are implicated in dealloying, embrittlement, and stress corrosion cracking. Specifically, divacancies are the species that migrate to the dissolving interface and enhance diffusion at that site. Other authors [81] have also recently returned to the vacancy enhanced mechanism for dealloying and SCC.

### Surface Diffusion

This is a critical feature of most models. Surface diffusion is faster than interdiffusion, discussed heretofore. Tischer and Gerisher [42] first proposed that surface diffusion could account for replenishment of the less noble metal to the corroding interface; Vermilyea [82] followed the initial lead, while theoretical advancements were made by Forty [43,45,83] and Galvele [84]. In Forty's model, the dissolution is thought to occur from kink sites on the surface, with the more noble metal diffusing to form islands. Forty suggests the dissolution of the less noble metal forms large numbers of surface vacancies that migrate inward and assist in the rearrangement. Vacancies initially create a disordered region that decomposes into noble metal islands that grow by surface diffusion, allowing removal of the less noble metal. However, even at the surface there is an energy barrier in vacancy formation, and data from Cook and Hilliard [77] found vacancies did not affect the overall diffusion rate significantly. Recently, surface diffusion has been the mechanism of most interest and several new groups have added their research to the growing body favoring surface diffusion as the mechanism that best explains the dealloying phenomenon [85-87].

Work has been conducted by Moffat et al. [88] involving scanning tunneling microscopy on copper-gold alloys. Several methods, including scanning tunneling microscopy, have been used by other authors [84-87] focusing on more rapid surface diffusion as the means for dealloying in various alloys. In all cases, the surface diffusion rates that are needed for complete dealloying are many orders of magnitude faster than the bulk diffusion rates. In some of the studies [85,87] new values quoted for the surface diffusion rates at room temperature are much faster than the rates previously accepted for surface diffusion.

Similar to surface diffusion is grain boundary diffusion, which is also much faster than bulk lattice diffusion. Pryor

and Lin [88] suggest both grain boundaries and pipe diffusion are active during dealloying with applied strain in copper-based alloys. Diffusion along grain boundaries has been considered as a possible means of allowing the less noble metal to rapidly diffuse to the surface and contribute to the rate at which dealloying occurs [82]. Grain boundaries were found to move during dealloying or under the influence of diffusion. This phenomenon, diffusion-induced grain-boundary migration (DIGM) [89–93], has been detected in single crystals and thin-film polycrystals. It may be worth consideration in dealloying studies, since direct movement of grain boundaries can occur in both alloying [92] and in dealloying [93], with solute diffusion leading to the formation of new grains (diffusion-induced recrystallization) [94].

Another form of the surface diffusion model relies on atomic rearrangement to create noble metal-rich islands and was proposed in a study of Ag-Au alloys by Forty [45]. Galvele makes use of rearrangement in his model [84,87], as does Young [95]. It is a way of managing the need for creating more surface without expending a great deal of energy. Young suggests that the remaining material will rearrange to accommodate the loss of the less noble material at the reaction front. He also cites surface diffusion along the interface between the dealloyed region and that which has not undergone dealloying as the mechanism of segregation of the less noble material. Forty, on the other hand, uses rearrangement to explain how the less noble material reaches the surface to be ionized. The more noble material rearranges, thus opening up pathways for the ionization to occur. In Galvele's model [87], rearrangement is an intermediate step on the way to formation of the porous microstructure.

### Oxide Formation Model

In the oxide formation model, oxidation of the more noble metal (gold, in the example of Forty [45] and Durkin and Forty [43]) occurs as a result of the change of chemical environment brought about by the selective dissolution of the less noble silver. The gold oxide is thought to be a metastable phase, which accounts for the rapid rearrangement of the gold into the islands noted in the microstructure. Surface diffusion is the mechanism by which this rearrangement occurs. Evidence cited for oxide formation involves electron diffraction patterns and dark field electron microscopy, but these interpretations are not without problems. One concern with this model is that stable oxides are not known to form in several of the alloy/environment systems where dealloying takes place [96,97]. Generally, this model can be considered as a subset of the surface diffusion model, since the formation of the oxide is merely an intermediate step.

### Percolation Model

Diffusion plays a minor role in a mechanistic model described recently by Sieradzki et al. [98] and Halley [99], which relies on the interconnected nature of the lattice material. As the less noble component goes into solution, percolation allows the solution to move into the bulk and ionize the less noble component because each atom of noble

metal is less interconnected to another less noble metal atom. This model relies on the new science of chaos theory to explain the complex behavior of the systems undergoing dealloying [99]. Mathematical modeling involving Monte Carlo simulation for diffusion, using percolation theory, with simple rules for dissolution of the less noble component was combined with known morphological features of the phenomenon. But in the initial simulation, these rules lead to cessation of the dealloying process if surface diffusion was not employed. When simulations of dealloying take place, involving the same rules of dissolution but with surface diffusion added, the results for the 2D square and the 3D simple cubic lattices produce many of the features usually associated with dealloying, such as a porous island/channel structure and coarsening of the porous structure on annealing, but on an atomic rather than molecular scale. Although the dimensions do not match the microstructure found experimentally, the mathematical model is interesting in its ability to produce an island/channel structure. A percolation model for dealloying was originally proposed by Keir and Pryor [17] and the contribution of Sieradzki et al. [98] is primarily in the computer-generated modeling of the lattice and the mathematical description of the model. Recent work on coarsening of dealloyed microstructures with annealing has shown microstructural features similar to those seen in the mathematical modeling [49,63,85,98–100].

There are some concerns about using percolation theory itself, which limits removal to 30 % of the original composition of the more noble component [101]. In work by Halley, mention is made that at high surface potentials, percolation will not occur since the surface will not be fractal, and an additional feature is needed to explain dealloying beyond the limits of percolation theory [99]. Sieradzki et al. [98] overcomes this limitation by allowing a small amount of surface diffusion to occur, which will initiate further fractal formation at the surface.

### Dissolution and Reprecipitation Model

One model that involves essentially no diffusion in the bulk or on the surface could be characterized as dissolution and reprecipitation. Dissolution of the entire alloy surface under anodic conditions is followed by reprecipitation of the more noble component. Early in this century, many authors postulated this as the most likely mechanism for dealloying [3,37,102]. Much of the early work was done on brasses and involved chemical analysis of the solutions during dealloying. This analysis showed the presence of both copper and zinc, under most conditions.

Holloman and Wulf [103] and Fink and Evans [104] suggested that electrochemical inhomogeneities could contribute to the redeposition, at copper-rich cathodic sites, of the copper that had been dissolved from anodic sites along with the zinc. More recently, Heidersbach [105,106] and Heidersbach and Verink [55] have shown, definitively, that under certain conditions, dissolution and reprecipitation occur in brasses. Swann [107] also showed that particles of pure gold were formed on the insides of tunnels formed by dealloying of copper gold alloys in nitric acid. The study of linear instability was the major thrust of the work by Halley [99], who

considered both the dissolution and deposition cases. Hamilton [108], who also considered only deposition, showed that the surface instability leads to the formation of particles rather than a smooth surface. Young [95] describes dealloying of copper-aluminum alloys and cites dissolution and reprecipitation of the copper as the mechanism by which the porous microstructure coarsens. Mathematical modeling by Newman et al. [109] has shown that for Fe-Cr alloys, particles of chromium can form on the surface under conditions of incomplete passivation.

The dissolution and reprecipitation model fell out of favor for certain alloy systems like copper-gold when no gold could be detected by chemical analysis of the solution sampled during dealloying [110]. Electrochemical techniques such as measurement with a ring disk electrode also showed that no gold was plated onto the surface of the ring, while the disk of copper-gold was under dealloying conditions, suggesting that no dissolution of gold occurred from copper-gold alloys.

Other possible difficulties with this model include the appearance of intermediate compositions between those of the noble metal and the original alloy, when precipitation of only the noble metal is predicted by this model. Dealloying is also known to occur at potentials far from the known dissolution potential for the more noble metal, leading to questions as to whether any of the more noble metal would dissolve under these conditions.

In summary, regarding the mechanistic models proposed for dealloying, none has been shown to be without problems. The volume diffusion model is much too slow at room temperature to allow dealloying to go to completion. Enhanced diffusion mechanisms have sought to remedy this problem by applying faster means of diffusion. The vacancy diffusion model encounters difficulty in explaining the energy required to form large numbers of di- or trivacancies, which are necessary for this model's success. Surface diffusion has been shown to be fast enough to account for the diffusion required for complete dealloying, if all the diffusion occurred by this means. The difficulty here is that much more surface would need to be created for surface diffusion to be the only means of diffusion needed. The percolation model, as it is presently discussed, involves a certain amount of surface diffusion. This model can account for the removal of the less noble alloy, but it cannot provide a means for formation of new surfaces such as the crystallites seen in some studies [51]. Currently, the only model able to explain formation of crystallites is the dissolution and reprecipitation model, which encounters problems explaining dealloying far from the dissolution potential of the more noble alloy.

### Discussion of "Parting Limits"

In some alloy systems, studies of dealloying appear to show a "parting limit." ASTM defines parting limit as:

"The minimum concentration of the more noble component in an alloy, above which parting (or preferential dissolution) does not occur" [1].

Parting limits have been suggested in many alloy systems, particularly binary alloys. A thorough review of parting limits up to the time of its publication is Pickering's 1983 article [8]. In order to explain the development of a parting limit,

FIG. 2—After a figure by Pickering in Ref. 8, outlining the polarization behavior of alloys that undergo dealloying. The value of potential, shown as  $E_c$ , is the value of the critical potential above which Type II dealloying behavior is expected.

the silver-gold system is considered as an example. In silver-gold alloys, a parting limit was first reported in the extraction of gold from native silver-gold alloys by beneficiation involving dissolution [111]. It is quite likely that the existence of certain compositions of gold-rich silver-gold alloys, which were virtually impossible to "part" by static dissolution processes, had been known since ancient times, and this knowledge was instrumental in determining the composition of alloys that were made from native ores [38,112]. Native gold is almost always alloyed with some silver. One gold-silver alloy that was well known in ancient times is called electrum and is approximately 20 % silver. Development of the concept of a parting limit in other binary alloys followed much the same path, from origins in the mining industry or from phenomenological studies that were usually chemical rather than electrochemical in nature, or from case studies in aqueous solutions [102–104,113]. Few electrochemical studies have questioned the existence of parting limits in a number of binary systems [22]. Most of the work on binary alloys has concentrated on the initiation of dealloying rather than its completion [24,105–109].

Parting of gold from silver was usually done with acids such as nitric or sulfuric acid. In order to separate fully the silver from the gold-rich alloys, additional silver was added before the acid dissolution process took place. Textbooks mention complete parting of gold from a silver-gold alloy; the amount of silver must be at least 2.5 times the amount of gold. Compositions of 20–25 % gold are suggested as best compositions for parting in mining textbooks. Even in textbooks that describe parting limits, the removal of gold from alloys containing various amounts of gold greater than 50 % is mentioned, but is deemed not "efficient" [111]. Reports of dealloying of other binary alloys in compositions beyond the parting limits have occasionally been seen, but have been considered controversial [55,114].

In approaching the issue of parting quite broadly, Pickering, in 1983, provided a widely used schematic representation of the anodic polarization behavior of any binary alloy (A-B), such as copper-gold, silver-gold, most brasses, and many others, which are known to undergo dealloying [8]. He covers the electrochemical behavior of binary alloys, as well as the parting limit. A figure of the same type as that by Pickering is shown here as Fig. 2; the markings follow

those of the original. Pickering designated three regions of dissolution behavior. In the first region (Region 1), which is characterized by very low current values over a wide range of potentials, the alloy is undergoing dissolution of the less noble component (A) and a buildup of the more noble component (B) on the surface. No porosity is expected in Region 1, only uniform dissolution of A. Region 2 begins with the initiation of a higher dissolution rate of A, and a marked increase in current with only a small increase in potential. Dissolution of the less noble component, A, preferentially occurs in this region. Dealloying occurs in this region over a range of potentials and for a range of alloy compositions, with the formation of a porous layer as the less noble component is dissolved. Pickering's explanation for the transition from this region of typical dealloying behavior to the next region is not absolutely clear, but is thought to go no further than the potential at which the more noble component, B, begins to dissolve. Above the dissolution potential for B, Region 3 behavior occurs. He describes this region as being characterized by nonselective dissolution with no porosity formed. The behavior in Region 2 is referred to by Pickering as Type I and Region 3 is said to exhibit Type II behavior. The transition from Type I to Type II behavior is dependent on potential and alloy composition. This transition from Type I behavior, with preferential dissolution and porous microstructure formed, to Type II behavior, with no porous microstructure and uniform dissolution, has been used by a number of authors to define the parting limit for several alloy systems. For example, in silver-gold alloys, the value cited for the transition from Type I to Type II dissolution (the parting limit) is a mole fraction of gold of 35–45 % for perchloric acid solutions, and references the work by Tischer and Gerisher. In their study, Tischer and Gerisher report that these alloys [42] show no microstructural evidence of the formation of porosity above 50 % gold when they were exposed to large anodic potentials.

Other systems such as brasses, copper-gold, platinum-copper, and several others are described by Pickering as having a mole fraction of the more noble metal above which Type I behavior is not found [7]. However, in copper-base alloys, other authors have shown dealloying occurring in all of the phases, even those assumed to be resistant to dealloying [20,55,114].

In the case of silver-gold, the value for the parting limit for silver-gold alloys has been reported in the literature from just below 50 % Au [111] to above 55 % Au [42]. In 1931, Tamman and Brauns [113] found that alloys containing more than 50 % Au were not attacked by immersion in hot sulfuric acid. More recent work connects the value for a parting limit to the mechanism outlined for dealloying. Duffo and Galvele, for example, defended a mechanism for dealloying related to surface diffusion and formation of a low melting point intermediate compound, a value for the parting limit of 20 % Ag [87] in Ag-Au alloys, 10 % Pd in Ag-Pd alloys, and 30 % Ag in Ag-Cd alloys. When the percolation model for dealloying is considered for silver-gold alloys in perchloric acid, a limit of 30 % Ag is cited [98,112], since this is the value at which an interconnected path of silver atoms can be found. In recent work involving scanning tunneling microscopy [44,85], alloys with Au content

as high as 96 % Au were shown to exhibit preferential silver dissolution and formed a porous surface. The example of silver-gold alloys shows that the concept of a parting limit, while widely accepted, has questions remaining behind it, which are beginning to be addressed. This is also true of other binary alloys where a parting limit has been found, and in some cases re-evaluation has taken place [24,55,114].

## TESTING TECHNIQUES USED IN STUDYING DEALLOYING

Since the existence of dealloying was first noted visually [2], much of the early work on dealloying involved discovery of the systems that were susceptible [3–10], and, to some extent, the environment and temperature where dealloying was found. Earliest work involved aqueous systems [2,69], but a short time later, work at high temperatures detected the existence of dealloying under those conditions as well [53,73]. When dealloying was linked with SCC [5,64], the testing of materials for dealloying became intertwined with testing alloys for SCC, with the initiation thought to involve dealloying at the crack-tip surface [7,12,22,29–31,48–51,64,85–87].

Dealloying has been found to initiate in small areas or patches and spread over the entire surface in stages [4,11,29]. Much of the work done on the mechanism of dealloying and on the initiation and the fundamental aspects of dealloying has been done electrochemically [8,11,14,29–32,60]. Electrochemical methods involve application of constant potential, constant current, or cyclic potential. Methods used for examining dealloying involve standard ASTM methods for making electrochemical measurements [1,54]. Examination of dealloyed microstructure may require SEM, TEM, or HRSEM. Recent work has made use of scanning tunneling microscopy [24,44,49].

## Immersion and Observation

The first method for examining susceptibility of alloys to dealloying was reported by Calvert and Johnson in 1866, who reported the complete removal of zinc when brass was immersed in sulfuric acid for several days [2]. The effects of dealloying had certainly been noted as long as brasses had been used in seawater. The ability to part silver from alloys of silver-gold had been noted much earlier, since it was used by pre-Columbian civilizations in production of gold-surfaced objects centuries before Columbus [112]. Systematic studies of dealloying seem to have begun in 1866. It could be speculated that the original reason for testing copper-zinc alloys in sulfuric acid was a result of the knowledge of the behavior of certain compositions in seawater (those which show dealloying behavior). The method of immersion of an alloy in certain acids, bases, or other solutions can also be cited as the beginning of the study of corrosion of metals.

Observing the effects of solutions on the alloys was done visually and with light microscopy. The examination of brasses by light microscopy is somewhat fortuitous, since the porous microstructure can be noted in most of these

alloys with only a light microscope. Had an alloy such as silver-gold been examined initially, the brittleness would have been noted but the microstructure would have been invisible, since it is on the order of a few hundred angstroms in size (dimensions of both the islands and the channels). When the porous microstructure of Cu-Zn was first noted, as Calvert and Johnson had done, most early authors suggested that one element had been dissolved, leaving the matrix of the other element [2,23].

Dealloying occurs over a wide temperature range from aqueous to gaseous environments [3-6,28,73,74], and in a large number of solutions [3-10,16-36]. Therefore, when one considers immersion, the term must be expanded to include gaseous environments as well as aqueous ones. Some of the most widely referenced studies of dealloying, such as that of Wagner [73,74], were done at high temperatures. The mechanistic information that was derived from such studies has been extended to room temperature and aqueous environments and forms the basis for much of the understanding of the mechanisms of dealloying still accepted presently [9,22].

One recent development in the static immersion testing from Newman et al. [116] originated with Bengough and May [115]. Recent experimentation [116] involved exposing samples of alpha-brass in NaCl solutions with additions to simulate the local environment in crevices or otherwise inhibited transport. Under these severe conditions, dealloying can be shown to occur without an applied potential and may be reduced or eliminated by addition of arsenic to the alloy. The authors suggest that these results support the percolation mechanism with surface diffusion for dealloying rather than mechanisms that rely on formation of metastable phases or disproportionation of the less noble element.

### Electrochemical Methods

In some cases, initiation of dealloying may require polarization of specimens to a potential where the less noble element in the alloy will begin to be dissolved. In addition to the applied potential, a specific combination of solution and alloy is required for dealloying to occur. Silver-gold in perchloric acid is an example of the combination of alloy and solution, which will not initiate dealloying without polarization. By contrast, however, silver-gold alloys in nitric acid will begin to dealloy immediately upon immersion. For combinations of alloy and solution where potential application is necessary to initiate dealloying, there is a value of potential below which bulk dealloying does not occur. This value is usually referred to as the critical potential. Investigation of the specific values of the critical potential for alloy systems has been an important part of the study of dealloying by electrochemical methods [8,10,19-26].

The nature of the critical potential has been debated as part of the mechanistic studies of dealloying. Authors such as Forty [45], who subscribe to a rearrangement model for dealloying, suggest that the critical potential is the potential at which dissolution from kinks and jogs on the surface is activated, while authors who argue for a diffusion-related mechanism suggest that the critical potential relates to the unblocking of pathways for the transport of the less noble metal to the surface [48-50,98-100]. Probably the most comprehensive discussion

of the critical potential is included in Pickering's graphical representation of dealloying and the parting limit [8]. Above the critical potential, dissolution of the less noble component, A, preferentially occurs over a range of potentials and for a range of alloy compositions. The formation of a porous layer as the less noble component is dissolved is the visible sign that dealloying has occurred.

Alloys that have a wide range of potentials where dealloying occurs, such as silver-gold alloys, provide an opportunity to examine closely the initiation and growth of dealloying as a function of applied potential. Under some carefully controlled conditions, one sample may be exposed to several different electrochemical conditions and examined following each exposure [51]. This minimizes sample-to-sample variation and allows examination of a specific region in the sample while the conditions are varied. In most cases, however, samples are exposed to only one potential and then examined [46]. Scanning tunneling microscopy has allowed even closer observation of the surfaces of alloys with applied potentials. Movement of the atoms on the surfaces as the potential is changed has been noted [24,44,49]. This and other in situ techniques may provide the electrochemical evidence needed to discern which mechanism of dealloying is operating under specific circumstances.

When electrochemical methods are used to ionize the less noble metal, current flow can be quantitatively measured. The number of moles of metal ionized can be calculated and compared with the mass lost from the sample. Detection of the relative amount of current can be used as a basis for deciphering the initiation or completion of dealloying. When current at constant potential drops to zero or nearly zero, dealloying will have stopped. Monitoring of the current can be used as an electrochemical indicator of the type of attack as well [117].

### Microstructural Examination

Transmission electron microscopy (TEM) has been used for examining dealloying for almost 30 years. The difficulty in preparing thin samples of uniform composition and also of dealloying very thin samples has made this type of study quite involved [19,42,46,47,62]. When the microstructure formed by dealloying was examined, several interesting issues were raised. Variations in the dimensions of the island/channel microstructure have been noted by several authors [42,44,46,118]. It has been shown that the dimensions of the microstructure vary with annealing [43], while other effects on the island/channel microstructure of potential are not quite so clear, but investigation on this segment of dealloying is continuing [44,49]. Use of scanning tunneling microscopy may lead to interesting information related to the island/channel dimensions.

## EVALUATION OF TEST RESULTS

### Service Performance versus Test Results

Samples that are dealloyed have a microstructure that is recognizable, depending on the magnification used and the extent of dealloying, since dealloying initiates in patches and

grows to cover the entire sample, with time in solution or at constant potential. The existence of the island/channel microstructure is often used to identify dealloying. Chemical examination of the solution is also used to detect the presence of the less noble metal when it is being dissolved in the dealloying process.

Examination of the surface to detect the presence of the porous microstructure can be used as a qualifying test for the presence of dealloying. Under laboratory conditions, dealloying is usually detected visually, using some type of microscopy. In service conditions, this may be far too late to prevent the dealloying from leading to catastrophic failure due to the lack of structural strength provided by the porous material or due to SCC following the dealloying [58]. Detection of the less noble metal in solution may be made at very low levels depending on the chemical test method used. This method could be done under conditions such as may be found in the electronics industry where dealloying of printed circuits may be a problem. Test methods have been developed to detect susceptibility to SCC [119–122], and these methods could be applied to dealloying since the two phenomena are linked, in many cases. Tests that are electrochemical, mechanical, or both have been used to investigate SCC for some time [119–122]. Electrochemical test methods exist for examination of dealloying and could be combined with chemical methods to provide instantaneous evidence of initiation of dealloying.

Other methods with possible application to dealloying include electrochemical noise measurements, which some authors have used to detect SCC [117]. Electrochemical impedance measurements have been used to evaluate dealloying, but not specifically to predict its existence [49]. Verink and Parish have shown that making use of overlaid Pourbaix diagrams for alloys, in the way that Pourbaix himself suggested [114,122], can yield information on the potential for dealloying in aqueous solutions. No specific electrochemical method exists for determination of susceptibility to dealloying, such as the polarization test showing a hysteresis suggestive of pitting; however, use of electrochemical techniques can provide data that can be used to support conclusions of dealloying sensitivity, and the development of sensitive monitoring methods, such as electrochemical noise, may lead to such specific tests.

## STANDARDS

### ISO Standards

The relationship between dealloying and initiation of SCC is the area of greatest technological interest and emphasis. The International Standards Organization (ISO) has developed a standard related to initiation of SCC by dealloying [124]. As the porous and mechanically weak surface layer develops on the surface or at the tip of a pre-existing crack by dealloying, additional stress will cause a brittle fracture to propagate in this otherwise ductile material. The level of stress may be such that the crack may even extend into the uncorroded material beyond the dealloyed region. It is the initiation and propagation of these brittle cracks in otherwise ductile material that leads to failure.

Consideration is given to the susceptibility of the alloy in the specific environment of interest in the ISO document. However, extension of the limits of the known ranges, compositions, and temperatures leading to dealloying is not addressed in the ISO draft standard. Predictability beyond accepted limits is often an issue with application of standards, and the study of dealloying is not unique in this area. Dealloying specifically is mentioned in the ISO draft standard, and reference to initiation of SCC is also mentioned.

### ASTM and NACE Standards

Although ASTM has a definition for dealloying [1], there are no ASTM active or draft standards that involve testing or examination of alloys for dealloying. In standards that deal with SCC, dealloying is not mentioned explicitly, although inferences are made to initiation by means of SCC [54].

By contrast, NACE has not published any standards that mention dealloying. NACE does have several standards and reference publications that deal with SCC [118–121], but dealloying is not mentioned in any of these.

### Use of Standards in Industry

Industries, such as the power industry, where dealloying continues to be a significant problem, use combinations of solutions and alloy composition in specifying materials for redesign. This is due, in part, to knowledge of some conditions where dealloying causes condensers to fail. The elimination of combinations of solutions and alloy compositions where dealloying may contribute to premature condenser failure [12] appears as an *ipso facto* industrial standard. In the mining industry, where the ability to part alloy compositions is related to dealloying, a series of procedures rather than actual standards is used to separate alloys of specific compositions. The efficient removal of the less noble metal is the primary goal, along with the minimization of the amount of energy used to accomplish this goal.

Recycling of precious metal alloys from diverse sources, such as electronics, jewelry, and medical or dental supplies, may require development of procedures for separation and removal of the less noble metal and concentration of the more noble metal. Dealloying and the effect of the composition of the starting material on the amount of energy needed to fully separate the more noble metal may be of importance with continued growth of the recycling industry and increased pressure on pricing of precious metals and alloys. Work is continuing on use of alloys containing lower content of noble metal for environments where corrosion continues to be a problem (such as dentistry) [125]. Increased usage by the aerospace or aircraft industry of age-hardenable high-strength aluminum alloys, such as the low-density aluminum-copper-lithium alloys, may further the discussion of dealloying in these alloys in order to lower the risk of corrosion (dealloying) related failure [25,26].

## SUMMARY AND CONCLUSIONS

Historically, dealloying has been known and studied for more than 150 years. The mechanism for dealloying has

been speculated upon for nearly that long. Many alloys are known to be susceptible to dealloying, which has been implicated in the initiation of stress corrosion cracking for a number of different alloys. Currently, dealloying is still of interest to scientists, but not as an industrial problem, although several industries such as the electronics industry were mentioned where the possibility of dealloying seems significant.

Six different mechanisms for dealloying were outlined with data on the features noted and the evidence cited for each mechanistic model. Alloys where each model has been studied were also noted. Detailed descriptions of the models were presented and information given regarding how well the models can explain what has been seen about dealloying. Most current research is focused on surface diffusion as the mechanism for dealloying, although vacancy formation and dissolution and reprecipitation have been suggested as well. In addition, recent results have led to questions regarding the parting limit in some alloys.

The initiation and growth of dealloying has been well documented and can be detected visually, using microscopy (including HRSEM and TEM) or chemically by analysis of the less noble metal ions in solution. Electrochemically, no specific test exists to detect dealloying, but passage of significant anodic current in susceptible alloys in well-known solutions can give evidence for dealloying. Some methods such as electrochemical noise seem to have promise for detection of dealloying by electrochemical means.

# Environmental Cracking— Stress Corrosion

*W. Barry Lisagor<sup>1</sup>*

WITH THE PUBLICATION of the first edition of *Corrosion Tests and Standards—Interpretation and Application* (Manual 20), this chapter concluded with the prediction that future work in the study and characterization of stress corrosion cracking (SCC) of engineering alloys would be directed to more quantitative information based on improved test control, procedures, and techniques to better serve the engineering community, and improved modeling and life prediction techniques. This same theme has been reiterated in the most recent ASTM sponsored conference [1] by Wei, who stated that the community should take a role in development of quantitative methodologies for assurance of reliability and continued safety of engineered systems [2]. In that same conference, Staehle [3] elaborated on a technique for predicting SCC using a corrosion-based design approach (CBDA), and a location for analysis matrix (LAM). More quantitative methodologies and SCC prediction are still recognized as desired entities. The initial publication of this chapter compiled a historical perspective of the SCC phenomenon as well as discussion of testing standards and techniques, and evaluation and interpretation of test results. To that end, the narrative included in the first edition is essentially preserved in the current chapter with additions included based on research and development since the first publication.

The first edition of *Corrosion Engineering* [4] identified stress corrosion cracking (SCC) as the eighth of the famous eight forms of corrosion. This phenomenon has been the basis for countless studies and engineering service problems over a wide spectrum of applications. It has been experienced in the process chemical, energy, and utility exploration and delivery, and aerospace industries, as well as in consumer products. Although SCC has certainly not been the most widely experienced form of corrosion, it has certain characteristics that are particularly troublesome from an applications' standpoint. Notable among these include the frequent lack of early warning or detection by evidence of corrosion products and the fact that catastrophic structural failure can be the first sign of an unfortunate material/environment combination, placed in service by design. Although Uhlig [5] and Fontana and Greene [4] cite riveted steam boilers as early examples of service failures attributed to SCC, the earliest examples frequently cited as the "season cracking" of brass cartridge cases were identified by Fontana, and more

recently by Jones [6], noting a 1906 reference in *Brass World* [7] in his preface. Historically, the period of most vigorous activity addressing SCC from both a research and technological understanding, and an applications standpoint, would likely be the period from the mid- to late 1960s to the mid-1970s, although it still remains an important corrosion topic as new high-strength alloys are considered for service to improve performance. During that period, a great deal of activity occurred relative to standards development and information interchange, through the sponsorship of ASTM Committee G.01 on Corrosion of Metals. Through Subcommittee G.01.06 on Stress Corrosion Cracking and Corrosion Fatigue, numerous test standardization activities were initiated, and many conferences and symposia were organized and held. The current chapter will highlight both the developments of the various activities during that time, as well as activities and standards development since the first edition, and provide an update on standards development regarding SCC testing. Test standardization procedures being pursued by other organizations including the International Standards Organization (ISO) and the National Association of Corrosion Engineers (NACE) were cited in the original edition, and remain essentially unchanged.

## BASIC PRINCIPLES

General theories regarding stress corrosion mechanisms initially supported one of two fundamental considerations: anodic dissolution or hydrogen-related phenomena. Much effort was expended in attempts to show which was the obvious predominant controlling mechanism. Studies over the last 30 years have shown that the factors controlling the SCC process are much more complex, and likely unique to alloy composition, metallurgical condition, chemical environment, electrochemical state, and state of mechanical stress. Considerable detail on mechanisms has been elaborated on in notable monographs published in the early 1970s [8] and later in 1992 [6]. Emphasis has shifted from attempts to relate all SCC phenomena to a single or near single mechanism to a better understanding of all factors contributing to its occurrence and control. Typically, alloy/environment systems susceptible to SCC do not suffer a more general form of corrosion, and the phenomenon is considered one of activation/passivation interaction. Frequently, the alloy system produces a protective film, making it more resistant to general corrosion in natural environments as in the case of aluminum and titanium alloys.

<sup>1</sup>Senior Scientist, Analytical Services and Materials, Inc., Hampton, VA 23666.

**FIG. 1—Sequence of events (left to right) in a stress corrosion test on an initially smooth specimen. For low-alloy steels in seawater, the rate of growth of SCC is faster than it is for pitting by a factor of about 106, and fast fracture propagates at about 1010 times faster than SCC [8].**

Originally it was considered a process of nucleation and propagation where breakdown of the protective film or establishment of localized electrochemical conditions were necessary for the cracking process to reach a propagation condition. This sequence is reflected in Fig. 1 [8], where an SCC crack results from localized breakdown of a protective film and initial formation of a corrosion pit. Traditional testing for SCC susceptibility was accomplished through time-to-failure tests of specimens exposed in the test environment under various levels of applied tensile stress. Although this approach has resulted in tremendous contributions to the understanding of behavior, and ranking of alloy and environmental combinations, it can also produce some misleading results, as evidenced by the sequence of conditions reflected in Fig. 2 [8]. Figure 2 reflects four conditions of failure phenomena, which, based solely on time to failure tests, could result in misinterpretation of SCC susceptibility by erroneously combining effects of pitting, SCC, and fracture toughness in the results. Young et al. [9] have reported on interaction of electrode potential and temper in aluminum alloy 7050, which describes that SCC susceptibility versus applied potential cannot be used to prove anodic dissolution or hydrogen embrittlement.

**FIG. 2—Kinetics for pitting (or, in D, nonpitting), SCC (A and B only), and fast fracture (lower plot). Line at top shows how time-to-failure combines the three phenomena to produce misleading results [8].**

The introduction of precracked specimens as a means of studying and characterizing SCC behavior led to the acceptance of another factor in the overall SCC process—that of incubation. Initially, it was thought that the initiation period was principally related to establishment of conditions producing a crack-like flaw for propagation. An early ASTM sponsored interlaboratory test program [10] exploring the use of precracked specimens for SCC testing showed that substantial periods of time were necessary for incubation, before a pre-existing crack would begin to propagate via SCC. In this study, specimens were tested under certain conditions of applied stress intensity that were known to be above the threshold level for SCC propagation of this high-strength steel in the chloride-containing aqueous test environment. In some instances, thousands of hours of exposure were necessary before onset of SCC propagation occurred in modified compact wedge loaded specimens. In this test program the pre-existing crack was introduced by fatigue, at stress intensity levels considerably below that which the SCC tests were performed. The specimens were then loaded in the test media to stress intensity levels which should have created local crack tip conditions expected in more traditional tests, and yet significant exposure times were necessary before propagation occurred. This gave rise to the recognition of the incubation period, a time period necessary perhaps to establish local crack tip chemistry and electrochemical conditions necessary for propagation. Based on the author's participation in interlaboratory test programs on high-strength steels and aluminum alloys, incubation times will be dependent on the combination of alloy and environment and the local stress state based on starting test conditions, and can vary from near zero to extended periods of time. Examples include thousands of hours for high-strength steels initially loaded to stress intensities only marginally above threshold levels, to hundreds of hours for aluminum alloys, to minutes or even seconds for titanium alloys under certain test conditions.

## FACTORS INFLUENCING SCC

Factors that influence SCC response will generally affect one of four basic variables in the process: the material or alloy system, the chemical service environment, the electrochemical state of the system relative to surroundings, and the state of mechanical stress. Nearly all structural alloy systems can be found susceptible to SCC under certain alloy chemistry, metallurgical condition, and service environmental conditions. SCC behavior relative to alloy system was detailed in an American Society for Metals (ASM) publication [6], for a broad range of structural alloys, and has also been covered extensively for aluminum, titanium, and high-strength steels [8].

### Alloying Additions

Alloying additions can have considerable effect on SCC behavior, impacting the formation of protective films on the alloy systems and impacting metallurgical condition, and subsequently impacting the electrochemical and chemical environmental states. These factors are evidenced by the

references cited throughout the chapter. Most notable among these is probably metallurgical condition, which in turn affects the local galvanic or electrochemical state. Precipitation processes and segregation resulting from casting and processing practices can produce inhomogeneous microstructural conditions and second phases that are more resistant or susceptible to crack propagation and produce a profound effect on response. Examples of these include the high-strength aluminum alloys that produce precipitate free zones adjacent to grain boundaries, which in turn are considered to greatly affect anodic dissolution behavior, and alpha/beta titanium alloys, where discontinuous beta significantly retards aqueous crack propagation depending on volume fraction and morphology of the discontinuous phase. Further treatment of effect of alloy composition can be found in the cited references.

### Metallurgical Factors

In addition to metallurgical factors related to alloy composition that result in complex microstructures, both yield strength and grain size effects can affect SCC behavior depending on alloy type and environment. In systems where crack propagation proceeds along intergranular paths, grain size can significantly affect response. In the case of low-alloy steels, yield strength effects can overshadow composition and metallurgical effects and are treated in some detail for both low and high yield strength conditions [6]. For other alloy systems, similar heat treatment and associated temper effects can be seen, although they cannot be generalized without considering composition. For instance, in high-strength aluminum alloys it is generally known that 7XXX series alloys have the highest SCC susceptibility in the peak-aged condition, whereas 2XXX series alloys have more SCC resistance in the peak-aged condition than the naturally aged condition. Connolly and Scully [11] have reported SCC in aluminum-lithium alloys, which show more susceptibility in underaged and overaged conditions, but more resistance in intermediate tempers.

### Environmental Factors

Chemical environmental factors play a major role as one of the four major variables in the SCC process. Chemical environments associated with SCC of the major structural alloy systems range from the naturally occurring environments such as marine and industrial atmospheric conditions to complex chemical environments like anhydrous nitrogen tetroxide ( $N_2O_4$ ). Minor contaminants or concentration level changes, or even minor process changes, can have massive effects on SCC susceptibility. One example of a minor process change that resulted in a near catastrophic result occurred in the aerospace application of titanium alloy Ti-6Al-4V, the workhorse aerospace alloy. Severe SCC was reported in oxidizer tanks undergoing exposure tests associated with the Gemini program [12]. The SCC susceptibility was ultimately determined to be the result of a modest process change in the production of  $N_2O_4$  to ensure lower oxides of nitrogen were not present in the oxidizer. Extensive SCC characterization was conducted and correlation between laboratory specimen tests and stored tank

tests was demonstrated [13]. Similarly, subtle changes in low-level chloride ion concentration and water of hydration have rendered Ti-6Al-4V susceptible in methanol, used as a test medium to simulate propellant fuel [14,15]. More familiar effects of oxygen, chlorides, sulfides, and sulfates, and their effects on SCC response of low-alloy steels and corrosion-resistant alloys for oil, gas, and energy industry applications are reported extensively [16–18]. In these applications, changes in exposure or service temperature may have a substantial effect on SCC response of a material; however, temperature does not always produce rate change effects but should always be considered in characterization or in alloy selection.

### Electrochemical Factors

Electrochemical factors are known to contribute to overall SCC response, dependent on the given material/environment system. For a low-alloy steel, such as 4340 heat-treated to various yield strength levels, applied potential has been shown to have little effect on threshold stress intensity ( $K_{ISCC}$ ) levels (Fig. 3), but significant effect on crack growth rates at stress intensity levels above the threshold value as shown in Fig. 4 [8]. For maraging steels, however, impressed electrochemical potentials had a significant effect on  $K_{ISCC}$  [19]. These effects can further be exacerbated by crack tip chemistries, which can be substantially different from that of the bulk chemistry [20–25]. This can produce changes in a number of variables affecting SCC behavior, including mass transport to the crack tip, protective film attack, adsorption and diffusion, and reaction with the material. Extensive work has been conducted and reported on electrochemical factors contributing to environment assisted cracking (EAC) response of AA 7XXX high strength aluminum alloys [26–30]. This work has included techniques to measure localized chemistry of the environment within the crack wall using capillary electrophoresis [26,27], studies addressing crack chemistry as well as effects of applied and localized measurements of electrode potential [28,29], and crack potential

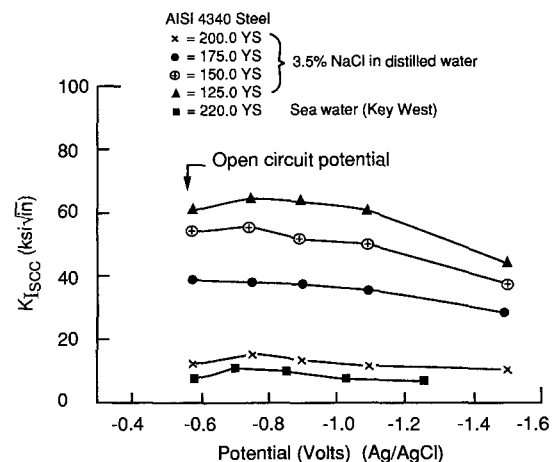

FIG. 3—Effect of (impressed) potential on cracking threshold stress intensity of AISI 4340 steel [8].

FIG. 4—Effect of (impressed) potential on cracking rates [8].

and modeling of the EAC process [30]. Discussion of mechanisms in this material/environment system [28,30] is elucidating but still leaves room for speculation on the relative significance of hydrogen environment embrittlement (HEE) and anodic dissolution (AD) as principal mechanistic contributors in the cracking process.

### Mechanical Stress Conditions

The mechanical stress conditions are the remaining major consideration necessary for the SCC process to occur and its importance is obvious, considering that most structural engineering applications result in applied loads and resulting stresses that increase the local stress state at the tip of an advancing crack. This means that sudden structural failure is likely if the crack initiation and growth process is allowed to continue in service. Failure will often be manifested by another consideration, such as fatigue, embrittling phenomena, or their interaction, which can reduce resistance to fracture. The mechanical stress condition can also be very complex, considering complex geometry of structural alloy designs as well as complex loading conditions including tensile and shear stress modes, plane stress and plane strain conditions, and biaxial loading modes. All of these factors ultimately affect the local strain and stress conditions in the vicinity of an initiation site or zone beyond an advancing crack front. These factors can also contribute to complex stresses even in relatively simple test specimens. Two factors are considered primary in consideration of the stress distribution and include the tensile or opening mode element of the stress condition, and the degree of constraint beyond the advancing crack front. Other factors may contribute to SCC response but may be secondary in nature. It is reported generally that SCC produces a three-stage initiation, growth, and failure or fast fracture process, often exhibiting a lengthy period of

FIG. 5—Generalized SCC kinetics. Fast fracture at one of the points marked  $K_{Ic}$  may preclude development of Region III or of Regions II and III. There may be a true threshold  $K_{Isc}$  or the kinetics may simply decrease continuously to ever smaller but finite values as  $K$  is decreased, denoted by broken line prolongation of Region I [37].

Stage II growth period where crack growth rate is independent of observed stress intensity or associated local stresses. This “plateau velocity” is observed in numerous material/environment systems, schematically represented in Fig. 5 [31]. The relative degree or observance of the three distinct stages depends on a number of factors including the inherent fracture toughness of the material, as well as the specimen geometry and the initial or continuous loading condition during test or exposure. The figure shows how variations in threshold stress intensity for onset or arrest of environmental cracking, and inherent fracture toughness (represented by possible  $K_{Ic}$  levels) may impact whether or not a classical three-stage behavior is observed. The observation of a well-defined “plateau velocity” in many systems suggests that a combination of known variables achieve a resultant steady state condition, and that such a condition will subsist as long as the interaction of those variables to create such a steady state are maintained. The four major variables (material, environment, electrochemical state, and stress) will also be affected secondarily by specimen geometry (affecting compliance and stress and strain rate behavior at the crack tip). Each in itself is complex, and this certainly gives rise to the degree of variability generally encountered in development of SCC data.

The interaction of these important variables to the process is often the most overlooked factor and should be carefully considered in future work regarding SCC. The greatest deficiency currently existing relative to this important form of corrosion is in behavior modeling to develop improved life-prediction capabilities and development of more quantitative data to be input into future developed models.

### TESTING TECHNIQUES

Test technique development has been related closely to purpose and application, and in some cases has been targeted to either specific alloy system and product form, or

specific test environment. Early work relative to ASTM technical committee standards development and technology interchange (with heaviest activity beginning in the mid-1960s) focused on smooth specimen configurations and specific test environments of interest to materials producers, and users in the aerospace, process chemical, and oil, gas, and other energy related applications. General categories for test technique development were initially focused in three areas: test specimens and loading equipment, test environments, and corrosion fatigue. As standards development continued, additional areas of focus were included. Precracked specimens were added as interests in this configuration of specimens were accelerated by both corrosion and fracture toughness specialists. Dynamic testing was also added as a result of increased activities associated with slow strain rate testing. SCC of aluminum alloys was the most recent organizational addition, a result of the extensive continuing activity with characterization and understanding of the SCC behavior of the high-strength alloys.

### Test Specimens and Loading Equipment

Smooth test specimens developed in various standards included the U-bend, C-ring, bent beam, and direct tension specimens, and a special compilation of specimens directed toward testing of weldments. The specimens considered for standards development were chosen based on widespread use, or by decision of the SCC specialists participating in ASTM technical committee activities.

The U-bend specimen was the first of the SCC specimen types to be included in the *Annual Book of ASTM Standards*, first published in 1972. Many standards activities were underway during that time, with the U-bend standard practice being the initial one reaching completion. The current standard practice (ASTM G 30, Practice for Making and Using U-Bend Stress-Corrosion Test Specimens) includes many details on specimen stressing, surface considerations, and combinations of specimen dimensions (Fig. 6) suitable for achieving a successfully formed specimen for material of adequate engineering ductility. This specimen achieved widespread use in early studies where SCC susceptibility for a given material environment system was desired. It continues to be extensively used by producers of specialty and corrosion-resistant alloys used in the process chemical and energy related applications. The standard now includes reference relative to use of the split tube U-bend (STUB) specimen [32], extensively used in the nuclear power industry, and use of the U-bend specimen for testing in pressurized water [33]. All standards included in the *Annual Book of ASTM Standards* are required to be reviewed for correctness and updating at least every five years, and standards may undergo major technical revision, minor editorial revision, or reapproval without change. Infrequently, standards are balloted for withdrawal, if they are judged to be no longer viable or needed.

The C-ring specimen has also received widespread use in development of SCC data on many alloy systems, but was probably pioneered by SCC specialists with the aluminum producers. Many of those specialists worked on the development of the standard practice, and provided research data to demonstrate its performance. The specimen lends itself

Examples of typical dimensions (SI Units)

Example	L, mm	M, mm	W, mm	T, mm	D, mm	X, mm	Y, mm	R, mm	$\alpha$ , mm

particularly to thinner gage plate and tubing product based on its configuration. It can be used in a constant deflection or constant load configuration with the use of springs to obtain the necessary spring constant response for eliminating load drop-off with crack extension. The specimen is almost always used in constant deflection, however. The standard practice includes details of stress considerations, stressing methods, and formulas and tables used for determining stress as a function of measured deflection. Figure 7 shows several C-ring configurations and how the methods of stressing can be accomplished, whereas Fig. 8 shows the correlation of deflection with applied stress based on experimentally measured

FIG. 7—Methods of stressing C-rings (see ASTM G 38).

FIG. 8—Stresses in 7075-T6 aluminum alloy C-ring stress-corrosion specimen (see ASTM G 38).

strains for 7075-T6 aluminum alloy from the current standard practice (ASTM G 38, Practices for Making and Using C-Ring Stress Corrosion Test Specimens).

Materials producers and users for its simplicity in stress application, particularly in the two-point loaded configuration, used the bent beam specimen extensively in atmospheric exposure studies. For a given specimen length and thickness, fixturing is relatively easy once the proper calculations to provide the correct shortening for the desired stress has been determined. The standard practice was initially published in the 1973 Book of Standards. The current version (ASTM G 39, Practice for Preparation and Use of Bent-Beam Stress-Corrosion Test Specimens) includes stress calculations for two-, three-, and four-point loaded configurations, and for a double beam configuration essentially achieving four-point loading. Figure 9 shows the four configurations described, while Fig. 10 shows an array of two-point loaded specimens on an outdoor atmospheric exposure rack. There are other configurations of bent beam specimens, one of which is used in a double beam configuration, but which achieves a uniform stress throughout the gage section as a result of the unique specimen geometry [34].

The direct tension specimen is also widely used in developing SCC data and conducting fundamental studies of a broad range of alloy/environment systems. The specimen is usually tested by axially loading along the test section, which is usually of a round or rectangular cross section. Specimen geometry is typical of that used for mechanical testing to obtain tensile properties. It is used in both constant deflection and constant load configurations, although most constant deflection stressing frames used are sufficiently compliant to result in some elevation of stress, as exposure and cracking or reduction in area of the net section of the specimen proceeds during test. ASTM G 49, Practice for Preparation and Use of Direct Tension Stress Corrosion Specimens, describes stress considerations in using this

FIG. 9—Schematic specimen and holder configurations (see ASTM G 39).

FIG. 10—Bent-beam specimens on atmospheric exposure rack (reprinted from ASTM G 39).

specimen configuration, as well as methods of loading. Figure 11 shows the effect of reduction of area on the net section of a test specimen on the resultant stress level for three conditions of compliance. This can affect the observed response, particularly if time-to-cracking or time-to-failure criteria are being used to evaluate test results. The direct tension specimen is widely used in dynamic testing, where applied stress is intentionally being varied. This includes

Note: The behavior shown is generally representative, but the curves will vary with specific alloys and tempers.

FIG. 11—Effect of loading method and extent of cracking or corrosion pattern on average net section stress (see ASTM G 49).

slow strain rate and breaking load testing, to be described subsequently.

ASTM G 58, Practice for the Preparation of Stress Corrosion Test Specimens for Weldments, describes use of all of the before-mentioned smooth test specimen configurations. It also includes some configurations unique to welding practices, and references citing use of specimens and procedures unique to SCC testing of weldments.

### Test Environments

Laboratory testing methods associated with specific test environments have been developed for two general purposes: producing accelerated SCC response for a given alloy system, or developing a test medium that more closely simulates SCC response with service for alloy systems known to be susceptible under given conditions. Test environments for specific alloy systems include polythionic acid for stainless steels and other nickel-chromium-iron systems<sup>2</sup>, boiling magnesium chloride for stainless steels and related alloys<sup>3</sup>, Mattsson's solution for copper-zinc alloys<sup>4</sup>, hot hydrated salt for high-strength alloys<sup>5</sup>, and the alternate immersion

3.5 % sodium chloride<sup>6</sup>, and boiling 6 % sodium chloride<sup>7</sup> tests primarily used for aluminum alloys. The alternate immersion test was developed primarily for aluminum alloys, but is also used for ferrous alloys. The boiling 6 % sodium chloride solution test is used primarily for low copper-containing Al-Zn-Mg alloys and has been shown to correlate better with atmospheric exposure tests than other accelerated tests [35]. ASTM G 123 (Test Method for Evaluating Stress-Corrosion Cracking of Stainless Alloys with Different Nickel Content in a Boiling Acidified Sodium Chloride Solution) is a standard test method for producing better correlation of accelerated test and service performance for stainless alloys with varying nickel content.

### Precracked Specimens

Precracked specimens and linear elastic fracture mechanics analysis methods have also been widely used in SCC testing. As was noted earlier, this type of specimen and technique was originally anticipated to result in revolutionary improvements in SCC understanding and development of quantitative information for use in selection and design.

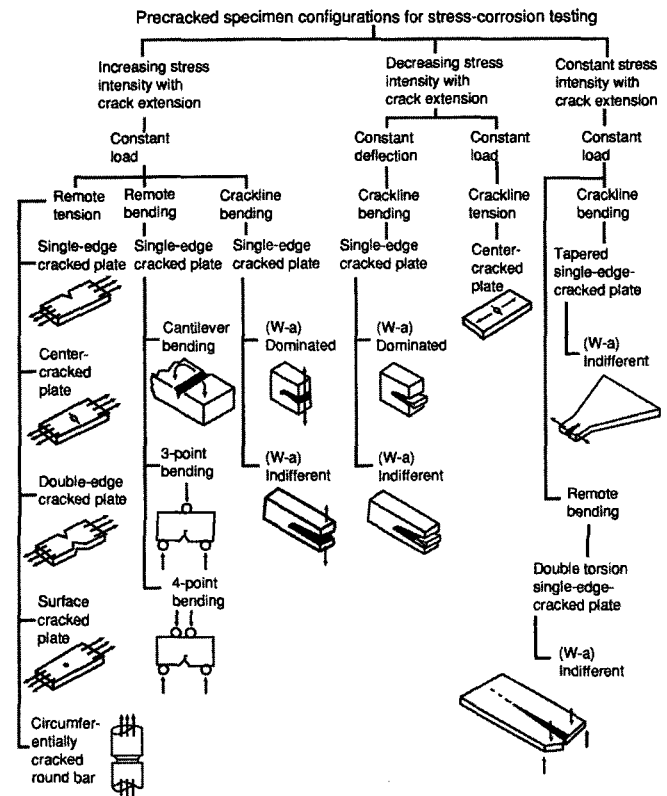

FIG. 12—Classification of precracked specimens for stress corrosion testing [8].

<sup>2</sup> See ASTM G 35, Practice for Determining the Susceptibility of Stainless Steels and Related Nickel-Chromium-Iron Alloys to Stress Corrosion Cracking in Polythionic Acids.

<sup>3</sup> See ASTM G 36, Practice for Performing Stress-Corrosion Cracking Tests in a Boiling Magnesium Chloride Solution.

<sup>4</sup> See ASTM G 37, Practice for Use of Mattsson's Solution of pH 7.2 to Evaluate the Stress-Corrosion Cracking Susceptibility of Copper-Zinc Alloys.

<sup>5</sup> See ASTM G 41, Practice for Determining Cracking Susceptibility of Metals Exposed under Stress to a Hot Salt Environment.

<sup>6</sup> See ASTM G44, Practice for Evaluating Stress Corrosion Cracking Resistance of Metals and Alloys by Alternate Immersion in 3.5 % Sodium Chloride Solution.

<sup>7</sup> See ASTM G 103, Test Method for Performing a Stress-Corrosion Cracking Test of Low Copper Containing Al-Zn-Mg Alloys in Boiling 6 % Sodium Chloride Solution.

Although precracked specimens have proven to be an invaluable tool for SCC studies, SCC information developed using precracked specimens has not been well standardized. Effective use of precracked specimens resulting in reproducible results has, in fact, proven to be very difficult to standardize with respect to appropriate test control and in analysis and reporting of results, including their significance. Notable unanswered questions that continue to perplex researchers and corrosion and fracture specialists include whether or not  $K_{Isc}$  can be considered a material property, whether the same threshold value will be measured from both increasing and decreasing stress intensity test techniques, and whether the same values will be measured from both constant deflection and constant load techniques. There is also considerable controversy over the relative accuracy with which crack growth rates or velocities can be measured. Figure 12 shows a broad classification of precracked specimen configurations for stress corrosion testing [8]. They represent configurations used for both increasing and decreasing stress intensity with crack extension, as well as two configurations that result in a constant value of stress intensity with increasing crack extension under constant load. Although all of these configurations likely have been used in experimental programs, relatively few have been included in interlaboratory test programs to address inter- and intralaboratory variability and to assess

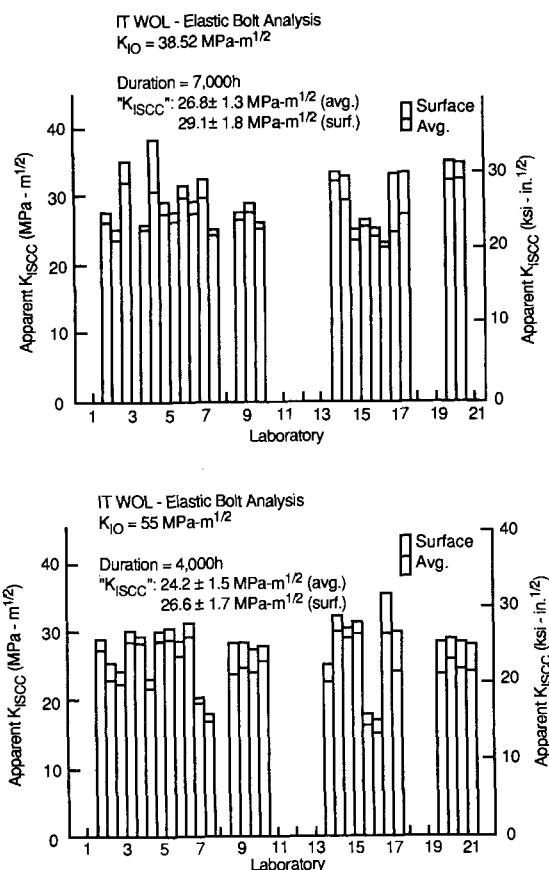

FIG. 13— $K_{Isc}$  results for modified compact specimens from ASTM Interlaboratory Program [10].

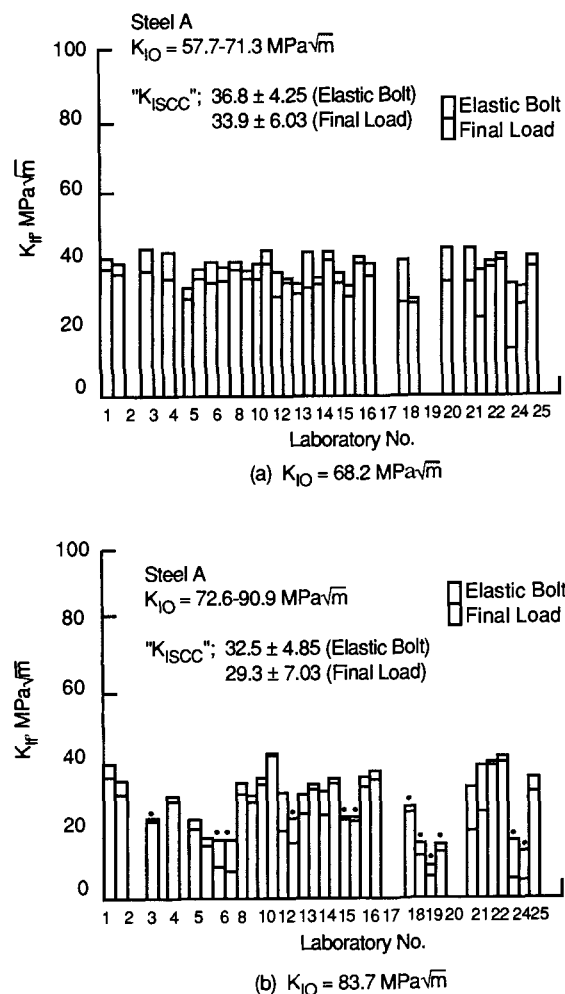

FIG. 14— $K_{Isc}$  results for modified compact specimens from the Japan Society for the Promotion of Science [38].

validity of concepts and techniques. Three studies have been reported in ASTM publications [10, 36–38], two of which were cosponsored by ASTM technical subcommittees on stress corrosion cracking and corrosion fatigue, and subcritical crack growth [10,36,37]. The first of these on low-alloy steel dates back to 1974 and has been reported summarily [36], and in some detail [10]. The second on high-strength aluminum alloy was initiated in 1981 and summarily reported [37]. The third study, conducted in Japan, was essentially similar to the ASTM sponsored study on low-alloy steel [38]. In the test programs, variables included specimen configuration (modified compact bolt loaded specimens, cantilever bend specimens, and double beam bolt loaded specimens), increasing and decreasing stress intensity with increasing crack growth, and alloy composition (AISI 4340 steel, heat-treated to 1240 MPa yield strength, JIS SNCM 439 steel heat-treated to 1170 and 1240 MPa, and 7075 aluminum alloy in the T6 temper). For the aluminum program, method of precracking was also varied. Figures 13 and 14 show representative data from the ASTM sponsored and the Japanese

FIG. 15—Crack growth behavior for AISI 4340 steel in 3.5 % NaCl solution [40].

studies. As can be seen from the figures, similar inter- and intralaboratory variability was observed in each of the studies, although for a given starting stress intensity, the ASTM sponsored study indicated slightly less scatter. It is also apparent that initial starting stress intensity had a significant effect on the reported  $K_{Isc}$  value. The total range of reported data would suggest that variations in test environment (3.5 % sodium chloride) over these long duration tests may have influenced the total scatter band. Lack of monitoring of the electrode potential in these tests is of concern, as well as solution chemistry changes, and control of these important parameters may be necessary for test reproducibility and comparison between laboratories to be meaningful [39]. The two studies did not reach the same conclusion regarding specimen configuration. Although the Japanese study reported good agreement between the two specimen configurations, the ASTM study chose to report preference to the modified compact configuration for a number of reasons. Results reported from one of the laboratories participating in the ASTM sponsored program raised the issue of a change in mechanism near the final stages of crack growth for the modified compact configuration [40]. Figure 15 shows a typical crack length versus time curve for a modified compact specimen, which shows the rapid transition from relatively high crack growth rate to significantly low rate. This seemed to occur at or very near the reported  $K_{Isc}$  value for the study. There was also examination of stress intensity solution equations and compliance calibrations in at least one of the participating laboratories individually reported [40]. Tables 1–3 show comparisons of stress intensity solution equations and crack mouth and load line displacement calibrations for the modified compact wedge loaded and cantilever bend specimens. These data suggest that different stress intensity solutions vary slightly, but do not appear to contribute significantly to the variability observed in reported  $K_{Isc}$ . Compliance calibration values, however, can be significantly different, and care must be taken to evaluate response in the crack length regime most insensitive to variation by different analysis techniques. General conclusions based on the ASTM sponsored programs suggest that  $K_{Isc}$  be considered a distributed quantity [10],

and identify a number of sources for variance including measurement of crack length, starting stress intensity, and test duration.

As a result of these interlaboratory test programs, standardized test technique development has proceeded even slower than ever anticipated, realizing the difficulties encountered in defining acceptable levels of reproducibility and control of test variables. Since publication of the first edition of Manual 20, ASTM Standard G 168, Standard Practice for Making and Using Pre-cracked Double Beam Stress Corrosion Specimens has been developed, a result of the interlaboratory program conducted on aluminum alloy 7075 [32].

## Dynamic Testing

The term dynamic testing is used here to mean intentional variation in applied load while accomplishing the actual stress corrosion test. It includes a wide variety of applied loading techniques including step loading of both smooth and precracked specimens for rapid estimates of threshold stress and stress intensity for SCC, ripple loading approaches to accelerate response of film passivating materials, and the slow strain rate test technique, used initially for mechanism studies but now also a tool for lot acceptance and material quality control. It is not intended to include interaction of corrosion and fatigue, which is extensively discussed as a separate area in itself. Both step and ripple loading techniques have been used in fundamental studies, and each has been proposed to have sufficient merit and use to be candidates for standardization. However, neither has yet been the subject of interlaboratory evaluation by sponsoring technical societies. The slow strain rate test has received more widespread use, both for fundamental studies of material classes and for a wide variety of test environments. It has been included as a principal topic in several technical symposia (see, for example, Ref 41), and has been the highlighted subject in a symposium dedicated to the technique [42]. The technique has been reported in studies on aluminum-base materials [43,44], as well as steels and nickel-base alloys [45,46]. An overview summary of the use and status of the technique was reported [47] and describes the efforts of both ASTM and NACE to develop appropriate standards for desired test control and general use of the slow strain rate test.

**FIG. 16—Load deflection curves for ferritic and duplex stainless steels using slow strain rate test techniques [47].**

As a result of the interest and activity using slow strain rate testing, ASTM Standard G 129, Standard Practice for Slow Strain Rate Testing to Evaluate the Susceptibility of Metallic Materials to Environmentally Assisted Cracking was developed. Additional papers by Kolman [48] and Little [49] describe issues to be addressed when using slow strain rate testing on beta titanium and aluminum-copper-magnesium-silver alloys, respectively. ISO has adopted a standard on the test that will be described subsequently. Figure 16 shows examples of load deflection response of ferritic and duplex stainless steels for selected aggressive environments along with inert environment response.

## EVALUATION OF TEST RESULTS

Stress corrosion test results have been traditionally evaluated and reported as time-to-failure data for a given set of test conditions related to test environment, electrochemical condition, and magnitude of stress or stress intensity. This has resulted in compiled data in the formal literature that is relatively unsystematic and is difficult for designers and material selectors to use. The results are usually targeted to report or define a threshold stress or stress intensity below which SCC is not expected to occur for a given set of environmental conditions. Lack of reproducibility, range of data scatter, and inability to adequately define anticipated service conditions have typically resulted in efforts by designers to use alloys and metallurgical conditions thought to be immune to SCC susceptibility.

### Correlation of Test Results with Service Performance

Numbers of service failures began to increase in the 1960s as higher strength alloys were used in a broad range of service applications where high structural performance was desired. Many of the standardized test environments were developed to produce accelerated results that would also rank materials in anticipated service (see footnotes 2–7). The development of new environments and techniques often has been the objective of better correlation with service performance. The most recent of these has been the adoption of ASTM G 123, which has been shown to correlate better with service performance of specialty stainless alloys in process chemical application than ASTM G 36, previously widely used. The new standard was developed on completion of an interlaboratory test program [50] that showed better correlation with service performance for the alloys tested.

An honorable goal of the SCC research community is that of predicting service life. It is also a very difficult endeavor at best and must be approached with caution considering the complexity of defining service conditions and lack of adequate models [51]. On the other hand, Staehle [3] maintains that SCC occurrence has nothing to do with the lack of good models for prediction, but with limitations of useable strength in a given environment. SCC data scatter, variables affecting material response, and uncertainties associated with correlation of test and service experience all contribute to relative scarcity of life prediction models.

## STATISTICAL TREATMENT OF SCC DATA

SCC test data are at best considered to be relatively imprecise. Variability in test results can be the result of inadequate control of factors contributing to the process, discussed previously in some detail. In the development of standardized test techniques, some effort has been aimed at identifying the level of data scatter to be expected. In ASTM standards, test methods are required to define expected precision and bias and be supported by results from an interlaboratory test program, while practices, guides, and other publications are not. Traditional pass/fail tests have typically resulted in data scatter sufficiently broad to prevent differentiation of performance of alloys in different heat-treat tempers. Figure 17 shows typical test results from an interlaboratory test program using traditional pass/fail evaluation (see ASTM G 47, Test Method for Determining Susceptibility to Stress-Corrosion Cracking of High-Strength Aluminum Alloy Products). A test technique based on measuring residual strength after exposure was developed to provide more quantitative data using fewer test specimens and to differentiate differences in SCC response of tempers, which could not be done with pass/fail tests [52–57]. The technique originally used extreme value statistics [52–54] and later Box-Cox transformations [55,56] to evaluate SCC response of 7075 aluminum alloy in tempers with little difference in susceptibility. Figure 18 [56] illustrates the concept of defining a statistical threshold stress determined from 99 % survival stress. This was accomplished with far fewer specimens and shorter exposure times than would be required for pass/fail results. These efforts resulted in the development of ASTM G 139 Standard Test Method for Determining Stress-Corrosion Cracking Resistance of Heat Treatable Aluminum Alloy Products Using the Braking Load Method.

FIG. 17—Aluminum alloy 7075 short transverse tension specimens at various levels and exposed in quintuplicate to 3.5% NaCl solution by alternate immersion per ASTM G 44.

FIG. 18—Plot of breaking load test results demonstrating the concept of statistical threshold stress [57].

## STANDARDS: SCOPE, SIGNIFICANCE, AND USE

The development and use of appropriate standards for SCC response in both research and characterization for application is extremely important if continued improvements in the literature database are to be realized. ASTM has put forth the most extensive effort in this endeavor, dating to the early 1960s, with the first standard published in 1972 (ASTM G 30). Since that time, 17 standards have been published on specimens, environments, alloys, and classifications, but only three have been added since the first edition of Manual 20. The development of such standards dealing with stress corrosion has been the responsibility of ASTM Subcommittee G01.06 on Stress Corrosion Cracking and Corrosion Fatigue, under ASTM Committee G01 on Corrosion of Metals. An additional important contribution to the standards development process is the sponsorship of technical symposia, which provide an effective technical forum for specialists to present current work in progress. The subcommittee has sponsored nine such symposia [1,41,58–64], which have served as catalysts for many developed standards.

NACE is also involved extensively in standards development pertinent to SCC. Two Specific Technology Groups, SG32 and SG62 on oil and gas and testing have oversight on the task group STG 85, which has jurisdiction over a multipart standard [65] that addresses specimens also incorporated in the ASTM standards. ISO, through work of its Technical Committee 156 Working Group 2, has adopted a multipart standard [66] related to SCC published in separate parts primarily based on test specimen design or technique [67–72]. These documents include standardization of precracked specimens as well as a slow strain rate test technique. The procedures described in the ISO standard relative to precracked specimens and slow strain rate would be better described as guides, rather than methods or practices. They do not include sufficient detail related to test control, or important test variables to provide users with adequate information to conduct well controlled tests that would result in reproducible interlaboratory results. This lack of agreement in test control has been, in fact, a major drawback in achieving approved standards through ASTM and NACE. Although

some progress has been made since the first edition of Manual 20, there has been little major breakthrough in SCC technology, and perhaps a diminished effort on research and development of the phenomenon, definitely on the part of industry. It is perhaps timely to quote Staehle [3] in conclusion, that in general, SCC continues to occur because designers do not have a useful conception on how environments affect the mechanical properties of materials nor of the circumstances when SCC occurs.

# Environmental Cracking— Corrosion Fatigue

Richard P. Gangloff<sup>1</sup>

CORROSION FATIGUE (CF) is an important but complex mode of failure for high-performance structural metals operating in deleterious environments. This view is based on the likelihood of cyclically varying loads and chemical environments in service, the need for predictable long-life component performance and life extension, the universal susceptibility of pure metals and alloys to CF damage, and the time-dependent multivariable character of corrosion fatigue. For example, stress corrosion cracking (SCC) immune alloys are susceptible to CF. Corrosion fatigue has affected nuclear power systems, steam and gas turbines, aircraft, marine structures, pipelines, and bridges; CF issues are central to the behavior of many aging systems [1–3].

The objective of this chapter is to highlight modern laboratory methods for characterizing the corrosion fatigue behavior of metals in aqueous electrolytes. The principles and mechanisms of CF are summarized in the first section of this chapter, followed by discussions of experimental methods in the second section. Specimen design and loading, environment control, strain and crack size measurement, and computer automation are discussed. The emphasis throughout is on exemplary experimental methods and results, as well as on CF data analysis and interpretation. The third section of this chapter cites applications of CF data to service, the advantages and limitations of the experimental methods, and directions for research on CF experimentation. Symbols and terms are defined in the Nomenclature. This chapter, with extensive references, extends previous reviews of corrosion fatigue test techniques [4,5]. This chapter was published originally in 1995, the following literature in the Bibliography reflects new developments in Corrosion Fatigue.

## Nomenclature

$\Delta\sigma$	applied engineering true stress range in a fatigue load cycle, $\sigma_{\max} - \sigma_{\min}$ , where $\sigma$ is load/initial cross-sectional area
$\Delta\epsilon_p$	true plastic axial strain range in a fatigue load cycle, $\epsilon_{p\max} - \epsilon_{p\min}$
$\Delta\epsilon_T$	true total axial strain range in a fatigue load cycle, $\epsilon_{T\max} - \epsilon_{T\min}$
$\epsilon$	true axial strain, $\ln(l/l_0)$
$\epsilon_d$	true diametral strain, $\ln(d/d_0)$

$l, d$	gage length and specimen diameter, respectively
$\sigma'_f, b$	Basquin relationship material property parameters
$\epsilon'_f, c$	Coffin-Manson relationship material property parameters
$N_f$	number of load cycles for specimen failure by fatigue
$N_i$	number of load cycles for fatigue crack initiation
$N_T$	transition fatigue life, or number of load cycles where the magnitudes of the elastic and plastic axial strain ranges are equal
$da/dN$	macroscopically averaged fatigue crack growth rate
$a$	fatigue crack length
$N$	fatigue load cycle count
$\Delta K$	applied stress intensity factor range, $K_{\max} - K_{\min}$
$A, m$	Paris Law material property constants
$\Delta K_{TH}$	threshold stress intensity range
$R$	stress ratio, $K_{\min}/K_{\max}$
$\rho$	notch tip radius
$f$	loading frequency in cycles per s or Hz
$1/\alpha_f$	time-portion of the load cycle where CF damage occurs
$K_{ISCC}$	threshold stress intensity for monotonic load SCC
$da/dt$	velocity of monotonic load SCC
$E_C$	free corrosion potential
$E$	modulus of elasticity
$\Delta K_{eff}$	effective stress intensity range, $K_{\max} - K_{cl}$
$K_{cl}$	stress intensity value in a fatigue load cycle where crack-surface closure contact is experimentally resolved and operationally defined
$\Delta K_o$	stress intensity range at a fixed crack length, $a_o$
$C$	constant in the $\Delta K$ -control equation with units of $\text{mm}^{-1}$
$da/dt_f$	time-based crack growth rate in fatigue, often approximated by $(da/dN)(f)$
CF	corrosion fatigue
SCC	stress corrosion cracking
HCF	high-cycle fatigue
LCF	low-cycle fatigue
FCP	fatigue crack propagation
HEE	hydrogen environment embrittlement
H	atomic hydrogen
HCP	hexagonal-closed-packed
LEFM	linear elastic fracture mechanics
SN	stress range versus life
CP	cathodic polarization
cpm	cycles per minute
Mode I	applied load perpendicular to the crack plane and growth direction [6–8]
Mode II	applied load parallel to the crack plane and the crack growth direction

<sup>1</sup>Professor and Chair, Department of Materials Science and Engineering, University of Virginia, Charlottesville, VA 22903.

Mode III	applied load parallel to the crack plane and perpendicular to the growth direction
$\nu_e$	Poisson's ratio for isotropic elastic deformation, often taken as 0.33
LVDT	Linear Variable Differential Transformer
EPD	electrical potential difference

## BASIC PRINCIPLES

### Fundamentals of Corrosion Fatigue

#### Definition

Corrosion fatigue is defined as the sequential stages of metal damage that evolve with accumulated load cycling, in an aggressive environment compared to inert or benign surroundings, and resulting from the interaction of irreversible cyclic plastic deformation with localized chemical or electrochemical reactions. Environment-enhanced fatigue is a modern term; however, corrosion fatigue is traditionally used when emphasizing electrochemical environments. Mechanical fatigue experiments and analyses, detailed in recent textbooks [6–8], provide the basis for understanding CF.

#### Stages of Corrosion Fatigue

CF damage accumulates with increasing load cycle count ( $N$ ) and in four stages: (1) cyclic plastic deformation, (2) microcrack initiation, (3) small crack growth to linkup and coalescence, and (4) macrocrack propagation. A cardinal principle is to design a CF experiment to isolate and quantitatively characterize one of these four stages. The methods in this chapter are organized as follows: (1) smooth specimen life for high cycle fatigue (HCF) described by  $\Delta\sigma$  versus  $N_f$  data, (2) smooth uniaxial or notched specimen life for low cycle fatigue (LCF) described by  $\Delta\epsilon_p$  versus  $N_f$  or  $\Delta K/\sqrt{p}$  versus  $N_f$ , respectively, and (3) fatigue crack propagation (FCP) kinetics described by  $da/dN$  versus the fracture mechanics  $\Delta K$ .

#### Mechanisms

It is important to understand damage mechanisms in order to correctly interpret and extrapolate laboratory CF data. Similar to SCC, the mechanism for CF may involve hydrogen embrittlement, film rupture, dissolution and repassivation, enhanced localized plasticity, interactions of dislocations with surface dissolution, films or adsorbed atoms, and complex combinations of these processes [9–16]. The contribution of each mechanism is controversial and depends on metallurgical and environment (thermal and chemical) variables. While providing significant insight, existing mechanism-based models are generally not capable of accurately predicting CF behavior beyond the range of laboratory data.

Hydrogen environment embrittlement (HEE) is an important mechanism for CF crack propagation in ferritic and martensitic steels, as well as aluminum, titanium, and nickel-based alloys exposed to gases and electrolytes within order of 100°C of ambient temperature [15–21]. This hypothesis is supported by extensive but circumstantial evidence, and is most readily accepted for high-strength alloys in strong hydrogen-producing environments. In HEE atomic hydrogen

chemically adsorbs on strained-clean initiation sites or crack surfaces as the result of electrochemical reduction of hydrogen ions or water. (Adsorbed hydrogen is also produced by the reactions of  $H_2$ ,  $H_2O$ ,  $C_2H_2$ , or  $H_2S$  molecules with metal surfaces.) Hydrogen production follows mass transport within the occluded crack (pit or crevice) solution, crack tip dissolution, and hydrolysis of cations for local acidification; and precedes hydrogen diffusion by lattice, interface, or dislocation processes in the initiation-volume or crack tip plastic zone. Fatigue damage is promoted by hydrogen-affected lattice bond decohesion, grain or dislocation cell boundary decohesion, enhanced localized plasticity, or metal hydride formation (in materials such as HCP titanium-based alloys). Hydrogen-enhanced CF cracking is either intergranular or transgranular, with the latter involving dislocation substructure, low index crystallographic planes, or interfaces.

A second mechanism for CF is based on damage by passive film rupture and transient anodic dissolution at a surface initiation site or crack tip. This model was developed with several necessary empirical elements to predict CF propagation in carbon and stainless steels in high-temperature pure water [22,23], and is sometimes applied to titanium and aluminum alloys in aqueous chloride solutions. Localized plastic straining, described by continuum mechanics or dislocation plasticity, ruptures the protective film. Crack advance occurs by transient anodic dissolution of metal at the breached film, and at a decreasing rate while the surface repassivates pending repetition of this sequence. The increment of CF growth depends Faradaically on the anodic charge (transient current-time integral) passed per load cycle. Charge is governed by clean-repassivating surface reaction kinetics for the CF-sensitive alloy microstructure in occluded crack solution, and by the time between ruptures given by local strain rate and film ductility. As with the hydrogen mechanism, film rupture modeling is complex and controversial; confirming data exist [22,23], but other research shows the model to be untenable for specific alloy/environment systems [24].

Several CF mechanisms were proposed based on interactions between dislocations and environment-based processes at initiation sites or crack tip surfaces. For example, in-situ transmission electron microscopy and dislocation modeling show that adsorbed hydrogen localizes plastic deformation in several pure metals and alloys [25]. Second, reaction-product films are not capable of extensive plastic deformation relative to the underlying metal, and may cause CF damage by one or more processes, viz: (1) interference with the reversibility of slip, (2) localization of persistent slip bands, (3) reduction of near-surface plasticity leading to reduced or enhanced CF depending on the cracking mechanism, (4) localization of near-surface dislocation structure and voids, or (5) film-induced cleavage [14,15,26–28]. Adsorbed cations could similarly affect fatigue [29]. Finally, anodic dissolution may eliminate near-surface work hardening and hence stimulate fatigue damage [30]. These mechanisms have not been developed and tested quantitatively.

### Factors Controlling Corrosion Fatigue

Two considerations are central to understanding the effects of mechanical, metallurgical, and chemical variables

on CF. The influences of electrolyte composition, conductivity, pH, electrode potential, temperature, viscosity, and biological activity are governed by the mass transport and electrochemical reaction conditions within occluded pits, crevices, or cracks, including the role of strain in creating reactive clean surfaces [31,32]. Second, CF can be time-dependent. Crack growth is often rate-limited by one or more of the slow steps in the mass transport and crack surface reaction sequence; slow loading rates enhance CF damage [17]. Increased crack tip strain rate is deleterious when the extent of per-cycle electrochemical reaction is promoted [22–24].<sup>2</sup>

Variables that affect CF were reviewed elsewhere [15–17]. Important factors are cited here to illustrate important CF test methods and to guide data interpretation.

### Mechanical Variables

An important issue is the influence of an electrochemical environment on the cyclic deformation behavior of metals [14,33–35]. As illustrated by the data in Fig. 1 for a carbon-manganese steel in high-temperature water, environment does not typically affect the relationship between stresses and strains derived from the maximum tensile (or compressive) points of steady-state (saturation) hysteresis loops [36]. Such loops should relate to elastic and plastic deformation prior to substantial CF microcracking. CF data of the sort shown in Fig. 1 are produced by either stress or total strain controlled uniaxial fatigue experiments, identical to the methods

FIG. 1—The nil effect of environment on the cyclic stress-strain response of a C-Mn steel in moist air and pressurized water at 288°C [36]. Data are represented as true stress—true total strain range.

<sup>2</sup>Considering HEE, it is important to consider the primary hydrogen source when designing CF experiments and interpreting results. In addition to occluded crack tip hydrogen production, hydrogen can diffuse over long distances from production sites at mildly strained bulk-solution-exposed specimen surfaces to the propagating CF crack tip. Bulk-surface hydrogen production is important for ferrous alloys at long exposure times in acidic or H<sub>2</sub>S-bearing solutions, and with cathodic polarization [21]. This hydrogen source is less important for aluminum and titanium alloys in electrolytes that form passive surface films capable of blocking hydrogen uptake.

developed for measuring purely mechanical cyclic stress-strain data [8,37]. While macroscopic constitutive properties may not be environment sensitive, slip localization can be affected by electrochemical reactions [14,33].

### Mechanical Driving Forces

Considering smooth specimens, the ranges of applied stress or plastic strain control the fatigue or CF responses of metals for HCF and LCF conditions, respectively. For HCF, smooth specimen CF life increases with decreasing elastic stress range, at cycles in excess of the transition fatigue life,  $N_T$ , according to the Basquin equation

$$\Delta\sigma = \sigma'_f (N_f)^{-b} \quad (1)$$

and due to decreasing globally plastic strain at cycles less than  $N_T$ , according to the Coffin-Manson equation for LCF

$$\Delta\epsilon_p = \epsilon'_f (N_f)^{-c} \quad (2)$$

Alternatively, Eq 1, divided by  $E$  to relate  $N_f$  to elastic strain range ( $\Delta\sigma/E$ ), is added to Eq 2 in order to relate  $N_f$  to total applied strain range, the sum of the elastic and plastic strain ranges.

The material property parameters for HCF and LCF ( $b$ ,  $c$ ,  $\sigma'_f$ , and  $\epsilon'_f$ ) depend on metallurgical, environmental, and time variables. Data in Fig. 2 show that the HCF life of AISI 4140 steel is degraded by aerated neutral NaCl solution, compared to similar fatigue lives for dry and moist air as well as deaerated chloride [38,39]. The data in Fig. 3 show that distilled water and aqueous 3 % NaCl similarly degrade the LCF resistance of an unrecrystallized precipitation-hardened aluminum alloy [35]. The Basquin and Coffin-Manson relationships are generally obeyed for fatigue in electrochemical environments; however, multiple power law segments may occur. Critically, the HCF endurance limit or threshold stress range can be

FIG. 2—The deleterious effect of aerated aqueous chloride solution on the HCF life of smooth specimens of tempered martensitic AISI 4140 steel. Symbols with horizontal arrows indicate that CF failure has not occurred after 10<sup>7</sup> load cycles [38].

FIG. 3—The deleterious effect of aqueous chloride solution on the LCF life of a precipitation hardened aluminum alloy [35].

eliminated by the action of the electrolyte, as illustrated in Fig. 2. A common explanation for this effect is pitting-based CF crack initiation.

Rates of CF crack propagation are uniquely defined by the linear elastic fracture mechanics stress intensity factor range that combines the effects of applied load, crack size, and geometry [17,40]. The similitude principle states that fatigue and CF cracks grow at equal rates when subjected to equal values of  $\Delta K$  [6–8]. The  $da/dN$  versus  $\Delta K$  relationship may be complex; however, an effective approach is based on a power (or Paris) relationship of the form [41]

$$da/dN = A \Delta K^m \quad (3)$$

$\Delta K$  is limited to stress intensity changes above zero because compressive loads do not cause appreciable crack tip plastic strain and damage. The material properties ( $A$  and  $m$ ) depend on environmental and time variables. For metals in vacuum and moist air, FCP is described by a single power law and an apparent threshold stress intensity range below which  $da/dN$  tends to zero [42]. More complex cracking behavior is observed for CF, as illustrated for aqueous chloride solution-enhanced FCP in titanium (Fig. 4) and advanced aluminum-lithium-copper alloys (Fig. 5) [43,44]. Note the complex  $\Delta K$ -dependence of  $da/dN$  for FCP in chloride solution, but not vacuum or moist air. Environmental effects on Paris regime FCP have been characterized broadly; however, data on near-threshold CF ( $da/dN < 10^{-6}$  mm/cycle) are scarce [16,42].

Crack closure can strongly affect fatigue and CF [45]. This phenomenon is based on crack surface contact during unloading, critically at stress intensity levels above zero and applied-positive  $K_{min}$  values. Crack wake contact is caused by corrosion debris, plasticity, crack path roughness, or phase transformation products; each mechanism may be sensitive to aqueous environmental reactions [6]. To account for closure,  $da/dN$  is correlated with an effective stress intensity range that is defined operationally as the difference between applied  $K_{max}$  and the  $K_{cl}$  level where surface contact is resolved (see Data Analysis and Evaluation in this chapter).

FIG. 4—The effect of solution pH and loading frequency on CF crack propagation in an  $\alpha/\beta$  titanium alloy exposed to aqueous chloride [43].

CF crack formation in notched specimens is most effectively characterized by the notch-root plastic strain range calculated by Neuber's method, elastic-plastic finite elements, or fracture mechanics approximation [7,8]. The latter approach is illustrated in Fig. 6, showing the results of over 100 experiments with C-Mn and alloy steels in aqueous chloride solution compared to moist air [8,46–48]. The load cycles to produce 1 mm of fatigue crack extension, measured optically, increase with decreasing  $\Delta K/\sqrt{\rho}$ , an estimate of notch root  $\Delta \epsilon_p$ , for air and chloride solution.<sup>3</sup> At fixed  $\Delta K/\sqrt{\rho}$ ,  $N_i$  is reduced by chloride exposure at free corrosion, relative to fatigue in moist air. An endurance limit is observed for moist air, but not this CF case. Cathodic polarization (CP) restores a portion of the moist air fatigue initiation/early growth life, as discussed in an ensuing section.

**Loading Frequency**—Slow frequency CF experiments may be necessary because of mass transport and electrochemical reaction rate limitations on damage, but are challenging

<sup>3</sup> $\Delta K$  is calculated assuming a sharp crack of length and geometry equivalent to the notch. This method is a reasonable alternative to a finite element or Neuber analysis of notch strain, but only for crack-like notches of the sort shown by the insert in Fig. 6 [7].

FIG. 5—The effect of aqueous NaCl on the CF crack propagation response of unrecrystallized sheet and plate of an advanced Al-Li-Cu-Zr alloy [44].

because of prolonged test time. The generally deleterious effect of decreasing  $f$  on smooth specimen CF life is illustrated in Fig. 7 for an LCF case involving a C-Mn pressure vessel steel, corroding freely in high-temperature water with varying dissolved oxygen levels between 0.01 and 8 ppm. (The free corrosion potential for these steel CF specimens increases as the dissolved oxygen concentration increases.) For fixed  $\Delta\epsilon_p$ , the ratio of  $N_f$  for fatigue in water to that for air, each at 270°C, declines with decreasing average total strain rate (proportional to frequency) [36]. LCF lives are rate-independent for fatigue in laboratory air at low to moderate temperatures where creep is minimal.

FIG. 6—The effect of chloride on the CF crack formation and early (<1 mm) growth resistance of notched steel specimens; solid line for four steels in NaCl, data points for seawater, and dashed line for four steels in NaCl [46–48].

FIG. 7—The effect of strain rate on low cycle CF in the C-Mn steel/high-temperature water system. The dissolved oxygen content of the pure water environment was varied, as indicated by the weight-parts-per-million values in the legend [36].

Frequency effects on CF crack propagation have been characterized broadly and modeled based on the HEE and film rupture mechanisms [16–18,22–24]. FCP rates are  $f$ -independent for alloys in moist air, inert gases such as  $N_2$  or  $Ar$ , or vacuum at low to moderate temperatures. For CF, there are three possible frequency responses: (1) purely time-dependent, where  $da/dN$  increases with decreasing frequency proportional to  $(1/\alpha f)$ , (2) cycle-time-dependent, where  $da/dN$  increases with decreasing frequency proportional to  $(1/\alpha f)^\beta$  with  $\beta$  on the order of 0.5, and (3) cycle-dependent, where  $da/dN$  is environmentally enhanced but frequency-independent. The parameter  $\alpha$  gives the proportion of the load-cycle time that produces CF damage, and is often taken as 2 for a symmetrical cycle, since environmental cracking may not occur during unloading [16]. An alternative model of the frequency effect considers that electrochemical reactions occur

FIG. 8—The varied effects of loading frequency on CF crack propagation rate in peak aged AA7075, 7017, 7475, and 7079 exposed to aqueous chloride solution (free corrosion) at constant  $\Delta K$  and  $R$ . The fatigue crack is parallel to the plate rolling plane in the SCC sensitive S-L orientation [50].

FIG. 9—The effect of loading frequency on CF propagation in API-2H and A710 steels, at the 625 to 750 MPa yield strength level, exposed to aqueous NaCl solution with CP to  $-1000$  mV<sub>SCE</sub> at constant  $\Delta K$  and  $R$  [51].

throughout the entire load-cycle [17]. A single alloy/environment system can exhibit each  $da/dN$ - $f$  relationship, depending on  $\Delta K$ ,  $f$ , and alloy composition, as illustrated for aged 7000 series aluminum alloys (AA) (Fig. 8) and steels (Fig. 9) [18,49–51]. These plots illustrate the two usual ways of presenting frequency-dependent CF  $da/dN$  data, with the abscissa as either  $\log(f)$  or  $\log(1/f)$ . The  $f$  range where  $da/dN$  is most cycle-time dependent varies with mass transport and reaction kinetics that are material-environment sensitive.

Time-dependent cracking is observed for high-strength SCC-prone alloys when  $K_{max}$  in the fatigue cycle is above  $K_{ISCC}$  and  $da/dt$  is rapid. This case, illustrated in Fig. 8 for AA7079 at  $f < 1$  Hz and for AA7075 at  $f < 0.001$  Hz, is modeled by linear superposition of SCC  $da/dt$  and inert environment  $da/dN$  data [49,52,53]. Cycle-time-dependent CF (or cyclic stress corrosion cracking) involves substantial CF at  $\Delta K$  levels that are below  $K_{ISCC}$  or where  $da/dt$  is slow. This

FIG. 10—The frequency independence of CF life for blunt notch specimens of A517 steel, freely corroding in aqueous 3.5 % NaCl as a function of notch root strain range [46]. (Initiation here is in fact crack formation plus early growth to a 1-mm depth.)

response is illustrated for AA7017 and AA7475 (Fig. 8) in seawater and acidified NaCl, respectively, and for two steels in neutral NaCl with cathodic polarization (Fig. 9), each at fixed  $\Delta K$  and  $R$  [18,50,51]. In both systems,  $\beta$  is 0.3 to 0.6. Note (Fig. 9) that cycle-time-dependent  $da/dN$  achieves a plateau or saturation level at slow frequencies below a critical value that depends on steel composition. The third case,  $f$ -independent CF, is illustrated for AA7075 in 80°C chloride solution (Fig. 8) and for the two steels at high frequencies in NaCl at 25°C (Fig. 9) [49,51]. This response (true corrosion fatigue) is often observed at low  $\Delta K$ , at high loading frequencies, or for alloys that resist environmental cracking. In some cases CF  $da/dN$  increases with increasing  $f$ . This behavior is illustrated in Fig. 4 for a titanium alloy at low  $\Delta K$ ; in addition, note a crossover to time-dependent CF above 20 MPa $\sqrt{m}$  and time-cycle-dependent CF at intermediate  $\Delta K$  [43].

Figure 10 illustrates the minimal effect of loading frequency on CF crack formation and early growth for blunt notched steel specimens in aqueous chloride solution at free corrosion [46]. These data are notable for the rare combination of low  $f$  and high cyclic lives (175 days were required to obtain  $3 \times 10^6$  cycles at 12 cpm), and for the lack of a frequency effect on the cycles required to produce 1 mm of CF cracking. This result indicates that one or more of the early

FIG. 11—The effect of environment on tensile and torsional high-cycle corrosion fatigue in the 7075/NaCl solution system [57].

stages of CF (cyclic plastic deformation, pitting, crack nucleation, and small crack growth) are frequency-insensitive, consistent with the  $f$ -independence of long crack CF at low  $\Delta K$  for many alloys including steels in NaCl [16,51]. Results of the sort shown in Fig. 10 are limited and this behavior has not been modeled.

### Other Mechanical Factors

Applied load or strain waveform, stress ratio, load spectrum, and overloads can affect CF [16,22,23,54–56]. This chapter emphasizes uniaxial tensile loading of CF specimens because environmental effects on fatigue under torsional or multiaxial loading have not been studied. An exception is illustrated in Fig. 11, showing fatigue life data for smooth specimens of AA7075 in moist air and aqueous NaCl [57]. Note the strong environmental degradation of  $N_f$  for uniaxial loading represented by normal stress range ( $\Delta\sigma$ ), but a reduced effect for torsion at a given applied shear stress range. Such results can be explained based on the deleterious role of triaxial tensile stresses, and the associated high hydrostatic (mean) tension, in CF propagation by HEE; this stress state is present for uniaxially loaded Mode I cracks, but not for torsional loading and Mode II or III cracks. Fatigue initiation may be similarly environment-enhanced for uniaxial tensile and torsional loading, explaining the modest reduction in  $N_f$  for torsion (Fig. 11).

## Electrochemical Variables

### Electrode Potential

Both anodic and cathodic polarization can affect CF, with different trends observed for crack initiation compared to propagation, and for steels compared to either aluminum or titanium alloys. For ferritic and martensitic steels in aqueous chloride solution, high-cycle CF occurs at electrode potentials near free corrosion for aerated solution ( $E_c \approx -650$  mV<sub>SCE</sub>), but is often reduced in severity or eliminated by cathodic polarization to near  $-1000$  mV<sub>SCE</sub> [58]. This behavior is illustrated in Figs. 6 and 12 for notched and smooth-uniaxial

FIG. 12—The beneficial effect of cathodic polarization on high-cycle CF crack initiation in a C-Mn steel in 1 % NaCl solution [59].

fatigue specimens, respectively [47,59]. CF of polished specimens of 1020 and 4140 steels, exposed to NaCl during high-frequency rotating bending, occurred only if a critical anodic current was exceeded [38,39]. In this study, CF was essentially eliminated by solution deaeration which reduced the steel corrosion rate current and free corrosion potential (Fig. 2). Applied cathodic polarization similarly reduced CF of polished specimens.

Understanding the effect of applied polarization on CF propagation requires a description of crack tip electrochemistry, particularly local pH and potential, as affecting the kinetics of passive film formation, dissolution, hydrogen production, and hydrogen entry. Occluded crack processes are complex, as are the observed dependencies of CF  $da/dN$  on electrode potential. For example, CF crack growth rates for steels in chloride increase with increasing cathodic polarization, with a modest minimum in  $da/dN$  at about 200 mV active to the free corrosion potential [16,20]. Figure 13 illustrates that the environmental enhancement of  $da/dN$  increases with the total rate of H production at the crack tip, raised to the  $-1/4$  power, for C-Mn steel in NaCl ( $E_c = -675$  mV<sub>SCE</sub>), polarized between  $-750$  and  $-1325$  mV<sub>SCE</sub> [16]. Hydrogen production was calculated from a crack chemistry model [60]. For this system, solution deaeration does not affect CF  $da/dN$  when electrode potential is fixed potentiostatically [61]. The opposite effects of polarization on smooth specimen CF life and crack propagation in steel can be reconciled. Dissolution and pitting probably govern environment-enhanced fatigue crack initiation [14,38,39]; hydrogen plays a secondary role for the fast loading frequencies, near-threshold stress intensities, and uniaxial stress states typical of smooth specimen studies. Slow loading frequencies and crack tip hydrostatic tension promote crack growth by HEE. Here, important contributions to crack tip hydrogen production are from crack acidification near free corrosion and water reduction at cathodic potentials [16,60].

Cathodic polarization of aluminum and titanium alloys in chloride provides an interesting contrast to steels. Duquette

FIG. 13—The effect of electrode potential on relative CF crack propagation rate in the C-Mn steel/chloride system, as portrayed by the crack tip hydrogen production current calculated from a crack chemistry model. The equation of the line from regression analysis is:  $y = 2.39 + 0.22 x$ , where  $y$  is the normalized (dimensionless) crack growth rate and  $x$  is crack tip hydrogen production rate in A/cm<sup>2</sup> [16].

and others reported that the fatigue lives of smooth specimens of AA7075 and Al-Mg-Li in NaCl solution were maximum at potentials mildly active of free corrosion; both anodic and highly cathodic polarization degraded corrosion fatigue life [15,57,58]. CF propagation occurs at the free corrosion potential, is exacerbated by either anodic polarization or extreme cathodic polarization, and is arrested by modest cathodic polarization. This trend was demonstrated for AA7079, AA7075 and AA2090 in NaCl and explained based on HEE [19,62,63]. At negative potentials from cathodic polarization, crack tip hydrogen production may be reduced by the effect of alkaline occluded-crack solution on the overpotential and exchange current density for hydrogen production on strain-bared surfaces, and hydrogen uptake may be blocked by crack surface films.

### Sulfur Ion Content

Sulfur ions in electrolytes exacerbate CF crack propagation in many alloys. Various forms of sulfur are important in sour oil or gas well and geothermal brine environments, and are also produced in unlikely ways. For example, the  $da/dN$  versus  $\Delta K$  data in Fig. 14 show the CF behavior of martensitic HY130 steel in sterile 3.5 % NaCl solution with CP, an environment that enhances cracking by two- to eight-fold relative to moist air and more compared to FCP

FIG. 14—CF crack propagation in HY130 steel in aqueous (sterile) chloride and active sulfate-reducing bacteria environments, both with CP to  $-1000 \text{ mV}_{\text{SCE}}$ .  $\Delta K$  values above  $20 \text{ MPa}\sqrt{\text{m}}$  were applied at  $R$  of 0.1 and  $f$  of 0.1 Hz, while  $\Delta K < 20 \text{ MPa}\sqrt{\text{m}}$  was applied at constant  $K_{\text{max}}$  of  $33 \text{ MPa}\sqrt{\text{m}}$  and  $f$  of 1 or 5 Hz. The dashed line represents literature data for FCP in the steel/vacuum system [64].

FIG. 15—The effect of alloy impurity-sulfur content on CF crack propagation in the C-Mn steel/high-temperature pure water system [22].

in vacuum. Note the strong environmental effect caused by a sulfate reducing bacteria (SRB; *desulfovibrio vulgaris*) cultured in Postgate C food-medium and with cathodic polarization [64]. These, and similar data for both biologically active and abiotic gaseous  $\text{H}_2\text{S}$  saturated sterile chloride solutions, are interpreted based on sulfide-stimulated HEE [64,65]. Bacteria metabolize the food-source and consume hydrogen to produce sulfide ions and other sulfur species. These anions poison recombinant hydrogen desorption to reduce  $\text{H}_2$  production and increase hydrogen entry into the metal at the crack tip, similar to the deleterious effect of dissolved  $\text{H}_2\text{S}$ .

In a second example, CF is promoted by increased impurity-sulfur in ferritic steels subjected to low-frequency loading in pressurized pure water at  $288^\circ\text{C}$  (Fig. 15) [22,23]. MnS inclusions, which intersect crack flank surfaces, dissolve to enrich the occluded crack solution in sulfide. These anions promote crack advance by increasing the anodic charge that is passed per film rupture event, or perhaps by the HEE mechanism. This effect of steel sulfur content is severe for a stagnant environment within the autoclave, and is eliminated by turbulent solution flow which reduces sulfide buildup within the crack [66].

### Other Chemical Factors

Solution pH, ionic composition, conductivity, and temperature can affect CF [14–17,22, 23,43,58].

### Metallurgical Variables

Metallurgical factors can influence CF crack initiation and growth. Prominent in this regard are sensitization of grain boundaries in austenitic stainless steels [22,23], locally intense slip in aluminum alloys from dislocation interactions

with shearable precipitates [67], and metalloid impurities segregated to grain boundaries in steels [68]. CF crack initiation often occurs at surface intersecting inclusions that concentrate strain and may dissolve to produce a locally aggressive environment [69]. CF crack propagation in the ferritic steel/aqueous chloride system is apparently not affected by substantial changes in steel composition, microstructure, and yield strength [51]. In another case, aluminum alloy processing route, and the resulting degree of recrystallization and grain size, did not substantially affect aqueous environmental LCF life and FCP kinetics [35,44,70]. Increasing copper content in precipitation-hardened Al-Zn-Mg alloys reduced the environmental enhancement of  $da/dN$ , with the importance of the effect depending on aging condition [67].

### Relationship between CF and SCC

Corrosion fatigue is related to, but uniquely distinct from, SCC [71]. Purely time-dependent CF crack propagation in SCC-prone alloys is governed by the integrated amount of time-based crack extension per fatigue load cycle. In such cases CF and SCC occur by the same mechanism and are affected by the same variables, as modeled by simple linear superposition [49,52,53]. SCC is discussed elsewhere in this manual.

Time-cycle and cycle-dependent CF are more complex, involve unique mechanisms, and occur at stress intensities where SCC is insignificant. In these cases, the CF damage mechanism is unique for reasons traceable to cyclic loading, and including: (a) increased crack tip strain rate [22–24], (b) resharpening of the blunted crack geometry during unloading, particularly at high  $\Delta K$ , (c) altered crack chemistry by convective mixing [72], (d) evolution of persistent slip band, slip step, and dislocation cell structures into embryonic damage, often at low  $\Delta\epsilon_p$  or low  $\Delta K$  [73,74], and (e) mobile dislocation transport of hydrogen in the crack tip process zone [18,50]. These additional factors must be considered when interpreting and modeling CF data [16].

### Literature Sources for CF Data and Mechanisms

In addition to the examples presented in Figs. 1 through 15, extensive CF data have been published in several volumes [1,2,9–12,58,75–78].

## TESTING TECHNIQUES

### Common Elements of a Corrosion Fatigue Experiment

An experiment to characterize the CF properties of a metal involves cyclic straining of a precisely machined specimen in an electrolyte. (Precorrosion effects on fatigue are not considered.) Environment containment about the specimen must guarantee constant solution purity and composition. Specimen potential should be monitored, often controlled potentiostatically, and not affected by galvanic coupling to the grips or test machine. The mechanical parameters that must be measured depend on the experiment, be it HCF, LCF, LEFM-crack propagation or notched, and are progressively more difficult to monitor from the HCF to notched cases. CF

experiments follow directly from procedures for mechanical tests with benign environments; the latter are well-developed and standardized, while CF experiments are not. For example, ASTM Committee G-1 has published 14 standards or practices for SCC experiments (see Volume 03.02, Section 3 of the Annual Book of ASTM Standards), but none for corrosion fatigue.

CF experiments are hindered by several common factors. Aggressive environments are difficult to contain at a constant condition, and hinder precise measurements of specimen displacement, load, and crack size. CF is influenced by many interactive mechanical, chemical, and microstructural variables that must be factored into experimental design. It is often necessary to investigate slow-rate deformation and cracking phenomena in a realistic time; experiments must be conducted for one day to one year or more. CF damage is localized at surface slip structure and near the crack tip; high resolution observations are not generally available and behavior must be interpreted from indirect measurements.

### Smooth Specimen $\Delta\sigma$ -Life Method for High Cycle CF

#### Governing Standards

Experiments to characterize high cycle CF life according to the Basquin Law (Eq 1) follow from ASTM standards for metals in moist air (see ASTM E 466, Practice for Conducting Constant Amplitude Fatigue Tests of Metallic Materials; and E 468, Practice for Presentation of Constant Amplitude Fatigue Test Results for Metallic Materials). Such methods were detailed for steels and aluminum alloys in aqueous chloride solutions [38,39,57–59,69,79,80]. Typical data are presented in Figs. 2, 11, and 12.

#### Specimens and Loading

High-cycle CF specimens focus failure in a carefully prepared reduced-uniform or mild-blend-radius gage section, often of circular cross section and with ends for gripping in the fatigue machine. Typical specimen designs are shown elsewhere, including methods for low-damage gage machining and polishing (see ASTM E 466 and Ref 81). HCF specimens are loaded in uniaxial tension or bending (three-point, four-point, or cantilevered) with electromechanical, servohydraulic, or rotating wheel/mass machines, and grips of various designs (see ASTM E 466 and Ref 81). Elastic straining is load or displacement controlled; involves either negative, zero, or positive mean stress; and varies with time symmetrically in a sinusoidal or linear-ramp waveform. Since CF is dominated by electrochemical surface damage,  $N_f$  could decrease and variability may increase with increasing surface area that is stressed.

High-cycle corrosion fatigue experiments are conducted for  $10^5$  to  $10^9$  cycles to failure, at a relatively high frequency of 25 to 100 Hz to conserve time. ( $N_f$  of  $10^6$  cycles requires 5.5 h, while  $10^9$  cycles require 230 days of continuous loading at 50 Hz.) Multiple, reliable, and inexpensive rotating-bend machines are often dedicated to these experiments. Caution is required when extrapolating the results of relatively rapid frequency experiments, to lower  $f$  and/or the very long life regime in excess of  $10^9$  cycles.

### Environmental Cell Design

The design of the environmental cell depends on electrolyte and temperature. A typical cell is illustrated in Fig. 16 for containing aqueous chloride solution at ambient temperature [79]. Glass, Plexiglas®, Teflon®, or other plastics are adequate cell materials. The specimen is gripped outside of the test solution to preclude galvanic effects, and the cell is sealed to the round or square/rectangular specimen with O-rings away from the high-stress gage section. Solution can be circulated from a large storage volume and at a constant flow rate. The cell should include reference and counter electrodes to enable specimen (working electrode) polarization with standard potentiostatic (or galvanostatic) procedures [38,39,59,79]. When fixing potential or current, care should be taken to correctly ground or isolate the test specimen, to uniformly polarize the gage surface, to account for IR effects when necessary, and to isolate counter-electrode reaction products. Provided that potential is controlled, there is probably no reason to control the oxygen content of the solution. Temperature is maintained between subzero and boiling levels with a heater or cooling coil, a specimen thermocouple, control electronics, and a condensation apparatus. Cells for more complex environments are detailed in ensuing subsections on Environmental Cell Design.

### Parameter Measurement, Control, and Computer Automation

The maximum and minimum applied loads (or, alternately, displacements) are measured with a load cell (or remotely attached extensometer/LVDT) and controlled during a HCF experiment.  $\Delta\sigma$  is calculated from standard elastic solutions for bars under uniaxial tension, or beams subjected to bending. Elastic strain range is calculated from  $\Delta\sigma/E$  and gage displacement is not typically measured.

### Crack Detection

Total load cycles to failure are measured, but crack initiation and growth are not monitored during an HCF experiment. Information on these stages of HCF is critical, but difficult to obtain. Methods for CF crack detection are discussed in the subsection on Small Crack CF Methods.

### Data Analysis and Evaluation

High-cycle CF data are presented in a logarithmic plot of stress range versus cycles to failure according to the Basquin Law (Eq 1). Data are also plotted as stress amplitude ( $\Delta\sigma/2$ ) versus reversals to failure ( $2N_f$  for simple waveforms). The Basquin Law is based on the initial applied elastic stress range and does not consider the complicating effect of a growing crack on  $\Delta\sigma$ . Material property constants  $\sigma'_f$ ,  $b$ , and the endurance limit (or fatigue strength at a given number of cycles) are environment-sensitive. The mechanical information that should be reported with HCF data is standardized (see ASTM E 468), and electrochemical factors should be cited as discussed in this manual.

Design and alloy development studies require mean as well as minimum (lower bound) Basquin relationships and statistics on the distribution of  $\Delta\sigma$  versus  $N_f$  data. This distribution depends on the fatigue damage mechanism. Most

FIG. 16—Uniaxially loaded smooth-gage specimen and environmental chamber for high-cycle CF experimentation with aqueous chloride solutions at near ambient temperatures [79].

CF studies have not provided such information, often because of time-intensive slow frequency experiments and the many important variables. A sense of the variability in CF data is portrayed by the extensive HCF results collected for C-Mn and alloy steels in marine environments [58]. The distribution of HCF lives at a given stress range was analyzed based on Weibull statistics applied to a database of 30 000 points for steels in benign environments [82]. While instructive, these statistical results are not necessarily relevant to high-cycle CF where electrochemical reactions introduce additional variability.

Future work must address two areas to provide the foundation for statistically based analyses of high-cycle CF (as well as environmental LCF and FCP). For simple laboratory conditions, the Weibull analysis of mechanical HCF failure probability [82] must be extended to include CF. Second, variable load, temperature, and environment chemistry histories are likely to be complex in applications and significantly affect CF life. Such history effects have not been studied. The scaling of Basquin relationship data to predict the life of a structure is qualitative and uncertain. Either the local strain approach to CF crack formation/early growth life or the fracture mechanics analysis of CF propagation provide a better foundation for life prediction and failure analysis.

### Smooth Specimen $\Delta\epsilon_p(N)$ Method for Low-Cycle CF

#### Governing Standards

Experiments to characterize low-cycle CF life according to the Coffin-Manson relationship (Eq 2) follow from an ASTM standard for LCF of metals in air, and a classic ASTM manual on laboratory methods (see Ref 37 and ASTM E 606, Practice for Strain-Controlled Fatigue Testing). Low-cycle CF

experiments are detailed elsewhere [33–36, 74,83], and typical data are presented in Figs. 3 and 7.

### Specimens and Loading

Uniform-gage or mild-radius (hourglass) round specimens are subjected to uniaxial tensile loading with rigid gripping and a test machine that provides for either tension-compression or tension-tension strain cycling. Square or rectangular specimens have also been successfully employed. Specimen alignment is critical for this rigid gripping system [81]. Total axial displacement is generally controlled, with regard to maximum and minimum limits as well as time-dependence, while load is measured, often with a computer-automated servoelectric or servohydraulic closed-loop test machine. Such machines provide a variety of strain-time profiles. Loading frequencies are typically less than those employed for HCF experiments because failure occurs in less than 10<sup>4</sup> cycles. Low-cycle CF experiments differ from the HCF case in that gage displacement must be measured with sufficient resolution to apply  $\Delta\epsilon_p$  between 10<sup>-4</sup> and 10<sup>-1</sup>.

### Environmental Cell Design

Cells for environment containment and control are identical for LCF and HCF (see previous subsection with this title). LCF cells are, however, more complicated because of the requirement to measure specimen gage displacement, as illustrated in Fig. 17 [33,36]. For simple aqueous environments, diametral or axial displacement is measured by a contacting (but galvanically insulated) extensometer, perhaps employing pointed glass or ceramic arms extending from a body located outside of the solution. A hermetically sealed extensometer or LVDT can be submerged in many electrolytes over a range of temperatures and pressures. Alternately, the specimen can be gripped in a horizontally mounted test machine, and half-submerged in the electrolyte, with the extensometer contacting the dry side of the gage (Fig. 17a) [33]. For both simple and aggressive environments, grip displacement can be measured external to the cell-contained solution, as shown in Fig. 17b for high-temperature water in a pressurized autoclave [34,36]. It is necessary to conduct LCF experiments in air (at temperature), with an extensometer mounted directly on the specimen gage, to relate grip displacement and specimen strain.

### Parameter Measurement, Control, and Computer Automation

Applied load and gage displacement are measured throughout an LCF experiment. From these data, it is possible to calculate true  $\Delta\sigma$ ,  $\Delta\epsilon_T$ , and  $\Delta\epsilon_p$ , where axial plastic strain range equals  $(\Delta\epsilon_T - \Delta\sigma/E)$ . For the hourglass specimen, true total diametral strain can be measured at any time, and converted to axial strain according to [37]

$$\epsilon = (\sigma/E)(1 - 2\nu_e) - 2\epsilon_d \quad (4)$$

If  $\Delta\epsilon_T$  or  $\Delta\epsilon_d$  is maintained constant by the test machine, then  $\Delta\sigma$  increases and  $\Delta\epsilon_p$  decreases until the hysteresis loop stabilizes at a constant form for a cyclically hardening material, and vice-versa for a softening alloy [7,37]. The stabilized-loop value of axial  $\Delta\epsilon_p$  is used in the Coffin-Manson Law to correlate  $N_f$ . When substantial crack growth occurs, these

FIG. 17—Environmental chambers for low-cycle CF in: (a) an electrolyte at ambient temperature [33], and (b) high-temperature water [36].

stress and strain range calculations are not accurate. Experiments are often terminated and failure is defined for a percent decline in  $\Delta\sigma$ . Total strain rate, average plastic strain rate, or the frequency of displacement cycling should be maintained constant during the low-cycle corrosion fatigue experiment.

Personal computer programs are available to control the closed-loop test machine during an LCF experiment and to analyze load-displacement-time data.

### Crack Detection, Data Analysis, and Evaluation

These procedures are identical for LCF and HCF, as discussed in the previous subsections, Crack Detection and Data Analysis and Evaluation.

### Fracture Mechanics Methods for Corrosion Fatigue Crack Propagation

#### Governing Standards

Experiments to characterize CF crack propagation kinetics, in terms of LEFM Paris relationships (Eq 3) and near- $\Delta K_{TH}$

data, are guided by an ASTM standard for metals in air (ASTM E 647, Test Method for Measurement of Fatigue Crack Growth Rates), a compilation of laboratory experience with this standard [84], and a review of inert environment FCP testing [85]. The ASTM standard contains an appendix specific to CF crack growth in marine environments (ASTM E 647 and Ref 86). Procedures for CF in other environments are not standardized; however, methods have evolved for specific technologies [2,4]. CF  $da/dN$  data are presented in Figs. 4, 5, 8, 9, and 13 to 15.

### Specimens and Loading

CF crack propagation data are obtained with a variety of notched and precracked specimen geometries that are well-characterized in terms of stress intensity and compliance functions [85,87]. The Mode I compact tension, single-edge crack, three- or four-point bend, and center-cracked tension specimens are used commonly, and are prepared based on standardized procedures (ASTM E 647). Specimen in-plane dimensions are selected to guarantee elastic deformation with limited small-scale crack tip plasticity. Specimen thickness, and the plane stress or plane strain deformation state, is a variable. Closed-loop servohydraulic test machines are most effective for CF propagation experiments, with the control parameter being load. (Load-line displacement or crack mouth opening displacement control are sometimes used.) Such machines provide a range of load or displacement waveforms (sinusoidally time-dependent is typical) and frequencies ( $10^{-4}$  to 100 Hz are typical values).

### Environmental Cell Design

Cells for CF crack propagation experiments are designed to control solution composition and specimen electrochemistry analogous to HCF and LCF (see previous subsections with this title), while allowing for measurements of applied load, crack opening displacement, and crack length. A variety of approaches is reviewed elsewhere, including electrochemical details for several environments [4]. Two cells for ambient temperature electrolytes are shown in Fig. 18. If the test machine and loading axis are mounted in a horizontal plane ( $90^\circ$  to the normal orientation), then the compact tension crack tip can be dipped into solution which is exposed to air without complex sealing (Fig. 18a). The alternate approach in Fig. 18b employs a vertical loading axis with a segmented Plexiglas or Teflon cell, sealed to the faces of the compact tension specimen with O-rings and including a short segment in the notch mouth. Solution flow is through the notch, parallel to the crack front. Small cells clamped to specimen surfaces (Fig. 18b) are equally effective for center-through-cracked plate specimens. Specimens with surface cracks or single-edge cracks are effectively contained in environmental cells that are large and sealed to the round or flat ends inboard from the gripping points [88]. Compact tension and surface crack specimens have been contained in pressurized metal autoclaves with electrolytes or steam at elevated temperature (Fig. 19) [89]. In this particular study, a yoke was employed to simultaneously test two specimens in one autoclave and load frame.

Reference and counter electrodes are readily employed in the various cells (e.g., Fig. 18b), perhaps with salt bridges to

**FIG. 18—Environmental chambers for CF in electrolytes where: (a) the CT specimen is loaded horizontally and dipped into solution [4], and (b) the CT crack is enclosed by a clamped cell and polarized potentiostatically. In part b load (P)-displacement ( $\Delta$ ) data are recorded by computer and autographically for compliance measurement of crack length and  $K_{ci}$ .**

remote containers and including high pressure and temperature compensation capabilities. Procedures to eliminate galvanic couples and to maintain solution purity and composition are identical to those employed in HCF and LCF experiments. Crack opening displacement is measured with a remote or immersed extensometer or LVDT. The cell must not interfere with specimen loading or displacement. For example, in Fig. 18b, the shaded midportion is a flexible membrane designed so that cell clamping forces do not alter specimen compliance. This is important for accurate measurements of crack closure.

Typically, metal-bellows/gasket sealed high vacuum chambers are utilized for environmental fatigue experiments in inert or deleterious gaseous environments [4]. Such an apparatus is outside the scope of this review.

**FIG. 19—Two compact tension specimens mounted in a high pressure-temperature stainless steel autoclave capable of containing water, steam, or acidified H<sub>2</sub>S bearing brine environments [4,89].**

### Crack Length Measurement

CF propagation experiments are unique in the need to monitor crack length, often over a long time. Much has been written on two widely employed methods, direct or alternating current electrical potential difference and compliance (see ASTM E 647, and Refs 84,90,91), as well as on less-tried methods such as eddy current, acoustic wave, optical, or crack surface marking [92]. Compliance and EPD are broadly calibrated and well-suited for precision ( $\pm 25 \mu\text{m}$  or better), long-term-stable monitoring of crack length in many common fracture mechanics specimens and aggressive CF environments. These methods can be computer-automated for test machine and stress intensity control (see following subsection). The principles and instrumentation for each method are detailed elsewhere (ASTM E 647 and Ref 84).

Several points are pertinent to CF. First, compliance allows monitoring of both crack length and crack closure [93]. The advantage of the EPD method is simplicity; it is not necessary to immerse a displacement gage in the electrolyte. (The compliance scheme illustrated in Fig. 18b avoids this complication.) The EPD method is best-suited for monitoring the growth of surface fatigue cracks. Second, there is no evidence that the 1 to 50 A direct or alternating current used in the potential difference method affects CF kinetics. Presumably, the resistance to current flow through the metal is orders of magnitude lower compared to that of the most conductive solutions in an occluded crack. Voltage differences along a crack surface, and

due to this current distribution in the metal, are small (less than 1 mV) and probably unimportant. Nonetheless, prudence dictates that the influence of applied current be tested by employing an independent monitor of crack length in limited qualification and calibration experiments. Third, the electrical potential signal often increases with increasing load in the fatigue cycle because electrically conductive crack surfaces are increasingly parted. Accordingly, potential should be measured at maximum load, and errors in crack length due to residual "crack surface-shorting contact" should be corrected based on post-test crack length measurements [94]. Finally, solution flow or temperature changes can upset the stability of the electrical potential signal due to thermally-induced voltages and material resistance changes.

Ground-loops between potentiostat and electrical potential crack monitoring electronics degrade the quality of polarization as well as CF crack length and growth rate measurements. A successful approach to this problem is based on a specimen (working electrode) that is grounded commonly with the test machine, constant-current power supply and EPD amplifier, coupled with a potentiostat that uses a grounded working electrode. In this case the specimen should not be grounded virtually through an operational amplifier. With this procedure, and the several-ohm (or larger) alternate current path through the typical loading system and test machine, it is not necessary to electrically isolate the CF specimen from the grips. As a test of ground-loop integrity in CF, guarantee that specimen electrochemical current does not change, at fixed electrode potential, upon reversing the polarity of the crack monitoring current.

Given the success of the direct-EPD method, with current applied through the bulk of the CF specimen, there is generally no need to employ an indirect method based on a foil gage bonded to the specimen surface and solely carrying the applied current. This latter method eliminates the effect of applied current on crack electrochemistry (if such an effect exists); however, long-term crevice and galvanic corrosion associated with the attached foil may be important. CF crack growth in the midregion of a specimen is reasonably indicated by compliance or direct EPD, but not by the surface-mounted foil gage method.

### Parameter Measurement, Control, and Computer Automation

Applied load and crack length from electrical potential or compliance are measured as a function of load cycles during a CF experiment. Apart from simple constant load range (increasing  $\Delta K$ ) loading, modern FCP and CF experiments are computer-automated to control the  $\Delta K$ -history, with the mode selection based on the goal of the work, be it mechanism- or application-based. Load is computer-varied, in real time and at frequencies between  $10^{-4}$  and 50 Hz, to maintain the crack length dependence of stress intensity range according to (ASTM E 647)

$$\Delta K = \Delta K_0 \exp[C(a - a_0)] \quad (5)$$

R-value is typically maintained constant as  $\Delta K$  changes. A programmed  $C$  of 0 yields a constant  $\Delta K$  experiment,

which is useful for establishing transient and steady state CF growth rates for mechanistic research. Negative  $C$ -values provide for a  $\Delta K$ -decreasing experiment for measuring near- $\Delta K_{TH}$  CF. Positive  $C$  gives a  $\Delta K$ -increasing experiment that yields data in a reasonable time and confirms stress intensity governed cracking when used in conjunction with a negative  $C$  experiment. Guidance on those values of  $C$  that minimize the effect of prior load history is standardized (see ASTM E 647).<sup>4</sup>

### Data Analysis and Evaluation

Applied stress intensity range and CF crack growth rate are calculated at regular crack length intervals, based on standardized analytical procedures (ASTM E 647). For continuously increasing or decreasing  $\Delta K$  experiments,  $da/dN$  is calculated by either a point-to-point difference (secant) or incremental polynomial method. For constant  $\Delta K$ ,  $da/dN$  is determined by linear regression of cyclic crack length data. The simple secant calculation amplifies  $da/dN$  variability, while polynomial methods average the growth kinetics over seven (typically)  $a$  versus  $N$  points. Growth rate variations depend on the size of the crack growth interval. It is particularly challenging to establish physically meaningful variations from an average growth rate law.

FCP variability was considered in conjunction with an interlaboratory test program that measured  $da/dN$  versus  $\Delta K$  for a well-behaved high-strength steel in moist air [95]. For this best case and 14 laboratories,  $da/dN$  variability from replicate standardized experiments within a single laboratory equaled between  $\pm 13\%$  and  $\pm 50\%$  ( $\pm$  two residual standard deviations about the mean regression curve) at fixed  $\Delta K$ . Variability in CF experiments has not been addressed quantitatively; however, the results from the moist air FCP program provide a lower bound. The increased complexity and prolonged test times typical of CF experiments, as well as the FCP behavior of more complex alloys, should lead to increased variability and uncertainty.

Two complications are notable for CF experimentation. CF  $da/dN$  versus applied  $\Delta K$  data may be affected by a crack closure mechanism that depends on aqueous environment exposure (see subsection, Mechanical Variables) [6,45]; such CF growth kinetics are defined as an extrinsic property that may be test method-specific. As a diagnostic, if CF  $da/dN$  depends strongly on  $R$ , if the environmental  $\Delta K_{TH}$  value is high and increases with decreasing loading frequency, or if crack arrest occurs during CF propagation at constant applied  $\Delta K$ , then environment-sensitive crack closure should be suspected. A bilinear specimen compliance trace (of applied load versus crack mouth or load line displacement) confirms the presence of crack closure.

Closure is characterized and eliminated approximately for a given  $da/dN$  by reducing the applied  $\Delta K$  to  $\Delta K_{eff}$ , the difference between  $K_{max}$  and  $K_{cl}$  rather than  $K_{max}$  and  $K_{min}$ .  $K_{cl}$  is determined by a global compliance method that is nearing

standardization [96]. CF  $da/dN$  versus  $\Delta K_{eff}$  data, as well as results obtained at high constant  $R$  (above about 0.7) or high constant  $K_{max}$  (see Fig. 5 and subsection, Programmed Stress Intensity Experimentation), are reasonably closure-free and are an intrinsic property for a given material-environment system [62]. Closure-free CF data are necessary for basic studies of crack tip process zone damage mechanisms, while crack closure phenomena may be important to applications. As an example, corrosion fatigue cracks in steels exposed to seawater at low  $R$  are arrested by cathodic polarization, because calcareous corrosion products precipitate within the growing crack and cause crack surface closure contact at  $K$  levels well above zero [20,97].  $\Delta K_{eff}$  is substantially less than both the applied  $\Delta K$  and the intrinsic  $\Delta K_{TH}$ . Rough intergranular CF crack surfaces, coupled with local Mode II displacements, may also promote crack closure. Closure benefits may, however, be limited to simply loaded laboratory specimens. For example, compression elements of a complex load history can crush corrosion debris and crack surface roughness asperities, and can thus reduce crack closure.

As a second complication, crack tip stress, strain, and strain rate within the process zone are more fundamental than  $\Delta K$  or  $\Delta K_{eff}$ , and govern CF crack growth kinetics. It is not presently possible to unambiguously calculate the stress intensity dependence of these more fundamental parameters [16,22–24]. Shoji and coworkers argue that the time-based rate of mechanical FCP ( $da/dt_f$ ) in an inert environment is proportional to the rate of dislocation emission from the crack tip, or equivalently, to the crack tip strain rate [98]. The value of  $da/dt_f$  for FCP in vacuum, or more typically moist air, is therefore an indirect crack tip driving force parameter for correlating CF  $da/dN$  data which are also often stated with respect to a time-rate. In this approach,  $da/dt_f$  is the product of  $da/dN$  and  $f$ . An example of this correlation is shown in Fig. 20 which represents the CF enhancement in  $da/dN$  relative to the air

FIG. 20—Time-based CF propagation rate for several heats of A302-B steel in high-temperature water versus mechanical  $da/dt$  for the same alloy in moist air and at several  $R$  values [99].

<sup>4</sup>During fatigue and CF crack propagation, a sudden large decrease or increase in the maximum stress intensity level of the load cycle produces a strong reduction in subsequent growth rates, or so-called delay retardation. These growth rates are important, but are not steady-state and not simply governed according to Eq 3 [6–8]. Most CF experiments are designed and conducted to avoid such overload effects.

case for three high-sulfur-content heats of a C-Mn steel in elevated-temperature water [99]. The speculation is that this relationship between the benign and CF time-based rates of cracking is followed independent of  $\Delta K$ ,  $R$ ,  $f$ , and loading waveform, as demonstrated for several material-environment systems [98]. In Fig. 20 these parameters are varied widely; for example,  $f$  between 10–4 Hz and 10–1 Hz, and  $R$  between 0.2 and 0.7, but a single CF crack growth law is observed. Based on the film rupture (and perhaps HEE) mechanism, environmental  $da/dt$  should increase with increasing crack tip strain rate [22–24], and hence with the mechanical  $da/dt_f$ , as suggested in Fig. 20.

### Specialized Corrosion Fatigue Experiments

Several new CF experimental methods have evolved over the past decade.

#### Programmed Stress Intensity Experimentation

Real-time computer-control of stress intensity during a CF experiment provides important benefits. For example, CF experiments can be designed with a large negative  $C$ -value (Eq 5) to produce continuously decreasing  $\Delta K$  at constant applied  $K_{\max}$  and increasing  $R$  [62,100]. This approach minimizes the complicating effect of crack closure and provides near- $\Delta K_{TH}$  data, albeit at high  $R$ . The CF results presented in Fig. 5 were obtained based on this method [44]. Since both  $\Delta K$  and  $R$  change during this type of experiment, the effects of these two mechanical parameters must be characterized and understood when using the constant  $K_{\max}$  method in CF [16]. Second, variables such as electrode potential, solution composition, or frequency are easily changed as the crack grows at constant  $\Delta K$  to probe subtle growth rate changes for basic research [61,64]. A constant  $\Delta K$  segment can be conducted over an interval of CF crack extension, then  $\Delta K$  can be step-increased or decreased at constant  $K_{\max}$  [51,62,64]. The data presented in Figs. 9, 13, and 14 were obtained with this method.

#### Cyclic Strain-Induced Dissolution

The cyclic-mechanical depassivation method involves measurement of transient electrochemical current during cyclic plastic straining of a smooth specimen in an electrolyte at fixed potential [34,101]. A three-electrode cell, coupled with a fast-response potentiostat and the mechanical LCF procedures described in the subsection on the Smooth Specimen Method, are employed in this regard. Data include time-dependent applied plastic strain, stress, and anodic current density. The phase difference between the mechanical and electrochemical parameters, the strain dependence of the current density during repeated repassivation repair of ruptured surface films, the anodic charge passed per fatigue cycle, and the charge accumulation with increasing cycles and time are interpreted to probe CF damage mechanisms. For example, peak anodic current density and the cycle-cumulative charge increased with increasing strain rate for LCF of a ferritic stainless steel in NaCl, consistent with the film rupture model [34]. (This current reflects metal oxidation to produce cations in solution and in formation of the passive film, or, collectively, metal removal.) Additionally, the time dependence of repassivation and the magnitude of current

transients depended on the sign of the plastic strain, and the repassivation characteristics for this system varied with cycle count, demonstrating the complexity of CF. This method was employed to rank the susceptibility of alloys to CF, based on the stability of surface passive films [101].

#### Small Crack CF Methods

An important goal of CF experimentation and modeling is to quantitatively couple smooth specimen and fracture mechanics approaches to understand the total life of components with microscopic defects. Studies of the so-called “small crack problem” have contributed in this regard [6]. Small crack size can be a particularly important variable that affects CF propagation rates [102,103]. For example, CF cracks sized between 100 and 1000  $\mu\text{m}$  grew up to 1000-fold faster than predicted compared to long crack compact tension specimen  $da/dN$  data at fixed  $\Delta K$ , for the case of a high-strength martensitic steel in NaCl [104]. Such crack geometry effects are traced to differences in crack solution mass transport and crack surface electrochemical reactions that govern HEE and film rupture processes [16,102,103].

Both electrical potential and high magnification optical methods have been developed to monitor the formation and growth of CF cracks smaller than 500  $\mu\text{m}$  [105,106]. Each method is capable of micron-level resolution. The electrical potential approach monitors average short crack growth into the specimen bulk, while microscopic methods focus on surface crack interactions with specific microstructural features including inclusions and corrosion pits. The data presented in Fig. 21 were obtained from in situ monitoring of AA2024 in aqueous chloride solution with a long focal length (15 to 40 cm) and high magnification (500 $\times$  with 1  $\mu\text{m}$  resolution) optical microscope interfaced with a servohydraulic test machine and video system [106]. Microstructurally small CF cracks initiated at constituent particles and grew at rates that were equal to values obtained with the standard LEFM method discussed in the subsection on Fracture Mechanics Methods. While the chemically small crack

FIG. 21—CF propagation rate versus  $\Delta K$  for microstructurally small cracks in AA2024 exposed to deaerated aqueous chloride at fixed potential. Crack growth was monitored by in situ optical microscopy [106].

effect is not observed for the system in Fig. 21 [106], data of this type are important and lacking for a range of materials and environments [102–105].

The use of short crack specimens provides an important benefit for corrosion fatigue experimentation. Since high-resolution crack monitoring is employed, crack growth rates are quantitatively defined with small crack extensions and the associated reduced  $N$ . It is possible to obtain accurate low growth rate CF data at low loading frequencies. For example, a short crack specimen was employed to measure a  $da/dN$  value of  $0.5 \mu\text{m}/\text{cycle}$  at constant  $\Delta K$  and  $f$  of  $0.0 \text{ Hz}$  during a CF test time of 10 days [16,105]. A 10- to 20-fold longer test time is required to obtain this measurement with a standard long crack method.

#### Measurement of CF Crack Solution pH and Potential

It is important to measure occluded crack pH, potential, and solution composition because these factors govern CF by either HEE or film rupture mechanisms. Several experimental approaches have succeeded in this regard for simple ambient temperature and complex high-temperature pressurized water electrolytes [107,108]. Reference and pH electrodes were located in small holes drilled in the compact tension specimen to intersect the CF crack plane growing from the notch, as shown in Fig. 22 [108]. This method provides information on the crack size and position dependence of local pH and potential, as well as on the effects of  $\Delta K$ ,  $R$ , and  $f$ . Additionally, crack solution can be sampled from crack-intersecting holes for composition analysis by ion chromatography and capillary electrophoresis [109]. Important data were obtained to test models of crack chemistry [72,108] and to understand solution-dissolved oxygen and metal sulfide effects on CF [22,23,109]. Given the very small volume of a typical CF crack, solution extraction methods are likely to upset crack electrochemistry and alter  $da/dN$ .

## APPLICATIONS OF CORROSION FATIGUE TEST RESULTS

### Modern Approach to CF Life Prediction

A cardinal principle is to design the CF experiment to isolate and characterize quantitatively any one of the four stages of fatigue damage defined in the Definition subsection of this chapter. The choice of stage depends on the problem, be it pitting-based crack nucleation in a polished and rigorously inspected medical implant or steam turbine blade, or macrocrack propagation from a weld defect in a large offshore marine structure. If a CF experiment measures total life, without quantifying the four damage stages, then basic understanding and component life prediction are compromised. This is the situation for standardized high- and low-cycle fatigue experiments that measure total  $N_f$  of a small laboratory specimen. The CF material properties embodied in the Basquin and Coffin-Manson relationships Eqs 1 and 2) are not directly scalable to predict the lives of components of alternate geometries and perhaps containing preexisting flaws. These data cannot be used to test models of CF because  $N_f$  embodies cyclic deformation, microcrack

nucleation and coalescence, small/short crack growth, and long crack propagation.

Implementing the correct method for CF life prediction and CF-resistant alloy development is often controversial, as existing approaches (often based on smooth specimen HCF data) are challenged by more modern approaches. A consensus is perhaps developing; an effective method couples the local strain approach to CF crack formation and early growth to a given detection threshold with the LEFM approach to propagation in order to calculate the summed total component life. The recommendation is that the Coffin-Manson approach be employed, but that the number of cycles to form a (reasonably) resolvable crack size (perhaps 0.1 to 1 mm) be measured in place of total cycles to failure. Equation 2 then describes the CF crack formation resistance of a given alloy-environment system, with the size of the initiated crack defined operationally. These material-environment property data are coupled with Neuber's method or finite element calculations of local plastic strain range in a component to define service initiation life [7].

The fracture mechanics approach should be employed to characterize CF crack propagation kinetics, with emphasis on both the microstructurally small, physically short, and conventional long crack regimes [6,8]. The Paris relationship (Eq 3), or more complex formulations, are employed with stress intensity similitude and an analysis of the stress and stress intensity conditions of the component to predict CF propagation life, integrated from the size of the crack formed in the initiation stage [41]. A variety of desktop computer programs have been developed for the LEFM portion of the fatigue life prediction problem [110]. If non-destructive testing so indicates, then the LCF initiation portion of the problem can be equated to zero, and the fracture mechanics integration started at the appropriate existing flaw size.

The output of an integrated CF prediction method is plots of total cyclic life as a function of applied stress range, or

crack length versus load cycles at constant applied  $\Delta\sigma$ , for specific material, time, and environment chemistry variables. Coffin-Manson and Paris Law data depend on the variables cited in the section, Factors Controlling Corrosion Fatigue. Since a legion of variables is important, and since prolonged CF test times are often required, mechanistic modeling of the nucleation and crack propagation processes is a critical tool to develop algorithms for extrapolating the results of limited laboratory experiments [111].

### Examples of Component Service Life Prediction with Laboratory CF Data

Corrosion fatigue problems have been attacked aggressively in several technologies over the past decade. The coupled local strain-formation and LEFM-propagation approach has not, however, been broadly employed. Early codified design predictions, using elastic smooth-specimen fatigue data (HCF-SN) adjusted empirically for deleterious time-dependent environmental effects, are being replaced by LEFM predictions of crack propagation from an inspection-based or estimated initial crack size [111]. Examples of this procedure were reported for CF in welded offshore structures in the marine environment [1,3,58,111–113], in-core and out-of-core components in commercial light water nuclear reactors [2,22,111,113], oil and gas pipelines [114], and aircraft [115,116]. Emphases focused on the conflicting effect of cathodic polarization on CF crack formation and growth (marine structures), the unifying role of crack tip strain rate (nuclear reactors), the deleterious effect of sulfur contaminants (nuclear reactor systems and pipelines), and the CF kinetics of small multiple fatigue cracks (aircraft). Tens of man-years are typically required to address a complex CF problem, and large databases for SCC and CF resulted from these efforts [58,117].

### Future Research Needs in CF Experimentation

Environmental effects have not been rigorously incorporated in fatigue life prediction procedures [110]. The time dependence of CF, the many important interacting variables, and several uncertainties confound the problem. From the experimental perspective, LCF and LEFM-based laboratory CF methods must be improved to address the following uncertainties:

1. Methods must be further developed to probe the growth of single small CF cracks sized below 500  $\mu\text{m}$ , and the interaction and coalescence of multiple small cracks must be characterized. Both LCF and LEFM approaches must be modified in this regard.
2. Near-threshold CF crack formation and propagation, and environment-dependent crack closure, must be characterized including the important effect of low loading frequency [118].
3. Load- and environment-spectrum history effects on CF crack formation and propagation must be characterized.
4. The statistical distribution of CF initiation/early growth and crack propagation properties must be defined.

5. High-resolution probes must be developed to measure occluded crack chemistry, transient crack surface electrochemical reactions, crack tip process zone damage processes, and microcrack advance.
6. Fractographic analyses of CF must be improved, including quantitative measurement of crack surface crystallography [119], and computerized image analysis methods to characterize and reconstruct the CF process [120].
7. For mechanistic modeling, CF results must be coupled with transient electrochemical reaction kinetics, hydrogen permeation, and hydrogen trapping analyses described elsewhere in this manual.

### Acknowledgments

This chapter was written based on the support of the Office of Naval Research (Grant N00014-91-J-4164, with Dr. A. John Sedriks as the Scientific Officer), the NASA Langley Research Center (Grant NAG-1-745, with Mr. D. L. Dicus as Grant Monitor), and the Virginia Center for Innovative Technology (Technology Development Center for Electrochemical Science and Engineering, with Professor G. E. Stoner as Director).

# Hydrogen Damage

C. G. Interrante<sup>1</sup> and L. Raymond<sup>2</sup>

## ENVIRONMENTAL CRACKING— HYDROGEN DAMAGE

THIS CHAPTER BEGINS with a brief review of the fundamental behavior of hydrogen in steels. It is presented as a primer that should aid in the understanding of (1) behaviors of hydrogen in materials, (2) the damage caused by hydrogen in various materials, and (3) the selection of appropriate test methods for a particular hydrogen problem.

## UNDERSTANDING THE BEHAVIORS OF HYDROGEN IN MATERIALS

### Basic Principles

Basic aspects of the problem of hydrogen in steels involve its limited solubility in the lattice, its high propensity for adsorption on internal and external surfaces, its absorption into the lattice and the transport by diffusion and by the motion of dislocations and the localization of hydrogen at internal sites in the bulk metal. This localization behavior is called trapping. A trap is a void, interface, or other physical site but may include a region of high stress.

Although it is not highly soluble in steels, hydrogen interacts readily with its host material in many ways that involve precipitates, inclusions, grain boundaries, and other imperfections in the lattice, and it may react with selected elements to form hydrides. These interactions and reactions frequently require transport of hydrogen within the bulk metal and the high mobility of the hydrogen contributes to the damaging character that it has in steels and other alloys.

Hydrogen molecules are relatively large and only the smaller atomic form of hydrogen can diffuse effectively. In gaseous hydrogen only a small fraction of  $H^+$  (hydrogen ions) are present, whereas they are abundant in aqueous solutions. Thus, aqueous solutions can be potent sources for "charging" steels with hydrogen. The uptake of hydrogen involves surface adsorption, followed by absorption into the lattice where it can be driven to diffuse through the bulk of the material. The driving force for diffusion is a gradient in the chemical potential which results from a gradient in one

of the following: the lattice hydrogen concentration, the hydrostatic component of an elastic stress field [1,2], an electric field, and temperature. Hydrogen diffuses away from a region of high chemical potential and towards lower chemical potential. For example, when a concentration gradient exists in the lattice of an unstressed body of uniform temperature without an electric gradient present, hydrogen atoms will diffuse from a region of higher interstitial concentration and towards a region of lower concentration.

In addition to its effects on decreasing the ductility of materials, the localization of hydrogen at regions of high levels of triaxial stress is well-known to be a very important factor in the characteristic delayed-failure behavior of steels containing hydrogen. The driving forces provided by gradients (in concentration, stress, etc.) act independently. Thus, the concentration gradient may be opposed or augmented by a gradient in stress. Hydrogen will diffuse towards an elastic stress field that is tensile in character. For example, this may occur from stress gradients nearby to notches, sharp defects (inclusions or microcracks), bending moments, and the stress field of a dislocation. Each can lead to hydrogen motion, with a hydrogen buildup occurring in the tensile regions, near the defects, and with the flux of hydrogen being proportional to the gradient in the triaxial component of stress.

### Diffusivity, Solubility, and Fugacity

#### Diffusivity

The lattice diffusivity and solubility both can be expressed by an Arrhenius-type equation. The diffusivity can be given by

$$D = D_0 \exp(-Q/RT) \quad (1)$$

where  $D_0$  is a pre-exponential term related to the vibrational frequency of hydrogen and the crystal structure of the metal,  $Q$  is an activation energy or heat of solution,  $R$  is the universal gas constant, and  $T$  is the absolute temperature.

Figure 1 gives results of diffusivity measurements on alpha iron [3,4], a ferritic steel [5], gamma iron [3], and stainless steel [3] by various investigators. These plots are shown to point out some general trends. Apart from the scatter in  $D$  for alpha iron and ferritic steels, the plots show that the lattice diffusivity of hydrogen in gamma iron is much lower than in alpha iron. The values for stainless steel are lower than those for gamma iron, presumably reflecting an influence of the alloy content. See Caskey [55] for a summary of "Hydrogen Effects in Stainless Steels."

FIG. 1—Diffusivity of hydrogen in iron and steel, after Geller and Sun [3] and Johnson and Hill [4], and in steels after Hobson [5] and Geller and Sun [3].

### Solubility

The solubility embodies Sieverts' law,  $C_H = k \times P^{1/2}$ , as the pre-exponential term, so as to account for the effects of pressure of hydrogen ( $P$ ) on the soluble concentration of hydrogen in metallic solution ( $C_H$ )

$$S = (k \times P^{1/2}) \exp(-Q'/RT) \quad (2)$$

Some materials are endothermic absorbers, while others are exothermic absorbers of hydrogen. For exothermic absorbers solubility decreases with increasing temperature for palladium, titanium, etc., and for endothermic absorbers like copper, iron, nickel, zirconium, etc., it increases with temperature, as illustrated below for iron.

Equation 2 for the solubility ( $S$ ) contains three constants— $k$ ,  $R$ , and  $Q'$ —and it demonstrates the dependence of the lattice concentration of hydrogen,  $C_H$ , on the square root of pressure. This dependence of  $C_H$  on the partial pressure of hydrogen in the environment is illustrated in Fig. 2, which gives hydrogen contents for iron for a range of values of partial pressure of hydrogen ranging from 0.01 atmospheres to 100 atmospheres [6].

Figure 2 also illustrates the effect of crystal structure, by the higher values over the range of temperatures (910°C to 1400°C) at which the FCC gamma phase exists. Solubility in the delta phase is an extrapolation of the alpha values indicating similar behavior for these BCC phases. In the liquid, solubility is much higher than in the solid. This plot is based upon measurements taken above 400°C (750°F).

FIG. 2—Equilibrium diagram, iron-hydrogen system, by Zapf [6].

When the solubility of hydrogen in iron is measured at temperatures below about 400°C (750°F), the observed values are generally much higher than those extrapolated from high temperature measurements, and this is taken as evidence of "traps." The subject of hydrogen traps is briefly introduced later in this chapter.

### Fugacity

Fugacity ( $f$ ) is a measure of the escaping tendency from liquid or solid solution to the surrounding environment or into the lattice or a void within a metal. In an ideal gas, the fugacity is equal to the vapor pressure, but hydrogen is not an ideal gas and the proportionality expressed by Sieverts' law is not exact. To account for this deviation in thermodynamic behavior, the fugacity of hydrogen furnishes a correction [51]. For hydrogen, and other diatomic gases like nitrogen and oxygen, when the partial molar Gibbs free energy ( $G$ ), which is synonymous with the chemical potential, is computed, the gas behaves like an ideal gas with a (equivalent) pressure ( $P$ ) equal to the fugacity ( $f$ ). When  $f$  is used in place of  $P$ , in Eq 2, the calculated lattice concentration is exact.

From data given by Baranowski [7], Fig. 3 is given to show the pressure for values of fugacity that extend over a very large range. At higher values of hydrogen pressure, the increases in fugacity, and hence in the concentration of hydrogen in the lattice, are comparatively much greater. Further, it is seen that as  $f$  increases, the difference between  $f$  and  $p$  increases, so that the values of  $f$  become increasingly greater than the corresponding values of  $P$ , which correspond to the internal pressure that can be exerted from within internal voids in the steel. In general, the pressure, e.g., that at internal sites, will not exceed that which corresponds with the fugacity of hydrogen at the exposed input

FIG. 3—Plot of the relationship between pressure and fugacity of hydrogen derived from data of Baranowski [7].

surface (where hydrogen enters the material) or that within the lattice. Figure 3 indicates that a pressure limit of under 20,000 atm (<300 ksi) can be imposed by hydrogen and that the hydrogen behavior is that of an ideal gas up to at least 200 atm.

In an analogous way, the non-ideality of solutions (liquid or solid) is accounted for when the chemical potential is computed for real solutions. The thermodynamic activity ( $a$ ) is used in place of the concentration ( $C$ ) in the Nernst equation; the equation is exact even if the concentration is high and the behavior is non-ideal. The activity is the driving force for the reaction of hydrogen within the lattice and is related to the concentration by a proportionality factor  $\gamma$ :  $a_i = \gamma_i C_i$ . Use of the activity is more important at higher concentrations, as the difference ( $C - a$ ) increases with concentration. Thus, the activity ( $a$ ) can be used to correct for the nonideality of the solution.

### Trapping Behavior

Hydrogen in excess of the solubility (interstitial) limit is believed to be contained not at interstitial lattice sites but at other sites referred to as "traps." In general, these trapping sites apparently do not affect solubility at elevated temperatures, as indicated for several ferrous materials in Fig. 1. At room temperature their ability to trap hydrogen is so great that only a small fraction of total hydrogen content is dissolved in the lattice for steel. The trapping behavior is affected greatly by cold work and the presence of nonmetallic inclusions. Other factors such as chemical composition of the matrix have a minor role. A "trapping state" defines a unique trap, i.e. dislocations, MnS inclusions, grain boundaries, etc. For every trapping state, there may be multiple "trapping sites."

The tendency for hydrogen to be trapped, the jump probabilities for the hydrogen atoms [8], is governed by the energy of motion  $G_m$  of the hydrogen atom, as well as by both the energy and the nature of the traps [9]. Attractive traps are regions of the lattice at which atoms are subject to a drawing force, for example, a region of local strain that

pulls the hydrogen to the center of the local region. Physical traps are modifications of the ideal crystal lattice, such as may result from high-angle grain boundaries, incoherent particle-matrix interfaces, and voids [52,57].

At lower temperatures, e.g., room temperature, at which a significant fraction of the hydrogen resides in traps, the trap acts like reservoirs whose behavior is governed by the fugacity of hydrogen in the adjacent lattice. Under equilibrium conditions, a net uptake of hydrogen by the trap occurs while the adjacent lattice hydrogen fugacity is higher, in relation to that inside the trap, whereas traps in a low-fugacity lattice region can lose hydrogen to the lattice. The kinetics of the uptake and loss during steady-state permeation are governed by behaviors at input and exit surfaces, the local fugacity through the lattice, the binding energy (reversibility) of the traps as well as the number of traps.

Traps are of two principal types, physical and attractive [52,53,57]. When a purely physical trap is compared with a purely attractive trap of the same depth, it is easier for hydrogen to escape the attractive trap, as smaller jump increments will lead to escape from it. Thus, attractive traps are regarded as being more reversible than physical traps, i.e., hydrogen that enters can leave more readily. Thus, the amount of trapped hydrogen is governed by both the nature of the defects and the fugacity of hydrogen in the lattice.

In general, it is observed that the very high values of the fugacity that can be achieved electrochemically (from aqueous solutions) are much greater than the fugacities that occur under hydrogen gas storage and industrial applications. Whereas from aqueous solutions, the fugacity can obtain values of hundreds of thousands of atmospheres, values of about 1000 atmospheres is about the limit for industrial gas; e.g., in hydrogen storage, chemisorption of hydrogen atoms at the charging surface is frequently less from the gas phase than that from aqueous solutions—fewer hydrogen atoms are made available for adsorption from the gas phase. This means that the gas-charged metal has a lower fugacity, a decreased tendency to escape or diffuse. Therefore, except for the cases of thermal charging and charging under the ionized atmosphere created by a welding arc, which are not dealt with in this chapter, gaseous environments have diminished effects in relation to those of some severe aqueous environments. The gaseous behavior further can often be greatly ameliorated by the presence of surface contaminants, e.g., oxygen gas, that block surface entry sites into the bulk lattice [10,11]. In many instances, this has proven to be an effective remedy to the deleterious effects of gaseous hydrogen. Very low levels of oxygen ( $10^{-3}$  atm) can have significant effects and the behavior can be abated completely using 1 to 10 % oxygen in hydrogen gas. The behavior observed under hydrogen gas strongly indicates that surface behavior governs the properties of steel in gaseous hydrogen environments.

## DAMAGE CAUSED BY HYDROGEN IN VARIOUS MATERIALS

### Effects of Hydrogen

There are few if any favorable effects of hydrogen in materials, while numerous types of mechanical damage may

result. While incomplete understanding exists on the details associated with the mechanisms by which hydrogen damage arises, the various mechanistic descriptions [12–18,54] that have been developed are adequate for problem solving by scientists and engineers. The most prominent and complex effects of hydrogen are those in steels. Hydrogen embrittlement is reported to occur in stainless steels [55], but austenitic materials including the stainless steels are much more tolerant of hydrogen when compared with ferritic steels. The damaging effects in austenite are generally most pronounced under high fugacities and where epsilon and alpha-prime martensite are present. Hence, this review focuses mainly on hydrogen damage in ferritic materials, as from a practical view these steels are most significantly affected by hydrogen damage. Hydrogen damage takes as many forms as there are mechanistic explanations for the effects of hydrogen:

1. At temperatures near room temperature, hydrogen in steel may cause a decrease in ductility, blistering, step-wise cracking or delayed cracking, which is crack extension that occurs at levels of stress intensity much below those required for crack growth in the absence of hydrogen.
2. At temperatures that are usually above room temperature, hydrogen gas at high pressure that diffuses into the steel can decrease the strength level of the steel by reacting with carbon, forming methane that can form internal bubbles that coalesce, usually at grain boundaries, and exert significant pressure that expands voids and causes decarburization. These are part of the problem called hydrogen attack, as described by Nelson [33].
3. In niobium, tantalum, titanium, and zirconium, brittle hydride phases can form and this may lead to loss of ductility and crack extension at decreased levels of stress intensity. The damage due to these hydride phases is governed not only by their quantity but by their orientations in relation to stress states in the nearby matrix.

### Internal Hydrogen Embrittlement (IHE)

Internal hydrogen embrittlement (IHE) is caused by hydrogen, contained (pre-existing) in the material, that acts in combination with extant stress, residual and applied. When a steel part fractures while sitting in air on a shelf, with no externally applied stress, this process of time-delayed fracture is caused by residual stress in a process that is classically termed internal hydrogen embrittlement (IHE). This behavior is usually associated with steels of relatively high strength levels, such as those used in bolts or landing gears. It is caused by the presence of residual hydrogen and residual stresses from processing. These “causes” initiate microcracking that proceeds eventually to rupture. Applied tensile stresses in combination with residual stresses from processing can also produce time-delayed fracture or IHE, as in electrochemically plated tensile bolts. Commercially, IHE is treated differently than environmental hydrogen embrittlement (EHE), which includes any gaseous or aqueous environment that promotes hydrogen charging of the material. In both processes, the cracking is associated with diffusion and localization of hydrogen near defects and microcracks.

### Environmental Hydrogen Embrittlement (EHE) and Stress Corrosion Cracking (SCC)

When cracking occurs in an aqueous solution, a distinction is made between two forms Environmentally Assisted Cracking (EAC): stress corrosion cracking (SCC), and Environmental Hydrogen Embrittlement (EHE). An impressed cathodic current may often provide protection against SCC, but steel that is “protected” against corrosion by this means may be subject to EHE by cathodic hydrogen absorption/adsorption. For an impressed anodic current, the converse is true. Although this is a simplistic view of SCC, it is sometimes useful. Nevertheless, it would be remiss to fail to note that under anodic polarization, hydrogen production might still result at a crack tip where its presence can be most harmful. Bulk anodic polarization does not ensure that the crack tip is polarized.

Differences and similarities between SCC and EHE are further described by Latanision [19], who also discusses hydrogen-induced phase transformations in the solid, the observation of hydrogen evolution from the tip of a propagating crack, fractography, crystal structure, and the influence of solid-state impurities.

Thompson, Bernstein and Pressouyre [20,52] discuss the significance of a number of metallurgical variables (including chemical composition), microstructural components (precipitates, grain size and shape, crystallographic texture), heat treatment and its effects on these variables, and processing, especially thermomechanical treatments for enhancement/optimization of properties.

Treseder [21] indicates ranges of electrode potentials for SCC in various environments and indicates that EHE may be a factor in complex environments of sulfides, cyanides, carbonates, and ammonia, and he notes that the term SCC is attributed to various literature references where EHE is the appropriate environmental influence.

### Effects on Ductility

Hydrogen contained in steel that is tested in air can lead to a decrease in ductility and the true stress at fracture. This effect is manifested in tension tests with smooth specimens as a decrease in reduction of area and elongation, but in notched specimens as a degradation in strength (in notched tension tests as a decrease in notch tensile strength) and in notched bend tests as a decrease in bend ductility. The magnitude of the decrease in ductility increases with decreasing strain rate, and for an SAE 1020 steel [31] this effect on ductility was observed to occur within the range of temperatures from about -250F to 130F after cathodic pre-charging with hydrogen.

Figure 4 illustrates the effects of hydrogen on ductility in a smooth bar tensile test. Steels containing residual hydrogen can be characterized by fracture after the onset of necking but at lower than normal strain values, as illustrated by data from Hobson and Sykes [22] for smooth bars. The table corresponding to this figure shows that the bars had hydrogen contents of from 0.1 ppm to 4.8 ppm, as the hydrogen content was decreased by baking. The plot shows that the true stress at fracture decreases as the hydrogen concentration in the steel increases, but fracture occurs only

FIG. 4—True stress-true strain curves for a hydrogen-impregnated 3Cr-Mo steel after standing in air for varying periods [22].

after the apparent maximum stress has been reached and necking is already in progress. Thus, in this study, the presence of hydrogen led to fracture after the apparent maximum stress has been reached, and necking is already in progress, so that the flow or yield behavior does not appear to have been affected, but fracture occurs at levels of true strain and true stress that decrease progressively as the hydrogen content is increased. In steels of higher strength level, which are more greatly affected by hydrogen effects, the presence of hydrogen may have substantial effects on both the tensile strength as well as on measures of ductility.

These effects of hydrogen are often reversible if no microcracking has occurred. Whenever specimens that have contained hydrogen have been outgassed of hydrogen but still exhibit decreased ductility, the observed effects are generally attributable to microcrack damage that occurred prior to outgassing and during the period of hydrogen containment.

It was shown that in IHE the plastic flow behavior after the point of maximum load is the dominant effect in smooth-bar testing, which is to say that ductility and toughness are decreased. As has been suggested by Beachem [17], hydrogen facilitates dimpled rupture and/or crack propagation. Hence, it is expected that the fracture toughness at the onset of crack propagation will not be as greatly influenced by hydrogen at conventional ASTM E 8 loading rates, when compared with propagation behavior. In J-integral and R-curve tests Nagumo's Figs. 22, 21, and 15 illustrate [59] significant effects for the "region of crack propagation" [<http://www.msm.cam.ac.uk/phase-trans/2003/nagumo/IMG/22.gif>]. Hirth discusses plastic instability in the presence of hydrogen [58]. Nagumo [59] attributes the role of hydrogen in decreasing the resistance to ductile crack-growth (Nagumo Figs. 18–20) as an increase in the density of vacancies and their agglomeration, a mechanism that he supports with recent findings of amorphization associated with crack growth (s.a. Nagumo Figs. 23–25). The classification

	Aging Period	Hydrogen Concentration ml/100g	Hydrogen Concentration ppm
H <sub>2</sub> gas	ABSENT	0.1	0.1
	21 days	1.4	1.3
	12 days	2.8	2.5
	7 days	3.7	3.3
	2 days	4.6	4.1
	1 day	4.4	4.0
	1 hour	5.3	4.8

of models in his Fig. 25 was adapted from his ISIJ International (2001) article [60].

### Effect of Notches

The decreased tensile ductility and true fracture stress/strength of steels containing hydrogen are particularly significant in respect to behavior at notches and other stress concentrators, as the local plastic strain that precedes fracture at these local sites is affected as described above, except that the result is a decrease in notched tensile or fracture strength. Because notched tensile strength (NTS) or notched fracture strength (NFS) is affected by ductility of the steel, those factors that govern the effects of hydrogen on the ductility of steels containing hydrogen, such as hydrogen content, strain rate, and temperature, are expected to similarly affect the behavior of the NFS. Thus, the effects on strength of notched specimens are qualitatively similar to the effects on ductility of smooth specimens.

### Delayed Failure

When subject to a sustained load, a steel containing residual hydrogen may exhibit a considerable degradation in strength. Thus, after an incubation period, hydrogen in steel can decrease the fracture strength, and for very-high-strength steels this behavior may occur at very low levels of hydrogen. This behavior is variously termed delayed failure, hydrogen-stress failure, and delayed, low-stress brittle failure, static fatigue, cold (or delayed) cracking, and internal hydrogen embrittlement (IHE). It represents a manifestation of the decreased fracture strength (or strain at fracture) in the presence of hydrogen, as exemplified by the results of the notch tension tests just described. These delayed fractures initiate in regions of highly localized stress in which hydrogen is concentrated as a result of locally augmented solubility,

which promotes diffusion of hydrogen into triaxially stressed sites near flaws, notches, and discontinuities. The term "brittle" sometimes used for this effect of hydrogen is an embrittlement observed to occur with a change from higher- to lower-energy fracture, with corresponding changes in the modes of failure. Thus, the fractographic features change from dimpled rupture to some combination of modes from quasi-cleavage to intergranular and cleavage.

The discovery and early exploitation of the understanding of this behavior was by Troiano and coworkers [13], who showed that in precharged samples, fracture occurs as a series of events: incubation, crack initiation, crack propagation, and finally failure. In the schematic drawing shown as Fig. 5 this behavior is represented by two stress-time curves, one for crack initiation and one for failure. Each curve is bounded by two stress levels, an upper-critical stress (UCS) and lower-critical stress (LCS), which are the highest and lowest applied-stress levels leading to delayed failure. Above the UCS, failure occurs without a time delay, and at stresses below the LCS (or threshold stress), hydrogen is not damaging and time-delayed failure will not occur. At intermediate stress levels, failure is inevitable and occurs as a series of events involving initiation and propagation of a crack.

After the specimen is loaded in tension at intermediate stress levels, an incubation period is required to initiate a crack. During this time, lattice-contained or weakly-trapped hydrogen diffuses ahead of the notches and local stress raisers, so as to equilibrate under the influence of any triaxial stress created there—this equilibration involves hydrogen redistribution associated with the equilibration of its chemical potential, under the combined influences of all factors that affect it. The first cracks will be initiated in this region after a critical hydrogen concentration has accumulated. The kinetics of the crack-initiation process are therefore dependent on the temperature and the stress gradient as they relate to the diffusion and concentration of hydrogen at the site of maximum triaxial stress in the steel.

The delayed-failure behavior of precharged steels may be affected by various factors, principal among which are the

hydrogen concentration and the strength level or hardness, but composition and processing may also affect the susceptibility of the steel. Other important factors are notch acuity and temperature, both of which strongly influence the observed behavior. An increase in either the hydrogen concentration or the strength level normally leads to a decrease in both the upper and the lower critical stresses, and to shorter delay times for failure.

## THE SELECTION OF APPROPRIATE TEST METHODS FOR A PARTICULAR HYDROGEN PROBLEM

### Interpretation of Test Results

Due to the complex nature of hydrogen embrittlement, the selection of a test method requires much thought to insure that the results truly predict the in-service behavior of a structural component. Test results may be influenced by a large number of variables: (1) those that affect the local concentration of hydrogen and state of stress; i.e., test specimen geometry (notched tension or bend specimens, cantilever, beam specimen, wedge-opening specimen), and specimen preparation (machining, grinding, fatigue precracking), (2) the susceptibility of the material that depends on the specific material, hardness and melting procedure i.e., air, vacuum, electroslag or vacuum arc remelting, etc., and (3) the environmental conditions i.e., potential, pH, oxygenation level, temperature, environment. As a result, test methods to assess hydrogen damage on a quantitative scale, are very difficult to design and control, and therefore, the test method should address a very specific set of conditions, so that the interpretation is facilitated and the results may be applied to solve a specific problem.

### Testing Techniques to Measure Hydrogen Concentration

Many test methods have been developed over the years [23–25] and new techniques to monitor the various aspects of hydrogen embrittlement are constantly being incorporated into ASTM Standards<sup>3</sup>. What many consider to be the most direct approach is to measure the concentration of diffusible hydrogen in the material. ASTM Committee E 3 focuses on these methods. No suitable fusion method has been developed to reproducibly measure hydrogen content at the precision of a part per million (or less) that may sometimes cause embrittlement in high-strength steels. For this reason, indirect mechanical test methods of measurement such as the amount of degradation in strength are being used.

### ASTM Test Methods Related to Hydrogen Uptake of Plated Materials

These ASTM standards are based on three types of controls: (1) monitoring indirectly the concentration of diffusible

FIG. 5—Schematic drawing of characteristic failure behavior of notched tension specimens containing hydrogen.

hydrogen in the material (ASTM F 1113<sup>4</sup>), (2) minimizing the amount of hydrogen introduced into the steel by keeping the hydrogen in a plating bath at acceptably low levels (ASTM F 326<sup>5</sup>) and (3) using mechanical tests to ensure that the amount of residual hydrogen after baking is below acceptable levels (ASTM F 519<sup>6</sup>).

### ASTM F 1113: Barnacle Electrode

A nondestructive electrochemical method for measurement of diffusible hydrogen in steels has been devised and standardized. The purpose of this test method is to evaluate the potential for hydrogen embrittlement based on the amount of diffusible hydrogen in steel. The method is limited to room temperature testing of flat carbon or alloy steels, excluding austenitic stainless steel specimens. The specimens must be bare or re-plated after the plating has been removed. One of the significant findings in the development of this technique is that 100-h baking time at 400°F (204.4°C) was shown to be required for a sufficient removal of all the hydrogen from a cadmium plated quenched-and-tempered 4340 steel specimen at 53 HRC.

### ASTM F 326: Lawrence Gage

This standard method electronically detects hydrogen in the plating bath and is related to hydrogen absorbed by the steel parts during plating and to the hydrogen permeability of the plating during post-plate baking. A specific application of this method involves controlling cadmium-plating processes in which the plate porosity relative to hydrogen is critical, such as with cadmium plating of high-strength steel.

This method uses a metal-shelled vacuum probe as an ion gage. A section of the probe shell is cadmium-plated at the lowest current density encountered during the electroplating process. During the subsequent baking, the probe ion current, which is proportional to hydrogen pressure, is recorded as a function of time. The slope of this curve has an empirical relationship to failure data, as discussed in ASTM STP 543 [26].

## MECHANICAL TESTING

An indirect, less expensive, and often more precise method for determining the amount of residual hydrogen due to processing is to quantitatively measure the change in a mechanical property that is sensitive to small variations in the hydrogen concentration [27–29]. This works best in higher strength steels in which comparatively small amounts of hydrogen lead to large changes in properties; in steels of lower strength levels, greater hydrogen contents are required to obtain significant effects. Measured tensile properties are affected by the temperature and strain rate of the test, the stress concentration of the specimen, the strength level of the steel, and the

amount of prior cold work. In fatigue-tests, the effects of hydrogen can be masked because hydrogen may not have sufficient time for diffusion to the crack-tip process zone for any significant effects of hydrogen to be observable. Nevertheless, in hydrogen “charging” environments significant effects of hydrogen may be observed.

Standard mechanical testing procedures are commonly used to measure the effects of hydrogen. Test results expressed as differences or ratios of the hydrogen-affected and nonaffected specimens are compared as a measure of the hydrogen effect.

Hydrogen embrittlement can also be revealed by a change in ductility of smooth-bar specimens and of strength level of notched-bar specimens. Likewise, the results of various other qualitative tests that are commonly used in corrosive environments, e.g., U-bend, C-ring, three- and four-point bend specimens, as well as stress-rupture constant load, constant-extension or slow strain rate tension and step-modified slow strain rate bend test specimens are used to detect embrittlement due to hydrogen. In addition, hydrogen attack, caused by high-pressure hydrogen at elevated temperatures, can result in decreases in absorbed energy in impact tests as well as decreases in other mechanical properties [30,32,33].

### Temperature and Strain Rate

Temperature and strain rate strongly affect the magnitude of the effect that hydrogen has on the ductility of (nonaustenitic) steels [33]. Hydrogen influences ductility over the range of temperatures from about –160°C (about –250°F) to above 200°C (400°F). The effect on ductility is a function of factors that influence the overall behavior, but the greatest effects occur near room temperature. The magnitude of the decrease in ductility increases with decreasing strain rate [31]. For the austenitic steels (in which effects are much less pronounced) the greatest effects are generally at and just below room temperature [55].

### Potential

Galvanic coupling from the use of dissimilar metals or the actual implementation of cathodic protection systems introduce hydrogen into the test environment in varying amounts. The amount of absorbed hydrogen is, of course, governed by the potential, and steel that is very resistant to EHE under open circuit potential may fail under galvanic action. Once exposed to a cathodic potential, the threshold stress required for subcritical crack growth can decrease significantly. Therefore potential is an extremely important test variable in evaluating a materials resistance to EHE.

### Process Control

Two standard test methods are used for hydrogen embrittlement prevention and control during processing of steel products. ASTM F 519 is directed at the plating process and maintenance chemicals used in aircraft such as landing gear (high-hardness steels, 45–52 HRC) and ASTM F 1940 is primarily directed at plating processes for fasteners (lower-hardness steels, 33–44 HRC).

<sup>5</sup> Ibid., Vol. 15.03, F326, “Method for Electronic Hydrogen Embrittlement Test for Cadmium Electroplating Processes.”

<sup>6</sup> Ibid., Vol. 15.03, F519, “Method for Mechanical Hydrogen Embrittlement Testing of Plating Processes and Aircraft.”

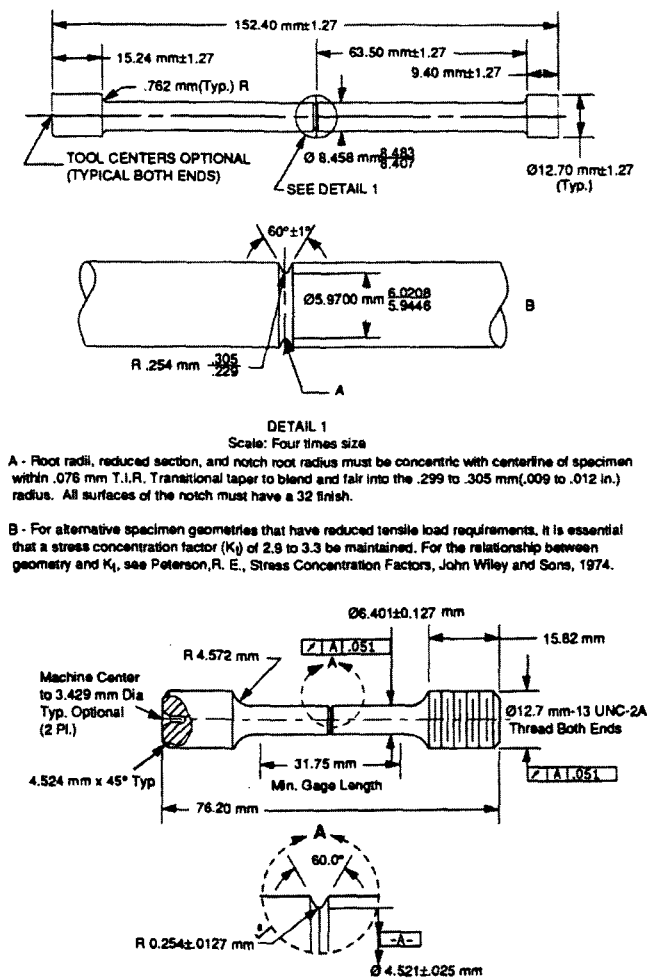

FIG. 6—Dimensional requirements for Type 1a specimens (reprinted from ASTM F 519, Type 1a).

Over 30 other military (MIL) and Federal (FED) specifications include hydrogen embrittlement relief treatments. Structural elements, such as springs or fasteners, are tested directly under constant load, constant displacement or decreasing extension rates (slow-strain-rate testing) for evaluation of the effectiveness of treatments directed at amelioration of hydrogen embrittlement.

### ASTM F 519: Aerospace & Aircraft

The ASTM F 519 method covers the evaluation of hydrogen introduced by electroplating processes and aircraft maintenance chemicals. The standard was originally written just for cadmium plated aircraft components, and specifically for high-hardness landing gear. Now the standard is being modified to evaluate other platings, some as replacements to cadmium and chromium because of their carcinogenic nature.

Test specimens are installed into the plating bath during the plating of hardware to monitor indirectly the amount of hydrogen in the plating bath. The acceptable level of hydrogen has been historically determined in a pass/fail test with

### Assembly of Type 1b Specimens with Type 1b Stress Ring with Locking Collar.

A flexible Plastic Collar is inserted over loaded specimen for protection.

Note 1—"L" to be 38.1 mm (1.5 in.) or greater.  
Note 2-Tolerance (unless otherwise specified):

XXX ±1.27 mm (.05 in.)  
XXOX ±.025 mm (.001 in.)  
XXXX ±.0051 mm (.0002 in.)

Note 3-Specimens and loading device that have been found to meet the standard are available from Stapleton Co., 1350 W 12th St., Long Beach, Calif. 90813.

FIG. 7—Dimensional requirements of Type 1b tension specimen (reprinted from ASTM F 519, Type 1b).

the fail being failure in less than 200 h under a sustained load with the specimen being stressed to 75 % of its notched tensile strength. With accelerated production schedules of 4- to 6-weeks, the 200 h (> 8 days) test period is creating an unacceptable and unnecessary time burden on production leading to the need and development of an accelerated, ≤ 24 h test method.

The procedures and requirements for ASTM F 519 are specified for the following six types of AISI 4340 steel test specimens grouped into three different loading methods are shown in Fig. 6 through Fig. 11:

#### • Constant Load

Type 1a: notched round bars, stressed in tension, under constant load (Fig. 6).

#### • Constant Displacement

Type 1b: notched round bars loaded in tension with loading rings (Fig. 7).

Type 1c: notched round bars loaded in bending with loading bars (Fig. 8).

Type 1d: notched C-rings loaded in bending with loading bolt (Fig. 9).

FIG. 8—Dimensional requirements of Type 1c loading bending bars (reprinted from ASTM F 519, Type 1c).

Type 2a: unnotched ring specimens loaded in bending with displacement bars (Fig. 10).

#### • Displacement Control

Type 1e: notched square bar loaded in bending (Fig. 11).

The Type 1e specimen is designed to incorporate the best attributes of all of the other specimens. The Type 1e has the same a notch acuity or stress concentration factor as the Type 1d specimen, which is the highest of all of the other specimens ( $k_t = 4.1 \text{ v } 3.1$ ), and therefore is considered to be

FIG. 9—Dimensional requirements of Type 1d ring bend specimens with loading bolt (reprinted from ASTM F 519, Type 1d).

FIG. 10—Dimensional requirements of Type 2a smooth ring specimens (reprinted from ASTM F 519, Type 2a).

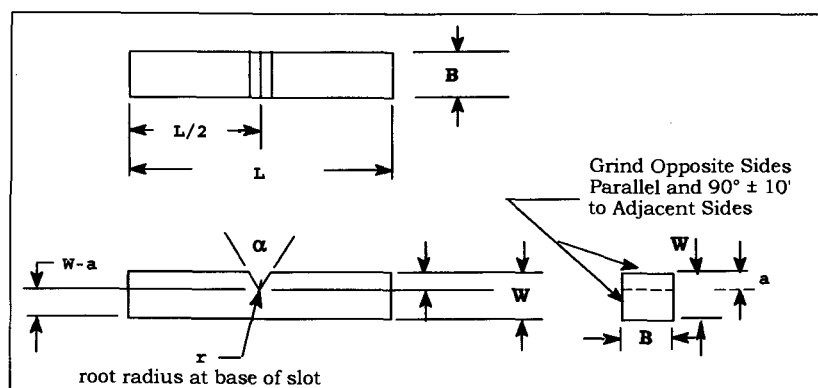

FIG. 10—Dimensional requirements of Type 2a smooth ring specimens (reprinted from ASTM F 519, Type 2a).

the most sensitive. The Type 1e specimen can have the same orientation relative to grain direction as all of the other specimens, which is the opposite of that in the Type 1d specimen. The Type 1e specimen is loaded in bending as with the Type 1c specimen, eliminating the need to establish axial tensile loads with great precision and minimizing the load requirements in addition to maximizing attainable stress levels. The Type 1e specimen is under displacement control as with the Type 1b, Type 1c, and Type 1d specimens. The Type 1e specimen has more size constraint than even the large diameter Type 1a specimen that is so designed to increase sensitivity. The Type 1e specimen has a larger notch angle for making deposition of a plating or coating more accessible. Finally, the Type 1e specimen is relatively inexpensive to manufacture, having the overall dimensions of a blank for a Charpy specimen.

The load is applied as a rising step load or step-modified slow strain rate testing protocol under displacement control that measures the threshold load for the onset of hydrogen assisted stress cracking by a drop in load that can be used as a quantitative, accelerated ( $\leq 24$  h) test method. Equivalence between the displacement control test method is assumed to occur when the threshold load in the accelerated test is  $\geq 75\%$  of the notched fracture strength of the square bar in bending.

For platings, no stress is applied until the parts have been baked, and baking must be initiated within one hour after plating. For maintenance chemicals and cleaners, stress is applied before the test specimens are exposed to the environment.

ASTM F 519 is based on the assumption that air-melted AISI 4340 at a hardness level of  $52 \pm 1$  HRC is a 'worst-case' condition. It is assumed that if no fracture occurs in the specimen after 200 h at 75 % or at a threshold of 75 % of the

All dimensions are in millimeters except for  $\alpha$ , which is in degrees.

$K_t$	$W = B$	$W - a$	$R$	$\alpha$	$L$ min	$L/2$ min
$4.1 \pm 0.2$	10.0	6.50	$0.28 \pm 0.03$	$90^\circ \pm 1^\circ$	50	25
$3.1 \pm 0.2$	10.0	6.50	$0.52 \pm 0.03$	$90^\circ \pm 1^\circ$	50	25

FIG. 11— Dimensional requirements of Type 1e Notched Square Bar Bend specimens (reprinted from ASTM F 519, Type 1e).

notched strength, then other 4340 steels processed by alternate melting processes (even steels with higher hardness levels that are vacuum-melted) will not have residual levels of atomic hydrogen that are high enough to produce sustained load (delayed) failure in the environment of concern. This test method is not intended to be a relative susceptibility test. The specimens are not to be fabricated from any material other than AISI 4340 according to MIL S-5000E.

### ASTM F 1940<sup>7</sup>: Automotive/Fasteners

This test method parallels the use of F 519, specimen Type 1e in specimen design and concept. The steel specimen has been modified to have a lower hardness of  $51 \pm 1$  HRC, and the notch root radius is 20-mil instead of 9-mil in order to reduce the stress concentration. The modifications were made with the intent of making the specimen less sensitive because the application was lower hardness fasteners (33-44 HRC) for automotive applications as compared to the higher hardness (45-52 HRC) steel used in aerospace applications.

The concept focuses on an accelerated  $\leq 24$  h test using a rising step load-modified, slow strain rate testing protocol to measure the threshold. An equivalence was established between the  $\geq 75$  % threshold acceptance level for the specimens and the  $\geq 90$  % threshold for product at 45 HRC.

As with F 519, the specimen is plated with the parts. A 'worst case' condition is again assumed since the hardness of the specimen is greater than the parts. A threshold of 75 % of the notched fracture strength of a bare specimen tested at ASTM E 8<sup>8</sup> loading rates is used as the acceptance

criterion. As a referee test, actual fasteners that have a lower hardness can be tested, but the threshold must be  $\geq 90$  % of the notched fracture strength of the fastener tested in bending.

It should be emphasized that this test method is not intended to be a relative susceptibility test, nor are the steel specimens to be fabricated with any material other than AISI 4340 steel.

### RELATIVE SUSCEPTIBILITY OF MATERIALS

#### ASTM F 1459<sup>9</sup>: Disk Pressure Test

The disk-pressure testing method is intended to measure the susceptibility to hydrogen embrittlement of metallic materials using a high-pressure gaseous environment [34]. The relative susceptibility to hydrogen embrittlement is based on the ratio of the burst pressure using hydrogen gas as compared to the burst pressure using helium. The test can be used for the selection and quality control of materials, and to evaluate the influence of protective coatings, surface finishes, and other processing variables.

In this test, a thin disk of the metallic material is placed as a membrane in a test cell and subjected to helium pressure until it bursts. Because helium is inert, the fracture is caused by mechanical overload; no secondary physical or chemical action is involved. An identical disk is placed in the same test cell and subjected to hydrogen pressure until it bursts. Metallic materials that are susceptible to gaseous hydrogen embrittlement will fracture at a pressure that is lower than the helium burst pressure; materials that are not susceptible will fracture at the same pressure for both hydrogen and helium.

<sup>7</sup> Ibid., Vol. 01.08, F1940, "Standard Test Method for Process Control Verification to Prevent Hydrogen Embrittlement in Plated and Coated Fasteners."

<sup>8</sup> Ibid., Vol. 03.01, E 8, "Standard Test Methods for Tension Testing of Metallic Materials."

<sup>9</sup> Ibid., Vol. 15.03, F 1459, "Standard Test Method for the Determination of the Susceptibility of Metallic Materials to Hydrogen Gaseous Embrittlement."

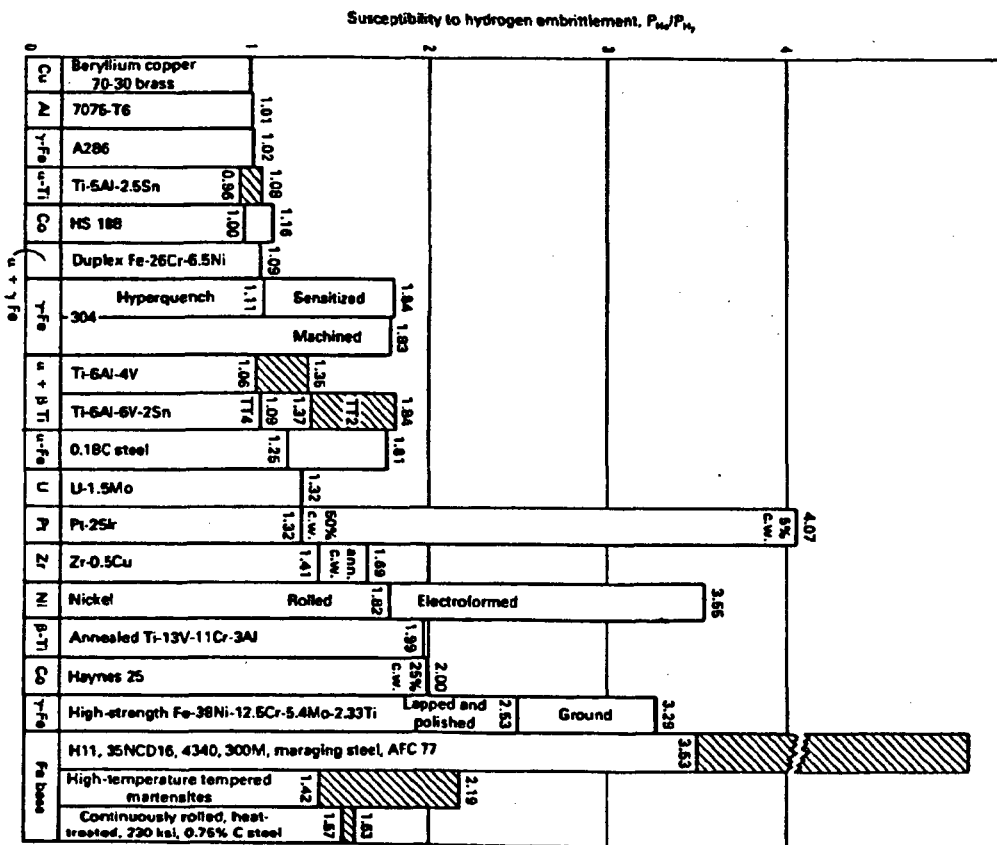

FIG. 12—Relative hydrogen susceptibility of various metals and alloys tested at a rate of 65 bars/min (6.5 MPa/min) at room temperature: c.w. is cold-worked; ann. is annealed [34].

The ratio between the helium burst pressure,  $P_{He}$ , and the hydrogen burst pressure,  $P_{H_2}$ , is a measure of the susceptibility of the material to gaseous hydrogen embrittlement or  $P_{He}/P_{H_2}$ .

If  $P_{He}/P_{H_2} \leq 1$ , the material is not susceptible to gaseous hydrogen embrittlement. When  $P_{He}/P_{H_2} > 2$ , the material is considered to be highly susceptible. At values between 1 and 2, the material is moderately susceptible, with failure expected after long exposure to hydrogen, and the material must be protected against exposure.

Alloys having little or no sensitivity are claimed to be 7075-T6 aluminum; Haynes 188 (cobalt-base); beryllium copper (copper-base); Types 304, 316, and 310 austenitic stainless steels; Type 430 high-hardness ferritic steel; and age-hardened austenitic A286 steel. Titanium-base alloy Ti-6Al-4V exhibits moderate sensitivity. Alloys with high sensitivity are Haynes 25 (cobalt-base) and iron-base alloys, including medium- and high-strength steels.

Specific test results are shown in Fig. 12. As noted, the test results can be significantly influenced by processing variables such as cold work that primarily affect the hardness.

## FRACTURE MECHANICS TESTING

In recent years, fracture mechanics methods have received increased usage in studies of the effects of hydrogen

and have been adapted to many of the testing protocols developed for notched specimens. Fatigue precracked specimens are used instead of notched specimens to eliminate the crack nucleation step, providing a quantitative design parameter in terms of stress intensity that can provide analysis not only in terms of fracture but also in terms of life based on measurement of crack growth rates. For hydrogen assisted cracking, design is generally based on 'infinite life' or designing to operate below the threshold stress intensity.

Hydrogen can cause a degradation in strength with time. It can cause subcritical crack growth or accelerate subcritical crack growth rates or rates of slow crack extension and lower the threshold stress-intensity for subcritical crack extension. The effect of hydrogen on materials can be monitored and characterized by plots of crack velocity ( $da/dt$ ) as a function of applied stress intensity  $K_{Ia}$ , as shown in Fig. 13. At high levels of  $K_I$ , Stage III, the critical value at which rapid failure would occur is designated as the plane-strain fracture toughness,  $K_{Ic}$ . The effect of hydrogen is to cause subcritical (below  $K_{Ic}$ ) extension of cracks. This behavior in Stage II yields crack-extension rates that increase with the hydrogen content. The effects are more pronounced for materials of higher strength. The Stage I effect of hydrogen is a decrease in the threshold value  $K_{Ith}$  ( $K_{Ith/IHE}$  or  $K_{Ith/EHE}$ ), which may be only a small fraction of  $K_{Ic}$ . In general, this subcritical behavior is affected by the parameters of strength level, hydrogen concentration, microstructure, etc.

FIG. 13—Schematic of crack velocity versus  $K_I$  curve showing three stages of subcritical crack-extension behavior.

The crack extension in Stage II occurs over a broad range of stress-intensity values at which failure can occur in times of only minutes to days. The behavior is generally governed by bulk diffusion, but may also be controlled by the kinetics of adsorption and absorption on external surfaces [35], and in high-strength steels by dislocation sweeping [36].

In the absence of a hydrogen or other environments, under plane-strain conditions, the material would fail only at the critical value of stress-intensity,  $K_{IC}$ , the plane-strain fracture toughness<sup>10</sup>. Elastic-plastic methods of calculating the fracture toughness are given in ASTM E 1290<sup>11</sup> by a crack tip opening displacement method and in ASTM E 1820<sup>12</sup> by a J-integral method. The threshold values are of great practical significance, as they represent the limiting values above which crack extension may be so rapid as to greatly curtail service life. The threshold stress intensity delineates the region of finite life from infinite life.

Conventional fracture mechanics testing specimens, such as the compact, cantilever beam, modified bolt-load compact previously referred to as wedge-opening load (WOL), and contoured double-cantilever beam specimens, have been adapted for testing in both aqueous environments and in a high-pressure gaseous hydrogen environment.

These various specimens are shown in Fig. 14. While, in tests of IHE, precharged specimens (IHE) or specimens in the hydrogen charging environments (EHE) can be tested in servohydraulic or equivalent motorized test machines, or

in self-loading frames as preloaded compact, double-beam specimens or three- or four-point bend specimens.

### Ripple Loads

Caution must be taken in designing against sustained load stress cracking in a hydrogen environment when low-amplitude fatigue or "ripple" loads are also encountered in service [37]. The ripple load can have significant effect on the threshold stress-intensity parameter  $K_{Isc}$  or  $K_{Ith}$  (Fig. 12). The benefits of using a softer steel, tempered back to a lower hardness to increase the threshold stress intensity for sustained load hydrogen stress cracking can be completely neutralized.

It has been shown [38] that under cathodic protection, AISI Type 4340 steel at 43 HRC (1400 MPa) with  $K_{Ith}$  equal to 50  $\text{MPa}\sqrt{\text{m}}$  and at 55 HRC (2070 MPa) with  $K_{Ith}$  equal to 25  $\text{MPa}\sqrt{\text{m}}$ , exhibited thresholds that decreased and converged to the same value of about 17  $\text{MPa}\sqrt{\text{m}}$  as the amplitude of the ripple load increased from 3  $\text{MPa}\sqrt{\text{m}}$  to 6  $\text{MPa}\sqrt{\text{m}}$ . Below 3  $\text{MPa}\sqrt{\text{m}}$ , there was no effect on  $K_{Isc}$ .

The test program was conducted on four-point bend specimens with a root radius of 0.25 mm under a rising step load-displacement controlled test method with the amplitude of the ripple load maintained constant and superimposed at each step load level. The hydrogen charging potential applied during ripple load testing was  $-1.2$  V versus SCE in a 3.5 % salt water environment.

### ASTM E 1681<sup>13</sup>: Threshold Stress Intensity for EAC

This test method can be used to measure the relative susceptibility of materials by "Determining the Threshold Stress Intensity Factor for Environment-Assisted Cracking EAC of Metallic Materials." Constant load specimens, both the fatigue precracked single edge beam SE(B) and precracked compact specimens are tested in bending. The SE(B) was originally referred to as the Cantilever Beam Test.

The specimen is inserted along a portion of the beam and enclosed by an environmental chamber (Fig. 15). A crack is initiated and extended by fatigue before testing. The specimen thickness requirement can often be excessive for high-toughness steels, requiring large size specimens if plain strain test conditions are to be maintained up to the critical stress intensity value or fracture toughness of the material. The specimen is subjected to a constant load over a predetermined run-out period of time. As the crack grows, the stress intensity increases. Time-to-failure is plotted versus applied stress intensity. The lower limit on this plot is a threshold stress intensity for hydrogen embrittlement,  $K_{EHE}$ , as shown in Fig. 16. Below the threshold stress intensity, no failures should occur.

The  $K_{EHE}$  results of a cantilever beam test can depend on how much time elapses before the test is terminated. Recommended test times for establishing the true threshold

<sup>10</sup> Ibid., Vol. 03.01, E 399, "Standard Test Method for Plane-Strain Fracture Toughness of Metallic Materials."

<sup>11</sup> Ibid., Vol. 03.01, E 1290, "Standard Test Method for Crack-Tip Opening Displacement (CTOD) Fracture Toughness Measurement."

<sup>12</sup> Ibid., Vol. 03.01, E 1820, "Standard Test Method for Measurement of Fracture Toughness."

<sup>13</sup> Ibid., Vol. 10.05, E 1681, "Standard Test Method for Determining a Threshold Stress Intensity Factor for Environmentally Assisted Cracking of Metallic Materials."

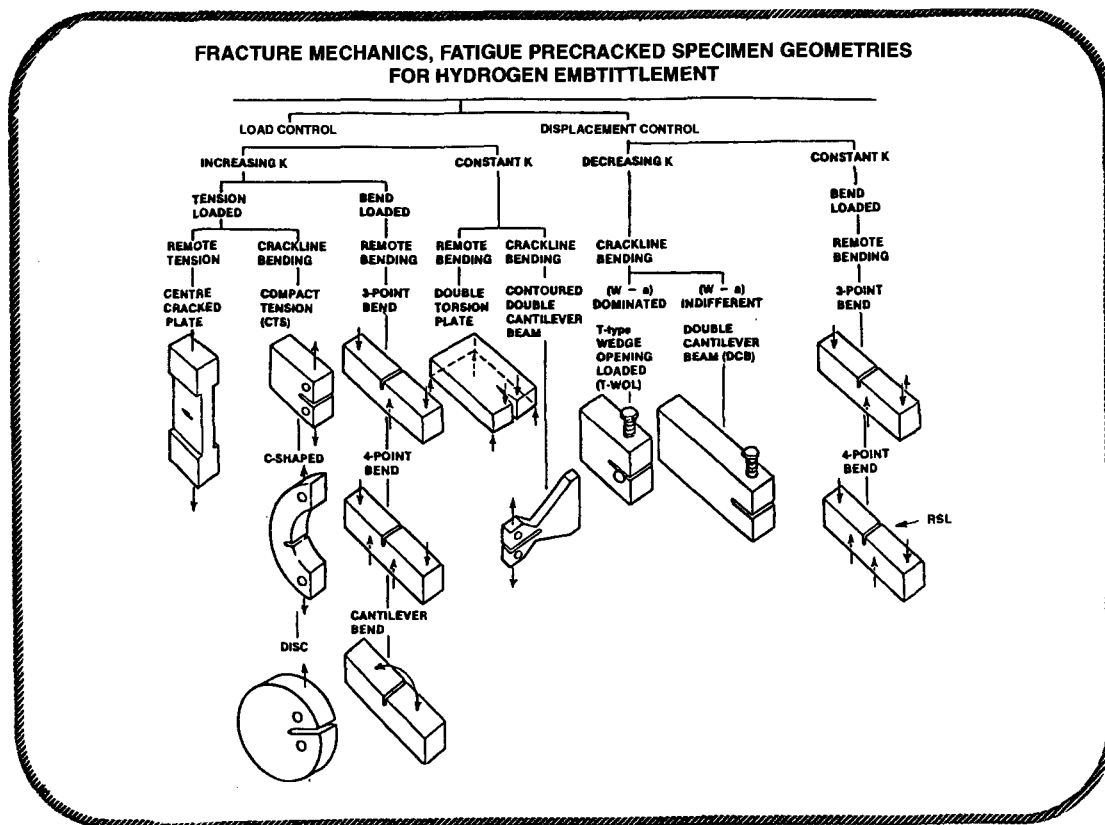

FIG. 14—Fracture mechanics, fatigue precracked specimen geometries for hydrogen embrittlement testing. (Courtesy of Naval Research Laboratory, Washington, DC and LRA Labs, Newport Beach, CA.)

stress intensity, range from 5 000 h to 10 000 h. A limitation of this test method is that it can be expensive in terms of materials, machining and test time. As many as 12 specimens placed under different loads in separate test machines are needed for each test in order to obtain valid  $K_{EHE}$  values. The Navy uses as much as 4–5 years for run-out times to establish the true threshold for HY 130 steels at 33–35 HRC [39].

The modified bolt-load compact specimen, originally referred to as the Wedge Opening Load (WOL) specimen under constant displacement (Fig.17) is best used for quality control rather than performing research studies. In concept it can be used to measure the threshold stress intensity but the result are extremely sensitive to the various material environment combinations with retardation and crack blunting playing a major role in the final test results, such that

Note: The length of the moment arm (L) should be equal to or greater than 8W

FIG. 15—Typical configuration of a Dead-Weight Beam loading fixture. (Source: ASTM E 1681.)

FIG. 16—Procedure to obtain  $K_{EAC}$  for internal (IHE) or environmental (EHE) embrittlement with pre-cracked cantilever beam test specimen [23].

FIG. 17—Schematic showing basic principle of Modified Bolt-Load Compact specimen (Source: ASTM E 1681).

from a practical point of view, the test method is very limited. It is best applied systems where the material sensitivity to test variable and threshold stress intensity are already well established.

A constant value of the wedge- or crack-opening displacement is used to generate the initial load for this type of specimen. As the crack extends, the stress intensity decreases until crack arrest occurs. The initial load is assumed to be slightly above  $K_{EHE}$ . The specimen is maintained under these conditions for about 5000 h to establish the threshold. The crack extends to a point after which further extension is not measured ( $K_{EHE}$ ). However, it is difficult to determine precisely when the "no-growth" criterion is met.

As subcritical crack extension occurs, stress intensity increases in the cantilever beam test and decreases in the WOL test (Fig. 18). Generally, the threshold stress intensity measured with the WOL test is lower than that measured with

FIG. 18—Change of stress-intensity with time of constant load cantilever beam compared to a contoured double-cantilever beam test specimen and a constant displacement bolt-load compact specimen [28].

FIG. 19—Comparison of single-edge-notched bend cantilever beam and wedge-opening load test results for hydrogen embrittlement threshold of iron-nickel-cobalt steels [28].

the cantilever beam test [40]. The advantage of the WOL test is that only one specimen is required to measure  $K_{EHE}$ .

In long-term tests, it is essential to ensure that the concentration and the composition of the environmental solution do not change over time, in ways that do not reflect service behavior. In addition, evaporation may cause the solution level to drop below the crack line of the specimen; this would render the test invalid.

The results of WOL and cantilever beam tests conducted on 25.4 mm (1 in.) thick iron-nickel-cobalt alloy steel specimens are presented as Fig. 19. The data imply that the WOL  $K_{Ith}$  threshold is the lower limit for the cantilever beam threshold.

The open circles in Fig. 19 represent "no fracture" at various exposure times for an overaged Fe-10Ni-8Co alloy in a cantilever beam test. The open squares indicate failure at increased stress intensities, following step-loading from the lower stress-intensity values of the open circles. This test was conducted at various exposure times. The results suggest that increasing the load leads to a shorter induction, indicating a more aggressive hydrogen embrittlement condition than at the lower value of the constant load. The change in behavior may be due to the breakdown of repassivation, i.e., cracking of the oxide film on the surface. When the load is increased, the oxide film is broken, exposing fresh metal, and more hydrogen is adsorbed and absorbed at the crack tip. For this reason, tests that use a rising load can be more aggressive than the constant-load cantilever beam test, which does not provide worst-case (fresh metal exposed) loading conditions.

The data also suggest that the cantilever beam test can generate an artificially high  $K_{EHE}$  threshold when the time under load is too short. If the test is terminated at 200 h rather than at 5000 h, the reported  $K_{EHE}$  values from the cantilever beam test (Fig. 19) are four times higher than those measured after the longer time period. Similarly, if insufficient time is allowed in the WOL test, the incubation period may not be exceeded, and no crack extension will be observed.

The cantilever bend test method is costly and time-consuming. However, it does furnish a quantitative fracture

FIG. 20—Dimensions and configurations for double-cantilever beam test specimen. Specimen contoured to  $3a^2/h^3 + 1/h + C$ , where  $C$  is a constant [28]. All values given in inches. (Note: 1 in. = 25.4 mm.)

mechanics threshold stress intensity parameter that can be used for designing against effects due to hydrogen. The WOL specimen, on the other hand, is more useful as a quality control test because the initial preload can significantly affect the results by the magnitude of the large plastic zone introduced at the onset of the test, which could retard crack extension.

### G 168<sup>14</sup>: Double-Cantilever Beam

Although this specimen can be used to measure the threshold stress intensity, the double-cantilever beam specimen was developed primarily for measuring crack growth rate. That is the reason for the extended gage length section for subcritical crack growth to occur. The specimen can be stressed by either constant displacement or constant load. ASTM G 168 provides the standard practice for "Making and Using Double Beam Stress Corrosion Specimens," formerly designated double cantilever beam (DCB) specimens.

The *contoured* double-cantilever beam test specimen is a modification that is used to measure crack growth rate at a constant applied stress intensity. This test simplifies the calculation of stress intensity by using a contoured specimen, as its stress intensity is proportional to the applied load and independent of the crack length. Under a constant load, the stress intensity for this specimen remains constant with crack extension. For the test geometry shown in Fig. 20, the magnitude of the stress-intensity factor  $K$  is observed to equal 20 times the load.

When relatively thin specimens must be used, data on hydrogen embrittlement can sometimes be obtained by using side grooves on subthickness specimens, even at values in excess of the ASTM requirement of  $K_{max}^2 \leq 0.4 B/YS^2$  (where  $B$  is the thickness and  $YS$  is the yield strength of the

material). The enhanced triaxial stress that is introduced by side grooves enables plane-strain conditions in a thinner specimen.

The contoured double-cantilever beam test can be particularly useful in studies of the effects of a single fracture mechanics or environmental parameter. For example, in Fig. 21, the incubation time, for the onset of hydrogen-stress cracking is shown to be dependent on the type of steel [41]. A decrease in the stress intensity factor ( $\Delta K$ ), from 44 to 22 MPa $\sqrt{m}$  or  $\Delta K/K_f = 1$ , may change the incubation time from less than one hour for AISI 4340 steel to about one year for Type D6Ac steel, which means that crack extension would initiate at the lower stress intensity in about one hour for the AISI 4340 steel, but would take over one year to initiate in the D6Ac steel. This method has been extensively used to study the effect of heat treatment (hardness) and environment on the hydrogen stress cracking of AISI 4340 steels.

The fact that the incubation times can vary by as much as three orders of magnitude for steels that are compositionally very similar provides the technical basis for exercising caution in using the WOL displacement controlled test specimen on new alloys to measure the threshold stress intensity. A rapid drop in load would produce an artificially high threshold stress.

### Three-Point and Four-Point Bend Tests

The contoured double-cantilever beam test, as described above, uses a contoured geometry to maintain a constant stress-intensity factor as the crack extends under constant load. Similar advantages can be produced by using a three- or four-point bend test under constant displacement. These tests use a ASTM E 1290 single-edge-notched bend SE(B) specimen that has the overall dimensions of a standard Charpy specimen. Because crack-opening displacement is constant as the crack extends, the load decreases; therefore, the stress intensity is approximately constant until the ratio of crack depth to specimen width exceeds 0.5. Typically, the stress intensity is

FIG. 21—Incubation time for crack extension as a function of decrease in stress intensity in AISI Type 4340 and Type D6Ac steels using contoured double-cantilever beam test specimen [28].

FIG. 22—Change in stress intensity factor with crack extension for a three-point bend specimen under load control compared to displacement control [28].

regarded to be constant within a small range of 0.25 to 0.5. In Fig. 22, the change in stress-intensity factor as a function of crack extension is shown for both the load control and the displacement control conditions, using a three-point bend specimen.

#### ASTM G 129<sup>15</sup>: Slow-Strain-Rate Tension Tests

This test method was developed and is most often used to measure the relative susceptibility of materials to hydrogen stress cracking (HSC) or hydrogen sulfide stress cracking (HSSC) in the petroleum industry using *smooth* tensile bars. The concept was also utilized and developed to measure the degree of embrittlement due to plating, the relief from baking and as a process control test in the aerospace industry using high-hardness, *notched* round tensile bars.

This test method can be useful in screening many product forms, including plate, rod, wire, sheet, and tubing, as well as welded parts. Smooth, notched, or precracked specimens can be used. The principal advantage of this test is that the relative susceptibility in a hydrogen-producing environment (for a particular metal-environment combination) can be rapidly assessed. ASTM G 129 is the standard practice for "Slow Strain Rate Testing to Evaluate the Susceptibility of Metallic Materials to Environmentally Assisted Cracking."

The test method was initially developed as the Slow Strain Rate (SSR) smooth bar Tensile Test (SSRTT), but more recently, it has incorporated the use of notched and precracked or fracture mechanic types of specimens. The SSR is conducted in tension at a constant displacement rate in the strain range of  $10^{-4}$  to  $10^{-7}$  s<sup>-1</sup> and always produces fracture of the test specimen. The degree of susceptibility is measured as a SSR-ratio in terms of the rupture properties, being more susceptible as the value of the SSR-ratio decreases from unity until it reaches a threshold (Fig. 23).

<sup>15</sup> Ibid., Vol. 03.02, G 129, "Standard Practice for Slow Strain Rate Testing to Evaluate the Susceptibility of Metallic Materials to Environmentally Assisted Cracking."

A variety of specimen shapes and sizes can be used; but the most common is a smooth-bar tensile coupon, as described in ASTM E 8, "Test Method for Tension Testing of Metallic Materials." In smooth-bar tests, the changes are measured in terms of time to failure, ductility (elongation or reduction-in-area), maximum load achieved, and area bounded by a nominal stress-elongation curve or a true stress/true strain curve, which are often supported by fractographic examination. The specimen is exposed to the environment while it is stressed under a constant displacement rate.

Some of the original studies with the use of smooth bar specimens found "It lacks correlation with service conditions. Interpretation of results is difficult. It often indicates stress corrosion cracking in alloy-environment combinations that do not cause failures in service. It does not address notch sensitivity" [42].

Pollack [43] addressed notch sensitivity when he initiated the SSR work on notched round bar tensile coupons of high hardness Type 4340 steel at 52 HRC for the aerospace industry. He demonstrated their usefulness as a screening test in evaluating different platings, coatings, and cleaners relative to hydrogen embrittlement per ASTM F 519. He found the measurement of the notched tensile strength to be a more discriminating and analytically definitive parameter. More recent work has been performed on fatigue precracked fracture mechanics type specimens, but use of the stress intensity data in design is not recommended unless long term tests per ASTM E 1681 are performed with identical material in an identical environment.

#### ASTM F 1624<sup>16</sup>: Step-modified SSR Test

The bridge between the long-term E 1681 and the accelerated or short-term G 129 testing protocols is ASTM F 1624,

FIG. 23—A comparison of the load-time curves of SSR-T and RSL-T tests under displacement control. The RSL-T test is used to detect crack initiation or threshold the onset of subcritical crack growth, while the SSR-T records the entire tensile curve to rupture [49].

<sup>16</sup> Ibid., Vol. 15.03, F 1624, "Standard Test Method for Measurement of Hydrogen Embrittlement Threshold in Steel by the Incremental Step Load Technique."

FIG. 24—A schematic of the effect of the strain rate range on the apparent threshold for EAC/SCC and HSC testing. The threshold stress intensity for hydrogen stress cracking is the minimum at the slowest rate (after Fig. 2, G 129).

the (Accelerated) Standard Test Method for Measurement of the Hydrogen Embrittlement Threshold in Steel by the Incremental Step Loading Technique.

A step-modified slow-strain-rate test is used to provide a threshold stress intensity that does correlate with long-term tests in the same environment [44]. Figure 24 is a graphical comparison between the two methods. By progressing in incremental steps, the onset of hydrogen assisted stress cracking can be accurately detected in a rigid testing system by a drop in load under displacement control. As with the slow strain rate test, the rate is progressively decreased from  $10^{-4} \text{ s}^{-1}$  to  $10^{-8} \text{ s}^{-1}$  until the measured value of the apparent threshold stress intensity becomes an invariant, which is the true threshold,  $K_{\text{IHSC}}$  that can be used as a comparison of the relative susceptibility of different materials and is considered to be the material property that can be incorporated into design.

The slow strain-rate test method ( $10^{-4} \text{ s}^{-1}$  to  $10^{-8} \text{ s}^{-1}$ ) is an accelerated test method when compared with a sustained-load test method. The “slow” strain-rate test provides an “accelerated” test for measuring the threshold when compared with the 5000 hours required by ASTM E 1681, for steels at a hardness of 50-52 HRC.

The step-modified slow strain-rate or Rising Step-Load™ (RSL™) test produces an increasing stress intensity that is different at each step-load but remains constant with crack extension for a Charpy-sized SE(B) four-point bend specimen while each load level is maintained constant for a period of time. The rising step-load test was developed as an accelerated low-cost test for measuring the resistance of steels and weldments to IHE or EHE [45,46]. The load is constantly increased under displacement control, but incrementally in steps with each step being sustained for a period of time so that the onset of subcritical crack extension can be detected, which is the threshold for the onset of IHE or EHE. The RSL test differs from the SSRTT, which measures the differences in ductility parameters over the

entire loading range to ultimate fracture and only provides relative parameters to index hydrogen embrittlement. When used with notched or fatigue precracked specimens, it has been found that the threshold is overestimated with the SSRTT. By comparison, the RSL is tested over the same range of strain rates but it detects the onset of subcritical cracking by a load drop (Fig. 24) and thus is considered to be quantitative and accelerated relative to a SSRTT.

The RSL is an economical test, as only one specimen may be required to obtain a measure of the threshold value, as compared to the dozen or so normally required to conduct sustained load run-out tests as with the cantilever beam type (ASTM E 1681). The test method takes advantage of using small specimens to measure the fracture toughness [47] and utilizes potentiostatic test methods to simulate conditions of galvanic coupling on the specimen [48].

The test can be conducted in tension or in the bending, which has lower load requirements than tension and thus may be helpful in testing larger diameter fasteners. The use as a bend test also has several advantages relative to alignment and increased sensitivity, since the limit load in bending is greater than the limit load in tension. This test can be conducted using either precracked specimens (that can be used to measure threshold stress intensities within the framework of fracture mechanics) or actual fasteners (to obtain an ‘effective’ threshold stress). The results from either test can be incorporated into design and the calculation of maximum installation torques to prevent in-service failures of fasteners [49,50].

### Choosing the Appropriate Method

Whatever test method is selected, whether it is for quality control, process control, or material susceptibility, it is imperative that the results be related to service conditions. The proper selection of torque or stress for a hydrogen embrittlement test should exceed the stress in service. If the stress

levels in the quality control test are less than the stress levels of service, the test is meaningless. The state of stress must also be accurately represented. For example, as was mentioned previously, the superposition of a low-amplitude cyclic or ripple load can totally negate the effects of the measured threshold stress-intensity parameter under sustained loading conditions.

It is also important to ensure that the actual types of environmental service conditions are adequately represented in a hydrogen-stress cracking test, including the pressure (fugacity) of hydrogen from the environment before the results can be used in design. Choosing a test method should always be critically reviewed before the results are related to service performance, especially in conducting long-term life analysis that takes into account the possibility of hydrogen embrittlement.

# **Section V: Testing in Environments**

*H. P. Hack, Editor*

# Outdoor Atmospheres

Herbert H. Lawson<sup>1</sup>

IT IS ESTIMATED THAT half the total cost of corrosion in the United States is spent on the protection of materials in the atmosphere [1]. Therefore, atmospheric testing has assumed a great degree of importance throughout the world, especially because of the emphasis on conserving natural resources.

## CLASSIFICATION OF ATMOSPHERES

On the basis of worldwide testing, atmospheres have been broadly classified into three qualitative categories: rural, marine, and industrial [2]. In rural atmospheres, there is minimal presence of ionic species to cause a strongly conductive electrolyte. Hence, the rural classification implies little, or at most moderate, corrosion. The corrosion depends primarily on temperature, humidity, and moisture retention. In industrial environments, the severity of corrosive attack also depends on these factors, but is significantly affected by the presence of industrial pollutants such as solid or gaseous sulfur compounds, and other emissions that increase the corrosion by strengthening the electrolyte, frequently by lowering the pH. Marine atmospheres are usually the most consistently severe environments, their corrosiveness being affected by the chloride ion, and influenced significantly by humidity, temperature, time-of-wetness (TOW), wind direction, and distance from the breaking surf [3,4].

Considering the above, test sites should be selected to provide general corrosion performance in one or more of these atmospheric classifications. ASTM Committee G01.04 on Atmospheric Corrosion operates sites that include all three, and testing can be done in these providing the data accumulated become part of the public record. In addition, there are several private, government, and commercial testing facilities already established where exposure space can be rented.

Exposure in the classified environments consists of testing in a "macroclimate," i.e., there are usually no significant point sources of industrial pollutants to unduly affect the corrosivity. There are instances, however, when testing is desirable to evaluate a "microclimate." This can generally be accomplished by less expensive means than full-scale testing in a formal test site. These means will be covered later in this section.

<sup>1</sup>Lawson Consultants, Inc., 4821 Manchester Rd., Middletown, OH 45042.

## SITE SELECTION AND PREPARATION

When planning a new test facility, possible point sources of contamination should be avoided, i.e., the atmosphere should represent the area rather than a specific corrosive source. This can be illustrated by the data in Table 1. Comparison of the two exposures in Halifax, N. S. shows significant differences, although the sites are relatively close together. The more severe corrosion at the Federal Building is the result of the presence of a coal-fired boiler stack at the site. Also, the effects of distance from a corrosive source as well as height above the ground are shown by the Kure Beach and Cape Kennedy [*sic*] data.

Test yards should be planned so that the test rack orientation for proper exposures can be maintained. In most instances, test yards in the northern hemisphere are situated so that the exposures will face south. The opposite orientation would be the case in the southern hemisphere (to achieve near maximum exposure to the sun). Quite frequently, marine exposure sites are oriented so that the racks face the surf; it is usually the case, however, that these are accompanied by the normal north or south facing racks, somewhat removed from the possibility of direct spray, but still within the macroclimate under study. In all cases, at least 100 ft (30.5 m) of clear space should be maintained

**TABLE 1**—Relative corrosivity of zinc and steel exposed for one year at various locations (State College, PA = 1.00).<sup>a</sup>

Site	Steel	Zinc
Phoenix, AZ	0.26	0.32
Detroit, MI	0.93	1.03
State College, PA	1.00	1.00
Halifax, NS (York Redoubt)	1.27	1.43

Pittsburgh, PA	1.60	1.90
Columbus, OH	1.65	1.54
London, UK	2.25	1.55
Newark, NJ	2.90	2.80
East Chicago, IN	4.43	2.38
Cape Kennedy, FL (0.5 mile from surf)	1.65	1.21
Cape Kennedy, FL (60 yds/60 ft elevation)	2.46	2.53
Cape Kennedy, FL (60 yds/30 ft elevation)	2.84	2.89
Kure Beach, NC (250 m)	3.41	2.09
Halifax, NS (Federal Bldg.)	5.50	6.56
Cape Kennedy, FL (60 yds/ground level)	7.66	3.16
Kure Beach, NC (25 m)	28.50	5.44
Cape Kennedy, FL (beach)	42.50	—

<sup>a</sup>From "Corrosiveness of Various Atmospheric Test Sites as Measured by Specimens of Iron and Zinc," A Report of Subcommittee G01.04, *Metal Corrosion in the Atmosphere*, STP 435, ASTM International, West Conshohocken, PA, 1968, pp. 360–391.

between the sample rack and the property line to avoid shading or disturbance of the existing wind patterns. Additional detail on test yards and much of the following information on hardware and testing appears in ASTM G 50, Recommended Practice for Conducting Atmospheric Corrosion Tests on Metals.

## HARDWARE AND TERMINOLOGY

For the sake of consistency, a terminology has developed within the atmospheric corrosion testing community with respect to testing. The test facility itself is commonly referred to as a corrosion yard. Racks, commonly fabricated from pipe or wood, are installed to hold the fixtures for the individual test specimens. The latter are referred to as "frames," and can be fabricated from wood or metal (nickel-copper alloy, stainless steel, aluminum, etc.). These frames are usually designed to hold approximately 75 specimens, isolated from each other and the test frame by porcelain, plastic, or rubber "insulators." Thus, a corrosion yard

FIG. 1—Typical atmospheric corrosion test yard at Middletown, Ohio, showing exposure racks and instrumentation. Reprinted with permission of Armco, Inc. [sic]

contains racks upon which frames are mounted to hold specimens isolated from metal-to-metal contact by insulators. Details for construction and use of these are contained in ASTM G 50. Figure 1 shows a typical corrosion yard, illustrating the appearance and use of racks, frames, and insulators. Figure 2 shows an overall view of the LaQue Center for Corrosion Technology [sic] test yard at Kure Beach, NC. Any fasteners employed to assemble racks, frames, and insulators should have corrosion resistance commensurate with the anticipated life of the installation. Common fastener materials include stainless steel, nickel-copper alloy, aluminum, or bronze. The exposure angle is usually 30 or 45° from the horizontal (the higher angle usually recommended for testing paints and other organic systems; see ASTM G 07, Recommended Practice for Atmospheric Environmental Exposure Testing of Nonmetallic Materials). The lower edge of the exposure frames should not be less than 760 mm (30 in.) from the ground. Although the foregoing specifies details of hardware, these should not be construed as limits to exposure requirements that might be necessary to measure corrosion at other angles or heights for specific purposes.

## CORROSION YARD INSTRUMENTATION

Most corrosion yards around the world have little or no weather instrumentation within their confines. As mentioned earlier, the temperature-relative humidity interaction is one of the foremost combinations of weather factors in affecting corrosion of metals. The installation of a thermograph and hygrograph is valuable as a means to determine TOW. Knowing the temperature is important for several reasons. Below freezing corrosion normally does not occur, as ice is a poor electrolyte. At elevated temperatures, adsorbed or phase water cannot exist. Therefore, most corrosion typically occurs between 0 and 25°C. Higher temperatures also contribute to more rapid drying after specimens become wet with rain, dew, or adsorbed water. At high values of relative humidity, relatively small drops in specimen temperature can exceed the dewpoint, resulting in condensation of water on the specimen surface. It has been observed, however, that wet conditions (dew) can exist in tropical environments up to 35°C.

Other standard weather instrumentation that has been used includes wind direction and velocity equipment and rain gages.

There are several other aspects of atmospheric characterization which, if measured, can provide pertinent information related to the performance of materials. Probably the most important and universal is the determination of the TOW, described earlier. ASTM G 84, Practice for Measurement of Time-of-Wetness on Surfaces Exposed to Wetting Conditions as in Atmospheric Corrosion Testing, describes instrumentation and techniques for measuring TOW. This parameter can most easily (and adequately) be estimated from weather bureau records. It is generally accepted that metal atmospheric test specimens are wet when the temperature is above freezing and the relative humidity is above 80 %. There are indications that corrosion can occur under arctic conditions down to 0°F if

FIG. 2—Marine atmosphere testing site at Kure Beach, NC. Reprinted with permission of LaQue Center for Corrosion Technology, Inc.

salt deposits are present. This will be discussed further when describing contributions to the science of atmospheric testing that have been made by investigators in Eastern Europe.

It is advantageous to measure the levels of other atmospheric corrosives; e.g., chlorides at marine sites and gaseous and particulate sulfur compounds at known industrial sites, or at sites where long-range sulfur contamination may be suspected. There are techniques available for adequately measuring both of these corrosives.

With respect to chlorides ( $\text{Cl}^-$ ), the most widely used procedure is the "chloride candle," a gauze wick in a flask of reagent water. The candles are exposed for a fixed period of time, usually 30 days, then removed. After leaching the exposed gauze into the flask water, the total chlorides are determined analytically, and reported as chloride deposition per unit of exposed area per unit of time ( $\text{mg}/\text{m}^2/\text{day}$ ). This method is described in ASTM G 140, Test Method for Determining Atmospheric Chloride Deposition Rate by Wet Candle Method. The other method more recently introduced uses a dry fabric panel, which is also exposed for a predetermined length of time, usually 30 days. Then the chlorides are washed out of the fabric and analyzed. Both procedures are currently described in ISO Standard 9225; however, the dry plate method has been found to produce inconsistent results, and probably will be dropped from the ISO document at its next revision.

There are two accepted methods for determining the sulfur dioxide ( $\text{SO}_2$ ) concentration in the atmosphere of interest. Both employ the affinity of lead oxide for sulfur dioxide. The most common technique uses sulfation plates. This procedure is covered in detail in ASTM G 91, Test Method for Monitoring Atmospheric  $\text{SO}_2$  Using the Sulfation Plate Technique. These devices are no longer available for purchase, but must be prepared in the laboratory. The second method is the peroxide candle, similar in its function to the chloride candle. The procedure suggests a 30-day exposure, followed by a standard sulfate analysis. This procedure is covered by ASTM D 2010, Test Methods for Evaluation of Total Sulfation Activity in the Atmosphere by the Lead Dioxide Technique. In both cases, the results are calculated as the capture rate of  $\text{SO}_2$  per unit area, normally per  $\text{m}^2$ .

If electric power is available, both  $\text{Cl}^-$  and  $\text{SO}_2$  levels in the atmosphere can be obtained by taking volumetric samples of the air into reagent water, and analyzing to obtain the actual concentration. Representative and frequent sampling should be carried out to obtain a realistic appraisal of the range and average of the contamination over a period of time. Chloride candles and sulfation plates measure deposition per area per time rather than instantaneous atmospheric content per unit volume. Therefore, the results of one can provide an indication of the other, but are not directly comparable.

## SITE CALIBRATION

Most atmospheric corrosion yards are monitored for consistency or to quickly identify any sudden changes in corrosivity. This is most often accomplished through

periodic exposure of standard materials, usually pure zinc (99.95 % Zn), and a copper-bearing steel (0.20 % Cu, min). The details of site characterization can be found in ASTM G 92, Practice for Characterization of Atmospheric Test Sites. Other materials are used sometimes, e.g., aluminum and copper, but in many environments their corrosion rates are too low to be definitive. As these are intended to be standards, it is advisable to purchase a quantity sufficient to provide many years of continuing calibration. As it is valuable to measure both short- and long-term corrosion rates, a statistically significant number of specimens should be exposed each year. The short-term exposures will alert the investigator to sudden changes in his environment, while the extended exposures will provide a continuing record of the corrosivity of the site.

## TEST SPECIMENS AND IDENTIFICATION

Accepted terminology for atmospheric testing includes sample, the material to be tested; specimens (or panels), the individual pieces of the sample that are actually exposed; and lot, a group of specimens, usually three to five, intended for a specific exposure time. Thus, a typical exposure plan might involve 40 specimens of a given sample divided into eight lots composed of five specimens each for removal at eight different times. The most frequently used specimen size is 4 in. by 6 in. (100 mm by 150 mm). This does not imply, however, that other sizes cannot be used. It is common that larger or smaller, thick or thin, specimens can be tested, as well as various shapes such as bolts, nuts, fasteners, angles, channels, pipes, and fabricated assemblies. It may also be desirable to evaluate galvanic corrosion in the atmosphere. The method for this is described in ASTM G 116, Practice for Conducting the Wire-on-Bolt Test for Atmospheric Galvanic Corrosion. This latter procedure has also been used to calibrate and monitor test sites by employing aluminum wire on nylon, steel, and copper bolt material. This calibration procedure will be discussed later.

There are almost as many means of marking specimens for identification as there are investigators engaged in atmospheric corrosion testing. The primary consideration is to select a system that will maintain the identification for the intended test period. The most common method is stenciling (metal stamping), which is easy, and adequate for short-term testing or for more corrosion-resistant materials. Another common means depends on drilling an identification code into the specimens. A typical template for accomplishing this is shown in ASTM G 92. Other investigators notch the edges, while still others put the identification on a corrosion resistant tag and attach it to the specimen by means of insulated wire through a drilled hole. The drilling technique has a distinct advantage in that several specimens can be identified at a time. However, it also has the disadvantage that edge corrosion may make decoding difficult.

After shearing and identification, the specimens should be properly cleaned prior to either additional processing or exposure. Cleaning procedures can be found in ASTM G 1, Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens. Information specific to stainless steel alloys can also be found in ASTM A 380, Practice for Cleaning and

Descaling Stainless Steel Parts, Equipment, and Systems. After cleaning, extreme care should be taken when handling the specimens to avoid contamination and fingerprinting. As mass loss is involved in evaluation of the samples in most cases, the individual specimens are then weighed. Analytical balances are used, and the precision of the weighing depends on the anticipated corrosion resistance of the material. It is common to weigh to the nearest milligram.

In addition to mass loss, some materials are further evaluated by determining changes in their mechanical properties. This is most frequently the case with materials that demonstrate good corrosion resistance, but may suffer pitting in the atmosphere. Nonmetals and organic finishes also suffer deterioration of properties due to ultraviolet (UV) effects. The possibility of this type of damage occurring points up the need to keep a supply of untested control samples.

Record keeping and tracking of exposure and materials can be as simple or as sophisticated as the laboratory needs. A simple card file or notebook system is adequate. By simply numbering the frames and using the row numbers, the location of every specimen exposed can be defined. A card file arranged by month and year can keep track of removals.

The site should be visited periodically to make certain everything is as it should be, i.e., panels are still properly exposed, and the site and facilities maintenance is satisfactory. Special attention should be paid to fences, gates, and locks. (Corrosion affects facilities as well as specimens.)

## CLEANING AND EVALUATION

After removal at the specified exposure period, the specimens are evaluated. Visual examination of the specimens upon removal is usually performed, and a photographic record of appearance is valuable. ASTM G 33, Practice for Recording Data from Atmospheric Corrosion Tests of Metallic-Coated Steel Specimens, can provide guidance for evaluation procedures. Before determination of mass loss, or for most other evaluation techniques, the specimens must be cleaned. Again, cleaning procedures are described in ASTM G 1 and A 380 for most materials of interest. ASTM G 1 also includes a procedure for determining when the corrosion products have been removed. After cleaning, specimens should be placed in a desiccator with fresh dessicant until ready for further evaluation.

The specimens are reweighed to the same precision as prior to exposure and the mass loss determined. Mass losses can then be used to calculate corrosion rates as follows:

$$\text{Corrosion Rate} = \frac{(K \times W)}{(A \times T \times D)}$$

where

- $K$  = a constant based on the rate units desired (see ASTM G 1),
- $T$  = time of exposure in h,
- $A$  = area in  $\text{cm}^2$ , and
- $D$  = density in  $\text{g/cm}^3$ .

Other means of evaluation can be used. Pit depth and pit density measurements are frequently employed. ASTM G 46, Guide for Examination and Evaluation of Pitting Corrosion, provides information on this means of evaluation. Once all the pertinent nondestructive tests have been completed, various destructive tests can be employed to further define the nature and extent of the corrosion. The measurement of changes in mechanical properties has already been mentioned. Metallographic examination will provide information on the nature of the corrosion that has occurred (parting, exfoliation, cracking, intergranular corrosion, pitting, etc.).

In the case of plastics or organic coatings, other factors must be considered. These include but are not limited to the size and density of blistering, delamination, loss of gloss, loss of adhesion, fading, chalking, crazing, cracking, and creep. In tropical and subtropical environments, algal and fungal growth can also be problems. Much more use is made of the loss of properties in the evaluation of organic materials than in the case of metals.

With the proper statistical design of exposure tests, including proper replication and multiple exposures, atmospheric corrosion data are readily amenable to statistical analysis. An excellent review of an applicable statistical procedure can be found in ASTM G 16, Guide for Applying Statistics to Analysis of Corrosion Data.

## SPECIAL TESTING PROCEDURES

To this point, the discussion has centered on standard conditions of exposure and evaluation of materials. Earlier it was mentioned that the details described in the various ASTM standards cited would allow investigators to develop data that are directly comparable to that determined by other investigators at other sites using the same procedures. However, sometimes there is a need to develop information related to some specific commercial need. Therefore, the standard conditions of exposure are frequently varied to develop the requisite data. All testing described, for instance, infers specimens boldly exposed at  $30^\circ$  from the horizontal facing the equator. This is the matter of obtaining consistency between tests and investigators. It has been demonstrated, however, that corrosion varies considerably if the specimens are exposed to face the poles rather than the equator, or if the specimens are sheltered from the direct effects of the elements. As recommended in ASTM G 50, the specimens receive almost the maximal solar effects, particularly in the middle latitudes. North or south facing racks (depending on hemisphere) receive no direct sun at all. This results in slower drying, and therefore longer times of wetness. Sheltered specimens can accumulate airborne contaminants but do not receive the washing action of rain. Therefore, the corrosive contaminants remain on the surface for a longer period of time, and the surfaces remain wet for longer periods. Vertical exposures corrode less than samples exposed at the recommended angle, because of better drainage, a poorer view of the sky that can slow dew formation, and less accumulation of deposits. However, these conditions exist in many atmospheric applications of materials, so testing under these conditions is certainly justified in some cases.

<sup>a</sup>N = negligible; M = moderate; MS = moderately severe; S = severe; VS = very severe.

<sup>b</sup>ACI = Atmospheric Corrosion Index; MCI = Marine Corrosion Index; ICI = Industrial Corrosion Index.

It has been established that corrosive conditions vary considerably with distance from a corrosive source, as well as height above the ground. Therefore, there can be a need for such evaluations to be made for determining such differences. One relatively easy way to accomplish this has been developed by the Alcan Research Laboratories from previous work done by ASTM Committee B-3 [5–7]. This technique is the basis for the wire-on-bolt practice

described in ASTM G 116. This means of rapidly developing data on the comparative corrosivity of a site or several sites has become very well accepted and has been widely used by various investigators. The procedure is identified as the CLIMAT test (from Classification of Industrial and Marine Atmospheres). Originally designed to measure galvanic effects between aluminum strands and the steel reinforcement in aluminum overhead conductors [8], particularly in marine environments, the test has been extended to provide information on the general corrosivity of atmospheres. It has proven valuable in assessing storage areas, microclimates, indoor corrosion, and in providing quantitative evaluations of the corrosivity of various atmospheres.

The assembly used for the corrosivity measurements consists of preweighed 1100 aluminum wire fastened to and tightly wound on threaded lengths of steel, copper, and nylon. Figure 3 shows a completed assembly. The details of preparation are given in ASTM G 116. The data derived from the individual wire-bolt combinations are used to develop "corrosion indices"; the aluminum-nylon results reflect the general atmospheric corrosion (ACI), the aluminum-steel the marine index (MCI), and the aluminum-copper the industrial index (ICI).

The rod assemblies are usually exposed to the environment in question for 90 days, after which the wires are removed, cleaned, and reweighed. The percentage mass loss of the aluminum is the corrosion index for that time period. The data obtained can then be used to describe the severity of the atmosphere by comparing the values obtained to those empirically determined by experience or by relevant testing. Environmental corrosivity is classified from "negligible" to "very severe" on this basis. Some typical atmosphere assessments made using this procedure are shown in Table 2. It has been found that a series of exposures must be made to fully characterize an environment, as the corrosion varies with the season of the year and the exposure is only for three months.

## ISO CORROSION CLASSIFICATION SYSTEM

The rural, industrial, and marine atmospheres described earlier are very broad classifications, and do not adequately define specific exposure conditions. Other categories have been proposed, such as desert, tropical, urban, semi-industrial, and industrial-marine, but even these are not satisfactory for predictive purposes [9]. In the mid-1970s, Technical Committee 156 on Corrosion of Metals and Alloys of the International Organization for Standardization (ISO) identified atmospheric corrosion as a priority area for study. From that, a classification system was developed, and described by four standards (Table 3). The system is based on quantitative values for TOW, SO<sub>2</sub>, and Cl<sup>-</sup> deposition rates, and/or mass loss of steel, aluminum, zinc, and copper samples exposed for at least one year. The TOW can be determined from meteorological data or measured by devices such as described in ASTM G 84, the ionic species deposition rates by ASTM G 92 and either of the Cl<sup>-</sup> methods described earlier, and the mass losses determined by the procedures discussed earlier in this section. The levels of ionic species, TOW, and mass losses are placed in categories as to

**TABLE 3**—ISO standards concerned with classification of atmospheric corrosivity [10].

severity, and from these corrosivity categories can be derived [10]. The system is currently being evaluated on a worldwide basis by means of the ISO CORRAG program [11].

## LABORATORY SIMULATION TESTS

It has long been the desire of investigators studying atmospheric corrosion to have a laboratory test that would duplicate and accelerate the behavior of materials in the atmosphere. Many years ago, the salt spray test was developed to evaluate defects in metallic coatings, but later extended as a means to simulate marine environments [12]. Similarly, the humidity cabinet has been used in an attempt to accelerate corrosion that might occur in less severe atmospheres. These test procedures are covered by ASTM B 117, Test Method of Salt Spray (Fog) Testing, and ASTM G 60, Method for Conducting Cyclic Humidity Tests. The ultimate aim of accelerated testing is to obtain realistic data in an abbreviated time period (atmospheric testing may take years to effect a failure of a material). As in the case of many other accelerated test procedures, laboratory tests frequently are misused or misinterpreted, often giving a quick answer in lieu of the right one. In addition to the above, there are several other tests used to evaluate materials intended for atmospheric usage. These include other variations of the humidity cabinet, ASTM G 87, Practice for Conducting Moist SO<sub>2</sub> Tests, and a variety of other cabinet tests which may include cyclic wetting and drying, exposure to salt spray, temperature cycles, the use of UV radiation, and the introduction of small concentrations of various corrosive gases into a single test regime. There has been considerable interest in these last described cyclic test systems on the part of the automotive industry worldwide, and several tests are being used.

In the development of any accelerated tests, several significant factors have been identified as contributing to corrosion [13]. These include the following:

- (a) Precipitation—a liquid film present, containing dissolved pollutants and salts
- (b) Evaporation—a liquid film present, salts and pollutants concentrating
- (c) Dry—liquid film absent, solid salts on surface
- (d) Re-wetting—liquid film present, salts diluting, or possibly removed under rain conditions

Step b in the above is very important, because it points out that the corrodents may concentrate on the surface

under drying conditions, providing a more corrosive condition should the material be wetted by condensation rather than being cleaned by the washing action of rain.

Therefore, a meaningful accelerated test must include each of the above to be realistic, i.e., it must include cycling the surface of the test material through both wet and dry conditions. Concentrations of the corrosives (other than water) must be realistic—not so concentrated that they dominate the reaction, nor so acid that they alter the corrosion products that would develop in normal environments. Care must be taken to avoid distorting the naturally occurring reactions. Perhaps the only effective acceleration can be in the frequency of wetting and drying, and the use of heat to facilitate the latter. Additional discussion of laboratory testing can be found in Section VIII of this manual.

# Indoor Atmospheres

*J. D. Sinclair*<sup>1</sup>

## DESCRIPTION OF THE ENVIRONMENT

CORROSION in indoor environments is an exceedingly complex process. Few environments have as many components that participate in the corrosion of materials as the indoor environments in which we live and work. While the indoor environment is less harsh than many other environments, e.g., chemical reactors and jet engines, its effects are particularly difficult to mimic through accelerated life testing because of the many possible chemical and physical interactions that can take place between environmental components and materials.

It can be argued that indoor environments are even more difficult to simulate than outdoor environments because they contain all the components present in outdoor environments, e.g., gases derived from fossil fuel combustion (sulfur dioxide (SO<sub>2</sub>) and nitrogen oxides (NO<sub>x</sub>)), particulate matter, and microbes, as well as components derived from indoor sources, e.g., outgassed vapors from carpets, paints, plastic furnishings, cooking, manufacturing activities, office equipment, appliances, cleaning solutions, waxes, and wax strippers. Also, items designed for indoor use may well be more sensitive to environmental effects. The optimum design is frequently one using materials that are no more resistant to the environment than is necessary to satisfy specified reliability criteria. Examples of common household or office items that are not designed for outdoor use include many computers, photocopiers and similar office machines, some plastics, silver-plated utensils and serving dishes, brass fixtures, and kitchen appliances.

In this chapter, the applicable environmental factors include temperature, vapor phase and condensed moisture, corrosive inorganic gases, organic vapors, particles, electric fields, and air velocity. While vibration, mechanical stress, thermal shock, and solar radiation can occasionally contribute to materials degradation in indoor environments, these subjects are covered in other chapters and MIL-STD-810E.

The relevant material components in indoor environments can be conveniently segregated into six categories. Corrosive gases include SO<sub>2</sub> and NO<sub>x</sub> (primarily NO and NO<sub>2</sub>), as well as organic acids such as formic and acetic

acids, hydrochloric acid (HCl), hydrogen sulfide (H<sub>2</sub>S), carbonyl sulfide (COS), mercaptans (RSH, where R is an alkyl group), and organic sulfides including dimethylsulfide ((CH<sub>3</sub>)<sub>2</sub>S) and dimethyl disulfide ((CH<sub>3</sub>)<sub>2</sub>S<sub>2</sub>). The concentrations of SO<sub>2</sub> and NO<sub>x</sub> are usually reduced by a factor of 2 to 10 from their outdoor concentrations in air-conditioned office buildings, while the concentrations of organic acids, hydrochloric acid, and other sulfur-containing substances can be less than, similar to, or even greater than the outdoor concentrations, depending on the existence of indoor sources. In parts of the world where air conditioning is less prevalent, exchange of outdoor air for indoor air can be quite rapid, making the indoor environment more like the outdoor environment than an air-conditioned environment. Air conditioning designs also vary significantly in different parts of the world. For example, in North America and Europe, the common practice is to positively pressurize buildings relative to outdoors by continuously pumping conditioned outside air into the building. With this approach, the quality of the filtration and the rate of air exchange are the largest determinants of indoor concentrations for all components except those that have substantial indoor sources. On the other hand, for many Asian countries, the common practice, especially for equipment rooms, is to eliminate air exchange pathways as much as possible and continuously re-circulate the indoor air through heat exchangers and air filters. No outside air is intentionally drawn into the building. In this case, corrosive gas concentrations are frequently much less than outdoor concentrations because the balance between the ingress rate (through leakage) and the consumption rate on surfaces is dominated by the consumption rate. At the same time, species with substantial indoor sources, such as outgassed substances from building and housekeeping materials, can reach much higher concentrations than commonly found in North America and Europe.

Typical indoor and outdoor concentrations of gases that equipment should be able to tolerate without exhibiting significant degradation are shown in Table 1. The values listed in Table 1 are based on U.S. Environmental Protection Agency (EPA) reports, published air quality studies, and proposed standards currently under consideration by such organizations as ASTM International, the International Electrotechnical Committee (IEC), and the European Telecommunications Standards Institute (ETSI). They are intended to represent average annual concentrations at roughly the 95th percentile, i.e., only 5 % of all locations are

likely to exhibit higher average annual concentrations than those indicated. Some judgment was exercised in setting these values, as the available data are frequently insufficient to be quantitative. It is also now generally accepted that environments in parts of Southern and Eastern Asia tend to be much more polluted than many other parts of the world but reliable data is very limited. Thus, the reader should exercise caution in using these values for materials and equipment intended for use in Southern and Eastern Asia.

A variety of techniques is used for determining the concentrations of pollutant gases. Where possible, instruments certified by government agencies such as the U.S. EPA are recommended. These are available for SO<sub>2</sub>, NO<sub>x</sub>, and ozone (O<sub>3</sub>). For the other gases, the techniques are more difficult and require specialized expertise and extensive standardization. In many cases these are proprietary or inadequately documented to be referenced. The reactivity of these gases for materials is very material specific. Atmospheric moisture is a critical ingredient for many of these degradation processes. Most corrosion processes depend strongly on relative humidity (RH). A couple of examples illustrate the complexity of RH effects. Silver is very reactive to H<sub>2</sub>S, with a strong RH dependence. However, silver shows no RH dependence in its reactivity with vapors of elemental sulfur. Iron, on the other hand, is rapidly corroded by SO<sub>2</sub> at RH about 75 % or greater but reacts much more slowly below this RH. Vernon [1] first described this critical relative humidity (CRH) concept in the 1930s. Outdoor RH spans a wider range than indoor RH in most climates. RH > 75 % is rare for most office buildings or homes, but typical outdoor conditions may be present in many manufacturing environments, storage sheds, and equipment huts used by utility companies.

Organic gases are usually not directly corrosive but can play an important mitigating role in the aging of surfaces. These gases may be derived from natural or anthropogenic (manmade) sources. The typical total abundance of all organic gases, shown in Table 1, is much higher than the total of all inorganic pollutant gases combined. Many of these organic species have much higher concentrations indoors than outdoors, especially those derived from outgassing of indoor materials. Some typical arrays of organic vapors found indoors and their likely sources have been described elsewhere [2]. These gases competitively adsorb on surfaces with the corrosive gases and atmospheric moisture. The presence of an organic film on a surface can alter

its wettability. The effects of these adsorbed films on corrosion rate have generally not been quantified and have rarely been considered in accelerated testing. The test engineer should, however, be aware of their existence.

The other major material component of indoor environments is particles. Most of the mass of particulate matter in the atmosphere exists in the size range 0.1–15 µm. Within this range, the mass exhibits a bimodal distribution. Particles 2.5–15 µm are largely derived from natural materials and are usually called coarse particles, while particles 0.1–2.5 µm are called fine particles. Coarse particles are largely mineralogical in composition and form predominantly as a result of human activity (mechanical processes) or by the action of wind or other abrasion processes on soils. Design guidelines for particulate mass are given in Table 2. Indoor and outdoor concentrations of water soluble ions in fine and coarse particles for a typical North American telecommunications office building and an electronics assembly environment [3,4] are shown in Table 3. All particle concentrations shown in Table 3 were determined using a dichotomous sampler, which provides particle collection on Teflon® filters. Mass concentrations are determined from the volume of air passed through each filter and gravimetric measurement of the mass of collected material. An important distinction between fine and coarse particles is their corrosivity. The higher the fraction of water soluble ions, the higher the corrosivity. The concentrations shown in Table 3 are determined by ion chromatography after the particles have been collected on the Teflon filters and then water extracted. Coarse particles tend to have a much lower fraction of water soluble ionic components (5–20 %) than fine particles (25–50 %), excluding

hydrogen ion (H<sup>+</sup>), hydroxyl ion (OH<sup>-</sup>), and carbonate (CO<sup>3-</sup>) [4]. As a result, coarse particles are less corrosive than fine particles. Recent work by the author and colleagues for telecommunications facilities in Eastern Asia, as shown in Table 4, found concentrations of particles to be typically 3–10 times higher than those found in North American facilities. The particles also tend to have a higher concentration of corrosive anions. In this work, fine and coarse particles were collected on the same Teflon filter (referred to as total suspended particulate).

Fine particles are largely of anthropogenic origin, though volcanic activity can sometimes be a significant source. The predominant source in developed parts of the world is fossil fuel combustion. These particles are formed by a complex ensemble of chemical and photochemical processes in which SO<sub>2</sub> and NO<sub>x</sub> formed by fossil fuel combustion are further oxidized over a period of days to sulfuric acid (H<sub>2</sub>SO<sub>4</sub>) and nitric acid (HNO<sub>3</sub>). These acids are neutralized to varying extents, depending on the environment, by ambient ammonia (NH<sub>3</sub>) derived from fertilization of farms, feedlot activity, and humans. The particles that initially form are smaller than 0.1 µm but rapidly grow, through condensation, on seed nuclei of carbonaceous material (also from fossil fuel combustion) to the stable size range of fine particles. The stability of this size range is attributable to the decreasing diffusivity and hence collision rate of particles, as their size increases. The mass abundance of fine particles outdoors is typically of the same order of magnitude as that of coarse particles, while their number density (typically 10<sup>7</sup> to 10<sup>8</sup> particles/ft<sup>3</sup>) is three or four orders of magnitude greater.

The concentrations of coarse particles within air conditioned office buildings, regardless of location in the world, are usually much lower than their outdoor concentrations, as shown in Tables 2 and 4, due to the effectiveness of even modest filtration systems in capturing particles in this size range. Within homes with open windows or doors, and within sheds and utility huts, the concentrations will be appreciably higher than for office buildings. If homes are well-sealed, the indoor concentrations are likely to be comparable to office buildings, except when items such as wood stoves, space heaters, and cooking appliances are operating. Mechanical processes in manufacturing environments, such

as cutting, grinding, welding, and polishing, can also generate locally high concentrations of coarse particles with the composition reflecting the source.

The indoor concentrations of fine particles in office buildings commonly range from 20–50 % of the outdoor concentrations, depending on: (1) the efficiency of the air filtration system, (2) the rate at which outdoor air is brought into the building or enclosure, and (3) indoor sources such as smoking or vigorous human activity. Concentrations within homes, sheds, and utility huts can range from 20–75 % of the outdoor concentration due to: (1) the penetrability of these particles through air-leakage pathways or open doors or windows; (2) the low efficiency of any air filtration; and (3) indoor sources like those mentioned above for coarse particles. Manufacturing environments typically have abundant sources of fine particles and their compositions may reflect the processing activity as much as ingress of outdoor particles.

An important distinction between coarse and fine particles is their predominant mode of transport through the air, which is determined by the combined effects of gravity, air velocity, temperature, electric fields, and surface configuration. Air velocity and flow direction are critical to the migration of fine particles but have little effect on coarse particles at normal indoor air velocities. Since coarse particles are sufficiently large to deposit by gravitational settling, they are found almost exclusively on topside horizontal surfaces, unless air velocities are very high and surfaces are tacky. Their residence time suspended in the air of an ordinary room is a maximum of a few minutes.

Many of the transport properties of fine particles are comparable to those of gas phase species. They migrate by convective diffusion and can remain in the air of a room for hours and even days, depending on the air exchange rate of the room. In the absence of thermophoretic forces or electric fields, they deposit with roughly equal propensity on all surface configurations and are more able to penetrate narrow spaces than coarse particles. The ratio of the surface accumulation rate (units of mass per unit area per unit time) to the airborne concentration (units of mass per unit volume) is a useful physical parameter that is commonly referred to as the deposition velocity (units of distance divided by time). The deposition velocity is the transfer

coefficient for transport across the concentration boundary layer that exists next to all surfaces.

With respect to corrosion processes, more important than the transport rate of particles or gases through air is their arrival rate and sticking probability on surfaces. These are determined by: (1) the air velocity across the surface and the resulting concentration boundary layer at the surface that controls transport to the surface; (2) the temperature of the surface relative to ambient; (3) the electrical charge on the surface and on nearby particles (electric field is not important for gases); and (4) bond strength between the surface and a freshly deposited particle or molecule. Typical deposition velocities for fine and coarse particles in various environments (in the absence of significant thermophoretic forces or electric fields) are shown in Table 5. Air velocity is well-established to have a dramatic effect on the arrival rate of gases and fine particles at surfaces. For example, the deposition velocity of fine sulfate containing particles was measured to be 0.005 cm/s in electronic equipment rooms where the linear air flow velocity is typically a few meters per minute [4]. However, for electronic equipment cabinets within these rooms, rapid airflow may be required to dissipate the high heat loads. In these situations, the air velocity is comparable to the typical outdoor wind velocity across the surfaces of vegetation (100 to 600 m/min). Deposition velocities to these surfaces has been found to range from 0.1–1.0 cm/s. From these data, the predicted arrival rate of particles on surfaces within forced-air-cooled electronic equipment cabinets is 20–200 times that for a normal office building environment at the same airborne concentration. The need to use forced-air cooling requires that the designer take steps to ensure that equipment has been adequately tested and hardened to the increased risk from environmental effects.

Particle transport through boundary layers in the presence of thermophoretic and electric forces is complex but predictable [5]. For coarse particles, thermophoretic and electric forces can usually be ignored. For fine particles, they can be very important. If the material to be tested is expected to exist in the field at  $>10^{\circ}\text{C}$  cooler or warmer than the ambient, or if the surface is expected to be  $>100\text{ V}$  above or below ground potential, these effects need to be considered. Cool surfaces increase the particle deposition rate while warm surfaces decrease it (analogous to condensation but for different reasons). Experience has shown that surfaces biased at a few hundred volts can collect fine particles at  $>5$  times the rate of grounded surfaces.

Detailed discussion of the modulating chemical and physical processes associated with continuing accumulation of fine and coarse particles over many years is beyond the scope of this chapter but can be found elsewhere [4]. Both

fine and coarse particles are expected to have sticking probabilities close to 1. Thus, in the absence of cleaning, accumulation will be continuous and linearly related to airborne concentration for all species that are chemically stable.

Bond strength of particles to the surface depends on many factors. Coarse particles do not normally adhere to vertical or bottom side surfaces unless the surface is very rough or tacky to human touch. The relationship between relative humidity and surface moisture can affect the degree of tackiness. For fine particles, chemical bonding and physical forces (van der Waals) are sufficiently strong to permanently hold all particles on surfaces, regardless of configuration, unless substantial mechanical forces, such as wiping or high-pressure air jets, are used to clean the surfaces. It is usually appropriate to assume that the sticking probability is 1 for both coarse and fine particles, recognizing that coarse particles only collect on top side horizontal surfaces. This behavior contrasts sharply with that of gas phase species, where sticking probabilities range from 0 to 1, depending on the surface, gas, and exposure time.

In electronic equipment, coarse particles sometimes cause malfunctions by interrupting electrical contact between mating pairs of contacts on connectors or relays. In manufacturing environments where air velocities may be high, these particles may erode passive surface films or coatings, resulting in accelerated corrosion. The CRH at which coarse particles begin to adsorb ambient moisture is substantially higher than that for fine particles, typically well over 80 %. In contrast, the CRHs of some of the major ionic components found in fine particles in most urban environments, given in Table 6 [6,7], are below 60 %. The electrolyte films that form upon moisture acquisition on surfaces contaminated with fine particles are responsible for their high corrosivity to many metals and can lead to electrolytic corrosion in electronics. Hygroscopic dust is a frequent cause of malfunction in electronics.

Another possible cause of materials degradation in indoor environment is microbes. A few research groups are investigating the effects of specific microbes on materials exposed to much harsher environments than are generally encountered indoors. Microbial corrosion has been largely ignored by the indoor design community. The test engineer concerned about indoor environments should be aware of microbial corrosion but will need to rely on engineering intuition to decide if microbial corrosion could be an issue. Since most corrosion engineers, including the author, have limited knowledge of how microbes interact with materials, the best approach seems to be to solicit the advice of a good microbiologist when devising a test method.

Finding a single accelerated test to evaluate materials against all these possible environmental hazards is unrealistic at this time. Each material needs to be evaluated by a series of tests to elucidate the possible degradation mechanisms.

**TABLE 5**—Deposition velocities of airborne particles (cm/s).

Conditions (Air Velocity)	Fine (0.1–2.5 $\mu\text{m}$ )	Coarse (1–15 $\mu\text{m}$ )
Outdoor (250–1000 cm/s)	0.6	0.6
Office Bldg (2–4 cm/s)	0.006	0.6
Cleanroom (50 cm/s)	0.009–0.09	0.6

**TABLE 6**—Critical relative humidity for saturated salt solutions,  $75^{\circ}\text{F}$  ( $23.9^{\circ}\text{C}$ ).

Salt	RH, %
$\text{NH}_4\text{HSO}_4$	40
$\text{NH}_4\text{NO}_3$	65
$\text{NaCl}$	75
$(\text{NH}_4)_2\text{SO}_4$	81

Experience has shown that our ability to predict what test to use when field failure data are not available falls well short of needs. In reality, the corrosion engineer must rely on past experience to make an educated judgment about potential failure scenarios and which accelerated-life-tests to run.

## UNIQUE ASPECTS OF TESTING

As has already been briefly discussed, the unique challenge facing the test engineer responsible for evaluating the effects of indoor atmospheres is the complexity of these environments. Each material or combination of materials and each product have unique considerations. The first step in deciding on a test protocol is to conduct a literature search on the atmospheric corrosion of each material. Consultations with experts in the corrosion of each material are also suggested. After establishing, as best possible, what the known corrosion tendencies are, the appropriate test(s) should be selected from among those described or referenced below.

At this time, the knowledge base and experience in conducting temperature/humidity testing (or temperature/humidity/bias for electronics) and corrosive gas testing is more developed than that for coarse and fine particles, organic vapors, and microbes. The test engineer should have little difficulty in finding a well-seasoned test procedure for accelerating the effects of temperature, humidity, and bias [8]. Unfortunately, for corrosive gas testing, there is still some disagreement among the various standards organizations about what combinations of corrosive gases are appropriate for each type of environment. A few of these tests, as will be outlined below, are in sufficiently widespread use to serve as acceptable evidence in most forums that a product will perform reliably in the intended use environments. Some national and regional standards organizations may insist that their test is the only acceptable test. Test engineers for companies with broad international sales may be required to perform several different tests.

Testing for the effects of particles is much less advanced than corrosive gas testing, but further along than organic vapors or microbial testing. A few proprietary, one-of-a-kind chambers have been developed for testing the effects of coarse particles. The typical dusts used in these tests include red china clay, fine sand, Arizona Road Dust, talc, silica, quartz, feldspar, fire extinguisher powder (usually sodium or potassium bicarbonate with additives to keep it free flowing), or some combination of ground materials that may include silica, calcite, iron oxide, alumina, gypsum, paper fibers, cotton fibers, polyester fibers, carbon black, and human hair. In a few cases, complex mixtures of ionic and water insoluble materials have been blended to produce a composition that resembles that of fine and coarse atmospheric particles combined. MIL-STD-810E, EIA Standard RS-364-50, proposed IEC Test L: Dust and Sand, and the published literature provide relevant background information.

With fine particles, work to develop test methods is just beginning. While experimental work in recent years has shown that these highly ionic particles can have severe

corrosion effects, especially for electronic equipment and devices [9], only in the past few years have test procedures and chambers been developed for evaluating effects [10,11]. These methods will be discussed below. Since only a few standards organizations have even recognized the need for fine particle testing, the test engineer has free reign in selecting a test. Often the most demanding customers only expect a good faith effort in demonstrating immunity to fine particle effects. Recent research may stimulate standards activity in the next few years. It should be noted that salt spray tests are usually too harsh for simulating fine particle effects in indoor environments, especially for electronics.

A valuable test, in conjunction with standard laboratory testing, is to deploy a prototype of the product in the harshest environment that can be found and to monitor and evaluate the performance of the materials for any early signs of unexpected behavior. High airflow velocity and elevated humidity will frequently provide even further acceleration. If unacceptable degradation is found that is representative of what would occur in a less severe environment, the originally selected laboratory tests should be re-evaluated to determine if they appropriately accelerate the observed condition.

Experience has shown that our best efforts to predict potential problem areas frequently miss the fatal flaws. For this reason it is advisable to perform at least one broad, severe corrosive gas test and one similarly harsh particle test, even if no obvious failure scenario can be envisioned that would be expected to be manifested through these tests. It is also helpful to stress the material or product sufficiently to produce significant corrosion or malfunction, even if this requires unrealistically harsh conditions. Such a test helps ensure that the designer understands the materials limitations and may indicate that the product is over-designed. Less resistant, less expensive materials may be sufficient for the intended use.

A danger in using extreme conditions is that unrealistic failures may occur. Several examples illustrate this hazard:

1. When testing the permeability of plastics or coatings to moisture and the possibility of corrosion of underlying materials, extreme humidity conditions, such as those present in steam bombs, can lead to unrealistic failures. An RH extreme that produces condensed water may result in degradation that would never occur in a field situation.
2. Many degradation processes are thermally activated. Use of extreme temperatures can give very high but unrealistic acceleration factors if there is a change in failure mechanism at the extreme condition. Further, if phase changes, e.g., recrystallization or plastic deformation, are induced that would not occur at the maximum conceivable operating temperature, the test may not give an accurate indication of material performance.
3. Breakdown of protective oxide films on many metals, e.g., aluminum, requires that environmental stresses exceed some threshold condition. Aluminum is likely to rapidly pit when exposed to high chloride concentrations at humidity levels sufficiently high to adsorb several monolayers of moisture. Most home and office environments do not cause these conditions.

4. In electronics, a common metallization used for connectors on printed wiring boards is copper with an overplate of nickel and then gold. Under most environmental conditions, the gold prevents oxidation of the underlying copper. However, if the conditions are harsh enough, very small pores that are always present even in the best quality commercial gold electroplates allow sufficient access to the underlying copper for it to oxidize. In time, the copper corrosion products creep over the surface of the gold, producing an insulating film and breaking the electrical integrity of the connection. Except for unfiltered air near pulp mills, oil fields, and similar extreme environments, gold-plated connectors have been used indoors for decades without experiencing harmful corrosion.

Testing of electronic equipment is particularly challenging because the degree of complexity is even higher than for most other indoor materials. The number of different materials typically ranges from dozens to hundreds and all the environmental influences discussed above are important. A detailed discussion is beyond the scope of this chapter. A recent review on testing of electronic components and assemblies covers this subject [10].

In fortunate cases, sufficient field and laboratory data are available and the failure mechanism is sufficiently well-understood to accurately determine acceleration factors. The corrosion rate of some metals, e.g., copper, silver, and nickel, can be accurately predicted for environments in which the major corrodents are  $\text{SO}_2$ ,  $\text{NO}_x$ ,  $\text{H}_2\text{S}$ , and  $\text{Cl}_2$ . (Note:  $\text{Cl}_2$  is too reactive to be a significant corrodent in field environments but is used in corrosive gas testing to simulate the effects of HCl and other corrosive chlorine-containing gases). The aging behavior (cracking, discoloration) of many plastics as a function of temperature, oxidant concentration, e.g., ozone, and sunlight can also be predicted with fair accuracy. In electronics, temperature/humidity/bias testing has reached a useful level of sophistication with respect to component testing and evaluation of plastic and hermetic packages for devices. Such testing is typically required by the customer as part of the data that go into evaluating the temperature/humidity performance of an entire assembly of electronic components.

In less fortunate cases, for example particle-related degradation, the best that can be done at this time is to compute acceleration factors for particle loading. How the rate of materials degradation brought on by gradual particle loading in field environments compares with the rate brought on by rapid loading in a test chamber is only beginning to be investigated. RH effects are widely agreed to be important in degradation induced by fine particles, but are not quantifiable at this time. The time-of-wetness (TOW) concept [12,13] can predict the corrosion rate of some metals in outdoor environments, but it is not applicable to most indoor environments where the RH is usually lower than that required for condensation to occur. A model that explains the dependence of surface conductance and electrical leakage of printed wiring boards as function of temperature and humidity exists [14], but it is not yet useful for predictions because the conductance also depends on the composition and amount of contamination on the surface in ways that are not fully understood.

Useful work on acceleration factors for degradation induced by organic vapors or microbes in indoor environments does not exist.

## IMPORTANT VARIABLES

The number of variables important to corrosion in indoor atmospheres is very large. The most important of these are: (1) the range and periodicity of temperature variations; (2) the range and periodicity of humidity variations; (3) the average and spread in concentration of corrosive gases such as  $\text{SO}_2$ ,  $\text{H}_2\text{S}$ ,  $\text{NO}$ ,  $\text{NO}_2$ ,  $\text{HNO}_3$ ,  $\text{HCl}$ , and organic acids; (4) the number concentration of coarse particles in air and their composition; (5) the number concentration, composition, ionic content, and CRH of fine particles; (6) microbial activity; (7) the concentration of organic vapors in air, their rate of condensation on surfaces, and their effects on surface wettability over time; (8) airflow velocity and turbulence; and (9) electric fields. Complicating all of these factors is the sequence of events that age the surface during the exposure. Some species may quickly reach a saturation concentration on the surface, while others will continuously accumulate over time (in the absence of cleaning). Many organic vapors are expected to saturate. Some corrosive gases initially reach an apparent saturation level but are then gradually consumed and replenished while residing on the surface. Other corrosive gases react with some materials as rapidly as they arrive at the surface until the material is consumed. All particles continuously accumulate on surfaces in the absence of mechanical effects or cleaning, though some components of the particles may react with the surface or some surface contaminants to form new products. Microbes may come and go depending on the nutrients available on the surface, relative humidity, and oxygen accessibility. The continuous accumulation of contaminants on indoor surfaces is an important difference from what occurs outdoors, where rain periodically removes components through solubilization or mechanical action.

Air velocity effects are frequently ignored in conducting life tests and in determining acceleration factors. This is unfortunate because, as discussed, the rate of arrival of gases and fine particles at surfaces depends on their rate of transport across the viscous boundary layer. The rate of transport increases rapidly as velocity increases and the boundary layer thickness decreases. Deposition velocities have been measured for enough different species and air velocities to reasonably estimate the deposition velocity for most situations of concern to the test engineer. The values given in Table 5 have been used by the author and colleagues [10] for approximate work, and are suggested as a guideline.

The two important points to recognize from this discussion of deposition velocity are: (1) the critical concentration parameter in accelerated life testing is not the airborne concentration but rather the surface arrival rate; (2) if airborne concentration is known, the surface arrival rate can be calculated from the equation: surface arrival rate = (airborne concentration)/(deposition velocity). Few workers in this field have evaluated the surface arrival rate of the corrodents in their test chambers. As long as airflow conditions

are constant and the corrosion rates of materials have been accurately standardized for the chamber, it is acceptable to base acceleration factors on airborne concentration. However, the test engineer needs to recognize that airflow velocities and turbulence can change dramatically with minor changes in the configuration of the exposure apparatus. Insistence on using airborne concentration instead of surface arrival rate also means that results from different chambers are not comparable. Much of the disagreement among test groups when round robin tests have been run can possibly be attributed to this factor.

## LABORATORY TESTING

### Testing for Thermal, Humidity, and Bias Effects

Thermal, humidity, and bias testing can be done individually or in any combination. Simple thermal testing without humidity or bias is usually done in conjunction with a mechanical stress or as a temperature cycling experiment. Both of these are intended to evaluate the effects of mechanical stress on materials degradation. These kinds of tests are covered in other chapters of this book. Occasionally, materials may be exposed to elevated temperature for extended periods to uncover instabilities like phase segregation, recrystallization, or oxidation under ambient conditions. Ambient in this case means room air with whatever contaminants may be present. The assumption is that oxygen or moisture in the air dominates any oxidation process and that the contaminating components have negligible effect. These tests are straightforward, usually follow Arrhenius behavior, and will not be discussed further.

Humidity testing is nearly always carried out at temperatures ranging from 351–100°C with relative humidity from nearly zero to 100 %. Occasionally, steam bombs are used so tests can be run above 100°C. In the last ten years, highly accelerated stress tests have been developed to enable materials to be tested at temperatures above 100°C, but at a non-condensing relative humidity, typically 85 %. The most common applications for these tests are in evaluating coatings, paper, adhesives, adhesion between mechanically or chemically bonded materials, and, in electronics, for evaluating the effectiveness of device encapsulation.

Bias is frequently added for testing of electronic devices, printed wiring boards, and assemblies of electronic equipment. The 85°C, 85 % RH, bias test has been the predominant one in electronics for many years [8]. While it sometimes misses failure mechanisms that later occur in the field, it also finds many weak points in new products. It is especially useful for quality control of seasoned devices for which long-term reliability is known to be high if the product passes this test. There are many commercial suppliers of temperature/humidity/bias test chambers and software is widely available to automate the operation, data collection, and data interpretation. Attention to data management is mandatory when hundreds of devices are tested simultaneously. This is frequently required in electronics to obtain sufficient data to make statistically valid predictions of lifetime and failure rate under use conditions.

### Corrosive Gas Testing

Corrosive gas testing became commonplace in the mid-1970s as a result of the need of the electronics industry to reduce the cost of materials used as electrical contacts on connectors and as conducting pathways on various kinds of insulating substrates. Studies at IBM [15–18] and Battelle [19] played a key role in the development of this technology. Studies at both institutions compared laboratory data to field data and achieved results in the laboratory that accurately reproduced field results. Field exposures of 20 years can be simulated in 5–30 days in the laboratory. Based on metal coupon exposures and simultaneous air pollutant measurements from over a hundred locations around the world, a four-level environmental classification scheme for environmental severity, which is now in common use around the world, was developed by the industry-sponsored Battelle group.

Differences of opinion have existed for decades with respect to the mixture of corrosive gases that should be used in test chambers. For air-conditioned electronic equipment rooms in urban environments that are well removed from industrial pollution (Class II Battelle environment, G1 IBM environment, and IEC Class II environment), the appropriate Battelle accelerated life test calls for use of 200 ppb NO<sub>2</sub>, 10 ppb H<sub>2</sub>S, and 10 ppb Cl<sub>2</sub> at an RH of 70 %. This test does an excellent job of simulating corrosion films on silver, copper, tin, and some gold-plated metals, but has been criticized in recent years because the films it produces on nickel are unrealistic.

Several groups, including Siemens and Bellcore, now prescribe a four-gas test that does a better job of simulating nickel corrosion. Their test gas contains 200 ppb NO<sub>2</sub>, 10 ppb H<sub>2</sub>S, 10 ppb Cl<sub>2</sub>, and 200 ppb SO<sub>2</sub>. Bellcore calls for a RH of 70 %, while Siemens stipulates 75 %. Standard setting organizations have not agreed on a standard test for electronic equipment, but the engineer can use the Battelle test with a high degree of confidence for silver, copper, and tin, and the Siemens or Bellcore test for nickel.

The greatest difficulty in using corrosive gas tests comes in deciding how to test entire assemblies of equipment, rather than just the metallization schemes used for connectors, and in evaluating equipment for those indoor environments where the RH may reach close to 100 %. The Battelle, Bellcore, and Siemens test conditions are intended for simulations of metals that will be used in office buildings, homes, and other air-conditioned environments. Enclosed environments such as sheds, utility huts, and non-air-conditioned manufacturing environments are more like outdoor than indoor environments with respect to RH. Standardized test conditions are not available. At this time, the test engineer has little alternative but to use the conditions that work for metals in indoor environments to cover all “enclosed” environments.

Suggested test conditions that cover both “indoor” and “outdoor” environments are given in Table 7. It can reasonably be argued both for and against using the same humidity for indoor and outdoor testing. Since most chambers have been set up to operate stably at 70 or 75 % RH, one possible approach is to do all corrosive gas exposure testing at this RH but, for outdoor simulations, to follow the

**TABLE 7**—Corrosive gas test conditions.

Location	Atmosphere	Test Duration, days
Indoors (Environmentally Controlled)	25°C, 75 % RH, 10 ppb Cl <sub>2</sub> , 10 ppb H <sub>2</sub> S, 200 ppb NO <sub>2</sub> , 200 ppb SO <sub>2</sub> , balance air	10
Outdoors <sup>a</sup> (Uncontrolled)	25°C, 75 % RH, 10 ppb Cl <sub>2</sub> , 10 ppb H <sub>2</sub> S, 200 ppb NO <sub>2</sub> , 200 ppb SO <sub>2</sub> , balance air	20

<sup>a</sup>Subsequent to the corrosive gas exposure, equipment intended for outdoor use should be exposed to cyclic high/low humidity (95/20 % RH) with the equipment powered. An appropriate exposure sequence is 12 h high, 12 h low for 20 days.

corrosive gas exposure with a cyclic RH exposure that covers the full range of expected outdoor conditions. Some would also argue that a factor of 2 difference in exposure time to the environments indicated in Table 7 for indoor and outdoor testing is insufficient. For the harshest environments, the test engineer needs to make a best judgment estimation of the proper test duration. With mechanical and electronic equipment and assemblies, it is also essential to undertake a complete series of functional tests following the testing prescribed in Table 7. Typically, the functional testing should be undertaken in a chamber in which RH is cycled during the testing over ranges representative of the expected use environment. It may also be desirable to undertake the testing at elevated temperature. For electronics, 85°C is frequently used.

Helpful guidance for conducting corrosive gas tests is provided in ASTM B 827, Practice for Conducting Mixed Flowing Gas (MFG) Environmental Tests. Proper technique for use of metal coupons for calibrating chambers is described in ASTM B 810, A: Test Method for Calibration of Atmospheric Corrosion Test Chambers by Change in Mass of Copper Coupons and other references [20–23]. A guide to commonly used gas mixtures and their historical significance is given in ASTM B 845, B: Guide for Mixed Flowing Gas (MFG) Tests for Electrical Contacts.

Occasionally failure mechanisms in the field are encountered that suggest the use of simpler one component gas tests. For example, design engineers for electronic equipment like to use fired silver paste to produce low-cost conductor patterns on insulating substrates. Silver is susceptible to silver migration under conditions of elevated humidity and bias. The presence of a reduced sulfur gas greatly accelerates the formation of metal dendrites between oppositely biased conductors. This condition eventually leads to short circuits. The susceptibility of these devices to silver migration can be easily evaluated using a simple bell jar with a feedthrough for supplying bias to the circuit pattern, a salt solution for achieving humidity control (described below), and elemental sulfur as the source of reduced sulfur. The test is typically run at 50°C. Elemental sulfur is much easier and safer to work with than hydrogen sulfide.

Exposure to organic vapors, when needed to simulate degradation of a plastic or perhaps change the wettability of a surface, can also be conducted in a simple bell jar. In this case it may be desirable also to collect material on a

quartz crystal microbalance to monitor absorption rate and possible saturation.

Whether these corrosive gas tests are realistic for materials other than those used for connectors or for operating electronic equipment is not clear. The test should be carried out, but the observation of no failures should not be taken to mean there will be no field failures in typical urban environments. Similarly, any failures that are observed should be carefully evaluated to ensure that the same mechanism would be operative in field situations. Connectors are a somewhat unique part of an electronic assembly in that the active part is frequently a noble metal and the sensitivity of the mated surfaces to failure may be lower than many other parts of electronic assemblies. Most failures in electronic assemblies attributable to the environment are due to ionic particle contamination in conjunction with atmospheric moisture. In 20 years of evaluating field failures in the United States, the author has never seen a failure that could be attributed to the effects of SO<sub>2</sub>, has seen a few caused by H<sub>2</sub>S or HCl, has heard of a few caused by NO<sub>x</sub>, and has seen several hundred that were caused by ionic contamination. Clearly, valid accelerated testing of electronic components, circuit boards, and assemblies must include ionic contamination. Emerging methods are discussed in the Fine Particle Testing section in this chapter.

### Coarse Particle Testing

Occasionally, some materials have been subjected to coarse particle dust tests in which the test dust is frequently a “real world” standard material such as Arizona Road Dust, talc, silica, or other mineralogically-derived substances, as discussed above. MIL-STD-810E, EIA Standard RS-364-50, proposed IEC Test L: Dust and Sand and the published literature provide relevant background information. Typically, the test dust is dispersed by mechanical means into a rapidly moving air stream that is directed at the test specimen. Internationally recognized standards for indoor coarse particle testing are not likely to be available for many years. Most of the existing or emerging tests use particle sizes much larger than would likely be encountered in indoor environments, except perhaps for some manufacturing processes. While typical indoor dust particles are within the size range 2.5–15 µm, many of the suggested tests use particles that span the size range 1–150 µm. Some standards prescribe that 100 % of the dust pass through a minimum screen size of 100 mesh (149 µm). MIL-STD-810E, Method 510.2, Sand and Dust considers sand particles in the size range 140–850 µm. The transport characteristics of these very large particles in an air stream, and their penetrability into narrow spaces, are very unrealistic of real indoor coarse particles.

In a typical test apparatus, coarse particles are mechanically injected into a rapidly moving air stream that is projected at the equipment undergoing the test. Deposition is largely by gravitational settling with some inertial impaction. A commonly encountered problem with this kind of test is that the dust tends to collect at certain points in the chamber, depending on how and where the dust is dispersed and how the test piece disturbs the airflow. Typically, the dust collects in thick deposits on some parts of the

test piece but hardly deposits on other parts. Recent failures of mechanical assemblies in wind-swept deserts, despite best efforts to harden the equipment against the effects of coarse dust through experiments in coarse particle test chambers, have had tragic consequences. These methods are fraught with difficulty that test engineers need to take into account when deciding on the confidence level of the result.

In electronics, these kinds of tests have been used to evaluate the effects of coarse particles on the insulation resistance of connectors. When the tests are done with the connectors mated, the connectors are sometimes vibrated in an attempt to drive particles into the interface. In other cases the connectors are exposed unmated. After exposure they are mated and the resistance is measured. Sometimes these tests are carried out iteratively, or multiple insertion cycles are undertaken to evaluate the ability of the contact metal (typically a gold or other noble metal finish) to withstand the abrasion from coarse particles. Acceleration factors either are not determined or, if they are, the confidence level is low because they are based on tests as simple as the weight gain of metal coupons. Under fortunate circumstances, these tests may point out opportunities for design changes that extend life, at least in a qualitative way.

Following coarse particle deposition on the surfaces of test specimens or equipment, a full series of surface characterizations and functional tests should be carried out. Ideally, testing of mechanical or electrical performance is carried out in-situ during particle deposition but frequently this is not practical. Since coarse particles usually have low chemical reactivity, post-deposition testing usually produces realistic results. In some cases it may be advantageous to carry out an iterative series of particle depositions followed by functional tests (mechanical and electrical).

In the absence of a widely accepted test suitable for indoor environments, the test engineer will have to use best judgment in deciding how to carry out coarse particle testing. Fortunately, the effects of coarse particles indoors are usually small.

### Fine Particle Testing

Physical designers are just now becoming aware of the need to harden materials and products against the effects of submicron particle contamination. Bellcore [24] recently suggested a test for simulating the electrical leakage effects on circuit boards of ionic contamination derived from particles. The test is intended to simulate the effects of fine particle deposition, though it uses an atomized spray of an aqueous solution to deposit the contamination.

Development of a suitable test chamber for evaluating the effects of submicron particles on indoor surfaces, including electronic equipment and devices, requires: (1) the capability to produce suspended ionic particles that accurately simulate the composition and size distribution of airborne particles responsible for the observed effects; (2) designing a chamber that combines continuous air-recirculation, filters out all background and once-through particles, and provides parallel airflow with uniform particle concentration over the flow cross section of the test area; (3) fabrication and evaluation of suitable test samples or devices; and

(4) for electronics, understanding what environmental factors cause electrical leakage and arcing. Over the last 20 years, the author and colleagues have been gradually and somewhat serendipitously acquiring this expertise [9].

In the mid-1980s, experiences with field failures in electronic equipment made it clear that existing accelerated test methods were inadequate for discovering failure processes caused by fine particle deposition. A method was needed to apply a realistic layer of particles on circuit boards or test substrates to answer questions such as: (1) Are the line separations and circuit voltages in a particular design safe with respect to electrical leakage or arcs that may occur on particle-contaminated surfaces? (2) Are pore defects in cover coats on substrates of sufficiently high density to present a significant risk of component damage due to electrical leakage or arcs between leads on components and metal lines running under the covercoat? (3) Will electric fields near components substantially accelerate deposition of fine particles? (4) What level of atmospheric moisture (RH) produces a sufficiently thick electrolyte film on particle-contaminated surfaces to observe soft electrical defects, e.g., cross talk, or, in the worst case, component failure?

Over the last several years, a series of methods for depositing particles on surfaces that are representative of submicron atmospheric particles has been developed. The first uses a synthetic dust produced by grinding. The finely ground dust is then mechanically dispersed on the test substrate. This test is useful for solving field problems because it is quick. The limitations in using this dust are: (1) the particle size is too large, so that gravitational settling dominates the deposition process; and (2) deposition on partially shielded surfaces, especially vertical and top-side horizontal surfaces, is inadequate. To overcome this problem, a recirculating chamber with a continuous feed stream of submicron atmospheric-like particles was developed. The details of these two methods are described in the following sections.

### Ground Synthetic Dust Mixture

Hand-grinding of a mixture of ammonium sulfate, ammonium bisulfate, sodium chloride, potassium bicarbonate, and talc in dry nitrogen produces a dust that can readily be dispersed onto test substrates. The resulting particles are typically 1–5  $\mu\text{m}$  in diameter. A typical composition is shown in Table 8. The composition of the dust can be adjusted to match the electrical leakage properties on circuit boards of fine particle dust found in telecommunications switching equipment centers [9]. Two methods of dispersion were found to be effective: (1) blasting a high-pressure stream of dry nitrogen into a dust-filled container with circular perforations in the top; and (2) applying the dust from a salt shaker or sieve. Subsequent exposure of an

**TABLE 8**—Composition of synthetic dust.

Component	Weight, g

FIG. 1—Leakage current as a function of RH, showing exponential dependence. The Blank is a clean circuit. Synthetic No. 3 is a finely ground mixture of the dust, as described in Table 7. Paris, Canfield, West Virginia, and Hartsville are U.S. sites. Mt. Pinatubo is volcanic ash collected at the time of the 1991 eruption. Its low dependence on RH is explained by its lower fraction of water-soluble ionic material. Kuwait dust was collected at the height of the oil fires in 1991. Its high conductivity at low RH is caused by its high graphitic carbon content.

interdigitated test substrate to an air environment in which the RH was gradually increased from 20–85 % produced a slow increase in the electrical leakage current until the CRH of ammonium sulfate (81 %) was reached, at which point the leakage current increased rapidly. This behavior was similar to the exponential dependence of surface conductance on RH seen for many different samples of atmospheric dust from locations all over the United States, as seen in Fig. 1. With the synthetic dust, it is possible to vary the effective CRH over the range of 40–81 %, depending on the relative amounts of ammonium sulfate (CRH of 81 %) and ammonium bisulfate (CRH of 40 %).

### Test Chamber for Fine Particles

A new, more realistic approach for fine particle dust testing is to disperse water-soluble, hygroscopic salts representative of those found in fine environmental particles into a chamber that is designed to provide uniform airflow of otherwise particle-free air across a rack of circuit boards [11]. Generation of submicron particles is achieved by atomizing an aqueous solution of the appropriate salt, followed by thorough drying of the resulting aerosol laden air stream. A picture of the dust generator and the dust chamber is shown in Fig. 2.

The specifications for the chamber are: particle size, 0.01–1  $\mu\text{m}$ ; particle concentration,  $1 \times 10^{10}/\text{m}^3$ ; flow velocity, 35 m/min; parallel airflow; and uniform dust concentration. The air velocity is similar to that found in forced-air-cooled telecommunications equipment cabinets. Air is re-circulated upwards through the chamber. Particles are introduced into the chamber at a point above a HEPA filter that removes the particles with 99.9995 % efficiency at

FIG. 2—Photograph of the fine particle exposure chamber with the HEPA filter and controls underneath and particle generation equipment at the right. The funnels are part of the distribution system. The two racks in the upper part of the chamber can hold up to 48 circuit boards.

0.12  $\mu\text{m}$  after they have made one pass through the chamber. With a 60 by 60 cm cross section and a height of 110 cm, the chamber is sufficiently large to hold a rack that supports up to 48 circuit boards. The HEPA filter, which is situated immediately below the chamber, and a screen just above the filter ensure that the airflow in the chamber is parallel to the vertical walls. The air velocity can be controlled at speeds up to 36 m/min.

Submicron (0.01–1  $\mu\text{m}$ ) ionic particles, such as ammonium sulfate, are generated from an aqueous solution of the salt by compressed high-purity, filtered air in an atomizer. The aerosol droplets are dried by a stream of preheated air. Residual moisture is removed from the particles by passing them through a diffusion dryer. Since the particles are highly charged when they exit the atomizer, they are neutralized with a Kr-85 source, which brings them to a Boltzmann equilibrium. The average size of the particles varies as the cube root of the solution concentration.

The particles are introduced into the exposure chamber through a 16-nozzle distribution system that was designed to give a uniform concentration of particles throughout the chamber. This was achieved by having all particles travel the identical distance and encounter the same type of obstructions and turns. The distribution system is made

from type 316 stainless steel the interior of which has been electropolished to minimize particle deposition and shedding. Steady-state conditions in the chamber are achieved by recirculating the air while constantly introducing new particles immediately downstream from the HEPA filter.

The air velocity distribution, measured at 49 points over the cross section of the chamber at a height corresponding to the middle of the rack that holds the specimens, exhibited an average speed of 38.2 m/min with a standard deviation of 10.6 m/min. The concentration of  $(\text{NH}_4)_2\text{SO}_4$  particles generated from a 0.01 M solution of the salt was found to be quite uniform over the cross section of the chamber (see Fig. 3). Variation of the deposition rate to surfaces being tested is accomplished by regulating the airflow velocity.

From the compositional data for Eastern Asia (Table 4), we know that airborne concentrations and surface deposition rates are substantially higher than those in the U.S. One approach to simulating the worst-case environment for Eastern Asia is to reduce the ammonium to sulfate ratio of the ground dust mixture. However, hand grinding salt mixtures is a tedious process that must be carried out in a dry box. A more appropriate approach for high volume testing is to use the fine particle test chamber. In this approach the proportions of ionic substances used for the Test Dust #3 are dissolved in water at a concentration that appropriately simulates a worst-case hazard for the environment under study based on comparing the surface conductance versus RH behavior of test dusts with the behavior of samples from the field. The amount of salt to be deposited is determined from knowledge of the worst-case environmental conditions and the expected lifetime of the component. Typically, airborne sulfate concentrations are used to estimate the expected deposition over the product life. The sulfate deposition rate in the field is estimated by multiplying the worst-case airborne sulfate concentration by the deposition velocity appropriate for the airflow rate across the component. For example, the highest sulfate concentration in this work was  $8.0 \mu\text{g}/\text{m}^3$ . Presuming the component is cooled by forced-air with a linear velocity of 250 cm/s, the appropriate deposition velocity is 0.6 cm/s.

For a lifetime of 20 years, the sulfate accumulation is expected to reach  $3000 \mu\text{g}/\text{cm}^2$ . (It should be noted that electric fields can increase this deposition rate by as much as 100 but this effect is ignored here.)

Following particle deposition, the test specimens should be evaluated in a temperature/humidity environmental chamber. With electronic equipment, bias should be applied to the specimen as well, and the device or equipment assembly should undergo a full series of functional tests.

While this method of testing is new and still being refined, it has been demonstrated to accurately simulate the deposition and electrical effects of fine particle dust as are found in a forced-air-cooled equipment frame. The resulting electrical effects on circuit boards and equipment assemblies are comparable to those found in field environments. This approach was found quite effective for testing the sensitivity of circuit boards intended for use in Eastern Asia to electrical leakage, and to evaluate the effectiveness of covercoats in preventing leakage. At the very least, use of this test demonstrates a state-of-the-art goodwill effort to show that equipment will operate reliably in the presence of fine, hygroscopic dust. The acceleration factor for fine particle deposition is about 200, depending on the surface area and configuration of the equipment undergoing test.

## FIELD TESTING

### Temperature, Humidity, and Dewpoint Monitoring

Since relative humidity plays such a key role in the corrosiveness of many environments, it is always desirable to monitor the interrelated humidity factors: temperature, humidity, and dewpoint temperature. Since reliable commercial equipment is widely available, it will not be discussed further. Closely related to dewpoint is time-of-wetness (TOW), which is measured by monitoring the resistance between oppositely biased electrical conductors as a function of relative humidity. Bias can be applied through an external power source [12]. Alternatively, adjacent metal conductors can be selected to have substantially different corrosion potentials [13]. Above a critical level of relative humidity, the test specimen will adsorb a sufficient amount of moisture to produce a sharply lower resistance between conductors. The fraction of time of lowered resistance is commonly referred to as the time-of-wetness. It is one useful measure of the corrosivity of an environment. Such measurements were popular in the 1960s and 1970s. More recently, the preferred measurement, due to ease of use, is fraction of time the dewpoint is reached. A procedure for measuring time-of-wetness is contained in ASTM G 84, Standard Practice for Measurement of Time-of-Wetness on Surfaces Exposed to Wetting Conditions as in Atmospheric Corrosion Testing.

### Metal Coupon Exposures

Relating laboratory exposures to field results is commonly accomplished through metal coupon tests. Three extensive studies of this type are described in Refs 16, 17,

**FIG. 3—Particle concentration distribution profile across the exposure chamber at the middle height of the test rack for particles within the approximate size range 0.018–0.032  $\mu\text{m}$ .**

19, and 25. While the results are only appropriate for validating the corrosion testing of the metals undergoing test, they are frequently used as an indication of test validity for all types of materials and functional assemblies. This leap of faith is usually necessitated by resource limitations. Environmental classifications that have been developed, e.g., the Battelle Class I-IV [19] or the IBM G1-G3 [18] environments, are a way of categorizing the severity of corrosion and the composition of corrosion products that are expected for the full range of environments found in the world, and for selecting appropriate test conditions to simulate these environments in the laboratory. The standard coupons used to classify environments using the Battelle scheme are: (1) a plated metallization consisting of porous gold over nickel over copper, and (2) unprotected copper. The Battelle Classifications, in order of increasing corrosion rate, are as follows:

Class I—No significant corrosion observed.

Class II—Mild pore corrosion of Au/Ni/Cu with chloride, oxide, and smaller amounts of sulfide in the corrosion product; corrosion product on unprotected copper contains oxide and chloride.

Class III—Pore and creep corrosion of Au/Ni/Cu with major amounts of sulfide, chloride, and oxide in the corrosion product; corrosion product on unprotected copper is rich in sulfide and oxide.

Class IV—Severe creep corrosion of Au/Ni/Cu with major amounts of sulfide, oxide, and chloride in the corrosion product; corrosion product on copper is primarily a sulfide film with some oxide.

### Measurements of Corrosive Gas Concentrations

The most commonly used method to measure the concentrations of corrosive gases in field environments is to adsorb the gases on chemically treated filter paper, sometimes followed by a water extraction or chemical treatment, and then to determine the composition and quantity spectroscopically. IBM [15] developed a stacked canister sampler that was adapted for use in the Battelle studies [19]. Each element in the canister stack collects a specific pollutant. The canisters are easily deployed anywhere in the world, the only inconvenience being that an air pump is required to draw a well-controlled air volume. The reliability of these pumps, based on the author's experience, is less than desirable but adequate. A similar technique, developed largely under the sponsorship of the U.S. EPA, is the "denuder" tube. This method is also based on species-specific absorption of pollutants on a chemically treated surface, but in this case a permanent honeycomb substrate is mounted inside a tube. For field sampling, the tubes are stacked, the number depending on the number of species to be analyzed. Airflow pumps are also required in this approach. While this method is more cumbersome than the IBM/Battelle canisters, all the equipment and follow-up chemical analysis can be obtained commercially.

The advantage of these adsorption methods is that the expensive analytical equipment remains in the laboratory. With all these methods, however, the sample integration period is typically days to weeks. The resulting average

concentration provides no information on variations or daily maxima, which may be important for some degradation phenomena, particularly where thresholds are important. If such measurements are required, equipment is commercially available for determining low ppb concentrations of common pollutants like SO<sub>2</sub>, NO<sub>x</sub>, O<sub>3</sub>, and H<sub>2</sub>S, though at a much higher cost than for the absorption methods. Unfortunately, no practical instruments are available for real-time measurements of corrosive chlorine-containing gases at the low ppb level.

### Measurements of Fine and Coarse Particle Concentrations

Because of the health implications of airborne particles, a large number of techniques has been developed in recent years for sampling fine and coarse particles. The most sophisticated, a high-volume cascade impactor, can separate particles into five or more size classifications between about 0.1 and 15 µm. These instruments are labor-intensive and usually provide much finer detail than is needed for evaluating environmental severity with respect to particles.

Two other sampling methods are preferred by the author. The least expensive and simplest to use is a plastic cassette containing filter paper that is connected to a low-volume sampling pump. A convenient filter and cassette size is 37 mm. Both are commercially available. The typical air sampling rate is 1–3 L/min. Particle mass concentration is determined gravimetrically, while composition can be determined by X-ray fluorescence, ion chromatography (preceded by water extraction), or other common laboratory techniques. Commercial analytical laboratories can also perform these techniques. This method provides the volumetric concentration (mass and individual components) of total suspended particulates (usually referred to as TSP). TSP is often sufficient for the experienced evaluator to gage relative corrosivity of all particulates. The disadvantage of this method is that no distinction can be made between fine and coarse particles. As has been discussed, fine particles tend to be the most corrosive, while coarse particles tend to be insulating and abrasive. Knowing the fraction of each and the chemical components of each fraction provides a more accurate assessment of the degradation hazard.

The equipment most commonly used for separating fine and coarse particles is a dichotomous sampler. Again, particles are collected on filter papers and the analysis is accomplished in the same way. The typical sampler operates at high airflow velocity (about 17 L/min, depending on the design) so that sufficient sample can be collected in hours to days, compared to days or weeks for the TSP sampler. The drawback of this method is that the sampling equipment is too large to conveniently ship as an ordinary parcel and requires a trained operator to set it up properly.

# Seawater

David A. Shifler<sup>1</sup> and Denise M. Aylor<sup>1</sup>

## INTRODUCTION

SEAWATER IS AN AGGRESSIVE, complex fluid that affects nearly all common structural materials to some extent [1]. There are two competing processes that operate simultaneously in seawater environments: (1) the chloride ion activity, which tends to destroy the passive film, and (2) dissolved oxygen, which acts to promote and repair the passive film on metallic materials of construction [2]. Metals and alloys that develop protective films by the formation of thin metal oxides can have the formation of passive films delayed or have films destroyed by chloride ions in seawater [3].

The type of corrosion testing required depends on the extent and type of information desired and the environmental conditions expected in service for an alloy component. Seawater corrosion is dependent on a number of factors including, but not limited to, alloy composition, water chemistry, pH, biofouling, microbiological organisms, pollution and contamination, alloy surface films, geometry and surface roughness, galvanic interactions, fluid velocity characteristics and mode, oxygen content, heat transfer rate, temperature, and the environmental zone to which the material is exposed. Understanding how these factors may affect experimental results can help the design of seawater corrosion testing to minimize experimental variations and to best simulate service conditions.

## DESCRIPTION OF THE SEAWATER ENVIRONMENT

### Composition

Seawater, the Earth's most abundant resource, covers 71 % of the Earth's surface. This electrolyte approximates a 3.5 weight percent sodium chloride solution but it is much more complex, containing almost all naturally occurring elements [4,5]. The major chemical constituents of seawater, listed in Table 1, are consistent throughout the world [1]. The minor constituents, including dissolved trace elements and gases, can vary substantially due to seasonal changes, storms, or tidal cycles. Biological organisms, which, combined with the minor constituents, often control

**TABLE 1**—Major seawater constituents at (35 parts per thousand (‰) salinity) and 25°C [1].

Ion or Molecule	Concentration	
	mmol/kg	g/kg
Na <sup>+</sup>	468.5	10.77
K <sup>+</sup>	10.21	0.399
Mg <sup>+2</sup>	53.08	1.290
Ca <sup>+2</sup>	10.28	0.4121
Sr <sup>+2</sup>	0.090	0.0079
Cl <sup>-</sup>	545.9	19.354
Br <sup>-</sup>	0.842	0.0673
F <sup>-</sup>	0.068	0.0013
HCO <sub>3</sub> <sup>-</sup>	2.30	0.140
SO <sub>4</sub> <sup>-2</sup>	28.23	2.712
B(OH) <sub>3</sub>	0.416	0.0257

the rate of the corrosion reactions occurring on metals in seawater [1,5,6]. In addition, the concentration of seawater can vary from full strength ocean water to coastal seawater or brackish conditions. The type of corrosion and the corrosion rate occurring on metals and alloys in seawater are highly dependent on the specific seawater composition, its salinity, and the environmental zone to which the material is exposed.

Seawater is a unique environment that cannot be duplicated in the laboratory. Throughout the world, seawater can vary widely in terms of its specific chemical composition, oxygen content, temperature, salinity, pH, and biological activity. At a given location, seawater is also prone to variations from seasonal influences. All of these variables, combined with the long-term time dependence of many metal reactions, will affect the corrosion occurring on metals and alloys in seawater. In addition, the composition of corrosion products and of calcareous deposits formed under cathodic polarization conditions will influence metal corrosion.

Seawater pH ranges from 7.8–8.3. This narrow pH range is due to reactions that cause the interchange of carbon dioxide in the air with seawater and photosynthesis. Changes in the pH of seawater are buffered by the carbonate system and the presence of undissociated boric acid [7]. The buffering capacity and the constancy of natural waters such as seawater are discussed in Ref 8.

### Environmental Zones

Environmental zones involving seawater include marine atmosphere, splash/spray, tidal, submerged/shallow ocean, deep ocean, and mud. Figure 1 illustrates the relative

<sup>1</sup>Carderock Division, Code 613, Naval Surface Warfare Center, 9500 MacArthur Boulevard, West Bethesda, MD 20817-5700.

FIG. 1—Corrosion profile of steel piling in seawater. Curve (a) represent behavior of uncoated piling; curve (b) represent steel piling corrosion at coating defect coated with organic, insulating substance [15].

corrosion rates of steel pilings in the different environmental zones [9]. The marine environment is generally considered a highly aggressive environment.

**Atmospheric**—Atmospheric corrosion is responsible for a large fraction of the total corrosion in the world. Factors that affect the atmospheric corrosion of materials in a marine environment are the time of wetness, temperature, material, atmospheric contaminants and pollutants, solar radiation, composition of the corrosion products, wind velocity, and biological species [10]. Atmospheric corrosion of a passive alloy tends to be localized. For electrochemical processes related to corrosion to occur, an electrolyte must be present to allow current to pass via diffusion and electrochemical migration of cations and anions. Seawater is a very conductive electrolyte. The severity of corrosion in an atmospheric environment is related to the time of wetness during which electrochemical processes and corrosion take place. There is also a direct relationship between atmospheric salt content and measured corrosion rates [10].

Atmospheric corrosion rates will tend to increase with winds directly from the ocean to the site, the lower the elevation, and the closer the ocean is to the specimen as shown in Table 2. The direction and velocity of the wind can affect the accumulation of entrained seawater-related particles on specimen surfaces. Generally, the closer the site to the ocean in the face of a prevailing wind the greater the corrosion rate of metals and alloys. Magnesium and calcium chlorides are hygroscopic and tend to keep surfaces wet or moist. Sulfur dioxide lowers the critical humidity required to activate corrosion [10] and increases the aggressiveness of the marine atmospheric environment such as found in an industrial marine environment versus a rural marine environment (Table 2). The dew-point temperature and the component/specimen temperature will influence the rate of corrosion.

TABLE 2—Corrosion rates of uncoupled steel panels after two years at different atmospheric test sites.

Location	Distance from Ocean (m)	Steel Corrosion Rate 2-yr. test

(Data compiled from Table 13 [6])

Solar radiation tends to degrade the performance of organic coatings and plastics, and stimulates biological formation and photosensitive electrochemical/corrosion reactions on copper or iron. Ultraviolet radiation can embrittle polymers unless UV stabilizers are added [10].

**Splash/Spray**—The splash/spray zone can be characterized as an aerated seawater environment where exposed metals are almost continually wet and biofouling organisms do not attach [11,12]. In an excessively windy seawater environment, the corrosion of metals can be increased as a result of seawater impinging on their surfaces. The aerated condition of the splash/spray environment is detrimental to many metals such as steel, where its corrosion rate is higher than in any of the other marine environments. This is because dissolved oxygen is easily accessible for electrochemical reactions and chlorides can concentrate during drying of moist films created by spray and condensation [13]. As illustrated by curve (a) in Fig. 1, the most severe corrosion occurs in the splash/spray zone for uncoated steel pilings. The splash/spray environment is also destructive to protective coatings such as organic coatings. Passive film-forming alloys such as stainless steels and titanium have good resistance in this well-aerated environment [12].

**Tidal**—The tidal zone is an environment where metals are alternately submerged in seawater and exposed to the splash/spray zone as the tide fluctuates. In the submerged condition, metals are exposed to well-aerated seawater and biofouling does occur [11,12]. A continuous cover of biofouling organisms protects some metal surfaces such as steel, while the presence of biofouling on stainless steel surfaces can accelerate localized corrosion. Steel is influenced by tidal flow, where increased movement due to tidal action causes an increased steel corrosion rate [12]. Curve (b) in Fig. 1 shows that steel corrosion at exposed coating defect sites is as severe in the tidal zone as it is in the splash/spray zone.

**Submerged/Shallow Ocean**—The submerged/shallow ocean environmental zone usually is characterized by well aerated water combined with marine biofouling organisms of both the plant and animal variety. As in the tidal zone, the

biofouling can either protect the metal surface from attack or can accelerate localized corrosion at the site of the attachment [11,12]. The temperature of the seawater in this environmental zone is dependent on seasonal and specific geographical location but, other than in the polar regions, it is substantially warmer than in the deep ocean environment. The corrosion rate of metals in the shallow ocean varies. Titanium exhibits excellent corrosion resistance in this environment while the corrosion resistance of steel is largely dependent on the availability of oxygen to be transported to cathodic sites on the surfaces [12].

**Deep Ocean**—The deep ocean environment is very different from the ocean at the surface. At sites in the North Atlantic and North Pacific Oceans, oxygen, temperature, and salinity vary with depth. At the ocean surface, the oxygen concentration in the North Pacific is 1.4 times the oxygen content in the North Atlantic. In addition, both the surface temperature and surface salinity are lower in the North Pacific than in the North Atlantic. Below about 1500 m, however, temperature and salinity levels are approximately the same at these two ocean sites [1,6].

The oxygen concentration also varies with seawater depth, as shown in Fig. 2. This figure compares the concentration level with depth at sites in both the North Atlantic and North Pacific Oceans. As the depth is increased to an intermediate level, the oxygen concentration decreases at both sites; however, the reduction in oxygen is much greater in the Pacific Ocean than in the Atlantic. As the depth is then increased even further, the concentration of oxygen increases once again at both ocean sites [6].

As a general rule, the pH varies with the change in dissolved oxygen content. Both variables decrease with depth and reach a minimum value before increasing again (as shown in Fig. 2 for oxygen content). The dissolved oxygen and carbon dioxide concentrations are related to pH in the ocean according to the following reaction [14]:

As organic matter decomposes, the dissolved oxygen content decreases and carbon dioxide is produced. The

FIG. 2—Variation in oxygen concentration with depth at sites in the northwest Atlantic (36°44' N, 64°28' W) and northeast Pacific (38°21' N, 133°38' W) [3].

production of carbon dioxide, a weak acid, results in a pH reduction in seawater. With photosynthesis, the above reaction is reversed [1,6].

Beyond a depth of 18–30 m, plant biofouling ceases due to the lack of solar radiation and any biofouling present is entirely due to animal life sources. In general, the degree of fouling decreases substantially as the depth is increased, an effect which is independent of the distance from the shoreline [12]. On the other hand, at a given depth, as one moves away from the shoreline where breeding of macroorganisms takes place, significantly less fouling on metal surfaces is observed.

**Mud**—The bottom sediments of the ocean comprise the mud zone. Anaerobic sediments contain bacteria that develop gases such as  $\text{NH}_3$ ,  $\text{H}_2\text{S}$ , and  $\text{CH}_4$ . Sulfides present in the mud zone can attack metals such as steels and copper alloys. The corrosion rate of low-carbon steel (as shown in Fig. 1) in this environment is, however, usually lower than that in the other seawater environmental zones described above, predominantly due to the reduced supply of oxygen [12].

## Uniqueness

Seawater is a unique environment. A recent worldwide test program was recently completed by ASTM Task Group G1.09.02.03 to evaluate the corrosivity of seawater at a number of sites [15]. Though these results indicated the uniqueness of natural seawater, corrosivity was site-specific and influenced by numerous factors. Seawater can vary widely in terms of chemical composition, dissolved oxygen content, temperature, salinity, pH, carbonate levels, flow, degree of fouling, biological activity, and pollution [16].

## ENVIRONMENTAL VARIABLES AFFECTING CORROSION RATES IN SEAWATER

### Temperature

As a general rule, the corrosion reaction rate in seawater increases as the temperature is increased. This applies only when the effect of temperature alone is a factor. Other variables such as oxygen concentration, diffusion rates, salinity, calcareous deposit formation, and biological activity vary as a function of temperature and must also be considered as to how it affects the overall corrosion rate of a material, component, or system.

Surface water temperatures vary mainly by latitude, with the temperature ranging from approximately  $-2^\circ\text{C}$  in the Arctic to about  $35^\circ\text{C}$  in the tropics [16]. Table 3 shows the variation of surface temperatures in selected oceans as a function of latitude in the northern and southern hemispheres [6]. The data suggest that for a given latitude, corrosion test results may vary slightly depending on the ocean location chosen. Also, metal corrosion rates are usually higher at the surface where temperatures are warmer than in the deep ocean where the temperatures are colder [6,12]. The effect of temperature as a function of ocean depth for low-carbon steel alloys is presented in Fig. 3.

**TABLE 3**—Average surface temperature (°C) of the oceans as a function of latitude.

North Latitude	Atlantic Ocean	Indian Ocean	Pacific Ocean	South Latitude	Atlantic Ocean	Indian Ocean	Pacific Ocean

NOTE: Data compiled from Ref 6 (original data courtesy of Prentice-Hall Inc. USA).

**FIG. 3**—Corrosion rate of low carbon steels at varying ocean depths [12].

Metal corrosion rates are similar at different locations throughout the world due to a number of controlling factors that compensate for one another [17]. Increasing seawater temperatures increases diffusion rates, but decreases oxygen solubility. Though increasing temperatures do tend to increase corrosion rates, rising temperatures also promote the formation of calcareous deposits [6,12] and microbiological colonization, which form barrier layers that often throttle corrosion attack [17]. Bacteria may participate in anaerobic corrosion reactions that replace the cathodic, oxygen reduction reaction.

Temperature variations due to seasonal changes may also affect corrosion rates in seawater. For many copper and iron alloys, the corrosion rates increase during the warmer months of the year. The start of the corrosion test, therefore, may be affected by the time that a corrosion test is initiated, and there is a tendency for corrosion rates to slow down with increased times of exposure to the natural seawater environment, depending on the actual environmental zone.

However, some of the highest corrosion rates in the world are found in cold weather climates. Corrosion rates in Alaska are reported to be twice as high as those in the North Sea and six times greater than the rates reported in the Gulf of Mexico. The high corrosion rates are caused by the high dissolved oxygen levels, abrasion from glacial silts, tidal changes of over 30 ft (9.1 m), and the action of ice floes in winter [18]. Corrosion rates on steel in the splash zones on docks in the Aleutians are estimated to be as high as 30–35 mpy (761–889  $\mu\text{m/y}$ ) [19].

## Dissolved Oxygen

Dissolved oxygen in seawater has a major influence on corrosivity since oxygen is the principal reactant involved in the cathodic reaction and is involved in the passivation reactions that occur for most metals and alloys in seawater. The solubility of oxygen decreases as the temperature is increased. The oxygen content in surface seawater can be as high as 11–12 ppm in the Arctic as compared to 6 ppm in the tropics. Oxygen solubility in surface seawater can become supersaturated by as much as 200 % of its equilibrium concentration due to photosynthesis by marine plants and by wave action [16]. Conversely, the dissolved oxygen concentration can decrease and become undersaturated due to oxygen consumption created by the decomposition of organic matter.

The combined influence of these natural cycles on the dissolved oxygen content can vary as a function of seasonal changes and the ocean depth at any given location [12]. Oxygen solubility in seawater goes through a minimum at intermediate ocean depths: the depth of minimum oxygen solubility ranges from 400 m in the equatorial Eastern Pacific to 2400 m in the Central Pacific Ocean. The minimum oxygen concentration at these ocean depths ranges from 0.16–6.4 ppm [6].

Seawater temperature and salinity also affect the dissolved oxygen content, with temperature having the larger influence on the oxygen solubility. The general rule is that as either the temperature or the salinity is decreased, the dissolved oxygen content increases [1,6]. The equilibrium concentration of dissolved oxygen in seawater as a function of salinity and temperature is shown in Table 4 [6].

The effect of the dissolved oxygen level on corrosion is dependent on the metal. For metals that form passive films like stainless steel and aluminum, a high oxygen content is favorable in that it helps to delay the initiation of pitting on

**TABLE 4**—Equilibrium concentration of oxygen in seawater as a function of temperature and salinity.<sup>a</sup>

Temperature (°C)	Salinity (ppt)					
	0	8	16	24	31	36

<sup>a</sup> Calculated based on data from Ref 6.

the metal surface. However, once pitting is initiated, the propagation rate is increased with high oxygen content in the seawater. For common steels and copper alloys, the effect of dissolved oxygen is dependent on the seawater flow velocity. The oxygen concentration has a negligible effect on copper alloy corrosion rates in quiescent seawater while at a seawater flow rate of 1.8 m/sec, an increasing oxygen content accelerates the copper corrosion rate. For metals such as iron and steel, the corrosion rate increases linearly with a rising oxygen concentration at a constant temperature [12,20].

Oxygen concentration cells can be created from deposits on a metal's surface or may be due to improper component design, which introduces crevices. Differences in oxygen content due to discrete films or deposits randomly scattered along a metal surface can cause pitting and/or crevice corrosion at these localized sites. In contrast, complete coverage of a surface by a film or a deposit can provide an effective barrier and reduce corrosion of the metal [6,21].

### Salinity

Salinity is defined as the total weight of solids dissolved in 1000 g of water. For example, 35 parts per thousand (‰) salinity is equivalent to 35 g of solids dissolved in 1000 grams of water or a dissolved matter content of 35 000 ppm [12]. Salinity usually is determined by measuring chlorinity and then deriving the salinity from the following relation:

$$S = 1.80655 Cl$$

where *S* (salinity) and *Cl* (chlorinity) are measured in parts per thousand [1,6].

The salinity of open ocean water at the surface typically varies from 32–37.5 ‰. Generally, this degree of variation does not alter metal corrosion rates. Some of the more isolated seas, such as those shown in Table 5, can have large variations in salinity, which may influence metal corrosion rates. Salinity variations can affect a metal's uniform corrosion rate. For example, in areas where there are high evaporation rates, the salinity can be very high. Conversely, at the mouth of a river, the salinity is more dilute than in the open ocean.

Variations in salinity can also alter the localized corrosion resistance of metals in seawater. As the salinity is increased, the chloride ion activity increases and can result in increased pit and crevice corrosion initiation and propagation [6].

### pH and Carbonates

The pH of open ocean water varies from approximately 7.5–8.3 and is buffered by a complex carbonate system. This

variation in pH does not affect the corrosion of most metals, except for aluminum. As the pH decreases from 8.2 at the surface to 7.5–7.7 in deep water, the initiation of pitting and crevice corrosion in aluminum alloys is accelerated [1,6].

Depending on various conditions, calcareous deposits form when the solubility of calcium and magnesium ions is exceeded. Calcareous deposits form at pH levels between 8 and 10 and consist mainly of  $\text{CaCO}_3$ ,  $\text{MgCO}_3$ , and  $\text{Mg}(\text{OH})_2$  [12]. Although changes in pH do not directly alter the corrosion behavior of most metals, pH variations can influence the formation of protective calcareous scales that subsequently can affect the corrosion rate of the substrate alloy. Spontaneous calcareous deposits are more likely to occur at higher pH values, but the function of these deposits is limited due to the presence of organic matter and seawater salinity [16].

At the surface, the ocean waters throughout most of the world are 200–500 % supersaturated in calcium carbonates and precipitation of these carbonate scales will influence the corrosion reaction occurring at the metal surface [6]. The buildup of protective calcareous deposits by cathodic protection can lower the subsequent current demand in natural seawater [22–24].

Dilute seawater is undersaturated in carbonates, which reduces the likelihood of forming protective calcareous films on a metal surface. In deep ocean waters, the calcareous deposits are not spontaneously formed in an ambient environment and are often not precipitated under cathodic protection conditions [6]. In the cold waters of the deep ocean environmental zones, the precipitation and/or dissolution of the calcareous deposits is mainly controlled by the calcium carbonate saturation level,  $\Omega$  [25].

$$\Omega = \frac{[\text{Ca}^{+2}][\text{CO}_3^{-2}]}{K'_{\text{sp}}}$$

where  $[\text{Ca}^{+2}]$ ,  $[\text{CO}_3^{-2}]$  = calcium, carbonate measure concentrations, respectively,  $K'_{\text{sp}}$  = apparent solubility product, and  $\Omega$  is the calcium carbonate saturation value. The calcareous deposits formed by cathodic protection will be stable when the degree of saturation is  $\Omega > 0.6$  as in most ocean areas down to depths of 3000 m [25]. However, at depths greater than 3000 m, the calcium carbonate formation may be unstable. At  $\Omega = 0.6$ , the dissolution rate of calcium carbonate may be at around 1  $\mu\text{m}/\text{y}$ .

### Biological Organisms

Seawater is a living medium sustaining a wide variety of organisms [26]. Marine biological organisms consist of either micro (bacterial) or macro (algae, barnacles) speciation. These organisms can affect the corrosion behavior of metals and alloys in a number of ways including: (a) influencing either or both the prevailing anodic and cathodic reactions, (b) influencing the formation and/or maintenance of protective films, (c) producing deposits on metal surfaces, and (d) creating a corrosive environment. The factors listed above can act singly or combine with one or more sources to alter a metal's corrosion behavior [21].

One of the keys to alternating conditions at the metallic surface, and the subsequent delay or acceleration of corrosion, is the formation of a biofilm. The exact sequence of

**TABLE 5**—Total solids in different seawater locations.

Body of Water	Total Dissolved Solids, ppm
Baltic Sea	8000
Caspian Sea	13 000
Black Sea	22 000
Irish Sea	32 500
Atlantic Ocean	37 000
Mediterranean Sea	41 000
Arabian Sea	39 000–47 000
(Doha, Kuwait)	
Dead Sea	260 000

events leading to biofilm formation depends on the environment and the organisms present [26]. Biological organisms attach and multiply on any solid surface in seawater. Within two hours of immersion, a non-living organic conditioning film develops on a solid surface. Within the first 1–2 days, a bacterial slime film develops over the conditioning film. The slime film creates a partial barrier to diffusion between the liquid/metal interface and the bulk seawater environment. These slime films are usually not continuous and can create oxygen or chemical concentration cells on the metal surface, which can result in accelerated localized corrosion.

Biofilms are structured, but complex assemblages of microorganisms embedded in exopolymers (extracellular material produced by microorganisms that define their shape, their ability to adhere to solid surfaces, and their ability to trap particulate nutrients) [26]. Biofilms include communities of colonies, consortia, newly created cells, dying cells, extracellular products, polymers, and trapped inorganic material. Biofilms and individual organisms that are contained within the biofilm interact with external influences originating from the substratum and the bulk medium to cause oxygen or chemical concentration gradients and other localized effects related to mitigating or accelerating corrosion [26,27].

Ammonia and sulfides can also be produced from the decay of organic matter within the slime film, resulting in increased corrosion of some alloys [28]. Sulfur-oxidizing organisms produce sulfuric acid from sulfur or other reduced sulfur species [28]. The presence of ammonia is known to cause stress corrosion cracking of copper alloys, while sulfides may lead to accelerated attack on copper alloys and steel. The presence of the slime film on the metal surface can locally change the local environment at the liquid/metal interface such that the corrosion behavior of a metal can be considerably altered from one that normally displays low corrosion rates in seawater to conditions where corrosion is accelerated [6].

The reduction or complete elimination of marine organisms in dilute seawater reduces the probability of forming protective biofilms and could result in increased metal corrosion [12].

Macrofouling films begin to develop over the conditioning and slime films within 2–3 days after immersion in seawater [6]. If the macrofouling is continuous along the solid surface, the film can decrease the amount of dissolved oxygen present at the surface and thus decrease the overall metal corrosion rate. If, however, the macrofouling is discontinuous, the film acts in the same manner as discontinuous slime films where oxygen or chemical concentration cells can be formed and result in localized corrosion of the metal [6].

The macrofouling organisms attach in embryonic form to the slimed solid surfaces. Once attached, they metamorphose and mature. The most common sessile fouling organisms in seawater include: (a) organisms with hard shells, annelids, barnacles, encrusting bryzoa, mollusks, and corals, and (b) organisms without hard shells: marine algae, filamentous bryzoa, coelenterates or hydroids, tunicates, and calcareous and siliceous sponges [12]. The accumulation of these biological organisms is dependent on specific environmental conditions. Conditions which are most conducive

to their development are: (a) relatively shallow water such as in a harbor, (b) warm temperatures, (c) low seawater flow, and (d) smooth, hard surfaces [21].

Both macro and microfouling can have a major impact on the performance of marine components [6,12,21]. Macro and microfouling organisms can break down protective paint films on a component surface. On ship hulls, these organisms increase drag and power requirements. In heat exchangers, fouling limits the heat transfer and seawater flow, and severe fouling can result in complete blockage [21]. Fouling also shields the component surface from any oxygen supply thereby creating the possibilities that differential aeration cells can develop. Fouling can cause catalytic effects [7]. Fouling, in addition to causing drag or blockage, can cause localized turbulence. Plant decay or secretion products from animal life can accelerate corrosion processes [7].

### Velocity of Seawater

Fluid velocity can significantly affect metal corrosion rates in seawater. Flow-assisted corrosion is dependent on variables such as water chemistry, pH, component geometry, surface roughness, biofouling, microbiologically influenced corrosion, pitting and crevice corrosion, water pollution and contamination, alloy composition and surface films, galvanic interaction, fluid velocity and mode, oxygen content, heat transfer rate, and temperature [29].

Corrosion rates and the type of corrosion are often dependent on environmental factors such as fluid flow and the availability of appropriate species required to drive electrochemical reactions [30]. A change in the motion of a corroding metal or alloy relative to its environment by fluid flow can increase corrosion rates by removing protective films or by increasing the diffusion or migration of deleterious species. However, an increase in fluid flow can decrease corrosion rates by eliminating aggressive ion concentration or enhancing passivation or inhibition by transporting the protective species to the fluid/metal interface [21].

Under high flow conditions, corrosion may take the form of impingement, erosion corrosion, or cavitation [12]. In any given velocity domain, different local velocities may exist over diverse areas of the component due to factors such as geometry or mode of fabrication [2]. The effect of seawater velocity on a metal's corrosion rate varies with the particular alloy. Alloys such as 304 and 316 stainless steel or nickel-chromium-molybdenum alloys exhibit deep pitting in low flow conditions, yet at high seawater velocities their corrosion rate decreases to less than 25  $\mu\text{m}$  per year. Contrary to this, iron and copper show significantly lower corrosion rates at low flow velocities than under high seawater flow conditions [31]. The corrosion rates for various metals as a function of seawater velocity are included in Fig. 4.

Seawater velocity for immersed samples may decrease to a lower magnitude as the seawater depth is increased; this decrease typically begins at depths of 18–30 m. Lack of flow can exacerbate crevice corrosion, which takes place with passive oxide film formers such as stainless steels where occluded, stagnant areas become oxygen-deficient anodic sites as compared to outer cathodic, oxygenated regions [21,32].

FIG. 4—Corrosion rate of metals and alloys in seawater as a function of flow velocity (Source: LaQue Center for Corrosion Technology). denotes critical range.

Removal of the corrosion product or oxide layer by excessive flow velocities leads to increased corrosion rates of the metallic material. Corrosion rates are often dependent on fluid flow and the availability of appropriate species required to drive electrochemical reactions. Surface shear stress is a measure of the force applied by fluid flow to the corrosion product film. For seawater, this takes into account changes in seawater density and kinematic viscosity with temperature and salinity [33]. Accelerated corrosion of copper-based alloys under velocity conditions occurs when the shear surface stress exceeds the binding force of the corrosion product film. Alloying elements such as chromium improve the adherence of the corrosion product film on copper alloys in seawater based on measurements of the surface shear stress. The critical shear stress for C72200 ( $297 \text{ N/m}^2$ ,  $6.2 \text{ lb}_f/\text{ft}^2$ ) far exceeds the critical shear stresses of both C70600 ( $43 \text{ N/m}^2$ ,  $0.9 \text{ lb}_f/\text{ft}^2$ ) and C71500 ( $48 \text{ N/m}^2$ ,  $1.0 \text{ lb}_f/\text{ft}^2$ ) copper-nickel alloys [33].

Alloys such as 304 and 316 stainless steel or nickel-chromium alloys exhibit deep pitting in low flow conditions, yet at high seawater velocities their corrosion rate decreases to less than  $25 \mu\text{m}$  per year. Contrary to this, iron and copper show significantly lower corrosion rates at low flow velocities than under high seawater flow conditions [31].

Seawater turbulence can substantially alter the flow rates and subsequent corrosion rate of metals. Consider, for example, a seawater piping system that operates at a  $1.8 \text{ m/sec}$  velocity. Increases of pipe diameter will increase the thickness of the velocity boundary layer and the diffusion boundary layer. The thicker velocity boundary layer leads to a decreased velocity gradient and reduced shear stresses at the piping wall. For design purposes, a single velocity value marking the initiation of erosion corrosion can provide misleading service life prediction [29]. Factors that affect erosion in pipe bends include the degree of internal ellipticity and asymmetry, sudden changes in cross section, and a reduction in cross-sectional area [34]. As the radii of directional change are reduced, the erosion corrosion rates are expected to increase. Ledges, crevices, deposits, and other obstructions disturb laminar flow and result in turbulence

at sometimes significant velocities [21]. In a turbulent area such as downstream of a valve, velocities far exceeding the  $1.8 \text{ m/sec}$  nominal velocity may occur and cause accelerated corrosion of the metal. In testing piping systems, turbulent areas should be accounted for and mitigated by choosing appropriate erosion and cavitation-resistant materials [31] and by implementing a proper design [35].

## Sulfides

Sulfides, sulfur, and other sulfur compounds can produce pitting, crevice corrosion, dealloying, stress corrosion cracking, and stress-assisted hydrogen induced cracking of susceptible metals and alloys [28]. Polluted waters, like those found in coastal harbors and estuaries, contain hydrogen sulfide and sulfur-containing compounds. Sulfides can be generated in several ways: (1) bacterial reduction of naturally occurring sulfates in seawater; (2) rotting vegetation; and (3) industrial waste discharge [29]. Hydrogen sulfides are known to adversely affect the corrosion rate of various metals and alloys. Sulfates themselves are not usually harmful; however, sulfates can be reduced to harmful sulfides by sulfate-reducing bacteria. These sulfide pollutants can contribute to the corrosion of steels, stainless steels, copper, and aluminum alloys [6].

Sulfide corrosion has been found to occur on a number of different copper-base alloys. Wrought 90/10 copper-nickel can exhibit sulfide-induced attack in the form of accelerated pitting with as little as  $0.01 \text{ ppm}$  sulfide concentration while 70/30 copper-nickel is susceptible at sulfide concentrations of  $0.05 \text{ ppm}$  or greater [36]. The presence of sulfide-modified films interferes with the formation of normal passivating films of copper nickel alloys found in unpolluted waters [37,38]. Sulfide-modified films generally are more loosely adherent than the normal cuprous oxide films; turbulence tends to selectively remove the sulfide-modified films. The accelerated corrosion rates of copper-nickel alloys in aerated sulfide-containing seawater remain high since the sulfides prevent protective corrosion product layers from forming [39].

A number of variables contributing to sulfide-influenced corrosion include duration of sulfide exposure, system operating velocity, and degree of turbulence must be assessed in conjunction with the sulfide concentration in order to accurately predict the sulfide susceptibility of copper-nickel alloys. Other research [12] on copper-base alloys has found that  $3\text{-ppm}$  hydrogen sulfide significantly increases the corrosion rates of several copper alloys as indicated in Table 5.

## Heavy Metals

Concentrations of copper in seawater can cause accelerated corrosion of metallic components. In unpolluted seawater, the copper concentration is  $0.2 \text{ ppb}$ , which is typically not high enough to influence a metal's corrosion behavior. If, however, the copper concentration is increased above approximately  $30 \text{ ppb}$ , corrosion of aluminum alloys can occur. The copper concentration may be increased due to a number of factors including copper leaching from anti-fouling paints, pollutants containing copper, or nearby copper alloy corrosion. If the copper deposits onto aluminum

**TABLE 6**—Corrosion of copper-base alloys in clean and polluted seawater [12].

Seawater Velocity, 7.5 fps (2.3 m/sec), Test Duration, 64 Days			
		Corrosion Rate, mpy (mm/yr)	
Alloy	CDA No.	Clean Seawater	Seawater (3 ppm H <sub>2</sub> S)
90/10 Cu-Ni	706	3 (0.08)	34 (0.86)
70/30 Cu-Ni	715	5 (0.13)	26 (0.66)
2% Al Brass	687	3 (0.08)	22 (0.56)
6% Al Brass	608	5 (0.13)	21 (0.53)

Phosphor Copper	122	14 (0.36)	105 (2.67)

alloy surfaces, a galvanic couple is formed, resulting in localized pitting of the aluminum [6].

The corrosion products generated from iron and steel have also been known to cause corrosion of aluminum alloys in desalination plants. However, the iron contamination effects are less and are not as consistent as for copper [6].

## CORROSION MECHANISMS

Seawater is an aggressive, complex aqueous medium that has unique properties that affect most common structural materials somewhat differently than in most other natural media. As stated earlier, two competing processes operate simultaneously in seawater environments: (1) the chlorinity in seawater tends to destroy alloy passive films, while (2) dissolved oxygen acts to promote and repair passive films on metallic materials [2]. Though oxygen is the reactant involved in the major cathodic (oxygen reduction) reaction that occurs in seawater, species such as hydrogen (involved with cathodic protection applications), sulfates, nitrates, or ammonium compounds (related to with reactions via bacteria or other microorganisms in polluted waters) can be involved in other cathodic reactions in seawater. Seawater is also a very conductive medium due to its inherent electrolyte content leading to reactions detrimental to alloy performance.

Corrosion can occur by numerous pathways. Fontana [40] lists eight forms of corrosion: (1) uniform corrosion, (2) pitting, (3) crevice corrosion, (4) galvanic corrosion, (5) intergranular corrosion, (6) selective leaching or dealloying, (7) erosion corrosion, and (8) stress corrosion. Some of these "classic" forms of corrosion are somewhat simplistic and are discussed in more detail [41]. Some additional background information on these corrosion mechanisms is discussed in Section IV: Testing for Corrosion Types.

Uniform corrosion is characterized by an electrochemical/corrosion reaction that proceeds over an entire surface area. This form of corrosion can be measured easily and is conducive to prediction of component failure.

Pitting is a mode of localized dissolution leading to the formation of cavities within a passivated surface that is boldly exposed [41]. Pitting is a probabilistic or stochastic corrosion mechanism that is dependent on electrochemical

potential, alloy chemical composition and microstructure, electrolyte composition, and temperature [41]. Natural seawater, with a relatively high concentration of chlorides, contributes to the development of pitting of passive alloys such as stainless steels.

Pitting corrosion usually initiates at surface inhomogeneities such as intermetallic phases, nonmetallic inclusions, grain boundaries, dislocations, defects, or mechanically damaged sites [41]. At low potentials, pitting is followed by repassivation; this is termed metastable pitting. Above a certain potential or potential range, a transition from metastable pitting to stable pitting formation occurs. If the environmental conditions do not change in the anodic pit site(s), the pit continues to grow due to, in part, the large cathode (where oxygen reduction occurs) to anode ratio over the specimen or component surface.

Crevice corrosion is localized corrosion that occurs within crevices or at shielded surfaces where a stagnant solution exists. To develop as a corrosion site, a crevice must be wide enough to permit entry of a corrodent, but sufficiently narrow to cause and maintain a stagnation environment. Crevices can be formed at metal-metal or nonmetal-metal junctions or at holidays that form in coatings on metals or alloys. The parameters leading to crevice geometries that will cause crevice corrosion of an alloy are difficult to quantify [40]. Like pitting, crevice corrosion involves both initiation and propagation processes. During the initiation stage, discrete areas develop within the crevice [42,43]. In a creviced site exposed to a seawater environment, the crevice becomes oxygen-deficient. The increasing concentration of metal cations causes an associated migration and build-up of chloride ions within the crevice in order to maintain electroneutrality. Metal chlorides are then hydrolyzed by water to form an insoluble metal hydroxide and free acid (in the case of chloride environments, HCl) thus creating overall acidification of the crevice site. The loss of oxygen, chloride ion buildup, acidification, and a large IR drop between the boldly exposed cathodic sites outside of the crevice and the anodic crevice propagate crevice corrosion [44].

Under-deposit attack or "poultice" corrosion may occur when a metal is locally covered by foreign, absorbent (organic or inorganic) materials [40,45]. In this case, attack can proceed even when the bulk of the system is dry due to retention of moisture in the poultice. The corrosion mechanism is similar to crevice corrosion in that the deposits act to limit the migration of oxygen to the covered area. This leads to acidic shifts in pH, concentration of Cl<sup>-</sup> ions in the shielded area, and a shift to a more active corrosion potential under the deposit. Local corrosion rates can be very high due to the large cathode-to-anode area ratio.

The coupling of dissimilar alloys in conductive, corrosive solutions such as seawater is called galvanic corrosion and can lead to accelerated corrosion of the more anodic, electronegative alloy and protection of the more cathodic, electropositive alloy. The extent of galvanic corrosion depends on factors such as: (1) the effective area ratio between the anodic and cathodic members of the couple; (2) solution conductivity; (3) flow characteristics of the solution; (4) temperature; (5) system geometry; (6) the potential difference of the dissimilar alloys; (7) solution composition and

environment; and (8) the cathodic efficiency of the more noble metal or alloy [46–48]. Galvanic corrosion and erosion corrosion can synergistically attack the passive films of susceptible alloys. Galvanic action between dissimilar metals can destroy the passive film of the more anodic member exposing the bared substrate to possible erosion corrosion. The removal of the protective films on copper-nickel alloys by flow may promote dissolution of the bare, exposed areas by galvanic interaction with the surrounding surfaces covered by corrosion product scales.

Under certain conditions, grain boundary interfaces are very reactive, causing intergranular corrosion. Intergranular corrosion can be caused by impurities at the grain boundaries, or enrichment or depletion of one of the alloying elements in the grain boundary region [40]. Iron segregation at the grain boundaries of aluminum alloys can initiate intergranular corrosion. Depletion of chromium in sensitized, unstabilized, austenitic stainless steels are susceptible to intergranular corrosion [40]. A form of intergranular corrosion called knife-line attack may occur on welded, stabilized austenitic stainless steels if proper post-weld heat treatment is not implemented [40].

Selective leaching or dealloying is the selective removal of one element from an alloy by corrosion processes. The most common example is the selective removal (dezincification) of zinc in brass alloys. Dezincification may either be plug-type or uniform. In other alloy systems, aluminum, iron, cobalt, nickel, chromium, and other elements may be selectively removed [49]. Little work has been done in differentiating susceptibility of selective leaching of alloys in synthetic and natural seawater [6].

A change in the motion of a corroding metal or alloy relative to its environment by fluid flow can increase corrosion rates by removing protective films or by increasing the diffusion or migration of deleterious species. An increase in fluid flow can also decrease corrosion rates by eliminating aggressive ion concentration or enhancing passivation or inhibition by transporting the protective species to the fluid/metal interface. Accelerated corrosion due to flow has been termed flow-assisted, flow-influenced, flow-induced, or flow-accelerated corrosion. There are several mechanisms described by the conjoint action of flow and corrosion that result in flow-influenced corrosion: (1) mass transport-controlled corrosion; (2) phase transport-controlled corrosion; (3) erosion corrosion; and (4) cavitation [50].

Mass transport-controlled corrosion implies that the rate of corrosion is dependent on the convective mass transfer processes at the metal/fluid interface. Mass transfer can have a significant effect on corrosion rates of metals and alloys depending on factors such as bulk solution chemistry, temperature, flow conditions, surface roughness, and geometry.

Phase transport-controlled corrosion suggests that the wetting of the metal surface by a corrosive phase is flow-dependent. This may occur because one liquid phase separates from another or because a second phase forms from a liquid. The distribution and morphology of the corrosive attack will be related to the distribution of the corrosive phase; the corroded sites will frequently display rough, irregular surfaces and be coated with or contain thick, porous corrosion deposits [29].

Erosion corrosion is associated with a flow-induced mechanical removal of the protective surface film that results in subsequent corrosion rate increases via either electrochemical or chemical processes. It is often accepted that a critical fluid velocity must be exceeded for a given material. The mechanical damage by the impacting fluid imposes disruptive shear stresses or pressure variations on the material surface and/or the protective surface film. Erosion corrosion may be enhanced by particles (solids or gas bubbles) and impacted by multi-phase flows [29]. Increased flow stream velocities and increases of particle size, sharpness, density, and concentration increase the erosion corrosion rate. Increases in fluid viscosity, density, target material hardness, and/or pipe diameter tend to decrease the corrosion rate. The morphology of surfaces affected by erosion corrosion may be in the form of shallow pits or horseshoes or other local phenomena related to the flow direction.

Factors that affect erosion in pipe bends include the degree of internal ellipticity and asymmetry discussed earlier, sudden changes in cross section, and reduction in cross-sectional area [51]. As the radii of directional change are reduced, the erosion corrosion rate is expected to increase. Ledges, crevices, deposits, and other obstructions disturb laminar flow and result in turbulence at significant velocities [40]. Short distances less than 10 diameters after directional changes or obstructions do not allow turbulence to dissipate [52].

Cavitation sometimes is considered a special case of erosion corrosion and is caused by the formation [53] and collapse of vapor bubbles in a liquid near a metal surface. Cavitation is a process by which a liquid is ruptured by decreasing the pressure at roughly constant liquid temperature. Cavitation removes protective surface scales by the implosion of gas bubbles in a fluid; calculations have shown that the implosions produce shock waves with pressures approaching 60 ksi [40]. Cavitation damage often appears as a collection of closely-spaced, sharp-edged pits or craters on the surface. It has been suggested [54] that the corrosion rate by cavitation can be influenced by surface roughness that permits a large number of nuclei for bubble formation. Under this condition, the concentration of deleterious ions in solution next to the metal surface will be greater, and the observed corrosion damage indicates that the steam bubbles may provide crevices or enhanced possibilities for dissolution at the solution/metal/steam interface.

Environmental cracking can take several forms: (1) stress corrosion cracking, (2) corrosion fatigue, and (3) hydrogen embrittlement. Stress corrosion cracking is caused by the presence of a tensile stress and a specific corrosion medium to a susceptible alloy. Failures from corrosion fatigue of alloys occur with time after the application of repeated cyclic stresses below the yield stress in a corrosive environment. It is generally considered that steels stressed below a fatigue limiting stress will endure an infinite number of cycles without fracture in non-corrosive environments [40]. Corrosion fatigue is influenced by the corrosive medium, pH, temperature, oxygen content, and the presence of any contaminants. In seawater, aluminum bronzes and austenitic stainless steels retain about 70 and 80 % of the normal fatigue resistance while high-chromium alloys retain only 30–40 % of normal fatigue resistance [40].

Hydrogen embrittlement lowers the yield stress and the ultimate tensile stress of a metal or alloy due to the diffusion of atomic hydrogen into susceptible alloys. This may occur in seawater for high-strength steels subjected to overprotection from cathodic protection systems. The term hydrogen embrittlement is used to characterize the near room temperature effects of hydrogen on materials. Among these effects are loss of ductility, loss of load carrying capability, delayed cracking, and loss of true stress at fracture. Although there is an incomplete understanding of the mechanisms of hydrogen related failures, the evidence indicates there is no single dominant mechanism operative over a broad range of materials. This may be mitigated if calcareous deposits have formed on alloy surfaces that can act as barriers to hydrogen permeation.

More recently, attention has been directed to the "ninth" form of corrosion, biologically influenced corrosion, which includes studies on an area referred to as "ennoblement." The presence of biofilms on metals and alloys immersed in natural seawater produces a complex, heterogeneous chemistry along the metallic surface. It has usually been observed that passive alloys such as aluminum, stainless steels, nickel-base alloys, or titanium show an increase to more noble (electropositive) potentials or ennoblement of several hundred millivolts with exposure time in natural seawater, thus magnifying the potential differences that may exist between dissimilar alloys [26,55–64]. Ennoblement is likely caused by the formation of microbiological films, which increase the kinetics of the cathodic reaction [55–63].

The ennoblement of these passive alloys by biofilms has been attributed to increasing the kinetics of the oxygen reduction reaction, or by the introduction of alternative redox reactions such as peroxide production or heavy metal (Mn or Fe) reduction [60]. The ennoblement caused by the influence of cathodic reactions occurring on these passive alloys results in increasing the initiation and propagation of crevice corrosion [26,61], pitting [61], and galvanic corrosion [63,64].

Figure 5 illustrates that the ennoblement of Alloy 625 occurred between 37 and 51 days of exposure to flowing natural seawater [64]. This ennoblement of Alloy 625 increased the driving force for increased galvanic corrosion of the

70/30 copper-nickel pipe [64]. Continued buildup of the microbiological film thickness gradually decreased the potential difference between the Alloy 625 and the copper-nickel alloy [64].

## CORROSION TESTING

Corrosion testing is important in evaluating materials in seawater and related marine environments. Tests can ascertain the performance of different materials, measure the degradation processes, and evaluate alternative materials and designs that optimize service life for given marine environments. Marine environments may include high temperature oxidizing or reducing conditions found in marine gas turbines or waste incinerators; testing may also be done in the marine environmental zones discussed earlier. Although most details are discussed in the chapter on High Temperature Gases, high temperature testing for marine applications must consider the presence of seawater salts contained in the air intake of the turbines or waste incinerators since such electrolytes enhance the high temperature corrosion processes of hot corrosion, sulfidation, and carburization.

Testing should be properly planned as discussed in Planning and Design of Tests. Tests should be relevant and correlate with actual field use. Accelerated tests often provide useful information, but degradation processes in such tests may not reflect the actual corrosion mechanisms by which the materials naturally deteriorate. Testing may require laboratory, field, simulated service evaluations, or a combination of the tests. Specific test methods are discussed in the following sections.

Before testing components in most practical applications, one should be knowledgeable of the corrosion properties of possible candidate materials, have an idea of the type and complexity of testing desired, and have a sufficient level of experience to comprehend possible materials interactions that a component may have with other material components and be able to interpret and translate the test results into the requirements of the service application [6].

The objective for performing a corrosion test should be identified during the initial phase of designing the testing procedure. The test conditions including specimen size, test environment vs. service environment, geometry, sample preparation, temperature, flow velocity, potential, and type of corrosion test (general, crevice, pitting resistance, galvanic, stress-related, dealloying, etc.) should be considered.

## Laboratory Evaluation

The corrosion behavior of metals or coatings is often evaluated in the laboratory rather than in an actual service environment due to time and/or budget limitations. Laboratory evaluation is generally of relatively short duration and is often used to study environmental effects on a metal's corrosion behavior because the specific environmental conditions can be controlled. The major disadvantage of testing in the laboratory is that the actual service environment and conditions may not be evaluated. Service conditions are being simulated, which involves accepting certain

FIG. 5—Alloy 625/70:30 Copper-Nickel Piping Couple. Potential profile shown as a function of time and location along the pipe (junction between the dissimilar alloys is located 10 ft (3 m) from inlet).

assumptions. It is important when testing in the laboratory to correlate field data with laboratory data so that the validity of the laboratory information can be assessed [65].

Natural seawater is the preferred environment for laboratory testing, but synthetic seawater solutions are often utilized. The term natural seawater refers to fresh seawater that is pumped directly into the laboratory, rather than seawater that has been stored and possibly shipped to an onshore location for the testing. Once seawater is removed from its natural environment, its composition changes and this can have a large impact on the resultant metal corrosion rate. Synthetic seawater solutions that are typically used include 3.5-weight percent sodium chloride (NaCl) and substitute ocean water per ASTM D1141 [66]. The substitute ocean water can be used either with or without heavy metals added according to the ASTM D1141 specification [66]. Both 3.5 % NaCl and substitute ocean water solutions do not contain the same organic and biological components as natural seawater. Substituting ocean water with heavy metals most nearly approximates the actual composition of natural seawater. The disadvantage in using any of the synthetic solutions is that, like the stored natural seawater, the composition varies from that of fresh, natural seawater and thus the corrosion behavior of the metals evaluated can be considerably affected. However, one advantage of using 3.5 % NaCl is that calcareous deposits will not form under cathodic polarization conditions in this solution. This is extremely useful in fracture surface evaluation of metal specimens, where the presence of calcareous deposits often prohibits examination of the surfaces unless the deposits are dissolved or mechanically removed, which could alter the original fracture surface.

### Immersion Testing

Immersion testing is usually performed on panel specimens or small component parts such as fasteners. Specimens are exposed to the seawater environment in fully immersed, partially immersed, or alternately wetted and dried in a cyclic pattern. Sample weight loss, physical surface changes, visually assessed modifications, as well as surface compositional changes can be documented. For example, long-term uniform corrosion testing is usually performed in test racks or in test loops. Immersion testing is useful to examine different variables such as environmental compositions, alloying elements, coating type, surface condition, controlled defects, etc. Immersion testing may be done in either natural or synthetic seawater. Natural seawater for laboratory immersion testing is often filtered to prevent macrofouling on the specimen surfaces. The filtering can be accomplished by passing seawater through a sequence of coarse to fine filters, with final filtering through 5–10  $\mu\text{m}$  pore size filter cartridges. Stagnant natural seawater solutions are not recommended for testing due to decay of the marine biological organisms, which will alter the seawater composition and can affect the resultant corrosion behavior [67].

### Salt Spray/Salt Fog Testing

Salt spray (fog) testing is an accelerated laboratory method for assessing the corrosion behavior of coated and

uncoated metals. The generally accepted methods in the United States for salt spray testing are discussed in ASTM B117 (Method of Salt Spray (Fog) Testing), ASTM G85 (Practice for Modified Salt Spray (Fog) Testing) and GM9540P [68]. These tests have been successfully used to screen both coated and uncoated metals and to evaluate coating performance, particularly in terms of thickness uniformity and porosity. Cyclically acidified salt spray tests have also been used to determine the exfoliation corrosion resistance of aluminum alloys [69].

Outdoor corrosion is influenced by a number of factors, including corrosive atmospheres, UV light, wet/dry cycling, and temperature cycling that can occur to varying degrees in environmental zones discussed earlier. ASTM D5894 (Cyclic Salt Fog/UV Exposure of Painted Metals) alternatively exposes samples to UV light with ASTM G85 salt fog exposures. Although salt spray testing is commonly used as a screening test, this method is not reliable for accurately predicting the corrosion rate of a metal in its service environment [6].

### Electrochemical Testing

*Direct Current Methods*—Laboratory test methods include a number of direct current measurement techniques that are commonly used in electrochemical testing. Specific methods include potentiodynamic polarization, potentiostatic polarization, galvanostatic polarization, Tafel extrapolation, and polarization resistance determinations. In seawater, passive film forming alloys like aluminum or stainless steel require an induction time for pitting to occur, and thus the scan rate in a potentiodynamic test can significantly influence the results obtained. Also, the dynamic nature of these test methods may preclude the natural formation of films on a metal or alloy surface, which can cause the distorted results. Potentiostatic and galvanostatic polarization methods are often applied in studying localized corrosion. Electrochemical methods to measure the susceptibility of alloys to pitting corrosion are reviewed elsewhere [70,71]. The disadvantages associated with selecting the proper scan rate in the potentiodynamic method do not apply to the potentiostatic and galvanostatic methods [69].

The Tafel extrapolation test is capable of determining very low metal corrosion rates in a short period of time. When conditions are ideal, its accuracy is equivalent to or better than weight loss measurements. However, to maintain accuracy, the Tafel regions must encompass at least one order of magnitude of current. Also, this method can only be applied to systems that have one reduction process or the Tafel region may be distorted and corrosion rate determinations will be inaccurate. Finally, the Tafel method only yields an average, uniform corrosion rate and is not sensitive to localized corrosion. Therefore, use of this technique in seawater is considered to be limited primarily to obtaining an indication of the corrosion rate within an order of magnitude [16,72].

*Nondestructive Electrochemical Methods*—Many of the disadvantages discussed above for the Tafel extrapolation method can be eliminated by using the polarization resistance technique. This nondestructive method can be used on systems that are under either activation or diffusion

control. Very low corrosion rates can be determined accurately, quickly, and monitored as a function of time. Polarization resistance can also be used to measure the corrosion rate of a component such as a seawater tank or piping system, where inspections and weight loss tests are difficult if not prohibitive [16]. The major disadvantage with this technique is that, like the Tafel extrapolation method, the calculated corrosion rate represents a uniform corrosion value and does not measure localized corrosion [73].

Electrochemical impedance spectroscopy (EIS) uses a small amplitude, sinusoidal potential perturbation to the test material for examining the corrosion behavior of nonconductive coated metals [72–79]. This method is essentially nondestructive and does not cause any acceleration of the corrosion reaction. The EIS technique can be used to monitor corrosion of a system or coating resistance as a function of time. Decreases in the measured coating resistance suggest that the electrolyte has permeated through the coating or that there are defects in the coating [69]. Reducing the distance between the working and counter electrodes to approximately 50  $\mu\text{m}$  allows local EIS measurements to be done over uncoated and coated metal and alloy surfaces to discern surface inhomogeneities that may lead to corrosion initiation before corrosion is visually observed [80].

Electrochemical noise involves the nondestructive measurement of electrochemical transients or noise generated during corrosion processes without disturbing the system. Measurements are made by (1) monitoring potential noise through measurement of potential difference between two identical electrodes, or (2) monitoring the current noise by assessing the current fluctuations between two short identical electrodes through a zero resistance ammeter, or (3) monitoring both potential and current perturbations. Electrochemical noise has been used to evaluate localized corrosion, stress corrosion cracking or uniform corrosion in laboratory or field applications [79,81–86]. Electrochemical voltage or current noise can determine the onset of pitting or crevice attack [87–89].

### High Velocity Flow Testing

A variety of high velocity tests have been designed to evaluate cavitation and erosion properties in seawater environments. Specific tests are as follows: (a) high velocity flow tests which include venturi tubes, rotating disks, and ducts with specimens positioned in the throat sections, (b) high frequency vibration tests that utilize magnetostriction or piezoelectric devices (described in ASTM G32 (Cavitation Erosion Using Vibratory Apparatus)), and (c) impinging jet tests where rotating or stationary specimens are exposed to a high-velocity jet or droplet impact (described in ASTM G73 (Liquid Impingement Erosion Testing)) [90]. A test loop using flowing artificial seawater and 1 weight % sand was able to evaluate the relative erosion resistance of materials under consideration for valves in a piping system [91].

There are a number of disadvantages in high velocity flow laboratory testing. First of all, the results from these tests can vary widely due to differences in test technique, specimen size and shape, and environmental conditions like salinity, pH, temperature, and oxygen content. Secondly,

these tests are designed to expose small specimens to high intensity flow conditions; however, the edges of the small specimens utilized can alter turbulent flow conditions in such a manner that the results do not simulate the actual service environment. The flow dynamics and conditions produced by the different high velocity techniques vary significantly. Although these high velocity laboratory tests may not accurately simulate the desired service condition, they are still useful in ranking different metals according to their resistance to velocity effects. For reproducibility among test laboratories, it is important to run a standard control material along with the candidate test materials so that the data can be normalized with respect to the control standard [69,90].

### Environmental Cracking Test Methods

A wide variety of stress corrosion cracking, corrosion fatigue, and hydrogen embrittlement tests to study environmental cracking phenomena have been developed. These tests, which employ either a static or a dynamic load, can vary widely in terms of specimen configuration, cost, test duration, etc. A detailed summary can be found in the chapters on Environmental Cracking and Hydrogen Damage in Section IV—Testing for Corrosion Types. These tests, which employ either a static or a dynamic load, can vary widely in terms of specimen configuration, cost, test duration, etc. These tests may include the effects of cathodic protection on the susceptibility of materials to environmental cracking. In general, they fall into three major categories:

1. Constant displacement techniques include bent-beam, U-bend, wedge-open loading, and proving ring tests. In these tests, specimens are loaded to some fixed displacement and then exposed to the corrosive environment. Initiation of cracking causes the stress to be relieved, thus causing crack arrest. These tests tend to be plagued by a high degree of data scatter and in many cases do not result in providing useful design parameters.
2. Rising load techniques include the slow strain rate (SSR) test [92]. In this technique, axially-loaded tension test specimens or fatigue precracked (fracture mechanics) specimens are subjected to a rising stress, typically applied by a screw-driven testing machine. SSR tests produce a result in a reasonably short time, usually within 1–2 days. The dynamic straining reduces incubation time to the onset of cracking in susceptible materials and sustains the cracking process. The SSR method allows for evaluation of the effects of metallurgical variables such as alloy composition, heat treatment, and processing and or environmental parameters in shorter times than is usually possible with constant load or stress specimens [93]. SSR evaluation of materials via environmentally assisted cracking is generally obtained through the comparison of test results conducted in a corrosive environment versus corresponding SSR results obtained in an inert environment [93].

SSR tests tend to produce conservative results (i.e., materials that show susceptibility in these tests may not show susceptibility in service) in a relatively short period of time. This conservatism may result from the fact that engineering structures are rarely loaded in this fashion.

As such, these tests are typically used only to relatively rank susceptibility of materials to different environments [94].

3. Load controlled techniques comprise methods such as the cantilever beam test. In these tests, specimens are dead-weight loaded to produce the desired stress. Any cracks that initiate grow into an increasing stress field, resulting in failure of the specimen. Unfortunately, these tests are time-consuming and costly. However, a critical linear elastic stress intensity factor can be obtained from these tests and this parameter can subsequently be used in design or to determine the flaw tolerance of an engineering structure.

ASTM E1681 [95] provides a standard method for determining a threshold stress intensity factor for environmentally-assisted cracking of metallic materials under constant load using a cantilever beam. The cantilever beam technique utilizes long term static load testing of fatigue pre-cracked, single-edge notched beam specimens (SEN-B) manufactured to guidelines designed to produce plane-strain SCC data [96]. Test durations range from several hours to over 10 000 hours. The 10 000-hour runout time is preferred to ensure sufficient time for crack incubation (hydrogen entry and transport to the crack tip region in the case of hydrogen embrittlement) without being excessively long. The threshold stress intensity ( $K_{Isc}$ ) obtained from these tests can subsequently be used in design or to determine the flaw tolerance of an engineering structure.

## FIELD EVALUATION

### In-Service Testing

In-service testing provides the advantage of examining the corrosion behavior of a metal in the actual service environment. The advantages and disadvantages of some of these tests are briefly described below. More detail can be found in the article titled "In-Service Monitoring" in Ref 69. Section III—Types of Tests—Seawater, describes further details on seawater testing.

*Small Specimen Testing*—Small specimen testing allows a large number of variables to be evaluated at minimal cost. Small specimens can be designed to determine specific types of corrosion; for example, creviced specimens can be exposed to assess localized corrosion [69]. ASTM G16 provides guidance for establishing the number of replicate samples required for the desired reliability of the test results.

Although small specimen testing allows examination in the actual service environment, the corrosion rate determined on a small specimen is usually not consistent with the corrosion rate of a large-scale piece of equipment predominantly because it is difficult to duplicate all of the metallurgical conditions of the large equipment on a small specimen. In addition, it is difficult to simulate erosion-corrosion by small specimen testing, since small specimens can shield each other from turbulence, thus providing inaccurate results [69]. The use of spool pieces for piping/tubing may provide useful test information related to in-service performance for similar components.

*Electrical Resistance Probes*—Electrical resistance probes are small in size and can be easily installed in the service environment; however, the walls of the test equipment must be penetrated for the probes to be installed and consequently, care must be taken to avert leakage in the system. The usefulness of the probes is limited in that they provide a measurement of uniform corrosion and can be continuously monitored, but provide no information on localized corrosion such as pitting or crevice corrosion. In addition, errors can result in the probe data if the temperature is varied during the time of the measurement [69].

*Ultrasonic Measurements*—The ultrasonic thickness measurement method is quite popular for in-service corrosion testing. The major advantage of this method is that the equipment is portable and very easy to use. The major disadvantage is that a bare metal surface is required for accurate measurements. The presence of coatings and/or corrosion products can introduce errors into the thickness measurements [69]. Curved surfaces such as piping bends and small tubing diameters require special attention.

### Simulated Service Testing

Like in-service testing, simulated service testing provides the advantage of exposure to the actual environment. Fluctuations in the weather, the influence of geographical location, and bacteriological influences are part of the simulated service test environment and are factors that cannot be simulated in the laboratory [69]. Simulated service testing in seawater typically consists of panel specimens exposed on test racks suspended from a pier or a float [11]. Testing in this environment is discussed in ASTM G52 (Exposing and Evaluating Metals and Alloys in Surface Seawater). Specimens may be exposed in full immersion, splash/spray, or tidal conditions. The disadvantage of exposing panel specimens in the full seawater immersion environment is the occurrence of extensive macrofouling on the panel surfaces. The presence of these organisms prohibits inspection of the test panels during the exposure period and can result in the difficult task of removing the macrofouling after testing to obtain accurate weight loss measurements. For coated specimens, removal of the macrofouling after testing could cause partial removal of the coating as well, making an accurate corrosion assessment impossible. For this reason, simulated service testing in the full immersion testing is often conducted using filtered natural seawater to eliminate microorganisms.

## STANDARDS FOR SEAWATER TESTING

The standard listed below is specific to testing in seawater.

- ASTM G52—Standard Practice for Exposing and Evaluating Metals and Alloys in Surface Seawater

The following standards apply only to artificial seawater environments.

- ASTM D1141—Specification for Substitute Ocean Water
- ASTM D5894—Practice for Cyclic Fog/UV Exposure of Painted Metal, (Alternating Exposures in a Fog/Dry Cabinet and a UV/Condensation Cabinet)

- ASTM E1524—Standard Test Method for Saltwater Immersion and Corrosion Testing of Photovoltaic Modules for Marine Environments
- ASTM G44—Practice for Evaluating Stress Corrosion Cracking Resistance of Metals and Alloys by Alternate Immersion in 3.5 % Sodium Chloride Solution
- ISO 4623—Paints and Varnishes—Filiform Corrosion Test on Steel
- ISO 7384—Corrosion Tests in Artificial Atmosphere—General Requirements

The standards listed below describe corrosion testing and data evaluation in natural seawater or artificial seawater environments.

- ASTM E606—Recommended Practice for Constant Amplitude Low-Cycle Fatigue Testing
- ASTM E647—Test Method for Measurement of Fatigue Crack Growth Rates
- ASTM E1681-99e1—Standard Test Method for Determining a Threshold Stress Intensity Factor for Environment-Assisted Cracking of Metallic Materials
- ASTM E739—Standard Practice for Statistical Analysis of Linear or Linearized Stress-Life (S-N) and Strain-Life (e-N) Fatigue Data
- ASTM E1049—Standard Practices for Cycle Counting in Fatigue Analysis
- ASTM G1—Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens
- ASTM G5—Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements
- ASTM G15—Terminology Relating to Corrosion and Corrosion Testing
- ASTM G16—Practice for Applying Statistics to Analysis of Corrosion Data
- ASTM G30—Practice for Making and Using U-Bend Stress-Corrosion Test Specimens
- ASTM G31—Practice for Laboratory Immersion Corrosion Testing of Metals
- ASTM G32—Test Method for Cavitation Erosion Using Vibratory Apparatus
- ASTM G38—Practice for Making and Using C-Ring Stress-Corrosion Test Specimens
- ASTM G39—Practice for Preparation and Use of Bent-Beam Stress-Corrosion Test Specimens
- ASTM G46—Practice for Examination and Evaluation of Pitting Corrosion
- ASTM G47—Test Method for Determining Susceptibility to Stress-Corrosion Cracking of High-Strength Aluminum Alloy Products
- ASTM G49—Practice for Preparation and Use of Direct Tension Stress-Corrosion Test Specimens
- ASTM G59—Practice for Conducting Potentiodynamic Polarization Resistance Measurements
- ASTM G61—Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-Based Alloys
- ASTM G71—Guide for Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes
- ASTM G73—Practice for Liquid Impingement Erosion Testing
- ASTM G78—Guide for Crevice Corrosion Testing of Iron-Base and Nickel-Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environments
- ASTM G82—Guide for Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance
- ASTM G100—Test Method for Conducting Cyclic Galvanostaircase Polarization
- ASTM G102—Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Measurements
- ASTM G129—Standard Practice for Slow Strain Rate Testing to Evaluate the Susceptibility of Metallic Materials to Environmentally Assisted Cracking
- ASTM G139—Determining Stress Corrosion Cracking Resistance of Heat Treatable Aluminum Alloy Products Using Breaking Load Method
- GM9540P—Accelerated Corrosion Test ©.
- ISO 1462—Metallic Coatings—Coatings Other than Those Anodic to the Basis Metal—Accelerated Corrosion Tests—Method for the Evaluation of the Results
- ISO 4540—Metallic Coatings—Coatings Cathodic to the Substrate—Rating of Electroplated Test Specimens Subjected to Corrosion Tests
- ISO 7539—Corrosion of Metals and Alloys—Stress Corrosion Testing—Parts 1–7
- ISO 8993—Anodized Aluminum and Aluminum Alloys—Rating System for the Evaluation of Pitting Corrosion—Chart Method
- ISO 8994—Anodized Aluminum and Aluminum Alloys—Rating System for the Evaluation of Pitting Corrosion—Grid Method
- ISO 9591—Corrosion of Aluminum Alloys—Determination of Resistance to Stress Corrosion Cracking
- ISO 11306—Corrosion of Metals and Alloys—Guidelines for Exposing and Evaluating Metals and Alloys in Surface Sea Water
- ISO 11463—Corrosion of Metals and Alloys—Evaluation of Pitting Corrosion
- ISO 11782-1—Corrosion of Metals and Alloys—Corrosion Fatigue Testing—Part 1: Cycles to Failure Testing
- ISO 11782-2—Corrosion of Metals and Alloys—Corrosion Fatigue Testing—Part 2: Crack Propagation Testing Using Precracked Specimens
- ISO 11845—Corrosion of Metals and Alloys—General Principles for Corrosion Testing
- NACE RP0173-73—Collection and Identification of Corrosion Products

## CORROSION PERFORMANCE OF SPECIFIC MATERIALS

Metals and alloys commonly used in the seawater environment include carbon steels, stainless steels, nickel alloys, copper alloys, titanium alloys, and aluminum alloys. All of these alloys exhibit differing degrees of corrosion resistance in seawater, and in general, coatings or cathodic protection are often applied to increase the corrosion resistance of these metals. The corrosion resistance within a class of alloys may also be dependent on metallurgical differences caused by fabrication and processing or heat treatments. Joining processes such as welding, brazing, and soldering,

use of adhesives or coatings, surface roughness, and proximity to dissimilar metals or alloys also will cause changes in the corrosion resistance of materials.

Carbon steels corrode in aerated seawater conditions. Their corrosion rate decreases with time as protective barrier films are formed on the carbon steel surfaces. These protective films may be a rust layer, calcareous deposits, or biofouling. The corrosion rate of carbon steels increases in high velocity seawater because the protective barrier layer is either not allowed to form or is stripped away under the flow conditions. Also, the available oxygen at the metal surface is increased in flowing seawater, which promotes a higher carbon steel corrosion rate.

Stainless steels are susceptible to localized corrosion in quiet seawater but maintain good corrosion resistance in seawater flow conditions due to the increased oxygen supply, which promotes passivity of these alloys. Biofouling is also minimized in high velocity conditions, and this in turn minimizes the number of sites for crevice or poulitice attack [12]. Type 304 and 316 stainless steels are not recommended in flow conditions less than approximately 1.5 m/s due to deep pitting of these alloys from crevices created by biofouling [19].

Nickel-copper and nickel-chromium-molybdenum alloys are the nickel-base alloys that are typically used in seawater. The nickel-copper alloys have good corrosion resistance in high velocity seawater, but do exhibit localized corrosion in quiescent seawater [19]. Alloy 625, a nickel-chromium-molybdenum alloy, is susceptible to crevice corrosion in both quiescent and flow conditions [97–100]. Other nickel-chromium-molybdenum alloys, such as Alloys C-276, C-22, 59 and 686 have increased seawater crevice corrosion resistance as compared to Alloy 625 [97,98].

A variety of copper alloys are used in seawater applications. Their generally good resistance is due to the formation of a protective film of cuprous oxide on the metal surface. Additional deposits such as copper-containing compounds and calcareous materials often form on top of this film, which can further increase the corrosion resistance [12]. Cu-30Ni (C71500) and Cu-10Ni (C70600) have excellent general and pitting corrosion resistance in seawater [12,19].

Copper and some copper alloys do exhibit corrosion under advanced velocity conditions. Their corrosion resistance is dependent on the growth and maintenance of the protective layers formed on the metal surface. The maximum velocity recommended for copper in seawater is 0.9 m/sec. Alloying with nickel or aluminum increases the resistance of copper alloys to impingement attack [12,19].

Copper-zinc alloys (brasses) with more than 15 % zinc are susceptible to a type of dealloying called dezincification. Some aluminum bronze (Cu-Al) alloys, especially those containing more than 8 % aluminum, are also susceptible to dealloying. The dealloying in Cu-Al alloys can be prevented by adding more than 3.5 % nickel or by heat treating to obtain an  $\alpha + \beta$  microstructure [19].

Aluminum alloys are susceptible to localized corrosion in seawater under both low and high velocity conditions. However, these alloys, particularly 5XXX series and 6061 aluminum, are commonly used in marine applications [12,19].

Titanium alloys have the best corrosion resistance of the metals and alloys typically used in seawater. Titanium is a passive film-forming alloy and retains excellent resistance in both low and high velocity seawater. Some titanium alloys, specifically the all alpha and near-alpha alloys, do exhibit a susceptibility to stress corrosion cracking [12].

In addition to metals, organic composites such as graphite-reinforced epoxy are gaining increasing use in the marine environment. The advantage of these composites over conventional materials is in their high strength-to-weight and stiffness-to-weight ratios. These composites also offer excellent marine corrosion resistance [101,102], but may be susceptible to attack from the alkaline environment produced by cathodic protection techniques.

# Freshwater

Walter T. Young<sup>1</sup> and Philippa Fairer<sup>1</sup>

CORROSION TESTING in freshwater environments is performed to determine the corrosion characteristics of water, evaluate the behavior of various materials when exposed to water, and evaluate various corrosion mitigation methods. For example, waters in cooling systems are often analyzed to determine how much and what forms of corrosion might occur on a given metal. Screening tests are used to select the most appropriate metal for use as piping material. Various water treatment alternatives can be tested in the laboratory or in a pilot plant. Tests are used to monitor the selected treatment scheme. Laboratory screening tests, detailed simulations, pilot plant studies, and system monitoring are typical corrosion testing methods. In any event, the selection of the appropriate test method will depend on the objectives of the test, details of the system, and the process parameters (e.g., flow, temperature, and chemistry). Test design and analysis are covered elsewhere in this book as well as in the referenced documents. This chapter discusses the causes and types of corrosion common in freshwater systems and the standardized tests used for evaluation. Freshwater can be defined simply as water that is not salty and brackish water is defined by the dictionary as water having a somewhat salty taste. A more quantitative definition of brackish water is water with a salinity between 0.5 and 17 parts per thousand [1] (Ref *ASM Materials Engineering Dictionary*, J. R. Davis Ed., ASM International, Materials Park, OH, 1992). Then freshwater can be further defined as water with a salinity less than 0.5 parts per thousand. For the purposes of this chapter, freshwater systems include potable water, heating/cooling, condensate, rivers, streams, and lakes.

## THE FRESHWATER ENVIRONMENT

In designing an effective laboratory test program, it is important to consider factors that influence corrosion in a freshwater environment. The following discussion summarizes these factors, but the complexity of the topic does not permit a detailed discussion in this chapter. Details on corrosion processes affecting metals in freshwaters are found in the references provided at the end of this chapter [1–5].

<sup>1</sup>Principal Engineer and Former Engineer, respectively, Corpro Companies, 610 Brandywine Parkway, West Chester, PA 19380.

## Water Chemistry

Although water has a definite molecular structure, freshwater is not a pure substance and may contain numerous ions, dissolved minerals, and gases. Examples of dissolved solids include calcium, magnesium, manganese, nitrates, iron, copper, lead, chlorides, sulfates, carbonates, and bicarbonates. Chemistry is one of the most important factors affecting the corrosion of metals in water. Dissolved salts, such as chlorides and sulfates, cannot only increase the aggressiveness of the water, but also affect the ability of the water to form protective deposits. Generally, waters with higher dissolved salt contents are more corrosive. Dissolved gases also affect the corrosivity of water. Oxygen and carbon dioxide concentrations can increase corrosivity, as does hydrogen sulfide. Not all metals are affected the same in a given water composition.

Acidity and alkalinity affect the corrosion rate. Generally, alkaline conditions favor lower corrosion rates; however, some metals, such as aluminum and zinc, are amphoteric and show increased corrosion at pH values above 9. For iron alloys, the corrosion rate is relatively steady between a pH of 4 and 10 at ambient temperature and where oxygen reduction is the primary cathodic corrosion reaction; however, the corrosion rate increases rapidly below pH 4 [4]. Iron passivates and the corrosion rate decreases rapidly above a pH of 10, except at very high pH levels where the corrosion rate again can increase.

The solubility of elements in freshwater is limited and the solubility of calcium and magnesium carbonates are of particular importance in freshwaters. The solubility of carbonates is inversely proportional to the temperature of the water. In other words, as the water temperature increases, calcium and magnesium carbonates become less soluble. If the solubility decreases sufficiently, carbonates will precipitate and form a scale on the surfaces of the system. This scale can provide a protective barrier to prevent corrosion of the metallic elements in a system. Excessive scale deposits can interfere with water flow and heat transfer. The quality of the scale is dependent on the quantity of calcium that can precipitate as well as water flow and the chloride and sulfate content of the water. The tendency of water to precipitate a carbonate scale is estimated from corrosion indices such as the Langelier Saturation Index (LSI) and Caldwell-Lawrence calculations [6–8] which use calcium, alkalinity, total dissolved solids, temperature and pH properties of the water. Other indices, such as the Ryznar Index

purport to indicate corrosivity directly using the same elements as the LSI [6]. Manganese in excess of 0.50 mg/L can cause pitting of copper in hot water systems [1]. Copper in excess of 0.1 mg/L causes pitting of galvanized steel and aluminum if the zinc and aluminum are downstream of the copper [1]. The reversal of the potential between zinc galvanizing and steel can occur in some water resulting in the steel becoming the anode in a bimetallic couple. This normally occurs in hot water with relatively high carbonates, bicarbonates, phosphates, and silicates relative to sulfate and chlorides.

### Process Conditions

Water velocity and turbulence can damage protective films and deposits on metal surfaces causing increased corrosion. Soft metals, such as copper, are particularly susceptible to erosion corrosion, but steel and other metals are also susceptible if the water velocity is sufficiently high. The critical velocity for erosion-corrosion of copper in freshwater is about 5 fps (1.52 m/s), but this velocity can drop sharply as the chemical corrosivity of the water increases. Suspended solids in the water can increase the erosion characteristics of the water [1]. Deposits can result in accelerated corrosion from the formation of oxygen differential concentration corrosion cells.

Generally, higher temperatures cause an increase in corrosion activity and a corresponding increase in metal loss, particularly in a closed (pressurized) system. If the system is open, increasing the temperature beyond 91°C causes a decrease in corrosion since oxygen is removed from the water. Higher temperatures can also cause the solids in a system (where evaporation occurs) to concentrate, which can lead to increased corrosion rates. Increased temperature can cause an increase in the scaling tendency of the water resulting in lower corrosion rates.

The use of water treatment can increase or decrease corrosion rate. Excessive amounts of chlorine (used as a biocide) can increase corrosion. Water softening can also lead to increased corrosion rates. On the other hand, additions of caustic, soda ash, or corrosion inhibitors are used to decrease corrosion rates. Aeration can decrease corrosion rates when used to remove carbon dioxide. Deaeration is also used to decrease corrosion rates in some systems.

### Biological Factors

Biological corrosion is not a separate corrosion type, but biological activity can increase corrosion rate either by increasing the occurrence of concentration cell corrosion beneath the biomass or by producing corrosives from metabolic processes. Corrosion occurs as one of the common forms discussed below. Bacteria can survive under most conditions found in water systems and are either aerobic or anaerobic. *Desulfovibrio desulficans* is an anaerobic sulfate reducing bacterium that can be found in cooling towers and potable water piping. *Thiobacillus thiooxidans* (an acid producer) is another anaerobic bacterium known to influence corrosion. An example of aerobic bacteria is iron bacteria (*Gallionella*), which are found in some water wells. Slimes also influence corrosion by promoting concentration cell corrosion [2]. Metal reducing

bacteria cause pitting of stainless steel. Manganese in the presence of anaerobic manganese fixing bacteria (e.g., *Gallionella*, *Sphaerotilus*) and chloride, can cause pitting corrosion of stainless steel in fresh water.

### Metallurgy

In gray cast iron, the iron can be selectively removed leaving the graphite matrix—a process called graphitization. High-zinc brasses and aluminum-bronzes might be subject to selective leaching of specific elements in the alloy. In brass, the zinc selectively corrodes, leaving behind a weak, spongy, porous, copper-rich matrix. The process, dezincification, generally occurs in relatively corrosive, soft, and acidic waters. Aluminum bronzes can undergo selective leaching of aluminum (dealuminification) under conditions similar to dezincification. Stainless steels can undergo intergranular corrosion at welds and elsewhere caused by the effective removal of chromium from the metal matrix by combination with carbides under high temperature exposure. Denickelification is the selective removal of nickel from copper-nickel alloys, which has been found in fresh waters under conditions of high heat flux and low water velocity [16]. Brass is also subject to stress corrosion cracking in water where tensile stress and a corrosion species, such as nitrate or ammonia, are present in the water.

### Other Factors

Poor workmanship and defective materials can increase corrosion. Water turbulence effects can be increased by poor workmanship, such as the failure to ream burrs from cut ends of copper pipe. This increases the turbulence at the joints and results in erosion of the copper. Excessive and corrosive flux used in soldered coppers joints results in pitting corrosion along the flux runs. Incomplete longitudinal welds in electric resistance welded (ERW) steel pipe result in concentration cell corrosion and rapid corrosion.

Contamination of the water system can increase the corrosion rate. In cooling tower systems, water corrosivity is increased by the absorption of sulfur gases from the atmosphere. Airborne salts can contaminate open water systems. Process water systems can be contaminated with process debris, such as fibers and chemicals that can increase the corrosion rate.

## TEST METHODS

Table 1 shows the most common forms of corrosion that affect metals in the freshwater environment. These corrosion forms are described in ASTM G 15, Terminology Relating to Corrosion and Corrosion Testing.

The following section provides information about the use and applicability of various corrosion tests. Details of performing the tests are provided in the cited references and in the chapter on Types of Tests. Tables 2 through 10 list the test methods applicable to the various tests.

### Electrolyte Chemistry

In designing a test program, it is important to know the chemistry of the system water in order to accurately simulate

**TABLE 1**—Corrosion forms affecting common engineering metals in freshwater.

the environment of interest. Knowledge of the water chemistry will not provide quantitative corrosion data, but will provide insight into the corrosivity of the water. The chemical constituents of importance in corrosion are: pH, conductivity (or resistivity), total dissolved solids, chlorides, sulfates, suspended solids, alkalinity, carbonates, bicarbonates, hardness, carbon dioxide, oxygen, sulfur dioxide, nitrates, manganese and heavy metals. Also, the scaling tendency of the water should be determined by either the LSI or Caldwell-Lawrence diagrams [7,8]. A computer program for calculating the scale-forming tendencies is available from the American Water Works Association, Denver, Colorado.

Applicable test methods can be found in the following publications:

1. ASTM Annual Book of Standards, Volume 11.01
2. Standard Methods for the Examination of Water and Wastewater, 20th Ed., American Public Health Association, Washington, D.C., 1998
3. NACE TM0374, Laboratory Screening Tests to Determine the Ability of Scale Inhibitors to Prevent the Precipitation

of Calcium Sulfate and Calcium Carbonate from Solution, NACE International, Houston, Texas

## Uniform Corrosion

Uniform corrosion is readily measured with standard test procedures. Weight loss testing, polarization resistance, Tafel extrapolation, resistance change measurements, and AC impedance all measure the average corrosion rate of a sample surface. Each test is conducted by immersing the sample in the environment and averaging the corrosion losses, current flows, or volume changes over the entire surface area. However, nonuniform corrosion will provide inaccurate corrosion rates since the results are averaged over the surface area. Specimens must be visually examined for signs of pitting, crevice corrosion, stress-corrosion cracking (SCC), or other localized corrosion. When using electrochemical or resistance tests, parallel immersion testing should be conducted to determine if localized corrosion will occur.

Weight loss is the easiest and least expensive method since that method requires only test specimens, the solution, a container, and the appropriate environmental parameters. Weight loss tests can be conducted in low and low conductivity solutions, even in the atmosphere. An analytical balance is required for both before and after weight measurements. Multiple specimens must be used when evaluating the change in corrosion rate over time. Specimens cannot be reused for corrosion rate versus time measurements after first exposed and cleaned because high initial corrosion rates will occur each time the specimen is used. This will lead to artificially high corrosion rate data.

Weight loss testing is widely used both in the laboratory and for in-plant testing. For in-plant tests, racks of corrosion samples or single coupons are inserted at locations where corrosion rates are desired. Test specimens can be inserted in pipes or other structures using "hot-tap" devices and in bypass loops. Weight loss testing is slow (especially in systems with low corrosion rates) and does not allow instantaneous measurement. Extreme care must be exercised in designing weight loss tests since velocity, crevice, stagnation, and heat transfer conditions will influence the results.

DC polarization measurements, both polarization resistance and Tafel extrapolation, provide the ability to measure instantaneous corrosion rates and corrosion rate variation over time [9,10]. Standard polarization techniques assume a uniform corrosion rate, although special techniques can be used to evaluate localized corrosion. The solution must have sufficient conductivity to perform this test. Solutions with low conductivity require correction factors or special techniques to account for the effect of voltage drops on the measured specimen potential caused by current flow through the solution (IR drop). Tafel extrapolation requires relatively large changes to the electrochemical potential that can damage the specimen. In addition, relatively long test times are required. Corrosion reactions that are not under activation control will obscure the Tafel slope. On the other hand, significant information on the corrosion process is obtained from full anodic and cathodic polarization curves. Polarization resistance requires only small changes in specimen electrochemical potential; therefore, this method is fast and does less damage to the specimen compared to

**TABLE 2**—Test methods for evaluating uniform corrosion.

Test Method	Test Title	Application
ASTM D 2688	Test Method for Corrosivity of Water in the Absence of Heat Transfer (Weight Loss Methods)	Provides weight loss methods to evaluate corrosion directly in piping systems.
ASTM G 1	Standard Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens	Provides methods for cleaning and evaluating weight loss coupons.
ASTM G 3	Standard Practice for Conventions Applicable to Electrochemical Measurements in Corrosion Testing	Information on reporting and displaying polarization measuring techniques, including both DC and AC methods.
ASTM G 4	Standard Method for Conducting Corrosion Coupon Tests in Plant Equipment	Provides guidelines for in-plant testing—weight loss coupons, specimen racks, reporting.
ASTM G 31	Standard Practice for Laboratory Immersion Corrosion Testing of Metals	Describes procedures for conducting laboratory weight loss tests Provides information on reporting and factors to be aware of.
ASTM G 59	Standard Practice for Conducting Potentiodynamic Polarization Resistance Measurements	Provides details on how to conduct DC polarization resistance tests.
ASTM G 96	Standard Guide for On-Line Monitoring of Corrosion in Plant Equipment (Electrical and Electrochemical Methods)	Provides details on conducting polarization resistance and electrical resistance tests.
ASTM G 102	Standard Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Measurements	Describes practice for converting corrosion current data from electrochemical polarization measurements to corrosion rate.
NACE TM-01-71 <sup>a</sup>	Autoclave Testing of Metals in High Temperature Water	Methods for testing water at temperatures greater than 100°C but less than 360°C Test is weight loss method, but could be modified for electrochemical techniques.
NACE TM-02-74	Dynamic Corrosion Testing of Metals in High Temperature Water	Similar to TM-01-71, but uses circulating loop and heat exchangers Weight loss method.
NACE TM-01-69	Laboratory Corrosion Testing of Metals for the Process Industries	Discusses factors of concern for laboratory testing. Discusses planning tests and evaluation Emphasizes weight loss methods.
NACE RP-0775-87 <sup>b</sup>	Preparation and Installation of Corrosion Coupons and Interpretation of Test Data in Oilfield Operations	Discusses the use of weight loss coupons, interpretation of data, and analysis Principals are applicable to freshwater systems.

<sup>a</sup>Test method.<sup>b</sup>Recommended practice.

Tafel extrapolation. Polarization can be applied to field testing and monitoring. Computerized equipment is available for both types of tests. Instruments based on the polarization resistance technique are widely used for process monitoring.

Resistance probes are used for in-plant corrosion testing. As a metal corrodes, its volume decreases with a corresponding increase in resistance. Resistance probe instruments are commercially available on the market. Probes can be made from many different metals and alloys. The probes are inserted into the environment and the loss of cross-sectional area of the probe element is detected by its increase in electrical resistance with time. The data obtained by plotting resistance against time of exposure provide a graphic history of corrosion rate. Resistance probes can be used in low-conductivity solutions. Visual inspection is necessary to differentiate between pitting and general metal loss. Pitting can result in the appearance of low corrosion rate followed by rapid increases in corrosion. The method is not very sensitive either to very low or to rapid changes in corrosion rate. The positions of the probe in the environment, the fluid velocity, and heat transfer have a pronounced effect on the results. ASTM Test Method G 96 provides the details about conducting this test.

Electrochemical impedance spectroscopy (EIS) provides detailed information on the corrosion reaction by determining the equivalent electrical circuit of a corroding system.

The method requires low potential changes in the system and can be used in low-conductivity solutions. Complex equipment is needed to conduct the tests and specialized knowledge is needed to interpret the data [11,12]. Table 2 provides information on standard test methods for evaluating uniform corrosion.

### Pitting Corrosion

Pitting corrosion is difficult to evaluate because it can initiate at random locations on a metal surface. Large areas of a surface can be corrosion-free with pits only at a few locations. Small corrosion coupons might not show pitting or might not provide enough pit depth data for a reliable analysis. On the other hand, the surface can have a large number of pits over a given area. Immersion testing using specimens of sufficient size and number should be used to measure corrosion rate accurately. The depth of pitting follows the normal probability distribution. Extreme value statistical analysis provides a useful tool to evaluate pitting [13,14]. Pit depths can be measured using calipers, micrometer, or metallurgical microscope with a calibrated focus. Cyclic anodic polarization curves are used to provide relative susceptibility to pitting corrosion. This method does not provide specific corrosion rate data. Table 3 provides the standard test methods for evaluating pitting corrosion.

**TABLE 3**—Test methods for evaluating pitting corrosion.

Test Method	Test Title	Application
ASTM F 746	Standard Test Method for Pitting or Crevice Corrosion of Metallic Surgical Implant Materials	Measurement of pitting or crevice tendency by measuring repassivation tendency after polarization at noble potential. Applicable only to passive alloys.
ASTM G 16	Standard Guide to Analysis of Corrosion Data	Discusses statistical analysis methods of corrosion data.
ASTM G 46	Standard Practice for Examination and Evaluation of Pitting Corrosion	Provides information needed for collecting and interpreting pitting data.
ASTM G 61	Standard Test Method for Conducting Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-Based Alloys	Provides information on conducting cyclic anodic polarization tests. Useful procedure for evaluating pitting and crevice corrosion susceptibility. Can be modified for other alloys that exhibit passive behavior.

### Crevice and Concentration Cell Corrosion

Crevice corrosion, and concentration cell corrosion, susceptibility can be measured directly, by exposing test specimens to the environment. ASTM F 746, G 48, and G 78 can be used for evaluating these forms of corrosion. These methods were designed to measure crevice corrosion in severe electrolytes such as salt solutions, but can be modified for freshwaters.

Electrochemical polarization can also be used by conducting cyclic anodic polarization scans. This technique, described in ASTM G 61, provides a qualitative approach to evaluating crevice corrosion. Polarization can be used to provide a more quantitative analysis by applying a graphical technique. This approach uses the same general method as described under galvanic corrosion in ASTM G 82. Its use requires knowledge of the solution chemistries inside and outside of the crevice and the ability to simulate these environments for the anodic and cathodic tests. Table 4 provides information on standard test procedures for evaluating crevice corrosion.

### Galvanic (Bimetallic) Corrosion

The galvanic series might be used to predict the possibility of galvanic corrosion, but it cannot be used to predict the quantity of corrosion that can occur. Most published

galvanic series apply only to the seawater environment and some metals behave differently in different environments. For example, stainless steels can behave either in the active state or in the passive state depending on the environment and the metals they are connected to. Sometimes the behavior of a galvanic couple in a particular environment can be the reverse of that shown in most published galvanic series. Also, metals polarize (change potentials as a result of current flow) when connected to each other in an electrolyte. This will affect the corrosion behavior and cannot be predicted from the galvanic series. The area ratio of the two metals has a marked influence on the corrosion rate of the bimetallic couple. The solution operating conditions (e.g., aeration, movement) also can have significant effect(s).

Two test methods can be employed to determine the susceptibility of two metals to galvanic corrosion in an electrolyte. In the first method, the two metals are immersed in the electrolyte and the current flow between them is measured using a zero resistance ammeter. The corrosion current is calculated according to the following relationship:  $I_{cl} = I_g + I_{la}$ , where  $I_{cl}$  is the total current,  $I_g$  is the measured galvanic corrosion current, and  $I_{la}$  is the local action corrosion current measured by another technique. The galvanic corrosion rate is calculated using Faraday's Law. ASTM G 71 describes the method.

The galvanic corrosion behavior can be predicted using polarization behavior. Electrochemical potential measurements

Useful procedure for evaluating pitting and crevice corrosion susceptibility. Can be modified for other alloys that exhibit passive behavior.
ASTM G 108	Standard Test Method for Electrochemical Re-activation (EPR) for Detecting Sensitization of AISI Type 304 and 304L Stainless Steels	Describes cyclic polarization technique for evaluation of sensitivity to intergranular corrosion. Specific to 300 series stainless steel, but might be adaptable to other passive alloys with laboratory evaluation.

**TABLE 10**—Test method for evaluating fretting corrosion.

Test Method	Test Title	Application
ASTM F 897	Practice for Fretting Corrosion of Osteosynthesis Plates/Screws	

are used to predict which metal is the anode and which is the cathode. Anodic and cathodic polarization curves are produced for the anticipated environments then superimposed on each other at the known initial potential difference. The corrosion current is graphically determined. ASTM G 82 describes the method as does Ref 15. Table 5 provides information on standard test methods for evaluating galvanic corrosion.

### Erosion-Corrosion

Erosion corrosion resistance is measured by immersion testing and impinging an electrolyte flow onto the metal of interest. ASTM G 73 provides standardized methods for performing erosion tests. See Ref 14 for a detailed discussion about various erosion tests. Table 6 provides standard tests for evaluating erosion corrosion.

### Cavitation

ASTM G 32 provides a standardized method of conducting a cavitation test. Another nonstandard method is to construct a flow channel and mount the specimens in such a manner as to produce cavitation on the downstream side of the specimen. See Ref 16 for a detailed discussion about various cavitation tests. Table 7 provides information on G 32.

### Stress-Corrosion Cracking (SCC)

Stress corrosion cracking susceptibility is directly evaluated by immersing stressed specimens in water, then evaluating the specimens for cracks using high-magnification metallographic or low-magnification macrographic examination. ASTM G 30, G 38, G 39, G 47, G 49, G 58, and G 64 provide methods of preparing specimens and conducting immersion tests. ASTM E 3 and E 807 provide methods of metallurgical examination.

SCC susceptibility is more readily detected using slow strain rate techniques than normal tension testing. This is because the slow straining procedure allows the corrosion effects to occur [17]. Table 8 provides information on standard test methods for evaluating SCC.

### Dealloying

Dealloying is a localized phenomenon that can be evaluated through the use of immersion testing and metallographic techniques (ASTM E 3 and E 80). Energy dispersive X-ray spectroscopy (EDS) and wavelength dispersive X-ray spectroscopy (WDS) are used to detect small amounts of dealloying. Using EDS and WDS, the surface chemistry of the sample is examined to detect losses in the active element(s) and enrichment in the noble alloying element(s).

### Intergranular Corrosion

Since intergranular corrosion is limited to corrosion at or immediately adjacent to grain boundaries and is detectable at the microstructural level, simple corrosion rate calculations using weight loss measurements provide no information. Standard ASTM tests, such as the oxalic acid etch test

(ASTM A 262) provide relative susceptibility only for austenitic stainless steels. These tests have little usefulness in freshwater environments. A metallographic analysis performed after test samples are exposed provides the most useful information about susceptibility to intergranular corrosion (ASTM E 3 and E 80).

Cyclic polarization measurements provide relative information about susceptibility as described in ASTM G 61. ASTM G 108 provides a test method applicable to type 304 stainless steel. Table 9 provides information on standard test methods.

### Fretting Corrosion

Fretting corrosion can occur between two metal parts having an electrolyte and slight vibratory movement. Although ASTM F 897 is intended specifically for surgical implants, it can be modified for use in other environments. Table 10 provides information on ASTM F 897.

# Soils

Lucien Veleva<sup>1</sup>

## DESCRIPTION OF SOILS

### Definition and Classification [1-4,6,8]

SOIL AS A CORROSIVE ENVIRONMENT is probably of greater complexity than any other environment. The corrosion process of buried metal structures is extremely variable and can range from rapid to negligible. In fact, pipes in soil can be perforated within one year, presenting very localized or uniform corrosion attack (Figs. 1-2). With background knowledge of the principal soil specifics and their influence on metal corrosion, the most serious corrosion problems can be prevented.

In discussion of the soil as an environment for corrosion, no strict definitions exist. However, soil itself has been defined in the Soil Survey Manual of the United States Department of Agriculture as "a collection of natural bodies occupying portions of the earth's surface that support plants and that have properties due to the integrated effects of climate and living matter, acting upon parent material as conditioned by relief over periods of time." The term "soil" has also been defined as "the first few feet of finely divided, modified rock material covering the level and moderately inclined portion of the earth." The origin of soil is in the earth's crust and four main classes of soil have been proposed:

1. Soils formed in situ from soft rocks, such as chalk and volcanic ash;
2. Soils formed in situ from hard rocks such as granite, limestone, and marble;
3. Soils transported from their place of origin before weathering to form soils; they include those moved by water, such as marine and beach sediments, and also those moved by wind, such as sands and those moved by glacial drift;
4. Soils formed in situ from organic material, such as peat.

Soils are commonly named and classified according to the size range of their particulate matter. For example, **sand**, **silt**, and **clay** derive their name from the predominant size range of their inorganic constituents. Particles between 0.02 and about 2 mm are classed as fine (0.02–0.2 mm) and coarse (0.20–2.00 mm) sands. Silt particle size is from 0.002 to 0.02 mm and clay particles have a mean

diameter <0.002 mm down to colloidal matter. Table 1 presents the terminology for different soils according to ASTM Practice for Description and Identification of Soils (Visual-Manual Procedure) (D 2488). The United States and over 50 other countries now use a more detailed classification of their soils, which includes 11 major orders and 47 suborders.

Variation of the proportion of soil size groups determines many of the properties of the soil. Terms commonly used for soil classification include sandy clay, clay loam, silt loam, loamy sand, silty clay loam, sandy loam, gravel, etc. The clays are very plastic mixtures with a high moisture content and are considered to be the most important inorganic constituents of the soil. Often the clays are grouped depending upon the weathering conditions (for example, montmorillonite, illite, kaolinite). Soils of fine texture, due to high clay content, present more packed particles and have less pore capacity for moisture and gases (oxygen) diffusion than an open-type soil such as sand. The clay mineralogy and properties are closely related to the corrosion aggressiveness of soil, and this fact needs attention.

Soil has a specific gravity from 1.1 to 1.7, which is measured as described in ASTM Test Method for Density of Soil in Place by the Drive-Cylinder Method (D 2937).

The main chemical constituent of soils, such as loam, clay, and silt is  $\text{SiO}_2$ , usually along with  $\text{Al}_2\text{O}_3$ . Commonly dissolved species in wet soils are  $\text{H}^+$ ,  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{HCO}_3^-$  ions. The soil mineralogy and chemistry determine the corrosion aggressiveness of soil and need attention. Soils with the poorest drainage, like clay, silt, and loam, are the most corrosive, while soils with excellent and good drainage (gravel and sand, respectively) are the least corrosive.

Because of the complex content of the soil (including organic matter and organisms, gases, mineral particles, moisture), the relative size range does not represent the whole nature of the soil. In fact, most soils consist of aggregates of particles, which gives the possibility for moisture penetration, less erosion by water and wind, and generally great aeration and biological activity. The destruction of this structure by mechanical action or chemical alteration (such as excess alkali accumulation) can alter the physical nature of the soil. To understand the corrosion behavior of buried metal, it is also important to have information about the soil profile (section through the soil showing the various layers).

Complex physical, chemical and biological nature, corrosion aggressiveness, and dynamic interactions with the environment

<sup>1</sup>Research Professor (Corrosion Engineer and Ph.D. in Electrochemistry) at Applied Physics Department, CINVESTAV-IPN, Unidad Merida, Yucatan, C.P. 97310, Mexico

FIG. 1—Buried pipe with detected corrosion failure.

distinguish the soil. Climatic changes of sun irradiation, air temperature and relative humidity, rainfall, winds, mechanical action of natural forces, various physical, chemical and biological factors, and man's manipulation can alter the soil properties, which directly affect the corrosion rate of metals buried in the soil. The amounts of moisture and rainfall are considered of primary importance in soil evolution. They affect the type of soil that forms, the weathering process, and all changes taking place within the soil. Plant and animal life with their soil-building action, acid or base reactions in the parent material, dissolution of soluble components, the leaching out of alkaline minerals of the weathering rock, and other phenomena are strictly influenced by the changes of all the above factors.

The metal corrosion in soils is *aqueous* (in an electrolyte) and its mechanism is *electrochemical*. Three elements are necessary for the operation of the corrosion cell:

1. Galvanic **corrosion cells** operating on the metal surface formed by **anode** and **cathode** sites. Usually the metal is a good conductor for electron flow. The corrosion reaction is done on the anode areas.
2. **Electrolyte** (moisture) on the metal surface. The moisture containing dissolved ionic substances is a good ionic conductor.
3. **Oxidizing agent** (such as oxygen in air).

The conditions in soils can range from atmospheric to completely immersed metal, depending on the soil compactness

(existence of capillaries and pores) and moisture content. The corrosiveness of a soil depends upon an interaction between climate and soil reactions. The variation in soil composition and structure can create distinct corrosive environments, which results in different metal activities and oxygen concentrations (differential aeration) at the metal/soil interface.

### Characteristics of Soils Related to Corrosion [1-6,9,10]

The metal corrosion in soils is determined primarily by such factors as moisture content and its level of electrical (ionic) conductivity, aeration and oxygen content, relative acidity or alkalinity, and amount of dissolved salts. The two conditions necessary to initiate metal corrosion in soil are water (moisture) and oxygen. After these factors, a number of variables can affect the corrosion process.

#### Soil Moisture

Principally three types of water provide the soil moisture: free ground water, gravitational water, and capillary water. They have significant influence on the metal/environmental characteristics and determination of the corrosion rate. The amount of moisture in a soil can be determined by the method described in ASTM Test Method for Laboratory Determination of Water (Moisture) Content of Soil and Rock by Mass (D 2216).

FIG. 2—Corrosion produced in soil on buried metal structure.

TABLE 1—ASTM terminology for soils (Standard D 2488).

Term	Description
Clay	<0.75 $\mu\text{m}$ (passes No. 200 sieve)
Gravel	<75 mm and >4.75 mm (No. 4 sieve)
Organic clay	Clay except that its liquid limit values after oven drying are <75 % of its liquid limit value before oven drying.
Organic silt	Silt except that its liquid limit values after oven drying are <75 % of its liquid limit value before oven drying.
Peat	Soil, primarily vegetable tissue, in various stages of decomposition, usually with organic odor, dark brown or black, spongy consistency, with fibrous to amorphous texture.
Sand	Rock particles passing No. 4 sieve (4.75 mm) and retained on a No. 200 (75 $\mu\text{m}$ ).
Silt	Soil passing No. 200 sieve; nonplastic or very slightly plastic, and exhibiting little or no strength when air-dried.

The **free ground water** is present in the soil at some depth (a few meters to hundreds of meters) below the surface and usually only river crossing pipelines are surrounded by ground water. In such a situation metal corrosion occurs in an aqueous environment, e.g., on a fully-immersed metal structure.

The principal sources of the **gravitational water** are rainfall, snow, flood, and irrigation. This water enters and flows through the soil, governed by its physical structure,

including pore and capillary spaces at various zones in the soil profile, and usually percolates to the level of permanent ground water. A measure of the compactness of mineral soils is the **apparent specific gravity index**. The amount of organic matter influences this value markedly. Some impervious soils, such as clay and water resistant materials, act as effective barriers to the passage of gravitational water and cause zones of water accumulation and saturation. The tendency of the soil to crack on drying and swell when wetted is defined by the term **volume shrinkage** and it is an indicator of the colloidal nature of the clay and loam particles in a soil. In drying, the soil forms cracks that allow oxygen to flow freely to buried metals.

The **capillary water** represents an important reservoir of water in soil. A considerable amount is held in the capillary spaces of silt and clay particles. The term **moisture equivalent of soil** is a measure of the retentiveness or water holding capacity of the soil. The water retained by a soil is a consequence of equilibrium between capillary and gravitational forces. The permeability and moisture retention of granular soils can be measured by the method described in ASTM Test Method for Permeability of Granular Soils (Constant Head) (D 2434). For the water-holding capacity of peat, one can use ASTM Test Method for Volume Weights, Water-Holding Capacity, and Air Capacity of Water-Saturated Peat Materials (D 2980). The existence of moisture in good conductivity soil indicates high ion content and a possibility for very strong corrosion attack.

### Aeration and Oxygen Content

The percentage of the volume of the soil occupied by air at a certain moisture content is defined by *air-pore space* and is used for permeability characterization of the soil. High values of air-pore space could provide a dry soil environment, which does not permit the electrochemical development of corrosion. The aeration and oxygen content in soil moisture are very important for the corrosion process, because the oxygen is the principal oxidizing agent in the cathodic (electron consumption) corrosion reaction. It is generally assumed that the gases of the upper layers of soil are similar in composition to the atmosphere above the soil, except for a higher carbon dioxide content. By the fact that the plant roots require oxygen to penetrate a soil, it may be assumed that soil gases at depths of 6 m or more contain a significant amount of oxygen. For soils with coarse texture, such as sand and gravel, the circulation of air is relatively free and the corrosion rate may reach that in the atmosphere.

From a corrosion perspective, the solubility of oxygen in soil moisture (electrolyte) is one of the most significant effects. The dissolved oxygen concentration increases until the saturation limit is reached. The solubility of oxygen in water is a function of temperature and the oxygen solubility decreases as soil temperature increases. However, the temperature also increases the corrosion kinetics, even at lower levels of oxygen concentration. Some specific climates, such as warm and tropical humid (and their daily temperature variations), may cause expansion and contraction of the surface-soil gases. The oxygen content also depends on the biological activity within the soil and the consumed oxygen can be replaced with gases from metabolic activity, such as carbon dioxide.

### Relative Acidity (pH) of Soil

The soil moisture (electrolyte) can be described as acidic ( $\text{pH} < 7$ ), neutral ( $\text{pH} = 7$ ), or alkaline ( $\text{pH} > 7$ ), based on the relative ratio of hydrogen ions ( $\text{H}^+$ ) to hydroxyl ions ( $\text{OH}^-$ ). When  $\text{H}^+$  ions predominate over  $\text{OH}^-$  ions, the soil is acidic and vice versa. In a neutral solution both ions are in balance. (The value of pH indicates only the hydrogen ion concentration.) Fresh water and seawater typically have a near neutral pH. The concrete environment has a strongly alkaline  $\text{pH} \approx 13$ . The corrosion effect of soil moisture acidity or alkalinity depends very much on the specific metal of interest.

Acidity in soils is the result of natural processes of weathering under humid conditions, such as mineral leaching, decomposition of acidic plants, industrial wastes, acid rain, and certain forms of microbiological activity. Most soils range from pH 4.5 to pH 8. In this range, pH is generally not considered to be a problem for buried steel pipelines and tanks. More acid soils (pH lower than 4.5) can cause rapid metal corrosion and serious risk to common construction materials, including some stainless steel grades. In areas with moderate rainfall, soluble salts accumulate only where the water concentrates in depressions. In areas with considerable rainfall, soluble salts and bases are removed, resulting in increased acidity.

### Dissolved Salts and Corrosion Agents

The soil water is a good solvent for salts of the soil, which dissociate to form cations and anions and render the soil

conductive. In moderate rainfall areas the soil solution is relatively dilute (80 to 1500 ppm total dissolved salts). Lower salt concentrations characterize regions with extensive rainfall as a result of leaching action. Soils in arid regions are usually quite high in salts, due to surface evaporation.

The most common *cations* in the soil electrolyte are potassium and sodium in alkaline soils, magnesium and calcium in basic (calcareous) soils. Salts containing the four cations,  $\text{K}^+$ ,  $\text{Na}^+$ ,  $\text{Mg}^+$ , and  $\text{Ca}^{2+}$ , can accelerate metal corrosion. However, in non-acid soils, calcium and magnesium tend to form insoluble metal oxides or carbonates, which act as an effective barrier against corrosion. The corrosion rate in these soils may diminish significantly.

The *anions* also play a very important role in the corrosion process. If they react with metal ions, produced during the anodic corrosion reaction, and form an insoluble salt precipitate on the metal surface, this layer could act as an effective barrier against corrosion. This is the case of corrosion of lead sheathing for power and communications cables in a soil solution that contains sulfate ions ( $\text{SO}_4^{2-}$ ). The most corrosive anion for metals is the chloride ion ( $\text{Cl}^-$ ), which is usually naturally present in soils and sands of the marine-coastal regions, or it may be present as a result of external sources such as de-icing salts applied to roadways. Its attack is localized and more dangerous than the uniform corrosion, because the formed pits could perforate the metal surface. The chloride ion concentration in corrosive soil electrolytes (moisture) varies as soil conditions alternate between wet and dry.

Compared to the corrosion aggressivity of chloride ions, sulfate ions are generally considered to be less aggressive. However, they can be converted to highly corrosive sulfide ions by anaerobic sulfate reducing bacteria (SRB).

The *salt* content of soil may be altered by several human activities, such as fertilizer use in heavy doses, industrial wastes, deicing salts on road and walk ways, salt brines from petroleum production, and many others.

Another important relationship between the salt in the soil and corrosion has to do with *biological activity*. Since the growth of plants and microorganisms depend on the proper inorganic mineral nutrients, the action of these forms of life varies with the salt content of the soil.

### Microbiological Activity

The role of microbes or bacteria in the corrosion of metals is due to the chemical activities associated with their metabolism, growth, and reproduction. For example, the *microbiologically induced corrosion* (MIC) of metals by sulfate-reducing bacteria (SRB) is a recognized problem in pipelines. These bacteria are anaerobic and live in poorly drained wet soils, with a pH from 6 to 8, that contain sulfate ions, organic compounds, and minerals in the absence of oxygen and temperature from 20 to 30°C. In well-aerated soils the anaerobic bacteria cause no problem. During metabolism of the bacteria, oxygen is extracted from the sulfate ions and this reaction converts the soluble sulfates to sulfides, which attack the metal surface, forming, for example, iron sulfide ( $\text{FeS}$ ). Numerous studies established the relationship of sulfides and sulfates to bacterial activity in microbiologically induced metal corrosion [11–17].

FIG. 3—Localized corrosion attack on buried pipe accelerated by the presence of sulfate-reducing bacteria.

The corrosive microbial effect on metals can be attributed to removal of electrons from the metal and formation of corrosion products principally by:

- a) Direct chemical action of metabolic products, such as sulfuric acid, inorganic or organic sulfides and chelating agents, such as organic acids;
- b) Changes in oxygen content, salt concentration, and pH that increase the possibilities for differential diffusion and concentration gradients, etc., which establish local electrochemical corrosion cells.

Anaerobic bacteria have been reported to accelerate the normal corrosion process and convert noncorrosive soil to a very aggressive environment (Fig. 3). The environmental conditions under which the microorganisms normally operate are: temperature from 20 to 30°C, pH from 6 to 8, and soil resistivity from 500 to 20 000 ohm-cm. Rate and extent of corrosion are related directly to bacterial growth in contact with the metallic surface. Bacteria have been found that are capable of growing on many kinds of coating materials, including hydrocarbons.

#### *Disturbance of Natural Soils*

Experience shows that the pipeline ditch markedly disturbs natural soil. The operation of ditching and back-filling create several zones around the metal structure. The soil in the ditch is less compact and sometimes the disturbed soil is a mixture of surface and sub-surface soils. This new

heterogeneous soil environment may have higher moisture content, increased aeration, and microbial population. Contact with organic matter in coatings applied over the pipeline and the above factors create conditions for accelerated localized corrosion attack.

### CORROSION IN SOILS [1-6,9,10]

The electrochemical corrosion of metals buried in wet soils is based on the creation of multiple **corrosion cells**, formed by coupled *anodes* and *cathodes*. The *cathodes* are characterized by metal areas with a higher level of potential energy (Gibbs Free Energy) and the *anodes* have a lower potential energy. This energy difference between anodes and cathodes sites is usually due to the heterogeneity of composition of the metal structure. The soil in which the metal resides could also contribute to corrosion cell formation.

The metal corrosion is an *oxidation process* and it occurs at the **anode** areas where the metal goes into soil moisture as metal cation (ion), leaving electrons. The principal **anodic reaction** is:

The generated free electrons flow through the metal to the **cathode** areas, where they are accepted by oxidizing

agents, such as air oxygen dissolved in the moisture. The oxidizing agents undergo a *reduction process* in the **cathodic reaction**:

In weak acid soils the cathodic reaction involves the participation of oxygen molecules and hydrogen ions ( $\text{H}^+$ ):

In strong acid soil the principal oxidizing agent is the hydrogen cation:

Different oxygen contents in the soil moisture at the metal surface can create local **oxygen concentration cells**. Wet soil with lower oxygen usually gives rise to anodic areas, while well-aerated soils form cathodic areas on the metal surface (Fig. 4). In most cases when the metal structure is exposed to different temperatures, the areas at higher temperatures become anodes and those at lower temperatures become cathodes. Since soils usually are a mixture of different kinds of soils, they often provide no uniform environment for the metal structure. This heterogeneous environment creates different and local aeration zones on the metal surface, and as a consequence can cause serious localized corrosion attack (Figs. 5–6).

Sometimes pipes are buried with mill scale ( $\text{FeO}$  and  $\text{Fe}_3\text{O}_4$  gray oxide layer) that is formed on their surface as a product of high temperature chemical corrosion during hot-rolling production and thermal treatments. This layer is an efficient protective coating for the metal, since it is resistant

FIG. 4—A metallic pipe is anodic in wet soil with lower oxygen content and cathodic in better oxygenated soil.

FIG. 5—Oxygen concentration corrosion cells caused by a mixture of different soils.

to corrosion and quite adherent. However, it is brittle and its structure presents a lot of heterogeneity and cracks that contribute to creation of local corrosion cells at the interface metal/scale. The *scale oxides* are electronic semiconductors, and they can serve as *cathodes*. Areas covered with scale are more cathodic than those where the metal is not covered and open to the environment. Such bare area can be a perfect *anode* for a corrosion cell (Fig. 7).

If the buried metal structure involves contact between different metals (such as mild steel, copper, bronze, brass, aluminum, zinc, lead, stainless steel, cast iron, etc.), it is possible that local **galvanic cells** can form in the contact areas (Figs. 8–9). Each metal has its own tendency to corrode. An alternative way to express the metal reactivity is to look at the excess of its free energy (standard electrochemical metal potential) and predict the *electromotive force (emf)* between metals in contact, as a general indication for the corrosion process (Table 2). The metal that has a more positive potential is nobler in the galvanic cell, and it is a cathode. The metal with a more negative potential is more active and acts as an anode in the corrosion cell, e.g., it suffers corrosion.

As corrosion proceeds, the steel changes its surface physical-chemical properties because of the formed corrosion layer. Insoluble corrosion products partially act as a physical barrier against the corrosion process. In this case, when a new repaired part of steel is connected to old steel, which has been in the soil for a relatively long time, the new section suffers corrosion because it is anodic with respect to old steel, even when the steel composition is identical.

*Stray currents*, picked up by a buried structure, could also cause metal corrosion. They are usually direct electric currents (dc) deflected from their principal service. Sources of stray currents could be direct current equipment and systems, such as electric railway systems, grounded d-c power supplies, electric welders, cathodic protection systems for underground natural gas pipelines, and electroplating plants, that are not well insulated from the earth. The metal structure suffers severe **stray current corrosion** at the area where the stray current discharges and leaves the metal, as it seeks for a new low resistance path. As shown in Fig. 10, when tracks are laid at ground level and not insulated well from the earth, some part of the load current enters the ground where the tracks are most positive (at the load) and follows an earth path back to the substation. The stray current corrosion looks like pitting on an otherwise smooth surface, and only a light rust and black carbon dust cover the spots where the stray current is discharged. Stray current prevention measures are corrective drainage and good insulation. Lead pipelines and lead cable sheathing also can suffer severe stray current corrosion caused by minor earth currents.

In certain specific soil chemistries the metal corrosion may be nonuniform, concentrated in relatively small areas that form sharply defined local holes called *pits* (Figs. 11–12), that grow deep into the metal and can cause failure by perforation. The pits are usually small in diameter, isolated from each other, and occur in more anodic metal areas with respect to the rest of the surface. The **pitting corrosion** is a very dangerous form of localized metal attack and sometimes cannot be detected by simple visual examination.

FIG. 6—General view of corrosion attack in soil at local aeration zones.

FIG. 7—Corrosion cell created on metal surface due to the presence of heterogeneity in the formed corrosion layer.

FIG. 8—Galvanic corrosion caused by contact of dissimilar metals. Steel is the anode, which suffers corrosion, and brass is the cathode. Electrons leave the steel and flow to brass.

For example, when pitting corrosion occurs together with slight or moderate general corrosion, the corrosion products often mask the pits. Soils in marine-coastal environments, containing relatively high concentrations of chloride ions (active anions), cause chloride-induced pitting corrosion on the metal structure. Once a pit initiates, an active corrosion cell is set up as shown in Fig. 13. The rapid dissolution of metal in the pit produces an excess of positive metal ions, which hydrolyze in the water solution, causing a high concentration of hydrogen ions. The cause of pitting could be associated with local inhomogeneity on the metal surface, mechanical or chemical defects (holidays) in a protective organic or oxide coating (Fig. 14), galvanic corrosion, or the presence of biological organisms. Pitting corrosion occurs in most commonly used buried metals and alloys.

Some specific corrosion environments, in the presence of applied tensile stress on the metal surface (above some threshold value), can cause **stress-corrosion cracking (SCC)**. The source of stresses can be external, but residual stresses can also cause SCC failures. Specific corrosive pollutants, which may contribute to the SCC of carbon steels, are for example, the carbonates in water. **Sulfide stress cracking (SSC)** commonly occurs on the outside of a pipe where sulfate-reducing bacteria are present at a soil pH of 3–7. Because of the produced iron sulfide (FeS), which adsorbs readily on the steel surface, hydrogen atoms generated

FIG. 9—Galvanic corrosion attack produced on the surface of buried pipe.

during the cathodic corrosion reaction cannot combine to form molecular hydrogen, and therefore, enter into the iron crystal, causing hydrogen embrittlement and initiating microcracks.

#### General Methods for Corrosion Protection

The electrochemical corrosion of metals occurs at the metal/corrosive electrolyte (metal/soil moisture) interface. Consequently, the first group of methods for corrosion protection aims to *create an efficient separation* of the metal from the aggressive environment, using metallic, organic, and inorganic coatings.

The second method includes *chemical treatment of the corrosive environment*, for decreasing its aggressiveness, by changing its pH, salt and moisture content, existing microbes, and existing bacteria, when it is economically and technically feasible.

The third method is *decreasing the metal activity*, by alloying with metals, like chromium, nickel, molybdenum, cobalt, titanium, copper, etc., that usually form passive oxide layers, that are resistant in a given environment.

From the thermodynamic point of view, some metals can be *polarized* in a range of potentials where the metal enters into an *immune* (no corrosion) or *passive state* (creation of resistant oxides). These states could be achieved, respectively, by *cathodic* and *anodic electrochemical methods of protection*, applying external polarization (potential) using direct current. *Pourbaix diagrams* provide useful

thermodynamic information on the possible metal states using metal *potential-pH* of water solution coordinates.

#### Steels, Lead, and Copper in Soils

The most frequently used materials for buried metal structures are the *carbon steels*. For prevention of their corrosion the most recommended, economical, and effective method is *cathodic protection* (CP). The use of CP is now standard procedure for long-term corrosion protection of underground pipelines, oil and gasoline tanks, and other structures. With a shift of the metal potential to more of a negative value of  $-0.85$  V versus a  $\text{Cu}/\text{CuSO}_4$  reference electrode, it is possible to make the metal surface a *cathode*, which ensures an immune (no corrosion) state of the carbon steel. Cathodic polarization is achieved by direct current, which can be supplied either by *sacrificial anodes* in galvanic contact with the steel structure, or by *impressed current* from a rectifier.

Some *organic coatings* like polymers, plastics and rubbers, other than paint, are used to advantage along with cathodic protection of steels. Coatings of coal tar, coal tar/epoxy, or fusion-bonded epoxy powders are used to ensure a passive metal protection, isolating the metal from the soil environment, and also to decrease the current required for CP. *Painting and chemical treatment* of the metal surface are seldom used. *Metal coatings* such as electroplating or thermal spraying are not recommended. Making *alloying additions* to steel buried in soils is considered not to be an

\*The metal that has a more positive potential is more noble in a galvanic cell between two metals, and it is the *cathode*. A more negative potential corresponds to the more active (*anodic*) metal.

The state of oxidation of the metal ion (cation) is equal to the number of electrons liberated by the metal during the anodic corrosion process. For example,  $\text{Ni} \rightarrow \text{Ni}^{2+} + 2\text{e}^-$ .

FIG. 10—Stray current in street railways. The area near the substation, where a current flowing in a pipeline leaves its surface to return to the negative bus bar, can suffer very severe corrosive attack.

effective method for prevention of *galvanic corrosion*. Elimination of galvanic contact between steel and more noble metals, selection of more compatible dissimilar metals in a junction, introduction of insulators, and protective coatings are recommended.

Stainless steel (SS) is also used as a material for buried metal structures. In principle, the SS should be in the passive

state in soils, due to the naturally formed very resistive oxide layer on its surface, composed of oxides of different alloying elements (nickel, chromium, molybdenum, copper, etc.) and iron. However, the presence of chloride in the soil can cause stainless steels to pit or corrode in crevices, so this material should be avoided in chloride containing soils. It is also known that SS can be attacked by certain species of microbes, contributing to their microbial corrosion (MIC).

Another metal with a successful service record in soils is *lead*. Thousands of kilometers of lead-sheathed power and communication cables and lead pipes have shown good performance underground. They are directly buried in the ground or installed in ducts or conduits. Lead corrodes less on the average than does steel. Most of the initially formed corrosion products of lead are relatively insoluble salts, such as carbonates, silicates, or sulfates. They are deposited on the lead surface and ensure very compact and dense protective layers for the metal. The formation of such a layer is responsible for the high resistance of lead to corrosion. Due to its less negative potential (Table 2), the lead is *cathodic* when connected to steel (except for strongly alkaline environments), aluminum, zinc, or cadmium, and thus will accelerate the corrosion process of these metals. Only in galvanic contact with copper, stainless steel, and titanium, will lead be an *anode* in the formed corrosion cell and suffer corrosion attack. In poorly aerated soils or soils high in organic acids, the corrosion rate may be four to six times higher than the average. Other factors that may accelerate the corrosion of lead are stray currents, microorganisms (like sulfate-reducing bacteria), a high concentration of hydroxides (up to 1000 ppm, for example, in a wet concrete tunnel), and contact with acetic acid (in a wooden duct).

*Copper* is also a metal used for underground cables and usually has very good corrosion resistance. Copper on the average corrodes at about one sixth the rate of iron, but in tidal marsh the rate is higher than in most other soils, about half that of iron. When connected to buried steel or iron, the copper will be a cathode of the galvanic cell and will not suffer any corrosion.

An increase in chromium content of steel decreases the observed weight loss in a variety of soils, but above 6 % chromium, the depth of pitting increases.

## TESTING IN SOILS [8,18-26]

### Direct and Indirect Measurements and Techniques for Use

The corrosion behavior of a buried metal structure needs to be indirectly controlled or monitored to determine the time for direct examination when repairs will be necessary. Looking at the corroded surface is usually expensive and is acceptable only for a special corrosion situation. However, direct external surface assessment is sometimes imperative, for example, to verify some indirect measurements or for visual examination of the coating for damage. Several *NACE Recommended Practices* are useful in this situation:

**RP0502**—Pipeline External Corrosion Direct Assessment Methodology;

**RP0169**—Control of External Corrosion on Underground or Submerged Metallic Piping Systems;

FIG. 11—General view of localized pitting corrosion on underground pipe surface.

- RP0285**—Corrosion Control of Underground Storage Tank Systems by Cathodic Protection;
- RP0274**—High-Voltage Electrical Inspection of Pipeline Coatings;
- RP0286**—Electrical Isolation of Cathodically Protected Pipelines;
- RP0375**—Wax Coating Systems for Underground Piping Systems;
- RP0487**—Considerations in the Selection and Evaluation of Rust Preventives and Vapor Corrosion Inhibitors for Interim (Temporary) Corrosion Protection;
- RP0174**—Corrosion Control of Underground Residential Distribution Systems;
- RP0177**—Mitigation of Alternating Current and Lightning Effects on Metallic Structures and Corrosion Control Systems.

Direct assessment gives a possibility for *direct mechanical* or *ultrasonic measurement* of pit depth and wall thickness change due to the corrosion. *X-ray radiography* is used to inspect welds immediately after they are made. This technique can also show stress corrosion cracks and corrosion pits in the weld area, where the coating has failed to seal the metal structure. A promising method of mapping corrosion on the metal surface is the use of *laser scanning equipment*.

Direct measurement of metal corrosion rate can be achieved using preweighed *metal coupons*. They are buried

in the pipeline trench, unconnected or connected to the structure at a controlled test post. Periodically, they can be removed and processed for their weight loss due to corrosion. A simple calculation can give the corrosion rate value, expressed, for example, in  $\text{g/m}^2$  year. This method is time-consuming, especially when a large number of samples are needed for removal at consistent intervals.

The buried coupons have no standard size or shape and are made of the same metal as the structure. Comparing the mass loss of connected and unconnected coupons may provide information about the effectiveness of cathodic protection. Connected coupons have not been fully accepted as a cathodic protection monitoring test, because the coupon may not always polarize to the same potential value as the metal structure.

An *electrical resistance (ER) probe* is designed to measure corrosion in soil, without the necessity to be dug up for examination. This is an advantage over the coupons. The ER of the probe, made of the same metal as the structure, will change its value because of loss of metal, due to conversion to corrosion products on the metal surface. The ER probe also gives indirect information about the soil corrosivity and its changes with time.

#### *Field and Laboratory Tests*

Several field and laboratory tests are used to correlate soil corrosion aggressivity to its physical and chemical properties. Sampling errors are the most common errors encountered

FIG. 12—General view of pit formed on buried corroded pipe surface.

FIG. 13—Pit action and active pitting cell.

in soil analysis, due to the extreme heterogeneity of the material. In the laboratory, grinding and mixing can minimize such errors, but the largest sampling error occurs in field measurements.

#### Potential Measurement *in Situ*

This measurement establishes the corrosion potential of buried metal in a given soil. Its value is an indication of the degree and extent of corrosion attack and the efficiency of applied cathodic protection. The metal potential usually shifts with time to less negative values, if the corrosion products form an inert and compact layer on the metal surface. Due to this fact, it is possible to observe more positive potential values on an old structure than those measured on

a new metal surface. A new, coated steel pipe may have a potential of  $-0.7$  V versus a  $\text{Cu}/\text{CuSO}_4$  reference electrode, while an old pipe surface is more positive ( $-0.1$  to  $-0.3$  V). The surface areas where the potential is less negative will be more cathodic, and as a consequence they will suffer less corrosion. Stray currents or interference from foreign cathodic protection systems may cause potential fluctuations and have to be taken into account.

The *in situ* cathodic protection test criteria for full protection of steel is that all measured points are close to  $-0.85$  V versus a  $\text{Cu}/\text{CuSO}_4$  reference electrode. For long pipelines, passing through different types of soil, the potential is usually measured every 30 m or less (often at 1.5 m).

Experience indicates that the corrosion potential value of buried copper cable correlates with its corrosion behavior (Table 3). A potential value of  $-0.50$  V or more negative, versus a  $\text{Cu}/\text{CuSO}_4$  reference electrode, indicates full cathodic protection of this metal, typically provided by a connection to a steel structure.

An indicator of soil corrosivity is the value of *soil oxidation-reduction* (ORP) or *redox potential*. It is calculated from the potential difference measured with a probe that contains an inert platinum (Pt) electrode and a saturated calomel electrode ( $\text{Hg}/\text{Hg}_2\text{Cl}_2/\text{KCl}$ ,  $+0.241$  V versus SHE) as a reference electrode. The value of this soil redox potential depends on the dissolved oxygen content in the pore water and provides some information on the conditions under which sulfate-reducing bacteria could grow. The use of redox potentials to predict soil corrosivity is presented in Table 4.

FIG. 14—Localized corrosion on buried metal structure, concentrated on holidays (defects) of the coated surface.

TABLE 3—Copper potential and corrosion behavior.

Potential vs. Cu/CuSO <sub>4</sub>	Corrosion Behavior
Positive to -0.1 V	Probably corroding
-0.1 to -0.25 V	Possibly corroding
-0.25 to -0.50 V	Probably not corroding
-0.50 V or more negative	Full protection

TABLE 4—Soil redox potentials as an indicator for soil corrosivity.

Redox Potential (vs. SHE*)	Aeration	Soil Corrosivity Category
Negative	Not aerated	Extremely severe
0–100 mV	None to weak	Severe
100–200 mV	Weakly aerated	Moderate
200–400 mV	Aerated	Slight
Above 400 mV	Strongly aerated	Noncorrosive

\* Standard Hydrogen Electrode (SHE), conventionally accepted to be 0.00 V.

Potential measurements of metal in soil require the use of some assistance tools, such as insulated wire, reels, alligator clips, terminal connectors, hand tools, a reference electrode (RE), and specialized equipment like voltmeters and ammeters.

The *saturated copper/copper sulfate reference electrode* (Cu/CuSO<sub>4</sub>) is the most used in soils (+ 0.316 V versus SHE

standard potential). This RE has poor reproducibility and needs to be frequently checked and renewed. In high chloride environments the most appropriate electrode is a *silver/silver chloride RE* (Ag/AgCl/KCl (0.1N) +0.288 V versus SHE standard potential). Usually it provides reproducible and reliable values. The *lead sulfate RE* (Pb/PbO<sub>2</sub>/PbSO<sub>4</sub>/H<sub>2</sub>SO<sub>4</sub> (0.1M), + 1.565 V versus SHE standard potential) is connected to lead-sheathed cables for measurement of their potential. Very dry soils may be wetted or a shallow hole dug to establish good electrical contact between the electrode and the soil moisture. The RE should be placed near the metal structure, augering a hole down to near the pipeline surface, to minimize ohmic potential drop (IR) due to the soil and coating resistance. The tester must avoid any damage to the coating or protective scale on the metal. The potentials over well-coated pipelines do not vary much over distance.

Factors affecting the potential measurements are broken test leads, corroded contact points, and defective insulation of test leads. An improperly calibrated RE can also be an important source of errors. The existence of vegetation or of other metals may introduce errors of over 100 mV.

The metal potential can be measured using *voltmeters* with more than 10 MΩ internal resistance. *Ammeters* are used to measure electric current passing through the structure protected by CP and are relatively low-resistance instruments.

### Soil Resistivity

The soil resistance ( $R$ ) to passage of electrical current is the most used parameter as an indicator of corrosion aggressivity of soils. It is related to three terms in the equation

$$R = \rho \cdot l / A$$

where  $\rho$  is *specific resistivity* of the particular soil,  $l$  is a length of the electrical path, and  $A$  is the cross-sectional area of the electrodes.

The resistivity indicates the probable corrosivity of the soil. Its value depends on the soil water content on the layers and on types of soils underneath (sand, rock, gravel, clay, mud, etc.). Vertically homogeneous soils are virtually nonexistent. Thus, it is convenient to consider a nonuniform soil to consist of different layers or strata [7]. Electron flow will deflect downward in the case of a high resistivity strata over a low resistivity one, and vice versa, as shown in Figs. 15 and 16. The electrical resistivity of the surface strata has greater influence on test results than does that of deeper strata. Also, the soil resistivity decreases with increasing water content and with increasing water salinity because of high contents of ions. Thus, nonporous soils exhibit relatively high values of resistance, since the water content is small. These include nearly all of the igneous and metamorphic rocks such as granite, plus many sedimentary rocks such as dense limestone or sandstone. The resistivity of bedrock can vary considerably depending upon the type of bedrock and the extent of weathering and fracturing.

FIG. 15—Low resistivity layer over high resistivity layer.

FIG. 16—High resistivity layer over low resistivity layer.

The resistivity of sand and gravel deposits is generally high and uniform, while many bedrock formations have high but erratic resistivity. Table 5 gives typical resistivity values of various minerals and soils.

Along the length of the pipe, variations in soil resistivity may stimulate localized metal corrosion and can cause long line currents; in the area of *lower resistivity* soil the buried metal surface is usually *anodic*, with a more negative potential, compared to that in the soil of higher resistivity.

Soil resistivity measurements are carried out by the *Wenner technique*, *four-pin method*, with or without Barnes Procedure, according to procedures of ASTM Standard Test Method for Field Measurement of Soil Resistivity Using the Wenner Four-Electrode Method (G 57) using commercially available instruments. Four steel electrodes, each spaced an equal distance from the next, are driven into the ground. An alternating current (ac) or direct current (dc) is passed between the outer two pins, and the corresponding potential drop (voltage  $\Delta V$ ) is measured between the inner pins, as shown in Fig. 17. The resistance  $R = \Delta V / I$ , where  $I$  is the applied current. This procedure is usually used to measure the average resistivity of the soil where a cathodically protected structure is to be installed.

The average resistivity value depends on how many measurements are taken in the area and when they were taken. Measurements should be made at various times and weather conditions (dry or rainy seasons, summer or winter, etc.). It is, therefore, impossible to give any precise assessment as to the rate at which corrosion will occur

TABLE 5—Electrical resistivity of various minerals and soils.

Minerals and Soils	Resistivity, $\Omega$ -cm
<b>Minerals</b>	
Pyrite	0.1
Magnetite	0.6–1.0
Graphite	0.03
Rock Salt (impure)	3000–500 000
Serpentine	20 000
Siderite	7000
<b>Igneous Rock</b>	
Granite	500 000–100 000
Diorite	1 000 000
Gabbro	10 000 000–1 400 000 000
Diabase	310 000
<b>Metamorphic Rocks</b>	
Garnet gneiss	20 000 000
Mica chist	130 000
Biotite gneiss	100 000 000–600 000 000
Slate	64 000–6 500 000
<b>Sedimentary Rock</b>	
Chattanooga shale	2000–130 000
Michigan shale	200 000
Calumet and hecla conglomerates	200 000–1 300 000
Muschelkalk sandstone	7000
Ferruginous sandstone	18 000
Muschelkalk limestone	18 000
Marl	7000
Glacial till	50 000
<b>Type of Soil</b>	
Sand	10 000–500 000
Oil sand	400–22 000
Gravel	20 000–400 000
Loam	3000–20 000
Clay	500–2000
Silt	1000–2000

FIG. 17—Four-electrode method for the electrical soil resistance measurement.

under any particular conditions, and the results of any survey must be taken as giving only a general indication of the probability of corrosion. Chemical and other forms of industrial contamination of the soil can significantly influence soil resistivity and corrosivity. In real life, the soil is not homogeneous and layers are not always horizontal. In fact, as the spacing between Wenner pins changes, soil resistivity readings may also change.

There are several *commercial meters* that allow measurement of soil resistivity. A commonly used resistance meter is shown in Fig. 18. One reliable and widely used instrument uses an alternating current 97 Hz square wave. It has several advantages such as eliminating the effect of polarization that can affect the measurements when using dc, and eliminating interference by 60 Hz sinusoidal currents.

Soil resistivity can be measured under either field or laboratory conditions. In the laboratory, the soil sample is placed and compacted to the same amount as the soil at the site in a *soil box*, with typical internal dimensions of  $4.0 \times 3.1 \times 21$  cm. The resistivity is measured between the two pins inserted in the sides of the box, applying low voltage dc or ac. Errors could result from polarization when using a d-c or a-c current of too low a frequency. The soil box measurement (representing a specific soil sample) is a point measurement, not an average soil resistivity as is the Wenner method. Another alternative way to measure soil resistivity is to combine the Wenner four-pins with the soil-box (Fig. 19) and follow the standard test method of ASTM G 57. In laboratory tests the soil resistivity can also be measured at 100 % water saturation using distilled water, which gives a value that could correspond to that of rainy climatic periods, when a lot of salts may be dissolved and cause a decrease of the soil resistivity. The temperature changes have only a slight effect on the soil resistivity value until total freezing of soil moisture occurs. However, the ice resistance increases sharply as temperature drops. Table 6 shows an approximate relationship between soil resistivity values and soil corrosivity categories for buried mild steel structures.

The soil box could be used also in laboratory tests to determine the corrosion rate (weight loss) of metal samples buried in a given soil for some period of time. This test can be conducted using ASTM Standard Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens (G 1). The soil in the box may be maintained in a saturated state with distilled water to keep all salts dissolved (dissociated as ions). Visual examination of the metal samples will give information on the corrosion appearance, especially useful when the corrosion is localized, such as pitting. Pitting can be evaluated in accordance with ASTM Standard Guide for Examination and Evaluation of Pitting Corrosion (G 46). Corrosion products could be analyzed for their composition. Figure 20 shows general views of mild steel samples corroded in different types of soils.

#### *Field and Laboratory Measurement of Relative Acidity (pH) of Soil*

Soil acidity, or its pH, is the most important measured parameter. Details for conducting field measurements of pH in soils for use in corrosion testing are covered in ASTM Test Method for Measuring pH of Soil for Use in Corrosion Testing (G 51). Two electrodes, glass and calomel, of a standard pH meter are pressed on undisturbed soil at a given site, and the value of their potential difference is linearly related to pH. Salts such as fertilizers in the soil can affect the correct value.

A sample of soil can be collected and taken back to the laboratory for pH analysis. There, the soil can be mixed with distilled water (1:1 by volume), shaken well, and then the pH measured in a sample of the filtered extract solution. In the case of soils rich in sulfide, the pH value could be more acidic because of the oxidation of sulfides to sulfates as the soil dries out. The treatment of the soil prior to pH measurement is still an open issue. Drying of soil samples and addition of distilled water are two of the treatments used. However, the soil resistivity value is not sufficient to unambiguously indicate the soil corrosivity. For example, a neutral soil (pH 6.6–7.3) could be very corrosive due to the presence of chloride ions. Table 7 presents an approximate relationship between pH of soil water extract and soil corrosivity.

In some cases a determination of the *total acidity* is desirable. Additional measurement requires a soil treatment by mixing the soil with a solution of neutral salts like KCl,  $\text{CaCl}_2$ , etc., to determine the *exchange* or *total acidity* of the soil, which includes the hydrogen ions loosely bonded to soil minerals. This extraction method is practically unaffected by fertilizers or other salts that may be present in the soil.

#### *Laboratory Measurement for Presence of Ions*

From a corrosion point of view, the important ions that can be found in soil and in soil moisture are:

1. *anions*: chloride ( $\text{Cl}^-$ ), sulfate ( $\text{SO}_4^{2-}$ ), nitrate ( $\text{NO}_3^-$ ), phosphate ( $\text{PO}_4^{3-}$ ), carbonate ( $\text{CO}_3^{2-}$ ), bicarbonate ( $\text{HCO}_3^-$ ), and
2. *cations*: calcium ( $\text{Ca}^{2+}$ ), potassium ( $\text{K}^+$ ), ammonium ( $\text{NH}_4^+$ ), magnesium ( $\text{Mg}^{2+}$ ), sodium ( $\text{Na}^+$ ), and ferrous ( $\text{Fe}^{2+}$ ) and ferric ( $\text{Fe}^{3+}$ ) ions.

Their concentration determines the ionic conductivity and resistivity of the soil moisture, and also the tendency

FIG. 18—General view of four-pin soil resistance meter

for formation of a precipitated layer on the metal, which may protect its surface from future corrosion attack. The most dangerous ion is chloride, which may accelerate the metal corrosion, causing deep pitting. In some cases, the presence of sulfides such as hydrogen sulfide ( $\text{H}_2\text{S}$ ) should be determined also. The ion concentration is measured in a water soil extract using various analytical techniques. Slightly alkaline ground water usually contains  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{SO}_4^{2-}$ , and  $\text{HCO}_3^-$  ions, as part of the dissolved salts (<1000 mg/L or in a higher range of 1000–10,000 mg/L). In slightly acidic water the principal ions are  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ , and  $\text{HCO}_3^-$ , with a lower concentration of total dissolved solids of <100 mg/L.

#### *Biological Activity Test*

Tests for sulfate-reducing bacteria include counts of total viable sulfate reducers. Other tests include measurement of the hydrogen uptake of a soil, and the time for a soil sample to blacken a medium used to grow sulfate reducers. Chemical analysis of the water source and the soil is helpful in determining the critical nutrients necessary to support microbiological activity. These tests should be conducted under the direction of a microbiologist who has experience in microbiologically influenced corrosion. Field test kits are currently available that employ an antibody tagging technique to identify and facilitate the determination of the population of microbes [27,28]. Microbiologically influenced corrosion (MIC) can be studied using field survey and other techniques, such as electrochemical polarization curves, polarization resistance, electrochemical impedance spectroscopy (EIS), thin-film electrical resistance (ER) probe, galvanic current measurement, SEM and EDS surface analysis, etc. [17].

#### *Electrochemical Laboratory Tests [29–32]*

Several electrochemical tests have been used successfully over the years to estimate the corrosion behavior of a given metal in soil or to determine the soil corrosivity. These tests can be carried out in water extract of soil and/or in water saturated soil, when all dissolved salts (ions) are present. The electrochemical test methods and practices are described in several *ASTM Tests Methods and Practice*:

- Standard Practice for Conventions Applicable to Electrochemical Measurements in Corrosion Testing (G 3);
- Standard Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements (G 5);
- Standard Test Method for Conducting Potentiodynamic Polarization Resistance Measurements (G 59);
- Standard Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-Based Alloys (G 61);
- Standard Guide for Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes (G 71);
- Standard Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Measurements (G 102);
- Standard Practice for Verification of Algorithm and Equipment for Electrochemical Impedance Measurements (G 106);
- Standard Practice for Evaluation of Hydrogen Uptake, Permeation and Transport in Metals by an Electrochemical Technique (G 148);

FIG. 19—Soil box in use, with inserted Wenner four-pin electrodes.

**TABLE 6**—Corrosivity categories of soils for buried mild steel based on soil resistivity ( $\rho$ ) values

Corrosivity of soil	Soil resistivity ( $\rho$ ) $\Omega$ -cm
Very severe	< 500
Severe	500–2000
High	2000–5000
Moderate	5000–10 000
Medium	10 000–25 000
Light	25 000–50 000
Low	>50 000

These standard methods and practices provide the necessary information for electrochemical potentiostatic and potentiodynamic anodic measurements, calculation of corrosion rate from electrochemical measurements, and conducting potentiodynamic polarization resistance measurements. Recently, *Electrochemical Impedance Spectroscopy* (EIS) has been introduced for corrosion measurements of steel structures corroding in soils. These tests can be

performed using a *commercial potentiostat*, appropriate computer software for analysis of the results, a standard electrochemical cell, a platinum or carbon counter electrode, a reference electrode, and a sample of the metal as a working electrode. Figure 21 presents a general view of equipment in use for electrochemical measurements. Recently, an Electrochemical Impedance Spectroscopy (EIS) technique has been introduced for measurements of steel structure corroding in soil.

*External Corrosion Direct Assessment (ECDA) of Buried Pipelines [33,34]*

As a result of regulatory changes in the U.S., the pipeline industry needed an alternative method to pressure testing on in-line tool inspection to assess buried pipelines [33]. *EDCA is a four-step process* consisting of:

- *Preassessment*: pipe data, construction data, soil/environmental conditions, corrosion protection data, and operating parameters/history;

FIG. 20—General view of mild steel samples corroded in different soil samples (a) clay, (b) sand, (c) and (d) calcareous sandy soil. These soils are part of Southeastern Mexico in the Mexican Caribbean Gulf.

TABLE 7—Corrosivity categories of soils for buried steel based on pH of water soil extract.

Corrosivity of soil	Relative acidity (pH) of soil extract
Low	>12
Moderate	7.5–12
High	4–7.5
Very high	< 4

- *Indirect inspection*: the purpose is to identify the locations of coating faults, insufficient cathodic protection, and electrical shorts (close-interval, on/off potential surveys, electromagnetic current attenuation surveys, alternating current voltage gradient surveys, etc.), interference, geological current surveys, and other anomalies along the pipeline.
- *Direct examination*, excavating the pipe and performing physical inspections and tests on the pipe surface and the surrounding soil/water electrolytes, to assess the degree of corrosion;
- *Post-assessment* gives one an opportunity to assess the overall effectiveness of direct assessment and to define re-assessment intervals based on remaining-life calculations.

The EDCA process incorporates standard techniques for compiling historical information, pipeline and soil surveys, external pipeline inspections, and data analysis. The procedure includes no new measurement techniques, but it does allow for the future addition of such techniques. Some rules and information about EDCA are present in NACE **RP0502**—Pipeline External Corrosion Direct Assessment Methodology.

New advances in satellite technology may soon help pipeline operators and utilities observe encroachments and

FIG. 21—General view of equipment for electrochemical measurements.

ground movements near their assets with unprecedented details [34].

# Concrete

Neal S. Berke<sup>1</sup>

## DESCRIPTION

### The Concrete Environment

CONCRETE IS ONE OF THE most widely used construction materials due to its good durability and relatively low cost. When reinforced with steel and other materials it has very good structural properties allowing for its use in numerous structures such as bridge decks, parking structures, marine piles and piers, and large buildings. The embedded steel does not corrode due to the high alkalinity of concrete which results from the portland cement used in its manufacture.

The pH of concrete is typically  $\geq 12.5$  with some measurements on squeezed pore water suggesting even higher values [1]. Thus in the absence of a depassivating ion such as chloride, or carbonation of the concrete to a lower pH value, steel will remain passive. Note that steel in concrete subjected to high stray voltages could corrode under environmental conditions that would normally be benign.

In addition to providing a high pH environment, concrete also has a high resistivity compared to most aqueous environments. Resistivities in water saturated concrete range from 2000 to over 300 000  $\Omega\cdot\text{cm}$  and are even higher in dry concrete [2,3]. Correction for high resistance is needed in making electrochemical corrosion rate measurements.

The high resistivity of concrete is related to a reduced permeability of concrete to the ingress of water and chloride [4–6]. Thus, it can take several years to decades for corrosion activity to initiate on steel embedded in concrete, even when the exposure to chloride is severe.

### Simulated Concrete Environments

The concrete environment is often simulated by a concentrated calcium hydroxide solution [7,8]. Addition of additional sodium or potassium hydroxide, or both, to increase the pH has no effect on changing the corrosion mechanisms, but increases the chloride threshold level [9]. Typically the effects of chlorides and corrosion inhibitors on the susceptibility of steel to pitting can be determined in these environments [7–9].

More realistic simulated environments are mortar or cement paste mixtures. The chemistry is much closer to that occurring in concrete. The drawback of these mixtures is that they

do not necessarily reproduce true concrete behavior due to the effects of coarse aggregates in concrete. For example, porosity and calcium hydroxide plate precipitation is highest at the coarse aggregate paste boundaries, and this plays an important role in the corrosion processes [10].

## ASPECTS THAT MAKE TESTING UNIQUE

### High Resistivity

The high resistivity of concrete requires the use of techniques to correct for the voltage drop through the electrolyte (IR drop). This is especially the case for concrete produced with pozzolans, such as silica fume, or latex modified concretes in which the resistivities of the wet concrete can be in excess of 300 000  $\Omega\cdot\text{cm}$ . It has been shown that IR interruption and electrochemical impedance spectroscopy are effective in properly correcting for the IR drop in laboratory specimens [3].

In addition to the high resistivity due to the concrete, the IR drop can be significant depending upon the placement of the reference electrode. This is due to the fact that concrete surrounds the embedded working electrode, and often the distance between the two electrodes is over 20 mm.

### Complexities Associated with Corrosion Evaluation

Determination of the area polarized in a concrete specimen is not clearly defined in most field applications. Typically bars are meters in length and spaced on the order of 25–30 cm in multiple mats. When a counter-electrode is at the surface of the concrete along with the reference electrode it is not a trivial matter to determine the area of bars being polarized. Furthermore, the area polarized is affected by whether or not the steel is passive [11].

Another hurdle involves making electrical connections to the steel. In laboratory specimens this can be performed by bringing the bar out of the concrete or by pre-attaching a wire and insulating the area at the connection point. The connection point must be electrically isolated and remain dry to prevent galvanic corrosion.

In the field one must locate the bar and drill or core to make an electrical connection. If there is good continuity between the bars, one connection can allow for testing at multiple sites. However, in the case of poor continuity, e.g., epoxy-coated rebars, multiple connections will be needed.

<sup>1</sup>Research and Development Fellow, Grace Construction Products, W. R. Grace & Co.-Conn., Cambridge, MA 02140.

It is not possible to perform a visual examination of the bars nondestructively. This requires concrete removal and replacement if necessary. In field structures this could be a site of future corrosion activity if the patch area is more permeable than the original concrete, or excessively cracks due to shrinkage or other causes. Laboratory specimens are typically removed from testing if the bars are to be examined. It is possible to make visual examinations of the concrete surface for staining or cracking, or both, and delamination determinations can be performed non-destructively.

Mass loss tests are a common means of testing many metals in atmospheric and submerged exposure. For steel in concrete they are destructive to the concrete and difficult to perform. Laboratory specimens typically have a portion of the embedded bar coated or taped to define a specific test area. These materials are often hard to remove and could gain or lose mass. Furthermore, at the initial stages of corrosion most of the damage is in pits which have relatively low mass loss relative to that lost in the formation of the passive film [12], and thus mass loss is not necessarily a good indicator of corrosion activity.

### Outdoor Exposures

Concrete in the field undergoes large changes in temperature and moisture content. Often these occur in the course of only a few hours. Thus, even on the same day corrosion rates can change at the same location, and over the course of the year corrosion rates can vary by orders of magnitudes.

Corrosion rates are typically under 25  $\mu\text{m}$  per year, thus requiring electrochemical corrosion rate measurements with longer scan times than those adequate for highly corroding specimens [13]. This can present difficulties due to problems with traffic control, assessability, and weather since long polarizations might see a change in the specimen due to a moisture or temperature change.

## IMPORTANT VARIABLES

### Chloride Ingress

In North America corrosion of rebars in concrete is primarily due to chloride induced pitting. The chloride ingress comes from exposures in marine environments, most notably the splash-tidal zone, and from deicing salts. The onset of corrosion is generally associated with chloride values above 0.9  $\text{kg/m}^3$  (1.5  $\text{lb/yd}^3$ ), even though there are several chloride threshold values that have been reported in the literature with values ranging from 0.17–2.5 % by mass of cement (approximately 0.5–7.5  $\text{kg/m}^3$ ) [14–20]. Therefore, one indirect method of assessing corrosion is to determine the chloride content of the concrete at the reinforcing bar level. If it is below 0.9  $\text{kg/m}^3$  corrosion rate measurements are frequently not performed.

### Admixed Chemicals

Numerous chemical additives are added to concrete to improve its plastic or hardened properties. The vast majority of

these chemical admixtures is noncorrosive. However, some admixtures such as calcium chloride, which is added to decrease setting time and increase early strength, could be corrosive. The presence of these admixtures at high dosage rates could initiate rebar corrosion even in a normally benign exposure. To prevent this, calcium chloride is usually not allowed in steel-reinforced concrete. Ionic salts could also affect the measurement of concrete resistivity [21].

### Carbonation

Though not considered a major problem in North America, carbonation of concrete is a major cause of steel corrosion in the world. Calcium hydroxide in the concrete can react with carbon dioxide or carbon monoxide to produce calcium carbonate. The calcium carbonate is not detrimental to the mechanical properties, but in the process the pH of the concrete drops below 10. At that point the corrosion rate of embedded steel can significantly increase. This phenomenon is mostly found in concretes with low cement contents, high permeability, and low concrete cover over the rebars.

## LABORATORY TESTING

### Solution Tests in Concrete-Like Solutions

As mentioned in the subsection on Simulated Concrete Environments, saturated calcium hydroxide solutions with various combinations of sodium or potassium hydroxide are often used to simulate concrete. Chloride salts are added to these solutions to represent the effects of chloride ingress into the concrete to the rebar level. Rebars or other metal specimens can be examined for corrosion when added to these solutions.

The simplest tests are mass loss and nonquantitative visual examination. Bars are weighed before and after immersion and are examined for surface rusting and pitting. Since pitting is the failure mechanism in alkaline solutions, there is little difference in the mass loss measurements until there is a substantial degree of corrosion, and these tests might have to run for several months or years. Furthermore, since oxygen availability and conductivities are much higher in solutions, corrosion rates will not be directly comparable to those expected in concrete. More quantitative approaches are to actually measure pitting depths. The qualitative effects of inhibitors can be noticed. Useful ASTM methods that can be used in this type of testing are ASTM G 1, Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens; G 16, Guide for Applying Statistics to Analysis of Corrosion Data; G 33, Practice for Recording Data from Atmospheric Corrosion Tests of Metallic-Coated Steel Specimens; and G 46, Practice for Examination and Evaluation of Pitting Corrosion.

Another more informative solution test is to perform cyclic polarization in the saturated calcium hydroxide solutions mentioned above. This quickly demonstrates whether the corrosion mechanism is one of pitting and determines the primary mechanisms of corrosion inhibitors [7–9]. A modified version of ASTM G 61, Test Method for Conducting

FIG. 1—Idealized cyclic polarization curve for steel in alkaline environments.

Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-Based Alloys, is quite effective [8,9,22]. A sample curve showing the effects of a corrosion inhibitor is in Fig. 1. An increase in the pitting ( $E_p$ ), and breakdown ( $E_b$ ) potentials is indicative of a good anodic inhibitor.

### Testing in Laboratory Concrete Specimens

The best environment in which to test rebars is concrete, and several test methods are available. A new ASTM test method, G 109, Test Method for Determining the Effects of Chemical Admixtures on the Corrosion of Embedded Steel Reinforcement in Concrete Exposed to Chloride Environments, was issued in 1992. This method uses relatively high water-to-cement (w/c) ratio concrete at a low concrete cover. Because these conditions are not representative of recommended field applications [23], this is a screening test method.

ASTM G 109 involves the measurement of a galvanic current between a single upper layer bar and two bars at a lower level, for concrete that is cyclically ponded with 3 % sodium chloride. When chloride permeates through the concrete the upper bar begins to corrode, with the bottom bars acting as cathodes. A schematic of the specimen is shown in Fig. 2. Visual observations of the bars at the completion of the test is required as is determination of the chloride content at the reinforcing bar depth.

Effective corrosion inhibitors will increase the time to initiation of severe corrosion currents and detrimental concrete admixtures will reduce the time to initiation of severe corrosion. A composite curve from the ASTM round robin is given in Fig. 3. The integrated macrocell current (Coulombs) is a measurement of the total corrosion due to the macrocell. The test is not designed to evaluate materials such as silica fume that increase the resistance between the steel bars and significantly decrease chloride ingress.

Since chloride ingress is relatively quick compared to that observed in field specimens, the difference in time to corrosion initiation between the control and a specimen with corrosion inhibitor is not directly proportional to the

FIG. 2—Diagram of a concrete minibeam (see ASTM G 109).

difference expected in better quality concrete with increased cover, and actually underestimates the improved performance of inhibitors that protect to a given chloride level [24].

The preferred concrete for laboratory studies is one that is representative of field concrete. The concrete mixture would follow the code and recommendations of the American Concrete Institute. For severe chloride exposures this would require a w/c ratio at or below 0.4 and minimum concrete covers of 38 mm (1.5 in.). Testing of these kinds of specimens will take two to five years even under accelerated laboratory test conditions. Though this is a disadvantage for specification writers, it provides a much better representation of expected field performance.

One method of testing would be to use a modified version of ASTM G 109. This would use the same specimen configuration

FIG. 3—Macrocell corrosion versus time for concrete mini-beams.

FIG. 4—Total corrosion of minibeam with  $w/c = 0.38$  and concrete cover = 35 mm.

with increased concrete cover and a better quality concrete mixture design. The test procedures would be the same as in ASTM G 109, except for the above changes. Figure 4 gives an example of longer-term testing using a modified version of ASTM G 109. In this figure, the integrated macrocell current over time is represented versus time.

The Southern Exposure Test Method is macrocell test similar in nature to G 109 with some major differences [25,26]. This method uses larger specimens, but the main difference is that one cycle involves four days of ponding with chloride solution followed by three days of accelerated drying at low RH at 40°C. Marine environments will not have the low relative humidity achieved in this method, which could lead to misleading results due to the drying of the concrete. Even in non-marine exposures, weather histories show that the relative humidity, where deicing salts are used, remains above 80 % in the summer, especially on the few days when the temperatures approach 40°C or higher [weather]. Thus, while this test method accelerates chloride ingress, it might change the performance of characteristics corrosion prevention systems that have enhanced performance under accelerated drying conditions.

In addition to the simple macrocell current measurement as described in ASTM G 109, polarization resistance and electrochemical impedance spectroscopy (EIS) can be performed. A modified version of ASTM G 59 (Practice for Conducting Potentiodynamic Polarization Resistance Measurements) using IR drop correction is recommended for the polarization resistance measurements [3,9]. EIS is conducted using equipment as described in ASTM G 106, Practice for Verification of Algorithm and Equipment for Electrochemical Impedance Measurements. The experimental data are commonly displayed using Nyquist or Bode plots. By applying an alternating current over a range of frequencies, which in concrete is generally between 0.4 mHz to 20 000 Hz [9], more mechanistic information of the corrosion process can be obtained than when a direct current method is used. This is because the electrochemical processes respond similarly as a network of capacitances and resistances which can be identified by measurements at various frequencies.

Another geometry for laboratory specimens is a concrete cylinder with an embedded reinforcing bar known as a lollipop specimen. These specimens can be used to simulate marine piles, and frequently are partially immersed to represent the splash tidal zone area [9]. Concrete mixtures

representing those used in the field are often tested with the only acceleration being a reduced concrete cover of approximately 35 mm, constant exposure to 3 % sodium chloride, and a laboratory temperature that is 22°C.

Corrosion tests that are performed on lollipops are corrosion potential readings as described in ASTM C 876 (Test Method for Half-Cell Potentials of Uncoated Reinforcing Steel in Concrete), polarization resistance as described in ASTM G 59, using IR correction [3,9], and EIS [9]. Specimens are broken open to visually examine the bars for confirmation of the electrochemical results, and chloride analyses are performed. The chloride analysis correlates the chloride content to the corrosion activity.

Testing in cracked concrete specimens can provide an indication of performance in less than ideal circumstances. These tests should be conducted in concrete meeting the minimum requirements of codes and recommended practices since mechanisms might be significantly affected by improper specimen design [27,28].

Testing procedures for cracked concrete are essentially the same as used for other laboratory specimens exposed to chloride solutions continuously or cyclically. Methods that can be used include polarization resistance, electrochemical impedance, and macrocell corrosion which were discussed above. Procedures for conducting these tests are described in Refs 27 and 28.

Large-scale laboratory specimens are typically about 2 m<sup>2</sup> in surface area or larger. They have depths exceeding 100 mm that are typical of field concretes that are actually used. The decks are reinforced with one to two mats of steel as would be found in actual use. For acceleration purposes the spacing of the steel can be less than used in the field.

One method of conducting these tests is to have two mats of reinforcing bars with or without admixed chlorides in the top mat and to pond with chloride. The macrocell current between the top and bottom mats as well as the corrosion potentials are measured according to ASTM C 876. This procedure is described in Ref 29.

Testing with one layer of reinforcing bars using a fine grid can also give good results [30]. The 51 mm (2-in.) grid gave very good potential contours that can be used to estimate the corrosion activity. The use of polarization resistance as described by Clear [31], Escalante [32], Andrade et al. [11], and the Strategic Highway Program [33] could also be employed on these kinds of slabs.

## FIELD TESTING

### Specimens in the Field

One method of field testing is to place laboratory size specimens in the field. These specimens could then be tested using the same techniques used in the laboratory. One advantage of this is the ability to have well-defined specimen dimensions and control of exposed steel areas.

### Field Structures

Test methods for field structures almost always include corrosion potential mapping as described in ASTM C 876.

Note that it is essential that the deck be moist without puddles on the surface. This method only gives an idea of the corrosion activity and does not provide corrosion rate data. A recent Transportation Research Board (TRB) paper on work in Virginia indicated that a 0.61 m (2 ft) spacing for the potential grid was much better than the typical 1.2 m (4 ft) spacings in relating corrosion damage to corrosion potential contours [34].

Polarization resistance methods can be used to measure the corrosion rates of steel embedded in concrete. This can be performed on embedded probes of known area or by having the counter-electrode and reference electrode at the surface. The high resistivity of the concrete requires some form of IR correction. The Strategic Highway Research Program Project (SHRP) C101 looked at several devices to measure corrosion rates [35]. These devices included the three electrode linear polarization (3LP) device [31] and the guard ring device [11] and a two frequency electrochemical impedance device [33]. A single galvanic current with current interruption as described by Escalante has also been used [32], as has traditional polarization resistance [36].

Though the absolute values for the corrosion rate do not agree for the various instruments described above, the devices show the same trends in the rates; that is, if one device shows a higher corrosion rate at one location, the others will also show a higher rate. More work is needed in this area.

EIS can be used in the field, but long test periods at low frequencies are impractical. This is because there are large temperature and moisture changes which affect the corrosion activity. One possible means to get an idea of the corrosion rate is to examine the inflection point of the Bode curve. If it occurs at a frequency above 1 mHz there is a good possibility that severe corrosion is occurring [37,38].

Several nonelectrochemical techniques for field corrosion assessment are the measurement of spalled and delaminated concrete from visual and chain drag operations. A measurement of the chloride contents at the reinforcing level also gives some idea as to the potential corrosion activity with chloride contents of 0.9 kg/m<sup>3</sup> (1.5 lb/yd<sup>3</sup>) typically being considered to be the threshold value for corrosion initiation.

## STANDARDS

ASTM C 876: Describes a technique to measure the corrosion potential of steel in concrete. In the past researchers have used absolute corrosion potential values to give probabilities of the existence of corrosion and to estimate corrosion rates. This is no longer the case and current thoughts are that the contours are an indication of corrosion activity for larger structures, but absolute corrosion rates must be determined by some other method.

ASTM G 109: This method is used as a screening test to determine if chemical admixtures inhibit or accelerate the corrosion of steel in concrete subjected to chloride ponding. The technique is useful for chemical admixtures, but due to the low concrete cover and relatively high w/c ratio does not provide quantitative results as to expected long-term performance in concrete meeting the minimum recommendations of the American Concrete Institute (ACI) [23]. As mentioned above, variations of this test method with better

quality concrete can be used to predict field performance more accurately.

## European Standards

The European organization for standards (Comite European de Normalisation-CEN) is considering a harmlessness test method based on polarizing steel embedded in a mortar, made with a cement with less than 5 % C<sub>3</sub>A, to +260 mV versus a saturated calomel electrode [39]. Admixtures would be tested to see if they gave detrimental effects (high currents, and corrosion damage on the bar) relative to a mortar without admixture. This method is still in committee at this time.

Work in Germany has resulted in a new admixture specification for Passivating Corrosion Inhibitors [40]. Schiessl et al. describe several of the test methods used by the specification [41].

## MATERIALS

A brief description of materials used to improve the corrosion resistance of steel in reinforced concrete is given in this section. The reader is encouraged to go to other sources for a more detailed description, since this article is emphasizing test methods.

### Concrete Admixtures

ASTM C 494 (Specification for Chemical Admixtures for Concrete) classifies several types of concrete admixtures. Of particular use for steel in concrete are the high range water reducers that are classified as type F or G admixtures. These chemicals significantly improve concrete workability at low w/c ratios, which is needed to produce low permeability concrete.

Corrosion inhibitors are also used to provide corrosion protection for steel in concrete. A TRB document describes the several corrosion inhibitors used in concrete [42] as do ACI 212 [43] and ACI 222 [44]. The corrosion inhibitor that is most used at this time is calcium nitrite [45]. Additional inhibitors and methods of predicting life-cycle costs are now addressed in the literature [46–51].

Damp-proofing admixtures or water repellents can also be added to concrete. However, several researchers indicate that they offer little benefit to corrosion protection in good quality concrete [52,53]. Succinate type admixtures have been tested at the Universities of Connecticut and Massachusetts [54,55]. Good dampproofing and corrosion resistance properties were shown; however, due to the extreme drying conditions and artificial cracks, it is not known if these materials raise the chloride threshold level at the reinforcing steel for corrosion initiation.

Mineral admixtures can be used to reduce concrete permeability. These are typically fly ash, microsilica, or blast furnace slag and are also addressed by TRB [42], and by ASTM Committee C09 on Concrete.

### Reinforcing Bar Coatings

The most popular coating for reinforcing bars is fusion bonded epoxy. Epoxy-coated steel is addressed in ASTM A 775M,

Specification for Epoxy-Coated Reinforcing Steel Bars; and ASTM D 3963M, Specification for Fabrication and Jobsite Handling of Epoxy-Coated Reinforcing Steel, and epoxy-coated wire and wire fabric in ASTM A 884, Specification for Epoxy-Coated Steel Wire and Welded Wire Fabric for Reinforcement. A TRB symposium [56] and circular [57] discusses the pros and cons of this approach. The general consensus was that much more attention to minimizing defects and damage to the coatings is needed from the manufacturing point up to the placement of the bars in the field.

Galvanized steel was found to be of marginal effectiveness in earlier Federal Highway Administration (FHWA) studies [58]. More recent work indicates that galvanized steel can offer increased protection and can be especially beneficial in carbonated concrete [59,60]. The ASTM standard for galvanized steel bars is A 767.

Other inorganic and metallic coatings have been applied to steel rebars, but their use is not widespread.

### Concrete Sealers

Concrete sealers have been used to reduce chloride and moisture ingress into concrete. Work in the Strategic Highway Research Program (SHRP) C 103 project indicated that they have a finite lifetime and need to be reapplied in bridge applications [61].

### Membranes

Membranes are widely used in Europe and Canada as well as some areas in the United States to limit the ingress of chloride into concrete. They provide good protection as long as the membrane remains leak-free and the riding surface does not deteriorate exposing the membrane. The lifetime of membranes in bridge applications was also addressed by SHRP C 103 [61].

### Cathodic Protection

Cathodic protection is typically used as a rehabilitation technique, but is also used in new construction. The steel in the concrete is made into a cathode and thus its corrosion rate is kept low. Broomfield reviewed the current state of cathodic protection systems in the United States [62]. Further information can be obtained from a SHRP report on cathodic protection of concrete structures [63]. NACE International holds symposiums on cathodic protection of steel in concrete on a biannual basis [64].

### New Steels

Stainless steel bars and cladding are now available [65] and ASTM is working on a standard. Results are significantly improved over standard reinforcing bars in testing, but dependent upon which alloys are used [65,66]. Though corrosion is reduced, it is not necessarily prevented [66].

Steel processed to have untransformed nano-sheets of austenite sandwiching dislocated martensite laths is available. There are no carbon containing phases present, so cathodic reaction rates are claimed to be low on this steel. The version with the most promise contains over 8 % chromium [67].

### Additional Information

More information relating concrete properties, corrosion, and corrosion protection systems is available in reference books. A few of these are included in the references [17,68,69].

## CONSIDERATIONS AFFECTING TEST PROGRAMS

The corrosivity of water to mild steel is related to certain chemical aspects of the water. The more important variables are dissolved oxygen, alkalinity,<sup>2</sup> pH, chloride, sulfate, hydrogen sulfide, carbon dioxide, and ammonia.

The most important single variable affecting corrosivity is pH. The relationship, with regard to carbon steel, is shown in Fig. 2 [1]. At a pH below about 4, corrosion increases rapidly with decrease in pH. In the pH range 4 to 9, changes in pH have a relatively minor effect on corrosivity to steel. Above pH 9, corrosivity decreases as pH increases.

Within the pH range of primary interest (the 5 to 9 range) dissolved oxygen is the dominant corrosive agent to carbon steel. The corrosion mechanism involves dissolution of metallic ions in an anodic area combined with consumption of the released electrons at a cathodic area. In the pH range of 5 to 9, the dominant cathodic reaction is reduction of dissolved oxygen. At a low pH (pH <4) the dominant cathodic reaction is generation of hydrogen.

At a given level of pH and dissolved oxygen content, the next most important determinants of corrosivity are the concentration of aggressive ions (primarily chloride and sulfate) and the buffering capacity of the water, which is roughly proportional to alkalinity. A number of attempts have been made to derive a reliable corrosion index. None have been fully successful. One approach to a usable "corrosivity index" is calculated by dividing chloride plus sulfate by alkalinity, all expressed in terms of equivalents per liter. This value, developed by Larson and Skold [2], is sometimes called the Larson-Skold Index. One reference [3] suggests that a value of this index <0.8 indicates that "chlorides and sulfates probably will not interfere with natural film formation"; while a value >1.2 "suggests that high local corrosion rates may be encountered." While useful, this index is only a crude guideline.

FIG. 2—Effect of pH on corrosion of steel in water in the absence of an inhibitor.

<sup>2</sup>Alkalinity, as used in water treating, is defined as the ability of a water to neutralize acid. It is measured by titration and the results are usually expressed "as  $\text{CaCO}_3$ ."

The rate of corrosion is controlled by the rate of dissolved oxygen reaction on the surface, which is controlled by the rate of transport of dissolved oxygen to the surface. Similar mass transfer mechanisms control the rate of transfer of fouling ions to the surface. In a system containing a corrosion inhibitor, the transfer of inhibitor to the surface is also controlled by the same factors. Once the reactants are at the surface, reaction rates are affected by temperature. Temperature also affects the properties of the fluid film in contact with the surface. For example, viscosity typically decreases in the film on the surface of a hot wall, facilitating reactant transfer. It is difficult to generalize about the affect of temperature on corrosion rates in a system treated with corrosion inhibitor. Increased temperature is likely to accelerate the corrosion inhibition reactions as well as the corrosion reaction. The net change in corrosion rate could be either an increase or a decrease, depending upon the effectiveness of the corrosion inhibition treatment.

In the near neutral pH range, corrosion rate is nonlinear with respect to time. Almost any clean carbon steel surface in contact with aerated water will corrode at a rapid rate for the first few hours. The rate decreases with time, eventually reaching a steady state. This steady state corrosion rate is the rate of practical interest in water systems.

The critical consideration in most industrial cooling operations is the situation on heat transfer surfaces exposed to flowing water. In order to simulate these conditions, the hydrodynamics must be properly modeled. The important variable is not velocity but turbulence, which is qualitatively proportional to the Reynolds Number. The second critical variable is temperature, particularly the temperature in the relatively slow-moving, laminar film flowing next to the heated wall.

In the following sections, test methods will be discussed in terms of how effectively each test method models these variables.

## LABORATORY TESTING

Laboratory corrosion tests in industrial water are used to help understand corrosion and inhibition mechanisms and to develop treatment systems. They are helpful in selecting treatments for a given system, but usually fail to model accurately the critical aspects of a field system.

The most common test method is the coupon immersion test, usually conducted under static or near-static conditions. Other methods, used to a lesser degree, include rotating electrodes, of which the best arrangement for water is probably the rotating cylinder, and small recirculating systems. Electrochemical tests and polarization studies are used primarily to elucidate the corrosion mechanism. Surface analysis is also used, primarily for mechanistic studies.

## PLANT TESTING

NOTE: Biological monitoring or testing is not discussed in this section. However, one should recognize that biological control is the first requirement in a cooling water system. If biological growth is not properly controlled, serious corrosion or fouling, or both, are almost certain to occur.

Virtually all definitive test work is done in a pilot plant or plant. The final test is performance of actual operating equipment. A systematic, quantitative inspection program is the final measure of success of a corrosion control program. All other methods are evaluated in terms of how closely they approximate this method. Other methods used are listed and described briefly below.

### Coupon Tests

Coupon tests are by far the most commonly used test method. The usual method is to mount coupons in the middle of a stream, frequently in a serpentine bypass loop as shown in Fig. 3. Detailed procedures for coupon tests are described in ASTM D 2688, Test Method for Corrosivity of Water in the Absence of Heat Transfer (Weight Loss Methods) (Method A). Tests with very low water flow (suspended coupons in the cooling tower basin, for example) are not recommended unless the objective is to measure corrosion under near stagnant conditions.

Coupon tests give reliable comparative numbers indicative of changes in average water corrosivity during the exposure period, provided tests are run for a long enough period (30 days or more) and only data from tests of comparable exposure time and velocity are compared. For interpretive purposes, some reasonably reliable rules-of-thumb have been developed. For systems using modern non-metallic based inhibitors, a coupon corrosion rate on steel for a 30-day test of  $<50 \mu\text{m/yr}$  (2 mpy) is indicative of excellent control of water corrosiveness. A rate of  $50\text{--}75 \mu\text{m/yr}$  (2–3 mpy) or less on a 30-day test is indicative of satisfactory results. A rate of  $75\text{--}125 \mu\text{m/yr}$  (3–5 mpy) are considered fair, possibly acceptable in some cases. Rates of  $>125 \mu\text{m/yr}$  (5 mpy) are usually considered excessively high. Note that these rules-of-thumb assume reasonably general corrosion. Severe localized attack on the coupon is a clear indication that the corrosion prevention treatment is not achieving acceptable results.

A basic limitation of coupon testing is that it fails to model properly either the hydrodynamic or thermal conditions on plant equipment. The coupon is exposed in the

most highly turbulent area and the coupon causes additional turbulence by its presence. As previously discussed, high turbulence facilitates inhibitor transfer to the surface; thus, the coupon has a better chance of being adequately protected than the wall of a tube or pipe. While not common, there have been cases where the treatment system protected the coupons but not the plant equipment.

The use of tubular (pipe or tube) samples with internal flow should be more reliable than conventional coupon tests because of the closer approach to proper hydrodynamic conditions. Such tests are seldom used in industrial water systems, despite the fact that ASTM standards, i.e., ASTM D 2688 (Method B), cover the use of tubular samples.

### Electrical and Electrochemical Methods

There are two commonly used tests. One is called “linear polarization (LP)” using either two element or three element probes. If a very low DC voltage (10 mV or so) is imposed between two identical metallic electrodes in an electrolyte, the observed current flow is approximately proportional to the corrosion rate of the probes. This was first demonstrated in the 1950s [5–7]. Stern and Geary [8,9] later developed a quantitative equation that allows estimation of the corrosion rate. Although this technique, when used with commercially available probes, does not replicate the hydrodynamic or heat transfer conditions, it is widely used because of its simplicity. It provides an instantaneous indication of corrosion rate. By arranging the instrumentation so that the DC potential is applied with one polarity, then reversed, two readings are obtained. The difference between the two readings is believed by some to be an indication of the tendency toward localized corrosion. There is a lack of consensus about the utility and reliability of this measurement.

The second method, called “electrical resistance” (ER), exposes a sample of the metal of interest, mounted on a probe inserted into the system. As the sample corrodes, the cross-sectional area decreases, increasing the electrical resistance of the sample. This increase, measured through suitable instrumentation, provides a continuous record of metal loss. This method does not give proper quantitative results in systems characterized by localized attack, a common situation in water systems.

While these methods have been used with success, they have deficiencies for water systems. As with coupons, the hydrodynamic and thermal conditions of critical plant surfaces are not properly modeled.

Both LP and ER methods are covered by ASTM G 96, Practice for On-line Monitoring of Corrosion in Plant Equipment (Electrical and Electrochemical Methods).

### Test Exchangers

A better method of replicating the hydrodynamics and thermal conditions of critical operating equipment is a test heat exchanger, using a small side stream of water from the cooling tower water circuit. This technique is more complex and expensive; as a result, it has been used less extensively than the techniques described previously. In a test heat exchanger, water flow and heat flux can be controlled. If

FIG. 3—Serpentine bypass loop used for coupon test in plant (see ASTM D 2688, Method A).

the test exchanger contains multiple tubes, tubes can be removed at different time periods and depth of attack measured quantitatively. Plotting these depths against time of exposure allows an estimate of the rate at which corrosion is penetrating the wall. In addition, thermal measurements allow calculation of heat transfer coefficients and fouling factors, providing a quantitative measure of fouling.

Test exchangers require both operating attention and maintenance work, making their use relatively expensive and troublesome. The method has the distinct advantage that it correlates reliably with equipment performance. While used less extensively than the methods described previously, a number of examples of use have been documented [10–13].

The type of test exchanger preferred by the author [14–18] is one that has multiple easily removable tubes, allowing data to be collected as a function of time. This method is covered by NACE Standard TM 286 [10].

Most water-treating suppliers supply single tube, electrical resistance heated fouling measurement units. These units consist of a heat exchanger tube with an internal electrical resistance heater. The water flow is in the annular space between the tube and an outer tube, which is frequently transparent to allow direct observation. These units are excellent for monitoring fouling. They are amenable to automated data acquisition. Heat transfer coefficients and fouling factors can be easily calculated. The fouling factor, a direct measure of resistance to heat transfer, is the preferred measure.

In addition to the direct thermal measurements, the weight of deposit formed per unit time is sometimes used as a measure of fouling. While this gives a measure of the quantity of fouling material precipitated, it does not tell how that deposit affects heat transfer efficiency.

## INNOVATIVE NEW TECHNIQUES

The techniques described above are well established. They are the primary tools used for most practical day-to-day monitoring. There are a number of newer techniques that show promise of giving better data, usually more quickly and sometimes more easily automated. These are discussed briefly below.

### Miniature Heat Exchanger with Combined Corrosion and Fouling Evaluation

This technique [19], developed by Capsis-March Ltd. for Amoco (now part of BP), is probably the most advanced attempt at an on-line continuous instrumental monitor of both fouling and corrosion of a heat exchanger tube. The test assembly consists of several short lengths of exchanger tube, electrically isolated by non-conductive gasketing. The assembly is carefully assembled to assure that the tube segments are precisely aligned and the gasketing does not introduce additional turbulence. Electrical heating elements are mounted outside each discrete tube section, with temperature sensors mounted to allow calculation of the heat flux and heat transfer coefficients.

Corrosion is monitored continuously by means of Electro Chemical Noise (ECN). Using this technique involves measuring the variance of both potential and current flow between adjacent, electrically isolated tube segments. The degree of variance (noise) provides an indication of corrosion activity on the tube segments. While there remains some debate concerning interpretation of such data, there is substantial evidence that increased noise is a reliable indicator of increased corrosion activity.

This approach shows promise of providing a real-time indication of both corrosion and fouling on a heat exchanger surface. The Winters et al. [19] paper shows instances where ECN changes indications correlated with changes in corrosion and fouling.

### Thin Layer Activation (TLA)

TLA was developed in the United Kingdom [20,21]. The surface of a sample (which can be a coupon or a section or tube or pipe) is irradiated to make it slightly radioactive. Two samples are irradiated. One sample is protected from corrosion; the second is exposed to the corrosive fluid, in this case the water system. The radioactivity of each of two samples is monitored as a function of time. There will be a radioactive decay curve characteristic of the protected sample and a second decay curve for the exposed sample. The difference between the two curves indicates metal loss, which can be converted to corrosion rate. This technique has not been broadly used, but some field use has been reported [21,22]. It shows promise of being an “automated coupon” which provides a continuous record of corrosion. Figure 4 shows a pipe specimen with an activated area, and Fig. 5 shows data generated in an inhibited cooling tower system.

### Synthetic Crevice Devices

Some work [23–25] has been done in which an occluded cell condition is set up, with electrically isolated anode and cathode connected through a zero resistance ammeter. The current flow between the electrodes is proportional to the corrosion occurring on the anode. This technique provides a measure of the rate of corrosion penetration in occluded areas. With this technique, it is possible to allow the corrosion reaction to start (forming oxide deposits) and then determine the ability of different inhibitors to control the corrosion in the presence of the deposits.

FIG. 4—Diagram of the test pipe section showing the position of the active layer.

FIG. 5—Plot of metal loss versus exposure time for a carbon steel pipe, as determined by TLA. The depth of corrosion is deduced from the activity loss of the test component. The correct inhibitor conditions were established between points a and c. At d, the component was removed for inspection and cleaned. After replacement, the apparent corrosion rate was very low, indicating the effectiveness of the inhibitor.

### Differential Flow Cell Technique

This recently reported [26] technique is similar to the Synthetic Crevice approach. In this method, two parallel flow channels are operated at different water flow rates. The low flow channel becomes an active anode, which is connected through a zero resistance ammeter to the high flow channel, which acts as a cathode. The current flow then indicates the corrosion rate of the anodic surface. This technique shows promise as a continuous on-line instrumental monitor that will show changes in corrosion rate under deposits.

## DISCUSSION

This presentation has focused on corrosion test methods in open recirculated cooling tower systems. This area is the most challenging, difficult, and important area of corrosion testing in industrial water. For economic and environmental reasons, water and inhibitor lost through blowdown must be minimized. Cooling tower systems are the systems that are most subject to operational upsets and operational variables.

The corrosion testing techniques described can also be used in closed cooling systems, once-through cooling systems, boiler feed water systems, etc.

# Industrial Chemicals

*Robert B. Puyear<sup>1</sup>*

## DESCRIPTION

THIS SECTION INCLUDES TESTS for determining the materials of construction requirements for equipment used for manufacturing chemicals. This includes both bulk chemicals, which are typically manufactured in dedicated equipment in large quantities, and specialty chemicals, which are most often made in smaller quantities and often in equipment used for more than one process. Tests for both organic and inorganic chemicals are included. Because some tests require the presence of an electrolyte, they are not suitable for many pure organic processes. Equipment intended for use in the pharmaceutical, petrochemical, or high-temperature gas phase or molten salt processes have special requirements that are not included in this section.

## ASPECTS THAT MAKE TESTING FOR INDUSTRIAL CHEMICAL EQUIPMENT UNIQUE

Unlike refineries and many petrochemical plants where each company has similar equipment, many industrial chemical units are one-of-a-kind. This characteristic means there may not be any history of similar equipment to use for making materials selections. Also, it may be only a few years before technology advances make the process obsolete. A third consideration is that the equipment may be called on to make more than one product. Sometimes this multiproduct use is part of the original design and sometimes it is the result of changing conditions or technology, or both. These factors create a tension between selecting materials that will give long, reliable life and materials of lesser reliability, but also of lower cost. There is no correct answer as to what strategy to use. However, whatever strategy is chosen it is always important that the tests conducted provide reliable results so that materials selection choices are made on the basis of accurate and meaningful data.

### Batch and Continuous Processes

Industrial chemical processes include both batch and continuous operations and some can include a combination

of the two. Each operation mode presents its own set of requirements on the tests that are to be used to characterize materials requirements.

In many cases continuous processes are easier to characterize because when the process is operating under control the environment in any part of the process is fairly constant. This permits the development of laboratory tests that can simulate the process conditions with some accuracy. Care must be taken to assure that the effects of process startups, shutdowns, and upsets are considered since the most corrosive conditions may occur during these times.

Process understanding is required to select the proper environments for corrosion tests in a continuous process. In some equipment such as distillation towers there is a continuous change in process conditions through the unit. It is not practical to conduct tests at all of these conditions, yet the raw material or product streams may not represent the most severe conditions. The use of a good process simulation model with good physical property data can go a long way in helping to identify the range of conditions present and therefore help select the best test conditions.

Another characteristic of continuous processes is that each unit supplies the raw materials to the following unit. Thus, if any piece of equipment fails, the entire plant is shut down until it is repaired. This adds a premium to the reliability of continuous process equipment and to our ability to predict the remaining life of equipment components.

In batch processes the equipment sees a continuing change in process conditions throughout the batch cycle. This requires the materials of construction to resist the entire range of environments encountered. On the other hand, it means that there may be a surface condition created in one step of the process that provides protection in a subsequent step where the material would otherwise corrode.

One approach to testing materials for a batch process is to expose samples of the candidate materials of construction in a number of batch cycles in a plant, pilot plant, or research laboratory. However, when this option is not available the problem of creating meaningful test environments is difficult and the results are subject to considerable error. A good understanding of the process chemistry and the behavior of candidate materials in various chemical environments is very helpful in improving the validity of these tests.

## IMPORTANT VARIABLES

Any variable that can influence a reaction between the material of construction and its environment is important. Some of these variables are:

- temperature,
- pressure,
- pH,
- velocity (fluid motion),
- temperature and heat transfer,
- presence of chlorides and other halides, and
- presence of small quantities of contaminating chemicals.

### Temperature

Plastics, coatings, linings, and the like have rather severe temperature limits and can be used only within these limits. Table 1 lists the maximum operating temperatures for a number of plastics and coatings used by industrial chemical firms. A word of caution is in order about the temperatures listed in this table. These temperatures are for noncorrosive applications. The maximum temperature for a specific application may be much different. For example, the maximum temperature for vinyl ester reinforced thermosetting resin construction for air immersion is 177°C and for steam it is 104°C. For deionized water the maximum recommended temperature is 82°C and for dichloroethane it is only 27°C. To be safe the person selecting a plastic for chemical service must obtain data on the behavior of that material in the specific environment. In addition to chemical degradation, plastics, coatings and linings are subject to permeation of process fluids through these organic materials. Permeation is a temperature-sensitive behavior. A recent Materials Technology Institute Publication [14] provides a comprehensive discussion of this issue. Even with materials of construction that do not have narrow inherent temperature limits such as alloys and ceramics, we are faced with the fact that temperature influences the rate of chemical reactions, and hence the corrosion rate.

Some forms of corrosion such as stress corrosion cracking and pitting are especially sensitive to temperature. This was borne out by the results of a study sponsored by the Materials Technology Institute [15] which showed a strong correlation between temperature and stress corrosion cracking of stainless steels in cooling water with low chloride concentrations (Fig. 1). This work showed that there was no true threshold temperature for the onset of stress corrosion cracking as failures were reported down to cryogenic temperatures in certain circumstances involving concentrated brines, low pH, microbial attack, or sulfur compounds. The data shown are for near neutral waters where there is an apparent threshold of about 60°C.

### Pressure

In most cases pressure does not have a large influence on corrosion behavior. However, it can affect the composition of the corrodent fluid and thereby have an influence. A classic example is the difference in corrosion behavior of carbon steel in water in an open and closed vessel [16–18] (Fig. 2). Dissolved oxygen is a major source of corrosion of steel by

Fluoroelastomer	FPM	204	13
Ethylene Propylene	EPM, EPDM	204	13
Polyacrylate	ACM, ANM	177	13
Fluorosilicone	FVMQ	177	13
Neoprene	CR	149	13
Epichlorohydrin	CO, ECO	135	13
Nitrile (high temperature type)	NBR	121	13
Chlorosulfonated Polyethylene	CM	121	13
Polysulfide	PTR	107	13
Nitrile (low temperature type)	NBR	107	13
Butyl	BR	107	13

<sup>a</sup>These temperatures are typical of the maximum operating temperature for these materials in noncorrosive environments. The maximum temperature for specific applications depends on the environment and may be very much lower than indicated here. Contact the manufacturer or its agent before selecting these materials for high-temperature or corrosive applications.

water. As the temperature increases, the corrosion rate increases until about 80°C. In this region the water vapor pressure increases rapidly, thereby reducing the oxygen partial pressure. This results in essentially zero oxygen in the open system at the boiling point. However, if the system is closed the oxygen cannot escape and the corrosion rate continues to increase as the temperature rises. This is why it is so important to remove dissolved oxygen from boiler feed water.

### pH

Dillon [19] provides a good discussion of the role pH and total acidity (or alkalinity) have on materials selection

FIG. 1—Chloride stress corrosion cracking of types 304 and 316 stainless steel as a function of chloride concentration and temperature [15].

FIG. 2—Retaining dissolved oxygen in a closed vessel boosts corrosion. (Based on curves in Refs 16–18.)

requirements. The following is a synopsis of this discussion. pH is defined as the negative of the base ten logarithms of the hydrogen ion activity. In strong acids and bases it is a valid measure of the total acidity or alkalinity because of the total ionization of the electrolyte. For weaker acids and alkalis, which are less completely ionized, total acidity (or alkalinity) is a better indication of corrosivity than is pH. With these acids (or alkalis) the unionized material serves as a reservoir of potential protons available for potential corrosion. Corrosion data are a more reliable indication than either pH or total acidity (or alkalinity) in complex process mixtures. Nevertheless, pH and total acidity (or alkalinity) are useful indicators of potential corrosion behavior and should be identified whenever possible.

Aluminum is a classic example of a metal where the corrosion resistance has strong pH dependency. Aluminum is a very active metal and its corrosion resistance depends on a barrier oxide film. This film contains two layers, an inner compact amorphous barrier layer and a thicker,

FIG. 3—EMF-pH (Pourbaix) diagram for aluminum in water at 25°C [20].

FIG. 4—Weight loss of aluminum alloy 3-H14 exposed one week in solutions of various pH values. pH values were adjusted with HCl and NaOH [20].

more permeable outer layer [20]. Potential-pH (Pourbaix) diagrams are used to map where the barrier layer would be expected to be effective (Fig. 3). These diagrams are based largely on the solubility of the solid species. In Pourbaix's terminology, passivity is achieved when the solubility of the solid species is less than  $10^{-6}$  moles/L. In this case aluminum would be expected to have good corrosion resistance between pH 4 and 8.5, but the corrosion rate might be well above zero. This correlates well with experimental data (Fig. 4).

In a similar manner carbon steel is sensitive to pH. In the pH 4.5–9 range the corrosion rate is governed by dissolved oxygen. (See the following discussion on velocity effects.) Below pH 4.5 the corrosion rate is controlled by hydrogen evolution and above about pH 9, the rate is suppressed by an insoluble film of ferric hydroxide (Fig. 5) [18]. At very high pH levels, especially at elevated temperatures, steel is susceptible to stress corrosion cracking [21].

FIG. 5—Corrosion of carbon steel versus pH in water at 25°C [18].

### Velocity (Fluid Motion)

The influence of fluid flow rate on corrosion is dependent on the alloy, fluid constituents, fluid physical properties, geometry, and corrosion mechanism. In some cases the dependence is fairly direct. For example, the corrosion of carbon steel and UNS S44626 (26Cr1Mo) in concentrated  $H_2SO_4$  is governed by the rate of mass transfer of  $FeSO_4$  from a saturated layer on the surface [21–23]. Carbon steel corrosion in water in the near-neutral pH range is governed by the rate of mass transfer of dissolved oxygen from the bulk fluid to the surface [21].

The presence of fluid flow can sometimes be beneficial in preventing or decreasing localized attack such as pitting and crevice corrosion. For example, alloys such as types 304 and 316 stainless steel and nickel chromium alloys will pit in quiescent seawater more readily than in flowing seawater. When the water is quiet, the mass transfer rate of oxygen is insufficient to maintain a completely passive surface and pitting can result [24]. Low flow rates in seawater also contribute to the formation of marine growth such as mollusks and barnacles and sedimentation, both of which create deposits that promote crevice corrosion attack.

Under other circumstances fluid flow can cause erosion of the surface through the mechanical force of the fluid itself. When solids are present in the liquid they can cause wear or solid particle erosion. In either case, the rate of attack can be accelerated by the combined effects of erosion and corrosion. Erosion corrosion results when the passive films that form on alloys are removed and the underlying metal is attacked [25]. The rate can be very rapid.

### Temperature and Heat Transfer

As a general rule corrosion rate increases with temperature. One notable exception is the corrosion of carbon steel by water in an open container (Fig. 2) that was discussed earlier. Temperature also influences the onset of localized corrosion such as pitting and crevice corrosion of passive alloys.

Fluid temperature changes can affect the polarity of galvanic couples. An example is the iron-zinc couple in some domestic waters where the iron may become anodic to the zinc at temperatures over 82°C [26].

The effects of heat transfer on corrosion rates depend on the system. If corrosion is under activation control the presence of heat transfer might not have much effect. On the other hand, if corrosion is controlled by diffusion of a species, such as oxygen, to the surface, then heat transfer may greatly change the corrosion rate. There are three possible causes. First, a temperature difference between the wall and bulk solution may affect the solubility and diffusion coefficient of the diffusing species. Second, boiling at the surface can increase turbulence or increase diffusion. Third, heat transfer in the absence of fluid flow, as in a stagnant tank, can cause natural convection currents that enhance mass transfer [19].

### Presence of Chlorides and Other Halides

Chloride ion accelerates the corrosion of iron in acidic solutions. The role of other halides is less clear and iodides and perhaps bromides may even serve as corrosion inhibitors. At near neutral pH values chloride has less effect than dissolved oxygen [21].

The most notable effects of the chloride ion are pitting and crevice corrosion of passive alloys and stress corrosion cracking of stainless steels and related alloys. Most pitting and crevice corrosion is associated with chlorides, bromides, and hypochlorites. Fluorides and iodides have comparatively little pitting tendencies [27].

Crevice corrosion may occur under deposits, under gaskets, or any other place where the opening is wide enough to permit liquid entry but narrow enough to create a stagnant zone. While halides are not necessary for crevice corrosion to occur, their presence promotes the formation of more acidic conditions in the crevice and much more rapid corrosion [28].

Oxidizing metal ions with chlorides are aggressive pitting agents. Even the most corrosion resistant alloys can be pitted by cupric chloride and ferric chloride. By comparison, chlorides of non-oxidizing metal ions such as sodium chloride and calcium chloride cause pitting to a much lesser degree.

Chloride stress corrosion cracking is a constant concern when stainless steels are used at elevated temperatures. There is no true threshold of chloride concentration or temperature below which stress corrosion will not occur, but experience has provided some guidelines where stainless steel can be used with confidence. An example of chlorides in cooling water was discussed earlier (Fig. 1). Equipment designed to reduce opportunities for chlorides to concentrate is helpful. The presence of deposits also provides an opportunity for chloride concentration.

### Presence of Small Quantities of Contaminating Chemicals

One variable frequently overlooked in designing tests for selecting materials for industrial chemical applications is the presence of small quantities of chemicals present as contaminants; that is, chemicals that are there unintentionally. Often these chemicals have no effect on corrosion behavior and can be safely ignored. However, all too often this is not the case. Consider, for example, the effect of a few

drops of water in an otherwise all-organic environment [29]. This water may have no effect on the process, but it completely changes the corrosion picture. Whereas carbon steel might have been satisfactory without the water, stainless steel may be required to avoid contaminating the process with iron corrosion products. If the organic chemicals include a halogenated compound, higher alloys or glass lining may be required to avoid pitting or stress corrosion cracking, or both.

A small quantity of a contaminating compound resulted in equipment failure at a gulf coast chemical plant that had a fiber reinforced plastic (FRP) tank for a process stream that was essentially dilute hydrochloric acid (HCl), a service where the FRP tank would be completely satisfactory. However, this stream contained a small quantity of benzene. Over time the benzene dissolved in the plastic resin, softening it to the point that the tank suddenly failed, sending a wave of HCl into a nearby control room. Fortunately no one was hurt, but the process was down until the tank was replaced.

In another case leaks developed in type 316 stainless steel (UNS S31600) piping in a new chemical plant during startup. None of the chemicals in the process were known cracking agents. Investigation determined that a chlorinated hydrocarbon had been used for "water batching" since ambient temperature was below freezing. This compound was not completely removed and it reacted with the process chemicals to form a very aggressive cracking environment [30].

## CORROSION TESTING

Refer to Sections II and III for information on designing tests and for detailed descriptions of common laboratory tests. Considerable skill is required to develop a corrosion test program that adequately defines materials requirements. First, we must identify those conditions that will limit the materials selections. This includes the conditions that will be encountered under nonstandard conditions such as startup, shutdown, and process upsets. In many cases we also need to consider the conditions encountered when the unit is in standby status; that is, when the unit is not operating but is being maintained so that it can be put back into operation when it is needed. The best materials selections are made when the full range of these conditions is identified and considered before the test program is started.

### Testing Methods

Corrosion test methods can be divided into electrochemical and non-electrochemical methods. Among the electrochemical techniques that have been used successfully for corrosion prediction are potentiodynamic polarization scans, electrochemical impedance, corrosion current monitoring, controlled potential tests for cathodic and anodic protection, and the rotating cylinder electrode for studies of velocity effects [31,32]. Though not literally a test, potential-pH (Pourbaix) diagrams have been used as road maps to help understand the results of other tests.

The non-electrochemical techniques include direct immersion of materials samples in the test fluid in either the laboratory or plant. These samples sometimes have an artificial crevice generated with a serrated washer. They may be welded to determine the effects of welds and weld heat affected zones. Real-time information can be obtained using electrical resistance probes. Heat transfer effects can be evaluated by having a test sample that is exposed to the corrodent on one side and the other side heated or cooled. Stressed samples are used to evaluate stress corrosion cracking tendencies [33].

The need for more rapid evaluation of plastics and elastomers prompted the development of a sequential absorption test to provide useful information on the durability of these materials in a few weeks [34]. A refinement to this test was developed more recently [35,36].

### Test Design

The selected test program must adequately simulate the limiting conditions. However, not all tests must be under process conditions. One strategy is to start the test program by sorting the promising and less promising materials with simple tests such as immersion corrosion tests in environments that crudely simulate the process conditions. There is a danger that this approach will exclude a material that would in fact be satisfactory in the process because the test environment did not properly simulate the process conditions. However, unless you already have a pretty good idea of the type of materials that are candidates, some sort of sorting process is necessary before detailed testing is conducted. Otherwise, the test program will be too cumbersome to manage.

Once the list of candidate materials has been reduced to a manageable number we can begin a program to understand how each behaves under the range of process conditions. Details of the test methods used for laboratory corrosion testing are included in Section III and special tests for corrosion types are included in Section IV. The specific program for a process must be based on the requirements of that process and each will be different. A typical program might include immersion and electrochemical tests in process fluids (simulated or from operating units). It might also include tests for velocity sensitivity, crevice corrosion, pitting, and stress corrosion cracking. If plastics or coatings are being considered it will be necessary to conduct the tests long enough for degradation to be measured. We would like to have six months or longer for these tests but often must settle for six weeks or less.

### For Existing Processes

There is a place for both plant and laboratory tests for exploring materials for a new unit of an existing process. Plant tests can be used to explore the behavior of new materials under current operating conditions far better than can laboratory tests. These tests do not require the simulation of plant conditions, which is always imperfect. Also, in most situations these tests can be conducted with more materials at a far lower cost than is possible with laboratory tests. One drawback to in plant testing is that it may be

necessary to time the start and end of the test with scheduled equipment outages, which may postpone the data collection. An advantage of laboratory tests is that they permit exploring the effects of process changes on corrosion behavior without putting plant equipment at risk.

Some of the more sophisticated corrosion tests are suitable for use in a laboratory setting only. These tests can give more information about a material's tendencies toward localized corrosion, velocity-influenced corrosion, and the like than can the conventional plant tests. Where these are of concern, a combination of plant and laboratory tests is probably the best choice. The following is an example of how complementary use of laboratory and plant tests was used to solve a complex chemical plant corrosion problem [36]. The problem was to determine how to treat a waste stream from an entire chemical plant so it could be handled in carbon steel equipment. One characteristic of waste streams is that their compositions vary widely over time. Therefore, a grab sample from the stream might not be representative of the most corrosive conditions to be experienced. The fluid for laboratory testing was prepared from "typical" compositions of the various plant streams that are combined to create the waste product. This fluid was used in the laboratory to evaluate the effects of a proprietary sulfite-containing inhibitor, pH, and fluid velocity using a combination of electrochemical impedance and rotating cylinder electrode techniques. Plant tests included corrosion coupons and electrical resistance probes. The laboratory tests indicated that the combination of inhibitor and pH control at pH 9 provided adequate protection to carbon steel. It also suggested that pH control was critical with the corrosion rate increasing by an order of magnitude at pH 7. The plant test results supported the laboratory data but showed that extended exposure to pH 9 fluid resulted in a steel surface that withstood short excursions to pH 7 without rapid corrosion.

### For New Processes

With a new process there is no history of materials performance and no existing operating unit available for plant testing. Therefore, laboratory testing is required to determine the relative performance of materials under the expected operating conditions. The exact conditions each unit will be exposed to may not be known. However, with modern process simulation models we can have a pretty good idea of what the operating conditions will be. Simulating these conditions in the laboratory may be quite another thing. From a practical standpoint we are usually restricted to testing in raw materials, reaction products and various cuts from distillation processes. In some cases we can test in intermediate reaction products, but often these compounds are not stable. For more information on designing a test program for a new chemical process see Ref 37. This reference includes a list of corrosion testing standards by ASTM and other organizations.

# Petroleum

*K. Daniel Efird<sup>1</sup>*

THE PETROLEUM PRODUCTION environment provides a unique challenge for corrosion testing in that it is not a controlled chemistry, as a chemical process environment, but is an environment provided by nature, with all the potential variability in phase distribution and chemical composition this implies. Petroleum environments are always complex, and often change during production from a formation, or may change due to production from formations that were not included or anticipated in the original planning for field exploitation. The corrosion test program for petroleum environments must, therefore, account for the environment nature has created with very little ability to alter or control it. In a very real sense the petroleum chemistry environment is a case of "what you see is what you get." The primary concern with corrosion testing in petroleum environments is to ensure that what you "see" is, in fact, what is really in the actual production environment.

The effect of petroleum chemistry on corrosion lies primarily in its influence on the formation, chemical composition, and characteristics of a liquid water phase, since liquid water in contact with the containing material is a necessary condition for corrosion to occur for the operating temperatures and pressures encountered in petroleum production. This fact dictates the direction of the discussion on the influence of petroleum chemistry in corrosion testing. This chapter deals solely with the effects of naturally occurring petroleum chemistry on corrosion testing and methods to deal with the effects of petroleum chemistry in corrosion testing. There is no elaboration on the actual test techniques except as they are affected by the petroleum chemistry considerations, and there is no consideration of refinery operations or alterations to the petroleum chemistry used to control corrosion.

## CHEMICAL AND PHYSICAL CHARACTERIZATION OF PETROLEUM ENVIRONMENTS

Petroleum production is generally classified on the basis of existing phases in the production stream, the relative proportions of these phases, and the presence or absence of hydrogen sulfide. Carbon dioxide, hydrogen sulfide, hydrocarbons, and organic compounds (gas and liquid), water,
