and dissolved salts are the primary constituents of the petroleum environment, and provide the basis for additional characterization. The acid gases, CO<sub>2</sub> and H<sub>2</sub>S, have the primary effect on corrosion, and hence provide a primary basis of classification.

The term "sweet" is commonly applied to petroleum production environments containing carbon dioxide (CO<sub>2</sub>) and no hydrogen sulfide. These environments are generally defined for corrosion purposes on the basis of the partial pressure of carbon dioxide in the gas phase. This grossly defines the level of dissolved CO<sub>2</sub> in the water phase and, according to many sources, roughly defines the relative aggressiveness of the water phase.

The term "sour" is applied to petroleum production environments containing hydrogen sulfide. Sour environments generally contain carbon dioxide as well as hydrogen sulfide. The concentration of H<sub>2</sub>S required to consider an environment "sour" is not well defined. The most widely used definition is found in NACE Specification MR0175 [1], which defines sour as greater than 0.003 bar (0.05 psia) partial pressure H<sub>2</sub>S in the gas phase. This definition is based on safety considerations and the susceptibility of materials to sulfide stress corrosion cracking and is not related to general or localized corrosion. The term sour could be more broadly defined as an environment containing sufficient H<sub>2</sub>S to produce primarily iron sulfides as a corrosion product on steel. The H<sub>2</sub>S concentration in the water phase required for this to occur is not well defined; however, a concentration of >50 ppm H<sub>2</sub>S in the water phase is sometimes used as a criterion for a sour environment.

The physical phases in a petroleum environment [gas, liquid hydrocarbon (gas condensate and/or crude oil), and liquid water phases] may occur singly or in combination in a wide range of phase ratios, and these phase ratios and compositions may change during production. Producing fields and individual wells are broadly classified as gas or oil fields and/or wells depending on the primary phase produced. Other types of wells or systems for which corrosion testing may be considered are used for subsurface injection, e.g., CO<sub>2</sub>, water or gas injection wells, and produced water disposal wells. A "gas" well is defined as one whose production consists primarily of a gas phase with possibly some gas condensate, condensed water and/or produced water, but no crude oil. An "oil" well is defined as one whose production consists of crude oil with varying amounts of gas, and produced water. The relative proportion of gas and crude oil in the well production is expressed as the gas to oil

<sup>1</sup>Efird Corrosion International, Inc., The Woodlands, TX.

ratio (GOR) in units of volume of gas at standard conditions per volume of crude oil at 20°C (68°F).

### Temperatures and Pressures Encountered

The temperatures and pressures encountered in oil and gas production can vary widely. In general, high pressures and high temperatures go together for gas wells, but this is not necessarily the case for crude oil wells. The total bottom hole pressure in gas wells can range from a low of 40–60 bar to a high of over 1500 bar. Bottom hole temperatures can range from 50°C to well over 150°C. The temperatures and pressures normally encountered in surface production facilities are generally significantly lower.

Changes in temperature and pressure occur along the length of a tubing string during well production. The temperature and pressure variations for a typical well are shown in Fig. 1 [2]. The significance of the change in temperature and pressure is that the phase behavior of the fluids present in the formation can change in the tubing string during production and in surface facilities. This can result in the formation of liquid water and gas condensate that were not present in the original produced fluid, which can dramatically affect corrosion. A valid corrosion test procedure must account for this effect.

### Gas Phase and Gas Condensate Phase

The gas phase is composed of various combinations and ratios of methane, heavier hydrocarbons (ethane, propane, etc.), acid gases ( $\text{CO}_2$  and  $\text{H}_2\text{S}$ ),  $\text{H}_2\text{O}$ ,  $\text{N}_2$ , and helium. The primary gas is usually methane. A typical gas analysis for a producing well is given in Table 1. The gases of greatest importance to corrosion are the acid gases  $\text{CO}_2$  and  $\text{H}_2\text{S}$ . The other gases in the well stream are important to corrosion primarily because of their influence on the concentration of the acid gases dissolved in a liquid water phase.

The gas condensate phase is composed of C3 and heavier alkanes and alkenes, present in the gas phase at reservoir conditions, that condense due to the temperature and pressure drop in the well string during production or in flowlines and production facilities. The gas condensate phase can occur in gas wells, flowlines, and in crude oil well gas processing facilities after separation of gas from the crude

oil. The primary effect of gas condensate on corrosion is the displacement of liquid water from the metal surface by the gas condensate, which prevents corrosion of the metal by the water phase. This relative condensation of liquid hydrocarbon and liquid water is very difficult to simulate in laboratory tests, but the effect on corrosion must be accounted for in assessing the corrosivity of production from a well. At this time there is no simple answer to the problem. Calculations of relative condensation from well data are about the only recourse.

### Liquid Water Phase

The liquid water phase in petroleum production can consist of produced water, injected water, and/or condensed water, and combinations of these in varying proportions. Produced water is present in the reservoir as a liquid water phase, and is produced along with the gas, gas condensate, and/or crude oil. Condensed water is liquid water condensed directly from gaseous  $\text{H}_2\text{O}$  in the gas phase as a result of changes in temperature and pressure along the length of a tubing string during production and in flowlines and surface facilities. The condensed water contains dissolved acid gases ( $\text{CO}_2$  and  $\text{H}_2\text{S}$ ) and low levels of dissolved corrosion product from the well tubing. Condensed water is the fluid studied by de Waard and Milliams in their landmark work on the effects of  $\text{CO}_2$  on steel corrosion in gas transmission lines, and the equations developed apply to condensed water [3]. The equation has since been modified to account for additional variables [4].

A special case of corrosion by condensed water occurs in the vapor phase of pipelines and vessels. This condensed water can be very corrosive, and must be accounted for in designing a corrosion test program, if the phenomenon is anticipated in the specific production system being studied. Extensive discussion of vapor phase corrosion by water condensation and possible remedies are given by Dugstad, Lunde, and Olsen [5], Olsen and Dugstad [6], and Nyborg, Dugstad, and Lunde [7].

Produced water is an extremely complex chemical solution, comprised of liquid water, minerals dissolved from formation rocks, and water soluble organics from the hydrocarbon phase. The most important inorganic compounds with corrosion implications are chlorides and buffering compounds (bicarbonate, borate, silicate, etc.). The presence of buffering compounds reduces corrosion by raising the solution pH, compensating for the effect of dissolved acid gases. An accurate, detailed analysis of the

produced water is essential so it can be accurately reproduced for corrosion testing, and accurate simulation of the produced water is essential for realistic laboratory corrosion test results. The basic analytical detail needed for produced water is given in Table 2. This degree of detail is necessary to allow the required simulation of the produced water for the laboratory corrosion experiments. Research into the effects of produced water chemistry have been reported by Crolet and Bonis [8,9], Schmidt [10], Murata [11], and Videm [12].

The original produced water chemistry can be altered during production by dilution with condensed water in the tubing string and in production facilities. The effect of this dilution is to reduce the concentration of buffering compounds in the produced water, resulting in potentially lower pH and increased corrosion.

### Crude Oil Phase

The crude oil phase is the most chemically complex phase in the petroleum environment. Crude oil contains aliphatic and aromatic hydrocarbons, heterocyclic and metal organic compounds, high molecular weight organic compounds, and a broad assortment of nitrogen, sulfur, and oxygen containing organic compounds.

## CHEMICAL AND PHYSICAL CHARACTERIZATION OF CRUDE OIL

Crude oils are generally classified according to API gravity (inversely proportional to the crude oil density), sweet or sour, and asphaltenic or paraffinic (hydrocarbon characteristics). A so-called "heavy" crude oil has a low API gravity (<20), a "medium" crude oil has an intermediate density (20 to 34), while a "light" crude oil has a high API gravity (>34). These ranges are not absolutely defined, but serve as a general reference. All crude oils are composed of some or all of eight basic classes of organic compounds, as given in Table 3. Another way of classifying crude oils is based on the nature of the organic compounds that make up the crude oil, specifically the proportions of paraffins, aromatic compounds, and naphthenic compounds, as shown in Fig. 2 [13].

The recommended physical and chemical analyses for determination of the general characteristics of a crude oil are given in Tables 4 and 5. Results of these analyses provide a solid basis for comparison of crude oils from different formations and fields. The crude oil components that have the greatest potential effect on corrosion are the polar organic

compounds, since the polar organic compounds are the most water-soluble components in the crude oil and are surface active. A flow chart diagram for the extraction of the polar components of a crude oil published by Donaldson is shown in Fig. 3 [14].

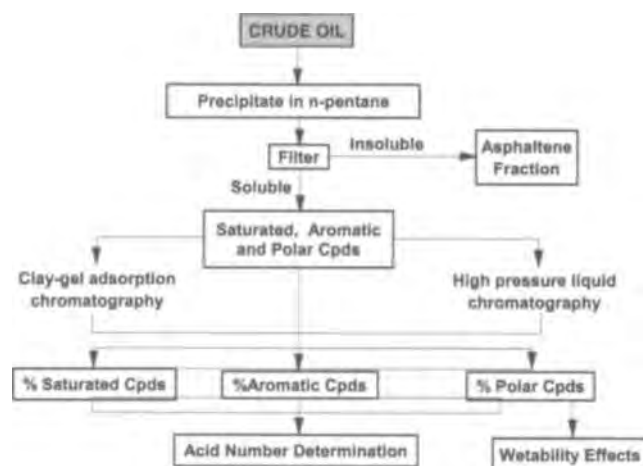

FIG. 3—Schematic diagram of chromatographic separation procedures for extraction of polar compounds from crude oil [9].

### Chemical Constituents of Crude Oil that Affect Corrosion

As stated earlier, the effect of petroleum chemistry on corrosion lies primarily in its influence on the formation, composition, and characteristics of a liquid water phase. This discussion deals with the chemical constituents in crude oil that affect the chemical composition of the liquid water phase. The water-soluble constituents in crude oil are primarily the heterocyclic and metal organic compounds, and the nitrogen, sulfur, and oxygen containing organic compounds. These include pyridines, indoles, benzofurans, phenols, amines, organic acids, thiols, ketones, and aldehydes. All are organic compounds, which are water-soluble and surface active to varying degrees [14–16].

The effect of these organic compounds on the corrosivity of the water phase is not well understood, but probably results from either direct chemical interaction with the metal surface in the manner of a chemical corrosion inhibitor, and/or their effect on wettability. An example of the effect of the crude oil acid number on crude oil wettability is given in Fig. 4 [14]. The relative wettability of the crude oil and water phases determines whether the metal surface will be oil wet or water wet, with significant effects on corrosion [17]. There is a great deal of scatter in these data, allowing determination of only a general trend.

There are also data correlating the corrosion rate of steel in crude oil/brine mixtures with the total nitrogen and sulfur content of the crude oil as shown in Fig. 5 [18]. For this set of crude oils, there is a definite decrease in the carbon steel corrosion rate with increased nitrogen and sulfur. This result is not surprising, since organic nitrogen and organic sulfur compounds are common active ingredients in formulated corrosion inhibitor packages.

### Variability of Crude Oil

The problem with corrosion testing for crude oil environments is the wide variability in the composition of the crude oils and the resulting variability in their effect on

FIG. 4—Effect of acid number and interfacial tension of the crude oil water interface on crude oil wettability [9].

FIG. 5—The relationship of the organic nitrogen and organic sulfur content of crude oil on carbon steel corrosion rate in crude oil/brine mixtures [13]. (4% NaCl brine at 5.2 mPa CO<sub>2</sub> pressure and 85°C.)

corrosion. An example of the variability in composition is shown for ten crude oils in Figs. 6 and 7 [14]. Differences in aromatic and polar organic content for the ten crude oils is given in Fig. 6, while differences in the acid numbers for these same crude oils are given in Fig. 7. The crude oil components shown in these figures are some of the components that can affect carbon steel corrosion.

These differences in composition result in wide variability in the influence of the various crude oils on corrosion of carbon and alloy steels. The effect of specific crude oils on the corrosion rate of carbon steel as a function of the produced water content with a constant produced water composition is shown in Figs. 8 and 9 [18].

This compositional variation also results in differences in the way the amount of brine in a crude oil stream affects carbon steel corrosion, as shown in Fig. 10 [19]. The three curves in Fig. 10 demonstrate the three main characteristics observed for a number of crude oils. Crude oil A demonstrates a crude

FIG. 9—Carbon steel corrosion rate on a linear scale for crude oil/brine mixtures using different crude oils with the same brine composition (4 % NaCl solution), showing different effects of increasing brine content [13].

oil that provides very little protection for carbon steel, even at water concentrations that would be expected to result in an oil wet, and thus essentially corrosion free, surface. Crude oil B provides corrosion inhibition to a high water concentration, with a subsequent rapid increase in corrosion rate. Crude oil C maintains significant corrosion inhibition at the full range of water concentrations tested.

## LABORATORY CORROSION TESTING

The unique characteristics of petroleum chemistry have a major effect on corrosion test methodology, experimental techniques, and considerations. The most important step preliminary to conducting corrosion tests is to ensure that the actual petroleum chemistry that occurs in the production system is the one investigated. This requires accurate field

data and rigorous sampling techniques. No corrosion test in the petroleum environment can be more precise than the accuracy of the production temperature and pressure data, the gas composition data, and the fluid sample analyses. The well fluids composition, particularly the gas, crude oil, and produced water analysis, must be correct.

Six basic test principles should be followed to preserve the petroleum chemistry for corrosion testing and allow valid laboratory corrosion tests in petroleum environments:

1. A representative production environment for the area of interest, or the most potentially corrosive or highest risk area in a production system, should be duplicated as nearly as possible for all corrosion testing, and its composition should not be altered, except for the purpose of investigating specific field or composition variable, e.g., changes in produced water level, CO<sub>2</sub> partial pressure, change in H<sub>2</sub>S partial pressure (field souring).
2. The composition of corrosive gases in the test solution should be calculated on the basis of gas fugacity not partial pressure for correlation with the production environment. The higher the total pressure of the production environment, the more important this becomes.
3. For crude oil corrosion tests, the actual production crude oil should be used for all corrosion testing, and oxygen must not be allowed to contact the crude oil at any time before corrosion testing.
4. Artificial produced water may be used, however, if crude oil is produced in service, the artificial produced water must be intimately contacted with the crude oil before testing to ensure that the soluble organics from the crude oil are present in the test solution.
5. Great care must be taken to prevent oxygen contamination during corrosion testing, unless oxygen is one of the test variables.
6. Each individual corrosion test must be completed before the chemistry of the water phase in the test environment is changed significantly by the corrosion process, or a flow through system must be used to maintain the solution chemistry.

### Corrosion Testing for Hydrocarbon Gas Systems

The following discussion applies to corrosion testing of hydrocarbon gas systems, and to the gas phase used for produced/condensed water and crude oil system corrosion testing.

Accurately reproducing the composition of the concurrently produced water phase is the primary concern with corrosion testing for hydrocarbon gas systems. The concentration of corrosive gases in the water phase must be accurately simulated, and simple equalizing of the partial pressure with the production environment is not sufficient. As stated previously, gas production wells are generally at high pressure. It is the high pressure that causes the error with the use of partial pressure as the determinant of acid gas concentration in the liquid water phase. This error is not as great for surface facilities operating at much lower pressures.

Using equality of gas fugacity rather than partial pressure to reproduce the production environment in the corrosion

test accounts for the effect of nonideality in the solubility of the gas in the water phase at increasing total pressure. For example, a test conducted at 1.5 bar total pressure of pure CO<sub>2</sub> will not result in the same CO<sub>2</sub> concentration in the water phase as 1.5 bar CO<sub>2</sub> partial pressure in a well with a total pressure of 350 bar with CH<sub>4</sub> as the other gas. There is significantly less CO<sub>2</sub> dissolved in the water phase at the high pressure well than in the low pressure test, even though the partial pressures are the same. This can have a major effect on the application of corrosion test results to the operating system, since the concentration of acid gas dissolved in the water phase strongly affects its corrosivity.

Care is required to ensure that unwanted oxygen is removed from the gas phase to prevent it from being introduced into the water phase. Oxygen contamination, even at a level in the water phase of 100 ppb, can result in significant errors in the test results. Anaerobic gases should be used wherever possible. Initial oxygen removal is obtained by passing the gas through commercial oxygen removal cartridges. Final oxygen removal is accomplished by passing the prescrubbed gas through an NiCl<sub>2</sub> catalyzed 10 000 ppm solution of hydrazine chloride.

Where hydrogen sulfide gas or gas mixtures containing hydrogen sulfide are used, there is rarely any oxygen in the supplied gas. However, these situations do require removal of oxygen from the test solution and the test cell gas space before introduction of the hydrogen sulfide containing test gas. Oxygen remaining in the test cell can react with the hydrogen sulfide to form oxy-sulfide compounds, which can greatly affect corrosion.

### Corrosion Testing for Produced Water Systems

The following discussion applies to corrosion testing in produced/condensed water systems and to the liquid water phase used for hydrocarbon gas and crude oil system corrosion testing.

Produced water is an extremely complex chemical solution, comprised of liquid water, minerals dissolved from formation rocks, and water soluble organics from the hydrocarbon phase, and simulated produced water used in corrosion testing must reproduce this complexity. Good initial analysis of the produced water to be tested is essential for success of the test program.

Removal of oxygen from the solution before testing is vital, since oxygen contamination can result in significant errors in the test results. The test solution is best deaerated by purging with a low oxygen test gas. Hydrogen absorption cells and/or heated copper turnings (300°C) can be employed to remove the final traces of oxygen in the test gas. Purging times must be sufficient to lower the oxygen concentration to <20 ppb. The actual purge time required will vary with the solution concentration and temperature. A hydrazine salt solution can be added to the test solution prior to its use to remove residual oxygen and maintain the solution in a reducing condition for the duration of the test period, if this is required. Hydrazine can interfere with some corrosion inhibitors, which must be considered when using hydrazine.

The test gas must be in equilibrium with the test solution before corrosion testing begins. Since chemical equilibrium

between the gas phase and the water phase, particularly for carbon dioxide, can require four to eight hours, purging overnight before testing begins is often necessary. If the gas and water phases are not at equilibrium, errors in the corrosion test results are possible. However, caution must be exercised if there are volatile components in the test solution that could be stripped out by the purge gas. The primary goal is to generate a test solution that accurately simulates the production environment.

### Corrosion Testing for Crude Oil Systems

The actual production crude oil must be used for all testing to evaluate corrosion in crude oil, and oxygen should not be allowed to contact the crude oil at any time if at all possible. The crude oil samples used in corrosion tests must be obtained in a manner designed to prevent contact of the crude oil with air. The sample container must be purged with inert gas before filling with crude oil, and the crude oil must be shipped under positive inert gas pressure. The sample container construction must be Type 316 stainless steel or a material of greater corrosion resistance, or the container must be lined with an inert material. The crude oil sample must be stored under an inert gas blanket. The crude oil must be transferred from its shipping container into the test cell using inert gas pressure or vacuum.

The extreme measures used to ensure the complete exclusion of oxygen are taken because oxygen can react with some crude oils to form organic acids that were not present in the original crude oil, and could alter the test results. Figure 11 shows the effect air exposure (oxygen) can have on the concentration of acid compounds in a crude oil. Acids in the crude oil sample were extracted with 0.06 M NaOH, which was then titrated with 0.01 M HCl. The crude oil sample not exposed to air shows a titration curve that implies carbonate/bicarbonate as the titrated species, probably originating from the carbon dioxide in the crude oil reacting with the NaOH. The crude oil sample that was

exposed to air contains 1.5 milliequivalents per liter of acidic compounds that are not present in the unexposed sample. This phenomenon does not occur for all crude oils, but it is not possible at this time to know which crude oils will be affected.

### Preventing Changes in Solution Chemistry

Contamination of the test solution with corrosion products is a very real problem, particularly for corrosion testing with carbon and alloy steel. In designing the corrosion test program, calculations using an estimated corrosion rate should be made to estimate the solution volume and maximum exposure time for the test. During the test, and at test termination, solution samples should be taken and analyzed to ensure that no significant changes in solution chemistry occurred that could affect the results. The formation of one mole of ferrous ion will generate two moles of bicarbonate in a sweet environment. For many produced water compositions, this is not necessarily a problem. For condensed water, however, the bicarbonate can result in a significant increase in solution pH. As a general guide iron concentrations should not be allowed to exceed 10 ppm during a test.

However, the above discussion assumes that there is no dissolved iron in the produced water. If dissolved iron is present in the produced water, this iron level should be duplicated in the tests. In this case the requirement becomes to not allow significant changes in the iron concentration during the test period. Many produced waters do contain dissolved iron, but care must be exercised to make sure that the iron concentration analyzed is actually contained in the produced water and not an extraneous artifact resulting from tubular corrosion.

Maintaining the dissolved acid gas concentration in the solution during the test period can be a problem, particularly when testing carbon and alloy steel for periods of over 30 days. This is generally overcome for corrosion tests in glassware by rapid stirring and sparging gas below the liquid surface. Autoclave testing is a particularly difficult problem in that the liquid volumes are small, and stirring efficiency for long time periods is difficult to assess. The most effective method for maintaining the solution dissolved acid gas concentration in autoclaves is to recirculate the test solution and allow it to fall through the gas phase on re-entering the autoclave.

### APPLICATION OF CORROSION TESTING TO NEW PRODUCTION

An approach using corrosion testing for application to new production is given in the logic diagram of Fig. 12 [20]. Carbon and low alloy steels, including corrosion testing of steels, are appraised before any consideration is given to corrosion resistant alloys. This is done because the very heavy cost penalty for alloys dictates that steels should generally be used if technically feasible.

The first step is to obtain valid field production data and samples. As discussed previously, no corrosion test is any more accurate than the accuracy of the temperature, pressure and composition data, and the sampling methodology.

FIG. 11—The effect of exposure to air on the titration curve for acidic compounds extracted from 200 mL of a crude oil with 10 mL of 0.06 M NaOH using 0.01 M HCl as the titrant.

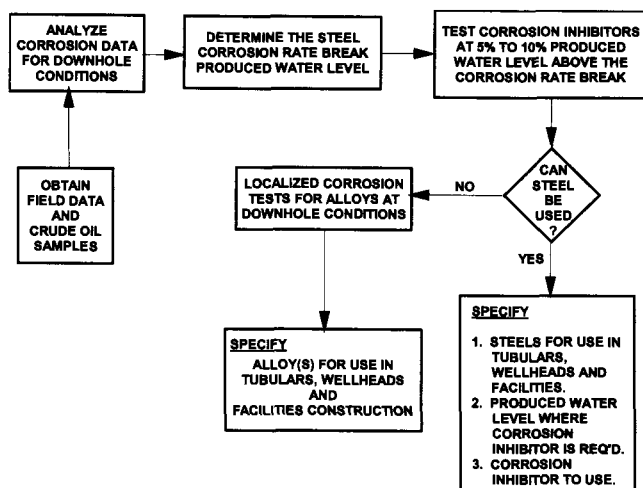

FIG. 12—The logic diagram for new field corrosion testing to determine the Corrosion Rate Break produced water level for carbon or low alloy steel corrosion, corrosion inhibitor application, and corrosion resistant alloy selection.

FIG. 13—Change in the corrosion rate of carbon steel in crude oil/produced water mixtures with increasing produced water content, showing a corrosion rate break at approximately 7 % produced water.

The well fluids composition, particularly the gas analysis and produced water analysis, must be reasonably accurate. The crude oil samples used in the corrosion tests must be obtained as described previously. The field data are evaluated as they relate to known corrosion information and corrosion prevention practices.

The corrosion tests are conducted to determine the Corrosion Rate Break produced water level for carbon or low alloy steel. The corrosion rate break is defined as a sudden increase in the corrosion rate between two produced water levels when testing in a series of produced water levels [20]. Generally, only one or two of the carbon or low alloy steels will need to be tested, since there is no significant difference in the Corrosion Rate Break produced water level measured for the various carbon and low-alloy steels commonly used

in crude oil service. The Corrosion Rate Break produced water level is determined from corrosion tests conducted at 10 % by volume produced water increments starting with 100 % crude oil until a high corrosion rate is obtained, the expected produced water limit for the field is reached, or to 90 % produced water level. If a Corrosion Rate Break is observed, additional corrosion tests are conducted at 2 % produced water increments between the two produced water levels that form the break [20]. An example of the results form this type of test sequence is shown in Fig. 13 [20].

The corrosion test methods may be any method that can provide corrosion data in the low water environments. This is generally coupon testing, but may include electrochemical tests that are applicable to the high resistivity crude oil continuous environments at low water levels, e.g., electrochemical impedance spectroscopy and electrochemical noise.

The Corrosion Rate Break tests are followed by tests for corrosion inhibitor effectiveness at a produced water content above the Corrosion Rate Break level. At this point the decision is made on whether or not carbon or low alloy steel can be used, based on the corrosion rate data and corrosion inhibitor effectiveness coupled with estimates of future produced water levels during the life of the field.

If carbon or low alloy steel can be used, the Corrosion Rate Break data are employed to specify:

1. The carbon or low alloy steels to use for tubulars, wellheads, and facilities,
2. The produced water level where the injection of corrosion inhibitor is required, and
3. The corrosion inhibitor to use when the corrosive produced water level is reached.

If carbon or low alloy steel cannot be safely used, corrosion resistant alloys must be evaluated. The production environment must be duplicated in alloy corrosion tests in the same manner as for carbon or low alloy steels. Standard corrosion tests modified to use the production environment are conducted for the corrosion resistant alloys with due consideration given the probable failure modes, e.g., crevice and pitting corrosion for stainless steels. On completion of this test sequence, the corrosion resistant alloy or alloys to use for tubulars, wellheads, and facilities construction are specified.

The possibility of sulfide stress corrosion cracking, including consideration of the possibility for future H<sub>2</sub>S occurrence even though it is not presently contained in the produced fluids is not addressed in this procedure. If sulfide stress corrosion cracking is a concern only resistant carbon or low alloy steels are included in the corrosion testing. The consideration of sulfide stress corrosion cracking must be made for the corrosion resistant alloys in the same manner as for carbon or low alloy steels.

## SUMMARY

Petroleum chemistry is very complex and very sensitive to error when translated to the laboratory. Great care must be taken when designing and conducting corrosion tests for the petroleum environment to ensure that the corrosion

measurements made are relatable to the intended service environment. These six basic principles will aid immensely in obtaining successful results.

1. Duplicate the production environment as nearly as possible including specific field or composition variables.
2. Use fugacity to calculate the composition of corrosive gases in the test solution.
3. Use the actual production crude oil excluding any contact with oxygen.
4. Artificial produced water must be intimately contacted with the crude oil before testing.
5. Prevent oxygen contamination during corrosion testing.
6. Complete each individual corrosion test before the chemistry of the water phase significantly changes.

The preventive corrosion engineering technique for determination of the Corrosion Rate Break produced water level for steel, corrosion inhibitor treatment requirements, and alloy selection can be used to minimize the cost of corrosion protection, while at the same time maximizing its effectiveness.

# High-Temperature Gases

*Gaylord D. Smith<sup>1</sup> and Brian A. Baker<sup>1</sup>*

## IMPORTANCE AND USES OF LABORATORY AND FIELD TESTING

LABORATORY AND FIELD TESTING is aimed at characterizing material performance for specific applications, or at evaluating the effect of variations in test conditions on candidate materials. The test environment should mimic, as faithfully as possible, the environment of the actual application. This includes simulating the chemical composition of the atmosphere, temperature and thermal cycle profiles, stress states, fatigue conditions, and design. Test racks placed in actual use are frequently employed. In other cases, prototype or scaled-down apparatus are designed and constructed to duplicate the end-use application. Laboratory service tests are commonly engineered specifically to evaluate the effect of one or more critical aspects of the exposure conditions. The data on material performance are then used to determine failure of mechanisms, components, or material life, or to screen materials for the application. This chapter will focus on high-temperature gaseous environment testing used to evaluate materials where the applications simultaneously involve high temperature and corrosive conditions. Common basic principles will be described that an investigator must consider in conducting and evaluating these tests. Generalized testing methods associated with specimen preparation, environment synthesis, and evaluation are briefly reviewed. Where applicable, reference is made to more detailed information and studies that are found in the technical literature.

## SAMPLE PREPARATION

Attention to detail in sample preparation begins with obtaining a complete metallurgical profile on the material to be tested. Included here are the chemical composition, fabrication history, and a knowledge of the microstructure. In general, if wrought materials are used in the end-use, the majority of materials tested should be wrought, while cast components should be modeled in test by cast materials. This is because cost, physical properties, and available forms are dependent on whether the alloys are of wrought or cast construction. If welded construction is involved in

the end-use, welded specimens should be part of the laboratory or field test series. The investigator must know the welding products and welding conditions used.

## Size and Shape

Size and shape of laboratory and field test specimens can vary widely but specimens must be large enough to obtain meaningful quantitative data. In testing where internal penetration occurs, such as in carburization, specimens must be large enough to not become saturated prior to completion of the test. Edges and corners do not behave the same as planar surfaces. The investigator should consider which to emphasize through test specimen geometry. For wrought specimens, large surface to edge area is desirable to more accurately reflect typical equipment. If the effect of environmental conditions on mechanical properties is sought, machined test specimens should be exposed.

## Identification

Positive identification of all specimens is essential. Stenciling of samples is frequently used, and brittle materials can be notched. Identification marks should be located to minimize the likelihood of being obscured by corrosion effects or corrosion products. If stress is a critical component of service performance, stamped numbers should not be permitted to be a stress raiser or serve as a notch.

## Replication

Because variations in test parameters cannot be guaranteed over time or place within the test apparatus, replication is essential. Duplicate samples will generally suffice, although a larger number of samples may be necessary for highly variable materials or test conditions. Consistency of test materials and parameters will reduce test result scatter and, hence, the need for multiple samples.

## Surface Preparation

Although clean, uniform, and defect-free surfaces are rarely found in plant equipment, it is important to strive for a clean, uniform surface condition in order to ensure meaningful and reproducible results. A common surface finish is produced by polishing with nominally #120 abrasive cloth or paper until the surface is uniform. Machining

<sup>1</sup>Technical Manager–New Products, and Metallurgist–Advanced, respectively, Special Metals Corporation, 3200 Riverside Drive, Huntington, WV 25705.

may be necessary to remove scale or other defects prior to polishing. Carburized or decarburized layers should be removed. Sheared metal may have a cold-worked layer that requires removal, although this could be less important in high-temperature test environments. Certain materials may require special handling or safety procedures that can be obtained from the manufacturer. After surface preparation, the sample must be carefully measured to permit an accurate calculation of surface area. The sample is then thoroughly cleaned in a solvent such as acetone, dried, and precisely weighed. Typically, small specimens should be weighed to within 0.1 mg. Changes in mass and dimensions will occur during service testing. Once weighed, the samples should be inserted into the test environment or stored in a desiccator. Direct handling of the specimens at any time is to be avoided.

### Controls (Reference Materials)

Setting up a pedigree material to be used repeatedly in order to "calibrate" each laboratory or field test is strongly recommended. This will ensure reproducibility of the test procedure. This material should be thoroughly characterized as to its chemical composition, process history, and microstructure. The size and shape of the reference material should reflect that of the candidate product forms being screened.

## LABORATORY AND FIELD TESTING CONTROLS

Simulating the environment of an industrial process or application can be as rudimentary or complex as the investigator chooses. Most industrial atmospheres consist of mixed oxidants of varying partial pressures (activities), temperature gradient profiles, and, in some cases, velocity and erosion parameters as well. Key application variables should be identified and suitably simulated in the laboratory or field test. Characterization of gas composition is as essential as the control of temperature and gas flow rate. The system should be at equilibrium and free of extraneous components. Care must be paid to flow stability and to maintaining calibration of equipment. Atmosphere synthesis may require multiple units, such as inlet saturators, exhaust condensers, gas preheater beds, catalyst beds, heat shields, bubblers, mass flow controllers, and analytical instrumentation. Flowmeter inlet pressure should be fixed while the gaseous components are metered with electronic mass flow controllers of the proper capacity range. Simple flowmeter-needle valve controls should be limited to single component gases or for purge streams. Mass flow controllers will maintain uniform flow rates until a back pressure of 36 kPa is reached. Any test environment that could cause system blockage through condensation, sulfate formation, coking, or line corrosion should be constantly monitored and relief valving provided. Corrosive gases, such as sulfur trioxide, will require corrosion-resistant materials of construction. Polyethylene is a convenient tubing material and does not appear to affect gas dew points as low as  $-73^{\circ}\text{C}$  (approximately 2 ppm). If the system is to be monitored using a gas chromatograph, septums must be appropriately

located in the gas stream, preferably both immediately before and after the specimen reaction chamber. For more information on atmosphere simulation and analysis, the reader is referred to Refs 1 and 2. Methods for purifying elemental gases are described in Ref 3.

Too infrequent data collection can lead to misleading conclusions, and perhaps complete failure of the test. It is common to space out field test observations to match plant shutdowns only to find complete disintegration of one or more specimens. Conversely, too frequent data collection could be unnecessarily time-consuming and expensive. Data collection can take on numerous forms depending on the purpose of the service test, including mass and dimensional changes, volumetric measurement of reactive gas consumption, changes in mechanical and physical properties, metallography, and radiographic analysis. These techniques are described in detail throughout this text. Common mistakes that can occur in high-temperature corrosion testing are described below. Gravimetric analysis that measures film formation during the initial period of scale growth usually is misleading when the results are extrapolated to long-term service. Only in the few instances where linear oxidation kinetics prevail over time would gravimetric data be valid for predicting service life. Care must be taken to assure that corrosion behavior has been measured over the entire range of temperature and pressure expected in actual service. For example, liquid phase formation is a function of temperature and can quite suddenly alter corrosion behavior in sulfur and chlorine containing atmospheres. Dependence on mass change data can be deceptive. Use of metallography to measure loss of metal and depth of internal penetration by the reactive gaseous species is essential to assess potential material degradation not necessarily apparent by mass change data only. For example, a net zero mass change effect for chromia ( $\text{Cr}_2\text{O}_3$ ) forming alloys can be observed at elevated temperatures in mixed oxidant environments where simultaneous mass loss of chromium by evaporation (as  $\text{CrO}_3$ ) and possibly scale spallation occurs, in addition to mass gain via internal attack by one or more oxidants.

## SPECIFIC ENVIRONMENTS

The principal high-temperature gaseous atmospheres to be discussed are:

- oxidation
- carburization
- sulfidation
- halogenization

Testing in each of these types of atmospheres will be discussed separately, but many industrial gas streams are best described as "mixed oxidant" atmospheres containing a combination of reactive gases. The interaction of these atmospheres with materials can be complex and vary dramatically with changing conditions of reactive gas species, temperature, pressure, and time. Another form of gaseous attack that can occur at high temperatures for a given substrate is nitridation. It shows characteristics of both oxidation and carburization. The reader is referred to the text by Lai for an overview of nitridation [4].

## Oxidation

An understanding of oxidation enhances the understanding of other types of high-temperature gaseous mechanisms [5-7]. Oxidation is often responsible for part, or all, of an engineering alloy's resistance to attack from these other gaseous environments.

### Oxide Formation

An understanding of protective oxidation of metal is enhanced by knowledge of the mechanisms of solid-state diffusion. For a particular metal, the reaction mechanism will in general be a function of pretreatment and surface preparation, temperature, gas composition and pressure, and elapsed time of reaction. When the large variations in properties of different metals and alloys and their oxides are also considered, it is not surprising that a large theoretical base is needed to describe the oxidation behavior of metals. Thermodynamics and kinetics are two basic factors associated with the formation and subsequent protection by these oxide layers at high temperatures.

### Thermodynamics

The overall driving force of metal-oxygen reactions is the free energy change associated with the formation of the oxide from the reactants. Thermodynamically, the oxide will be formed only if the ambient oxygen pressure is higher than the dissociation pressure of the oxide in equilibrium with its metal. See Fig. 1. Free energy of formation of metal oxides as a function of temperature is included in many reference books [7]. The fact that the activity of the oxide-forming metal will be less than unity should be considered as well. This information allows the determination of whether or not a particular oxide will form under a given set of operating conditions.

### Kinetics

Once it has been determined that the thermodynamic conditions are met for the formation of a particular oxide, the kinetics need to be considered [8]. A number of methods can be used to study the oxidation mechanism quantitatively. One of the simplest is to plot mass change per unit surface area of a metallic specimen versus time of exposure and examine the applicable oxidation rate laws. Using the maximum depth of attack, or penetration, is another excellent means of gaging an alloy's resistance to oxidation. It requires additional time and the internal examination of the sample. An ideal way of using both of these methods is to periodically weigh the sample and finally conduct a metallographic examination after the desired total exposure time has been reached.

An oxide layer that forms on an engineering alloy can generally be classified as a "good" (protective) oxide or as a "poor" (non-protective) oxide. The performance of this oxide, good or poor, determines whether a satisfactory alloy has been selected for the particular application.

## Oxidation Rate Laws

The most commonly encountered reaction equations are rate laws [9,10]; by determining which reaction rate law or

FIG. 1—Equilibria between the dissociation pressure of the certain elemental oxides and their metal activity (Ellingham Diagram [23,24].

laws apply, the corrosion resistance of an alloy can be categorized for a particular set of conditions and time.

### Linear Rate Law

The linear rate suggests the rate-controlling step is simply the reaction of metal with oxygen. Any corrosion product or scale formed is generally assumed to be non-protective, due to its porous, non-adherent, powdery, or volatile structure. In some cases, the corrosion product may even be a liquid. Overall reaction rates may be very fast up to and including ignition. Magnesium, cerium, and lanthanum are typical examples of pure metals that exhibit linear oxidation rates over a wide variety of conditions.

### Parabolic Rate Law

The parabolic rate law is applicable when the controlling step is by diffusion of the oxide-forming metal through a barrier such as an oxide or passive film. The oxidation rate is inversely proportional to time and approaches a slow constant rate after finite time. This is the most common type of high-temperature oxidation found on engineering materials.

### Paralinear Rate Law

In most practical oxidation processes, any particular rate law lasts for only a limited time. At the end of that time, the reaction rate is immediately describable by another law, or passes through a transition period before another rate law

is established. This change may be associated with failure of the protective scale. The slower process step may become more rapid and another may take over as rate controlling. If the mechanism of oxidation changes, oxide morphology may also change, giving another clue to the mechanism.

Many commercial alloys exhibit what is called a parabolic rate law. Initial scale buildup is parabolic, followed after some time by scale breakaway [11]. A linear weight loss then develops. This linear rate may be related to the initial parabolic rate, as in the case of scale breakaway and reformation. It may also be independent of the parabolic rate if the reformed oxide is non-protective in nature. The changing of rate laws, over time, is one of the reasons for the desirability of long-term test exposures.

## Testing

ASTM G 54, Practice for Simple Static Oxidation Testing, describes standard procedures for this test. This service test practice covers determination of preliminary information on the relative growth, scaling, and microstructural characteristics of an oxide on the surface of a pure metal or alloy under isothermal conditions in still air. The advantages of laboratory testing include being able to use small amounts of material, having a controlled environment where the parameters can be closely monitored and adjusted as desired, and being able to test with alternate materials for comparison [3]. The main disadvantage is that laboratory tests seldom, if ever, completely duplicate actual service conditions. While laboratory test data can be beneficial in assisting in selecting materials for construction, the overall test conditions, especially time duration of testing, should be closely examined. Some laboratory testing is conducted for short periods of time, i.e., less than 100 h. This type of testing can be beneficial in studying initial scale formation or oxidation theories, but is often of little benefit to actual service conditions. Laboratory oxidation tests of 500–1000 h and longer should generally be used to select materials.

Field testing can be conducted using test coupons in actual service environments or by using service equipment. The coupons offer the advantage of being able to test small samples and compare materials by testing several materials at the same time. They still, however, may not provide conditions that are identical to actual service.

Field testing of real equipment may be conducted on small, or pilot plants, or full-scale installations. The main disadvantage of this type of testing is the expense and time required. The advantage is that the data and information more accurately reflects actual operating conditions than that obtained in the laboratory. In these pilot plant environments, materials may be evaluated to determine the type of oxides formed and the degree of protection provided. This in turn provides information to permit selection of the material that will provide the required service life.

## CARBURIZATION AND METAL DUSTING

Metals and alloys are susceptible to carburization when exposed at elevated temperatures to atmospheres containing carbon-based species, such as CO or CH<sub>4</sub>. Carburization,

a form of internal attack resulting in carbide formation, can be highly embrittling. A unique mode of carburization is metal dusting in which a metal or alloy experiences significant pitting or thinning, or both, due to disintegration of a carbide-saturated surface layer. The distinguishing characteristic of metal dusting is that it requires that the calculated carbon activity be greater than unity; carburization can occur when the carbon activity is less than unity. Metal dusting environments, which commonly contain H<sub>2</sub>, CO, and various hydrocarbons, are relatively stagnant and usually between 430 and 900°C (806 and 1652°F) [12,13].

Carburization is common in heat treatment equipment, especially where endothermic gas is used for creating a protective atmosphere [14]. A typical endothermic atmosphere consists of about 40 % N<sub>2</sub>, 20 % CO, 39 % H<sub>2</sub> with less than 1 % CH<sub>4</sub>, and a dew point of –20 to –4°C (–5 to +25°F). An endothermic atmosphere, enriched in CH<sub>4</sub> or C<sub>3</sub>H<sub>8</sub>, etc., is used for gas carburizing steels (case-hardening). Carburization is also found in equipment for carbon and carbon fiber production. In the petrochemical industry, ethylene and olefins are produced in pyrolysis furnaces where petroleum feed stocks, such as ethane and naphtha, are cracked at temperatures up to 1150°C (2102°F) [15]. Of more recent origin are the carbonaceous problems associated with emerging energy conversion systems. Problems with carburization of high-temperature alloys have been identified in both liquid metal and gas-cooled nuclear reactors and in equipment for gasification and coal combustion.

## Carburization Variables

Carburization is a function of both the carbon activity of the environment and of the metal or alloy. Thermodynamically, one can determine the carbon activity of the atmosphere as follows:

When the environment contains CH<sub>4</sub>, CO or H<sub>2</sub>, the reactions are:

Then the carbon activity in the environment of Eq 1 can be calculated as follows:

$$\Delta G^\circ = -RT \ln \left( \frac{a_c \cdot P_{\text{H}_2\text{O}}}{P_{\text{CO}} \cdot P_{\text{H}_2}} \right) \quad (4)$$

Rearranging

$$a_c = e^{-\Delta G/RT} \left( \frac{P_{\text{CO}} \cdot P_{\text{H}_2}}{P_{\text{H}_2\text{O}}} \right) \quad (5)$$

Similarly, the carbon activity in the environment (2) can be calculated as follows:

$$\Delta G^\circ = -RT \ln \left( \frac{a_c \cdot P_{\text{CO}_2}}{P_{\text{CO}}^2} \right) \quad (6)$$

Rearranging

$$a_c = e^{-\Delta G/RT} \left( \frac{P_{CO}^2}{P_{CO_2}} \right) \quad (7)$$

For Eq 3, the carbon activity in the environment can be calculated as follows:

$$\Delta G^\circ = -RT \ln \left( \frac{a_c \cdot P_{H_2}^2}{P_{CH_4}} \right) \quad (8)$$

Rearranging

$$a_c = e^{-\Delta G/RT} \left( \frac{P_{CH_4}}{P_{H_2}^2} \right) \quad (9)$$

Computer programs to determine the carbon activity, as well as other constituents of the gas are available, including SOLGAS-MIX-PV developed by Besmann [16] and CORGA, developed by Bresselers et al. [17]. More recently, computer programs have become available including Thermo-Calc® developed by Sundman [18], ChemSage® by Eriksson and Hack [19], F\*A\*C\*T\*® by Thompson et al. [20], and MTDATA by Davies et al. [21].

An excellent description of the use of the Brinkley method for characterization of high-temperature gaseous environment is given in Ref 22. The Brinkley method is an iterative one, based on solving two sets of equations alternately until a consistent set of values is obtained for the mole number of each species and the total number of moles. The first step is to select the major components, i.e., those expected to constitute the bulk of the equilibrated mixture. Chemical reactions are then written for the formation of each expected minor constituent in terms of only the major ones selected, and a set of equations (Series I) is formed by the equilibrium relations for these reactions. The magnitude of each major component is then estimated, and the equations are solved to obtain trial values of the minor species.

New values for the major components are derived from a second set of equations constructed from a mass balance (Series II). The first series of equations is solved again, using the new values of the major components or weighted averages of new and old ones and the process repeated until values calculated on successive iterations converge to a consistent set of mole numbers. Partial pressures or activities can then be computed.

Reactions (1) and (2) will show decreasing carbon activity with increasing temperature while reaction (3) exhibits the reverse. Thus, at high temperatures, the carburizing tendencies of atmospheres containing  $CH_4$ ,  $CO$ , and  $CO_2$  will be dominated by reaction (3). See Fig. 2. Carbonaceous atmospheres tend to be slow in reaching equilibrium. Consequently, preheating furnaces containing an appropriate catalyst may be necessary in laboratory testing to properly simulate actual process conditions.

The carbon activity of a metal or alloy in equilibrium with its environment can be determined using similar thermodynamic principles. The relative stabilities of selected binary carbides are depicted in Fig. 3 for various partial pressures of the constituents in equations in Refs 2 and 3 versus  $a_c$ . Stability diagrams (modified Ellingham

FIG. 2—Equilibrium constant,  $K_p$ , versus temperature for various reactions producing carbon.

diagrams) of selected metals in equilibrium with both carbon and oxygen are available in various publications [23,24]. These diagrams are generated by computer programs similar to those developed by Besmann and the others [16–22]. Figure 4 is an example of one such diagram for Cr-C-O at 620°C (1150°F). These diagrams may not represent the actual events of any given alloy since the activity of the scale-forming elements will vary with their concentration in the alloy. Also, the characteristics of the scale that forms will influence carbon activity in the substrate by controlling carbon diffusion through the scale.

## Carburization Effects

Carburization usually results in the formation of internal carbides, which initially strengthen and harden a metal or alloy and then in excess begin to degrade the mechanical properties, ultimately resulting in embrittlement and potential brittle fracture at low temperatures and creep failure at elevated temperatures. Carburization is a diffusion-controlled reaction that results in a carbon gradient with its maximum at the reaction surface. Grain boundary diffusion of carbon tends to be significantly faster than intragranular diffusion, usually producing a carbide network around grains. Carbon will react with the alloy constituents that are energetically favored at any given temperature, pressure, and carbon activity. It is not uncommon to see a variation in carbide type from the surface to the interior, as dictated by the carbon activity within the alloy matrix such as  $Cr_3C_2$  to  $Cr_7C_3$  to  $Cr_{23}C_6$  to carbon in solid solution in a high-nickel austenitic alloy. Carbide formation resulting from carburization can lead to loss of both aqueous and high-temperature corrosion resistance. This is due principally to the loss of chromium from solid solution, although other elements can be involved as well. Initial carbide formation in some structural alloys can cause slight shrinkage, but gross carburization is more likely to cause expansion.

FIG. 3—Standard free energies of formation for carbides [22].

FIG. 4—Stability diagrams of Cr-C-O system at 620°C (1150°F) [22].

Mixed oxidant environments such as those that contain both carbon and O<sub>2</sub> or both carbon and sulfur can result in simultaneous internal carburization and breakaway oxidation (rapid and unpredictable metal loss) or, in other cases,

internal carburization and accelerated carbide scaling reactions [25,26]. Cycling conditions may cause a phenomenon called “green rot” in nickel-chromium alloys, whereby chromium carbides are precipitated along grain boundaries during a reducing (carburizing) cycle and subsequently oxidized during an oxidizing cycle [27].

### Testing

High-temperature carburization studies have become quite complex in the past few years resulting in much better simulations of industrial environments. Laboratory testing can now duplicate the atmospheres of coal gasification and liquefaction atmospheres, combustion gases, petrochemical process streams, and gas-cooled reactor environments. Much of this progress has been enabled by the availability of electronic flow meters to synthesize the atmosphere, and gas analysis equipment such as the gas chromatograph, mass spectrometer and individual analyzers including the electrolytic cell for oxygen, the dew point hygrometer, the chemiluminescence detector for nitrogen oxides, and the infrared absorption cell for carbon monoxide. For a detailed guide to practical usage of this equipment, the reader is referred to Ref 3.

### Laboratory Testing

Pack carburization testing as described by Mason et al. is perhaps the oldest method for characterizing the carburization resistance of alloys [28]. In such a test, the samples are packed in a heat-resistant alloy retort containing usually a 20 % mixture of alkali or other metal carbonates bound to a hardwood charcoal by oil, tar, or molasses. Approximately 20 % of coke is added to act as a diluent and to enhance heat transfer. While variations on the pack carburization test are still currently being used for screening purposes, although now typically with carbon granules, the current popularity of gas carburization technology has nearly led to its replacement.

Gaseous environmental testing, usually in multiple component atmospheres, is much more versatile and accurate and one such test configuration is depicted in Fig. 5. The dry inlet gases pass through pressure regulators and filters and are then metered through flow meters and electronic flow controllers at the desired total flow rate. The gas streams then pass through a mixing manifold and optional equipment to add water vapor or alcohol, or both. The addition of water vapor requires a water saturator and a constant temperature bath. Due to the sluggish tendency of carbonaceous atmospheres to equilibrate, it is recommended that the gas stream pass through a preheater containing a suitable catalyst, such as 0.3 % platinum on alumina. Electrically heated ceramic tube furnaces with end caps make ideal retorts for carburization testing. Specimens can be readily positioned on EX-20 cordierite [Mg<sub>2</sub>Al<sub>3</sub>(AlSi<sub>5</sub>)O<sub>18</sub>] boats drilled to accept the test specimens. Cordierite boats avoid the use of reactive metallic specimen holders in the hot zone. Cordierite is readily available in corrugated monolithic form, extremely resistant to both corrosion and thermal shock, and is easily machined. Alumina (Al<sub>2</sub>O<sub>3</sub>) is preferred for test temperatures above 1000°C (1832°F) due to the volatilization of silicon

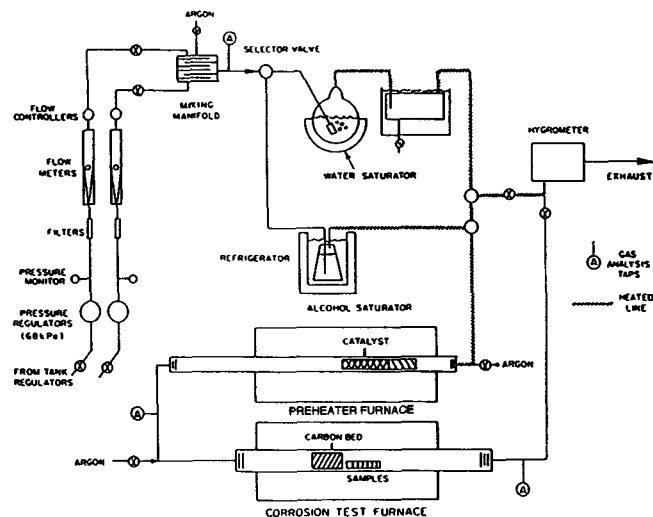

FIG. 5—Schematic representation of carburization-oxidation test apparatus.

oxide from silicon-containing ceramics. Inlet and outlet piping may be constructed with polyethylene or stainless steel tubing. Furnace end caps may be gasketed with castable silicone rubber. A plunger, which passes through an O-ring cell in the end cap, inserts and extracts the boat from the hot zone. This prevents atmospheric exposure from oxidizing reactive surfaces during thermal cycling (to weigh the samples). In the case of metal dusting testing, typically done in mixtures of  $H_2$ ,  $CO$ , and water vapor, attention to the iron content of refractory specimen holders is warranted to avoid catalytic carbon deposition on non-metallic surfaces.

The composition of the inlet mixtures and the test gases can be monitored by gas chromatography, dew point hydrometry, and individual gas component analyzers. This procedure is essential in maintaining consistency of test results, to assure equilibrium, and to check for leaks. Properly placed rubber septums in the transfer lines make monitoring relatively easy. Placing the septums in a T-type compression tube fitting using a rubber septum squeezed between a back ferrule and the fitting nut works well. The systems are usually good for dozens of injections before replacement is necessary. If properly done, less than 0.15 % air is entrained in the gas specimen.

Furnace purging for up to 1 h prior to inserting specimens into the hot zone is recommended to assure that all air trapped in the furnace during loading is expelled. Similarly, upon removal of the specimens from the hot zone, the furnace should be flushed with argon while the specimens cool to room temperature in the end of the furnace tube. This procedure negates any explosion hazard and protects the specimens from oxidation.

Mass change data can be collected from each cycle of the specimens (cycle time is entirely arbitrary and can vary from daily to weekly or longer depending on the aim of the investigation). Upon completion of the testing, the specimen can be sectioned for metallographic evaluation, hardness profile measurements or serially machined for

carbon profile analysis as described in ASTM G 79, Practice for Evaluation of Metals Exposed to Carburization Environments.

### Field Testing

Carburization testing in the field usually requires dedicating all or a portion of a particular piece of equipment for evaluating alloys' performance or for evaluating the effect of process variables on the materials of construction. Such testing is performed to confirm laboratory data because of a lack of access to laboratory equipment or professional material expertise, or because of difficulty in duplicating certain carburization conditions in the laboratory. Atmospheres of low oxygen potential have proven difficult to duplicate in the laboratory. Direct simulation of ethylene furnaces is difficult in the laboratory because of the simultaneous interaction of long-term creep and high-temperature corrosion by carbonaceous atmospheres on the inner diameter and oxidizing combustion gases on the outer diameter of the furnace tubes.

Carburization testing in the laboratory offers the convenience of access to the necessary equipment for precise control of conditions along with the ability to control measurement schedules. However, the laboratory test may not mimic all environmental and mechanical conditions such as stress, design effects (corners, crevices, dead zones, etc.), thermal fluctuations in service abrasive damage, flow stream effects, and metal-to-metal contact reactions. The investigator may not be able to reproduce the complete atmosphere that is being simulated in the laboratory and thereby runs the risk of missing a key element in determining the rate of carburization degradation. This concern prompts many investigators to seek confirming field test data.

### Materials

Because of the multiplicity of carbeneous environments in industry and the broad spectrum of mechanical property, product form, and cost requirements, a large number of heat-resistant, carburization-resistant, cast, and wrought alloys are currently available. Nickel-containing austenitic alloys are widely used in the thermal processing and petrochemical industries to resist carburization. The typical workhorse of the pyrolysis furnace tube market in ethylene cracking is now an HP-type cast (35 %Ni-25 %Cr) iron-base alloy. Many modifications, both cast and wrought, compete for this market [29,30]. High-nickel alloys find application in carburizing environments, particularly where high stress, thermal fatigue, and exceptional carburization resistance is required [31]. Alumina ( $Al_2O_3$ ) scales are deemed more protective than chromia ( $Cr_2O_3$ ) scales in conveying carburization resistance to an alloy, making alloys such as Haynes® alloy 214 UNS N07214 or INCOLOY® alloy MA 956 (UNS S67956) likely candidates for extremely carburizing environments. Silicon additions, which form silica ( $SiO_2$ ) subscales beneath chromia, offer enhanced carburization resistance; INCOLOY® alloys DS and 890 plus alloy 330 (UNS 08330) are three examples of silicon-containing, carburization-resistant alloys.

## SULFIDATION

At high temperature, sulfur is very damaging to materials of construction as many of the metallic elements that compose an alloy form low melting eutectic sulfides. The extent of corrosion depends on the partial pressure of sulfur relative to oxygen at a given temperature and the relative stability of the oxides and sulfides at the same temperature. High-temperature sulfidic corrosion of metals and alloys occurs in petroleum refining and processing. Sulfur-induced hot corrosion also occurs in gas turbine components during combustion of fuels that contain sulfur as an impurity. Similarly, sulfide corrosion is possible in environments associated with coal combustion and conversion systems.

In petroleum processing, sulfur compounds originate with crude oils and include polysulfides, hydrogen sulfide, mercaptans, aliphatic sulfides, disulfides, and thiophenes [32]. Corrosion by these sulfur compounds occurs between 260°C (500°F) and 538°C (1000°F). The corrosion rate increases with temperature to 454°C (850°F) and then decreases. Corrosion rate curves as a function of temperature for various steels with different chromium levels for a specific amount of sulfur in the processing streams are called McConomy curves [33] or modified McConomy curves [32]. If the sulfur content in the system is different, a corrosion multiplier is then applied for varying sulfur amounts. In addition, Copper-Gormen curves have been developed for various alloys that predict corrosion rate with respect to temperature for a range of H<sub>2</sub>S composition [34].

## Laboratory Testing

In the laboratory, corrosion from sulfur-containing gases can be assessed by exposing samples to the environment simulating the process. Most of the chemical processes involving sulfur would most likely have a significant partial pressure of oxygen as well. Although there is no standard sulfidation test, a typical oxidizing environment can be represented by H<sub>2</sub>-45 %CO<sub>2</sub>-1 %H<sub>2</sub>S mixture and a H<sub>2</sub>-1 %H<sub>2</sub>S mixture for reducing conditions (simulation of a coal gasification environment). The volume of gas used in the test should be sufficient so as not to influence the specimens placed in front as compared to specimens located in the back of the chamber. A flow rate of about 500 cm<sup>3</sup> per min [at standard temperature and pressure (STP)] should be more than adequate for the size of the furnace tube and the sample size mentioned below. Bottled gas premixed to the required composition can be used. Gases can also be mixed in-situ using electronic flow meters and a mixing chamber.

The sulfidation test is normally done in an electrically heated mullite tube 100 mm in diameter. The gases are mixed and passed into the mullite tube furnace. Typical specimens are in the form of pins 7.6 mm (0.3 in.) diameter by 19 mm (0.75 in.) length. Specimens are placed in a cor-dierite boat that can hold about 10 to 20 specimens at a time. To avoid any oxidation during cooling to room temperature for weighing, the samples are pulled by means of pusher rod to the cold end of the furnace and cooled in argon. After weighing, the samples are pushed into the hot zone under argon and switched to the sulfidizing environment as soon as the test temperature is attained. The test

data are plotted in the form of mass change versus exposure time. Mass change is reported as mg/cm<sup>2</sup> obtained from the measured mass change, and dimensions of the samples measured at the beginning of the experiment. The data are used to compare all the alloys tested.

The mass change in sulfidation tests is usually negative. One has to be careful in using sulfidation testing to measure weight gain using thermogravimetric equipment. Some alloys may form, at certain temperatures, low melting eutectics resulting in molten droplets dripping off the coupons under investigation. Such testing should be limited to lower temperatures or preoxidized specimens that do not form eutectics on the surface.

Another laboratory test that has been successfully used in screening candidate gas turbine alloys uses a mixture of 96 % O<sub>2</sub> and 4 % SO<sub>2</sub> [35]. When using O<sub>2</sub>-SO<sub>2</sub> gas mixtures a platinum catalyst should be used to aid establishment of equilibrium. In this oxidation/sulfidation environment, sub-surface sulfides normally get oxidized, releasing sulfur for further ingress into the metal. The extent of corrosion in this case should be assessed by cross section metallographic examination of the test specimens at the conclusion of the test, in addition to the measurement of mass change.

Another oxidation/sulfidation test to assess the performance of gas turbine alloys is the burner rig test. A schematic of the burner rig is shown in Fig. 6. Here a jet fuel is burned in a combustion chamber with an air-fuel ratio of 30:1. The flame passes down a tube at the end of which are the samples to be evaluated, mounted in a rotating platen. The samples are in the form of pins. The jet fuel normally contains a certain amount of sulfur. There are provisions to add additional sulfur in the form of volatile sulfur compounds. In addition, seawater can be added into the gas stream to simulate a marine environment. The samples are typically exposed to the flame temperature for 58 min and cooling air for 2 min in a 1-h cycle. The test is typically conducted for about 500 h.

In a standard burner rig test, mass change data are not usually acquired during testing. The metal loss and depth of maximum attack can be obtained after completion of the test by mounting transverse sections cut from the

FIG. 6—Schematic of the G. E. Lynn burner-rig test setup.

specimens and polishing using standard metallographic procedures. Samples can then be evaluated using the criteria described below under Metallographic Analysis.

In addition to burner rig tests, additional laboratory tests such as the Dean test and modified Dean tests have been developed to study the hot-corrosion resistance of gas turbine alloys [36]. These differ from the burner rig in the way salt is carried to the specimens at a specific temperature.

Considerable work has been done on the performance of conventional engineering alloys and advanced nickel- and cobalt-based alloys in environments simulating low oxygen partial pressures and moderate to high sulfur partial pressures that are typical of coal gasification and substoichiometric combustion systems [37]. Figure 7 shows the schematic of a laboratory setup used for evaluation of materials. The setup is used to internally air-cool the specimens to simulate heat exchanger tubes exposed in a coal gasification type environment. Thermocouples are welded on the inside and outside surfaces of the metal tube. The gas temperature is measured by another thermocouple in the thermowell. The fireside temperature of the metal is controlled by adjusting the coolant flow rate. Flow rates of the mixed gases such as  $\text{CO-CO}_2\text{-CH}_4$  and  $\text{H}_2\text{-H}_2\text{S}$  are adjusted

through a gas flow system to achieve the desired oxygen and sulfur partial pressures in the reaction mixture.

### Field Testing

Coal ash corrosion is a widespread problem for superheater and reheater tubes in coal fired power plants that burn high-sulfur coals. The accelerated corrosion is caused by liquid sulfates on the surface of the metal beneath an overlying ash deposit. Coal ash corrosion is very severe between 540 and 740°C (1000°F and 1364°F) because of the formation of molten alkali iron-trisulfate. Considerable work has been done to predict corrosion rates based on the nature of the coal (its sulfur and ash content). This was accomplished by the exposure of various alloys to synthetic ash mixtures and synthetic flue gases. The corrosion rates of various alloys were reported in the form of iso-corrosion curves for various sulfur dioxide, alkali sulfate, and temperature combinations. An equation was developed to predict corrosion rates for selected alloys from details of the nature of ash by analyzing deposits removed from steam generator tubes and from test probes installed in a boiler [38]. Then laboratory tests were conducted using coupons of various alloys coated with synthetic coal ash that was exposed to simulated combustion gas atmospheres.

The U.S. Department of Energy sponsored various materials testing projects in operating coal gasification pilot plants. The results for several coal gasification pilot plants are summarized in Ref 39.

Atmospheric and Pressurized Fluidized Bed Combustion (AFBC and PFBC) of coal using calcium oxide as a sulfur absorbent is an emerging technology that burns coal efficiently and eliminates the need for expensive flue gas desulfurization systems, as sulfur in this case, is removed in solid form. However, solid-state oxygen sensors have shown that the average oxygen concentration is not a valid indication of the in-bed combustion chemistry [40]. The oxygen sensors identified localized areas within the fluidized bed that have very low (as low as  $10^{-25}$  atmospheres) or oscillating oxygen partial pressures. Low oxygen partial pressures result in relatively high sulfur activity (as high as  $10^{-5}$  atmospheres). Several corrosion studies of coupons and tubular specimens exposed in various pilot plants have shown that heat exchanger alloys can undergo very severe sulfidation attack within the bed environment [41].

### Materials for Test Equipment and Reference Samples

The most effective way to combat sulfidation is to develop a protective oxide layer using adequate amounts of chromium and/or aluminum. High-temperature alloys should contain at least 20 % chromium to form a continuous chromium oxide scale to prevent sulfur from getting into the metal. High nickel-containing alloys are often not suitable for use in reducing sulfur-containing environments. Depending upon the relative partial pressures of sulfur and oxygen, nickel-containing alloys can be used in oxidizing environments containing small amounts of sulfur. INCONCLAD® alloy 800H/671 has been used in coal ash corrosion involving coals containing appreciable amounts

FIG. 7—A schematic of the corrosion setup developed by Argonne National Lab to study the corrosion rates of alloys in cooled and uncooled condition at selected partial pressures of oxygen and sulfur.

of sulfur. Alloy 309 SS (UNS S30900), alloy 310 SS (S31000) and INCOLOY® alloy MA 956 (S67956) can be effectively used in reducing environments containing sulfur.

## HALOGENIZATION

High-temperature, halogen-containing environments are potentially extremely aggressive. The reaction products of halogen gases can be liquid or can possess a high vapor pressure, depending on the reactions and temperature. In either case, degradation of most metals and alloys can be rapid. Table 1 lists 14 metal chlorides, their melting and boiling points, and the temperature for  $10^{-4}$  atmosphere vapor pressure [42].

### Laboratory Testing

Laboratory testing environments are divided into two groups, those halogen environments possessing no measurable oxygen and those environments containing both halogens and oxygen. In the oxygen-free environments, liquid phases and volatile reaction products may lead to erratic corrosion attack. Halogen plus oxygen environments exhibit parabolic behavior as oxide scale and volatile halide reactions occur simultaneously.

Halogen testing is properly conducted in electrically heated furnaces using ceramic tubes with end caps containing pusher rods to manipulate the corrosion specimens under atmosphere. The end caps should be protected with a corrosion-resistant sealing gasket. Gas compositions may be either purchased or synthesized from the components using halogen-resistant electronic flow controllers and mixers. Polyethylene is recommended for the tubing and cordierite is ideally suited for the specimen holder. The specimens are in the form of pins with dimensions similar to those mentioned for sulfidation tests. Gas flow streams of a total flow rate of  $500 \text{ cm}^3/\text{min}$  ( $30.5 \text{ in.}^3/\text{min}$ ) are considered adequate to assure a consistent environment for all specimens. The effluent stream should be reacted with a caustic solution before venting to remove the reacted and unreacted halogens. At the completion of testing, the specimens should be examined metallographically for evidence of voiding or liquid phase corrosion. Scale identification by X-ray

diffraction or SEM-EDX can be helpful in clarifying reaction mechanisms.

Two representative laboratory test programs are those depicted by Brown et al. who conducted short-term studies in chlorine on various temperatures [43,44]. Tyreman and Elliott have described a laboratory procedure for testing in fluorine as has Jackson [45,46].

Laboratory screening of alloys and weld overlay compositions has become increasingly important as efforts to utilize waste incinerators for disposal of waste gains momentum. One such procedure is described in a paper by Baker et al. [47]. Testing was performed in a sealed electrically heated muffle furnace having a 100 mm (3.94 in.) diameter mullite tube. To form the test gas mixtures,  $\text{O}_2$  and  $\text{N}_2$  were passed through a constant temperature water bath before the addition of  $\text{CO}_2$ . The  $\text{SO}_2$  and  $\text{HCl}$  test gases, pre-mixed with  $\text{N}_2$ , were then added to the gas stream. All flow rates were measured using electronic mass flow controllers. The flow of the gas mixtures was  $250 \text{ cc/min}$  ( $15.3 \text{ in.}^3/\text{min}$ ). The test gases flowed through a nickel oxide catalyst before reaching the samples to ensure gas equilibrium. The resultant gas mixture was composed of  $\text{N}_2$ -10 %  $\text{O}_2$ -20 %  $\text{H}_2\text{O}$ -1500ppm  $\text{HCl}$ -300ppm  $\text{SO}_2$ .

Samples were exposed in the flowing gas with and without the application of one of two chloride slurries. The slurries were prepared by first grinding the chloride salts into a fine powder in a mortar and pestle and then mixed with acetone and applied to the specimens with a soft bristle brush. Mass gain resulting from application of the coating averaged  $40 \text{ mg/cm}^2$ . Samples painted with the slurry were cycled at one-week intervals during which loose scale was lightly removed mechanically and the slurry re-applied. The composition of the two salt mixtures were (a) 20 %  $\text{ZnCl}_2$ -40.9 %  $\text{PbCl}_2$ -21.9 %  $\text{KCl}$ -17.2 %  $\text{NaCl}$  by weight and (b) 4.7 %  $\text{ZnCl}_2$ -0.7 %  $\text{PbCl}_2$ -2.0 %  $\text{KCl}$ -2.60 %  $\text{NaCl}$ -6.1 %  $\text{K}_2\text{SO}_4$ -4.9 %  $\text{Na}_2\text{SO}_4$  (equimolar amounts of each salt) -70 %  $\text{Al}_2\text{O}_3$  by weight. Testing was conducted at  $650^\circ\text{C}$  ( $1202^\circ\text{F}$ ) for 336 h with and without the application of the first salt mixture and at  $550^\circ\text{C}$  ( $1022^\circ\text{F}$ ) for 336 h with the application of each salt mixture. Corrosion performance of each candidate alloy was sectioned and evaluated metallographically after each test. Additionally, mass change results were obtained when salt mixture (a) was not used during one of the test cycles.

Spiegel and Warnecke employed a crucible test using a salt mixture of 46 %  $\text{KCl}$ -46 %  $\text{ZnCl}_2$ -8 %  $\text{PbCl}_2$  which was molten at  $350^\circ\text{C}$  ( $662^\circ\text{F}$ ) to test their thermal spray coated specimens [48]. The furnace atmosphere was controlled by a gas metering system in which  $\text{N}_2$ -5 %  $\text{O}_2$  was added as a pre-mix and  $\text{HCl}$  added by passing a portion of the gas flow through a saturator of azeotropic  $\text{HCl}$  solution placed in a thermostat.  $\text{SO}_2$  was added from a pre-mix of  $\text{N}_2$ -5 %  $\text{O}_2$ -1 %  $\text{SO}_2$ . This gas was dried by passing through columns filled with  $\text{Pb}_2\text{O}_5$  and mixed before entering the furnace. Each test was conducted for 360 h.

### Field Testing

An excellent example of field testing in conjunction with laboratory testing to solve a heat exchanger corrosion problem in an industrial chlorinated solvent incinerator is described in Ref 49. A corrosion rack containing three

TABLE 1—High-temperature properties of 14 chlorides.

Chlorides	Melting Point	Temperature $^\circ\text{C}$ at $10^{-4}$ atm	Boiling Point
$\text{FeCl}_2$	676	536	1026
$\text{FeCl}_3$	303	167	319
$\text{NiCl}_2$	1030	607	987
$\text{CoCl}_2$	740	587	1025
$\text{CrCl}_2$	820	741	1300
$\text{CrCl}_3$	1150	611	945
$\text{CrO}_2\text{Cl}_2$	-95	—	117
$\text{MoCl}_3$	195	58	268
$\text{WCl}_5$	240	72	—
$\text{WCl}_6$	280	11	337
$\text{TiCl}_2$	1025	921	—
$\text{TiCl}_3$	730	454	750
$\text{TiCl}_4$	-23	-38	137
$\text{AlCl}_3$	193	76	—

stainless steels, two high-nickel austenitic alloys and three nickel-base alloys was placed within the hot gas stream of a heat exchanger containing HCl and chlorine. The in-situ test results were correlated with laboratory tests of the same alloys for this application.

Waste incinerator effluent streams contain halogen compounds arising principally from the burning of plastics and organic matter. A ten-year study of candidate alloy boiler tubes in several field test sites is described in Ref 50. Again, these field results were confirmed by simulated laboratory tests. Metallography and scanning electron microscopy (SEM) were used to define the corrosion modes of this mixed oxidant environment. Ultrasonic thickness measuring equipment was used to follow tube corrosion/erosion rates at the field sites. Tubes were periodically removed from service for laboratory evaluation. Use of test racks to evaluate the performance of candidate materials for municipal incinerator hardware is discussed in Ref 51. Test racks have proven to be a valuable source of performance information for waste incinerator environments [52].

### Materials

Nickel and nickel-base alloys have consistently been proven to be the most resistant materials to halogen- and halide compound-containing environments. An extensive summary of alloy performance data in these environments is presented in Refs 53 and 54.

## CORROSION SAMPLE ANALYSIS

### Analysis of Corrosion Products

Corrosion products should be examined for both composition and morphology. Compositional analysis can be wet chemical analysis, X-ray diffraction, high and low energy electron diffraction, X-ray fluorescence, electron probe microanalysis, or mass spectrometry. Morphology can be determined using light microscopy, hardness measurements, transmission electron microscopy, SEM, field ion microscopy, plus other techniques. For details on these methods, the reader may refer to basic texts and pertinent review articles, such as Ref 3.

SEM is excellent for observing scale features providing photographs and permitting simultaneous chemical analysis of surface features. Along with scale composition, the phases present in the scale should be determined by X-ray diffraction or other methods. Care should be taken to assure the sample is taken from a representative area. Care must also be taken during metallographic preparation to avoid spalling of the scale during cutting, mounting, or polishing. Mounting in liquid epoxy resin or nickel or copper plating the surface aids significantly in preserving original structure. For subsequent metallographic analysis, it is important to ensure that the sample is mounted perpendicular to the cut surface. Due to the friable nature of oxide scales, it is recommended that more time than normal is spent on each successive abrasive paper in order to remove any damage to the scale caused by each grade of abrasive paper. If chemical analysis is to be done by SEM or other methods

and the scale is water soluble (as in halogen corrosion), it is best to avoid water during cutting and polishing. In such cases, use of non-aqueous lubricants, such as kerosene is recommended for polishing. The mount should be examined in the unetched condition to properly assess the true depth of penetration. Etching can result in voiding due to galvanic pitting of the substrate near the surface where alloy depletion has occurred. Care must also be taken to remove any etchant absorbed by porous scale since the etchant may subsequently ooze from the scale and stain the substrate. Techniques for analysis of the metallographic sample are described below.

### Metallographic Analysis

Metal loss is defined as one half the difference between the original thickness and the remaining thickness after exposure. This thickness extends to just beneath the scale/substrate surface and excludes the thickness of internal attack. This is schematically shown in Fig. 8, as depicted in ASTM G 54, Practice for Simple Static Oxidation Testing. Thus metal loss is defined as:

$$\text{Metal Loss} = \frac{T_o - T_{mi}}{2} \quad (10)$$

where:

$T_o$  = original thickness or diameter, mm

$T_{mi}$  = as-exposed sample thickness or diameter, mm.

where:

$T_o$  = original coupon thickness,

$T_{mi}$  = as-exposed coupon thickness, and

$T_m$  = remaining good metal.

FIG. 8—Schematic showing thickness measurements.

Metal loss may be assumed to be that position of the substrate lost to scale formation and no longer capable of fully participating in bearing a load over time.

Depth of attack describes the formation of voids or internal precipitates. This is sometimes referred to as depth of penetration or in the case of oxidation as internal oxidation. This attack can occur when an alloy constituent is lost to the scale or to the high-temperature gaseous environment. Voids are generally associated with grain boundaries as they are the path of fast diffusion of the alloying element being lost. Alloying elements of high vapor pressure or which form volatile species with the gaseous environment are especially prone to cause voids. Conversely, internal precipitates form if the gas pressure is below the dissociation pressure of the precipitate. When a gaseous species diffuses into a substrate it will form the most stable compounds possible. These are usually the precipitates of the most reactive components of the alloy. Internal precipitates can form only if the reactive element diffuses outward more slowly than the gaseous component diffuses inward; otherwise, only surface scale will form. From Fig. 8, depth of attack is described as:

$$\text{Depth of Attack} = \frac{T_o - T_m}{2} \quad (11)$$

where:

$T_m$  = remaining round metal, mm.

It may be necessary to quantify the extent of attack (voids or precipitation) as a function of depth beneath the surface. It is likely that the extent of voids will decrease with depth. Generally, the extent of precipitation is relatively uniform to a given depth and then tapers off rapidly. In making metal loss and depth of attack measurements, it is recommended that at least three measurements across the thickness of the metallographic section be averaged. Measurements should be made to the nearest 0.0025 mm (0.0001 in.).

### Structural Changes

Structural changes in the substrate can result due to alloy depletion and thermal effects on the stability of the alloy. An example of a typical alloy depletion effect is the dissolution and thermal effects on the stability of the alloy. An example of a typical alloy depletion effect is the dissolution of carbides near the substrate surface due to the loss of carbon and carbide-forming elements resulting from high temperature exposure. A common thermal effect is the precipitation of topologically close packed phases such as Mu, Sigma, etc., over time within certain high-temperature ranges. SEM X-ray diffraction of extracts and other methods can be used to confirm these structural changes.

### Mass Change Analysis

Mass change measurements are made by calculating the weight change per unit area, usually as a function of time, temperature, and pressure. Mass change is typically calculated as follows:

$$\text{Mass Change} = \frac{W_f - W_o}{A} \quad (12)$$

where:

$W_f$  = final weight, g,

$W_o$  = original weight, g,

$A$  = original area, cm<sup>2</sup>.

A plus or a minus sign indicates a net gain or loss, respectively. Report whether the sample has been descaled or not descaled. If mass change data are collected as a function of time, it is customary to not descale the sample until the exposure is complete, although the loose scale may be gently dislodged by tapping the sample against a clean solid surface. Descaling can be difficult for a tightly adhering scale or a deep oxide substructure. If descaling is felt to be necessary, ASTM G 1, Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens should be consulted for typical electrolytic and chemical techniques. Gentle grit blasting is another alternative for removing adherent scale. Specimen weighing should be to the nearest 0.1 mg.

Carburizing atmospheres result in considerable internal attack and ASTM G 79, Practice for Evaluation of Metals Exposed to Carburization Environments describes the four methods of evaluating samples exposed to these environments. Besides total mass gain and metallographic evaluation, ASTM G 79 describes techniques for measuring carbon diffusion profiles and changes in mechanical properties. Additionally, ASTM E 10, Test Method for Brinell Hardness of Metallic Materials, is applicable for measuring hardness profiles due to carbon absorption.

As a final precaution, whatever the test atmosphere, single data points and single analytical measurements can be potentially highly misleading. Corrosion rates and modes vary with time. Data as a function of extended time are vital to define true performance in engineering applications. Because of the multiplicity of corrosion modes that can occur simultaneously in many environments, it is important to use as many analytical techniques as practical to fully understand all factors affecting performance.

### SERVICE TEST STANDARDS

High-temperature service test standards have been prepared by ASTM. No other technical organization has as yet published any standards pertaining to high-temperature corrosion service.

#### ASTM G 54, Practice for Simple Static Oxidation Testing

This service test practice covers determination of preliminary information on the relative growth, scaling, and microstructural characteristics of an oxide on the surface of a pure metal or alloy under isothermal conditions in still air.

#### ASTM B 76, Method for Accelerated Life Test of Nickel-Chromium and Nickel-Chromium-Iron Alloys for Electrical Heating

This service test method covers the determination of the resistance to oxidation of nickel-chromium-iron electrical

heating alloys at elevated temperatures under intermittent heating. Procedures for a constant temperature test are provided. The test method is used for comparative purposes only.

### ASTM B 78, Method for Accelerated Life Test of Iron-Chromium-Aluminum Alloys for Electrical Heating

This service test method covers the determination of the resistance to oxidation of iron-chromium-aluminum alloys for electrical heating alloys at elevated temperatures under intermittent heating using a constant temperature cycle test. This test is used for comparative purposes only.

### ASTM G 79, Practice for Evaluation of Metals Exposed to Carburization Environments

This service test method covers procedures for the identification and measurement of the extent of carburization in a metal sample and for the interpretation and evaluation of the effects of carburization. It applies mainly to iron- and nickel-based alloys for high-temperature applications. Four methods are described:

- Method A, Total Mass Gain.
- Method B, Metallographic Evaluation.
- Method C, Carbon Diffusion Profile.
- Method D, Change in Mechanical Properties.

These methods are intended, within the limitations as noted, to evaluate either laboratory or field samples that have been exposed in carburizing environments.

# Organic Liquids

*C. S. Brossia<sup>1</sup> and D. A. Shifler<sup>2</sup>*

## DESCRIPTION OF ENVIRONMENT

### Overview

ORGANIC LIQUIDS ARE USED in a wide variety of industrial applications. They can be characterized as liquids that consist of one or more carbon atoms joined to other atoms via covalent bonds. Common atoms included in organic molecules are hydrogen, oxygen, nitrogen, sulfur, and halogens. Both the rate and yield of certain reactions have been found to greatly increase when performed in organic liquids. Thus, they are widely used in the chemical process industry for synthesis. With the increase in the use of organic liquids, increases in observed corrosion problems associated with the exposure of materials to them have also occurred. In some cases, failures involve an unacceptably large loss of metal or degradation of material properties. However, in many other cases, the major issue is discoloration or degradation of the organic solution resulting from corrosion of the processing vessel, as the solution is the product of commercial interest. For example, many pharmaceuticals are synthesized in organic solutions in large vessels. For these applications, the corrosion resistance requirements for materials used are stringent. The introduction of metals into a product can lead to rapid degradation of the product, as well as health and safety concerns.

While corrosion in pure organic liquids can occur, many corrosion problems in organic liquids involve solutions with multiple components. For example, a solution containing ethanol, water, oxygen, and hydrogen chloride (HCl) contains four components. Some of the components may be present at small concentrations, but have dramatic effects. This is often the case with water due to its low molecular mass compared to many organic liquids. Small mass percentages of water can represent significant concentrations in moles/L. For example, 100 ppm water in acetonitrile results in a water concentration of over 4 mM.

Organic liquids are classified in a variety of ways. A common classification scheme is based on the nature of the bonding between molecules during solvation. Three general categories exist: protic liquids, nonpolar aprotic liquids, and dipolar aprotic liquids. Protic liquids (e.g., alcohols, carboxylic acids, amines, amides) are those that can provide protons to

other molecules. Solvation in protic organic solvents occurs through dipole-dipole interaction, ion-dipole interaction, and hydrogen bonding. These are generally miscible with water (another protic liquid) and can solvate both organic and inorganic acids. Nonpolar, aprotic liquid molecules (e.g., aromatic and aliphatic hydrocarbons) interact through weak van der Waals bonds and have little solvating ability. The protons in these liquids do not dissociate to any measurable extent. Dipolar, aprotic liquid molecules (e.g., acetonitrile, aldehydes, esters, ethers, dimethyl sulfoxide, tetrahydrofuran, dimethylformamide) interact via ion-dipole and dipole-dipole forces and usually strongly solvate cations and tend to be poor acceptors of electrons and poorly solvate anions in solution.

Organic solvents may also have functional groups that are either hydrophobic, which repel water molecules, or hydrophilic, where the functional groups readily react with water. It has been shown that the predominant interaction of a metal with an organic adsorbate is through its functional groups [1].

The wide variety of organic liquids leads to complexity in the analysis of corrosion problems. In addition, the large number of different liquids leads to difficulties due to the limited physical and chemical data on specific liquids. This has ramifications both for the recording of corrosion data, and for the development of a broad-based understanding of the important corrosion processes. The lack of physical and chemical information is a limiting factor in any broad description of behavior, such as found in this chapter. Also, while many testing considerations can be generalized for organic liquids, the corrosion behavior of materials in nonaqueous solvents is not nearly as well understood as in aqueous solutions.

### Types of Corrosion

The types of corrosion (i.e., the morphology of attack and the oxidation process) that can be encountered in organic liquids are the same as those observed in aqueous solutions. The solution chemistry and solution electrochemistry may be different, but the types of fundamental corrosion processes that occur remain the same. An excellent review of examples of corrosion in various organic solutions can be found in the work of Heitz [2]. In addition to a review of the fundamental principles involved, Heitz critically evaluates the literature published before 1973 and describes a number of industrial case histories of component failures due to

FIG. 2—Increase in water content in methanol due to absorption from ambient atmosphere [7].

pure, dramatic differences in corrosion rate due to small water additions are observed. This can also be true for other impurities that are often present in organic liquids. Thus, the measurement and control of water levels can be a key aspect to corrosion testing in organic liquids.

A popular technique to measure water content is the Karl Fischer Titration method [6]. This method can reliably analyze water contents as low as 100 ppm (0.01 mass %). Aliquots of solution can be taken before, during, and after an experiment to follow any changes in water content. Such changes can occur due to the tendency of some organics to absorb water from the ambient atmosphere. For example, it has been found that the water content of a 100 mL sample of methanol, exposed to laboratory air at 25°C with a relative humidity of approximately 55 %, increased from 0.035 mass % to 0.42 mass % in 2 h, as shown in Fig. 2 [7]. This illustrates the need for incorporating a sealed experimental cell or a dry glove box when working at low water levels. By using one or both of these, water absorption can be minimized and water levels of 100 ppm and below can be realized in the pure liquid. Care must be taken when adding other components to the anhydrous liquid, as most salts as well as electrodes can add appreciable amounts of water to the solution, which is then very difficult to remove. Also, extremely dry solutions can sometimes pose a safety hazard if suddenly exposed to air or water.

Organic liquids encompass an extremely wide variety of compounds. However, they can be classified into two main categories: aprotic (which are generally water insoluble) and protic (which are generally water soluble). Many solution properties, such as solvating power, depend on the primary functional groups of the organic liquid. Thus, the protic nature of a given organic liquid will determine the solubility of various impurities and corrosion products. Even within a type of organic liquid, important differences emerge among individual liquids. For example, the corrosion rate of iron decreases in monocarboxylic acids as the chain length increases (Fig. 3) [2]. These differences among similar organic liquids add another layer of complexity to the corrosion phenomena as compared to aqueous solution.

FIG. 3—Corrosion rate (mm/yr) of iron in mono-carboxylic acids of different chain lengths (formic acid, acetic acid, propionic acid, butyric acid) [2].

Related to liquid composition effects are cosolvent interactions. In many applications, a mixture of liquids (organic/organic, organic/inorganic) is of interest. Several aspects need to be considered when testing in such organic liquid mixtures, which are not considered in aqueous solutions. First, there exists the possibility that when two or more liquids are combined they are either immiscible or have limited miscibility. This results in the formation of multiple liquid phases (phase separation) where the properties of each phase could be significantly different from others. The net result is that testing in mixtures can be difficult. The difficulty arises in trying to determine which phase or composition is detrimental to material behavior and may also involve partitioning of dissolved species between the various phases present. The possibility also exists that it is not an individual phase, but rather the interface between two phases in solution that is deleterious. Multiphase solutions cause special problems, such as concentration of aggressive species into one phase (e.g., HCl into the aqueous phase of a HCl/water/dioxane mixture) [2], specific adsorption of one phase at the metal surface, and preferential attack at the phase boundary (akin to water line attack). Additional discussion of multiphase attack is outside the scope of this chapter, but can be found in Heitz's review [2].

One important manifestation of the large variety of organic liquids is the paucity of thermodynamic data. Thus, no equivalent to Pourbaix diagrams [8], used widely in aqueous solution, has been developed for any organic liquid. In fact, pH in organic liquids is not relevant in aprotic organic solvents, since there is no readily available hydrogen. However, in nonaqueous solutions, it is possible to generate more powerful proton donors than the hydronium ion found in aqueous solutions. The strength of extremely strong acids in nonaqueous solution is measured by the Hammett acidity function, which is defined for the reaction  $B + H^+ \rightleftharpoons BH^+$  [9]:

$$H_o = pK_{BH^+} - \log ([BH^+]/[B])$$

where B is the nonaqueous solvent. No standard metal/solution potential difference has been defined for all liquids. Some of the behavior in organic liquids can be explained by using the concept of Lewis acids and bases employed in

FIG. 4—Normal electrode potentials of metals in different liquids on the ferrocene/ferricinium<sup>+</sup> scale at 25°C [2].

the aqueous chemistry. A Lewis acid is an electron pair acceptor, while Lewis base is an electron pair donor. All the usual ligands can be considered Lewis bases and metal ions as Lewis acids.

In general, thermodynamic data in the literature pertaining to specific material/aqueous solution systems (e.g., Pourbaix diagrams) may not necessarily be valid for the same material in organic liquids. Some efforts have been made to develop electromotive series in different liquids, as shown in Fig. 4. The reference point is given by the ferrocene/ferricinium<sup>+</sup> couple. The selection of a reference electrode is discussed in a later section in this chapter. In general, the order of reversible potentials is maintained from aqueous solution, though the numerical values can change appreciably.

Finally, as is the case for water, organic liquids have a limited range of electrochemical stability. The products of these reactions are often also electroactive and can become involved in electrochemical or chemical reactions of interest. While solution oxidation or reduction can also occur in aqueous solutions, the products are simple bases or acids (i.e., H<sup>+</sup> and OH<sup>-</sup>). However, the products resulting from electroactive liquids are usually a mixture of complex organic acids. These complex organic acids can combine with other ions in solution and form other chemicals that could be even more aggressive than the acid from which they were derived. This has been shown to be an issue in methanol by Smialowska [10], who found that galvanostatic polarization of stainless steel in pure methanol resulted in the formation of formic acid as follows:

The observed oxidation current was a mixture of metal dissolution and methanol oxidation, complicating comparisons

of material loss and charge passed based upon Faraday's Second Law.

## IMPORTANT ENVIRONMENTAL VARIABLES

The environmental variables that influence corrosion testing in organic liquids include metal, alloy or nonmetallic material in contact with the organic solution, solution conductivity, solution acidity, water content of the solution, presence and stability of oxide or other pre-existing films, type and concentration of surface contaminants or inclusions, functional group and concentration of organic solvent, solvent oxidation or reduction products, type and concentration of supporting electrolyte, applied potential, possible mechanistic paths for passivation, and temperature. As in all corrosion testing, matching the test environment to the actual service environment is critical for obtaining useful information. In addition, by studying the effects of these variables on the corrosion processes, better insights into the controlling mechanisms, as well as the sensitivity of the corrosion processes to changes in the service environment, can be gained.

As mentioned above, the high resistances often associated with organic solutions can distort electrochemical measurements. To minimize these ohmic losses, supporting electrolytes are often used. Ideally, supporting electrolytes dissociate and increase the solution conductivity without altering the corrosion process under study. A commonly used electrolyte is lithium perchlorate (LiClO<sub>4</sub>) in concentrations ranging from 10<sup>-2</sup> to 5 × 10<sup>-1</sup> mol/L. The perchlorate anion is thought to be inert in most solutions, and very weakly adsorbing to surfaces. Thus, LiClO<sub>4</sub> is not expected to affect the electrochemical reactions considered in most organic liquids. The addition of 0.1 M lithium perchlorate as a supporting electrolyte to methanol can increase the conductivity from 10<sup>-6</sup> S/cm [4] to 6 × 10<sup>-3</sup> S/cm, thereby reducing the ohmic resistance by a factor of 200. This reduction allows the experimenter to more easily compensate for the ohmic drop. For fundamental studies of corrosion in organic liquids, the addition of a well-chosen supporting electrolyte is a reasonable approach to allow electrochemical information to be gathered. For more applied measurements, the addition should be carefully considered and comparison tests (e.g., coupon exposures) should be performed to verify the absence of an effect of the supporting electrolyte on the corrosion process. If a supporting electrolyte is not added, caution must be used in the gathering and interpretation of electrochemical data. In some cases, where a supporting electrolyte cannot be added and the solution resistance is very high, the performance of meaningful electrochemical measurements is extremely difficult.

Acids have often been used as supporting electrolytes [4]. Strong acids (e.g., H<sub>2</sub>SO<sub>4</sub>, HCl, HNO<sub>3</sub>) generally enhance the conductivity of organic solutions greatly. However, some organics are susceptible to degradation in acids. When water is present, acid hydrolysis becomes an additional degradation pathway [11]. Also, the acidity of the solution can have a controlling effect on the corrosion behavior of metals in organic solutions. For example, a recent review [3] of the

literature on the corrosion of metals in aprotic liquids has shown that corrosion behavior, and more specifically, the mechanisms of passivity, are affected by the acidity of the solution. The mechanisms of passivation were classified into four types: (1) air-formed film, (2) salt film, (3) chemisorption of the liquid, and (4) oxide/oxyhydroxide formation. Acidity is deleterious to all four passivation mechanisms in organic solutions. Hence, control of acidity is important. In addition to  $H^+$ , acidity also implies the presence of a corresponding anion. Its presence can alter material behavior by adsorbing to the surface in addition to increasing the solution conductivity. Thus, acids should not be considered as supporting electrolytes, since they influence the behavior observed, unless the service environment contains acids, in which case they should be included in the test solution. An additional passivation mechanism has been proposed by Shifler et al. involving the formation of a passive electropolymerized film (polymer films in which the polymerization process is electrochemically activated) on bare steel surfaces in dimethoxyethane(DME)/LiAsF<sub>6</sub> solutions at potentials above the oxidation potential of DME [12]. The complex electropolymerization mechanism for carbon steel in dimethoxyethane/propylene carbonate mixtures with LiAsF<sub>6</sub> as the supporting electrolyte is dependent on: (1) DME concentration, (2) cationic intermediate adsorbed concentration and degree of coverage, (3) LiAsF<sub>6</sub> concentration, (4) applied potential, (5) rate of iron cation dissolution, and (6) water concentration. Decreases in any of these factors will either decrease the rate of electropolymerization or may prevent electropolymerization entirely [13]. Numerous other investigators have also examined the role of electropolymerized films as a means of metal passivation in dioxolane [14,15], ether [16–19], pyrrole [20,21], and carbazoles/dicarbazoles with polyether chain substitution [22], and phenol [23]. For clarification purposes, Table 2 contains the physical data for many solvents commonly encountered. Table 2 is not intended to be a complete list, but rather to provide the reader with a sense of the range of physical properties of organic solvents.

The supporting electrolyte may also play an integral role in passivation processes. In supporting electrolytes, increasing the size of the counter-ions may lead to a decreased film mobility and polyvalent ions, acting as stronger acids, may enhance the formation of cross-links between chains and electrolyzed films [24]. It has also been observed that AsF<sub>6</sub><sup>-</sup>, added as a supporting electrolyte, can be an integral component of the polymerization process on iron [19] and carbon steel [12] in DME; the use of either tetrabutylammonium

FIG. 5—The effect of water content on the anodic polarization behavior of nickel in methanol containing 1 M H<sub>2</sub>SO<sub>4</sub> [29].

perchlorate (TBAP) or lithium perchlorate as supporting electrolytes leads to alloy breakdown around the solvent oxidation potential [25]. The oxidation of aluminum was found to be influenced by the nature of the passivation mechanisms in nonaqueous solutions, which depended on the kind of electrolyte salt [26].

The water concentration in the experimental testing solution should duplicate as accurately as possible the water concentration found in the actual service solution. This is because the concentration of water present in the testing environment affects material behavior and the solvating ability of the solution. The presence of water in minimal concentrations (0.1–0.5 mass %) in acidified protic organic liquid solutions leads to the passivation of several materials. For example, iron, stainless steel, and nickel exhibit this behavior in methanol [27–29], as shown in Fig. 5. Water concentrations outside this range generally lead to increased corrosion rates [28,29]. In neutral aprotic organic solutions, water in any concentration, except in high concentrations (i.e., 80 + mass %), tends to be deleterious. For example, iron and nickel in neutral dimethylsulfoxide were passive only when the water content was low (0.02 mass % for iron and 0.01 mass % for nickel) [30,31]. Iron in neutral propylene carbonate solutions exhibits similar behavior

TABLE 2—Some typical physical properties of selected solvents at 25°C.

Solvent	M.W. g/mole	Density g/cm <sup>3</sup>	Dielectric constant - $\epsilon$	Viscosity cP	Dipole moment (Debye)	Formula

FIG. 6—The effect of water content on the anodic polarization of iron in propylene carbonate at 25°C [33].

FIG. 7—The effect of water content on the anodic polarization of carbon steel in dimethoxyethane at 25°C [12].

[32,33], as shown in Fig. 6. For other materials and liquids, for example, molybdenum and chromium in methanol and dimethylformamide, and iron in acidified dimethylformamide, no clear dependence upon water content is observed [29,34]. Additionally, water can decrease the solvation ability of organic liquids, thus inhibiting the solvation of impurities and corrosion products. On the other hand, anhydrous ethers cannot form hydrogen bonds, but the small additions of water allow hydrogen bonds to form between the water hydrogen and the ether oxygen. Water added to dimethoxyethane (DME) increases the passive range of steel, as shown in Fig. 7, by several hundred millivolts [12] and of iron by contributing to hydrogen bonding or as a Lewis acid [35]. Thus, as stated above, water content needs to be closely monitored and controlled.

The pre-existence of a surface film can affect testing in organic solutions in several ways. In the absence of aggressive species, an air-formed film can be protective even under anodic polarization. Examples of this include iron in propylene carbonate [32,33] and ferritic stainless steel (Fe-18 %Cr) in methanol [36]. The presence of competing mechanisms may also contribute to breakdown of metals and alloys in multicomponent organic mixtures as observed for steel in PC/DME mixtures [37]. Propylene carbonate interferes with DME electropolymerization by solvating organic cations or cationic radical, or by contaminating the polymer to form pores that allow charge and ionic species to pass through. Adding water to PC-DME mixtures allows the possibility of aqueous passivating mechanisms that further complicate solvent interactions and competition [13]. However, even if aggressive species are present in the solution, the air-formed film may be protective until sufficient anodic polarization is achieved. This creates the need for a testing technique that permits removal of the film, enabling examination of the base metal. This can be accomplished by using a stylus to scratch the surface, thereby removing any pre-existing protective film to expose new metal. By monitoring the current over time, the corrosion behavior of the material in the absence of any pre-existing film can be observed. The long-term stability of air-formed oxides in organic solutions is not known, and thus, the corrosion processes that occur on bared surfaces may be the most relevant to the service conditions. In aqueous solution, cathodic polarization is often used to remove air-formed films. Extensive work in the literature on iron and ferrous alloys [38], as well as other materials [39], support the idea that this approach leads to an oxide-free surface. Such information does not exist for oxide reduction in organic liquids. However, many workers cathodically polarize their samples before performing electrochemical measurements [28,40-43].

Since the composition and purity of the organic liquid can strongly affect the corrosion process, a key feature to testing is the choice of an appropriate experimental testing solution. This solution should be as close in composition and impurity concentrations to the service solution as possible, unless accelerated testing is desired. The composition of organic liquids can influence the corrosion rate. For example, the corrosion rate of iron in monocarboxylic acids of different chain lengths was studied and showed that as the chain length increased, the corrosion rate decreased [2]. Often, organic liquids contain impurities such as water, acids, and metal ions. While these impurities generally have low concentrations in commercially purchased organic liquids, these concentrations could still be significant. For example, nickel in dimethylsulfoxide was only passive when the water concentration was below 100 ppm. Therefore, the testing solution may need to be purified such that the experimental testing solution closely matches the service solution. On the other hand, some corrosion problems develop due to the presence of impurities, so that an initially pure liquid may need to have impurities added to mimic the attack observed. Additionally, if accelerated testing is desired, care should be taken to ensure that the corrosion mechanisms and the location of the corrosion attack (e.g., vapor phase, immersed phase, etc.) accurately mimic in-service observations.

In most organic solutions, the nature of the cathodic process is unclear. In aqueous solutions, water reduction is the most common cathodic reaction, with the reduction of dissolved oxygen also being very important. However, the electrochemical reduction of many organics is very sluggish, and usually poorly characterized. Often, the reduction of residual water is assumed to be the predominant cathodic reaction. The role of molecular oxygen on the corrosion process in organic solutions has not been characterized. However, its solubility is nearly ten times higher in methanol than in water [2,44], making it a potentially much more influential oxidant. Additionally, aliphatic ethers are slowly converted to unstable peroxides when in contact with oxygen or air, leading to an unsafe condition that could induce a violent explosion during distillations [11]. Deaeration by the passage of an inert gas through the solution must be performed with care to avoid the selective evaporation of the liquid. For low boiling point liquids such as methanol, this is of particular importance. For high boiling point liquids such as propylene carbonate, the passage of ultrahigh-purity nitrogen through the solution for extended times can be used to selectively evaporate the water, leading to higher purity solutions, even after the addition of electrolytic salts [33]. The study of solution electrochemistry on platinum can often give insight into the nature of the cathodic as well as anodic reactions.

Temperature affects corrosion testing in organic liquids in that the reaction rates, charge transport diffusional coefficient, and rate of liquid evaporation are increased and the potential for ignition or explosion is greater. The effect of temperature on reaction kinetics, in general, follows the same principles that hold true for other heterogeneous chemical reactions [2]. Corrosion rates of iron in monocarboxylic acids increase by a factor of 8 to 20 by increasing the temperature from 25 to 80°C. While this behavior is not unique to organic liquids, it is important to realize that deviations in testing temperature compared to service temperature could lead to erroneous conclusions. Elevated temperatures may also lead to alternative reaction pathways, leading to other organic intermediate species. Temperature may result in hysteresis in macroscopic polymer properties such as swelling, elasticity, and turbidity [24]. If testing at elevated temperatures is called for, caution and appropriate safety preparations are needed.

## LABORATORY TESTING

Laboratory testing can be of two types: coupon testing and electrochemical testing. This section discusses the special considerations for each type of testing when organic liquids are involved.

### Coupon Testing

Exposure of coupons to the solution of interest with post-test evaluation according to accepted standards, such as ASTM G 31, Practice for Laboratory Immersion Corrosion Testing of Metals, is the most directly applicable method of testing in organic liquids. Because of the general lack of data on corrosion in organic liquids, coupon testing often

takes on additional importance. While standard test practices have been developed mostly for aqueous solutions, the protocols are essentially independent of the chemical nature of the environment, with minor exceptions. More detailed information on laboratory coupon testing can be found in the relevant chapter of this manual, as well as in ASTM G 31. One of the most important caveats for such testing in organic solutions is the need to check that the materials that make up the test apparatus are not affected by the liquid. Many nonmetallics are degraded by or preferentially absorb organic liquids, leading to dimensional and mechanical property changes. If such materials are used as spacers in a coupon exposure rack, unexpected experimental variability can result. For example, the nonmetallics may act as getters for aggressive species, produce aggressive species that would not normally be present, or produce inhibiting agents that bias the results. Compounds that have been used as mounting materials successfully in aqueous solution often do not perform well in either completely organic solutions or in mixed organic/aqueous solutions. Thus, a first step in coupon testing is careful selection of the exposure rack and spacer materials. Often, information of this sort is available from the material manufacturer. For example, many nonmetallics have been tested for weight loss/gain and mechanical properties after exposure to a range of different types of organics (e.g., alcohols, aliphatics, aromatics, etc.) at ambient and elevated temperature. While these data can provide general guidance, accelerated tests in the environment of interest may often be warranted.

A second important aspect of laboratory coupon testing in organics is the possibility of an evolution of the solution composition during the test. These changes can be severe, especially at elevated temperatures used to accelerate the corrosion process. Elevated temperature will also accelerate many organic liquid degradation processes, including oxidation by ultraviolet (UV) light. This can be severe in some instances. Thus, it is important to run solution blanks simultaneously. In these tests, no coupon is added to the solution under test, so its composition can be checked both before and after the testing to see if any significant changes in composition have occurred. Degradation reactions for many organics are well studied and available in the organic chemistry literature. This allows an identification of the by-products expected. Analysis of solutions after the exposure will allow a quantitative measurement of the degradation rate of the liquid in the absence of any interaction with the corroding materials. Comparison of the results with analyses of the liquid exposed to metal coupons may also give insight into the nature of the cathodic reaction that occurs.

Water ingress during coupon testing must also be monitored if it is suspected that water concentrations are important in the system under study. During testing, seals can develop minute leaks, allowing water levels to increase. Constant purging with an inert gas is an option if the boiling point of the solution is high. For many organics, this is the case. For example, the boiling point of propylene carbonate is over 200°C. However, for low boiling point liquids, such as methanol (b.p. = 64.9°C), constant purging will drive off liquid, increasing the concentration of the dissolved, nonvolatile species with time [45].

## Electrochemical Testing

For the most part, electrochemical testing in organic solutions is no different than such testing in aqueous solutions. The same experimental arrangements are used, and the appropriate standards, such as ASTM G 5, G 59, and G 61, are still applicable (see section titled Relevant ASTM Standards in this chapter). The chapter in this manual that describes electrochemical testing [4] should be consulted for other information on that subject. This section will focus on the special considerations in electrochemical testing in organic solutions.

The most central difficulty in electrochemical testing of materials in organics is the choice of a suitable reference electrode. Aqueous reference electrodes, such as saturated calomel (SCE), have been widely used in such studies, [28,34,36,40,43,45,46], but can suffer from three types of problems. Since these reference electrodes are in contact with the test solution, water can diffuse from the reference electrode into the test solution, thereby changing the concentration of water during the test. The organic liquid will also diffuse into the reference electrode, and may foul the interface, leading to irreversible changes in its potential. Such a change cannot be detected easily, as it would be superimposed on any change in the potential of the working electrode. A second difficulty with using aqueous reference electrodes is the development of a liquid junction potential. This potential develops at the interface of the aqueous solution and the nonaqueous solution due to the large difference in composition. Such potentials are extremely difficult to measure or calculate and vary with time due to the interdiffusion of the two solutions. The third possible difficulty that may be encountered is reference electrode plugging. This is particularly troublesome when potassium chloride-based reference electrodes are used in perchlorate solutions. As the potassium diffuses out of the reference electrode, precipitation of  $\text{KClO}_4$  may occur.

Some literature exists on organic liquid-based reference electrodes that have been successfully used in electrochemical studies [47–49]. These include the  $\text{Ag}/\text{AgClO}_4$  (propylene carbonate) [47],  $\text{Ag}/\text{AgCl}$  (methanol) [48], and numerous others, as detailed in Ref 49. The  $\text{Ag}/\text{AgClO}_4$  (propylene carbonate) reference electrode developed by Kirowa-Eisner and Gileadi [47] is easy to prepare, stable over time, highly reproducible, and easily stored. This electrode has been used successfully in conducting electrochemical experiments in propylene carbonate solutions. Similarly, the  $\text{Ag}/\text{AgCl}$  (methanol) reference electrode developed by Brossia and Kelly [48] has similar characteristics and has been successfully employed in electrochemical experiments conducted in methanolic solutions. Using a reference electrode where the electrolyte is based upon the testing solution will minimize contamination of the testing solution, and fouling of the reference electrode and the liquid junction potential.

Another aspect of electrochemical testing in organic solutions is the isolation of the counter-electrode from the working electrode. In aqueous solutions this is often ignored, since the predominant reactions at the counter-electrode are either oxygen evolution (producing  $\text{H}^+$ ) or hydrogen evolution (producing  $\text{OH}^-$ ) during cathodic and anodic polarization of the working electrode, respectively.

Especially in a buffered solution, these reaction products have little effect. However, in an organic solution, the products of the reactions at the counter-electrode are often more complex, and usually unknown. Thus, it is usually good practice to isolate the counter-electrode from the working electrode with porous frits. This will minimize, though not eliminate, any effects of those reaction products.

- G 61 Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron, Nickel, or Cobalt-based Alloys

## FIELD TESTING

The approach to field studies of corrosion in organic liquids is no different than that used for aqueous corrosion. The choice of coupon size, rack design, test length, and other variables is more strongly influenced by the goals of the testing than by the testing medium. Safety concerns must also be addressed. Different organic liquids have different properties and safety issues, and appropriate references and experts should be consulted. More guidance on the general topic of field testing can be found in the relevant chapter in this manual and in ASTM G 4, Standard Guide for Conducting Corrosion Tests in Field Applications. However, the concerns expressed in the section above on laboratory coupon testing with regard to the effects of the organic liquid on the nonmetallic components of the mounting hardware should be considered.

Since the corrosion behavior of materials in organic liquids can be influenced by low levels of water, minimizing the introduction of water from the ambient atmosphere during the introduction of samples or probes should be carefully considered. For long-term testing at sites where there is a constant turnover of solution, these effects may be small for a one-time insertion of coupons. However, if, for example, a retractable electrochemical probe is used, the solution with which it comes into contact should be flushed in order to allow it to sample the most relevant environment.

In all field testing, the effects of variability in the composition of the stream being studied on the corrosion processes must be considered. Since small changes in the composition in organic solutions can have dramatic effects on the corrosion rate as well as the stability of passive films,

large transients in corrosion rate may be experienced. Thus, it is important to complement the corrosion measurements with solution composition measurements in order to develop an understanding of the role of stream composition on the corrosion behavior. Besides ionic composition, water concentrations and the level of liquid by-products should be monitored.

## SUMMARY

Corrosion testing in organic liquids has taken on greater importance in recent years due to the increase in the use of nonaqueous and mixed liquids in material and chemical synthesis as well as energy production. While the basic types of corrosion processes are similar in both aqueous and organic liquid environments, special attention must be given to the direct application of testing tools to organic testing due to the complexity of organic systems. The wide variety of organic liquids and mixtures increases the number of experimental variables that need to be considered and controlled.

# Molten Salts

*F. S. Pettit<sup>1</sup>*

MOLTEN SALT INDUCED CORROSION may be encountered whenever molten salts contact metallic or ceramic surfaces at elevated temperatures. There are numerous industrial processes in which such conditions can develop. For example, during combustion, deposits such as  $\text{Na}_2\text{SO}_4$  can accumulate on hardware and cause corrosion. The combustion may occur, for example, in gas turbines, incinerators, or in diesel engines. The conditions are such that the deposits form as a thin ( $\sim 1 \mu\text{m}$ ) liquid layer separating the alloy from the gas phase. There are also other industrial processes, such as molten carbonate fuel cells, where molten salts are held in metallic or ceramic containers at elevated temperatures. The molten salts can corrode the container materials, but the conditions differ from the combustion environments because the amount of salt is very large with much larger diffusion distances between the gas phase and the container material. Because of the complexity of the environments, no tests have been developed that find general acceptance. In this section, testing in molten salts present as thin layers and as deep melts will be discussed, using illustrative examples to show some of the tests that have been developed.

## SELECTION OF TEST CONDITIONS

Test conditions should be the same as the application under consideration. Unfortunately, the application conditions are often not precisely known, and even when known, can be extremely difficult to establish as a controlled test. Moreover, true simulation testing is usually impractical because we want the material to perform for much longer times than we are willing and able to test. The answer to this problem is accelerated, simulation testing.

Accelerated, simulation testing requires knowledge of microstructure and morphological changes of the exposed material. All materials used in engineering applications exhibit a microstructural evolution, beginning during fabrication and ending upon termination of their useful lives. In an accelerated test, we must select test conditions that cause the microstructures to develop that are representative of the application, but in a much shorter time period. In order to use this approach some knowledge of the degradation process is necessary.

In selecting the conditions for molten salt corrosion testing, the application must be considered, but it is also useful to have some knowledge of the degradation process, especially the microstructural and morphological changes that occur. When metallic alloys or ceramics are exposed to molten salts at elevated temperatures, the reactions that occur depend upon a number of factors that include: the composition of the molten salt; the amount of molten salt, especially its thickness or depth; alloy or ceramic composition; gas composition over the molten salt; and temperature including thermal cycles. Some examples of molten salt corrosion are useful to illustrate factors relevant to accelerated, simulation testing. In some cases of molten salt corrosion, the alloy or ceramic would react with components in the gas phase had the molten salt not been present, and it is necessary to consider how the molten salt affects such reactions. If the molten salt is very thin and the corrosion products are insoluble in the molten deposit, the reactants from the gas can diffuse through the deposit to react with the alloy or ceramic. For example, in the case of  $\text{Na}_2\text{SO}_4$  on a Ni-30Cr-6Al (wt%) alloy [1] in oxygen at  $1000^\circ\text{C}$ , a continuous layer of alumina is formed on the alloy separating it from the molten deposit during isothermal oxidation. However, during cyclic oxidation, the alumina scale cracks and spalls, and eventually sulfides are formed in the alloy, which cause much more rapid oxidation. The gas phase usually does not play as important a role if the molten deposit is so thick that diffusion of reactants from the gas is negligible. When pure nickel is immersed in a crucible containing  $\text{Na}_2\text{SO}_4$  at  $1000^\circ\text{C}$  in air, the reaction involves sulfur and some oxygen from the  $\text{Na}_2\text{SO}_4$  with the nickel [2]. There is little influence from the gas environment. In all cases, the important point is how the molten salt affects the protectiveness of the corrosion products.

## SOME ILLUSTRATIVE TESTS

The European Federation of Corrosion has begun to attempt to develop standards for high temperature corrosion testing [3], including the case of molten salt deposits [4]. Some progress has been made but they have concluded more work is necessary. For the case of deposit-induced corrosion, Saunders [4] has shown that there are a number of key parameters that control the corrosion rate. Some of these factors have been mentioned previously in the present paper, but will be presented again, along with some of Saunders' remarks.

<sup>1</sup>Materials Science and Engineering Department, University of Pittsburgh, Pittsburgh, PA 15261.

**Deposit Composition:** The deposit should be present as a solid or liquid phase because direct reaction between this deposit and the material being tested plays an important role in the corrosion process.

**Deposit Structure:** Solid deposits can contain porosity that may affect the corrosion process, and consequently, good simulation of the pore structure may be necessary.

**Deposition Rate:** In most processes deposition takes place more or less continuously. The deposition rate plays a critical role in determining the corrosion rate and should be simulated.

**Aerodynamics/Gas Velocity:** Deposition is affected by gas flow over the component. At high velocities, depending upon the size of the deposit, erosion may occur. Deposition will also be affected by the shape of the component.

**Gas Atmosphere Control:** The gas atmosphere can affect the nature of the deposit. In some equipment the gas atmosphere can be cyclic with fluctuations in the oxidizing potential. Such fluctuations must be incorporated into the test.

**Gas and Metal Temperatures:** Generally these are different, and consequently, temperature gradients can exist across the deposits.

**Catalytic Effects:** Deposition is affected by the condition of the surface and the time that deposit particles are in contact with one another on the component surface. Whether the component surface provides catalytic activity may be questioned, but relevant surface preparation procedures must be used.

**Time:** The corrosion process may go through different stages with time, and it is important to account for such conditions in the design of the experiment.

**Thermal Cycles:** Most hardware is subjected to thermal cycles in use, and such cycling can exert profound effects on protectiveness of the corrosion products. The test must simulate thermal cycles.

In discussing molten salt corrosion tests, the task is to develop guidelines that may be used to develop tests for various situations. Since no standardized tests for molten salt-induced corrosion are available, the tests to be described are presented by way of example. Tests for other situations could, in principle, be devised by following procedures used in these examples. It is also important to emphasize that this chapter is not concerned with the various mechanisms for molten salt corrosion, but only the conditions that cause attack.

## Metals and Alloys

In discussing molten salt tests, it is useful to consider first thin deposits where diffusion through the deposit of reactants from the gas plays a significant role in the corrosion process, and thick deposits where such diffusion is less important and sometimes negligible.

### Thin Molten Salt Deposits

Thin molten deposits of  $\text{Na}_2\text{SO}_4$  are formed on alloys used in gas turbines. Depending upon conditions, different types of hot corrosion attack can occur. High-temperature hot corrosion is observed during operation of gas turbines when deposits of  $\text{Na}_2\text{SO}_4$  accumulate on alloys at temperatures above

FIG. 1—Diagram of burner rig used to test alloys for high-temperature hot corrosion.

about  $800^\circ\text{C}$ . Nonprotective reaction products are developed because sulfides are formed in the alloys and also because some oxides dissolve in the molten deposit via basic fluxing reactions [2,5–8]. Low-temperature hot corrosion occurs at temperatures below about  $800^\circ\text{C}$ , where the accelerated attack involves dissolution of oxides in the molten deposits via acidic fluxing reactions [2,5–8]. Still another form of hot corrosion occurs when elements from the alloys enter the molten deposit and cause self-sustaining hot corrosion [1]. Each of these types of hot corrosion have distinctive microstructural features. Three types of tests have been used to examine alloys for resistance to these types of hot corrosion attack.

**Simulation Burner Rigs**—In the gas turbine industry, burner rigs have been developed to rank materials. The designs may

FIG. 2—Weight change data and degradation microstructures for alloys tested in a burner rig and a laboratory cyclic hot corrosion test. The microstructures after 70 h in the burner rig (left) are similar to those of the laboratory test after 12 h exposure (right).

FIG. 3—Diagram of ducted burner rig used in low-temperature hot corrosion tests.

vary [9–13], but as shown in Fig. 1 the essential features are a combustion chamber, a means to ingest the salt, and a specimen holder that is rotated and often periodically removed from the hot gas stream to induce thermal stresses. The specimens are usually bars about 10–11 cm in length and about 1 cm in diameter. In the burner rig tests the specimens are periodically removed from the test to measure weight changes, or thicknesses, and to be examined visually. Upon conclusion of the tests the specimens are sectioned, metallographically prepared, and examined using optical metallography and scanning electron microscopy. Some typical weight changes and degradation microstructures are presented in Fig. 2 for the high-temperature hot corrosion of a Ni-25Cr-6Al alloy. The degradation microstructure contains a sulfide phase accompanied by oxidation, which is typical of high-temperature hot corrosion attack.

Burner rigs were initially developed to rank alloys for hot corrosion resistance in aircraft gas turbines. The various types of rigs and the important operating parameters are described in detail in Refs 14 and 15. When gas turbines began to be used on ships, hot corrosion with different microstructural features was observed. In order to duplicate such degradational microstructures, the burner rigs had to be ducted and operated at lower temperatures to establish the  $\text{SO}_3$  pressures in the gas necessary to produce low-temperature hot corrosion [16]. A schematic of a ducted burner rig is presented in Fig. 3, and the microstructural features typical of low-temperature hot corrosion are presented in Fig. 4.

The important feature of the burner rig approach to testing is simulation; for example, high gas velocities and hot gases with continuous deposition of molten salts as occurs in gas turbines. Very often, the exact conditions in the simulation test are not known. For example, some of the conditions established by the burner rigs were not known for 20 to 30 years after their inception [17]. The conditions are always more severe than in the application of interest, because the purpose is to accelerate failure. These types of tests are effective in ranking alloys for use in the application for which the simulation test was designed. It is also important to note that testing in burner rigs is expensive. Furthermore, the construction and operation of burner rigs requires experienced designers and operators.

*Controlled Laboratory Testing*—Hot corrosion testing has also been performed using conditions much different than those typical of gas turbine engines. For example, tube furnaces have been used with controlled compositions of flowing gases where the salt is deposited intermittently at specified times. In this type of testing the conditions are well defined and precisely controlled, but they are far removed from the environment of the gas turbine. The testing conditions must be varied until degradation microstructures are obtained representative of those observed in service. A laboratory test used for high-temperature hot corrosion testing consists of cyclic oxidation using periodic applications of  $\text{Na}_2\text{SO}_4$ . The alloy specimens can be small coupons (1 cm by 1 cm by 0.1 cm). The  $\text{Na}_2\text{SO}_4$  is applied at predetermined intervals (e.g., every 20 h or 100 h). The specimens are cycled from the test temperature to room temperature every hour. The gas can be air, oxygen, or oxygen with about 1 wt %  $\text{SO}_2$ . The specimens are weighed and visually examined at selected times. Based upon weight changes and visual examination, the specimens are removed from the test when degradation has

FIG. 4—Scanning micrographs showing low-temperature hot corrosion degradation microstructure after 4800 h of gas turbine marine service (upper micrographs) and after 17 h at 700°C in a laboratory low-temperature hot corrosion test (lower micrographs).

FIG. 5—Weight change versus time data obtained for high-temperature hot corrosion testing of specimens in a laboratory cyclic apparatus. Large weight increases or weight losses indicate failure.

progressed to failure limits. Typical results are presented in Fig. 2. The weight changes are different from the burner rigs, but the microstructures are virtually identical. In the laboratory cyclic test, the weight changes must be correlated with the amount of hot corrosion attack. In the case of the Ni-25Cr-6Al alloy for which the data are presented in Fig. 2, a protective  $\text{Al}_2\text{O}_3$  scale is developed initially, and the weight changes are small. As the testing is continued, the  $\text{Al}_2\text{O}_3$  cracks and spalls and eventually sulfides are formed that result in more rapid oxidation. This phase of the attack corresponds to the large weight losses evident in Fig. 2. Cyclic hot corrosion test results are presented for a number of alloys in Fig. 5. Abrupt changes in weight indicate a change in the corrosion mechanism and indicate failure is imminent. Usually this type of test results in large weight losses as the products spall from the surfaces of the specimens, but if spalling does not occur, large weight gains can be observed. The results presented in Fig. 5 show that the CoCrAl alloys have better high-temperature hot corrosion resistance than the NiCrAl alloys, which is consistent with burner rig test results. Various versions of these type of tests have been used by numerous investigators [1,2,5,8].

For low-temperature hot corrosion, the conditions must be altered to produce the appropriate microstructures [8,16]. The temperature must be lowered to 650–750°C, and most importantly an oxygen- $\text{SO}_2$  gas must be used. This gas must be passed over a platinum catalyst to ensure equilibrium conditions whereby  $\text{SO}_3$  pressures between  $10^{-3}$  to  $10^{-5}$  atm (101.3–1.013 Pa) are established. Deposits of  $\text{Na}_2\text{SO}_4$  are applied periodically. The tests may be isothermal or cyclic. For such conditions, degradation microstructures shown in Fig. 4 are developed that are very similar to degradation observed in service.

Most superalloys contain some refractory elements such as molybdenum and tungsten. When the oxides of these elements accumulate in molten deposits, very severe hot corrosion attack can occur. The degradation is characterized by an incubation period during which the attack is not severe, followed by much more rapid attack as the refractory metal oxide in the molten deposit reaches a level to produce catastrophic degradation. Microstructures typical

of this type of attack can be produced in both burner rigs and in a laboratory cyclic oxidation test with  $\text{Na}_2\text{SO}_4$  deposits [1]. It is important to emphasize that the incubation time prior to the onset of catastrophic attack is much longer in a burner rig than in the laboratory cyclic oxidation test. This occurs because some of the refractory metal oxides are removed from the molten deposits by the high gas velocities in the burner rig, and longer times are required for the refractory metal oxides to reach the critical level required for hot corrosion attack. In Fig. 6, data are presented to show that the incubation period prior to the onset of hot corrosion attack is increased in a flowing gas compared to static conditions.

**Immersion Test**—Immersion tests involve placing coupons in deep melts. This type of test is usually used for deep melts. Some investigators have attempted to use electrochemical techniques to measure corrosion kinetics. These techniques will be discussed in the following section on deep melts. The results from immersion tests must be used

FIG. 6—Weight change versus time measurements for the isothermal hot corrosion of a Ni-8Cr-6Al-6Mo alloy in static air and in oxygen having a linear flow rate of 31 cm/s.

FIG. 7—Weight changes versus time data for the hot corrosion attack of Ni-8Cr-6Al specimens with different amounts of  $\text{Na}_2\text{SO}_4$ . The amount of degradation increases as the amount of deposit is increased.

FIG. 8—Surface and microstructural features developed for Ni-8Cr-6Al-6Mo specimens after exposure at 1000°C in air to (a) thin ( $\sim 5 \mu\text{m}$ , 7 min exposure) and (b) thick (1 cm, 4 min exposure) melts of  $\text{Na}_2\text{SO}_4$ . Attack with the thin deposit was evident visually after less than 1 min and usually spread laterally over the surface from the point of initiation. The specimen in the thick melt showed no attack after 4 min.

with great care when applied to cases where the molten salts are present as thin layers in practice. For example, as shown in Fig. 7, the hot corrosion attack of a Ni-8Cr-6Al alloy becomes more severe in an immersion test, but the hot corrosion of a Ni-8Cr-6Al-6Mo is less (Fig. 8). In the case of the latter alloy, the attack is more severe with the thin layer of molten salt, because the degradation process involves the

accumulation of  $\text{MoO}_3$  in the molten salt, and a critical level is reached sooner with a smaller amount of deposit.

### Thick Molten Salt Deposits

Tests for corrosion of alloys in deep melts should involve primarily immersion tests. The procedures to be followed in using immersion or crucible tests are similar to those used for thin deposits; namely, exposure of specimens with weight change versus time measurements and metallographic examination of the exposed specimens.

Electrochemical techniques have been used by a number of investigators to determine the corrosion resistance of alloys [18–24] and also to investigate the properties of salt mixtures [25–28]. When attempting to measure the corrosion resistance of alloys, the molten salt is used as the electrolyte with the alloy as the working electrode of the cell. A typical cell used by Kim and Devereux [23] to investigate the corrosion of alloys in molten  $\text{Na}_2\text{CO}_3$  is described schematically in Fig. 9. By using a reference electrode and auxiliary electrodes, electrochemical voltages and currents are measured and the results are interpreted by using principles and concepts applicable to aqueous corrosion [29]. Rahmel and coworkers [19,20,24] have used electrochemical cells to investigate the hot corrosion of superalloys in sulfate melts at temperatures of 800 and 900°C. They observed a strong dependence of corrosion behavior on the cell potential and showed that positive potentials established acidic conditions in the sulfate melts, whereas basic conditions were developed with negative potentials. In Fig. 10, data are presented for some superalloys exposed to a  $(\text{NaK})_2\text{SO}_4$  melt at 900°C where the depths of attack, measured metallographically after 100 h of exposure, are presented as a function of electrode potential. The potential range over which negligible attack occurred was used to compare the resistance of alloys to attack by this molten salt. Hence, the hot corrosion resistance was concluded to increase in the order IN-738 < IN-657 < IN-939, IN-597. These investigators also used current versus time measurements to detect the breakdown of protective scales on some of the alloys studied. Shores [18] has used electrochemical techniques to determine corrosion currents for a number of nickel- and cobalt-base alloys exposed to fused  $\text{Na}_2\text{SO}_4$  and showed that the corrosion currents could be related to the depths of attack of these alloys in a burner rig.

Electrochemical cells can also be used to attempt to obtain data on the mechanisms of the salt-induced corrosion processes. Cyclic voltammetry has been used [18–22] to obtain information on the oxidation and reduction reactions that may occur during molten salt corrosion. Chronopotentiometric investigations with platinum as the working electrode in cells can also be used to determine and control the compositions of molten salts, as well as to measure the solubilities of various oxidation products in melts [25–28,30].

Electrochemical techniques are difficult to use for thin deposits. Otsuka and Rapp [31], however, have constructed a cell that uses thin deposits of  $\text{Na}_2\text{SO}_4$  and have obtained results consistent with the  $\text{Na}_2\text{SO}_4$ -induced hot corrosion of nickel [2].

### Ceramics

The testing of ceramics in molten salts is similar to that for metals and metallic alloys. This is especially the case for

FIG. 9—Schematic diagram of a polarization cell used to investigate the corrosion of materials in molten salts.

FIG. 10—Results obtained in an electrochemical test at 900°C to compare the hot corrosion of some superalloys.

FIG. 11—Schematic diagram showing an apparatus to test coupons in gases containing SO<sub>3</sub> and vanadium oxides.

monoxide ceramics such as SiC and Si<sub>3</sub>N<sub>4</sub>, where resistance to degradation derives from the formation of silica scales. In the case of oxide ceramics, the testing techniques used for metallic alloys have been used with good results, but testing using immersion in deep melts has also been used to good advantage. Since ceramics are often not good electronic conductors, testing with electrochemical cells has been confined to investigations concerned with the solubilities of oxides in melts.

In Fig. 11, a laboratory apparatus to test coupons of metallic alloys and ceramics is presented. The coupons are coated periodically with thin deposits of Na<sub>2</sub>SO<sub>4</sub> or a Na<sub>2</sub>SO<sub>4</sub>-NaVO<sub>3</sub> mixture, and the gas composition is controlled to maintain the stability of the deposit [32]. The specimens are removed at selected time intervals to examine the corrosion. Typical results obtained for Al<sub>2</sub>O<sub>3</sub> [32,33] are presented in Figs. 12 and 13, showing a porous zone that developed in accordance with a parabolic rate.

FIG. 12—Photomicrograph showing porous zone that developed in alumina specimen after 46 h at 700°C with a deposit of Na<sub>2</sub>SO<sub>4</sub> containing 20 mol % NaVO<sub>3</sub>.

FIG. 13—Depths of corrosion front penetration for alumina exposed to various deposits in gases containing oxygen, SO<sub>2</sub> and SO<sub>3</sub>.

FIG. 14—Schematic of apparatus used to test ceramics in deep melts of molten salts.

The effects of deep melts on the dissolution of solid oxides have been studied by numerous investigators [34,35]. Dissolution studies of oxides are often performed using a rotating disk apparatus shown in Fig. 14 [35]. This apparatus can be used to measure the rates of corrosion under well-defined fluid dynamic conditions. After exposure, the specimens are examined by using optical metallography and scanning electron microscopy (SEM). The rates of corrosion can be determined by thickness measurements and by weight change measurements.

## CONCLUDING REMARKS

Standardized tests using molten salts are not available. In order to develop tests for the molten salt corrosion of materials, hardware should be obtained after service in the application of interest. The microstructures and surface morphologies of this hardware should be characterized in detail using optical metallography, X-ray diffraction (XRD), SEM, and other surface analytical techniques as required. The test must then be designed to duplicate the degradation microstructures documented in the service hardware. A wide range of tests is possible and extends from simulation of the presumed exposure conditions to conditions far removed from the actual exposure conditions.

# Liquid Metals

Chris Bagnall,<sup>1</sup> Peter F. Tortorelli,<sup>2</sup> Steven J. Pawel,<sup>2</sup>  
Jack H. DeVan,<sup>3</sup> and Steven L. Schrock<sup>4</sup>

## DESCRIPTION OF ENVIRONMENT

THIS SECTION ADDRESSES the design, control, and interpretation of corrosion tests conducted in liquid metals. The emphasis in this chapter is placed on techniques that should be employed for determining the suitability of metals and alloys for liquid metal containment. Because one of the most important applications of liquid metal is for heat transfer, or thermal management within an engineered system, a focus will be placed on methods for study and measurement of corrosion in a circulating system in which there is a temperature gradient. Metals and alloys with relatively low melting points and high thermal conductivities are commonly used for these applications. A range of heat capacities and boiling points then permits specific selection for a variety of applications; for example, a lead system for applications below 500°C, sodium for operation up to 700°C, and lithium up to about 1300°C. The properties of potassium make it suitable for use as a working fluid in a two-phase Rankine cycle. In each case, however, the combination of liquid metal and candidate containment material requires careful evaluation before a final selection is made.

The environmental boundaries of a liquid metal system are set by the containment material. This material may experience other types of corrosion on the exterior surface (of pipe or tubing for example), but it isolates the liquid metal from interaction with any external atmosphere. This specification of "contained and isolated" sets the limits for the liquid metal corrosion system. Other more general areas of liquid metal/metal interaction, such as that produced when, for example, liquid steel or aluminum come into contact with materials employed in their production, are excluded by this definition. Liquid metal embrittlement will not be addressed. Information on this topic can be found elsewhere [1–3].

## UNIQUE ASPECTS

The approach to testing in liquid metals involves design of the test system, design and placement of samples, the control and monitoring of test conditions, the assurance of

wetting, and the measurement and evaluation of corrosion damage. One unique aspect is that liquid metals are excellent conductors, and hence electrochemical techniques cannot be employed to determine rates. Another important issue is that the containment material has its own effect on test results in systems in which dissimilar metals or alloys are involved. The chemical balance between dissolution and deposition is strongly influenced by all materials (i.e., containment and test coupons) exposed to the circulating liquid metal. Relative surface areas of different metals and alloys and surface:liquid metal volume ratios are important points to consider when designing small-scale tests for corrosion trends in a large multicomponent heat transport system. In general, materials with large compositional differences should not be exposed together to determine relative corrosion behavior.

The chemical activities of individual species in the system and the "corrosion potential" of the liquid metal are important factors in understanding the corrosion process. Reactions are complex; they involve the following phenomena:

- Dissolution—in its simplest form, or through compound or complex formation with one or more impurity elements in the liquid metal.
- Diffusion in the solid and liquid states—supply of dissolving or dissolved species to the liquid/solid interface.
- Influence of activity and temperature gradients.
- Mass transport by the liquid metal, even when elemental concentration gradients are at the lowest levels of detection.
- Influence of impurities in the liquid metal and the containment material.
- Influence of operating parameters, system geometry, and thermomechanical condition of the exposed materials.

The simplest corrosion reaction that can occur in a liquid metal environment is direct dissolution: the release of atoms from the containment (or test coupons) into the liquid metal, driven solely by solubility relationships, and independent of impurity elements. The solution reaction is governed by the rate controlling step in the dissolution reaction. The net rate,  $J$ , at which an elemental species can enter solution may be described by the expression

$$J = k(C - c) \quad (1)$$

where  $k$  is the solution rate constant for the rate controlling step,  $C$  is the solubility of the particular element in the liquid metal, and  $c$  is the actual instantaneous concentration of

<sup>4</sup> Oak Ridge National Laboratory, retired.

the element in the liquid metal. Under isothermal conditions, the rate of dissolution would decrease with time as  $c$  increases. After a period of time, the actual elemental concentration becomes equal to the solubility, and the dissolution rate is then zero. Therefore, in view of Eq 1, corrosion by the direct dissolution process can be minimized by selecting a containment material whose elements have low solubilities in the liquid metal of interest and/or by saturating the liquid metal before actual exposure. Measurements of weight changes as a function of time for a fixed  $C - c$  (see discussion below) yield the kinetic information necessary for determination of the rate-controlling mechanism.

Corrosion resulting from dissolution in a nonisothermal liquid-metal system is more complicated than the isothermal case. Although Eq 1 can be used to describe the net rate at any particular temperature, the movement of liquid—for example, due to thermal gradient or forced circulation—tends to make  $c$  the same around the liquid-metal system. Therefore, at temperatures where  $C > c$ , dissolution of an element into the liquid metal will occur. But at lower temperatures in the circuit, where  $C < c$ , a fraction of the particular element, dependent on nucleation kinetics and system variables, will tend to come out of solution and be deposited on the containment material in systems where wetting occurs. A schematic of such a mass transfer process is shown in Fig. 1. If net dissolution or deposition is measured by weight changes, a mass transfer profile such as the one shown in Fig. 2 can be established. There are exceptions to such behavior, however. For example, the movement of carbon in a  $\Delta T$  stainless steel/sodium system is found to be counter to the activity gradient (i.e., cold-to-hot) due to the overriding effect of liquid metal transport, even though concentration differences (in the liquid metal) are in the ppb–ppm range. Or, maximum corrosion in a two-phase potassium system is not found in the region of boiling (liquid-to-vapor), but in the area of condensation where the (liquid) metal is in its purest state and its corrosion potential is greatest. Liquid metal corrosion studies have led to

FIG. 2—Mass transfer as characterized by the weight changes of type 316 stainless steel coupons exposed around a nonisothermal liquid lithium type 316 stainless steel circuit for 9000 h [93]. (Reprinted with permission from Elsevier Science, New York, NY.)

considerable understanding of the mechanisms involved and the reader is referred to the selected bibliography for additional insight into specific systems [4–16]. Careful design of corrosion experiments and experimental apparatus is essential to eliminate unwanted, unexpected, or unpredictable results.

Liquid metal corrosion is also unique in the degree of selectivity with which certain constituents of a metal sample may be attacked. In aqueous or atmospheric corrosion, it is not uncommon for one phase or metal constituent in an alloy to be preferentially attacked. However, in liquid metals, the ability to remove interstitial elements from depths more than an order of magnitude greater than the surface damage can impart major degradation to mechanical strength, and may, under severe conditions, result in a breach of the containment. Furthermore, the design of most heat transfer systems involves narrow pathways for liquid metal flow, so that the useful life of a system may be as dependent on deposition phenomena as on corrosion. Corrosion deposits may increase pressure drops through an increase in surface roughness as well as restriction of the flow channel(s), and therefore place greater demand on pumping power and reduce heat transfer efficiencies. Understanding the process of deposition may be as vital as monitoring corrosion rate.

The goal of any scientist or engineer is to conduct tests that will allow predictions to be made for long-term behavior. For the liquid metal experimenter, the task is formidable since, in many cases, large size factors must be taken into consideration (a commercial nuclear reactor versus a laboratory test loop, for example), activity conditions of the complete system must be simulated, and the high chemical reactivity of the test medium (especially alkali metals) causes a major concern for safety of operation. In addition, the difficulties of sample handling, cleaning, and evaluating are challenging. An example is the removal of solidified lead or sodium from a test coupon without damaging the coupon surface or destroying a layer of deposit. However, perfect predictions are neither sought nor required; rather, a methodology for testing backed by a depth of understanding

FIG. 1—Schematic of thermal gradient mass transfer in a liquid-metal circuit [92].

for the physical and chemical changes occurring within the system is needed. This will permit design of liquid metal containment systems to meet basic operational criteria within acceptable limits of safety.

## IMPORTANT VARIABLES

There are at least 15 factors of major importance that require special attention in the consideration of corrosion by liquid metals:

1. Thermophysical condition of the material and base composition
2. Physical and chemical condition of the containment surface
3. Exposure temperature
4. Reactive impurity content in the liquid metal
5. Liquid metal velocity
6. Location (test coupons or containment), in relation to heat input/removal zones
7. Type of liquid metal circulation
8. Axial heating rate
9. Mechanical stress of material
10. Loop temperature differential,  $\Delta T$
11. Test specimen configuration
12. Exposure time
13. Monometallic or multi-metal/alloy containment system
14. Deposition of corrosion products
15. Effect of external environment

In liquid metal corrosion testing, all of these variables should be recognized and addressed. It is not possible in this chapter to provide a full account of the ramifications of each of them. Instead, one or two of the more important ones have been selected for illustrative purposes; in some cases, these illustrations are presented as specific examples of behavior in liquid sodium or liquid lithium. Numerous references are cited from the literature for information on the variables not described in detail.

### Thermophysical Condition of the Material and Base Composition

The thermophysical state of a material may be defined as the end result of prior thermal treatment and its interaction with mechanical deformation introduced in the final fabrication process. All of these conditions can have an effect on corrosion and must be characterized for definitive analysis. Surface condition of a specimen may also have an important influence on corrosion rate. The thermophysical condition of a material under test may be affected by the exposure environment. For example, if the intended application for a given metal or alloy is as a component in a nuclear reactor, then care should be exercised to ensure that high neutron fluxes do not significantly alter predicted corrosion behavior. Radiation can enhance nucleation reactions, and this may result in precipitation at lower than normal temperatures, or precipitation of normally unstable phases. In addition, radiation can dramatically affect the defect structure of a material and, therefore, significantly

influence solid state mass transport. These radiation effects may have an impact on corrosion rate or corrosion behavior.

A surface layer partially transformed to, or approaching the composition of, ferrite has been found to form on all austenitic materials exposed in a corrosion zone of nonisothermal systems based on sodium, lithium, lead, mercury, and other liquid metals, principally due to the preferential loss of nickel (or other soluble austenite stabilizing elements such as manganese and carbon) according to the mechanism described by Eq 1 [4,7,9-11,16-19]. The effect varies in degree and depth, depending on the operating parameters of the system, the liquid metal, and the time/temperature/location data of a given specimen. The plot in Fig. 3 illustrates this phenomenon in a more general sense. The figure shows the depth variation of a depleted zone as a function of corrosion rate in sodium. This depleted zone is formed as a result of two processes, either one of which may be rate-controlling; the diffusion of alloy species (including iron) down the activity gradient to the steel/sodium interface, and the removal of each element from the interface with subsequent transport by the liquid metal. The removal step may be either by direct dissolution (e.g., nickel, manganese) or by formation of a sodium-oxygen-metal complex (e.g., iron, chromium). The result is the eventual establishment of an equilibrium condition where the growth of the depleted zone is balanced by the receding corrosion surface [4,20]. Example A (Fig. 3) shows that an austenitic steel corroding in liquid sodium at  $5 \mu\text{m/y}$  will require 1000 h at  $700^\circ\text{C}$  to establish a steady-state depleted zone depth of  $10 \mu\text{m}$ . Example B indicates that corrosion at a rate of  $0.5 \mu\text{m/y}$  results in a  $100 \mu\text{m}$  depleted zone depth, but that about 60 000 h would be required to reach this condition at  $700^\circ\text{C}$ . However, at  $650^\circ\text{C}$  about the same depth of depletion ( $10 \mu\text{m}$ ) would be reached as in Example A after 10 000 h of exposure. Finally, since the corrosion rate in sodium is proportional to oxygen concentration [21], either parameter could be used as the variable on the abscissa axis in Fig. 3.

The amount of nickel present in an alloy exposed to liquid sodium, lithium, mercury, lead, and others has a direct impact not only on the overall weight loss, but also on the

FIG. 3—Elemental depleted zone depth as a function of corrosion rate: type 316 stainless steel exposed to flowing sodium [69] (copyright 1980 by the American Nuclear Society, La Grange Park, IL).

morphology of the corroded surface. Features may range from relatively planar, where wall thinning is equivalent to weight loss, to a situation in which there is negligible wall thinning and corrosion produces a labyrinthine structure below the original liquid metal interface. In contrast to the behavior of nickel, molybdenum (as an alloy addition or as the primary metal) is very resistant to corrosion by many liquid metals. For example, if the molybdenum content is in excess of about 2 %, nodes of Laves phase,  $\text{Fe}_2\text{Mo}$ , form in the ferrite layer at the corroding surface and produce highly dissolution-resistant particles. With increasing molybdenum content, the surface structure can develop into coral-like features [22]. This has led to the development of corrosion-resistant coatings [23].

The ferrite regions on the austenitic steels often exhibit a porous-like structure that may be related to surface destabilization due to selective leaching [7,11,16,17], dissolution-triggered phase separation [18], or a localized corrosion product [19]. In contrast, the ferritic/martensitic steels tend to dissolve more slowly and maintain planar surfaces in contact with the liquid metal (although such surfaces are not smooth on a microscopic basis).

Solubility-driven reactions are not the only significant degradation mechanism for steels. Nitrogen in lithium has deleterious effects [24–28]. For stainless steel surfaces exposed to molten lithium [25,26], a specific nitrogen-related corrosion product was identified ( $\text{Li}_3\text{CrN}_3$ ). This key finding has formed the basis for a much better understanding of the various corrosion processes in lithium/steel systems. Furthermore, there is also definite evidence that carbides can play an important role in the corrosion of steels by lithium [25,29–33].

Refractory metals and alloys are generally dissolution-resistant in liquid metals and corrosion is often controlled by reactions with impurity/interstitial elements [13,14,27]. In the case of refractory metal alloys based on niobium or tantalum, the concentration of oxygen in the alloy is an important parameter with respect to corrosion in alkali metals, particularly lithium [34–38]. As little as 300 wppm of oxygen in niobium will induce catastrophic penetration of the niobium by lithium. Interstitial oxygen will also cause penetration of niobium and tantalum by sodium or potassium, but the threshold of oxygen concentration is higher.

In liquid metals other than the alkali series, such as lead, bismuth, and lead-lithium, solubility considerations tend to dominate and corrosion rates are usually higher than they are in many of the alkali metals. In general, increasing the nickel and/or manganese content of containment alloys results in significant increases in corrosion rates [9,16,39–46]. However, impurities, particularly oxygen and nitrogen, and additives to the liquid metals can play important roles in forming surface layers that, in some cases, can inhibit the dissolution process [9,47–50].

### Physical and Chemical Condition of the Containment Surface

Important considerations include the topography that results from the final preparation treatment given to the containment or corrosion test coupons and the chemical

condition of the surfaces to be exposed to the liquid metal. Several factors are clearly important in this regard:

- Smoothness—A corrosion test coupon should start its period of exposure with a relatively smooth and readily reproducible surface condition.
- Characterization—The surface morphology and microstructure should be thoroughly characterized and documented.
- Chemical condition—The starting chemical condition of the specimen surfaces is important, not as much as for the transient effect on the corrosion reactions of interest, but because contaminants can inhibit wetting, particularly for the heavier liquid metals like lead and mercury. Specimens should be free of finger oils, films from cleaning agents, and surface oxides or other products that form during materials processing. Otherwise, corrosion can be inadvertently delayed due to lack of wetting or atypical reactions and results will not be reproducible. Apparent incubation times can be quite long in some cases, even using specimen surfaces that were carefully cleaned prior to exposure—see, for example, the work of Pawel et al. with a mercury/stainless steel system [16].

### Exposure Temperature

Under dissolution-controlled conditions, corrosion by liquid metals should increase with increasing temperature. For example, assuming all other factors affecting corrosion are fixed, the corrosion rate-temperature relationship can be expected to follow the classical Arrhenius expression,  $\log k \propto \exp(-Q/RT)$ , where  $k$  is corrosion rate,  $Q$  is the activation energy,  $R$  is the gas constant, and  $T$  is the absolute temperature. This is shown graphically in Fig. 4 for type 316 stainless steel in sodium. In this case, the corrosion rate can be related directly to mass loss, which can be expressed in terms of wall thinning.

Mass transport of elemental or alloy constituents from the hot to cold regions around nonisothermal systems can be

FIG. 4—Corrosion rate versus oxygen in sodium (type 316 stainless steel) [69] (copyright 1980 by the American Nuclear Society, La Grange Park, IL).

obscured or substantially altered by effects of reactions involving impurities. For example, in molten lithium-steel systems, nitrogen and carbon can lead to irregular mass transfer profiles, particularly at lower temperatures (400–500°C) [7,19,25,26,32,33,51–53]. Therefore, nature of the corrosion of steels by lithium can be very sensitive to the temperature range of interest and the magnitude of corrosion losses does not necessarily scale with the maximum temperature of the system. Depending on the temperature range, corrosion can be dominated by formation of  $\text{Li}_3\text{CrN}_5$  and/or carbides, carbon transport around the lithium system, and, at sufficiently high temperatures, solubility-driven reactions. At higher temperatures, for steels containing substantial amounts of soluble elements such as nickel and manganese, reactions involving nitrogen and carbon can often be minimal compared to mass transport by solubility-driven dissolution and deposition. In theory, such competing reactions can occur in most all liquid metal systems, particularly when solubilities are limited and care must be taken in evaluating corrosion as a function of temperature.

Another complicating factor in correlating corrosion rate data for certain systems stems from surface area-to-volume and temperature gradient effects. For example, for lithium, stainless steel corrosion rates determined for a given temperature condition are very reproducible among test systems (test loops) of the same geometry [54]. However, altering the dimensions of the system significantly changes the corrosion rate and also mass transfer profiles, even for the same maximum and minimum temperature conditions [54–56]. Similarly, the inclusion of a bypass, continuous flow cold trap system can affect mass transfer by extending the effective cold leg surface area of the loop.

### Reactive Impurity Content in the Liquid Metal

While reactive impurities are of concern for most liquid metals, most studies related to such have been with alkali metals, lead, and bismuth. As examples, some of these findings are described immediately below.

Oxygen in sodium is a key factor influencing the corrosion rate in sodium. Methods of measurement have included on-line and off-line vacuum distillation, mercury amalgamation, the use of a plugging meter or a cold trap temperature, vanadium wire equilibration, and several electrochemical metering devices. All methods suffer from some inherent fault or are open to reasonable doubt in regard to absolute interpretation of oxygen in ppm. For detailed information related to the various types of determination of oxygen in sodium, the reader is referred to several conference proceedings in which individual sessions devoted to this topic can be found [57–62].

Nitrogen is the main impurity element in lithium with respect to the rate of corrosive attack. Off-line monitoring techniques based on the Kjeldahl method are routinely used to determine nitrogen concentration.

While metering devices for on-line monitoring of oxygen in sodium and for hydrogen in both sodium and lithium have been successfully developed [63], only small-scale experiments have been attempted for direct measurement of nitrogen in lithium. The method is based on resistivity measurements in which it is assumed that total resistivity

increase, measured from a base value for “pure Li,” is due to the sum of resistivity contributions from hydrogen and nitrogen activities. Nitrogen concentration is hence determined by difference, using the base value for pure lithium and a value for the hydrogen resistivity contribution, determined from hydrogen activity measurements using an on-line hydrogen meter [64]. The reader is referred to a book by Addison [65] for additional information regarding the chemistry of liquid alkali metals.

In liquid metal systems that are oxidizing with respect to the solids they contact, corrosion inhibition is dependent on formation of protective surface films. For example, in lead or lead-bismuth, [47–49] equilibria controlling film formation are governed by the following: the uniform distribution of calcium, (or magnesium), to reduce the activity level of oxygen impurity in the lead (one common “alloy” often selected is Pb-225 ppm Mg) and the constant presence of active zirconium at the containment surface, where it reacts with nitrogen (or carbon, or both) diffusing from the containment bulk, to form a protective layer. (NOTE: The solubility of zirconium in pure lead is nil, and is only about 100–300 ppm in Pb-Mg or Pb-Bi alloys.)

### Liquid Metal Velocity

Much work on liquid metal velocity has been done with sodium and serves to illustrate its influence on corrosion. Bagnall and Jacobs [21] have attempted to unify the available data in the literature and correlate corrosion rate with temperature. Sodium velocity and oxygen were the two major variables taken into consideration. With oxygen interpreted on the vanadium wire equilibration scale, it was shown statistically that corrosion rate,  $R$ , was independent of velocity above about 3 m/s and directly proportional to oxygen concentration. An example of this correlation is shown in Fig. 4 where the variation of  $R$  with oxygen is plotted for type 316 stainless steel at 700°C. Data obtained at very low oxygen levels (<0.5 ppm by vanadium wire) deviate from the predictive curve. At these low concentrations, mass loss appears to approach the model developed by Weeks and Isaacs [4]. Such behavior is not unreasonable since it is clear that mass loss will, in any event, not drop to zero at zero oxygen. Also, an approximate correlation between the vanadium wire scale and vacuum distillation values is shown on the abscissa. Note that the latter scale is not linear and that the vacuum distillation analytical method becomes insensitive below about 5 ppm.

Another example of the influence of velocity on corrosion rate is from work with lead-lithium. Corrosion kinetics observed in the hot zones of austenitic steel loops containing Pb-17at.%Li show good agreement and appear to be linear after a nominal incubation period [49] in which differing initial surface conditions (e.g., oxidation, mechanical working) are eliminated (see above). The following corrosion expression, including an allowance for velocity effects, was derived by Flament et al. [9] for data collected in the temperature range 400–550°C:

$$v = 8 \times 10^9 e^{-25,600/1.98T} V^{0.875} d^{-0.125} \quad (2)$$

where  $v$  is metal loss rate in  $\mu\text{m/y}$ ,  $T$  is absolute temperature,  $V$  is the liquid metal velocity in m/s, and  $d$  is the hydraulic diameter in  $m$ .

### Location (Test Coupons or Containment) in Relation to Heat Input/Removal Zones

In sodium, corrosion rates have been shown to decrease as soon as heat input ceases to cause a temperature rise [7]. This phenomenon is known as the downstream effect and is applicable only in reference to isothermal zones. This effect is related to the hydraulic length-to-diameter ratio in the isothermal zone, and can be expressed as  $L/D$ , where  $L$  is the linear distance from the end of the temperature rise zone and  $D$  is the hydraulic diameter, defined as

$$D = \frac{4 \times \text{cross area of flow}}{\text{wetted perimeter}} \quad (3)$$

The decrease in corrosion rate with downstream position can be approximated by the equation

$$\log R_c = \log R_0 - K(L/D) \quad (4)$$

where

$R_c$  is corrosion rate at any value of  $L/D$ ,

$R_0$  is corrosion rate at  $L/D = 0$ , and

$K$  is the linear downstream coefficient.

This relationship is shown graphically in Fig. 5 for a liquid sodium corrosion test. In order to compare corrosion data between different laboratories, the corrosion rate at zero  $L/D$ , ( $R_0$ ), must be established. As an example, this was accomplished for the data in Fig. 7 by fitting a line by the least squares method and projecting this line to  $L/D = 0$ . Caution must be observed, however, when the data cover a limited range of  $L/D$  values. Corrosion experiments should be designed to cover a substantial range of  $L/D$ s ( $>200$ ), with data acquired as near  $L/D = 0$  as practical. Austenitic alloy/lithium  $\Delta T$  systems, apart from some interesting topographical changes, show little or no change in either chemical composition or mass loss as a function of  $L/D$  in isothermal corrosion zones

FIG. 5.—Typical downstream effect in a liquid sodium system [69] (copyright 1980 by the American Nuclear Society, La Grange Park, IL).

[66,67]. Downstream effects have not been observed for lithium and other liquid metals. However, the phenomenon has only been studied in detail for sodium.

### Type of Liquid Metal Circulation

Three basic types of liquid metal environment may be identified for engineering systems: forced circulation, thermal convection, or a stagnant isothermal containment system. These three types may be designed for single phase (liquid) or two-phase (liquid/vapor) operation. Laboratory testing, however, may involve numerous variations of the three types, and a description of the more important system configurations for data collection is given in the *Lab Testing* section of this chapter. In all liquid metal systems, the corrosion mechanisms will depend largely on the number of phases present, the concentration of active species available to participate in the process, and the characteristics of the various sources and sinks available to add or remove active elements. There are several considerations, however, that illustrate differences in behavior between the different liquid metals. Three examples are given:

In sodium, the corrosion rate generally increases in changing from static to thermal circulation to forced circulation systems.

In lithium, the same rules may not hold, because the solubility of nitrogen in lithium, even at its freezing point, is high (about 300 ppm). Hence, the best purification (“gettering”) techniques may not be good enough, and dissolution in a static system may remain high for a prolonged period.

In lead, or lead-bismuth systems, since the corrosion rate is highly dependent on the formation of surface films, the type of circulation has less effect on the corrosion rate than do those factors that affect film formation or spallation, (e.g., vibration or thermal/mechanical shocks).

### Axial Heating Rate

An increase in axial heating rate (i.e., increase in temperature divided by axial heat input distance), called  $dT/dL$ , has been related to an increase in corrosion rate in sodium [68]. Data were compared in experiments at three different laboratories. Results from two similar sodium loops, one with a  $dT/dL$  of  $\sim 40 \text{ C}^\circ/\text{m}$ , and the other with a  $dT/dL$  of  $300 \text{ C}^\circ/\text{m}$ , showed that consistently higher corrosion rates were obtained in the high  $dT/dL$  loop.

It is conceivable that the cause for the heating rate effect is closely linked to the mechanism controlling the downstream phenomenon. Sodium leaving the heater zone in the high  $dT/dL$  case has a greater “potential” for dissolution in the adjoining isothermal zone than in an otherwise identical low  $dT/dL$  case. The total change in solute concentration is extremely small in either case, but the change in terms of chemical activity may nevertheless be sufficient to affect the distribution of iron, nickel, and chromium atoms on active corrosion sites, a smaller number of “active” iron atoms existing in the lower  $dT/dL$  situation.

### Mechanical Stress of Material

There has been no detailed attempt to investigate the effects of stress on corrosion rate. It may be theorized that

an increase to some degree will result since diffusional processes, precipitation reactions, and dissolution kinetics at the solid/liquid interface will all be enhanced. However, the experimenter should bear in mind that the type of stress is important—whether it is tensile, compressive, cyclic, or residual. Residual stresses may be relieved at the test temperatures conventionally employed for liquid metal corrosion testing.

### Loop Temperature Differential, $\Delta T$

Temperature differences in a loop system provide the driving force for mass transport of corrosion products. Although no definitive experiments have been conducted, indications are that the magnitude of the  $\Delta T$  in sodium has no effect above a minimum value of about  $100^\circ\text{C}$  [69]. From a consideration of heat transfer properties, in any heat transfer system at a given flow velocity, different liquid metals would require different  $\Delta T$ s to deliver the same heat load. If the surface area and geometry are fixed by heat flux considerations, the  $\Delta T$  and/or flow velocity, and hence mass transfer fluxes, will change for liquid metals with different heat transfer characteristics.

### Test Specimen Configuration

Relative corrosion and mass transfer sources (dissolution) and sinks (deposition) are of vital importance in the analysis of corrosion experiments. It is important that the sink area is larger than the source area in order to determine the maximum corrosion effect at a given temperature. Cascading of test specimens in series or in parallel, as illustrated in Fig. 6, can lead to questionable conclusions about general corrosion results. Experiments in series, where different specimens are at different temperatures, can be particularly troublesome if some of the specimens act as both sources and sinks for corroding species, and careful post-exposure measurements of mass and surface composition changes are not made. Parallel experiments are more amenable to analysis providing all of the factors such as velocity,  $\Delta T$ , and  $L/D$  are known. The test geometry should always be given in detail when reporting corrosion results. The use of tubular (cylindrical) specimens allows a better hydrodynamic analysis of the flow conditions (e.g., Ref 32).

### Exposure Time

Experience has shown that accelerated corrosion takes place in the first few hours of exposure for certain alloys in liquid metals. After this initial period, which may vary for different materials, a steady-state corrosion rate is usually attained. Figure 7 graphically illustrates this phenomenon for sodium. Period  $t_1$  is generally on the order of 500–1000 h, but can extend appreciably beyond this duration. Period  $t_2$  indicates the steady-state corrosion rate that must be determined for long-term predictions. Historically,  $t_1$  and  $t_2$  have been combined when reporting corrosion data. This has little significance on long-term tests lasting thousands of hours, but becomes very important in short-term tests of a few hundred hours or less.

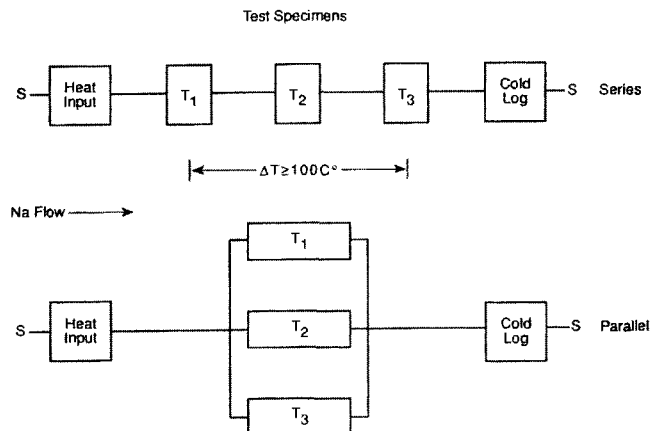

FIG. 6—Examples of series and parallel corrosion test circuits [69] (copyright 1980 by the American Nuclear Society, La Grange Park, IL).

### Monometallic or Multi-Metal/Alloy Containment System

The ideal corrosion experiment would contain only two materials: the liquid metal (or alloy), and the solid metal or alloy under test. This situation is rarely practical; every effort should therefore be made to prevent erroneous conclusions caused by masking. Masking can be described as the lowering of element loss from a downstream specimen because a specimen rich in this (these) element(s) is located upstream.

The removal of nickel from nickel-containing alloys is an important factor determining the corrosion rate of these materials in several liquid metals. If a high nickel source is placed upstream in an isothermal zone, the nickel removal rate from an alloy sample downstream could be reduced. If several alloys with different nickel contents are included in the same test it would seem appropriate to arrange them in

FIG. 7—Typical mass loss showing increased corrosion rate in first few hours of sodium exposure [69] (copyright 1980 by the American Nuclear Society, La Grange Park, IL).

order of increasing nickel concentration with respect to liquid metal flow direction. In the long term, this masking may become negligible in austenitic materials because all exposed surfaces move towards a ferritic composition with time.

Besides masking, elemental transfer can occur between two dissimilar materials in contact with the same liquid metal (even isothermally) due to an activity gradient. Again, experiments with only one solid material in contact with the liquid metal would avoid this complication. However, if this type of system cannot be used, careful surface analysis of as-exposed specimens should be used to try and understand mass transfer contributions from dissimilar material driving forces.

### Deposition of Corrosion Product

Deposition of corrosion products in a circulating  $\Delta T$  liquid metal system is important for three reasons. First, the degradation of heat transfer performance of heat exchangers must be predicted. Second, radiation exposure limits for maintenance in certain areas of nuclear reactor systems that transport and deposit radioactive species must be controlled. Third, the tendency for all deposits to become detached by thermal shock or flow perturbations must be known since there is concern that these types of debris could block critical coolant channels. It is therefore valuable, when possible, to monitor reactions involving deposition as well as dissolution.

The reader is referred to the literature for more information on deposits and deposition phenomena. Considerable work has been reported on characteristics of sodium, lithium, and lead-lithium systems [56,70–72].

### Effects of External Environment

Since the corrosion and mechanical properties of refractory metals and alloys based on niobium, vanadium, or tantalum are strongly affected by interstitial impurities (carbon, nitrogen, and oxygen), these metals must be maintained under ambient environments that do not contain sources of these impurities. In the case of lithium, the uptake of oxygen by niobium and Nb-1%Zr from the ambient atmosphere has induced localized penetration of the metal by lithium, with subsequent weeping or wicking to the outer surface of the containment [34]. In the case of liquid-vapor potassium or sodium systems, oxygen is depleted from the condenser regions and transferred to the evaporator [73]. Oxygen from the external atmosphere can thereby be transferred through the wall, and can increase the oxygen content of the liquid metal in the evaporator to levels where catastrophic corrosion will occur. Hydrogen embrittlement of refractory metals and alloys is also a potential problem during the removal of alkali metals after corrosion testing. The use of water- or alcohol-based solvents to remove the alkali metal residues can cause cracking as a result of the hydrogen generated from this reaction. Anhydrous ammonia is the preferred solvent for cleaning these metals.

### SUMMARY

Fifteen factors have been identified that can significantly affect the corrosion of materials in liquid metals. The collective

importance of all of these factors should be recognized and adequate information related to each of them should always be recorded. The more important of these factors are summarized below:

- Composition of the material being exposed and its thermophysical condition—The compositional variations and thermophysical condition of a material must be characterized prior to corrosion experiments in liquid metal.
- Exposure temperature—In general, corrosion rates increase with temperature. However, corrosion rate/temperature relationships can be strongly influenced by system geometry and impurity effects.
- Reactive impurities.
- Downstream effect.
- Axial heating rate.
- Liquid metal velocity.
- Loop  $\Delta T$ —There must be a difference in temperature in a forced circulation loop system to provide the driving force for solution-controlled mass transport.
- Exposure time—Accurate kinetic measurements must be made over an extended time period for useful comparisons and predictive analysis.
- Dissimilar materials—Care must be exercised to prevent dissimilar materials, whether in containment construction or in the sample inventory, from masking the true corrosion and mass transfer rates for individual materials.
- Deposition—Deposition can affect the efficient operation of a heat transfer system, and may lead to blockage of key flow channels. Characterization of deposition characteristics in a given system geometry is an important part of any liquid metal corrosion study.
- External environment—For tests involving reactive and refractory metals and alloys, care must be taken to preclude sources of carbon, nitrogen, and oxygen from the external environment, since their presence can adversely affect test data and the integrity of the liquid metal containment.

## LAB TESTING

### Test Procedures

Historically, testing routines have generally progressed from an evaluation of specimens encapsulated in static liquid metals through natural convection loops, forced convection loops, loops simulating reactor circuits, and large engineering experiments. As the tools have become more sophisticated, researchers have sought to identify the corrosion effects of system parameters such as temperature, geometry, flow velocity, turbulence, heat transfer rates, and system impurities.

In the case of the alkali metals, impurities such as oxygen, nitrogen, and carbon can have a significant effect on the corrosion of steels and refractory metals. For this reason, it is imperative that impurities initially present in the alkali metal and those entering during test be carefully monitored and controlled. In effect, any corrosion testing program must be designed around the sampling procedures and analytical techniques used to measure impurities in the alkali metals.

In the following sections, various test procedures are discussed and examples are given. The examples illustrate the principles involved in the test method. Each investigator's test design, although using these principles, may differ in detail. Alkali metals react vigorously with air. Consequently, although beyond the scope of this chapter, any operation on alkali metals (i.e., melting, loading, or welding the test system) must be performed in an inert gas or vacuum atmosphere. Additional details and references may be found in Ref 74. Some important safety aspects are reviewed in Ref 75, and devices for rapid leak detection are described in Ref 63.

### Specimen Examination

Correct interpretation of test results requires that the extent of wetting be confirmed for each test condition. In some liquid metal/containment combinations, many subtleties of surface condition may substantially influence wetting and thereby potential interactions (see above). In particular, wetting of metallic surfaces by Hg is very sensitive to precise temperature and extent of surface cleanliness/films [76,77]. As a result, wetting under test conditions can be easily disrupted and initial post-test examination of as-removed specimens must assure that complete wetting has taken place.

Mass loss alone is not a true indication of the total damage caused by corrosion in many materials. As indicated earlier, subsurface metal removal can be linked to the nickel content of the alloy, or any other element with high solubility; this is true for corrosion in sodium, lithium, mercury, and several other liquid metals. Subsurface attack can take the form of localized bulk removal producing a porous region in the depleted zone or a more general selective loss of alloy elements without microstructural damage. Either of these cases, or the presence of intergranular attack extending beneath the depleted zone into the base metal, causes damage greater than would be expected from wall thinning alone. In sodium studies, a total damage function was developed to express the corrosion process, as shown in Fig. 8. Here, total damage is shown as a combination of surface regression, a zone of degradation (with respect to mechanical properties) and intergranular attack. It should be noted, however, that this behavior is not limited to interaction with sodium, and this damage function can be used to describe corrosion damage produced by numerous liquid metals.

### Static Isothermal Capsules

Static capsules of the type shown in Fig. 9 are used to determine the extent of solid dissolution, interstitial transfer, or interalloying between the solid and liquid. The capsule can serve as the test specimen, or the test specimen can be incorporated as an insert in the capsule. In the latter case, it is a general requirement that the capsule and test specimen be of the same composition unless the test is intended specifically to study dissimilar-metal mass transfer effects. Incorporation of a test specimen simplifies the determination of any changes in weight, dimension, or mechanical properties due to liquid metal exposure.

Static capsules (Fig. 9) have also been used to determine the effect of oxygen on the compatibility of niobium and

FIG. 8—Representative modes of surface damage in dynamic sodium or lithium systems [7].

tantalum with sodium and potassium [34–38]. The capsules were contained in the outer stainless steel container for protection against oxidation. By making weighed additions of  $K_2O$  to potassium, niobium dissolution was found to be strongly affected by the oxygen concentration of the potassium. Capsule tests with liquid metals have also been used to study carburization/decarburization behavior (see, for example, Refs 30 and 31) and nitrogen reactions (Ref 78).

Static isothermal capsules are also useful for studying dissimilar metal mass transfer. DiStefano [79] studied the interactions of type 316 stainless steel with niobium or Nb-1 % Zr in Na and NaK by exposing tension specimens of the niobium or Nb-1 % Zr to the liquid metal in a stainless steel container (Fig. 10). A transfer of carbon and nitrogen from the stainless steel to the niobium or Nb-1 % Zr was noted. The carbon and nitrogen transfer depended on temperature, time, and the surface area ratios of stainless steel to niobium (varied by changing the number of spacers shown in Fig. 10).

Static capsules or pots of special design are used to measure the solubility of solids in liquids. Eichelberger et al. [80] used bimetallic capsules made by welding two crucibles,

FIG. 9—Static capsule test system used to study the effect of oxygen on the corrosion of niobium by potassium (Note: 1.0 in. = 25.4 mm) [94].

**FIG. 10—Dissimilar-metal test system (1.0 in. = 25.4 mm) [77].** (Reprinted with permission from the Oak Ridge National Laboratory, which is managed by Martin Marietta Energy Systems, Inc. for the U.S. Department of Energy.)

one of the test material (solute crucible) and one that contains none of this material (sampling crucible). The liquid was equilibrated in the solute crucible and inverted at temperature to allow the saturated liquid to drain into the sampling crucible. After cooling, the liquid was analyzed for the test material.

### Refluxing Capsules

In systems where a liquid metal is used as the working fluid (e.g., the Rankine-cycle), liquid is converted to vapor in one part of the system and vapor to liquid in another part. The distillation effects of the vaporization process result in extremely pure condensing vapor that may be able to dissolve and transport container material. As opposed to an all-liquid system, where the liquid is always partially saturated with container material constituents, dissolution in the condenser region can continue undiminished; the dissolution rate will depend on the condensation rate and temperature. In contrast, liquid in the evaporator section will ultimately become supersaturated with respect to container material constituents, so that the heated sections of a liquid metal boiling system will be subject to deposition rather than corrosion [81].

The effect of a boiling-condensing liquid metal on its container material is most easily studied in a refluxing capsule experiment. The capsule design illustrated in Fig. 11 was used for evaluating the effect of refluxing potassium on refractory metals. A 300 mm capsule containing machined insert specimens in the condenser section was half filled with potassium and heated. Liquid metal vaporizes, condenses in the water-cooled upper section of the capsule, and

**FIG. 11—Refluxing alkali metal test (1.0 in. = 25.4 mm) [79].** (Reprinted with permission from the Oak Ridge National Laboratory, which is managed by Martin Marietta Energy Systems, Inc. for the U.S. Department of Energy.)

flows back to the boiling pool. Under steady state conditions, the evaporation rate is determined by the vapor condensation rate, which in turn is determined by the amount of heat extracted from the vapor region. Knowing the water flow rate, the water temperature, and the latent heat of condensation of the liquid metal, the condensation rate can be calculated. After testing, the insert specimens are checked for changes in dimensions, weight, chemical composition, and microstructure.

DiStefano [82] has shown that the ratio of the diameter to length of a refluxing capsule is critical in achieving steady state boiling-condensing conditions. Also important in the case of refractory metals (e.g., niobium, tantalum) is the protective atmosphere maintained outside the capsule. Aside from limiting oxide film formation, the atmosphere must afford a sufficiently low-oxygen pressure to prevent oxygen infusion into the capsule. This is why such capsule (and loop) tests are often operated in vacuum systems.

### Seesaw (Tilting-Furnace) Capsules

The "seesaw capsule" provides the simplest technique for simultaneously introducing flow and a temperature gradient into a test. A capsule with specimens in both ends is partially filled with liquid metal and heated to maintain a temperature difference between the two ends. The capsule is then rocked slowly back and forth about a horizontal axis (perpendicular to the capsule axis) so that the liquid flows

from one end of the capsule to the other. After test, the extent of mass transfer is determined by examining test specimens from the alternate ends of the capsule. Although this device is useful for screening purposes, the dynamic nature of the heating and cooling cycles prevents a rigorous analysis of mass transfer in terms of time and temperature.

### Use of Capsules for Pre-Exposure

Capsule test facilities can also be used for pre-exposure of specimens for subsequent mechanical testing. Tortorelli and coworkers used this technique to study decarburization of ferritic steels in lithium under a variety of heat treatments. Weight change data, carbon analysis, and tension testing were collectively used in this evaluation [31].

### Rotating Cylinder (Disk) Technique

As noted above, the mass transfer kinetics of temperature gradient loops are usually described with reference to dissolution in the hot leg. It is possible to quantitatively study the dissolution step using the rotating cylinder technique. Unlike loop studies, this technique allows one to study dissolution in a system where the hydrodynamic conditions are fully defined. Experimentally, solid cylinders of the test material are rotated at various speeds in an isothermal liquid-metal bath. Changes in the concentration of solid in the liquid and changes in the cylinder radius are determined as a function of time. With these data it is possible to determine the mass transfer coefficient and the rate-controlling step for dissolution.

A rotating disk method has also been used to study effects of high-velocity corrosion, and the potential for damage from erosion mechanisms [83]. A rotating dissolution cell has also been used for measurements of corrosion in liquid mercury [84].

### Thermal-Convection Loops

The simplest nonisothermal flowing system where processes associated with dissolution and deposition occur is one in which flow is induced by thermal convection. This is accomplished by heating one leg of a closed loop and cooling another leg. The flow rate is dependent on the height of the heated and cooled sections, on the temperature gradient, and on the physical properties of the liquid. Both single-phase (all-liquid) and two-phase (liquid-vapor) loops have been tested. In some cases, thermal convection loops are destructively examined after operation [55,67]. In others, specimens are removed and replaced numerous times for cumulative periods of 10 000 h or more [22,54,68].

Figure 12 is a diagram of the loop used by DeVan and Sessions [85] to study the mass transfer of niobium-base alloys in flowing lithium. Each loop (254 by 610 mm) contained a continuous string of interlocking test specimens that gave a weight change profile around the loop along with information on changes in alloy composition and microstructure. These loops were heated by tantalum resistance furnaces placed concentrically about one vertical leg (hot leg). A water-cooled heat sink was located around the other vertical leg (cold leg), and the heat was rejected to this

FIG. 12—Diagram of lithium thermal convection loop (1.0 in. = 25.4 mm) [83] (copyright 1967 by the American Nuclear Society, La Grange Park, IL).

sink together with the cold-leg entrance and exit temperatures was used to calculate the liquid flow rate. The remainder of the loop was insulated with tantalum foil to minimize heat losses. A temperature profile between the thermocouples on the loop corners was derived from a heat balance for each leg. During test, the loops were protected from oxidation by a bell-jar enclosure, which provided a vacuum of  $10^{-8}$  to  $10^{-9}$  Torr.

Similar loops, constructed of stainless steel and operated with radiant heating devices in air, have been used for liquid metal corrosion studies in laboratories around the world (e.g., Refs 16,54). In some cases, removable sample strings are situated in the hot and cold legs to facilitate removal of specimens without interruption to liquid metal flow [54].

The thermal convection loop is also useful for studying dissimilar-metal mass transfer. The bimetallic loop design shown in Fig. 13 was used by DeVan and Jansen [86] to determine the transport rates of nitrogen and carbon between vanadium alloys and stainless steels in a sodium circuit. Mass transfer rates and carbon and nitrogen effects on mechanical properties were monitored by means of insert specimens in the hot and cold legs. The effects of surface area ratios of the two materials were determined by adding or subtracting insert specimens.

Still another use [87] of thermal convection loops has been the study of corrosion effects in two-phase (vapor and liquid) potassium systems. In this case the lower half of the loop is filled with liquid and the upper half with vapor. The data derived from such a system are basically similar to

FIG. 13—Vanadium-stainless steel-sodium thermal convection loop (1.0 in. = 25.4 mm) [84]. (Reprinted with permission from the Oak Ridge National Laboratory, which is managed by Martin Marietta Energy Systems, Inc. for the U.S. Department of Energy.)

those obtained from refluxing capsule experiments discussed above. However, the use of a loop allows the boiler and condenser legs to be separated so that condensate flow parallels rather than opposes vapor flow.

### Forced-Convection Loops

The utility of thermal convection loops is limited by the low flow velocities (maximum of about 60 mm/s), making extrapolation to the higher velocities in operating systems doubtful. Higher flow velocities are obtained in forced convection loops where the liquid is moved through the loop with an electromagnetic or mechanical pump. Electromagnetic pumping is generally preferred for corrosion studies, since it alleviates the problem of pump seal leakage, but such pumps can act as traps for deposition of magnetic species. As with natural circulation systems, forced circulation loops have been developed to test both single-phase (all liquid) and two-phase (vapor and liquid) systems. The latter systems have been used to evaluate not only corrosion processes but also the effects of vapor impingement on turbine blade and nozzle simulators [88,89].

Figure 14 shows a schematic diagram of a simple "figure-of-eight" loop [90]. Basically, such loops consist of three parts: (a) the hot leg, where the liquid metal is heated to the maximum temperature, (b) an economizer or regenerative heat exchanger to minimize the energy transferred to and from the system, and (c) the cold leg, where the liquid is cooled to its minimum temperature. For the loop in Fig. 14,

FIG. 14—"Figure-of-eight" forced convection test loop: sodium-Inconel pumped loop (1.0 in. = 25.4 mm) [88].

the oxygen concentration of the alkali metal was controlled by bypassing a portion of the pump flow through a cold trap in parallel with the loop. The loop was completely closed except at the expansion tank, which was held under a positive pressure of purified helium to prevent pump cavitation. The material under test was used for constructing all parts of the loop, and the loop was destructively examined after a given test period.

Because forced-convection loops are costly to construct, it is now the usual practice to operate the loops as permanent testing facilities, with corrosion specimens cycled in and out of the facility. Test specimens of various materials are generally placed in the hot leg, and the effect of the flowing liquid on the specimens is determined from changes in weight, dimensions, composition, mechanical properties, and microstructure. Such an approach yields data on maximum corrosion rates as a function of temperature and liquid metal flow rate. Any attempt to elucidate corrosion mechanisms, however, is hampered by the inability to interrelate dissolution and deposition processes.

Forced convection systems have sometimes been used to screen test materials that differed widely in composition [91]. Corrosion data generated in such tests are useful to the extent that some information is gained about dissimilar-metal mass transfer among the materials, but it is normally not realistic to rate the thermal gradient mass transfer behavior of individual materials on the basis of such a test.

There are numerous accounts in the literature of liquid metal test facility design and operation, and it is not possible to list them all in this chapter. However, in addition to those already cited, the reader is referred to Refs 57 to 62 for a selection of reports addressing facility design for lithium, lithium-lead, lead, and sodium.

### Large Engineering Experiments

The final step in most testing programs is the design, construction, and testing of loops simulating the exact system for which data are needed. Here an attempt is made to duplicate all possible interactions involved in the operating system and to demonstrate system feasibility from an

**TABLE 1**—Range of applicability for various metals and alloys with liquid metals.

Material	Maximum Temperature of Operation for Nominal Corrosion(°C)			
	Na	Li	K	Pb,Pb-Bi
Stainless Steels	600	450	600	400
Cr-Mo Steels	600	500		425
Ti and Alloys		550		
Nb-1Zr	900	1300	750	

engineering standpoint. The reader is referred to numerous conference proceedings in which accounts of large facilities, including operating liquid metal-cooled nuclear reactors, are given [57–62].

## FIELD TESTING

Not applicable.

## STANDARDS

None.

## MATERIALS

As a general rule, assuming impurity and dissimilar metal effects are controlled and not overriding, the lower the nickel content of an alloy, the better is its corrosion resistance in liquid metals. The materials shown in Table 1 have proven to be corrosion-resistant to the specified liquid metals up to the temperature limit indicated. For additional information on materials compatibility, the reader is referred to the *Liquid Metals Handbook* [92,93].

# Corrosion Inhibitors

Rudolf H. Hausler<sup>1</sup>

## SCOPE

THE PRESENT DISCUSSION IS neither intended as a review of the myriad products and formulations that have over the years been proposed for the inhibition of corrosion processes in a multitude of environments with various substrates, nor a dissertation of the many mechanistic concepts that have been proposed for corrosion inhibition. Rather, an effort shall be made to outline a methodology (or methodologies) narrowly focused on a specific objective: *the assessment of the reduction of the rates of corrosion (all manifestations thereof) caused by chemicals added to the environment for specific, well defined, purposes*. However, in pursuing a specific methodology neither the nature of the inhibitor, nor the underlying corrosion and corrosion mechanisms can be ignored, and all chemical, physical, and metallurgical realities, as well as their interactions and relationships, must be taken into consideration if the results shall have predictive value.

The most crucial aspect of the above definition of the objective, which must remain foremost in the technician's mind at all times, is "*the specific well-defined purpose*." Corrosion inhibition is no longer an academic endeavor. Rather, the focus must be on prolonging the useful life of a metallic structure in the realistic (or relevant) environment at an *acceptable cost advantage*. The design engineer in general has three options:

- Select the most economical metal for the environment and hope that the useful life of the structure will outlast the process for which the metal has been selected. (Example: The carbon steel tubing in an oil well may outlast the production capacity of the well. Similarly, it is often more economical to replace a carbon steel heat exchanger than build it out of an exotic material.)
- Select a high-grade material and save on maintenance, while avoiding the risk of catastrophic failure.
- Select a combination of low-grade material and corrosion inhibitor, and hope that the useful life of the structure is appropriately extended.

Experience has shown that the third option is viable, provided that inhibitor performance has been assessed predictably. Experience has also shown dramatic failures where these conditions had not been met. Selection of a corrosion inhibitor, therefore, boils down to *quantitative risk assessment and cost performance*, which can only be achieved on the basis of reliable/believable performance data.

## INTRODUCTION

### Historical Perspective

Chemical corrosion inhibitors have been used for a long time, probably for as long as 150 years. Early applications involved the addition of inorganic chemicals to drinking and cooling water, and organic chemicals added to pickling acids. In the 1930s, and even more so after World War II, corrosion inhibition emerged as a separate science. The literature already in the 1950s has become vast, and reference needs be made to pertinent summaries. J. I. Bregman's book [1] published in 1963 has become a classic, but was soon out of print. NACE followed up with a second compilation in 1973, edited by C. C. Nathan, on the use of corrosion inhibitors across a broad spectrum of industries [2]. A further excellent update was generated by the European Federation of Corrosion in 1994 [3]. In 1983 the author brought together representatives from academia and industry in an attempt to discuss the interphase and its relevance to corrosion inhibition [4]. The interphase was defined as that three-dimensional region between metal and environment that is different in all its properties from either bulk phases.

All work on corrosion inhibition, indeed all work in the field of corrosion, is dependent on some sort of measurement or observation. In the early days weight loss, time to failure, or visual observation were the main tools. With the advent of electronic instrumentation, methods of measurement became more sophisticated. Electrochemistry and quantitative surface characterization became major tools. Unfortunately, emphasis was on the "electro-" part while the "-chemistry" often was sorely neglected. Mercer published a first overview of the various investigative techniques in 1985 [5], which was updated in 1994 [6].

The industry has always attempted to standardize materials and their applications. Despite great and protracted efforts to standardize test procedures, and there are many standard corrosion tests; there are no standard tests for corrosion inhibitor evaluation.<sup>2</sup> The reasons for this are complex as may become clear below. However, basically it had been thought that inhibitors, once evaluated under a specific set

<sup>2</sup>There are, however, currently efforts underway within ASTM Committee G-1 to develop a "Standard Guide for Evaluating and Qualifying Oilfield and Refinery Corrosion Inhibitors in the Laboratory." Such a guide, rather than specific standard test procedures, has become necessary for all the reasons spelled out in this chapter.

of circumstances, could be ranked according to efficiency, and that such ranking would carry through to other conditions as well. This proved to be erroneous for essentially all organic corrosion inhibitors and very likely for a good number of inorganic ones as well. Therefore, corrosion inhibitors have to be evaluated in an application specific manner; even the so-called screening procedures lead to faulty conclusions.

### The Importance of the System Analysis

The evaluation of corrosion inhibitor effectiveness is significantly different in many respects from corrosion testing for the purpose of evaluating material performance. The addition of a chemical to a corroding system requires compatibility, chemical and thermal stability, and in some cases physical stability as well. Transport properties become important where localized or gasphase corrosion (dew point) are an issue. Finally, no corrosion inhibitor, no matter how effective in preventing corrosion, can be considered successful if it causes process upsets. This latter aspect is usually summarized under secondary properties testing [7]<sup>3</sup> (cf. also Chapter 1 in this book).

- **Compatibility:** Corrosion inhibitors can undergo reactions with components of the environment. Amines react with H<sub>2</sub>S. Unsaturated fatty acids and derivatives thereof (imidazolines) are subject to vulcanization in the presence of elemental sulfur or oxygen in combination with H<sub>2</sub>S. Polyfunctional acids react with polyfunctional amines to form gels or solids. Such considerations are important, since production or process streams are often treated with more than one chemical (oil and gas production processing, transport and refining, cooling water circuits—the examples are endless).
- **Chemical Stability:** Since all inhibitors contain functional groups (carboxylic acids, amines, Schiff's bases, phosphates, phosphonates, sulfur derivatives, and many more), they are pH sensitive, and therefore, their activity varies over actually fairly narrow pH ranges. For example, it has been shown that certain amines in sour systems lose activity if the pH of the environment shifts from 4 to 7 [8], while in CO<sub>2</sub> systems the reverse has been observed [9].
- **Thermal Stability:** It is known that corrosion inhibitor effectiveness varies with temperature. This can be due to chemical degradation, decreased adsorption at higher temperature, or changes in surface properties (e.g., iron carbonate converts to magnetite at higher temperature).
- **Physical Stability:** Some corrosion inhibitors are polymeric in nature. As such, they become subject to degradation at high shear forces.
- **Transport Phenomena:** Many corrosion inhibitors are higher molecular compounds, and are usually present in small concentrations. If the objective is localized corrosion inhibition (crevice corrosion, under-deposit corrosion, etc.), the ability of the inhibitor to migrate where it is needed becomes a major concern that needs to be included in the design of the test methodology.

<sup>3</sup>Throughout this discussion predominantly examples from the oil field will be used. However, the principles discussed are universally valid.

Because of the above concerns, the first step in the development of any successful test methodology is the *systems analysis*, which must include the identification not only of the nominal levels of all prevailing physical, chemical, mechanical, and metallurgical parameters, but also their ranges and extreme values. For instance, the nominal temperature in a heat exchanger is that of the heated fluid exiting the tube bundle. The maximum temperature, however, is that of the tube surface. This becomes particularly important in direct fired boilers or reboilers. Other often overlooked parameters are flow rate (shear stress) and mechanical stresses (particularly alternating stresses), which tend to decrease inhibitor efficiency. Finally, a dark area of concern is the metallurgy. It is still not well understood why inhibitors are quite sensitive to small changes in the composition or physical properties of iron and/or carbon steels.

### Some Definitions

There are a myriad of tests that have been proposed, used, and will no doubt be developed in the future. The notion that a test per se can generate an understanding of the prevailing corrosion, or corrosion inhibition processes, and have some predictive value, even if performed under nominal conditions, is far from realistic. It may, therefore, be indicated to attempt to define the various concepts of testing, and apply certain critical measures to evaluate the validity of each. This shall lead to a set of broad quality criteria that, if applied consistently, will go a long way to improve overall the predictiveness of such testing.

### Quality Criteria

The objectives of corrosion testing and inhibitor evaluation may be varied and are often the preference of the technician, but they have to be clearly defined prior to selecting the test methodology. The simplest objective one can imagine may be to establish whether a substance added to a solution can retard the corrosion process. Uncomplicated immersion tests can easily fulfill such an objective. One may want to determine the mechanism by which such retardation occurs. This in itself can be a fascinating endeavor, but has little practical value, other than understanding the chemistry of interaction between a metal surface (in whatever state it may be) and the chemical added to the system. Many test procedures and methodologies have been proposed that can accomplish this, from the trivial to the most complicated [5,6]. Finally, however, corrosion inhibitors are being evaluated for the purpose of protecting metallic structures in some industrial process equipment, be it oil and gas production, refining and processing of crude oil, the pulp and paper industry, and many others. For this kind of testing, three *simultaneous* quality criteria have been defined [9]. The results have to be

- Unique,
- Relevant, and
- Predictive.

These terms are rigorously defined. Uniqueness, a mathematical term, refers to the fact that the end result, the

corrosion rate, must first of all be explainable by a unique set of corrosion kinetics. For example, the average weight loss corrosion rate can be explained by a decreasing, increasing, or steady state corrosion rate over the period of the test, and is, therefore, only for the steady state a unique value. It follows that almost all corrosion test results based on average weight loss violate the first quality criterion and have neither predictive nor mechanistic value.

Relevancy is obtained only if all operative parameters are controlled at constant levels during the test. The operative parameters are those that directly affect the corrosion mechanism. This definition creates a problem, in that the corrosion mechanism is itself based on results obtained from corrosion tests. Mechanistic understanding cannot possibly be complete if the relevancy condition has not been adhered to. Therefore, the study of corrosion and corrosion inhibition mechanisms is an ever-evolving field, as one can learn from history.<sup>4</sup> For example, inhibitor effectiveness is now known to be pH dependent. In CO<sub>2</sub> corrosion testing the pH increases continuously due to the formation in solution of bicarbonate (a buffering agent). It follows that unless the pH is maintained constant, the final result, even if at the end of the test a steady state corrosion has been measured, cannot be said to be relevant because the final pH is not defined. Similarly, if testing is performed in sour media, the build-up of (insoluble) iron sulfide results in a diminished inhibitor concentration due to generally unknown adsorption effects, and again, the results cannot be said to be relevant.

Predictiveness refers to the fact that during the corrosion test all operative parameters must be controlled at levels prevailing in the field. Even if relevancy has been adhered to under the above definition, the test results may not be predictive unless the test parameters mirror field conditions. In the past 20 years major problems arose because inhibitors tested in the laboratory under some flow conditions failed in the field at the predicted concentrations because the field flow conditions were not properly assessed and duplicated in the laboratory.

To illustrate the above, inhibitor evaluations by means of the so-called "Wheel Test" [10] fail all three quality criteria. This test has in the past been used extensively to evaluate corrosion inhibitors for use in oilfield applications. The results are always based on weight loss and are, therefore, not unique. They are not relevant, because as the test bottles turn on the wheel to which they are affixed, the flow regime or agitation is not defined. The results are also not predictive, because the controlling variables do in general not reflect field conditions.<sup>5</sup> Disregarding these most basic quality criteria has in the past been, and still is, a major reason for costly failures in the field of oil and gas production.

### Tests, Test Methods, and Test Methodology

The distinction between the three terminologies begins to approach a paradigm shift in the approach to corrosion

<sup>4</sup>A full discussion of this paradigm would exceed the framework of this article. However, one can readily understand that improved understanding of mechanisms can only come from discrepancies between new results and what might have been expected on the basis of mechanistic understanding. It therefore behooves the technician to be constantly on the lookout for such discrepancies.

<sup>5</sup>For a critical discussion of this test method see Ref 4.

testing. A **corrosion test**, many of which have been used to evaluate inhibitors, is nothing more than the hardware with which such evaluations are performed. A detailed compilation of all manner of corrosion tests has been presented by A. D. Mercer in 1985 [5] and updated recently in 1994 [6]. These compilations, however diligently brought together, merely describe and reference the various approaches to test apparatuses researchers have pursued over the years. It is interesting to note that Mercer characterized the state of the art of inhibitor testing as follows:

Since corrosion inhibitors are used in a wide range of applications, no universal test method is possible. Furthermore, even within one type of application, there will be a range of requirements and a diversity of opinion on the definition of effective inhibition [5].

In other words, the quest for a standardized corrosion inhibitor evaluation test is as elusive as it ever was and continues to be so.

More recently, particularly in discussions of various NACE or ASTM working groups, one encounters the terminology of **test method**. By this term one generally understands the combination of test (hardware) and the applications of it, which includes the preparation of the solutions, the metallurgy, the preparation of the test specimen, the monitoring of what happens during the test period, and the final evaluation of the results. Many of these steps have been standardized in various standards [11–21].

A third concept comprises the **test methodology**. Here one goes a step further and includes the system analysis (often complex and time consuming) of all the environments the test has to address and the objectives the results have to fulfill. What results from such analysis is not only a clear idea of the conditions to which a metal has to be resistant, or under which an inhibitor has to afford protection, but also an experimental test matrix that has to be executed before the application of the specific metallurgy in conjunction with an inhibitor can be reasonably recommended (see also Chapter 1).

## DISCUSSION OF SOME BASIC ASSUMPTIONS

### Protection and Inhibitor Adsorption

The conduct of corrosion or corrosion inhibition tests always aims at some objective, and therefore, is based on some implicit or explicit assumptions. For instance, the effectiveness of a corrosion inhibitor is preferentially expressed in terms of percent protection ( $P^*$ ) formulated by the well-known equation:

$$P^* = \left( \frac{cr^o - cr^i}{cr^o} \cdot 100 \right) \quad (1)$$

where:

$cr^o$  = uninhibited corrosion rate,

$cr^i$  = inhibited corrosion rate.

FIG. 1—Inhibitor performance in constant pH kettle test; note dashed line represents Langmuir behavior.

The assumption in Eq 1 is the notion that the blank (uninhibited) and inhibited corrosion rates are obtained under the same conditions. This is rarely the case and is certainly not true for the much studied  $\text{CO}_2$  corrosion. There are many other commonly held assumptions in corrosion inhibitor testing that are equally not true and will be discussed in greater detail below. Let's first look at some of the objectives that may be involved in corrosion inhibitor testing.

The degree of protection ( $P$ ), or percent protection ( $P^* = P \times 100$ ), has been used in the past extensively to assess inhibitor effectiveness and to compare the performance of different products. For this purpose,  $P^*$  is customarily plotted against inhibitor concentration. Because 100% protection is approached asymptotically as the concentration increases, differentiation between products is difficult. Alternatively, differentiation is accomplished numerically by comparing percent protection at a given concentration. This comparison neglects the different performance characteristics of inhibitors because, as will be shown below, one product may surpass another at one concentration while lagging behind at another concentration. For these reasons, and essentially totally practical purposes, another presentation of the results was proposed with some interesting conclusions.

Assume, as has been proposed in the past, that inhibition follows some basic law of adsorption of the inhibitor on the metal surface, or more realistically on a corrosion product covered surface, and that the degree of protection is somehow related to the degree of coverage. The simplest of adsorption isotherms is the Langmuir isotherm, which states that the degree of coverage is related to the concentration as follows:

$$\theta = \frac{K \cdot c}{1 + K \cdot c} \quad (2)$$

where:

$\theta$  equals the degree of coverage,  
 $K$  is the adsorption constant, and  
 $c$  is the (adsorbate) inhibitor concentration.

Assuming that degree of inhibition equals the degree of coverage,<sup>6</sup> one obtains an explicit relationship between the degree of inhibition and the concentration, which can be expressed as:

$$c = \frac{1}{K} \cdot \frac{P}{(1-P)} \quad (3)$$

Using Eq 3, presented graphically in double logarithmic fashion, as used below in Fig. 1, not only leads to better distinction between products, but also demonstrates some of the fundamentals that need to guide inhibitor testing and the interpretation of the results.

### Basic Test Procedures

There are two (perhaps three) basic corrosion tests that can be performed. The first, and certainly the most prevalent, is the so-called constant inventory test. Here, a metal specimen is exposed to a finite amount of test liquid (usually preconditioned) in a closed container. The test has a relatively short duration during which the corrosion rate asymptotically approaches a *pseudo* steady state. However, over this period of time all conditions keep changing, from the composition of the solution to the metallic surface conditions (real surface area, scale buildup, accumulation of iron carbide, and many more). Constant Inventory tests are characterized by the liquid volume to specimen surface area ratio. This ratio should always be maximized.

The second procedure is the flow through test. Here, a properly conditioned fluid is continuously flowed over the metal specimen [22]. While this does not eliminate initial effects, a more realistic steady state can be obtained if the test duration is long enough. The changes in the corrosive fluids are characterized by the flow rate and the total corrosion per unit time (corrosion rate  $\times$  surface area), and in some cases, the volume of the container holding the corrosion probe.

Third, a hybrid procedure is being used frequently where conditioned fluids are circulated over the test specimen from a reservoir [20]. If the reservoir is large enough, changes in fluid composition can be minimized. A particularly ingenious version of this hybrid test method has been developed in Norway [23], where the circulating fluids are continuously reconditioned by automatic pH maintenance and corrosion product removal. The distinction of these three approaches must always be kept in mind when discussing corrosion and inhibition tests.

The degree of protection afforded by an inhibitor ( $P$ ), or the percent of protection ( $P^* = P \cdot 100$ ) is based, as per Eq 1, on two measurements: the blank (uninhibited) and the inhibited corrosion rates. The measurements themselves will be discussed below. At this point we wish to point out that for  $P$  to have any real meaning, the measurements must be obtained under identical conditions. This means that not only the initial (nominal) conditions, but the final conditions as well must be identical. This requirement is hardly ever met in constant inventory tests, except perhaps in strong

<sup>6</sup>This assumption by no means implies a factual relationship, but is used as a working hypothesis to test whether corrosion inhibition might fulfill the assumptions underlying the Langmuir isotherm.

acid solutions, and can be most effectively approximated in flow through systems.<sup>7</sup> The reasons are obvious: during the test the composition of the solution, as well as the nature of the metal surface, keeps changing. These changes are more rapid and pronounced in the blank test. Therefore, it is impossible in constant inventory tests to obtain results that are strictly comparable, unless special provisions are taken.

### Effects of pH and Flow

Since the pH is probably the most important of the controlling test parameters, particularly in CO<sub>2</sub> corrosion, it can be held constant by continuous pH controlled acid injection as the corrosion process progresses [9]. This prevents the build-up of iron carbonate scale. Indeed, in the constant pH test, using a brine saturated with CO<sub>2</sub> at one bar, the blank corrosion rate was found to be constant (or slightly increasing) at about 220 mpy for at least 48 h, whereas in the simple constant inventory test without pH compensation the corrosion rate would decrease from an initial 220 mpy to 20 mpy after 24 h due to iron carbonate "passivation," with a concomitant pH increase of from 4 to about 6.

In order to keep conditions as constant as possible the constant pH "Kettle Test" was used to evaluate a large series of corrosion inhibitors of which a few results are shown in Fig. 1, represented according to Eq 3.<sup>8</sup> The inhibitors were intended for use in oil field systems and were, therefore, tested in fluids containing brine and a hydrocarbon phase saturated with 1 bar CO<sub>2</sub>. The results show the following:

- None of the inhibitors obeyed the Langmuir isotherm. In fact, all of them became more active than predicted with increasing concentration.<sup>9</sup>
- The slopes of the performance characteristics are not the same. As a consequence, comparison at an arbitrary concentration would be misleading.

When the same inhibitors were examined in the floating pH Kettle test,<sup>10</sup> under otherwise identical conditions (Fig. 2), it was observed that INHIB-28 performed slightly better in the cpHKT, while for INHIB-85 the slope of the performance changed leading to a crossover of the two curves. INHIB-337 performed better in the stdKT (higher pH) but exhibited saturation at already low concentrations. However, it needs to be noted that the degrees of protection derived from constant pH test results are real, because the blank corrosion rate was well identified. The blank rate in the floating pH test is not well defined. The continuously

FIG. 2—Non-pH compensated std. kettle test (note that the blank corrosion rate was assumed to be 220 mpy, although in a floating pH test the blank rate is not defined).

increasing pH causes a continuous decrease of the blank rate. As a consequence, comparing the degrees of protection of inhibitors at different pH's is nearly impossible because of the nonsteady state blank corrosion rates.

These results show that practical corrosion inhibitors<sup>11</sup> are single-minded entities hard to squeeze into a mechanistic framework suitable for easy comparison. This means that ranking of inhibitor performance, by means of percent protection based on one test procedure and one concentration only, necessarily leads to erroneous, misleading, conclusions. Indeed, the work of Garber [24] had led to the same results. Garber tested some 50 oilfield corrosion inhibitors from different companies in six or seven different tests and found it impossible to arrive at a uniform performance ranking. Additional work by the author further substantiates these conclusions [25]. It is, therefore, nonsensical to argue that screening and ranking inhibitors are only for the sake of discarding the bad and then continuing to test only the good ones. It follows from the above that this is a totally arbitrary paradigm, which depends on the test procedure and the specific test conditions, and in general, bears no relationship to field application. In particular, the above demonstrates that the percent protection is not independent of pH.

The world, however, is not unidimensional, and there are many more parameters that affect inhibitor performance, including their interactions. One parameter that has caused workers in this field much concern and consternation is the flowrate under which the inhibitors are tested. Table 1 below summarizes some results obtained under controlled constant pH and various degrees of agitation in Kettle Test arrangements. Even though the experimental design was not complete, the data show that with the exception of Inhibitor D the other three are either pH or flow sensitive or both.

<sup>7</sup>Strictly speaking, the conditions of constancy of environment and true steady state can only be obtained with point measurements in flow-through systems.

<sup>8</sup>The degrees of protection were determined on the basis of the steady state corrosion rates obtained at the end of the test run determined from differential iron counts.

<sup>9</sup>From a mechanistic point of view this is not surprising because all inhibitors are either by nature, or due to formulation, surfactants. Therefore, as concentration increases the micelle concentration in the aqueous phase increases as well, and adsorption occurs by mechanisms other than envisaged by Langmuir.

<sup>10</sup>The blank corrosion rate here was assumed to be the same as in the cpH test, i.e., the initial corrosion rate.

<sup>11</sup>As opposed to single compounds with identical functional groups, and only distinguished by hydrocarbon chain length, as are often used in model studies.

**TABLE 1**—Average differential corrosion rates (in mpy) for the test period of 2 to 24 h, excluding initial corrosion transients.

pH	Inhibitor	Stirring Rate (rpm)	
		400	800
3.9	F		182
	C	0.15	21.6
	A		1.82
	D	0.5	0.57
4.9	F	0.3	3.6
	C	0.16	1.2
	A		0.2
	D	0.85	1

Note: Inhibitors F and C tested at 20 ppm; Inhibitors A and D at 50 ppm.

To summarize the above discussion of the status quo, it may have become clear that the degree of protection in general is a useless number because:

- It is defined only for one concentration, and
- Refers to only one test condition.

Furthermore, because the inhibitor performance characteristic (protection versus concentration)

- Is different for different inhibitors, and
- Varies from test condition to test condition,

ranking of inhibitors in so-called screening tests has no practical value within the quality criteria defined above.

## PURSuing A NEW PARADIGM

### The Steady State Corrosion Rate

Corrosion testing and corrosion inhibitor evaluation are done (apart from mechanistic studies) for the purpose of determining

- Whether corrosion preventive measures are necessary, and
- Whether the required life-time can be achieved with an inhibitor.

From a practical point of view it is only necessary to assess the level of the inhibited corrosion rate. The degree of inhibition is immaterial, once one has decided that inhibition is required. In order to answer these questions, it is necessary to establish a valid steady state corrosion rate that is predictive of field conditions. This is actually a rather demanding task because

- In the field the steady state is measured in years, while in the laboratory test, periods are generally of the order of 24 to a few hundred hours. Tests exceeding one week are usually only run in cases of extreme importance.
- In all laboratory tests the corrosion rates are subject to an initial transient characterized by a transition from high to low corrosion rates. During this transient the actual surface area adjusts to a steady state (constant roughness).<sup>12</sup>

<sup>12</sup>It has been observed that for polished probes the uninhibited corrosion rate increases, while for sandblasted coupons the initial corrosion rate shows a downward trend.

**FIG. 3**—Inhibited differential corrosion rates obtained in a HSACT experiment based on iron counts. The insert shows that the decrease of the corrosion rate follows a power law.

- Corrosion product scales can build up and inhibitors interact with these scales, or may actually become part of these scales (as, for instance, in the case of iron sulfide). Due to inhibitor adsorption the nature of the scales (crystal structure, porosity, and semiconducting properties) changes as well. While adsorption is usually considered fast (seconds or minutes), the structural relaxation of the metal surface composite is generally slow (hours to days).

The time dependent processes involved in inhibitor testing make it necessary to monitor the corrosion kinetics during the testing in order to estimate at what point a steady (or pseudo steady) state may have been achieved. A typical example is shown in Fig. 3. The data were obtained in the *High Speed Autoclave Test* [26] (HSACT, details see below) under 1000 psi CO<sub>2</sub> partial pressure and 1500 rpm of the cage holding the coupons. The inhibitor was added from the beginning. The individual points represent differential corrosion rates for subsequent time periods obtained by iron count measurements and confirmed by the overall weight loss.<sup>13</sup> The corrosion rates decrease in hyperbolic fashion, which actually translates to a near straight line decrease if plotted double logarithmically. The average corrosion rate for the entire test was 7 mpy, whereas the corrosion rate determined for the last 20 h was less than 2 mpy. Risk assessment of field conditions may indicate that 7 mpy is excessive, while 2 mpy is acceptable. This highlights the importance of the ultimate corrosion rate achievable under inhibited conditions. It must, however, be kept in mind that during the above constant inventory test, about 100 ppm of iron were introduced into the brine. This corresponds to about 210 ppm of bicarbonate, which in turn resulted in a calculable pH change. The closer these final conditions approach field conditions, the more predictive the results. Changes in the environment can be controlled by properly assessing the ratio of brine volume to surface area.

<sup>13</sup>The data are plotted in the center of the time period for which they were obtained, indicating the true average corrosion rate for that period.

### Alternate Performance Characteristics and Cost Effectiveness

If experiments of the above nature are carried out at different concentrations, an inhibitor performance characteristic can be obtained. A typical example is shown in Fig. 4. In most instances, one finds that double logarithmically again a straight line is obtained. Indeed, if Eqs 1 and 2 are combined, one obtains a relationship between the corrosion rate and the inhibitor concentration as expressed in Eq 4.

$$cr^i = cr^o \cdot \frac{1}{1 + K \cdot c} \quad (4)$$

If  $Kc \gg 1$  an inverse relationship between the concentration and the inhibited corrosion rate results where the position of the curve depends on  $cr^o/K$ , and the slope is 1 for the Langmuir assumptions. This is demonstrated in Fig. 4. However, the slope of the experimental line is much steeper than predicted, again demonstrating that these inhibitors adsorb much more strongly than the Langmuir assumption would predict. Another interesting effect, routinely observed, is the fact that with higher inhibitor concentration (better inhibition) the average and final corrosion rates are closer together. This is to be expected, since better inhibition also tends to minimize initial effects, which then become negligible over longer test periods.

From Fig. 4 one can now determine the effective inhibitor concentration, i.e., the concentration at which the desired steady state corrosion is obtained; and since the concentration translates directly to cost, Fig. 4 also lends itself to determine the cost-effectiveness of inhibition, which is defined as the cost to achieve a certain objective. Now, one has the means to compare different products objectively on a cost-effectiveness basis.

It is a general shortcoming of technicians in this field to assume that once such comparisons have been established for

FIG. 4—Performance characteristic of an oilfield corrosion inhibitor in the HSACT at 1000 psi CO<sub>2</sub> partial pressure, 200°F and 1500 rpm. The hypothetical Langmuir behavior is shown to indicate the much stronger adsorption of the inhibitor.

one set of conditions, they can harmlessly be extrapolated to different conditions. This is far from reality. It has already been shown that different corrosion inhibitors behave differently under different conditions, while a single inhibitor can change its behavior unpredictably as conditions change. The example to be shown here in order to illustrate the point deals with the effects of pressure and velocity. Specifically, it was found that the CO<sub>2</sub> partial pressure and the speed of rotation of the cage in the HSACT affect the cost-effectiveness in a complex unpredictable fashion [27,28]. Figure 5 shows a contour plot of inhibited iso-corrosion rate lines from 5 to 30 mpy for 100 ppm inhibitor on a J-55 steel in a pressure-velocity grid. Clearly, the inhibited corrosion rates increase with both velocity and CO<sub>2</sub> partial pressure. However, there is a complex and unpredictable interaction between these two parameters, reflecting the nonlinearity of the effects.

Alternatively, one can focus in on the cost-effectiveness and present the data in terms of the necessary inhibitor concentration required to achieve a given corrosion rate (field performance). Figure 6 shows a contour plot for the inhibitor concentration necessary to achieve a steady state corrosion rate of 1 mpy in the velocity/pressure grid with the experimental data highlighted. The data are for a specific metal. Clearly, velocity (flow intensity, rpm) is a major parameter, but increased pressure also demands higher inhibitor concentrations, particularly at higher velocities. This reinforces the notion that there is an interaction between the two parameters and it is nonlinear. Additional parameters that affected this evaluation were the metallurgy and the brine to hydrocarbon ratio. Indeed, the inhibitor concentration required to inhibit L-80, an alternate oilfield carbon steel, was quite similar under the milder conditions but doubled under the most aggressive condition of 1500 rpm and 750 psi CO<sub>2</sub> partial pressure. Alternate inhibitors, which had been selected as promising in screening tests, performed worse in varying degrees.

The new paradigm discussed here recognizes that performance in a realistic parameter field is the predominant

FIG. 5—Contour plot of iso-corrosion rate lines for J-55 at 100 ppm inhibitor evaluated in the HSACT. The points indicate the experimental matrix and results.

FIG. 6—Contour plot for J-55; inhibitor concentrations necessary to achieve 1 mpy; based on final corrosion rates from iron counts.

characteristic to be established for field application and, therefore, must focus on

- Steady state long-term performance of inhibitors within a realistic parameter field.
- The extent of the parameter field must be derived from a detailed system analysis.
- It can never be assumed that results from one set of conditions can be extrapolated to other conditions without penalty.

In order to follow such guidelines, one must also have a good grasp of the value of the results obtainable from certain experimental facilities, as well as the controlling parameters, such that they can be varied over the range of interest. Industry abounds with glaring examples where neglect of realistic evaluation of inhibitors resulted in catastrophic and expensive failures.

## CORROSION RATE MEASUREMENTS

Weight loss corrosion rates, which represent an average of corrosion over the test period, are useless from a predictive point of view, but are often used in conjunction with other measurements for quality assessments. Corrosion kinetics can be measured in different ways. Most favored are electrochemical techniques. They are, however, contrary to common belief, indirect techniques and must be properly calibrated and interpreted to be useful. If corrosion products are soluble in solution (as, for instance, iron carbonate), the buildup of such in solution can be used to monitor how corrosion progresses. Hydrogen, a byproduct of anaerobic corrosion, can also be used to monitor kinetics. Less common, but equally direct, are methods that use the removal of radioactivity from irradiated surfaces. Kinetic measurements have also been carried out with electrical resistance probes. As a general principle, no one method is in itself without some problems and should, therefore, always

FIG. 7—Cleaning procedure of corrosion coupons for weight loss determination yields scale weight, total corrosion weight loss, and error due to cleaning procedure.

be interpreted on the basis of mechanistic understanding, and furthermore, be verified by multiple approaches.

## Weight Loss Corrosion Rate Measurements

While weight loss corrosion rate determinations by themselves are of little value because they are a priori not unique, they can and must often be used for verification of other data, or simply for quality control purposes. For example, iron count measurements for the purpose of determining corrosion kinetics can be misleading if, during the corrosion process, a corrosion product scale forms. In the above examples, the corrosion rates determined from iron counts were verified by establishing a mass balance between total weight loss, iron found in solution, and iron contained in the scale. Similarly, electrochemical measurements in inhibited solutions must at all times be verified by alternate measurements, weight loss being one of them.

In order to determine the weight loss on a corroded coupon, it is necessary in most instances to remove first adherent oil and inhibitor (which is usually done with acetone), and second, the corrosion product scale. In many instances, the scale weight is of interest as well, in which case the coupon is weighed before scale removal. There are many ways to remove the scale, some of which have been standardized [11]. For iron or steel samples, inhibited acid is used at an appropriate temperature. The important part of the cleaning procedure is an assessment of the metal loss during the cleaning procedure. This must be done by repeated timed immersions into the cleaning acid after the scale has been removed. Figure 7 illustrates the procedure. The additional weight loss due to the cleaning acid is extrapolated as shown. When the amount of metal removed in repeated cleanings is translated to a corrosion rate, one gains a measure of the possible error that can occur due to cleaning. In the above example, the total weight loss is 190.3 mg, corresponding to 24.4 mpy. When the weight loss due to cleaning is subtracted the corrosion rate is 23.5 mpy. The cumulative loss during four cleanings corresponds to about 1 mpy or 0.25 mpy per cleaning (about 2 mg). These numbers indicate more or less

the minimum corrosion rate that can be determined by weight loss in this example and highlight the importance of not only choosing the best conditions for cleaning, but controlling them, as well as an awareness of the possible errors introduced by cleaning. This is underlined by the fact that when inhibitors are used one often targets corrosion rates below 1 mpy in order to minimize and eliminate localized corrosion as well.

## CORROSION RATES FROM CORROSION PRODUCT ANALYSIS

### Iron Counts

The buildup of soluble corrosion products can be used to monitor corrosion kinetics. This method has been used extensively in oil field corrosion inhibitor testing, particularly in sweet ( $\text{CO}_2$ ) systems with only small amounts of  $\text{H}_2\text{S}$  present [29]. Iron analysis in the laboratory is most rapidly done on the bench with the Hach method (Phenanthridine) [30], although a host of other wet chemical methods are applicable. Instrumental methods include Atomic Absorption Spectroscopy (AAS) and Inductively Coupled Argon Plasma Spectroscopy (ICAP). While both these methods are well suited for high volume routine analysis, care must be taken that the samples are not contaminated by even traces of hydrocarbons. This includes soluble hydrocarbons such as methanol, chelating compounds such as EDTA, or scale inhibition products. Also used in the laboratory is Ion Chromatography (IC). This latter method is even more sensitive to sample composition and not recommended on a routine basis.

Iron counts are first used to confirm weight loss and scale weight. However, more interesting is the use of iron counts for kinetic studies, as shown in Fig. 4. The incremental increase of iron in solution between subsequent measurements is converted to a differential corrosion rate for the time period between measurements. Since the differential corrosion rate is an average for the specific time period, it should be plotted in the center of the period rather than at its end. Measurements of this kind are used for mechanistic studies in order to assess the rapidity of the onset of inhibition and related effects of inhibitor composition. However, it is also important, as has been pointed out above, to assess the steady state inhibited corrosion rate. A note of caution: Even if thermodynamically the corrosion products are soluble, they can still form on an actively corroding surface. For this reason the scale formation has to be monitored, and if important, the kinetics have to be corrected for scale formation. It has been observed, for instance, that iron carbonate formation in a corroding system is fast, but its dissolution rate is frustratingly slow.

## HYDROGEN MEASUREMENTS

### Direct Hydrogen Measurements

Molecular hydrogen is the other corrosion byproduct in aqueous anaerobic corroding system. In closed, oxygen free, constant inventory systems (by far the most prevalent test

systems), hydrogen builds up in the gas space at a rate reflecting the corrosion rate. By monitoring the hydrogen concentration versus time, and calculating the differential hydrogen evolution rates, corrosion kinetics can be determined. The method is old and predates in its application electrochemical measurements. In cases where electrochemical sensors made from the metal of interest are not available, or in systems where electrochemical measurements are virtually impossible, hydrogen evolution measurements have proved extremely valuable in recent times. The author has developed a methodology to study the behavior of corrosion inhibitors in high pressure, high temperature systems for oilfield steels under extreme flow intensities (HSACT) [31]. Using the rotating cage (see below) and oilfield tubular steel coupons (J-55, N-80, L-80, etc.), it would have been impossible to use electrochemical techniques, and iron counts were not applicable either when the brine was buffered into the pH range where solid iron carbonate could form. Small amounts of gas were continuously and automatically sampled from the gas space in the autoclave (mainly  $\text{CO}_2$ ) and analyzed by gas chromatography at a frequency of about 4 times per hour for the 100-h duration of the experiment. The sensitivity of this arrangement was 1 mpy in about 10 h, or sufficient to establish corrosion rates in the range of 0.2–0.5 mpy, which under the prevailing conditions corresponded to extremely efficient inhibition. The methodology was also used to establish inhibitor action on severely pre-corroded specimens, a feat that would have been literally impossible electrochemically (see below).

### Indirect Hydrogen Measurements

Hydrogen as a byproduct of corrosion can also diffuse into the metal. If corrosion occurs on one side of a metal wall, a hydrogen stream can be observed on the other side [32,33]. This phenomenon of hydrogen diffusion through metal has been routinely measured in the Devanathan-Stachurski cell and made use of in many different ways. In the field, it has been used to monitor inhibitor efficiency by means of various hydrogen probes [34]. Theories have been developed to assess the hydrogen concentration in the metal based on the diffusion rate and to establish correlations with the hydrogen cracking phenomenon. This area is complex and full of pitfalls, and for a detailed discussion the reader may be referred to some original literature. Suffice it to say here that in the presence of corrosion inhibitors, there is no general relationship between the corrosion rate on the corroding side of the metal and the hydrogen diffusion rate observed on the bare side of the metal. Corrosion inhibitors can either push hydrogen into the metal or prevent it from entering. Thus the reduction of the hydrogen diffusion rate observed upon the application of an inhibitor has no relationship to the degree of inhibition occurring on the corroding side. Similarly, the rate of hydrogen exiting the metal is controlled by the recombination reaction occurring on the exit side. If this rate is much faster than the diffusion rate, the hydrogen concentration on the exit side is zero and the hydrogen concentration in the metal can be estimated from the diffusion current on the basis of the first Fick's law. However, it is also known that the

recombination rate on the exit side depends on the surface condition and the nature of extraneously and fortuitously adsorbed chemicals. Thus, it has been observed that certain chemicals can retard the hydrogen exit reaction to a degree, such that the concentration in the metal is much greater than estimated from diffusion equations. Hydrogen diffusion measurements in the presence of inhibitors constitute waters difficult to navigate under the best of conditions. (For an in-depth discussion see also Ref 35.)

## ELECTRICAL RESISTANCE MEASUREMENTS

ER-measurements are based on the fact that as corrosion progresses the metal becomes thinner. Since the resistance of a metal strip (or wire) depends on its thickness, such probes lend themselves to direct corrosion rate measurements and the study of corrosion kinetics; hence, with respect to inhibitors, their effectiveness can in principle be studied with a minimum of basic assumptions.

The resistance for a metal strip can be expressed

$$R = \rho \cdot \frac{l}{A} = \rho \cdot \frac{l}{\Delta \cdot w} \quad (5)$$

where:

$R$  is the resistance in ohms,  
 $A$  is cross-sectional area in  $\text{cm}^2$ ,  
 $\rho$  is the specific resistance of the metal in  $\text{ohm} \cdot \text{cm}$ ,  
 $l$  is the length of the metal strip,  
 $w$  is the width of the strip.

A preferred probe for ER measurements is a wire. In this case, the resistance is inversely proportional to the square of the radius of the wire.

$$R = \rho \cdot \frac{l}{\pi \cdot r^2} \quad (6)$$

Practically, resistance measurements are made with a d-c or pulsed current Wheatstone bridge. There are many commercial instruments that incorporate this principle. The difficulty, of course, is the fact that resistance is inversely proportional to either the thickness or radius of the probe, and therefore, long-term results have to be interpreted carefully. Alternatively, such measurements can be made by measuring a d-c current at a constant potential (using, for example, a potentiostat).

$$I = V \cdot \frac{w}{\rho \cdot l} \cdot \Delta \quad (7)$$

Here, the current is directly proportional to the thickness of the probe via some probe constants.<sup>14</sup> Hence, the slope of the current/time curve is directly proportional to the corrosion rate, and changes in the slope represent the corrosion kinetics [36].

<sup>14</sup>The error introduced by the fact that the probe also corrodes from the side is generally minimal since the width is 10 to 20 times greater than the thickness.

It is well known that the specific resistance  $\rho$  is temperature dependent in a well-defined but metal specific way. In commercial instruments, this is accounted for by means of a noncorroding reference element built into the probe. However, commercial probes are, in general, still temperature sensitive because of the temperature gradient present when inside and outside temperatures differ significantly. If the measurements are accomplished according to Eq 7, temperature compensation can be accomplished by means of a thermocouple via microprocessors.

Whenever a current flows along a resistance element, a voltage (potential) drop establishes itself along the probe. This potential drop causes electrochemical reactions to proceed. The rate of these grows with the conductivity of the electrolyte. This phenomenon has actually been observed as an instantaneous current drop when inhibitors are added and is especially pronounced in concentrated hydrochloric acid. It is, however, an artifact and does not materially affect the  $I = f(\text{time})$  or the  $\Delta = f(\text{time})$  behavior. When corrosion product scales are present, however, the nature of this voltage drop along the probe can lead to artificially induced localized attack. This has also been observed in  $\text{H}_2\text{S}$  containing systems that were contaminated with oxygen.

## ELECTROCHEMICAL MEASUREMENTS

### Theoretical Principles

Electrochemical corrosion rate measurements have many advantages, in particular, because they are nearly instantaneous, they lend themselves to the study of corrosion kinetics, the assessment of the steady state, and, with regards to inhibitors, the inhibition transients. This is especially important in the laboratory where the exclusion of initial experimental effects is imperative for establishing predictive results.

The various electrochemical techniques employed for corrosion rate measurements have been discussed in detail by Scully in Chapter 7 and extensively referenced. This chapter also highlights the many pitfalls encountered with the interpretation of electrochemical polarization measurements. Some of these difficulties are generic to all polarization techniques, while others are more germane to inhibition. These latter ones will be discussed in greater detail.

At the core of all electrochemical techniques is the translocation of an external current flowing through a corroding electrode as a result of a potential perturbation. It does not matter whether this perturbation is the result of external d-c or a-c polarization, or manifests itself as electrochemical noise attributable to the inherent anisotropy of the metal. In all cases, one needs to come back to the fundamental relationships describing electron exchange at the metal surface. This relationship in its simplest form was established empirically by Tafel in 1904 [37] for general current/potential relationships, and later derived for corrosion currents by, among others, Stern and Geary [38] is:

$$\log i = \log i_{\text{corr}} + \frac{\eta}{\beta} \quad (8)$$

such that 
$$\frac{d(\eta)}{d(\log i)} = \beta \quad (9)$$

where

- $\log i$  is the external polarization current,
- $\eta$  is the polarization overpotential ( $E_{cor} - E_{applied}$ ),
- $\beta$  is the slope of the  $\log i$  versus potential curve, normally referred to as the Tafel slope.

The Tafel slope has a well-defined thermodynamic meaning: in essence, it represents the energy barrier for electron transfer across the metal/liquid interface. Anodic and cathodic Tafel slopes can easily be determined by polarization experiments. In order to fulfill the requirements of its definition, one should obtain a straight line of  $\log i$  versus  $\eta$  over two to three decades of current. In practice this is hardly ever the case, indicating that other controlling mechanisms are at play.

### Linear Polarization

In order to avoid some of the difficulties cited by Scully, Stern and Geary showed that for small potential perturbations Eq 8 can be linearized<sup>15</sup> such that

$$i_{cor} = \frac{i_{ext}}{\eta_{pol}} \cdot \frac{\beta_a \cdot \beta_c}{2.3 \cdot (\beta_a + \beta_c)} \quad (10)$$

where:

- $i_{ext}/\eta_{pol}$  = the polarization admittance, or  $1/R_p$ , the inverse of the polarization resistance, and the second term in Eq 10 is often referred to as the  $\beta$  factor.

Equation 10 is valid for small polarizations of about 10 mV. Ideally, anodic and cathodic Tafel slopes should be of the order of 60 and 120 mV, respectively. This would result in a  $\beta$ -factor of about 17 mV. However, in practice, Tafel slopes much larger than this are measured. Table 2 below shows  $\beta$ -factors for various anodic and cathodic "pseudo"-Tafel slopes.

These hypothetical calculations show that the assumption of ideal behavior can easily lead to underestimating the corrosion rate by a factor of 2.5. In practice, even higher Tafel slopes have been observed for a variety of reasons.

### The IR-Problem

The first problem encountered with electrochemical measurements (either potentiostatic or potentiodynamic) is the

**TABLE 2**— $\beta$ -Factors for various anodic and cathodic measured or pseudo Tafel slopes.

Cathodic Tafel Slopes	Anodic Tafel Slopes			
	60	100	150	200
60	13.04	16.30	18.63	20.07
120	17.39	23.72	28.99	32.61
150	18.63	26.09	32.61	37.27
200	20.07	28.99	37.27	43.48

fact that the applied overpotential ( $\eta$ ) not only reflects the charge transfer resistance, but also the resistance associated with current flow. One must, therefore, carefully think about this second component usually called the IR-drop. As discussed in Chapter 7, the most obvious cause for IR drop is the solution resistance. This can be minimized in the laboratory by properly positioning the reference electrode. However, in practice, where commercial three electrode arrangements of the same material are used, the reference electrode is hardly ever close enough to the working electrode to eliminate the IR drop. A typical example was shown in Ref 9, where the initial corrosion rate for CO<sub>2</sub> in a 300 ppm TDS brine measured by iron counts was 10 times higher than that measured by linear polarization. While this may be an extreme case, it reflects the magnitude of the effects one may encounter.

### Corrosion Product Layers

Resistance to current flow also occurs as a consequence of solid corrosion product buildup on the metal surface. This phenomenon is most pronounced in environments containing H<sub>2</sub>S. Iron sulfide is a semiconductor whose conducting properties depend on the nature of the environment. It had been observed [39] that the anodic and cathodic polarization curves on iron sulfide covered electrodes are linear rather than exponential. In this case, the current flow is entirely controlled by the charge transfer across the interphase (not interface) consisting of FeS. The polarization admittance ( $1/R_p$ ) becomes

$$\frac{i_{ext}}{\eta_{pol}} = \frac{a_c + a_a}{a_c \cdot a_a} \quad (11)$$

where  $a_a$  and  $a_c$  are the anodic and cathodic ohmic resistances (rather than Tafel slopes). The polarization admittance is no longer proportional to the corrosion current. Since most practical systems (oxides, carbonates, and many others [40,41]) exhibit mixed control, the  $\beta$ -factors can assume an almost infinite array of values.

### The Interphase in the Presence of Corrosion Inhibitors

When corrosion inhibitors are present, the problems become infinitely more complex. First, inhibitors in most (perhaps all) practical systems adsorb on corrosion product layers. This notion has now been quite well accepted [39].<sup>16</sup> Second, most inhibitors that are effective enough to be used in practical systems are organic in nature and more or less hydrophobic. A schematic representation of the *Interphase* forming in most practical systems is shown in Fig. 8. In order to visualize the effects of a potential perturbation and current flow across this interphase, a number of phenomena need to be considered. In the steady state of a corroding surface, many different transfer reactions must occur. From the basic corrosion reactions

<sup>15</sup>For detailed derivation see also H. H. Uhlig, *Corrosion and Corrosion Control, An Introduction to Corrosion Science and Engineering*, John Wiley and Sons, New York, 1962, pg. 341.

<sup>16</sup>For many years it was believed that inhibitors adsorb on the metal surface, and test methods were developed to examine the "filming behavior" of inhibitors. It had been shown early that such filming inhibitors need an iron sulfide film to be effective. Later the same was shown for iron carbonate systems.

**FIG. 8—Schematic representation of corroding and inhibited metal surface.**

it is clear that the positive and negative ions generated have to come together in order to maintain electro-neutrality. From this simplified model a variety of interesting possibilities emerge. While Reaction 12 always occurs at the metal surface, Reaction 12a can occur either at the metal surface or at the scale-inhibitor interface, provided that in the first case the scale is porous and permeable to the corrodent, or is a semiconductor in the second case. If the scale is a semiconductor, it must be permeable to positive charges (electron holes of metal ions) or negative charges (electrons or anions). In either case, mass transfer occurs across the scale layer, and in the case of the semiconductor, charge transfer. Any of these transfer processes can be rate determining and then fall outside the Stern-Geary assumptions. This has been discussed in detail by Heitz and Schwenk [40] and by Ijsseling [41] among others. These authors have concluded that the polarization resistance methods are not applicable in cases where protective corrosion product layers are formed.

A problem, which is rarely discussed, presents itself by the fact that because of the ongoing surface reactions during corrosion, the surface pH is not equal to the solution pH. The steady state surface pH is also disturbed during polarization. This, in essence, manifests itself by a potential shift, which is superimposed to the external polarization [42].

Since essentially all corrosion product layers have some ion exchange properties, and since these result in an osmotic pressure gradient across the interphase, one can expect a structural relaxation following a potential perturbation. It has been shown that iron sulfide scale, for instance, has a different permeability for corrosion reactions depending on solution pH [39]. This structural relaxation due to surface pH changes is slow (much slower than interfacial capacitance charging) and makes it practically impossible to measure a representative polarization curve.<sup>17</sup>

<sup>17</sup>The effect is also noticeable at the low frequencies of EIS.

When an inhibitor is applied to a corroding specimen (or when the interphase forms in a corrosion test system containing an inhibitor), the situation becomes again much more complex, and one has to consider thermodynamic as well as transport effects. The presence of the inhibitor, in essence, represents a nonaqueous phase. (It does not matter whether one deals with a typical oilfield situation, HCl inhibitors, or in fact cooling water inhibitors. In all cases, a new phase will be formed on top of the metal-scale composite.) This new phase, first of all, changes all conditions that previously prevailed at the scale-brine interface. The water concentration is greatly reduced, and with it, occur changes in the ionic strength, the pH, and the osmotic pressure. More importantly, however, the corrosion reactions and associated transport processes must occur through this additional layer, which of course represents an additional resistance; otherwise, the chemical would not be an inhibitor. It is reasonable to postulate now that the rate determining steps are no longer the electron transfer reactions (basis for Stern-Geary theory), but transport processes. This, in essence, has been confirmed by Roy et al. [43] who indicated that in the absence of truly linear Tafel regions on polarization curves obtained in inhibited conditions, physically meaningful Tafel parameters cannot be obtained from polarization curves.

Now, it is known that uncharged molecules ( $\text{H}_2\text{O}$ ,  $\text{CO}_2$ ,  $\text{H}_2\text{S}$ , and under certain circumstances even  $\text{HCl}$ ) can diffuse through organic films. It is then perfectly possible and has again been observed with certain compounds, that corrosion can occur underneath such films without any exchange of charges with the environment.<sup>18</sup> Considering the nature of corrosion inhibitors, which are rarely single compounds, coupled with the fact that they need to be formulated to be "soluble," "dispersible," or "partitioning" into the corrosive environment, the proposition of measuring their effectiveness by electrochemical means alone becomes highly questionable.

## Practical Applications

Nevertheless, electrochemical measurements, particularly linear polarization, coupled with other qualifying measurements are a valuable tool to monitor corrosion kinetics — i.e., does inhibition occur and at what point in time does one observe a steady state inhibited corrosion rate? Under no circumstances, however, can results obtained from either linear polarization or potentiostatic polarization measurements be taken as realistic within the quality parameters outlined above.

Table 3 represents an example of a comparative study of weight loss and LPR corrosion rates in inhibited hydrochloric acid at 200°F [44]. The corrosion rate was continuously monitored and plotted as a function of time. Subsequently, the area under the curve was integrated, converted to weight loss, and compared with the actual weight loss. In this manner a ratio,  $R$ , of actual weight loss versus LPR

<sup>18</sup>This is not a case for chemical corrosion; it is a case for corrosion that cannot be measured electrochemically. It has been said that this can be overcome by electrochemical impedance spectroscopy measurements. However, the models are so complex that they have little practical value at this time.

**TABLE 3**—Corrosion inhibition measurements in 17 % HCl at 200°F on various steels with three different inhibitors.  $R$  = weight loss corrosion rate over integrated LPR measurement.  $R^2$  = same for first two hours of exposure,  $R^{22}$  same for 2 to 24 h,  $R$  = same for average of total exposure time. Average 24-h corrosion rates in mpy, P indicates coupon pitted or PP pitted severely.

Inhibitor Formulation	$R^1$	$R^{22}$	$R$	AISI 1020 mpy	N-80 mpy		
					1	2	3
1	5	5.2	5.7	75	117	89	320 P
2	2.8	6.8	3.6	49	52	68 P	1130 PP
3	2.3	15.5	8.2	61.4		85 P	1820 PP

weight loss was determined. Ideally, this ratio should be one if the  $\beta$ -factor (Eq 10) were 17 mV as corresponds to anodic and cathodic Tafel slopes of 60 and 120 mV, respectively. In fact, as can be concluded from the  $R$  ratios in Table 3,  $\beta$ -Factors from 3 to 15 times larger were observed. It is worth noting that the  $R$  ratios (and hence also the  $\beta$ -factors) increase with time (except for Inhibitor 1). The degree of inhibition in all these cases was very large and the inhibitors were such that a visible hydrophobic, protective layer formed with time. It would seem understandable, if not intuitive, that under such circumstances the electron transfer reactions are no longer rate determining and that, therefore, Tafel slopes have lost their traditional meaning. From a practical point of view it is clear that without calibration of the LPR response for each inhibitor, the electrochemical measurements would underestimate the real corrosion rates by a wide margin.

Similar results were presented in [9]. In uninhibited  $\text{CO}_2$  environments it was observed that in general the  $\beta$ -factors were of the order of 15–20 mV for pH-statted test procedures. However, as soon as a corrosion product layer formed, the factors increased. It is for this reason that the original PAIR<sup>19</sup>-meter by Petrolite pre-programmed a  $\beta$ -factor of 37 mV based on extensive laboratory and field calibrations [45].<sup>20</sup> Newer commercial instruments allow the user to dial in a value for the  $\beta$ -factor. However, this presupposes that the Tafel slopes are known, and since these cannot be reliably determined as indicated above, the user is still left to guess, unless calibration procedures are in place, such as weight loss determinations or iron counts.

In general,  $\beta$ -factors increase with the presence of corrosion product layers, the density and thickness of these layers, the presence of inhibitors, and the degree of inhibition. These effects, however, are unfortunately both metal and inhibitor specific and do not lend themselves to modeling, to the point where a model could be used uniformly, or electrochemical methods could be standardized to the point where the results were meaningful without qualifications.

<sup>19</sup>PAIR stands for Polarization Admittance Instantaneous (Corrosion) Rate and is Petrolite trade mark. PAIR is the inverse of polarization resistance, and was considered a more practical terminology since the corrosion current is directly proportional to  $I/V$ , the admittance.

<sup>20</sup>This had the effect of overestimating the blank corrosion rate and underestimating the inhibited rates, thus leading to higher degrees of inhibition, because of the compounded error.

## Other Approaches

Many other techniques and methodologies have been used to monitor effectiveness in inhibitor testing and the evaluation of inhibitors. Some of these are EIS (electrochemical impedance spectroscopy), EN (electrochemical noise measurements), galvanic testing, and many variations of these methods. The theoretical bases for these techniques have been discussed by Scully in Chapter 7 of this book, and specific applications are extensively referenced there.

## Electrochemical Impedance Spectroscopy

EIS basically determines the polarization and ohmic resistances, capacitance, and inductive impedances of electrochemical systems. While these electrical terms are straightforward and can be determined relatively easily with today's frequency spectrum analyzers, their chemical meaning is considerably more complex. In simple systems consisting of a metal surface and an electrolyte polarization resistance, capacitance and ohmic resistance simply represent the electron exchange, the solution resistance, and the Helmholtz double layer capacitance, and they can be determined independently in various ways. However, when the interphase is as complex as shown for instance in Fig. 8, the chemical meaning of these electrical terms is anything but straightforward. Without expanding this discussion into a lengthy mechanistic discourse of EIS and the underlying chemical realities, let's just look at three major difficulties.

Both the corrosion product layer and the inhibitor layer constitute resistances both to the transport of charged and uncharged species. The transport of water, carbon dioxide, oxygen, etc., through this interphase cannot be measured electrochemically and manifest themselves as diffusion resistance, also called a Warburg resistance. In the EI spectrum the Warburg resistance is observed only at very low frequencies, at which the corroding system is not in steady state any longer. An attempt to separate the polarization resistance from the Warburg resistance does not make any sense, because the system is under partial or full diffusion control to begin with.

The next difficulty has to do with the inherently anisotropic corrosion under the inhibitor film. It has been observed that on inhibited carbon steels corrosion often occurs along grain boundaries, while the grain faces can be well inhibited. This is particularly prevalent in the  $\text{CO}_2$  corrosion of carbon steels where often corrosion burrows into the steel, sometime to great depths, without affecting the surface to a great extent. The corroding surface, therefore, is much smaller than the apparent surface. Hence, translating the EIS polarization resistance to a corrosion rate would result in uncharacteristically low values. (This problem, of course, is inherent in all electrochemical measurements.)

Finally, corrosion inhibitors often lead to so-called inductive loops, the chemical meaning of which is totally unclear.

Nevertheless, EIS has its place in mechanistic studies. For instance, organic inhibitor films constitute imperfect dielectric barriers. The capacitance of the interphase is no doubt affected by the inhibitor film. Therefore, if the system were to lend itself to the measurement of the incremental capacitance due to the presence of the inhibitor film, such change

could be related to the chemical nature of the inhibitor. Such speculations, however, are way off in the future.

If the system under study is in a transitional state, or inherently unsteady because of local corrosion, EIS measurements will be unstable and noisy as well. Systems that exhibit this kind of behavior consist of passive metals in an environment that has a destructive effect on the passive layer (stainless steels and valve metals (such as aluminum)). Inhibitors (both inorganic and organic) have been observed to “tame” this noisy behavior. However, in such cases, electrochemical noise measurements may be more indicated.

In summary, EIS may have its place in mechanistic studies of corrosion inhibitors and should be used to elucidate some of the mysteries of corrosion inhibition from a chemical point of view. For routine evaluations of inhibited systems EIS has no specific advantages over LPR and is afflicted with the same uncertainties discussed above.

### Electrochemical Noise Measurements

Electrochemical noise of a corroding system manifests itself as potential fluctuations (measured against reference electrode), current fluctuations (measured at constant potential via a zero resistance ammeter), or both current and potential fluctuations (when measured between two identical electrodes in the same medium). Measurements of electrochemical noise have also been discussed by Scully in Chapter 7. Inhibitors have an attenuating effect on the noise and have often been associated with the inhibition of localized corrosion. Noise measurements are passive and inherently the ideal methodology for corrosion measurements, because the electrode is not polarized in an external circuit, and hence, the steady state of all interfacial constituents and processes is not disturbed. However, in order to translate the noise signals to a corrosion rate, both the potential and the current spectra have to be reduced to a single value each, which can then be processed according to the Stern-Geary equation. What's missing in this process, however, is the assessment of the corroding surface.

Again, EN is a very useful technique for the study of inhibition of localized corrosion, and tremendous progress has been made in the evaluation of the data using mostly proprietary computer algorithms [60]. It is a methodology that certainly lends itself for monitoring purposes. However, the results are strictly qualitative.

### Galvanic Measurements

An early method for the assessment and monitoring of corrosion inhibitor effectiveness in the oilfield, for instance, consisted of the coupling of a steel electrode with a copper electrode via a zero resistance ammeter. It can readily be understood that the inhibitor can or might reduce the rate of the electrochemical reactions on both electrodes and not necessarily to the same degree. The measured galvanic current in the inhibited situation indicates that inhibition occurred, but it might be the copper electrode that was inhibited rather than the steel electrode. The latter might continue to corrode. While this may be the extreme case, anything from inhibition of the steel to inhibition of the copper to inhibition of both may occur. The residual

galvanic current after inhibition is, therefore, no direct indication of the inhibited corrosion rate of the steel.

Additionally, there are situations where the system that needs to be inhibited contains several metals, which are already galvanically coupled. Such a system was encountered in nuclear steam generators where the shell is high strength carbon steel and the tubes are Inconel metal. Under normal operating conditions this is not a problem; however, when the generator needed to be cleaned (removal of iron oxides), the most effective cleaning solution also turned out to be most aggressive to carbon steel and needed to be chemically inhibited. The work was described in detail in Ref 63. It was found that the large Inconel surface in the generator accelerated the steel corrosion dramatically. Inhibitor dosage had to take into consideration this acceleration, and needed to be much higher than in the uncoupled condition. When an attempt was made to assess the degree of inhibition on couples with varying steel to Inconel surface area ratios, it was found that the galvanic current was always smaller than the actual corrosion rate of the carbon steel. The technician has to be very much aware of this problem. The galvanic current is only a measure for the galvanic acceleration of corrosion. The total corrosion consists of both the self-corrosion of the steel plus the galvanic acceleration. If the potential differences between the two electrodes is relatively small, the self-corrosion of the steel may not be suppressed to a large degree by the galvanic couple, and may therefore still be substantial, as was the case in the steam generator. The decrease of the galvanic current due to the inhibitor, therefore, has to be calibrated against the weight loss of the corroding electrode before zero resistance ammeter currents can be used as an indication of corrosion rate.

In summary, all electrochemical methods used and proposed for corrosion monitoring and evaluation of corrosion inhibitors serve useful purposes and certainly have their place in the industry. However, careful interpretation of the results is always called for. In this context, it must be emphasized that all commercial instruments employing one or the other technique are sold with exaggerated claims of accuracy, reliability, or usefulness.

## TEST PROCEDURES AND PRIMARY VARIABLES

### Atmospheric Testing

Corrosion inhibitor testing was in the past mostly performed under atmospheric pressure. Typical test procedures were the Wheel Test [10], the Bubble Test [46], the Kettle Test [47], and many variations thereof. While the Wheel Test is pretty much antiquated, the others are still used routinely by many technicians. A serious consideration in this type of testing is the exclusion of oxygen. Many procedures, even standardized ones, advise “bubbling” nitrogen through the solution at a given rate (100 mL/min) for a length of time (one hour) [48]. It has been the author's experience that bubbling nitrogen, even for longer periods of time, do not lead to full removal of oxygen. The solution needs to be heavily agitated to cause dispersion of the bubbles and increase

their residence time in the solution. Often overlooked is the fact that Tygon tubing, much used for connecting the source of the nitrogen to the test vessel, has a finite permeability to oxygen. The residual contamination of oxygen caused by this effect can easily be calculated from the oxygen diffusion coefficient, the length of the tubing, the tubing wall thickness, and the nitrogen gas flow.

Agitation can be achieved with magnetic stirrers, e.g., bubble test [46], or motor driven paddle or turbine driven stirrers [9,47]. The effective velocity for magnetic stirrers depends on the size of the magnet, the rpm, and the size of the vessel, and is in general ill defined. The effective velocity of the turbine stirrers also depends on the same parameters, but is in general higher because of the higher rpm that can be achieved. However, because of the drag on the vessel walls the actual velocity is again ill defined.

External stirrers, such as motor driven turbines or paddle stirrers, require some kind of a Teflon gland or bearing for pass through of the stirrer shaft. While it has been said that maintenance of a positive pressure in the vessel (a few centimeters of water) will prevent air entry into the vessel, such is not the case when the shaft is rotated at high speeds. If high velocities are a requirement for testing, the best solution is an airtight cover over the test vessel and a magnetically coupled stirrer such as are being used in autoclaves routinely. It is the only practical way to keep air from entering the test solution.

The pH of the test solution is, as has been pointed out above, a critical factor. Not only does the pH affect the effectiveness of the inhibitor, it also controls its partitioning behavior and other secondary properties of the chemicals such as foaming, and to a lesser extent chemical stability. The pH should be kept constant during the test. Compensation for the buildup of buffering components (e.g., bicarbonate) can be achieved inexpensively with a pH controlled acid injection pump [9]. Strong acids<sup>21</sup> that are not involved in the corrosion process, such as sulfuric or perchloric acids, have been used successfully. When high degrees of inhibition are achieved from the beginning of the test, pH maintenance may be less important, since the composition of the aqueous phase will not change much. However, when the concentration/performance characteristic of the product is to be established, it is important that all tests at different concentrations be carried out at the same pH all through each individual test.

In order to expand the usefulness of the constant inventory systems, flowloops were built such that brine and/or a combination of brine and hydrocarbon could be circulated from a large reservoir over relatively small corrosion coupons or probes. One of the first such systems [31] employed a reservoir constructed such that a mixture of brine and hydrocarbon could be pumped with a single pump at variable velocity and controlled by variable brine/hydrocarbon mixture ratio. The problem with flowloops used for inhibitor testing is cleaning; nevertheless, many laboratories built

such systems for a variety of purposes. High-pressure systems will be discussed below.

### High Pressure Testing: Autoclaves, Flowloops, and Flow-Through Systems

Many corrosive industrial systems operate under high pressure, either because of high temperature (above boiling point of water or brine), or because of a high pressure environment consisting of acid and inert gases. Autoclaves are constant inventory devices, and because of the severe corrosive conditions, the environment changes rapidly in the uninhibited situation. The results obtained from such tests have no other value than to demonstrate qualitatively the severity of corrosion and the corrosion morphology [26]. When inhibitors are used, it often takes a long time to reach a steady state corrosion rate [49]. The reason for this is the time necessary to build up a protective layer. It is, therefore, considered necessary to monitor the corrosion kinetics in autoclave tests. While this can be done electrochemically [50], it is an absolute must to verify the steady state corrosion rate through chemical analysis of the medium and weight loss measurements. Chemical analysis will also give the technician an idea of the composition of the brine after the test and will give him an opportunity to calculate the pH associated with the steady state.

Again, in order to extend the volume/surface area ratio of the test system, high pressure flowloops [51,52] were built and later high pressure flow-through systems [22,53<sup>22</sup>]. Both flowloops and flow-through systems were ideally suited to generate the type of shear stresses needed to study the effectiveness of inhibitors under extreme situations occurring in the field. These systems were not limited to the oil field but were also used to study corrosion in cooling water circuits, steam generation, and other technologies. More recently, the focus shifted to the interrelationships between pressure and flow intensity.

### The Effects of Flow and Pressure on Corrosion Inhibition

The effects of flow rate (flow intensity, turbulence, shear stress) on corrosion have been known for a long time and have been variously called erosion corrosion or flow induced localized corrosion (FILC), which latter term is preferred because it denotes a purely aqueous (liquid) phenomenon, while erosion generally includes the presence of a solid phase. An attempt was made in 1990 to summarize the state of the art of FILC in a symposium [54]. The following is a brief synopsis of the developments in this area, with emphasis on corrosion inhibitor testing.

Schmitt was one of the first to recognize that fundamental studies in this area were necessary [55]. This author developed the rotating cage to generate high flow intensities in autoclaves and demonstrated that corrosion phenomena

<sup>21</sup>The use of weak acids, such as acetic acid, would defeat the purpose for two reasons: first, such acids contribute to the buffering system (just like carbonic acid) and, second, organic acids in general are complexing moieties and become involved in the corrosion process.

<sup>22</sup>Mobil Oil company built a large flow-through installation wherein a mixture of brine, hydrocarbon, and acid gases was passed through an autoclave containing high shear devices. Inhibitors could be injected separately. The system resembled a large pilot plant and could operate at pressures up to 5000 psi with both CO<sub>2</sub> and H<sub>2</sub>S or mixtures thereof.

observed in the field could be duplicated in the laboratory and effectively inhibited. The rotating cage is a device where corrosion coupons are mounted between two discs, which in turn are fixed onto a rotating shaft. The assembly can be rotated in the autoclave using a magnetically coupled stirring motor. Schmitt then formulated a fundamental relationship between inhibition and flow intensity [47]: For every inhibitor at a given concentration there exists a critical flow intensity beyond which inhibition begins to be lost; and for every inhibitor concentration (for a given inhibitor) there exists a critical flow intensity beyond which inhibition begins to be lost. In addition, it was recognized that acid gas partial pressure can also play an important role.

The rotating cage, which subsequently was used by others [26,31,49,54], served its purpose in demonstrating that severe corrosion phenomena observed in the field could be qualitatively duplicated in the laboratory and inhibited. However, because it was necessary to quantify the flow intensity by some measurable parameter, e.g., shear stress, other methods were developed as well. Among these were the rotating disc and rotating cylinder electrodes, and the jet impingement technology. A detailed comparison of these methods and quantitative assessment of shear stress is given in [56]. At this stage, further development of both the jet impingement [57] and rotating cage occurred in parallel [58].

The drawback of the jet impingement method is the fact that the corrosion rates have to be monitored electrochemically and cannot easily be verified by alternate methods. While tests with the rotating cylinder electrode are also monitored electrochemically, the corrosion rate can be verified by weight loss. However, the rotating cylinder suffers in general from a limitation in the magnitude of the shear stress that can be achieved. Hence, it was desirable to attempt to quantify the shear stresses to which various parts of the coupons mounted in the rotating cage are subjected. Papavinasam et al. [58] attempted this in model experiments, but could not really derive a shear stress for the leading or trailing edges of the coupons.

That it would be necessary to obtain a quantitative assessment of shear stress on flow upsets in tubing had already earlier been demonstrated by Schmitt et al. [59]. The authors demonstrated by finite element analysis and experiments that peak shear stresses on the leading edge of a groove cut into 2-in. tubing and subject to full bore liquid flow velocities of up to 20 m/s were from 4 to 7 times higher than the nominal shear stress calculated for such flow. Thus, flow intensifier numbers were defined for flow upsets of different geometries. Since it was well known by this time that inhibitor concentrations had to be optimized for the maximum shear stress encountered in a practical system, it was understood that it would be desirable to quantify shear stresses in test systems as well. Schmitt developed microsensors with the help of which exact shear stress measurements could be achieved on the jet impingement electrodes [60] by means of limiting current measurements.

The next step, currently in progress [61], is the use of microsensors built into coupons used in the rotating cage for the determination of localized shear stresses in various locations of the coupons. By defining the exact geometry of the cage and the test vessels, as well as the fluids, the shear stresses will be mapped as a function of the speed of rotation

of the cage. This work, when completed, can lead to the first truly standardized test method for flow induced corrosion and the evaluation of inhibitors under FILC conditions.

## OTHER IMPORTANT VARIABLES

### Surface Preparation

The surface preparation of coupons or electrodes used in inhibitor testing has become so much of a routine that the problems involved with the state of the surface prior to testing are rarely given any thought. Mercer [6] put it as follows: "... The desirability of approximating the surface state of a test specimen to that encountered in service is opposed to by the need to generate a surface condition most conducive to producing reproducible results." The emphasis has almost exclusively been on reproducibility. Specimens are degreased with various solvents; at times, complex procedures are used (e.g., soxhlet type apparatus). Scale layers (including mill scale) are removed by sandblasting, acid etch, polishing with Emery paper, etc. (see also Ref 62). While all these procedures have improved the reproducibility, the question of relevance and predictiveness remains unanswered today. That inhibitors work in the field is unquestioned, but whether the cost-effectiveness has been reliably assessed does remain an open question.

Any specimen preparation procedure leaves the surface in some state of roughness. It has been observed that the corrosion on polished specimens tends to increase in the first stages of a test, while on rough surfaces the rate decreases. Eventually, both specimens will reach a similar steady state. However, a large real surface area requires more inhibitor for inhibition than a polished one. Thus, surface preparation will affect the determination of the effective inhibitor concentration, particularly in constant inventory tests with a small liquid volume to surface area ratio.

Corrosion specimens are usually cut from sheet metal or machined from rod material. Often, specimens are both machined and cut from tubing and piping material. Changes in the metallurgy due to these processes will alter the metallurgy and, thereby, the corrosivity and response to inhibitors. Anisotropic corrosion, particularly in presence of corrosion inhibitors, is a little known phenomenon, which should be paid more attention to (see below).

### Selection of Metallurgy

It is absolutely imperative that all corrosion inhibitor evaluations be made on metal specimens encountered in the field. It had been pointed out above that [27,28] the effective inhibitor concentration on two different oilfield steels (J-55 and L-80) was vastly different under severe conditions. Examples of this abound in the industry. Weldments of carbon steel piping containing a small amount of copper were more difficult to inhibit under relatively mild conditions.

A large study on the inhibition of carbon steel in 15 % hot hydrochloric acid showed that mild steel coupons could be extremely well inhibited [44] with degrees of protection in excess of 99.99 %, while at the same time coupons from oil field tubulars corroded from 4 to 30 times faster. While the

oilfield tubulars were designated as N-80 material, there were again big differences observed on N-80 material of different origin (see Table 3). The most perplexing observation during these investigations was the occurrence of anisotropic corrosion. Round electrodes, for instance, cut from AISI 1018 mild steel rod stock tended to be well inhibited on the sides, while the ends, the so-called cross-grain surfaces, corroded 10 to 20 times faster and exhibited pronounced intergranular corrosion. On the N-80 materials, it was observed that cross-grain surfaces were covered with a thin layer of ferritic steel (formed during cutting due to the heat generated), while the bulk of the material was martensitic. As it turned out, the ferritic material was well inhibited, while the martensite underneath corroded at a much increased rate.

Similarly, the development of an inhibitor for an EDTA based chemical cleaning solvent to be used in nuclear steam generator cleaning showed differences of the degree of inhibition for various structural carbon steels used in steam generators [63]. It was during this work that it was shown for the first time that corrosion inhibitor effectiveness may be dependent on the strength of the material. In these cases, it was also observed that surfaces parallel to the rolling direction were well inhibited while the cross-grain surfaces corroded much faster. All this points to the need to carefully select and prepare the test specimens.

### Conditioning of Environment

Under this heading, one needs to discuss the elimination or addition of gases to the test environment. Deoxygenation was discussed in some detail above. The diffusion of a dissolved gas from the liquid into an inert gas phase is a slow process, limited by the gas/liquid interface area and the contact time. It is, therefore, necessary to increase this area by finely dispersing the inert gas, and by extending the contact time. This can be achieved by vigorous agitation. Bubbling nitrogen through an electrolyte without agitation is never enough to fully deaerate a solution. The reverse process is equally slow. Saturating a solution with  $\text{CO}_2$  or  $\text{H}_2\text{S}$  must occur under vigorous agitation, particularly in high pressure testing.

While small amounts of residual oxygen (10 to 20 ppb) are not critical when inhibitors are evaluated in a  $\text{CO}_2$  atmosphere, except under high shear stress, the situation is different in the presence of  $\text{H}_2\text{S}$ . It has been shown that as little as 200 ppm of oxygen in the purge gas can dramatically alter the corrosion kinetics of iron in the presence of  $\text{H}_2\text{S}$  [36]. This corresponds to as little as 10 ppb oxygen in solution. It is, therefore, also important that the purge gases are analyzed for impurities. The  $\text{CO}_2$  purchased from a certain supplier was found at times to contain as much as 1000 ppm oxygen. This did not per se affect the inhibitor performance, but a residual corrosion due to the oxygen remained present, such that the steady state inhibited corrosion current was much larger than it would have been in the absence of oxygen. When inhibited corrosion rates of the order of 1 to 2 mpy or smaller are to be achieved, traces of oxygen can easily prevent this goal to be attained even with the best of products.

Another source of error often occurs when one must work with mixed gases, such as  $\text{CO}_2$  containing small amounts of

$\text{H}_2\text{S}$ . When a solution must be saturated with a mixed gas under atmospheric pressure by means of purging, the gas mixture may be equivalent to the partial pressure ratio to be achieved in the test. When, however, autoclaves are to be pressured with mixed gases, the gas composition must be carefully predetermined such that the correct partial pressure ratio in the autoclave will be achieved. The reason for this is that the gases have different solubilities. This problem was discussed in some detail by the author [64]. An in-depth analysis of test procedures carried out with mixed gases at high pressures reached the conclusion that most such tests carried out in the past were not done at the nominal partial pressure ratio. In some cases the discrepancies were rather large.

### Inhibition of Precorroded Surfaces

It had been demonstrated [39] early on that in hydrogen sulfide corrosion the inhibitor has to be in contact with a sulfided (precorroded) surface in order to show inhibition. This observation rendered useless all those test procedures in which the inhibitor is applied to a clean metal surface in so-called film persistency tests. While it is well established that certain chemicals, such as high molecular weight fatty acids, have an affinity for metal surfaces and can form a water repellent film, they are readily replaced by other compounds that have a stronger affinity, for instance  $\text{H}_2\text{S}$ . Fatty amines, on the other hand, adsorb strongly on iron sulfide, and their desorption from sulfided surfaces takes much longer than the desorption of fatty acids from bare metal surfaces in the presence of  $\text{H}_2\text{S}$ .

Table 1 shows that some inhibitors are active in  $\text{CO}_2$  corrosion at pH 4 where it is believed that no iron carbonate scale builds up, while others are only effective at the higher pH where a certain amount of passivation occurs due to iron carbonate buildup. Indeed, the inhibitors of the first kind are also the most effective ones against flow induced localized corrosion (also called "Mesa corrosion"), where due to high turbulences the protective iron carbonate is washed away. However, some interesting observations were made when carbon steel was precorroded in a  $\text{CO}_2$  environment [65]. Figure 9 shows that, at a constant inhibitor

FIG. 9—Effect of precorrosion on inhibitor performance. Constant pH kettle test, 55°C, 1 bar  $\text{CO}_2$ , 100 ppm inhibitor. Corrosion rates monitored by Fe-counts or weight loss corrected LPR measurements.

concentration in the constant pH Kettle test at pH 4, inhibition is much less effective when the specimens are precorroded for 4 h. On the other hand, when the same tests were performed without maintaining the pH constant, such that a carbonate layer could in fact build up during the test procedure, precorrosion had very little effect, if any.

The relationship between a corrosion product layer and inhibitors has also been discussed, among others, by Lorenz [66], and Lorenz and Mansfeld [67]. These authors point out that in many practical systems, for instance aerated water and carbon steel, an interaction occurs between, in this case, iron oxide and the inhibitor to the point where the inhibitor is not only adsorbed on the oxide surface, but actually incorporated into the three-dimensional oxide layer. Clearly, three-dimensional or interphase inhibition cannot be achieved in short tests or by filming procedures. Furthermore, measuring techniques have to take into consideration the altered chemical and electrochemical conditions across such bulk interphase layers. It is unfortunate that this aspect of corrosion and corrosion inhibition has not received more attention, and it is suggested that this lack of attention has seriously held back all aspects of corrosion inhibitor applications and monitoring of effectiveness.

## SUMMARY

Corrosion inhibitor testing has over the years progressed from the trivial (immersion tests) to the most complex (high flow rates under verifiable shear stress). The presence of inhibitors in a corroding system adds a new dimension to corrosion testing and measuring in general. The presence of an inhibitor in the interphase between the metal and the liquid environment negates and invalidates in all but perhaps a few cases the electrochemical assumptions underlying electrochemical measuring techniques so prevalent in the industry today.

Within the framework of carefully defined quality criteria, it has become necessary to reinterpret the all too prevalent weight loss measurements and the methodology of constant inventory test systems. Since all corrosion inhibitor tests experience a corrosion rate transient in the early stages of the test for a multitude of reasons, the corrosion rates during the test must be monitored as a function of time in order to assess attainment of the steady state. Furthermore, the environment changes with time in most constant inventory test vessels. Therefore, there has been a tendency to either counteract these changes (continuous fluid conditioning) or minimize such changes by optimizing the liquid volume to surface area ratio.

The effectiveness of inhibitors is affected by a number of environmental, physical, and metallurgical parameters. These variables interact with each other in unpredictable nonlinear fashion, and moreover, such interactions are inhibitor specific. This state of affairs negates the validity of screening or standardized testing. Relevant and predictable inhibitor evaluation must be carried out under conditions simulating as closely as possible those of ultimate usage.

The ultimate objective of using corrosion inhibitors is failure inhibition. Failures always occur under the most aggressive conditions, be it due to flow intensity, pH, metallurgy,

or the combination of high pressure and temperature. Failure inhibition requires the largest inhibitor concentration and is the most costly option. Therefore, the technician must begin to model corrosion inhibition within the parameter field of the operating facilities in order to optimize overall inhibitor cost. One such model, empirical as it may have been, has recently been developed for the first time [27,28].

# Corrosion Testing in *In Vivo* Environments

K. J. Bundy<sup>1</sup>

## DESCRIPTION OF THE ENVIRONMENT

THE *in vivo* corrosion environment is complex, characterized by dynamic, constantly changing chemical and physiological processes, mechanical loading patterns, and bioelectric potentials. There is, in fact, more than one *in vivo* environment. Subenvironments, each presenting rather discrete corrosion conditions, exist, e.g., the oral cavity, the cardiovascular system, the environment surrounding orthopaedic implants, etc. Implant materials are vulnerable to various forms of corrosion attack. For some materials under certain conditions, uniform attack, pitting, crevice corrosion, galvanic corrosion, and various forms of interaction between applied loads and corrosion (fretting, corrosive wear, corrosion fatigue, and stress-corrosion cracking) have been reported.

One aspect of this environment that is different from the situation usually encountered in other environments is that the interaction between the metal surface and the electrolyte is modulated by an adsorbed protein conditioning film layer. Another atypical aspect is that, in some situations, the influence of the corrosion products on the environment (in terms of biocompatibility problems) may be of primary importance, while the damage to the material by the environment may be a secondary consideration.

In this chapter the variables affecting *in vivo* corrosion, the tests used to assess it, the materials used for implants (and the standards governing them), and various aspects that make the *in vivo* corrosion environment unique are discussed. Much useful information related to these subjects is found in the Medical and Dental chapter in the "Testing in Industries" section.

## ASPECTS THAT MAKE TESTING UNIQUE

The corrosion response within the human body is of most interest in this field. However, direct electrochemical testing in humans ranges from difficult (in the mouth) [1], to virtually impossible (for orthopaedic devices for example) because of ethical, safety, legal, and regulatory considerations. Consequently, much effort has been devoted to identifying alternative environments which, to a greater (or lesser) degree, simulate the corrosion conditions *in vivo* in humans.

Animal experimentation and testing in cell cultures represent alternative possibilities in this regard. When testing in animals, one important consideration, not always accounted for in earlier work in this area, is that significant IR drops occur *in vivo* (and require compensation) because of limited conductivities of certain tissues and anatomical difficulties that preclude optimal electrode placement. Another possibility for obtaining insight into *in vivo* corrosion is simulation of the conditions in the laboratory. Tests in such environments are more controlled, but in some ways less realistic, than tests with animals or cells. The determination of variables needed in a given case to adequately simulate the environment is difficult because of the many parameters that affect the relevant electrochemical processes.

## IMPORTANT VARIABLES AFFECTING *IN VIVO* CORROSION

Temperature is an important factor influencing *in vivo* electrochemical behavior. Internal body temperature is homeostatically regulated at 37°C, so it is important to test at this value in the laboratory. For dental materials exposed to the oral cavity, the temperature fluctuates due to food and drink intake and can range from about 0–70°C. Dissolved salts, particularly chlorides, are probably the most influential components for implant corrosion *in vivo* [2], although by no means the only ones. The internal body electrolyte has the equivalent of 0.9 % NaCl in solution.

The gases dissolved in body fluids also can play an important role in implant alloy corrosion. The most important of these is oxygen, whose partial pressure within the body is widely variable from about  $2.67 \times 10^2$  to  $1.33 \times 10^4$  Pa [3]. Sometimes implant surfaces can be in contact with areas of widely different  $pO_2$ , creating the possibility for differential aeration cells to develop. Carbon dioxide is another gas that can be important for *in vivo* corrosion, because of its influence on pH.

The pH of the *in vivo* electrolyte(s) has an important effect on corrosion of implant materials. pH usually is homeostatically regulated to a value of 7.4, but in certain circumstances the value may be quite different from the normal 7.4. Gastric juice [3], for example, has pH = 1.0. Saliva pH is variable and has been reported in the 5.5 to 8 range, although 6 to 7 is most common [4]. At sites of inflammation, there is a so-called transient "acid tide" in which the pH may fall to as low as 4.5 for a period of hours, or longer if a hematoma is present [5].

<sup>1</sup>Professor, Biomedical Engineering Department, Tulane University, New Orleans, LA 70118.

The role played by proteins regarding corrosion *in vivo* is one of the most important aspects of the unique environment within the body and can cause differences between corrosion behavior in laboratory chloride environments and *in vivo*. There are many thousands of proteins *in vivo*, and the influence of each individual species on corrosion processes is usually far from clear. Virtually from the time an implant is inserted into the body, it will become covered with a layer of adsorbed protein [6]. The characteristics of this layer can change with time, because both thermodynamic and kinetic factors are involved in the adsorption [7] and because cells in the vicinity are actively involved in protein synthesis [8]. The effects of proteins on corrosion are complex, and generally the influence of each protein is different. For example, a specific protein may sharply increase the corrosion rate of one alloy while not influencing the rate of another, or may even reduce the rate [9]. The fundamental effect is how the protein influences the passive layer, i.e., whether it disrupts it, or, conversely, whether it acts as a sort of "passive film," protecting the underlying surface from the electrolyte. Characteristics of the surface itself, such as charge, also influence adsorption of specific proteins.

Metallic biomaterials are generally stronger than other classes of biomaterials. Thus, they are customarily used in situations where they are subjected to significant static and dynamic forces, e.g., the loads in dentistry associated with mastication and, in orthopaedic applications, the forces applied to the skeletal system in standing, walking, stair climbing, etc. These loads may be of sufficient magnitude to cause corrosion fatigue [10], or on very rare occasions, stress-corrosion cracking (SCC) [11]. Many cases of fretting corrosion have also been reported [12]. Additionally, these loads may increase corrosion rate, while the mechanical integrity of the biomaterial is maintained. Such stress-enhanced ion release may occur for both static and dynamic loads [13] and has been observed at stress magnitudes below those that cause gross macroscopic plastic deformation.

An additional unique feature of the *in vivo* corrosion environment is the existence of bioelectric effects. These are potentials and ionic currents of physiological origin resulting from nerve and muscle activity, heart and brain function, stresses applied to skeletal tissues, etc. Since their magnitudes are small, usually they cannot be expected to have much influence on *in vivo* corrosion processes. In cases of border-line passivity, however, it is possible that these potentials could polarize portions of implant surfaces sufficiently to exacerbate pitting processes [14].

Implant design can alter the corrosion performance of alloys *in vivo*. A case in point of a device whose complex design has spurred much interest in its corrosion behavior is that of the cardiovascular stent [15,16]. To consider another example, many prosthetic devices and fracture fixation implants are by nature multicomponent or modular. This means they have various pieces that mate together, e.g., screws and screw holes in plates. These locations may be foci of localized corrosion processes such as crevice corrosion or (in the case of relative motion) fretting corrosion or both. Careful design of such components can minimize *in vivo* corrosion problems.

Galvanic contact between dissimilar metals is another aspect of the *in vivo* environment, which is important under

certain conditions. For example, in dentistry, two opposing teeth may have different alloys, e.g., an amalgam restoration and a gold-based crown, that come into contact during chewing [17]. Modular total hip replacements are often made from titanium- and cobalt-based alloys in contact. Although it was once thought that such devices would not suffer excessive corrosion because of the markedly passive behavior of both alloys, retrieval studies have shown otherwise [18]. The degree to which this form of attack is related to fretting, crevice corrosion, and galvanic contact has been controversial and the subject of intensive research [19–22].

The presence of inflammatory processes [5] or microorganisms [23], or both, at implant sites *in vivo* may affect corrosion behavior due to effects such as changes in pH. Conversely, the release of ions and other aspects of corrosion processes may affect these physiological events, leading, in the worst case, to a type of destructive feedback loop, in which cells release agents that exacerbate corrosion processes (which in turn provoke a more severe tissue response).

## LABORATORY TESTING

Because of the manifold complexities associated with the *in vivo* corrosion process, much attention has been devoted to control of the environment in the corrosion cell used for testing. The basic environment is a physiological saline solution usually kept at 37°C and pH 7.4, but there is no consensus regarding the exact composition that is appropriate. Ringer's solution, Hanks's solution, and 0.9 % NaCl are commonly used test environments for orthopaedic alloys. For environments simulating the oral cavity, termed artificial salivas, there is a similar lack of consensus, and a number of variations exist on a basic environment that has the equivalent of 0.1 % NaCl [24,25]. The chemical compositions of various solutions that are used for *in vitro* testing of orthopaedic and dental materials are given in the Medical and Dental chapter. There has also been a wide range of aeration used in testing. Aerated and deaerated solutions have been used as well as ones exposed to ambient conditions. When solutions containing protein are required for testing orthopaedic implants, it is most common to use albumin, an ubiquitous plasma protein. For dental materials, mucin, an important salivary protein, is widely used.

Testing in the laboratory allows the many complex variables discussed in the previous section to be investigated individually and in combination with each other. The *in vivo* corrosion environment is one that is sufficiently aggressive to cause a variety of corrosion phenomena. Therefore, a number of different types of tests have been developed and should be used to assess the *in vivo* resistance to corrosion of newly developed materials.

Considerable attention has been devoted to the interaction between mechanical loading and corrosion phenomena. Corrosion fatigue has been investigated with sinusoidal loading [26] and with force patterns more representative of actual *in vivo* stresses [27]. Both specimens of simple geometry [28] and actual prosthetic devices [29] have been tested. SCC has been studied using U-bend [30], stress ring [31], bent beam [31], and fracture mechanics [32] type

specimens (to obtain crack growth rate versus stress intensity curves). The fracture mechanics approach has also been employed in corrosion fatigue research [33]. Special corrosion cells have been developed for study of fretting corrosion [34–36] and corrosive wear [37]. Stress-enhanced ion release is also investigated with specialized specimen geometries, sample holders, corrosion cells, and a variety of loading patterns.

A number of additional corrosion phenomena have been the focus of laboratory testing. Crevice corrosion has been investigated using a variety of specimen designs with artificial crevices [38,39]. Galvanic corrosion has been investigated mainly via polarization curves and mixed potential theory [40]. Uniform corrosion and pitting also are examined by polarization curve measurement. Passive film stability may be investigated using methods that combine polarization and controlled surface scratch testing [41–43].

Most electrochemical testing conducted to date has used various DC approaches. The most common methods involve linear polarization (to determine the polarization resistance for calculation of corrosion current via the Stern-Geary equation) [44] and potentiodynamic polarization (to determine breakdown and repassivation potentials). Other tests are also conducted, however. For example, long-term open circuit potential versus time measurements, potentiostatic chronoamperometry, and galvanostatic measurements are occasionally conducted for specialized purposes.

In the past decade or so, there has been increasing interest in the use of electrochemical impedance spectroscopy (EIS) to study *in vivo* corrosion of implant materials [45,46]. An equivalent circuit modeling approach has been used to measure circuit parameters in order to gain insight into corrosion rates, surface areas of irregular surfaces (such as porous-coated implant alloys), and *in vivo* IR drop; to study corrosion mechanisms (e.g., charge transfer versus diffusion control); and to identify cracking processes and crevice corrosion, to name just some of the applications. Because protein adsorption is so important to implant corrosion processes, EIS has been used to measure capacitance versus applied bias potential [47]. Surface charge can be determined from these data. Since proteins themselves are charged, electrostatic interactions with charged surfaces play an important role in their adsorption.

A variety of surface observational tools have been used to assess various aspects of implant corrosion. For example, scanning electron microscopy (SEM) is often employed to study surface damage [48]. Scanning electrochemical microscopy (SECM) can be used to image localized corrosion currents with a high degree of spatial resolution [49]. The identification of released corrosion products has been another important focus of laboratory corrosion testing of implants. Electron microprobe analysis, Auger electron spectroscopy, and X-ray photoelectron spectroscopy of implant alloy surfaces (before and after corrosion has taken place) have been used to monitor surface changes and damage due to electrochemical action [50,51].

Atomic absorption spectrophotometry has often been used to analyze total amounts of released trace metals in the electrolyte [52]. In some circumstances, it is desirable to know the actual valence states of released corrosion products. Chromium, for example, as shown by Pourbaix

diagrams [53], may exist in either trivalent or hexavalent form for potential/pH ranges expected *in vivo*. The hexavalent form poses potentially much greater toxicity hazards. Polarographic methods have been used to differentiate between these two states [54–56]. Additionally, this electrochemical technique can perform trace element analysis in the part per billion range and has been employed for chemical analysis of the electrolyte. Ion exchange resins have also been used for chromium speciation [57]. Another analytical method that can be used for valence state determination is ion chromatography [58], which is capable of simultaneous measurement of multiple ions. A biologically-based technique that uses an assay of monoclonal antibody inhibition has recently been described [59] to measure the concentration of free ions in solution.

To simulate loading for fretting experiments, devices known as joint simulators are often used. Such apparatus attempts to duplicate the loading and motion patterns in actual prosthetic joints [60–63]. Other equipment (based upon universal testing machines) uses specimens of simple geometry, with more or less realistic loading patterns, to investigate interaction of stress and corrosive environments. Corrosion fatigue and some aspects of stress-enhanced ion release are investigated in this manner [26,27,64].

Because many corrosion phenomena *in vivo*, and therefore in laboratory environments, have long incubation times associated with them, the question of accelerated corrosion testing has arisen. Increasing the temperature can, via the Arrhenius equation, substantially increase corrosion rate [65], but there are pitfalls associated with this technique to be considered. It works best when the main component affecting corrosion is the chloride ion. Since proteins denature at relatively low temperatures, elevated temperature testing is less suitable for proteinaceous environments.

Testing in a chemical environment related to *in vivo* conditions, but more severe than that associated with the body, for example, the testing of dental materials in Ringer's solution [66] rather than artificial saliva, is another accelerated testing approach. The limitation of accelerated methods is that one cannot straightforwardly extrapolate the data to determine what the corrosion rate would be under *in vivo* conditions. Regardless of the medium used, *in vitro* testing will only serve as a comparative screening technique for materials, since it is not a direct determinant of *in vivo* rates.

Specimen geometry is also a concern for corrosion testing to simulate *in vivo* conditions. When studies involve material behavior alone, then usually simple shapes are used, but when functional behavior (such as fretting due to applied loads), or implant design (presence of crevices of given geometry), is at issue, then actual implant devices are usually tested.

Since there is such uncertainty regarding corrosion of implant materials, there are few standards that govern this field. Those that do exist, as well as future needs in this area, are discussed later.

## FIELD TESTING

Because of the many previously mentioned difficulties associated with electrochemical testing in humans, most of the information about corrosion resistance *in vivo* has come

from other methods. Foremost among these is retrieval analysis [67–70]. Here implants that have been removed, either routinely or for cause, along with adjacent tissue, are examined. Visual, low-power light microscopy, and SEM examinations are usually performed. Often a metallurgical examination is conducted, as well, to determine hardness, grain size, nonmetallic inclusion content, and other parameters [71].

Many large-scale retrieval studies have been conducted involving hundreds of implants. Although corrosion of the devices is only one of many topics that are the subjects of retrieval analyses, this type of investigation has yielded the majority of the knowledge that has been amassed regarding corrosion *in vivo*. ASTM F 561, Practice for Retrieval and Analysis of Implanted Medical Devices, and Associated Tissues, governs the performance of implant retrieval analyses.

Another “field testing” methodology for *in vivo* corrosion involves measuring corrosion product concentrations in blood and other physiological fluids, usually via atomic absorption spectrophotometry [72]. Such studies may be of a clinical nature, involving human patients. Elevated concentrations of various elements have been reported [73,74]. In other studies, controlled injections of implant corrosion products in animals are made to assess kinetics and modes of their excretion and storage in various body tissue compartments [75]. An alternative strategy has been to implant materials with large surface areas (e.g., powders) to simulate large degrees of corrosion product release, with storage and clearance monitored as before [76].

*In vivo* electrochemical testing is possible in humans (in the oral cavity) under restricted conditions [77,78]. Open circuit potentials and galvanic currents between dissimilar metals have been measured. Linear polarization and AC impedance tests have been conducted. The paramount concern for these measurements is obtaining accurate data under conditions that present no hazard to the human subjects.

A more wide-ranging set of experimental methods can be employed for testing in animals. Potential versus time data have been obtained over periods of 60 days [79]. Linear polarization tests have been conducted to determine corrosion rates via the Stern-Geary equation [80]. Potentiodynamic polarization tests (which are effectively impossible to conduct in humans because of safety concerns) have also been conducted in animals [81,82]. A diverse group of animal species including goats, rabbits, rats, and primates has been used for corrosion testing *in vivo*.

As previously pointed out, one difficulty with these tests is that, due to geometrical problems regarding electrode placement and somewhat limited ionic conductivities of certain tissues, significant IR drops are created that need compensation [83]. Electrochemical impedance spectroscopy would provide an excellent means for measurement of the ohmic resistance, but so far, this method has been very infrequently employed in *in vivo* animal testing. Nonelectrochemical approaches have been used to investigate the corrosion of implant materials *in vivo*. U-bends and stressed rings have been placed in rabbits to investigate the stress corrosion cracking behavior of implant alloys [30,31]. Dynamic loads have also been applied *in vivo* to investigate the corrosion fatigue process [84].

An additional field-testing approach that has increasingly been employed in the past decade to assess corrosion *in vivo* involves the use of cell culture techniques. Although systemic effects such as circulation that could impact corrosion processes are not modeled with this method [3], the basic biological environment at the metal/electrolyte interface, the protein conditioning layer, is simulated with some degree of realism, as are active cellular processes. The response of biomaterials in a cell culture environment can be gaged either through use of electrochemical techniques [47] or from chemical analysis of corrosion products in solution [85,86]. An advantage of the cell culture approach is that various assays related to cell viability, proliferation, histochemical status, function, gene expression, etc. can be performed in addition to corrosion measurements, thus providing insight into the material's biocompatibility [87,88] as well as its electrochemical behavior. A variety of cell types has been used in such studies including fibroblasts, osteoblasts, macrophages, as well as carcinoma, neuroblastoma, and bacterial cells. This approach appears to offer considerable promise of yielding further valuable information on corrosion and biocompatibility in the future.

## STANDARDS

Only four ASTM standards are explicitly concerned with corrosion of surgical implant materials. ASTM F 746, Test Method for Pitting or Crevice Corrosion of Metallic Surgical Implant Materials, is a test in which a specimen has an inert sleeve simulating a crevice. Anodic polarization is used to raise the potential and initiate pitting, as determined by a large and rising current. The potential is then potentiostatically controlled to various values, and the current is monitored to establish the highest potential not resulting in repassivation.

ASTM F 897, Test Method for Measuring Fretting Corrosion of Osteosynthesis Plates and Screws, is concerned with the fretting behavior of orthopaedic fracture fixation plates. A plate is attached to a rod with bone screws, and the assembly is loaded with a fretting apparatus described in the standard. The degree of fretting is gaged with gravimetric methods, atomic absorption spectrophotometry of the solution, and observation of surface appearance. There is another standard that deals specifically with fretting of the modular total hip replacement devices mentioned previously, F1875, Practice for Fretting Corrosion Testing of Modular Implant Interfaces: Hip Femoral Head-Bore and Cone Taper Interface. F1801, Practice for Corrosion Fatigue Testing of Metallic Implant Materials, is another test for monitoring the interaction between applied loads and corrosion processes.

Besides the standards mentioned above, there are several additional ones that have some bearing on the corrosion behavior of implant materials *in vivo*. A number of standards govern the chemical composition and metallurgical conditions of metallic implant materials.

The following ASTM standards govern the use of stainless steels:

- F 138, Specification for Wrought 18 Chromium-14 Nickel-2.5 Molybdenum Stainless Steel Bar and Wire for Surgical Implants (UNS S31673)

- F 139, Specification for Wrought 18 Chromium-14 Nickel-2.5 Molybdenum Stainless Steel Sheet and Strip for Surgical Implants (UNS S31673)
- F 621, Specification for Stainless Steel Forgings for Surgical Implants
- F 745, Specification for 18 Chromium-12.5 Nickel-2.5 Molybdenum Stainless Steel for Cast and Solution-Annealed Surgical Implant Applications
- F 1314, Specification for Wrought Nitrogen Strengthened- 22 Chromium-12.5 Nickel-5 Manganese-2.5 Molybdenum Stainless Steel Bar and Wire for Surgical Implants
- F 1350, Specification for Wrought 18 Chromium-14 Nickel-2.5 Molybdenum Stainless Steel Surgical Fixation Wire (UNS S31673)
- F 1586, Specification for Wrought Nitrogen Strengthened- 21 Chromium-10 Nickel-3 Manganese-2.5 Molybdenum Stainless Steel Bar for Surgical Implants

The following ASTM standards are concerned with titanium-based material:

- F 67, Specification for Unalloyed Titanium for Surgical Implant Applications (UNS R50250, UNS R50400, UNS 50550, UNS 50700)
- F 136, Specification for Wrought Titanium-6 Aluminum-4 Vanadium ELI (Extra Low Interstitial) Alloy (UNS R56401) for Surgical Implants Applications
- F 620, Specification for Alpha Plus Beta Titanium Alloy Forgings for Surgical Implants
- F 1108, Specification for Ti6Al4V Alloy Castings for Surgical Implants
- F 1295, Specification for Wrought Titanium-6 Aluminum-7 Niobium Alloy for Surgical Implant Applications (UNS R56700)
- F 1341, Specification for Unalloyed Titanium Wire (UNS R50250, UNS R50400, UNS R50550, UNS R50700) for Surgical Implant Applications
- F 1472, Specification for Wrought Titanium-6 Aluminum-4 Vanadium Alloy (UNS R56400) for Surgical Implant Applications
- F 1580, Specification for Titanium and Titanium-6% Aluminum-4% Vanadium Alloy Powders for Coatings of Surgical Implants
- F 1713, Specification for Wrought Titanium-13 Niobium-13 Zirconium Alloy for Surgical Implant Applications
- F 1813, Specification for Wrought Titanium-12 Molybdenum-6 Zirconium-2 Iron Alloy For Surgical Implant Applications
- F 2066, Specification for Wrought Titanium-15 Molybdenum Alloy for Surgical Implant Applications (UNS R58150)

The following standards apply to the nickel-titanium shape memory alloy:

- F 2004, Test Method for Transformation Temperature of Nickel-Titanium Alloys by Thermal Analysis
- F 2005, Terminology for Nickel-Titanium Shape Memory Alloys
- F 2063, Specification for Wrought Nickel-Titanium Shape Memory Alloys for Medical Devices and Surgical Implants

- F 2082, Test Method for Determination of Transformation Temperature of Nickel-Titanium Shape Memory Alloys by Bend and Free Recovery

Cobalt-chromium alloy systems are covered by the following ASTM standards:

- F 75, Specification for Cobalt-28 Chromium-6 Molybdenum Casting Alloy and Cast Products for Surgical Implants (UNS R30075)
- F 90, Specification for Wrought Cobalt-20 Chromium-15 Tungsten-10 Nickel Alloy for Surgical Implant Applications (UNS R30605)
- F 562, Specification for Wrought Cobalt-35 Nickel-20 Chromium-10 Molybdenum Alloy for Surgical Implant Applications
- F 563, Specification for Wrought Cobalt-20 Nickel-20 Chromium-10 Molybdenum Alloy for Surgical Implant Applications
- F 688, Specification for Wrought Cobalt-35 Nickel-20 Chromium-10 Molybdenum Alloy Plate, Sheet, and Foil for Surgical Implants (UNS R30035)
- F 799, Specification for Cobalt-28 Chromium-6 Molybdenum Alloy Forgings for Surgical Implants (UNS R31537, R31538, R31539)
- F 961, Specification for Cobalt-35 Nickel-20 Chromium-10 Molybdenum Alloy Forgings for Surgical Implants (UNS R30035)
- F 1058, Specification for Wrought Cobalt-Chromium-Nickel-Molybdenum-Iron Alloy for Surgical Implant Applications
- F 1091, Specification for Wrought Cobalt-20 Chromium-15 Tungsten-10 Nickel Alloy Surgical Fixation Wire (UNS R30605)
- F 1377, Specification for Cobalt-28 Chromium-6 Molybdenum Powder for Coating of Orthopedic Implants (UNS-R30075)
- F 1537, Specification for Wrought Cobalt-28-Chromium-6-Molybdenum Alloy for Surgical Implants (UNS R31537, UNS R31538, and UNS R31539)

Tantalum is governed by ASTM F 560, Specification for Unalloyed Tantalum for Surgical Implant Applications.

ASTM standards that have additional relevance to *in vivo* corrosion behavior are F 86, Practice for Surface Preparation and Marking of Metallic Surgical Implants, and those that deal with biocompatibility. The efficacy of the passivation procedures described in F 86 has recently become controversial [89]. Examples of standards related to biocompatibility include F 763, Practice for Short-Term Screening of Implant Materials, and F 981, Practice for Assessment of Compatibility of Biomaterials for Surgical Implants with Respect to Effect of Materials on Muscle and Bone. The latter two standards describe how to detect untoward tissue reactions due to released corrosion products. F 748, Practice for Selecting Generic Biological Test Methods for Materials and Devices, provides general guidelines as to what biocompatibility tests are appropriate in given situations.

Some standards cover corrosion testing for devices used in specific medical applications. Examples in this area

include F 1089, Standard Test Method for Corrosion of Surgical Instruments, and F 2068, Specification for Femoral Prostheses-Metallic Implants.

In addition to the ASTM Committee F 4 standards mentioned above, some of the standards from Committee G 1 are useful for testing alloys that see *in vivo* service. The following are examples of ASTM standards that are useful for studying specific corrosion mechanisms of implant materials:

- A 262, Practices for Detecting Susceptibility to Intergranular Attack in Austenitic Stainless Steels
- G 30, Practice for Making and Using U-Bend Stress-Corrosion Test Specimens
- G 36, Practice for Evaluating Stress-Corrosion-Cracking Resistance of Metals and Alloys in a Boiling Magnesium Chloride Solution
- G 38, Practices for Making and Using C-Ring Stress-Corrosion Test Specimens
- G 39, Practice for Preparation and Use of Bent-Beam Stress-Corrosion Test Specimens
- G 46, Guide for Examination and Evaluation of Pitting Corrosion
- G 49, Practice for Preparation and Use of Direct Tension Stress Corrosion Test Specimens
- G 71, Guide for Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes

Standards governing testing methodology such as:

- G 5, Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements
- G 59, Practice for Conducting Potentiodynamic Polarization Resistance Measurements
- G 61, Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-Based Alloys are also useful for testing implant materials. Besides ASTM standards, international organizations such as the ISO and various national groups (such as in Britain and Germany) have standards that relate to corrosion of metals that are used *in vivo*. For example, ISO 5832 Implants for Surgery-Metallic Materials, is a twelve part standard governing various biomedical stainless steel, titanium-based, and cobalt-based alloys.

So far, except for specifications for use of 0.9 % NaCl and other "physiologic" solutions (including "protein" solutions) at 37°C (see ASTM F 746 and F 897), standards are lacking that provide guidelines as to environmental conditions that could simulate various aspects of *in vivo* behavior. Load levels and waveforms, bioelectric effects, and the details of environmental chemical composition so far have not been addressed in standards governing testing. Efforts in the future to fill these gaps would be helpful.

## MATERIALS

Because materials that are used *in vivo* face demanding requirements with respect to corrosion resistance, other engineering aspects (such as mechanical behavior), and biocompatibility, only a handful of metallic materials have been judged over the years to be suitable for *in vivo* service.

The majority of orthopaedic devices are fabricated from 316L stainless steel. Cobalt-chromium and titanium-based alloys are used for the remaining share. These latter materials tend to be more durable in *in vivo* fluids than 316L [90]. Thus, their use tends to be more prevalent in permanent applications such as total joints. 316L, on the other hand, is often used in temporary situations such as fracture fixation.

A wider spectrum of materials are useful in dental applications, perhaps because of the much lower chloride content in saliva [4] as compared to blood and extracellular fluids [3]. Besides resistance to chloride attack, the oral environment is one where resistance to tarnishing due to sulfur in foodstuffs is important [4]. Precious metal and base metal alloys are used for casting of various dental restorations. The former consists of compositions based on gold, platinum, silver, and palladium alloy systems. Base metals consist of nickel, chromium, and copper systems and have become more common in recent times as alternatives to high priced precious metals. The most commonly used metallic dental material is amalgam. This is a silver-tin alloy powder mixed with mercury. In the past decade the use of mercury in amalgam has become a controversial topic. Stainless steel is used in certain orthodontic applications. Wrought materials, particularly ones that are titanium based, are often used to fabricate dental implants. The most corrosion-resistant materials are the precious metal and titanium systems. The amalgams and copper-based materials are most prone to corrosion in the oral cavity, with some of the base metal casting systems having intermediate corrosion resistance. Compositions of common alloys used in dentistry are provided in the Medical and Dental chapter.

## CONCLUSION

The corrosion of materials *in vivo* is an extremely complex process. This area has been intensively investigated in the past, resulting in the accumulation of a great deal of knowledge on the subject. Much remains to be done, however, before optimal means for corrosion testing in *in vivo* environments can be fully developed. The most advanced methodology from the corrosion testing field as a whole should be brought to bear on this topic as rapidly as it becomes available. In addition, approaches that are biologically based have already yielded considerable insights into corrosion behavior and biocompatibility of biomedical alloys. These techniques should be exploited even more intensively in the future.

# Microbiological Effects

Stephen C. Dexter<sup>1</sup>

## DESCRIPTION AND UNIQUENESS

THERE IS NO SINGLE, unique microbiological environment. Rather, the microscopic organisms present in all natural aqueous (and many artificial) environments should be regarded as having a potential influence on any corrosion reaction that takes place in that environment. Theoretically, that influence can range, as shown in Fig. 1, anywhere from the organisms being the sole causative agent for corrosion, to innocent bystanders having no influence on corrosion, to corrosion inhibitors. In practice, when the influence of the organisms is a significant factor in determining the overall rate and extent of corrosion, that influence will usually make the corrosion more localized, and the penetration rate higher, than it would be in a sterile environment with the same chemistry. In such cases the corrosion is often referred to as "microbiologically influenced corrosion," or MIC. As of late 2001, a significant influence of microorganisms has been reported on uniform corrosion of a variety of materials in both aerated (aerobic) and deaerated (anaerobic) environments [1,2], pitting and crevice corrosion [3-8], corrosion fatigue [9], galvanic corrosion [10,11] and cathodic protection [12,13]. Effects have also been reported on cracking and embrittlement related to hydrogen evolution [14]. For additional general information on various types of microbiologically influenced corrosion the reader is referred to the books by Borenstein [15], Gaylarde and Videla [16], Kobrin [17], Stoecker [18] and Videla [19] as well as a conference proceedings edited by Angel, et al. [20].

The critical issue for both corrosion testing and corrosion mechanisms is how microscopic organisms exert their influence on corrosion. Generally, they do so by changing the chemistry of the electrolytic solution in a thin layer at the metal surface [8]. In liquid environments they do this by colonizing the metal surface, forming a thin film, or biofilm (usually with thickness in the 10-500  $\mu\text{m}$  range). In buried soil environments, a film may form, but it is not necessary because the moist soil itself is able to localize organisms near the surface. In this latter case, all that is needed is a sufficient density of organisms to change the chemistry of the pore water in the soil at local sites adjacent to the metal surface. In either case, once corrosion initiates, it is common to find intense microbiological activity in the corrosion products at and immediately adjacent to the corrosion site.

The mass of corrosion products, microbes, and their polymeric byproducts often take the form of a tubercle. At the same time, there may or may not be a distributed film of microorganisms on the general metal surface. The organisms associated with a tubercle usually influence the chemistry under which the anodic dissolution reaction takes place, while the organisms in the distributed film influence the chemistry of the cathodic reduction reaction. In a given situation either the anode or cathode reaction may be rate limiting, and it is not always easy (or even possible) to determine which set of organisms has the greater influence.

The process of biofilm formation begins immediately upon immersion of the metal in the liquid environment. The first step is the adsorption of a nonliving macromolecular organic film. This "conditioning film" is nearly complete within the first 2 h of immersion in natural waters at 25°C, but the process may take longer at lower temperatures. The initially colonizing bacteria also begin to attach in substantial numbers within the first 2-4 h of immersion in natural fresh, brackish, and sea waters. The biofilm then goes on to develop a highly complex and spatially heterogeneous structure of microbial colonies and their extracellular polymers. In some cases this structure can be substantially developed

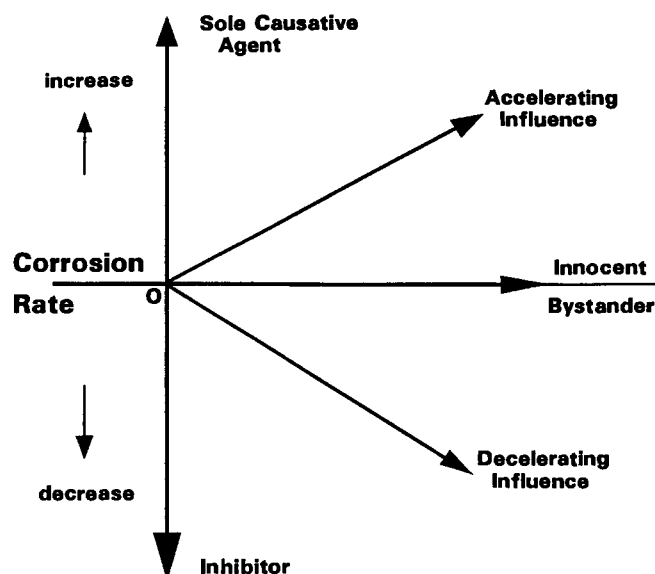

FIG. 1—Schematic diagram showing the range of influence microorganisms may have on corrosion.

<sup>1</sup>700 Pilottown Rd., College of Marine Studies, University of Delaware, Lewes, DE 19958.

within the first 48 h of immersion. In other cases the structure develops over a period of two weeks to a year depending on the temperature. The literature on biofilm formation is extensive, and the reader is referred to the proceedings volumes edited by Berkeley et al. [21], Costlow and Tipper [22] and Keevil et al. [23], and the books by Marshall [24] and Characklis and Marshall [25], Bryers [26], and An and Friedman [27] for further information.

Once formed, a microbial biofilm changes the chemistry at the metal-liquid interface in a number of ways that have an important bearing on corrosion [8]. As the biofilm grows, the bacteria in the film produce a number of metabolic byproducts. Among these are organic acids, hydrogen sulfide, and protein-rich polymeric materials commonly called exopolymers or "slime." The first effect of the composite film of microorganisms and their associated exopolymers is to create a highly heterogeneous micro-environment between the metal surface and the bulk electrolyte [28,29]. Since the biofilm itself is mostly water, it does not truly isolate the interface from the bulk environment, but it does support larger chemical concentration gradients both perpendicular to and parallel to the metal surface than would the laminar sub-boundary of liquid alone. Thus, the water chemistry at the interface may be quite different from that of the bulk solution, although the two chemistries will be coupled through diffusive and convective processes.

Two chemical species, oxygen and hydrogen, that are often implicated (or even rate controlling) in corrosion, are also important in the metabolism of microorganisms. A given biofilm can be a source or a sink for either oxygen or hydrogen. Moreover, biofilms are rarely homogeneous. Sometimes they provide only spotty coverage of the metal surface. Even when they provide nominally complete coverage, their thickness and composition may vary from point to point along the surface. Thus, they are capable of inducing oxygen (or other chemical) concentration cells. Even when the dissolved oxygen in the water is at air saturation, the oxygen tension at the metal surface under a microbial film can be zero [30–32]. In bringing this about, the biofilm acts both as a physical oxygen diffusion barrier and as an active oxygen sink in which the living organisms consume oxygen during respiration [8]. Alternatively, photosynthetic organisms consume carbon dioxide and produce oxygen.

Large changes in pH are also possible under biofilms. Values as low as 5 can be expected under general aerobic films containing acid producing bacteria [33]. Even more acid pH in the range of 1–2 can be expected under discrete biodeposits [34], and a pH of 3 is thought to be required for some of the effects produced by marine biofilms on passive alloys in seawater [35]. Recently, pH values in the 2–5 range have been directly measured at discrete locations within marine biofilms using micro-electrode techniques [36]. Some microbes are capable of directly producing acids such as formic, succinic, acetic, and sulfuric, while others are involved in metabolizing nitrogen compounds [37]. Some can reduce nitrates (used as corrosion inhibitors) to nitrite or nitrogen. Others can convert between nitrate and ammonia compounds, which cause stress corrosion cracking of copper alloys. Still other species of bacteria are involved in the sulfur cycle [38]. Some can oxidize sulfur or sulfides to

sulfate, and ultimately to sulfuric acid. Others, particularly the anaerobic sulfate reducing bacteria (SRB), can reduce sulfates to sulfides, often producing corrosive hydrogen sulfide ( $H_2S$ ) as an end product [39–41]. Many of these organisms have both fresh and salt water strains.

Organisms with a fermentative metabolism can be net producers or consumers for the dissolved gases carbon dioxide and hydrogen [37]. Finally, certain types of bacteria are directly involved in the oxidation of metal ions. Particularly damaging are those fresh water bacteria that oxidize ferrous and manganous ions to ferric and manganic [37,40]. Redox cycling of manganese dioxide within the biofilm matrix is currently thought to have a major effect on corrosion in both fresh [42–46] and seawater [32,47,48] environments. Dissolved manganese has been directly measured in seawater biofilms using microelectrodes [32], and it has been associated in those seawater biofilms with microorganisms of the correct morphological type to be manganese oxidizers [47]. Manganese dioxide has also recently been shown to have the current capacity to account for the observed increase in crevice and galvanic corrosion rates in the presence of marine biofilms [48].

In all these examples, the biofilm is able to substantially change the chemistry of the electrolyte at the metal-water interface. Thus, the corrosion rate may depend more on the details of the electrolyte chemistry at the interface under the biofilm than it does on the bulk environment chemistry. The fact that biofilms tend to be spatially heterogeneous allows them to support sharp chemical gradients both parallel and perpendicular to the metal surface. This is one of the reasons why corrosion tends to become more localized in the presence of microorganisms. On top of this is the tendency for films of microbes to develop and change with time. This can produce corrosion rates, which also vary with time and are thus hard to predict.

## IMPORTANT VARIABLES

It is difficult to specify just what the important variables are when corrosion is being influenced by microorganisms. In addition to their effects on corrosion itself, variables such as dissolved oxygen, pH, temperature, hydrodynamics of flow, and nutrient concentrations also affect the life cycle of the microorganisms. The difficulty is that in most cases, the organisms that affect corrosion are in a thin film or under a deposit on the metal surface. These structures support chemical gradients both parallel to and perpendicular to the metal surface. They can also shield the organisms from adverse chemical and physical situations. Thus, bulk electrolyte properties may have little relevance to the corrosion as influenced by organisms in a film on the metal surface.

The organisms present within the corroding system are also an important factor. A list of most of the types of organisms known to be directly implicated in corrosion, along with the environmental conditions that favor their growth, is shown in Table 1 [41]. This list should not be regarded as complete because new organisms are still being identified as having an influence on corrosion. In addition to these organisms, all microbes found in biofilms that form on metal surfaces have a potential effect on corrosion of that surface.

**TABLE 1**—Microorganisms most commonly implicated in microbiologically influenced corrosion. (Reprinted with permission from Ref 41.)

Genus or Species	pH Range	Temperature Range, °C	Oxygen Requirement	Metals Affected	Action
<b>Bacteria</b>					
<i>Desulfovibrio</i>					
Best known: <i>D. desulfuricans</i>	4–8	10–40	Anaerobic	Iron and steel, stainless steels, aluminum, zinc, copper alloys	Utilize hydrogen in reducing $\text{SO}_4^{2-}$ to $\text{S}^{2-}$ and $\text{H}_2\text{S}$ ; promote formation of sulfide films
<i>Desulfotomaculum</i>					
Best known: <i>D. nigrificans</i> (also known as <i>Clostridium</i> )	6–8	10–40 (some 45–75)	Anaerobic	Iron and steel, stainless steels	Reduce $\text{SO}_4^{2-}$ to $\text{S}^{2-}$ and $\text{H}_2\text{S}$ , (spore formers)
<i>Desulfomonas</i>	...	10–40	Anaerobic	Iron and steel	Reduce $\text{SO}_4^{2-}$ to $\text{S}^{2-}$ and $\text{H}_2\text{S}$
<i>Thiobacillus thiooxidans</i>	0.5–8	10–40	Aerobic	Iron and steel, copper alloys, concrete	Oxidizes sulfur and sulfides to form $\text{H}_2\text{SO}_4$ ; damages protective coatings
<i>Thiobacillus ferrooxidans</i>	1–7	10–40	Aerobic	Iron and steel	Oxidizes ferrous ( $\text{Fe}^{2+}$ ) to ferric ( $\text{Fe}^{3+}$ )
<i>Gallionella</i>	7–10	20–40	Aerobic	Iron and steel, stainless steels	Oxidizes ferrous (and manganous) to ferric (and manganic); promotes tubercule formation

Just as bulk electrolyte chemistry does not necessarily define the conditions at the metal surface under a film of microorganisms, direct counts of organisms present in the bulk aqueous environment have also been found to indicate little of relevance to predicting their influence on corrosion. This is because it is the organisms right at the metal surface that influence corrosion, and those organisms multiply so rapidly on the surface that a low density of organisms in the bulk quickly becomes irrelevant.

In some cases where corrosion is being triggered by a single known microorganism, a change in temperature or pH of the environment outside the range of tolerance of that organism can alleviate the effect. It should not always be assumed, however, that such a tactic would work because there are organisms that can thrive, or at least survive, under extreme conditions including boiling water and space travel. In fact, some types of high-temperature corrosion are influenced by organisms that are only active at temperatures above 60°C (the so-called obligate thermophilic bacteria) [49].

## LABORATORY TESTS AND STANDARDS

Virtually all electrochemical tests used for corrosion in the laboratory are also applicable to corrosion as influenced by microorganisms. The reader is referred to the literature

on this subject for more detail than can be given here [50–52]. In general, the standards listed elsewhere in this publication for various types of corrosion will still be useful when that corrosion is being influenced by microorganisms. No standards have been written specifically for microbiologically influenced corrosion. However, a monograph on Microbiologically Influenced Corrosion [53] has recently been added to the “Corrosion Testing Made Easy” series. That monograph contains chapters on many types of testing that can be employed for looking at corrosion in cases where a microbial influence is suspected. These types of testing include: metallurgical, microbiological and biochemical, chemical and electrochemical, as well as procedures for specimen identification and collection. The reader is referred to this monograph for many additional references [53].

## Importance of Proper Sampling Techniques

Prior to discussing various testing techniques applicable to MIC, one must consider the proper sampling and specimen handling techniques to preserve the evidence. When evaluating a corrosion site in the field at which MIC is suspected, the evidence must be examined, recorded, and sampled and often transported from the site to a laboratory for further analysis. A suspected influence of microorganisms mandates that special procedures are followed to

preserve the microbiological evidence in addition to the procedures used for the chemical and physical evidence.

The sheer complexity of the corrosion process in the presence of microorganisms and microbial biofilms makes data interpretation difficult. Thus, whenever possible, multiple techniques should be used for assessing any microbial corrosion situation before conclusions are drawn. An outline of the laboratory techniques used most successfully in the past, along with any cautions for applying those techniques when the corrosion is influenced by microorganisms will be given below.

### Open Circuit Corrosion Potential

Due to its simplicity, open circuit corrosion potential measurements (see Chapter 20 of this manual) have been used in MIC studies for many years. Corrosion potential measurements as a function of time have been used to obtain information on MIC of steel, aluminum alloys, stainless steels, and other passive alloys. By itself, the corrosion potential of plain carbon and low alloy steels indicates very little because these steels can corrode at a wide range of potentials. Rapid changes in the corrosion potential, however, can be used to indicate cathodic depolarization, or an enhancement of the anodic reaction, or to the formation of a semi-protective film.

Changes in the corrosion potential with time have also been used to study the behavior of aluminum aircraft alloys in the presence of aggressive metabolites produced by *Horcomonis resiniae* during the degradation of jet fuel [54]. In this work it was possible to detect the onset of localized pitting due to microbial action by the change from a steady corrosion potential to one with strong oscillations.

There have been numerous reports in the literature in which variations in the corrosion potential of stainless steels and other passive alloys have been used to follow the effects of biofilms on localized corrosion in natural aqueous environments [3–8,55,56]. These data showed that the corrosion potentials of a variety of alloys were often, but not always [57,58], ennobled (shifted in the electropositive direction) to values above +400 mV SCE in the presence of a biofilm. Alloys with high resistance to chloride induced localized corrosion, such as the 4 % molybdenum ferritic and 6 % molybdenum austenitic stainless steels, the high-temperature superalloys and titanium, could sustain those high potentials indefinitely. Alloys with lesser corrosion resistance, such as the ordinary 300 series stainless steels, however, suffered corrosion initiation usually in the form of either pitting or crevice corrosion, with a sudden negative shift in the corrosion potential [5,59]. Similar data taken with the metal immersed in waters from which the film-forming microbes had been removed showed potentials remaining steady at values below +150 mV with greatly reduced corrosion initiation [59]. Several techniques for removing the film-forming organisms from natural waters without altering the inorganic chemistry of the water have been given in the literature [7,59,60]. These techniques, as discussed below in the section on Techniques for Crevice Corrosion, usually involve various combinations of filtering and low-temperature pasteurization.

### Redox Potential

Another potential that has been used to predict whether or not a given metal will suffer an increase in corrosion due to microorganisms is the reduction-oxidation (or redox) potential of the environment (see Chapter 7 of this manual). The redox potential in general is a measure of the oxidizing power of the environment. In a moist aerated soil, it is dominated by the pseudo-equilibrium potential of the oxygen reaction as measured on a platinum electrode immersed in the soil. At a given temperature and pH, the redox potential of most natural aqueous environments becomes more negative (or active) with decreasing dissolved oxygen concentration.

Redox potential measurements have been used frequently in microbiology to assess the suitability of a given environment for growth of the anaerobic SRB. Since these organisms grow only in the absence of oxygen, they require an environment with an active redox potential, generally less than –400 mV SHE. The redox potential has been used to estimate the aggressiveness of soils toward buried metals, and it has been considered by some authors to be the most significant factor in assessing the aggressiveness due to SRB [61]. Other authors, however, consider the combined use of several parameters such as electrical resistivity and water content of the soil in addition to redox potential to give a more reliable indication [62]. It is important to note that the redox potential is a function of soil pH as well as oxygen content. Therefore, when the purpose of measuring the redox potential is to learn something about the oxygen concentration or to detect when the oxygen content changes, it is necessary to concurrently measure and record the pH. It is also important when making such measurements to keep the immersion time of the platinum electrode short enough that it is not colonized by the microorganisms. Otherwise, the measured value will correspond to the chemistry at the platinum surface under the film of microorganisms, rather than to that of the bulk environment.

Redox potentials have also been used in conjunction with Pourbaix diagrams to predict the probable behavior of aluminum, nickel, and zinc alloys in aerated environments [63]. Unlike the negative redox potentials that signal corrosive conditions for steel in anaerobic environments, a positive redox potential usually indicates conditions favorable for corrosion under aerobic conditions. For example, positive redox potential values, along with positive corrosion potentials and negative pitting potentials, can explain the aggressiveness of *H. resiniae* toward aluminum [64]. In fuel/water systems where different species of bacteria and fungi often grow together, the redox potential can be useful in studying the role played by each species in modification of the environment. For active/passive metals like aluminum and its alloys, the use of redox potentials together with the corrosion potential and the pitting potential can be helpful in assessing when the oxidizing conditions of the environment reach the values needed to initiate localized corrosion [64]. It should be cautioned, however, that this can only be done reliably under conditions in which the organisms change the chemistry of the bulk environment, and that chemistry, along with the behavior of the metal, are easily simulated and measured. In contrast, as will be

discussed in a later section of this article, such measurements are much more difficult to both make and interpret when the organisms form a thin film on the metal surface and change the local chemistry within the film, rather than in the bulk solution.

### Direct Current Polarization Techniques

In this section the utility and limitations of various direct current electrochemical polarization techniques for investigating corrosion in the presence of microorganisms will be discussed. The reader is referred to other sections of this manual for a description of the techniques themselves.

### Polarization Resistance

The polarization resistance technique (described in Chapter 7 of this manual, and recently reviewed by Scully [65]) has been applied frequently to the measurement of corrosion rates as influenced by microorganisms. This technique is most useful for systems undergoing uniform corrosion controlled by a single set of anode and cathode reactions. An exact calculation of the corrosion rate by this technique requires the simultaneous determination of the polarization resistance itself and the anode and cathode Tafel slopes [66]. A simplified version of the technique, called linear polarization resistance (LPR), is based on the two assumptions [67] that (1) the corroding interface behaves as a simple resistor whose magnitude is inversely proportional to the corrosion current, and (2) there is a linear relationship between changes in an applied potential and the resultant current density when the applied potentials are within about 10 mV of the corrosion potential. Such small applied potentials are favorable for the study of MIC [50–52] because the minute changes they cause in chemistry at the interface are not likely to interfere with the metabolic processes of the microorganisms present. This allows the polarization resistance technique to be used repeatedly during an experiment to determine evolution of the biological influence with time.

In practical situations, electrochemical systems are often more complex than the simple model assumed by the polarization resistance method. The presence of biofilms on the metal surface may introduce a capacitance as well as resistance to the interface. Moreover, the biofilm may introduce additional electrochemical reactions and adsorptive processes, which can lead to nonlinear polarization behavior. Even so, a polarization resistance value can be found as long as a sufficiently slow polarization scan rate (determined by the rate of the slowest reaction present) is used to maintain steady state conditions and a correction can be made for solution and biofilm resistances.

Patchy biofilms and localized colonization give rise to localized corrosion reactions and to anodes and cathodes that are fixed in space and stable in time [68] as opposed to the randomly spaced and mobile oxidation and reduction reactions required by uniform corrosion. Under these conditions, the calculated polarization resistance value is correct but the anode and cathode areas are unknown, so that one does not know how to determine the current density (i.e., the penetration rate). Adding to the level of

uncertainty in the localized corrosion rate as measured by the polarization resistance technique is the observation that the data often show large fluctuations with time [51]. Even with these limitations, the polarization resistance method has been used successfully by many authors [69–76] to assess under what conditions microbes accelerate (or decelerate) corrosion rates.

### Tafel Polarization

Methods for making these measurements are given in the literature and in Chapter 7 of this manual. Polarization studies have been used for several decades in the study of anaerobic corrosion of iron by SRB. Anodic and cathodic polarization curves of mild steel in the presence of different strains of SRB were used to ascertain the effect of the enzyme hydrogenase on cathodic depolarization of the metal and to identify the basic mechanisms of anaerobic corrosion induced by SRB [77]. Others measured cathodic polarization curves for mild steel in sterile media containing suspensions of iron sulfide [78] or dissolved hydrogen sulfide [79] to demonstrate that cathodic depolarization can be enhanced in the presence of those chemical species. Polarization experiments have also been used to assess variations in the depolarizing effect of several species of microorganisms on steel under different experimental conditions [80,81] and to investigate the effects of natural biofilms on the cathodic kinetics of stainless steels [3–8,10,11,82,83].

Although these methods have been used with considerable success, several limitations should be kept in mind when applying them to situations in which the action of microorganisms may be important. First, the rather large polarizations required may change the electrochemical conditions (particularly the pH) in such a way as to be deleterious to microorganisms in the biofilm [84]. Thus, Tafel polarization measurements should not be made periodically during a microbial corrosion experiment. They may, however, give useful information for research purposes if done once at the end of an experiment. For purposes of following changes in the corrosion rate with time under the influence of microorganisms, the polarization resistance technique, which employs very small polarizations, should be used rather than Tafel polarization.

A second set of cautions about use of Tafel polarization in microbial corrosion experiments involves the tendency of films of microorganisms to (1) introduce new electrochemical reactions and diffusion barrier films [35], or (2) cause the corrosion potential to drift or fluctuate with time [5]. All of these effects make the linear region of the curve less distinct, and thus the extrapolated corrosion rates less reliable. Even so, data from the technique can still be useful for research purposes in that changes in shape of the curves from one experiment to the next can reveal that the organisms are changing conditions at the metal surface. If the changes are taking place slowly compared to the time for making a polarization run, the data can give valuable information on short-term effects, even though they will not be useful for measuring long-term corrosion rates. Finally, Tafel polarization measurements alone give no information on either the distribution of corrosion on the metal surface

(MIC is usually localized) or on the relative contribution to corrosion of the microorganisms as compared to other factors. This means that careful work and well-designed control experiments are required if the results are to be useful, or even interpretable.

### Potentiodynamic Sweep Techniques

The potentiodynamic sweep techniques are most useful for characterizing, and sometimes predicting, the corrosion behavior for metal-electrolyte systems in which the metal passivates by formation of a protective (or passive) film, as described in Chapter 20 of this manual. One of the main experimental variables that can be manipulated is the sweep rate. Relatively high scan rates (60 V/h) are used to indicate regions where intense anodic activity is likely. Slower scan rates (1 V/h) are used to identify regions in which relative inactivity is likely. High scan rates are used to minimize film formation so that the currents observed relate to thin film or nearly film free conditions, while slower scan rates allow time for film formation to occur. Slow scan rates provide for maximum stability of the metal surface conditions, but increase the chance of changes in the environment or in biofilms, particularly at the potentials furthest from the corrosion potential. High scan rates disturb the steady state reaction conditions at the metal surface, but better maintain stability of the environment.

At any scan rate, the large applied potentials often used in potentiodynamic experiments may disturb the organisms in the biofilm, as was the case for the Tafel polarization technique discussed above. Thus, the same caution against doing polarizations during the middle of a long-term experiment applies here as well [50]. MIC involves the action of relatively fragile organic and biological films that are affected by pH and the concentrations of oxygen and hydrogen at the metal-film interface. Thus, the scan rates and ranges discussed above, which can affect these variables, are very important when applying potentiodynamic techniques to MIC systems. Rapid scan rates can be used to develop a database for possible expected corrosion regimes for the film-free metal in a given environment. Intermediate scan rates may be selected to correspond to a particular biofilm formation rate, while very slow scan rates may be selected for measurements of the relatively steady state conditions in the presence of a mature biofilm. The combination of slow scan rate with a large scan range, however, maximizes the probability of adversely affecting organisms on the metal surface, so this type of experiment should only be done at the end of an experiment [e.g., 11]. Thus, no single scan rate is appropriate for use in all MIC investigations [50].

### Determination of Pitting Potentials

Pitting potentials in the presence of microorganisms are of interest because microbes often bring about localized corrosion. There is a wide variety of techniques for measuring pitting potentials as discussed in Chapter 18 of this manual. In general, the validity of these techniques is not changed by the microorganisms. The degree to which the

data can be interpreted, however, may be affected [85]. This is particularly true if the microorganisms that affect corrosion are present in the form of a thin biofilm on the metal surface. The chemistry within the film is often very complex and difficult to characterize. Thus, a measurement showing that the pitting or breakdown potential has decreased upon exposure to microorganisms will indicate correctly that conditions at the metal surface have become more conducive to localized corrosion, but it may not be possible to say anything about the mechanism without additional measurements [85]. Zhang and Dexter [86] used these techniques to show that the critical pitting and breakdown potentials of S30400 and S31600 stainless steels immersed in seawater changed upon natural biofilm formation.

### Alternating Current Methods

Direct current techniques assess the overall corrosion process occurring at a metal surface, but treat the metal-solution interface as if it were a pure resistor. Electrochemical impedance spectroscopy (EIS) using small alternating currents has been developed in part to eliminate this restriction. For a full description of the EIS technique itself, the reader is referred to the literature [87] as well as to Chapter 7 of this manual. EIS has been particularly useful in the presence of nonconducting and semiconducting surface films.

EIS data are most helpful and easiest to interpret for metal-electrolyte systems involving continuous thin films and low solution conductivity. Some caution, therefore, should be exercised in data interpretation from MIC systems because the adsorbed organic and biological films tend to provide spotty, rather than continuous, coverage, and these films can vary widely in thickness. Nevertheless, EIS can provide many useful types of information on biofilm covered electrodes [50–52].

Two examples of the successful use of EIS in determining the influence of microorganisms involve the deterioration of coatings and the localized corrosion of aluminum alloys. Mansfeld and co-workers have used EIS, along with electrochemical noise analysis (ENA), to monitor the impact of microorganisms on degradation of protective polymeric coatings on steel immersed in natural seawater for up to three years [88]. EIS spectra for most coatings showed a gradual decrease in the impedance modulus  $|Z|$  with immersion time, and they could be fit to suitable equivalent circuits. Using EIS data together with visual observation of the coatings surface the investigators also were able to follow the increase in percentage of damaged area of the sample (damage function) with time.

EIS has also been used to monitor the effect of microorganisms on localized corrosion of aluminum alloys [89,90]. In this effort [90] the EIS spectra were fitted to the pitting model of Mansfeld et al. [91], and a special software package [92] was used for data analysis. Tests on aluminum alloy 2024 were performed in sterile growth media as well as in the presence of three different bacterial strains, two of which were genetically engineered to produce a known metabolic product. Large differences in pit growth rates were observed, including some significant reductions in active pit growth rates.

Several difficulties with the use of the EIS technique for MIC research [50] recently have been alleviated through the development of improved instrumentation and software. First, the combination of microbial film and corrosion products often encountered in MIC causes the impedance to become very high at low frequencies. The large extrapolations needed in such cases with older equipment have been greatly reduced through the introduction of new instrumentation with increased frequency and impedance ranges. Second, the difficult task of developing equivalent electrical circuits required for quantitative EIS data interpretation can now be done automatically through commercially available software programs. A third difficulty stems from the nature of biofilms themselves. Microbial films are not static like paint or metal oxide films. Rather, microbial films are dynamic entities, within which changes are continually occurring under the influence of the organism's metabolism. Such changes can cause fluctuations in electrochemistry at the metal-film interface that are of shorter duration than the length of the EIS measurement. This can mean that the highest and lowest frequencies within the overall EIS signal may not be responding to the same interface conditions [93]. Once this difficulty is recognized, it can be addressed through proper experimental design.

### Scanning Vibrating Probe Techniques

The scanning vibrating probe is a technique in which the electrochemical potential field, or localized anodic and cathodic currents, above a corroding metal electrode, is mapped in a raster pattern. The generic apparatus developed by Isaacs [94,95] requires a flat horizontal specimen, with some means of vibrating, positioning, and scanning a fine-tipped platinum wire electrode, or alternatively a micro-reference electrode [96], above the metal surface. The scanning vibrating probe technique is ideally suited for mapping localized anodic and cathodic areas on a smooth metal surface. Franklin et al. [97–100] have used such a probe to study anodic areas associated with bacterial films. By coupling the scanning vibrating probe with autoradiography of bacterial cells labeled with  $^{14}\text{C}$  acetate, Franklin et al. were able to correlate sites of anodic activity with sites of bacterial activity [100].

### Microelectrode Techniques

Various microelectrode techniques can be powerful tools for evaluating effects of microbial activities on corrosion behavior at metal surfaces. Membrane type microelectrodes have been developed for measuring microprofiles of dissolved  $\text{O}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{H}_2\text{S}$ , and pH across the thickness of microbial mats and biofilms [101–106]. These have been used successfully to determine oxygen diffusion fluxes [101,102], microbial photosynthetic and respiration rates [103], nitrogen cycling [104], and to locate the oxic/anoxic boundary [105,106].

Solid state voltammetric microelectrodes with tip diameters in the range of 10–50 microns are especially useful for measuring chemical profiles within thin biofilms on corroding metal surfaces. Lewandowski and coworkers have used iridium-iridium oxide microelectrodes for measuring

profiles of oxygen, peroxide, and pH perpendicular to the metal surface in natural and cultured fresh water biofilms [28,29,31,107–109]. Dexter and Chandrasekaran [36] also used the iridium-iridium oxide electrodes for measuring pH profiles within natural marine biofilms. Brendel and Luther developed Au-Hg amalgam voltammetric microelectrodes for measuring profiles of dissolved oxygen/peroxide,  $\text{Fe}^{+2}$ ,  $\text{Fe}^{+3}$ ,  $\text{Mn}^{+2}$ ,  $\text{Mn}^{+4}$  and various sulfur species in marine sediments [110]. Their original electrodes with tip diameters of 100 microns were too large for measuring chemical profiles across thin biofilms. Xu, Dexter, and Luther [32] further developed this technique to make the Au-Hg electrodes with tip diameters of 25 microns. These were used to directly measure  $\text{O}_2$ ,  $\text{H}_2\text{O}_2$ , Fe, Mn and sulfur species in natural marine biofilms using square wave voltammetry. These electrodes can also be used to measure pH values below 4 in the absence of iron [32]. When dissolved iron is present, the proton and  $\text{Fe}^{+2}$  peaks are so close together that the pH value is difficult to determine. All of the above measurements with solid state voltammetric microelectrodes showed that there are steep chemical gradients both perpendicular and parallel to the substratum surface, even in biofilms less than 50 microns in thickness. This was true for both fresh and seawater biofilms, and it is believed to be one of the major reasons why MIC tends to be localized.

Ideally, microelectrodes for use in thin biofilms grown on metal surfaces should have small tip diameters with small sensor surfaces to minimize distortion of the local environment and give optimal spatial resolution [111]. They should also produce a stable signal with low noise levels and high selectivity, and they should be robust enough to survive gentle contact with the solid surface [111] so that they can be reused. Tip diameters of 10–35 microns are necessary to achieve the spatial resolution needed to characterize the degree of heterogeneity in natural biofilms. However, the smaller the tip diameter, the more difficult the electrodes are to make and the more easily they are damaged.

Errors in the signal produced by microelectrodes can come from both chemical and physical sources. Contamination of the sensor element by reaction with the environment should be avoided. Investigators doing this type of work are careful to calibrate the electrode ahead of time for the species to be measured and then make sure the electrode will recalibrate after the measurement. One should consult the literature cited for specific procedures and cautions for using each type of electrode. Physical errors come from electrodes that are inappropriately sized for the variability of the environment. Problems may also come from vibration of the electrode tip or flow of bulk water along the outer sheath of the electrode into the measurement volume [31,36].

When coupled with observation of the surface by various techniques, the chemical data from microelectrodes can be correlated with the positions of microbial colonies and corrosion sites on the metal surface. Franklin et al. [97] have used confocal laser scanning microscopy (CLSM) to image microbes preferentially attached to corroding particles of zinc and iron. Xu [47] has used both CLSM and epifluorescence microscopy to image colonies of microorganisms associated with various combinations of oxygen, peroxide, and manganese revealed by the Au-Hg microelectrodes on passive metal surfaces.

### Dual Cell Techniques

The dual cell technique used for many years in galvanic couple studies and as biological fuel cells [112] can also be applied to the assessment of microbial activity in corrosion processes [113]. This type of cell consists of two similar compartments filled with the same electrolyte and each containing an identical metal electrode. For work on MIC, one of these cells is maintained under sterile conditions, while the other is inoculated with the microorganisms under study. The external circuit is completed through a zero-resistance microammeter, and the contact between the solutions in the two chambers is made across a semipermeable membrane. In this way, the current obtained under short-circuit conditions is considered as a measure of the biological effect on the inoculated electrode. Under ideal conditions this enables one to experimentally separate areas of sterile, bare metal surface from those of the same metal in the presence of microorganisms [113]. The corrosion currents flowing between these separated areas can then be measured. The method, however, does not separate the anodes and cathodes of local action microcells, but only measures the effect of coupling. Thus, it is not a simple matter to relate the data obtained from this method to MIC on real structures covered with spotty biofilms or discrete biodeposits. This type of device has been used successfully to study the effects of: a marine pseudomonad on corrosion of copper [114], an obligate thermophilic filamentous bacterium on the corrosion of nickel [115], an iron-oxidizing stalked bacterium on the corrosion of mild steel [113], and an aerobic acetic acid producing bacterium on the cathodic depolarization of stainless steel [116].

Inherent in this method is the assumption [50] that the two electrodes can be made identical, and that there would be no current flow as long as both cells were maintained in the sterile condition. This may be a reasonable assumption in the case of steady state uniform corrosion, or for stable passivity where neither electrode undergoes potential fluctuations in the absence of microorganisms. It may not be valid for systems, such as the 300 series stainless steels in seawater, where the electrode potentials are sufficiently variable that currents can flow in either direction whether or not microorganisms are present. In such systems, interpretation of the data will not be straightforward [50].

### Electrochemical Noise

In electrochemical noise (EN) measurements fluctuations in potential or current are measured as a function of time. The measurements can be done (see Chapter 7) either without or with an externally applied signal. In the first case one monitors the open circuit corrosion potential of the test metal versus a suitable reference electrode or versus a second electrode of the same material exposed under identical conditions. The advantage of this technique for use in MIC research is that there is no external signal to disturb the biological community on the metal surface. Alternatively, one can measure fluctuations in potential ( $E$ ) at an applied current ( $I$ ), or the reverse, fluctuations in  $I$  at an applied  $E$ . It has also been suggested that one could couple the metal of interest to a platinum electrode and measure the noise

across a resistor between the two electrodes [117]. As pointed out by Mansfeld and Little [51] this second technique applies an unknown polarization through the galvanic coupling to platinum. This has the dual disadvantage that the noise recorded could be due to that polarization and the applied signal may have an effect on processes within the biofilm.

Within the past decade there have been major developments in methods for analyzing and interpreting EN data [118–123]. Improved methods for collection of EN data also have been reviewed recently [124]. In spite of these developments, many of which have been summarized in the “Corrosion Testing Made Easy” series [87], there have been few applications of EN techniques to MIC. EN techniques have been applied to the study of anaerobic corrosion of iron by SRB [125]. Potential fluctuations accompanying the breakdown of an SRB produced iron sulfide film on iron have been recorded in the laboratory. Such fluctuations have also been recorded from steel pipelines in the field [126], and it may be possible to correlate these data with areas of anaerobic corrosion of the pipeline. In another study, EN techniques were used in combination with EIS to study the effects of SRB in the corrosion of reinforced concrete structures [127]. Little et al. used EN techniques together with EIS to examine the relationship between marine bacteria and the defect structure of polymer coatings on steel [128]. Very few bacteria became associated with the coating defects on cathodically protected samples, while many bacteria became associated with the corrosion products at the coating defects on unprotected samples.

Using EN techniques, it has been claimed that it is possible to detect the onset of corrosion, determine whether it is uniform or localized, and even distinguish between pitting and crevice corrosion [129]. There is evidence, however, that this claim should be taken with some caution [122]. At its present state of development the most common use for the EN technique has been in corrosion monitoring [124]. Although EN shows great promise for use in monitoring of MIC, there have been few applications to date.

### Electrical Resistance Probes

The electrical resistance method (see Chapter 15) is widely used as an industrial corrosion monitoring technique [130]. The electrical resistance method is excellent for indicating a change in the general corrosion rate, but the results are harder to interpret in the presence of localized forms of corrosion, such as pitting, crevice corrosion, stress corrosion cracking, and corrosion fatigue, which take place with very little mass loss. Workers have attempted to correlate characteristic jumps in resistance with localized forms of corrosion, but with only limited success. An electrical resistance probe will indicate very little corrosion if the corrosion products have an electrical conductivity approaching that of the metal, or if an electrically conducting film forms on the metal surface. MIC usually produces localized forms of corrosion, and it is sometimes associated with conductive corrosion product films. Therefore, in cases of known or suspected MIC, the electrical resistance method should be used only with caution, and in conjunction with other methods.

## RESEARCH TECHNIQUES FOR STUDYING CREVICE AND GALVANIC CORROSION IN THE PRESENCE OF BIOFILMS

### Multiple Crevice Assembly

The multiple crevice assembly technique (see Chapter 19) using a serrated washer to create many crevice sites on each side of a test panel, has become commonplace in the investigation of crevice corrosion. The multiple crevice assembly device, or the earlier version of it having a solid washer with only one crevice site per side, has been used to study biofilm effects on both initiation and propagation of crevice corrosion in natural waters by several authors [6,7,131]. Initiation can be inferred by observation of visible corrosion products or by a change in corrosion potential of the device. Propagation of corrosion is determined by measuring the weight loss and the number of sites (or percentage of area under the washer) attacked at the end of the experiment. The success of this technique for measuring the extent to which the microorganisms present affect either initiation or propagation depends on the ability to run a parallel experiment without any influence from microbes.

### Remote Crevice Assembly

The remote crevice assembly technique (see Chapter 19) is a research tool that allows one to separate the anode and cathode areas of a crevice corrosion test sample so that the current flowing between them can be measured with a zero-resistance ammeter. This technique is similar to the dual cell method, and it lends itself well to studies of microbial effects on crevice corrosion [7]. It allows direct measurement of microbial effects on both the initiation time and propagation rate for crevice attack, provided again that a suitable control experiment without the microbial influence can be done concurrently. The same technique of separating the anode and cathode can be used to study the influence of microbes in biofilms on galvanic corrosion [11].

### Performing the Test Without the Influence of Microbes

The most difficult problem to solve when using the two techniques above to demonstrate an effect (or lack thereof) of microorganisms on crevice and galvanic corrosion has been to devise an effective method for making the measurements with the same geometry and chemistry but without the organisms [132]. In a research context, this is called "running the control experiment." The word "control" as used in this section refers to running the same corrosion experiment without the microbes present. This should not be confused with a practical program designed to control, or mitigate, biocorrosion.

Ideally, one should have a sterile "control experiment" running concurrently, and under the same chemical and geometrical conditions as the one in the natural, or laboratory culture, environment. However, it is quite difficult to maintain truly sterile conditions in such corrosion experiments. The problem is compounded as the required duration of the experiment becomes longer and the volume of

water involved larger. For the long durations (several months) and large volumes of water required for most crevice corrosion experiments, it becomes impractical (some would say impossible) to maintain truly sterile conditions with no change in chemistry of the water. Given these difficulties, the objective of the control experiment changes from that of having no organisms present to that of delaying the onset of microbial effects long enough to do a meaningful experiment. If it is impossible for practical purposes to have an absolutely sterile control experiment, then some way must be found to have a control condition that is demonstrably effective in order for the data generated to be interpretable.

Several techniques, none of which is perfect, have been developed for creating such an effective, rather than an absolute, control condition. These techniques all involve one, or a combination of, three approaches: (1) use an artificial chemical water, (2) treat the natural water, or (3) treat the specimen surface. If the natural electrolyte is seawater, the first inclination will be to use a 3.5 % NaCl solution as the control water. This approach will not sterilize the water, but the organisms will be different from those in the marine environment. Thus, whatever biofilm does form will behave differently than a natural marine biofilm. This simple solution provides an electrolyte that is chemically stable over long periods of time, but it does not reproduce either the inorganic or organic chemistry of seawater very well [133]. A chemical improvement is to use an artificial seawater, such as the ASTM D 1141, Specification for Substitute Ocean Water. Other artificial seawaters that more accurately reproduce the chemistry of open ocean water than ASTM seawater have also been developed [134]. In general, however, the more chemically accurate the artificial formulation is, the more difficult it is to make, and the less stable it is over time. Moreover, no artificial seawater can reproduce the organic chemistry of natural seawater. It is important to realize that biofilms do eventually form in all the above artificial waters, and the investigator must be able to demonstrate that the level of biofilm control actually achieved is sufficient for the purposes of a given experiment.

The next approach to making an effective control is usually to modify the natural water itself in such a way as to eliminate the microorganisms, or at least to delay their tendency for biofilm formation over the desired length of the experiment. Many methods have been tried, but no one has yet devised an easy way to maintain sterile control conditions without also changing the water chemistry. Biofilm formation can be prevented by continuous photooxidation or addition of biocides to kill or inhibit the organisms, but these techniques also change the chemistry of the water. Perhaps the most successful technique has been to sterilize the water by combination of mechanical filtration at the 0.2 (or even 0.1) micrometer level with a low temperature (75–80°C) pasteurization [60]. This does not guarantee continued sterility of the water but it does delay the formation of a biofilm for four to eight weeks. This combination of filtration and pasteurization is usually the method of choice for short-term (<1 month) laboratory experiments. The disadvantage is that this control water has to be changed every two or three days to keep it fresh. Since filtration at the 0.2  $\mu\text{m}$  level is a slow process, this means that new water

must be continuously under preparation, and the experimental logistics become difficult if the volume of water required for a given experiment is more than about 5 L.

The final approach to creating an effective "control" experiment involves periodic removal of the biofilm by physical or chemical treatment of the metal surface. Techniques such as periodic wiping or scraping with or without chemical cleaning and even autoclaving the metal samples have been tried with varying degrees of success [135]. These techniques are all temporary, and they must be repeated frequently in order to be effective. Recently, Zhang and Dexter [7] found that the control condition for long-term crevice corrosion experiments requiring large volumes of water could be maintained by simple treatments of both the surface and the water. In their experiments the remote crevice assembly technique was used to measure the effect of biofilms on the cathode member of the assembly. They were able to maintain acceptable control conditions (i.e., no measurable biological effect) by pasteurizing the control water and recycling the cathodes. Two identical cathode panels were prepared for each experiment. These cathode panels were exchanged approximately every three days. The panel that was removed was immediately immersed in fresh water at 60°C for 1 h, then air-dried and kept in a desiccator until it was time for the next exchange. At that time the treated panel was connected into the circuit before disconnecting the old panel in order to avoid an open circuit condition on the anode. This simple method was found to be nearly as effective, and much less labor intensive than filtering the water. The disadvantage was that the current and potential record for the assembly showed large (although short-term) fluctuations each time the cathodes were changed, and each anode was momentarily connected to twice the normal area of cathode. It was not known exactly how these fluctuations affected the long-term corrosion of the anode. Nevertheless, the anodes connected continuously to cathodes with biofilms usually showed much higher weight losses at the end of the experiment and currents during the experiment one to three orders of magnitude higher than those of the control anodes [7].

None of the control methods described above is ideal, and the one chosen for a given experiment will depend on the intended purpose and duration of the experiment. The utility of these control methods is not limited to studies of crevice corrosion. In general, they can also be used for the study of any type of corrosion in which the effect of a natural or cultured biofilm is being measured.

## FIELD TESTS AND STANDARDS

As was the case in the laboratory, no standards have been written for field tests involving microbiologically influenced corrosion. Many of the electrochemical techniques evaluated above for use in the laboratory can also be taken into the field. The limitations on using these techniques on large structures in the field are described in other chapters of this manual. The same cautions outlined above for using them in laboratory MIC work should generally be carried into the field as well.

When attempting to analyze whether or not a particular type of corrosion on a real structure has been influenced by microorganisms, one should first observe proper procedures for dealing with the metallurgical and electrochemical aspects of the evaluation for that type of corrosion. Beyond those procedures, there are also some unique procedures for dealing with MIC. For the most part, these procedures, as outlined below, relate to the biological (i.e., living) nature of the evidence. For further information, the reader is referred to the review by Pope et al. [136], any of a number of books on microbiological laboratory methods [e.g., 137,138], the books by Borenstein [15], Videla [19], Kearns and Little, Eds., [139], Kobrin, Ed., [17] and Stoecker, Ed., [18], and the Corrosion Testing Made Easy volume on MIC [53].

When dealing with a suspected case of MIC in the field, it is of vital importance to remember that much of the evidence is living or is directly produced by living organisms. That evidence changes, or even disappears, very quickly when the specimen or structure is allowed to dry out or to sit under conditions different from those under which corrosion took place. Therefore, if MIC is to be either identified or eliminated, the proper type of sampling needs to be done quickly. In most cases, the evidence also needs to be transported to the analytical laboratory quickly. For nearly all metallic systems, there are several careful observations that need to be made while the corroding site is still fresh and wet. These include:

1. The form and distribution of corrosion (e.g., uniform or localized, tuberculation or not);
2. The color of the wet fouling and corrosion products;
3. The appearance and colors of the metal both within and immediately adjacent to the corrosion site (bright, shiny areas under corrosion products indicate active corrosion); and
4. The presence or absence of H<sub>2</sub>S odor as revealed by adding a drop or two of HCl to the corrosion products or the general environment adjacent to the corrosion site.

It is also important to gather information on the general state of the bulk water chemistry, including oxygen and sulfide concentrations, pH, salinity (or chloride ion concentration), and temperature (or temperature range) during the time of corrosion. These water chemistry measurements, however, need not be taken while the corrosion products are still wet, provided the bulk water chemistry does not change with time.

If it is suspected that a certain type of organism, such as the sulfate-reducing bacteria (SRB), sulfur oxidizing bacteria, any one of a number of acid producing bacteria or metal oxidizing bacteria is involved, then it is important to sample for and try to culture those bacteria. Generally, samples of the environment or corrosion products containing biological materials should be taken in duplicate, one preserved for microscopic and chemical analyses, and the other kept live for microbiological analysis. All such samples should be taken as soon as possible after the "normally corroding" material or structure is disturbed. It is vital that the live samples be handled properly, transported to the laboratory immediately and analyzed within 12–24 h. Procedures for

taking these samples are outside the scope of this manual, but the reader is referred to the review by Pope et al. [136] and the Corrosion Testing Made Easy volume on MIC [53] as a guide to the literature on the subject.

*E. L. Hibner, Editor*

# Zinc

*Frank E. Goodwin<sup>1</sup> and Safaa J. Alhassan<sup>1</sup>*

THE LARGEST USE OF zinc is as a protective coating for steel, and therefore corrosion tests and data [1,2], have been developed and widely used to describe its performance in specific situations or determine its usefulness for new applications. The corrosion resistance of zinc in cast or wrought form is less often a criterion for selection for a given application, although substantial published corrosion data on these product forms exist [2]. Another class of product, zinc anodes, is used to provide corrosion protection to iron and steel structures that are buried or immersed by simply making an electrical connection between the ferrous material and the anode. By this means, it is not necessary to provide a protective coating to the ferrous object. The use of a coating, however, reduces the current demand and extends anode life. Corrosion data for this application are also widely published [1].

Zinc-coated steel and monolithic zinc objects corrode similarly; a useful reference on the mechanism of corrosion of a galvanized coating is that of Daesen [3]. In dry air, a film of zinc oxide initially forms; however, the presence of moisture and carbon dioxide changes the corrosion product to a basic zinc carbonate film. Similarly, a dilute presence of sulfur compounds can result in a production of a basic sulfate film. Zinc oxide, basic zinc carbonate, and basic zinc sulfate are stable protective layers if left undisturbed; however, the pH of the environment can interfere with these layers, resulting in the formation of more soluble products. Because zinc forms an amphoteric oxide, both strong alkaline and acid conditions interfere with the formation of these protective layers. Attack is most severe at pH values below 6 and above 12.5. Within this range, corrosion is relatively slow.

Unalloyed zinc corrodes uniformly unless in contact with more cathodic materials, in which case a more localized galvanic corrosion can occur at the interface. In other cases, nonuniform corrosion is generally not encountered. Zinc alloys, particularly those with aluminum, can suffer from pitting and intergranular attack. This tends to be influenced by the fineness of the alloy microstructure.

The addition of aluminum to zinc is beneficial in improving its corrosion resistance and has resulted in development of coatings with aluminum contents between 5 and 55 %, like Galfan and Galvalume for hot dip and Zn-15 % Al alloy for thermal spray applications. In these coatings, the initial

surface layer formed is an aluminum oxide. Under humid conditions, additional corrosion products of aluminum and zinc hydroxides are formed as protective films. The addition of iron can improve the corrosion resistance of zinc in mildly acidic conditions, while copper additions up to 2 % can improve atmospheric corrosion by up to 20 % [1]. Lead was traditionally added to galvanized coatings to increase fluidity and produce a characteristic "spangle" solidification pattern. Segregation of lead to zinc grain boundaries, however, lowers corrosion resistance in comparison with pure zinc, especially in humid environments.

## GALVANIC PROTECTION

When zinc and steel are connected in the presence of an electrolyte, current flows from the zinc to the steel through the electrolyte so that the zinc becomes an anodic electron-producing area, while the steel is cathodic and electron-consuming. The zinc therefore corrodes in preference to the steel and in doing so protects the steel surface. This protection occurs with zinc anodes or with zinc coatings on steel surfaces subjected to cuts or scratches that expose the steel. Zinc's cathodic protection for steel depends upon the dimensions of the exposed steel and the coating thickness of the pure zinc layer. Scratches up to 5 mm wide and cut edges on galvanized parts up to 10 mm thick can be effectively protected by the surrounding zinc layer [1]. Under special situations in water immersion, zinc can become cathodic to steel; examples include immersion in fresh water between 60 and 90°C and 0.01M NaHCO<sub>3</sub> saturated with oxygen containing 1 % CO<sub>2</sub> at 65°C. In general, however, zinc is anodic to steel and is widely used for this property. There are a number of standard specifications for zinc-coated steels, while sacrificial anodes are covered by ASTM B 418, Specification for Cast and Wrought Galvanic Zinc Anodes. Application of zinc anodes is covered by BSI Code of Practice 7361, Part 1 (1991).

Zinc coatings are applied to steel by hot-dipping, electroplating, mechanical coating (i.e., tumbling in zinc dust at room temperature), sherardizing (i.e., tumbling in zinc dust just below the melting point of zinc), thermal spraying, and zinc-rich paints. The overwhelming tonnage of coatings is produced by hot-dip or electrogalvanizing processes. These coatings initially provide barrier protection, and then start to corrode sacrificially, therefore protecting the steel underneath.

<sup>1</sup>International Lead Zinc Research Organization, Inc., P. O. Box 12036, Research Triangle Park, NC 27709-2036.

Rolled zinc is produced as sheet, strip, plate, rod, and wire in numerous compositions and alloys. Sheet zinc for building uses contains copper and titanium and is covered by ASTM B 69, Specification for Rolled Zinc. Rolled zinc is also used for dry cell battery cans; however, composition and corrosion requirements for these are largely proprietary. Cast zinc is almost always in the form of zinc-aluminum-copper-magnesium alloys containing between 4 and 27 % aluminum. These alloys are covered by ASTM B 240 (Specification for Zinc Alloys in Ingot Form for Die Castings) and B 669 (Specification for Zinc Alloys in Ingot Form for Foundry and Die Castings).

The corrosion resistance of zinc can be improved by subsequent application of either conversion coatings or synergistic systems. In the former category are included processes such as zinc anodizing, using either phosphate-chromate-fluoride or silicate electrolytes to MIL-A-81801 (1971), and chromate conversion coatings. In the latter, the zinc surface is reacted to form a complex surface layer of chromium hydroxide, zinc hydroxychromate, and zinc chromate. Application of the chromate conversion coating is covered by ASTM B 201, Practice for Testing Chromate Coatings on Zinc and Cadmium Surfaces. Alternatives to chromating include phosphate, molybdate, silicate, and several organic coatings. Chromating is frequently found effective as an inhibitor against white rust. However, safety questions on chromate treatment tanks that contain sodium dichromate particularly with regard to spent solution disposal have been increasingly raised. Bans are already operating in some areas of Europe and North America. The issue of "white rust" is an important issue to galvanizers because it limits their market. White rust forms when freshly galvanized steel is exposed to water in the atmosphere in closely packed spaces. Zinc surfaces in this environment produce voluminous, bulky, and white deposits of zinc hydroxide/zinc oxide with thickness of the white rust layer of the order of 1000 Å. Zinc surfaces that already have a normal protective layer of corrosion products are seldom attacked. The protective layer on zinc consists of complex carbonate oxide films. Despite a considerable effort, researchers have yet to produce a direct replacement for sodium dichromate solution. The requirements for a chromate-free treatment are that it be nontoxic, water soluble, and environmentally safe, and that it maintain the original appearance, low cost, be easily painted over, and have an easy control and maintenance procedure.

Synergistic coatings include a variety of organic coatings applied by either coil coating or powder coating. If properly applied, the overall useful life of the organic coating-galvanized steel system will be longer than the sum of the lives of the individual components.

## SENSITIVITY TO PARTICULAR ENVIRONMENTAL FACTORS

In solutions with pH levels lower than 4.5, zinc reacts with hydrogen ions to produce zinc ions plus hydrogen gas. At pH values higher than 4.5, there is an insufficient supply of hydrogen ions to make this reaction significant and the rate of corrosion is controlled by the availability of oxygen diffusing

to the metal surface. Curves describing the effect of pH level have been published by Rotheli [4] for immersion corrosion and by Goodwin [5] for atmospheric corrosion.

In aqueous corrosion, the oxygen content of water is a controlling factor. Of other anions, chloride is the most corrosive to zinc in aqueous corrosion. The effectiveness of chloride becomes stronger as water softness increases and carbonate levels decrease; thus, a chloride content of 80 mg/L in soft water causes quite severe corrosion while in hard water no corrosion occurs, even with 700 mg/L chloride levels. Sulfate is less active than chlorides towards zinc. Nitrates are also fairly benign at normal levels. Hydrogen sulfide and other sulfides are sometimes produced by anaerobic decomposition of sulfur-containing organic matter in the water. Zinc is less sensitive to such waters than are copper and iron. Salts of metals more noble than zinc can sometimes be found in industrial waste streams. In these cases, the more noble metal will normally deposit onto the zinc, while an equivalent amount of zinc goes into solution. Small amounts of dissolved salts, such as copper, can set up local cells producing pits, while other salts can inhibit attack by sequestering corrosive species. Substances that form complexes with zinc but do not form protective films, such as salts of ammonia, may promote corrosion in water. Oxidizing salts may also stimulate attack under special conditions.

In aqueous corrosion, raising the temperature increases the dissolution of zinc in water. A marked increase occurs up to around 60°C followed, by a decrease at higher temperatures due to the decrease in oxygen supply and the formation of more compact and adherent scale. Intergranular corrosion of zinc casting alloys is a risk above 70°C in wet or humid conditions, such as in steam, when no protective layer can form and selective dissolution of the structure occurs. In hot hard waters, scale forms at water temperatures above 55°C. This scale has a coarse grain structure and does not adhere well to the zinc surface. Corrosion of the zinc occurs locally because of the discontinuities in the scale or local electrochemical action. Above 60°C, zinc usually becomes cathodic to steel; therefore, the steel will corrode to protect the zinc coating.

In air, sulfur dioxide is the most important contaminant to be considered. At relative humidities of 70 % or above, it usually controls the corrosion rate of zinc. Observed corrosion rates on atmospheric panels are much less than those calculated using available sulfur deposition levels from the atmosphere. This is related to washing of the panels by rain and an incomplete dissociation of hydrogen and zinc on the surface. Chlorides have far less effect on the atmospheric corrosion of zinc than sulfur. Results of tests in Nigeria indicated that an approximate linear relationship between corrosion rate and salinity. Appreciable corrosion, however, occurred only at sites very close to the sea [1]. Chloride corrosion in atmospheric exposures is usually accelerated because of the presence of sulfur gases, as occurs on the coast in highly industrial areas [1]. A similar situation exists for ammonia, which is usually found in high quantities near agricultural land and petrochemical plants. By itself, ammonia does not accelerate zinc corrosion, but it does react with atmospheric sulfur oxides to produce ammonium sulfate, which accelerates paint film degradation and zinc

corrosion. Ammonium can also react with NOX compounds to form ammonium nitrite and nitrate. Both compounds accelerate zinc corrosion, but to a much lesser extent than oxides of sulfur. Nitrogen oxides by themselves also increase the corrosion rate of zinc, but to a lesser extent than sulfur oxides. Atmospheric corrosion of zinc is roughly proportional to the time of wetness in a particular location, providing that the nature and quantity of environmental pollution does not change. Increasing temperature usually reduces the time of wetness, lowering the corrosion rate. Decreasing temperature can increase the time spent below the dew point of the surrounding atmosphere, increasing the time of wetness. Rain also increases time of wetness, but it can have an indirect beneficial effect by removing corrosive materials. Time of wetness is often in practice considered as the time when relative humidity exceeds 80 % and the temperature is above 0°C.

## SPECIFIC CORROSION PRACTICES

General approaches to a zinc corrosion testing program are described in the remainder of this chapter. A summary of tests and practices is provided in Table 1.

### Methods of Evaluation of Corrosion Damage

Under many situations, zinc corrosion is uniform in nature, while in other cases nonuniform or localized corrosion can occur. Overall determinations of corrosion mass loss in a galvanized coating can be made by “weigh-strip-weigh” methods such as described in ASTM G 1 (see Table 1) for zinc. This procedure dissolves some uncorroded zinc along with the corrosion products; correction procedures are given in the specification. It is also possible to electrolytically remove corrosion products using the procedure given in the same specification; however, electrolytic removal of corrosion products from zinc usually causes some of the zinc coating to be removed, especially in the case of zinc-aluminum coating alloys. Results from the “weigh-strip-weigh” method are reported as mass lost per unit area of coating. The results of this procedure can be validated, and further insights into the nature of corrosion obtained by metallographic cross sectioning of the corroded coating. Suitable etchants for preparing galvanized coatings are found in references such as Kehl [6].

Nondestructive determination of coating thicknesses can also be made by magnetic interference (like ASTM B 499 and ASTM E 376) or X-ray spectrometry (like ASTM B 568), provided that the measured surface is first cleaned to remove corrosion products that would otherwise result in measurement inaccuracies.

Impurities such as lead, tin, and cadmium are cathodic to zinc-aluminum alloys and can cause relatively rapid intergranular corrosion under humid conditions. The effects of these impurities are checked by humidity tests such as exposing test samples to saturated steam at 95°C for a period of ten days [1].

Nonuniform corrosion can be assessed using ASTM G 46. Cleaning procedures for examining specifications under this

procedure are covered by ASTM G 1. Pit density can be determined by the grid counting method noted in ASTM G 46. Metallographic examination allows for determination of pit depth and can allow determination of which coating constituents have actually been attacked.

## Tests for Specific Corrosion Types

### *Atmospheric Corrosion—Accelerated Tests*

The most widely used test to provide a rough determination of corrosion performance is the standard salt spray test, ASTM B 117. This is despite the fact that ASTM Committee B08, as early as 1943, confirmed that salt spray testing was a poor means of estimating coating performance and was especially unsuitable for coatings of a sacrificial nature. Despite this, the procedure continues to be widely used for manufacturing control purposes because of its simplicity and the availability of many results from this test for comparison. A better test for determining the behavior of galvanized coatings in a chloride-containing environment, such as for automotive applications where deicing salts are used or in marine environments, is a cyclic test such as that described by SAE J 2334 and Swedish Standard SS117211, Corrosion Tests in Artificial Atmosphere—Accelerated Outdoor Tests (1992). This test allows for simulation of a twelve-month outdoor test in a period of twelve weeks and is accomplished by artificial salting and other acceleration techniques along with outdoor exposure.

Accelerated simulation of industrial exposure environments can be carried out using the moist SO<sub>2</sub> test described in ASTM G 87. The concentration of sulfur dioxide gas used in this test will determine the degree of acceleration obtained relative to actual service. If past results using actual exposure sites are available to compare with accelerated test results, then some extrapolation is possible, provided that other variables do not change. Of these, the most important is likely the rate of sulfur oxide deposition on the exposure site that can be measured using ASTM G 91. One use of the sulfur dioxide ASTM G 87 test is to determine the location of any thin portions of the coating or pores. Such areas are the first to fail in this test. A more rapid test of such weaknesses or discontinuities, termed the Preece test, is covered by ASTM A 239. This test involves immersion of zinc-coated steel samples in a copper sulfate solution; however, continuous galvanized sheet products and all wire products are excluded from the ASTM A 239 test because of the additional forming undergone after coating. This test should only be used for materials that are coated after final forming operations; for other materials the sulfur dioxide ASTM G 87 test should be used. The endpoint of the Preece test is either the specified number of dips or the appearance of a bright adherent copper deposit where the zinc coating has been dissolved in its thinnest locations.

Accelerated tests such as ASTM B 201 are very useful in evaluating the quality of chromate films on zinc or zinc-coated surfaces. The test proceeds until white corrosion products have formed and should not be allowed to continue until red rust forms. Only the time to formation of “white rust” is relevant. The effects of impurities on the corrosion rate of zinc can be determined by humidity testing.

**TABLE 1**—Summary of standard tests and practices for evaluating zinc corrosion.

Standard Number	Description	Usage
ASTM G 1	Recommended Practice for Preparing, Cleaning and Evaluating Corrosion Test Specimens	Determines amount of corrosion loss on test samples by removing corrosion products.
ASTM B 499	Test Method for Measurement of Coating Thicknesses by the Magnetic Method: Nonmagnetic Coatings on Magnetic Basis Metals	Nondestructive measurement of coating thickness remaining after testing.
ASTM B 568	Test Method for Measurement of Coating Thickness by X-Ray Spectroscopy	Same as ASTM B 499.
ASTM G 46	Practice for Examination and Evaluation of Pitting Corrosion	Determines presence and density of pitting corrosion.
ASTM B 117	Test Method of Salt Spray (Fog) Testing	Most widely used accelerated test to determine general corrosion resistance of zinc coatings, particularly in marine and other salt-laden environments.
SS117211 (1992)	Corrosion Tests in Artificial Atmosphere-Accelerated Outdoor Tests	Twelve-month outdoor exposure test with artificial salting to determine general corrosion resistance.
ASTM G 87	Practice for Conducting Moist SO <sub>2</sub> Tests	Widely used accelerated test to determine corrosion resistance to industrial atmospheres.
ASTM G 91	Practice for Monitoring Atmospheric SO <sub>2</sub> Using the Sulfation Plate Technique	Determines rate of SO <sub>2</sub> deposition at corrosion site.
ASTM A 239	Test Method for Locating the Thinnest Spot in a Zinc (Galvanized) Coating on Iron or Steel Articles by the Preece Test (Copper Sulfate Dip)	Determines presence of discontinuities in zinc coatings.
ASTM B 201	Practice for Testing Chromate Coatings on Zinc and Cadmium Surfaces	Determines quality of chromate coatings by determining white rust resistance.
ASTM B 380	Methods of Corrosion Testing of Decorative Electrodeposited Coatings by the Corrodokote Procedure	Determines resistance to corrosion by chlorides.
ASTM G 92	Practice for Characterization of Atmospheric Test Sites	Gives information for comparison of results from one exposure site with others.
ASTM G 50	Practice for Conducting Atmospheric Corrosion Tests on Metals	Recommendations for locating test sites, constructing racks.
ASTM G 33	Practice for Recording Data from Atmospheric Corrosion Tests of Metallic-Coated Steel Specimens	Recommendations for recordkeeping practice for exposure programs.
ASTM G 31	Practice for Laboratory Immersion Corrosion Testing of Metals	Addresses issues relating to general immersion testing and its interpretation.
ASTM D 2688	Test Method for Corrosivity of Water in the Absence of Heat Transfer (Weight Loss Methods)	Determines water corrosivity by corrosion weight loss.
ASTM D 2776	Test Methods for Corrosivity of Water in the Absence of Heat Transfer (Electrical Methods)	Determines water corrosivity by solution conductivity.
ASTM G 61	Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-Based Alloys	Determines susceptibility of named alloys to localized corrosion in immersion.
ASTM G 57	Method for Field Measurement of Soil Resistivity Using the Wenner Four-Electrode Method	Allows soil corrosion results to be compared with results of similar experiments.

The most effective test is termed "steam testing" and carried out at a temperature of 95°C. Samples are weighed and then placed in a cabinet for intervals up to several hundred hours. Samples are observed to undergo a mass gain in many cases after steam testing, which is usually related to the quantity of impurity elements in the zinc. This mass gain is caused by intergranular corrosion, with the formation of corrosion products occurring along zinc grain boundaries where impurities usually segregate.

Although originally intended for evaluation of nickel-containing decorative electroplated coatings, the Corrodokote test, ASTM B 380, has been used to qualify the performance of galvanized products for automotive applications. Apparently, the chloride ions introduced in this process provide a useful indication of automotive underbody performance for products such as tubing for containment of automotive fluids and other small components. The Corrodokote test applies a corrosive slurry to the

component to be tested, after which it is allowed to dry. Samples are then exposed to high humidity for a specific period of time.

#### *Atmospheric Corrosion—Extended Tests*

To determine suitability for service in atmospheric conditions, atmospheric exposure tests provide the most valid results, although testing time may be unacceptably long. Shorter test times are usually appropriate to detect defects in the coatings that usually appear quickly. Before beginning an atmospheric exposure program, sites should be characterized using the procedures described in ASTM G 92. The relevance of these characteristics to the intended service of the product should be carefully considered by suggesting sites with different characteristics to gain information for range of possible conditions. ASTM G 50 should also be referenced in locating test sites and specifying or constructing exposure racks for samples. As this specification notes, most published data on atmospheric corrosion of metals are based on an exposure angle of 30° from the horizontal facing south. ASTM G 33 describes recordkeeping methods that should be used for such long-term exposure tests.

#### *Immersion Corrosion—Accelerated Tests*

To simulate service of components that will be immersed in fluids, ASTM G 31 should be followed. This standard includes many precautions relating to how laboratory testing environments may differ from actual service. Issues such as immersion solution composition, temperature, aeration, velocity, and volume must be addressed thoroughly before the design of the test can be considered complete. For tests involving corrosion in water, two ASTM D 2688 and ASTM D 2776 should be referenced, which determine corrosivity by weight loss and electrical methods, respectively.

Many immersion tests based upon electrochemical principles can also be used to evaluate corrosion resistance. Most of these have been developed for automotive applications. For example, Dattilo [7] has developed a practice for measuring corrosion rates by Tafel line extrapolation and the polarization resistance technique. Value of the Tafel slopes and the corrosion currents can be compared for different coated products. The effects of the immersion medium employed can thus be determined. Electrochemical impedance measurements (e.g., ASTM G 106, Practice for Verification of Algorithm and Equipment for Electrochemical Impedance Measurements) are useful for determination of the rate of inhibition of corrosion. The frequency sweep with AC impedance measurements can passivate the electrode with an increasing product formation at intermediate reaction speeds. A key assumption is that observations at high frequency are also valid at low frequencies because of the high rate of zinc dissolution in acid environments [8]. ASTM G 61 describes a procedure for conducting cyclic potentiodynamic polarization on iron-, nickel-, and cobalt-based alloys. This test is also useful for determining susceptibility to localized corrosion such as pitting or crevice corrosion in zinc-coated steels, although all scratches or other cut surfaces exposing iron or steel to the solution

must be sealed so that only the zinc is exposed to the solution. ASTM G 61 could also be used to detect coating defects and holidays. For example, linear polarization techniques (like ASTM G 3) have been used to investigate the behavior of Zn and Zn + Al thermal spray coatings on steel.

#### *Soil Corrosion*

Corrosion in soil is largely influenced by soil chemistry. A summary of the characteristics and properties of soils is given in the National Bureau of Standards circular on underground corrosion [9]. There are over 200 soil types in the United States, categorized according to texture, color, and natural drainage. Physical properties of importance in corrosion are those of determining the permeability of the soil to air and water. Many chemicals are present in soils but those relevant to corrosion studies are those that are soluble in water. Analyses are usually made for base-forming elements such as sodium, potassium, calcium, and magnesium and for acid-formers such as carbonate, bicarbonate, chloride, nitrate, and sulfate. Electrical resistivity of the soil is determined by the nature and concentration of the ions formed by the chemical salts dissolved in the soil moisture. ASTM G 57 gives a method for measurement of soil resistivity. The U.S. Department of Agriculture Soil Conservation Service has developed a useful classification of soils that allows comparison between sites. Many galvanized samples buried in soil are also exposed to concrete, mortar, or plaster. Each of these substances attacks zinc, but the attack ceases after the materials have dried. However, the attack is sufficient to give a good bond [10–13]. Zinc is resistant to mildly alkaline conditions, unlike steel and aluminum, and thus is preferred for encasing of steel in concrete.

#### **Comparison of Corrosion Behavior among Zinc Coatings**

As noted before, the ASTM B 117 salt spray test is the most widely used accelerated test for determining coating performance even with its shortcomings, for manufacturing control purposes. The hours to a fixed fraction of red rust are widely accepted as a figure of merit, allowing comparison of different zinc coatings. Similarly the hours or cycles in accelerated sulfur dioxide tests such as ASTM G 87 are widely used to give accelerated information on the relative performance of zinc coatings in simulated industrial environments. These tests, and cyclic tests evolved from them, are the most widely used in providing comparative rankings of zinc coatings. Electrochemical tests are also used as screening techniques. A useful survey on applications of these techniques is given by Berke and Friel [14]. More detail is also provided in Chapter 7 of this manual.

# Lead (and Alloys)

Safaa J. Alhassan<sup>1</sup> and Frank E. Goodwin<sup>1</sup>

## INTRODUCTION

LEAD IS A MEMBER OF Group IVB of the periodic table with two oxidation states ( $\text{Pb}^{2+}$  and  $\text{Pb}^{4+}$ ), but the chemistry of the element is dominated by  $\text{Pb}^{2+}$  ion. Lead has four isotopes with three of them being the ultimate decay products of uranium ( $^{238}\text{U}$  and  $^{235}\text{U}$ ) and, therefore, widely used in geological dating. The crystal structure of lead in solid form is face-centered cubic (FCC) with a lattice parameter of 4.95 Å at 20°C. Lead is a blue-gray metal with density (11.3 g/cm<sup>3</sup>) 50 % more than that of steel and four times that of aluminum. However, lead is malleable, soft, and melts at only 327°C, and therefore, readily cut and shaped into pipes and sheets since ancient times.

The total world consumption of refined lead in 2000 was 6 449 000 tonnes closely matching the total world production of refined lead in 2000, which was 6 630 000 tonnes. The total world production of primary lead in 2000 was 2 936 000 tonnes, meaning the balance of consumption was from recycled sources. The 3-month price for lead ranged between \$515.00 and \$419.00 per tonne [1]. The main ore deposit is galena,  $\text{PbS}$ , which contains an amount of silver and that adds economic value to ore deposits. Other lead deposits are in the form of sulfate and carbonate. Lead ranks fifth in tonnage consumed after iron, copper, aluminum, and zinc, but is rare in earth's crust where it ranks 34th among other elements.

The primary market for lead at the present time is in energy storage batteries, followed by the chemical, joining, and cable sheathing applications. About 95 % of the lead in spent batteries is recycled and used in new products. Lead can be used as cast, pipe, sheet, or as a thin protective coating for steel. A growing use of lead is in the manufacturing of seismic isolator (or earthquake dampers) for buildings. Several types of isolators are used, one of which is a lead rubber design combining bearing (support) and isolation (damping) functions. The isolator core is made of pure lead. Since the Hanshin (Kobe) earthquake of 1995, lead-containing seismic isolators have been used in Japan at an increasing rate with recent emphasis on residences and banks. In the USA, particularly California, bridge deck seismic isolation has also been increasingly used.

Inorganic lead compounds were used in paints and organic compounds in fuel to increase octane number, until concerns about lead's toxic properties arose. Lead is relatively opaque to ionizing radiation and is a valuable shielding material in X-ray applications and nuclear facilities. Another market for lead is in alloys that are used as solders in applications ranging from circuit boards to heat exchangers. Lead is also used in acoustic barrier panel, glassware and ceramic, and fiber optic cables.

## NATURAL PROTECTIVE FILMS

In a normal atmospheric exposure, a fresh lead surface will slowly be oxidized into a thin, protective lead oxide, which halts further oxidation of the metal. The rate of formation of lead oxide is determined by the absorption of oxygen and water vapor into the lead. Such factors as industrial and marine pollution, humidity, temperature, and rainfall profoundly affect the aggressiveness of the atmosphere, and most metals suffer accordingly. However, the protective films formed of lead are so effective that corrosion is insignificant in most natural atmospheres. The extent of this protection is demonstrated by the survival of lead roofing and auxiliary products after hundreds of years of atmospheric exposure that may continue for a much longer time if these films are not damaged [2].

The greatest value of lead is often in its very long service life and low maintenance costs, which when taken as part of an overall systems approach, often swings the materials selection choice balance in lead's favor, especially as labor costs continue to rise. Lead has an excellent record of service in three major types of environments: chemical, atmosphere, and underground. Resistance of lead to corrosion in contact with sulfuric acid has been critical in many chemical industries, like paper, plastics, petroleum, and photographic materials. Of particular importance in recent years has been the use of lead in the protection of devices for the removal of sulfur from industrial waste gases. Several industries, like ore roasting or burning of fossil fuels for power generation, produce large volumes of waste from which sulfur-containing species must be removed.

The current environmental regulations do not permit the use of lead in the drinking-water supply system, despite the excellent corrosion performance of lead and lead alloys in specific environments. This corrosion resistance is attributed to the formation of a strong, adherent, and impermeable

<sup>1</sup>International Lead Zinc Research Organization, P. O. Box 12036, Research Triangle Park, NC 27709-2036.

protective film that is stable or insoluble in these environments. Lead or lead-lined components continue to be used in the handling of alum used in industrial-water-treatment systems. Lead-sheathed cables have shown reliable long-term performance worldwide because of the extraordinary corrosion resistance of lead alloys to a variety of soils. Using lead-covered copper for grounding systems or in roofing has provided a superior performance in a variety of atmospheres around the world [3]. Lead with a small addition of bismuth is used in cable sheathing, while lead-calcium alloys are used in wire, pipe, anodes, and storage battery grid applications. Lead-copper alloys are of interest in cable sheathing and preferred by the chemical industry for its structural stability in handling sulfuric acid. Antimony additions increase hardness, tensile strength, and fatigue resistance, and such alloys are used in storage battery components. Lead-tin alloys are used in cable sheathing and as solders. A listing of lead alloys and their applications is reported in Ref 3.

## EFFECTS OF ALLOYING

There are four common grades of lead: pure lead, common lead, chemical lead, and acid-copper lead. These grades are covered by ASTM B 29-92, Standard Specification for Refined Lead. Pure lead and chemical lead contain 99.94 % minimum lead, while the latter two contain 99.9 % minimum. Typical impurities include Bi, Cu, Ag, Fe, Zn, Ni, Sn, and Sb [4]. Higher purity is also available in commercial quantities, like low bismuth low silver pure lead with 99.995 % minimum lead. However, because lead does not possess the level of required mechanical strength for material of construction, and in many cases, it is unable to support its own weight, alloys have been developed to improve its physical and mechanical properties, especially mechanical rigidity.

### Lead-Antimony

Lead alloy with 6 % antimony is frequently used in sheet and pipe forms for its superior strength and hardness over soft lead. Lead-antimony alloy is used to make battery plates. Antimony additions increase hardness, tensile strength, and fatigue resistance, and form alloys used in storage battery components.

### Lead-Tin

Lead-tin with lead-antimony alloys occupies the status of the most important alloy groups of lead. Pb-Sn alloys are used in cable sheathing, solders, or to wet steels [3]. Solders can contain between 50 and 95 % Sn and can be used for joining sheet metals for roofs, gutters, and downspouts. Pb-Sn solder has been used in joining copper radiators in the automotive industry and in the construction of other heat exchangers carrying fresh water with no significant galvanic corrosion. However, if a solder in the range of 10 to 25 % Sn has been used in radiator joints, movement during solidification should be avoided to prevent hot tearing in solders due to a wide freezing range [5]. Solders with 40–50 % Sn are widely used for general joining purposes. Furthermore,

solders with 60–63 % Sn are used most extensively in the electronic industries and sometimes with additions of silver to reduce dissolution of silver-based coatings. However, solders cannot be used in joining corrosion-resistant chemical equipment like tanks for photographic developers [2]. Pb-Sn coating used on steel is called "Terne" and contains 3–15 % Sn and is used to wet the steel, and therefore, allowing metallurgical bond formation between lead and steel. Painting of Terne further raises its resistance to corrosion in outdoor environments and makes it attractive to automotive industry for fuel tanks and small diameter tubing [5]. Other applications for lead-tin alloys are storage battery connectors, roofing, and type and bearing metal [4].

### Lead-Calcium

The addition of a small amount of calcium produces alloys of interest for wire, pipe, anodes, and storage battery grid applications. The addition of calcium to Pb-Sn alloys, and with proper processing, produces alloys with improved breaking strengths up to 75.8 MPa from 58.6 for the Pb-Sn binary alloy, due to a fine grain structure [4]. The corrosion resistance for Pb-Ca-Sn alloys is also higher than that of Pb-Sn in many applications.

### Lead-Copper

Lead-copper-tellurium alloys, up to commercial content of 0.08 % Cu and 0.04 % Te, are of interest in cable sheathing, and also in the chemical industry in handling sulfuric acid. Alloys containing copper have a superior mechanical strength due to grain growth inhibition and higher corrosion resistance than pure lead. Copper additions in the above range do not increase the corrosion rate of lead [4].

### Lead-Silver

Lead alloyed with silver shows excellent resistance to sulfuric acid. The addition of 1 % Ag produces alloy bars, extruded or cast, that are the excellent insoluble anodes with very good corrosion resistance over a wide range of current densities. Alloys with 1.5 % Ag and 1 % Sn are used as solders with high melting point [3].

## EFFECTS OF MICROSTRUCTURE

Since lead has a low melting point, lead based alloys can recover and recrystallize at room temperature, while high purity lead (99.99 %) may be subjected to grain growth at 25°C. The addition of elements, like Cu, Te, and Ca, to lead alloys is designed to inhibit grain growth. Grain growth can play an important role in intergranular corrosion, which can cause significant loss in strength [4].

## VARIOUS MILL PRODUCTS

As mentioned before, there are four common grades covered by ASTM B 29-92: pure lead, common lead, chemical lead, and acid-copper lead. Pure lead and common lead

contain 99.94 % minimum lead, while the latter two contain 99.9 % minimum, with Bi, Cu, Ag, Fe, Zn, Ni, Sn, and Sb being main impurities. Alloys with higher purity than 99.99 % are also available in commercial quantities. Corroding lead refers to a process that was formerly used, rather than to corrosion characteristic, and is another name for pure lead. This product is free of unwanted impurities and, therefore, is the most widely used grade of pure lead. Chemical lead is used in the chemical industry and contains small amounts of silver and copper, which increase the corrosion resistance and the mechanical strength of the grade. Common lead contains higher amounts of silver and bismuth than corroding lead and is used in battery oxide and general alloying. Acid-copper lead provides higher corrosion resistance than that of chemical lead in most applications that require corrosion resistance. Acid-copper is used in several types of fabricated lead products [4].

## GENERAL CORROSION OF LEAD

A fresh lead surface slowly oxidizes into a thin, protective lead oxide (PbO) that stops further oxidation of the metal. Lead gives satisfactory resistance to corrosion in rural, marine, and industrial environments. The corrosion rate data for lead is shown as 0.5–0.7  $\mu\text{m/y}$  in industrial (New York, NY), 1.2–2.2  $\mu\text{m/y}$  in marine (Kure Beach, NC), and 1.05–1.85  $\mu\text{m/y}$  in rural (State College, PA) [6]. Lead corrosion products in such environments, in addition to lead oxide, are sulfate, chloride, and carbonate, with lead chloride being the most soluble of all four products (see Table 1). However, lead in outdoor exposures was found to produce sulfate ( $\text{PbSO}_4$ ) and/or carbonate ( $\text{PbCO}_3$ ), and indoor exposures lead carboxylates. The primary atmospheric agents responsible for degradation of lead are  $\text{SO}_2$ ,  $\text{CO}_2$ , and carboxylic acid [7]. The corrosion rate of chemical lead in Key West, Florida, and La Jolla, California is 0.58 and 0.53  $\mu\text{m/y}$  (0.023 and 0.021 mpy), respectively [2].

Because of the toxicity of lead salts, lead should not be used to handle drinking water. The corrosion rate of lead is generally quite low in a wide variety of water environments, with major exceptions found in some pure waters containing oxygen and in soft natural water where contamination is an issue. Natural waters with hardness greater than 125 ppm calcium carbonate form protective films, and therefore, attack on lead is negligible. Certain salts, like silicate salts, enhance the resistance of lead to corrosion by water

because of its effect on water hardness and film formation [2]. In contrast, nitrate and chloride ions interfere with film formation and, thus, increase corrosion rates. The corrosion rate of lead is high in underground waters if they contain organic acids or carbonic acid. Furthermore, lead usually has low corrosion rates in seawater with influencing factors like flow, wave action, sand or silt content, temperature, and marine growth.

Lead has high corrosion resistance to chromic, sulfurous, sulfuric, and phosphoric acids and is widely used in their manufacture and handling, e.g., lining material for acid precipitators. Lead is not suitable for very dilute strengths of sulfuric acid [2] because lead does not develop protective film under these conditions.

Lead is a relatively active metal and is oxidized at the anode, and either enters the solution at the anodic sites as metallic cations or forms solid insoluble compound films. The reaction at the anode could be represented by:

The standard oxidation potential ( $E^\circ$ ) makes lead cathodic to most common metals like iron, aluminum, zinc, magnesium, and cadmium, but anodic to copper and silver. As a cathode, lead accelerates corrosion of steel, aluminum, and zinc. The cathodic reaction accompanying the lead dissolution is either the reduction of oxygen in neutral solutions or reduction of hydrogen ions in acid solutions. In the case of lead and its alloys, the physical characteristic of the film formed at the anode is the rate-determining step; therefore, the corrosion rate of lead is under anodic control. Furthermore, impurities in lead, especially Fe and Zn, which are anodic to Pb, can precipitate and segregate at the grain boundary. Therefore, it is important to keep Fe and Zn content to a minimum to avoid dissolution of their precipitates and subsequent strength loss due to grain boundary weakening. In contact with titanium and passivated stainless steels, lead itself would suffer accelerated corrosion. The formation of a protective film extends over a wide range of pH in aqueous solutions, except at very high and very low pH levels, which include both very weak and very strong sulfuric and phosphoric acids. The extent of protection depends on the compactness, adherence, and solubility of these films. The solubility of various lead compounds in water at room temperature, as shown in Table 1, is an indicator of the behavior of lead in solutions that promote the formations of these compounds. A comprehensive list of corrosion rates of lead in a variety of chemical environments

TABLE 1—Solubility of lead compounds [1].

Lead Compound	Formula	Temperature, °C	Solubility, g/100 mL $\text{H}_2\text{O}$
Acetate	$\text{Pb}(\text{C}_2\text{H}_3\text{O}_2)_2$	20	44.3
Carbonate	$\text{PbCO}_3$	20	0.00011
Chlorate	$\text{Pb}(\text{ClO}_3)_2 \cdot \text{H}_2\text{O}$	18	151.3
Chloride	$\text{PbCl}_2$	20	0.99
Chromate	$\text{PbCrO}_4$	25	0.0000058
Fluoride	$\text{PbF}_2$	18	0.064
Hydroxide	$\text{Pb}(\text{OH})_2$	18	0.0155
Nitrate	$\text{Pb}(\text{NO}_3)_2$	18	56.8
Oxalate	$\text{PbC}_2\text{O}_4$	18	0.00016
Oxide	$\text{PbO}$	18	0.0017
Sulfate	$\text{PbSO}_4$	25	0.00425
Sulfide	$\text{PbS}$	18	0.01244
Sulfite	$\text{PbSO}_3$	—	Insoluble

is given in Ref 2, and reported in Ref 4 as well, in which the corrosion data is divided into four categories. Categories A and B are environments where the corrosion rate is less than 0.05 and 0.5 mm/y (2 and 20 mpy), respectively, and in both cases lead is considered resistant and, therefore, recommended for use. Category C is for environments where corrosion rate is between 0.5 and 1.25 mm/y (20–50 mpy) and lead can be used if the effect of corroded lead can be tolerated. Category D is for environments where corrosion rate is more 1.25 mm/y (50 mpy) and lead is not recommended.

## SENSITIVITY TO PARTICULAR ENVIRONMENTAL FACTORS

The corrosion rate of lead in soils rich in sulfates or silicates is low, but in soils containing organic acids the rate might be higher than that of steel. Furthermore, lead-sheathed cable installed in continuous concrete ducts in concrete tunnels under waterways was found to be severely corroded [5]. That was because the seepage water was found to contain 1000 ppm of hydroxide ion (mainly from incompletely cured concrete), and the ducts were designed without the removal of seepage water. The use of completely cured, impervious concrete in ducts with proper drainage is the suggested remedy.

### Acidity/Alkalinity

Being amphoteric, lead can be susceptible to attack by both acids and alkalis under certain conditions. However, the formation of protective film extends over a wide range of pH in aqueous solutions, except at a very high and very low pH level, which includes very weak and very concentrated sulfuric and phosphoric acids. Lead is used commercially in equipment to handle sulfuric, sulfurous, chromic, and phosphoric acids in commercially used concentrations. However, lead is less resistant in hydrochloric and hydrofluoric acids. For example, lead is suitable to handle concentrated  $\text{H}_2\text{SO}_4$  up to less than 95 % strength at room temperature. Lead use in sulfuric acid depends on the protectiveness of its sulfate film with velocity limit up to 1 m/s. The protectiveness of a lead compound is directly related to its solubility in that specific environment. Lead sulfate is more soluble in water than in sulfuric acid. Even in the latter, the solubility of  $\text{PbSO}_4$  changes with acid concentration and temperature and reaches a minimum at  $\text{H}_2\text{SO}_4$  concentrations of 30–60 % at medium temperatures (25–50°C), resulting in a negligible corrosion. Furthermore, adding sulfuric acid to acids corrosive to lead will often lower the corrosion rate. Nitric acid of less than 50 % strength is quite corrosive to lead, while in presence of 54 % sulfuric acid, the corrosion rate for 1 and 5 % nitric acid is quite low, even at 118°C [2]. Lead has fair corrosion resistance to dilute hydrochloric acid up to 15 % at room temperature, with corrosion rate increasing as temperature and acid concentration increase. However, field experience has not been good, because of soluble corrosion products that can easily wash away. The presence of 5 % ferric chloride accelerates the acid attack

and doubles the corrosion rate. Lead has also a good corrosion resistance in dilute hydrofluoric acid (up to 10 %) at low temperature, given that the acid is air-free. Addition of sulfuric acid to hydrofluoric acid reduces the corrosion rate of lead as well.

In caustic solutions the use of lead is generally limited to concentrations of no more than 10 % up to 90°C. Little attack is seen in cold, strong amines, while dilute aqueous solutions will result in attack of lead. Lead can be attacked by calcium hydroxide solutions at room temperature, including solutions that have been in contact with fresh cement. The attack by caustic solutions also depends on several variables like temperature, concentrations, and aeration [4]. The influence of increasing additions of nitrate on the anodic features of lead in alkaline solutions was investigated [8]. The addition of 0.1–1.5 M sodium nitrate was found to enhance the anodic dissolution of lead in 0.1–1.5 M NaOH solutions and that the critical potential decreased linearly with logarithmic concentration of nitrate and temperature. Increasing the alkaline concentration increased the pitting potential. Originally, in nitrate-free alkaline solution,  $\text{PbO}$  was formed and the current density decreased, and there was no evidence of pitting.

### Soil

Soils vary widely in physical and chemical characteristics and, consequently, in their corrosive effect. More than 200 varieties of soil in the United States have been classified according to texture, color, and natural drainage. The physical properties of soils that are of most interest in corrosion are those that influence the permeability of soil to air and water. Lead can corrode less than steel and more than copper. Lead has been used in sheathing of underground cable for its resistance in soil. The corrosion resistance of Pb and Pb-Sb sheathing alloys depends upon the presence of silicate, carbonate, and to a lesser extent sulfates, which contribute to passive film formation. There is evidence that silicate and carbonate ions exert a marked inhibitive influence on corrosion of lead in soil. However, lead alloys might suffer from stray current effects due to street railways and can corrode rapidly in soils that contain some organic acids. Organic acid vapors, like acetic acid from wooden ducts for lead-sheathed cables or wood under lead roofing, have been the cause of corrosion in lead. Douglas fir and oak are known to give such vapors, while hemlock and cedar are not. However, and in general, test results indicate that corrosion in soil decreases with increasing particle size, and the average corrosion rate of lead in most soils is low and ranging from 2.5 to 10  $\mu\text{m}$  (0.1 to 0.4 mil) per year [2]. However, the depth of pitting is often a more important measure of corrosion in soil than the rate of general corrosion, as in the case of applications like cable sheathing.

### Salts and Gases

If lead is resistant to an acid, then it generally can resist the corresponding salt as well. Nitrates, for example, are corrosive and, therefore, cannot be handled with lead. Hydrochloric acid is corrosive to lead and so are most chlorides. Lead can be used with chlorine up to 100°C, wet or dry.

Gases of sulfur oxides can be handled in lead pipes. Hydrogen sulfide, on the other hand, can cause erosion to lead at high velocities. Furthermore, hydrogen fluoride is corrosive and, therefore, lead cannot be used with it.

## METHODS OF EVALUATION OF CORROSION DAMAGE

The procedures in ASTM G 1, Preparing, Cleaning, and Evaluating Corrosion Test Specimens, can be used in preparing bare, solid metal specimens for tests, for removing corrosion products after the test has been completed, and for evaluating the corrosion damage that has occurred. The chemical cleaning of lead and lead alloys for corrosion product removal suggests the use of either 10 mL of acetic acid in 990 mL of water for 5 min at boiling temperature, or 50 g of ammonium acetate in 1 L of water for 10 min at 60–70°C. A concentrated solution of 250 g of ammonium acetate in 1 L of water for 5 min can also be used at 60–70°C.

To simulate service of components that will be immersed in fluids, ASTM G 31, Practice for Laboratory Immersion Corrosion Testing of Metals, should be followed. This standard includes many precautions relating to how laboratory testing environments may differ from actual service. Issues such as immersion solution composition, temperature, aeration, velocity, and volume must be addressed thoroughly before the design of the test can be considered complete. For tests involving corrosion in water, two ASTM specifications relating to determination of water corrosivity should be referenced, D 2688, Test Method for Corrosivity of Water in Absence of Heat Transfer (Weight Loss Methods), and D 2776, Test Methods for Corrosivity of Water in Absence of Heat Transfer (Electrical Methods), which determine corrosivity by weight loss and electrical methods, respectively. The corrosion rate of lead and lead alloys by electrochemical method can be evaluated by using ASTM Standard G 102, Calculating of Corrosion Rates and Related Information from Electrochemical Measurements. This standard is intended to provide guidance in calculating mass loss and penetration rates for alloys. However, since the standard involves the conversion of electrical currents into mass loss rates or penetration rates, the calculations can be complicated for alloys and metals with elements having multiple valence values.

### Galvanic

Lead is cathodic to most elements but anodic to highly alloyed materials, and that could lead to galvanic corrosion. The effect of galvanic corrosion on lead or by lead on other metals immersed in an electrolyte can be evaluated by using ASTM Standard G 71, Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes, and G 82, Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance. In the latter standard, a list can be developed that arranges materials according to observed corrosion potentials in environment of interest. The metal that suffers increased corrosion in a galvanic couple can then be predicted from the relative position of the two metals in the

series. Precaution should be taken in the use of the galvanic series because environmental changes can reverse the galvanic positions of the two metals. For example, when lead is galvanically connected to a copper or a copper alloy in  $\text{H}_2\text{SO}_4$ ,  $\text{H}_2\text{CrO}_4$ , or  $\text{H}_3\text{PO}_4$  solution, lead is protected by a firm film, even though lead is considered the anode in the galvanic cell. However, corrosion of Monel (e.g., UNS N04400) will be accelerated if coupled with lead in 6 %  $\text{H}_2\text{SO}_4$  solution [5].

### Salt Spray

In seawater, lead may form oxide, chloride, carbonate, and chloride hydroxide as corrosion products. Only carbonate can protect lead from further corrosion. Furthermore, waters with hardness less than 125 ppm as calcium carbonate can cause significant corrosion. Therefore, the combination of soft water and sodium chloride can lead to significant corrosion to lead coatings. ASTM B 117, Salt Spray (Fog) Testing, can be used to evaluate the suitability of lead coatings in atmospheres containing salt spray or splash. This is an accelerated test in which time is reduced by exposing the specimens continuously to conditions which in service would arise only intermittently. It has been widely observed, however, that rankings of different alloys or coating systems do not fall in the same order as atmospheric tests in marine or road splash environments.

### Soil

As mentioned before, soil is a physically, chemically, and biologically complex system. Factors that affect corrosion in soil, in addition to specific ions, are resistivity of soil, oxygen content, and acidity. Field measurements of soil resistivity are covered in ASTM G 57, Method for Field Measurement of Soil Resistivity Using the Wenner Four-Electrode Method, which is the most widely used test, and using the proper meter produces accurate and reproducible results. Conducting field measurements of soil pH is covered in ASTM G 51, Test Method for pH of Soil for Use in Corrosion Testing. The corrosion resistance of lead and its alloys depends mainly upon the presence of silicate, carbonate, and to a lesser extent sulfates, in contributing to the passive film formation.

## LEAD IN ENERGY STORAGE BATTERIES

The main use of lead, with more than 70 % of the lead produced, is in the manufacturing of lead-acid batteries. It is hard to imagine a transportation industry today without lead-acid batteries. The total capacity of electrical energy storage of these batteries far exceeds any other competing devices. Lead-acid batteries are currently used in the electric vehicle (EV) to reduce air pollution. The relatively low cost and availability of raw materials, room-temperature operation, ease of manufacturing, long cycle life, versatility, and excellent reversibility of the electrochemical system make lead-acid batteries very attractive compared with other systems. Lead-acid cells have extensive use both as portable power sources for automobile service and traction and in

stationary applications ranging from small emergency supplies to load-leveling systems. Based on the application, there are three main types of batteries, namely SLI (starting, lighting, and ignition), industrial (traction and stationary), and small sealed portable batteries [3], with capacities ranging from 2 Wh to 40 MWh. The lead-acid battery system consists of negative electrodes of porous lead and positive electrodes of lead dioxide ( $\text{PbO}_2$ ) in a solution of sulfuric acid. Both electrodes form lead sulfate ( $\text{PbSO}_4$ ) on discharge, with a free-energy change of  $-372.6 \text{ kJ/mol}$  and standard potential of 1.93 V. Corrosion phenomena in a lead-acid battery occur during cyclic discharging and recharging. It is important to design grid so that corrosion on the positive grid is uniform. Very fine grain sizes promote a uniform corrosion morphology. Various alloys are used to make grids, including pure lead, Pb-Sn (0.5–6 % Sn), and Pb-Ca alloys. Pb-Sn alloys are widely used because of their higher strength compared with pure lead. However, antimony decreases hydrogen overvoltage. Grids made of lead-calcium alloys are widely used in batteries in the automotive industry in what is known as maintenance-free batteries over a normal service life. These batteries have smaller amounts of antimony; therefore, the amount of hydrogen and oxygen evolution is reduced. Lead-acid batteries are now completely recyclable.

## LEAD IN THE ENVIRONMENT

Health hazards posed by lead are a concern, and lead and its compounds should be handled with recommended precautions. Information on occupational protection in the workplace and publications on lead in architectural applications, in solders, and in batteries are available from the lead industry.\* Lead has been eliminated from applications like paint, gasoline, and water pipeline joints, in which lead recovery and recycling is difficult or human contact cannot be avoided. The toxic properties of lead have been known since the Roman period. When lead is released into the environment, it has a long residence time compared with most other pollutants. As a result, lead and its compounds tend to accumulate in surface soils and sediments where, due to their solubility and relative freedom from microbial degradation, they will remain accessible to the food chain and human consumption far into the future. Lead can reach the human body through the digestive system by entering the food chain (plant roots and leaves, canned food, cooking utensils), or through contaminated drinking water. Lead can also be inhaled (car exhausts, paint dust).

Lead runoff from outdoor surfaces was investigated, and it was found that lead corrosion products at unpolluted marine (in Albany) and unpolluted rural sites (in Newport) are composed of lead carbonate and lead hydroxy carbonate [9]. The average Pb concentration in the runoff, once the corrosion film was developed, was 2.1 mg Pb/L for both

sites. The steady-state Pb runoff rates were  $0.26 \mu\text{m Pb/y}$  for unpolluted marine and  $0.36 \mu\text{m Pb/y}$  for unpolluted rural site.

In most of the applications in which the use of lead is increasing and in which lead is expected to be used, the lead and its alloys have minimal contact with the user. The lead in these applications is expected to be recycled. However, the users must be aware of the health effects of lead absorption in the body [3]. Lead in the environment is regulated in different parts of the world, and there has been a significant increase in the public awareness on the health effects associated with lead exposure, particularly concerning young children. The current environmental regulations do not permit the use of lead in the drinking-water supply system. The World Health Organization stated that it intends to revise its guideline value for lead in water from 50 to  $10 \mu\text{g/L}$ , while the U.S. Environmental Protection Agency (EPA) proposed a lower level of  $5 \mu\text{g/L}$ . The EPA's air quality standards call for  $1.5 \mu\text{g/m}^3$  for lead averaged over 90 days. The U.S. Centers for Disease Control (CDC) guideline indicates that average blood lead in preschool children of  $10 \mu\text{g}$  of lead per dL (dL equal to 100 mL) of blood ( $10 \mu\text{g/dL}$ ) is a level of concern. However, the CDC does not recommend specific action, unless and until a blood lead value of 15–19  $\mu\text{g/dL}$  is reached [3]. The average blood-lead level among children has dropped in the U.S. from a national average of over  $30 \mu\text{g/dL}$  in the 1930s to an average level in 1994 of about  $2.7 \mu\text{g/dL}$ , according to the CDC.

# Magnesium (and Alloys)

James E. Hillis<sup>1</sup>

## THE CORROSION CHARACTERISTICS OF MAGNESIUM AND MAGNESIUM ALLOYS

### Overview

THE USE OF MAGNESIUM METAL has grown significantly in recent years, averaging 7 % annually for the past six years. Its major applications include use in the production of aluminum alloys; for magnesium die cast alloys; in iron desulfurization for the production of high strength steels; in graphite nodularization for production of ductile iron; in the metal reduction industry—primarily for zirconium and titanium production; in chemical applications for the production of pharmaceuticals, organometallics, and silicone compounds; in electro-chemical applications—primarily as anodes for cathodic protection of ferrous metal structures; for magnesium wrought products, and for magnesium gravity cast parts. The three largest applications—aluminum alloying, die cast magnesium alloys, and iron desulfurization—accounted for almost 90 % of the total world-wide market of 367,000 metric tons in 2000 [1,2].

The discussion that follows deals with magnesium and its alloys in cast and wrought forms, but it may be noted that the discussion often focuses on the die cast alloy. This is mainly due to the fact that in 2000 die cast alloy accounted for roughly 90 % of all alloys produced and 30 % of the overall world-wide market for magnesium. The die cast market has experienced double-digit annual growth rates in North America and Europe over the past decade, a result of increasing use in automotive applications for weight reduction and enhanced performance. This growth is projected to continue well into the coming decade [2,3].

### Nature of Protective Films

With few exceptions, magnesium exhibits good resistance to corrosion at normal ambient temperatures, unless there is significant water content in the environment in combination with certain contaminants. The reaction, which typically occurs, is described by the equation

In neutral and alkaline environments the magnesium hydroxide product can form a surface film that offers considerable

protection to the pure metal or its common alloys. Electron diffraction studies of the film formed in humid air indicate that it is amorphous, with the oxidation rate reported to be less than 0.01  $\mu\text{m}/\text{yr}$  (0.0004 mpy). If the humidity level is sufficiently high, so that condensation occurs on the surface of the sample, the amorphous film is found to contain at least some crystalline magnesium hydroxide (brucite). On immersion in deionized water, weight loss studies indicate that the crystalline hydroxide formed is also protective at room temperature and that aeration of the water has little or no measurable effect. However, as the water temperature is increased to 100°C the protective capacity of the film begins to erode, particularly in the presence of certain contaminants in either the metal or the water [4,5].

In extended atmospheric exposures of magnesium and magnesium alloys, the reaction of the magnesium hydroxide with acid gases ( $\text{CO}_2$  and  $\text{SO}_2$ ) has been reported to play an important role in the stability and composition of the film present. X-ray diffraction analysis of the oxidation products present on unalloyed magnesium ingot revealed it consists of a mixture of crystalline hydroxycarbonates of magnesium: hydromagnesite [ $\text{MgCO}_3 \cdot \text{Mg}(\text{OH})_2 \cdot 9\text{H}_2\text{O}$ ], nesquehonite [ $\text{MgCO}_3 \cdot 3\text{H}_2\text{O}$ ], and lansfordite [ $\text{MgCO}_3 \cdot 5\text{H}_2\text{O}$ ]. In the case of a common commercial wrought alloy, AZ31B (magnesium, 3 % aluminum, 1 % zinc, 0.2 % manganese), analysis of the adherent corrosion product by X-ray diffraction revealed only two crystalline phases—hydromagnesite and hydrotalcite [ $\text{Mg}_6\text{Al}_2(\text{OH})_{16}\text{CO}_3 \cdot 4\text{H}_2\text{O}$ ]. In an industrial atmosphere with high  $\text{SO}_2$  content, traces of  $\text{MgSO}_4 \cdot 6\text{H}_2\text{O}$  and  $\text{MgSO}_3 \cdot 6\text{H}_2\text{O}$  were detected, in addition to the hydroxycarbonate products for unalloyed ingot. It was suggested that  $\text{SO}_2$  exposures accelerate the corrosion of magnesium through the conversion of the protective hydroxide and carbonate compounds to the highly soluble sulfate and sulfite, which are then eroded [4,6].

### Alloys and Compositional Effects

Table 1 lists some of the common commercial alloys of magnesium, plus two developmental alloys, AE42 and AJ52, along with their nominal compositions. The alloys, described in accordance with ASTM B 275, Practice for Codification of Certain Nonferrous Metals and Alloys, Cast and Wrought, can be generally classified as belonging to either the aluminum or zirconium families. These two elements play the critical role of nucleating the formation of magnesium grains during solidification such that reasonably fine

grain structures are produced, providing good mechanical properties, while simultaneously imparting no deleterious effects on the corrosion properties of the alloys. The aluminum content employed varies from 3 to 10 %, depending upon the product form and the properties desired. The zirconium alloys consistently employ about 0.5 % zirconium, which is near the solubility limit at normal metal processing temperatures.

Magnesium alloys have a reputation for poor corrosion performance, particularly in saltwater exposures. In large part, this is due to a lack of control, historically, of the

**FIG. 1**—Corrosion rates of magnesium binary alloys determined in alternate immersion testing in 3 % sodium chloride [7].**FIG. 2**—Effect of iron, nickel, and copper contaminant levels on ASTM B 117 salt spray corrosion rates in AZ91 alloy versus cold-rolled steel and 380 die cast aluminum [10, 19].

contaminant content. The importance of metal composition in determining the susceptibility to saltwater attack has been recognized for more than 50 years; however, the first complete definition of the compositional limits needed for common commercial alloys was only first accomplished in the mid 80s [8,9]. In 1942, Hanawalt et al. published a summary of the effects of 14 separate elements on the saltwater corrosion performance of magnesium (Fig. 1) [7]. Six elements (aluminum, manganese, sodium, silicon, tin, and lead) were identified as having a negligible effect at concentrations exceeding their solid solubility or up to 5 %. (In addition to these elements, thorium, zirconium, beryllium, cerium, praseodymium, and yttrium have also been found to have little or no effect [4].) Four elements (silver, calcium, zinc, and cadmium) had moderate effects, and four elements (iron, nickel, copper, and cobalt) were found to have severely degrading effects.

Of the four elements with degrading effects, three are common contaminants of standard commercial alloys: iron, nickel, and copper. It is these elements that, in large part, led to magnesium's poor reputation for saltwater corrosion durability. When these elements are controlled at levels lower than established limits (referred to as "tolerance limits") for a specific alloy composition, the saltwater corrosion rates may be reduced by more than 100-fold based on accelerated corrosion testing per ASTM B 117, Test Method for Salt Spray (Fog) Testing. Figure 2 illustrates the effect of reduced levels of iron, nickel, and copper on the corrosion rates of high pressure die cast AZ91 alloy, versus cold-rolled carbon steel and 380 die cast aluminum alloy [8,9].

Table 2 summarizes the known contaminant tolerance limits for the common commercially die cast alloys of magnesium plus the recently published tolerance limits for the developmental alloy AE42 [11]. As may be noted in Table 2, while the tolerance limits for nickel and copper are essentially independent of the alloy composition, within its normal

**TABLE 2**—Contaminant tolerance limits for cast alloys.

Element	AZ91 [9]	AM50 [10]	AM60 [55]	AS41 [58]	AE42 [11]
Iron (@ 0.2 % Mn)	64	32	42	20	40
Nickel	50	35	30	40	200
Copper	400	170	100	200	1000

limits the iron tolerance is directly dependent upon the specific level of manganese present in the alloy [9,10]. This is thought to be due to the formation of an electrochemically compatible, ternary intermetallic of iron, aluminum, and manganese on solidification  $[\text{Al}_5(\text{Fe-Mn})_2]$ , as opposed to the formation of the binary intermetallic,  $\text{Al}_3\text{Fe}$ , known to be an active cathodic phase relative to the magnesium matrix. While the manganese was recognized by Hanawalt et al. [7] to have a passivating effect on the nickel and copper contaminants, its passivating effect on iron in aluminum alloys was only recently recognized [9,12]. It was previously assumed that the manganese alloying addition was effective only through the precipitation of the iron contaminant from alloy melts prior to casting [13]. In addition to the beneficial effects of manganese, Hanawalt et al. [7] also published data indicating that zinc additions to magnesium or magnesium-aluminum alloys were beneficial in controlling the detrimental effects of nickel, copper, and iron contamination through increasing the alloy's tolerance limit for the contaminants.

In generating the tolerance limit data for the developmental alloy AE42, it was recognized that rare earth elements, in this case misch metal (the naturally occurring mixture of approximately 50 % cerium, 25 % lanthanum, 18 % neodymium, and 7 % praseodymium), also enhance the alloy's tolerance for each of the critical contaminants but most notably for nickel and copper [11]. Despite the good corrosion performance and elevated temperature properties of the AE42, the alloy has not seen commercial application since its introduction in 1990. Several new alloy compositions based on Al-Sr-Mn (e.g., AJ52), or a combination of Al-Ca-Mn-Sr, have recently been proposed for elevated temperature applications. While these alloys have been demonstrated to possess corrosion resistance equivalent to existing commercial high purity alloys, the effect of strontium and calcium on tolerance limits for the critical contaminants has yet to be reported [14–16].

In principle, the aluminum-containing alloys of magnesium should all be capable of providing corrosion performance competitive with that established for high-purity alloys AZ91D and AZ91E in die cast and sand cast applications (i.e., <0.25 mm/yr (10 mpy) in ASTM B 117 salt spray), if the critical contaminants are controlled at appropriate levels [9,17].

While the zirconium alloys should also be capable of providing competitive performance, many of these alloys possess zinc or silver contents at levels above that identified as detrimental to the alloys performance (Fig. 1); therefore, one should expect somewhat reduced corrosion resistance from these alloys, although the performance is typically better than that associated with the magnesium-aluminum alloys of the past with high contaminant levels. Of those zirconium alloys listed in Table 1, the WE43 alloy (as well as its forerunner WE54), with only yttrium and rare earth elements in addition to the zirconium, provides the best corrosion durability [17]. One advantage of the zirconium alloys is that the zirconium content strongly limits the solubility of the iron contaminant in the melt phase prior to casting, so that the purity of the alloys with respect to this detrimental element is naturally enhanced [18].

In addition to the cast and wrought alloys of magnesium used for structural applications, several alloys are used for cathodic protection of ferrous metal structures primarily in

underground applications, but also as in internal anodes for the protection of glass-lined water heaters. The alloys used are identified in Table 1 by the "A" designation. ASTM B 843 covers the specifications for these alloys, and ASTM G 97 describes the test method used in determination of anode performance, which is dependant on both the trace contaminant content and metallurgical factors.

## Effects of Metallurgical Treatments

The effects of grain refining and heat treatment, or temper, on standard purity AZ91C and high-purity AZ91E sand cast alloy were evaluated using salt spray testing [9]. Sand cast aluminum alloys of magnesium are commonly employed in one of four tempers: F—as cast, T4—solution-treated (condition of maximum ductility), T6—solution-treated and artificially aged (condition of maximum strength), or T5—artificially aged (condition of improved strength and dimensional stability); see ASTM B 661, Practice for Heat Treatment of Magnesium Alloys. Table 3 compares the ASTM B 117 salt spray performance of the alloys versus temper and grain size. The only significant difference in contaminant levels between the AZ91C and AZ91E alloys was the iron content, and this was the dominant factor in determining the corrosion performance obtained, although the best high-purity performance was obtained with samples in the aged T5 or T6 tempers, as may be noted. The critical iron, nickel, and copper contaminant tolerance limits have also been defined as a function of temper and reported in Refs 12 and 46.

The accelerated corrosion associated with cathodic contaminants occurs typically in the form of severe pitting, uniformly distributed over the exposed part surfaces, both cast and machined. It has been suggested that this attack is due to the segregation or precipitation of the contaminant phase within the alloy matrix. However, attempts to correlate the corrosion severity associated with the samples used in establishing the tolerance limits for AZ91 with the precipitate phases found within the microstructure using electron microscopy were not successful [8,9]. This may indicate that the "segregation" that occurs is a partitioning of the contaminant between the  $\alpha$ -magnesium phase and the aluminum-rich eutectic phase, as opposed to the precipitation of a discrete phase. This would appear to be consistent with the fact that microscopy studies of corroded magnesium samples reveal the attack occurs on the  $\alpha$ -phase within the individual grains, while the aluminum-rich grain boundary phase remains unaltered in the early stages of attack [12,21].

Highly localized pitting attack can be catalyzed by the presence of discrete phases within the microstructure; however, these are not introduced through the segregation of

**TABLE 3**—ASTM B 117 Corrosion performance of AZ91 versus temper, grain size, and iron-manganese content [9,10].

Alloy	Grain Size, $\mu\text{m}$	Mn %	Ratio Fe:Mn	Temper/Corrosion Rate, mm/yr			
				F	T4	T6	T5
AZ91C	187	0.18	0.087	18	15	15	...
AZ91C	66	0.16	0.099	17	18	15	...
AZ91E	146	0.23	0.008	0.64	4	0.15	0.12
AZ91E	78	0.26	0.008	2.2	1.7	0.12	0.12
AZ91E	160	0.33	0.004	0.35	3	0.22	0.12
AZ91E	73	0.35	0.004	0.72	0.82	0.1	0.1

the contaminants on solidification, but rather through the suspension of contaminants in molten metal processing and casting operations. Such contaminants are often associated with flux-oxide inclusions, which serve as suspension agents in the molten metal processing and casting operations, and later in the cast objects serve as a source of electrolyte when exposed to humid air. Such inclusions produce active localized corrosion cells on the magnesium surface. This may occur with both cast and wrought alloys; however, it is most commonly encountered on machined surfaces of sand cast alloys and often involves the iron-manganese-aluminum or the zirconium-iron intermetallic precipitates, which tend to associate with the suspended flux-oxide phase. The introduction of SF<sub>6</sub>-air-CO<sub>2</sub> gas mixtures for the control of magnesium oxidation in casting operations, however, has served to reduce the frequency of such failures [22,23]. The high global warming potential of SF<sub>6</sub> (23 900 times that of CO<sub>2</sub>), however, has recently brought pressure on magnesium producers and processors to find a new alternative for the control of melt oxidation. An industry-sponsored project has recently produced several promising alternatives, these include SO<sub>2</sub>, HFC-134a, and other fluorocarbons with low environmental impact [24,25].

### Magnesium Mill Products

As with magnesium cast alloys, the dominant type of general corrosive attack is of a pitting character. This can be catalyzed by the presence of the same critical contaminants already discussed—iron, nickel, and copper at the parts per million level within the alloy matrix—or by the presence of cathodic contaminants on the material surface. The surface contaminants could be imbedded contaminants from a blast operation, such as sand or steel shot blasting, or due to charred lubricants used in rolling, forging, or impact extruding the component. The surface contaminants can be readily removed by common surface cleaning methods such as sanding, abrading, or acid pickling. Typically, mill products are acid pickled and oiled prior to shipping or storage to protect against the surface contaminant effects.

Intergranular attack of magnesium mill products has not been a common mode of corrosive attack for the commercial alloys. An exception noted by Loose [5] was magnesium, 14 % lithium, 2 % aluminum alloy sheet, which suffered an intergranular layer attack similar to the exfoliation attack of aluminum-copper alloys. The 14 % lithium alloy adopts the body-centered cubic lattice structure of lithium over that of the magnesium and, consequently, possessed very high ductility. Unfortunately, the difficulty of handling the highly reactive alloy in the molten state, combined with a loss of ductility with aging, led to its demise as a commercial alloy some years ago.

### Stress-Corrosion Cracking and Corrosion Fatigue

Pure magnesium can be considered immune to stress-corrosion cracking (SCC) in both atmospheric and aqueous environments, with no reported failures occurring when loaded to its yield strength [5,26].

Aluminum containing alloys of magnesium are generally considered the most susceptible to SCC, with the tendency

increasing with the aluminum content. Thus the alloys AZ61, AZ80, and AZ91 with 6, 8, and 9 % aluminum, respectively, can show high susceptibility to SCC in laboratory and atmospheric exposures, while AZ31, a 3 % aluminum alloy used in wrought product applications, is considered to show good resistance [19,27,28].

Magnesium-zinc alloys such as ZK60 and ZE41 that are alloyed with zirconium, or zirconium and rare earth elements are typically considered only mildly susceptible, while magnesium alloys containing no aluminum or zinc are the most SCC-resistant. Thus, M1 alloy, a 1 % manganese alloy, like unalloyed magnesium itself, shows no evidence of SCC when placed under tensile stresses as high as its yield strength [5,8].

In controlled laboratory exposures it has been shown that SCC occurs only when the relative humidity exceeds 85–98 % with O<sub>2</sub> or CO<sub>2</sub> additions slightly accelerating the rate [29,30]. In atmospheric exposures rainfall, dew, and high humidity have been reported to accelerate SCC of magnesium alloys, with failures often occurring during the drying period following a rain [28,30]; yet a comparison of identical materials in rural, industrial, and seacoast exposures has produced nearly identical results, suggesting that SCC severity is not necessarily associated with the corrosivity of the environment [5,31]. To date, standard and preferred procedures for the evaluation of SCC in magnesium alloys have not been established.

In aqueous exposures, only strong alkalis, concentrated hydrofluoric acid, and chromic acid are considered not to induce SCC in magnesium alloys [5]. In other exposures from deionized water to a wide variety of aqueous salt solutions SCC failures have been observed in full, partial, or alternate immersion [32]. The most severe acceleration of failures has been found to occur with NaCl + K<sub>2</sub>CrO<sub>4</sub> solutions, which have been used in many laboratory studies of magnesium SCC; however, the results have been found to correlate poorly with service experience [28,31,33].

Both transgranular and intergranular crack propagation have been reported for magnesium alloys; however, transgranular failures with significant secondary cracking, or branching, are the most common mode of failure. Of the many mechanisms proposed over the years, hydrogen embrittlement is best supported by experimental evidence such as:

- Crack initiation and propagation are accompanied by hydrogen evolution;
- Immersion in a cracking solution before the stress is applied produces a fracture similar to a SCC fracture;
- The effect of pre-immersion in a cracking solution is reversed by vacuum annealing or exposure to room temperature air;
- Testing in gaseous hydrogen results in the same crack characteristics produced in aqueous solution test [34,40].

As with other metals, the control of magnesium SCC failures has involved the control of the three factors required for SCC to occur: the long-term tensile stress above a critical level, a susceptible alloy, and a SCC inducing environment. In practice, this has been interpreted as designing to continuous loads of 30–50 % of the yield stress and employing finishes that serve as effective corrosion barriers, combined with the selection of less susceptible alloys where feasible. Design precautions should also include limiting the stresses imparted in bolting and riveting

components together, and the use of heat treatments to relieve the stresses induced by welding [32,41].

The recent review by W. K. Miller, cited in Ref 22, provides an excellent summary of the published SCC literature on magnesium and magnesium alloys and provided the basis for the preceding summary.

Magnesium alloys in die cast and wrought forms, unlike some nonferrous alloys, show marked fatigue limits in dry air. In corrosive environments such as water or saltwater exposures the results have been less clear. For example, in a recent study the bending fatigue limit for AM50 die cast alloy (bending yield 142 MPa) was found to be 105 MPa in both air and seawater, but when tested in tap water or deionized water no endurance limit was found at stresses as low as 70 MPa. In contrast, testing on AZ91 die cast material (bending yield 164 MPa) in the same laboratory produced a fatigue limit of 110–115 MPa in air, but when tested in seawater the fatigue limit was significantly degraded, with failures still occurring at a stress of 70 MPa. Tests conducted with tap water, 3.5 % NaCl, and deionized water all produced very similar results to those generated in seawater [42]. In a separate study of die cast and wrought alloys roller burnishing was found to consistently produce superior results in both air and 3.5 % NaCl exposures, but the fatigue limits established for both AZ91 and AM50 in air in the roller burnished condition were still well below those established in the preceding study [43]. In a third recent study roller burnishing was again found beneficial to the fatigue performance of AZ31 and AZ80 alloys, but interestingly the burnished AZ31 alloy demonstrated very similar behavior in both air and 3.5 % NaCl with the data suggesting a fatigue limit of 110–120 MPa in both exposures [44].

In earlier studies Loose [5] summarized data for AZ61A and AZ31A sheet subjected to plate bending at 1500 cycles/min in both a dry air exposure and in a 0.01 % sodium chloride spray. At  $10^7$  cycles the observed fatigue strength was 103 MPa and 117 MPa (15 and 17 ksi), respectively, in air versus 34 MPa and 40 MPa (5.0 and 5.8 ksi), respectively, in the salt spray. In a summary by Bothwell [4] it was related that AZ31 subjected to an axial load cycled at  $10^5$  cycles/h in air, and then subjected to increasing levels of humidity showed a slow decrease in the fatigue strength once the humidity exceeded 50 %. At 93 % relative humidity, the measured fatigue strength had declined to about 75 % of that in dry air, or about 124 MPa (18 ksi), while in condensing humidity the strength was 89 MPa (13 ksi). Interestingly, in total immersion in deionized water or deionized water saturated with magnesium hydroxide the fatigue strength was reported to be 124 MPa (18 ksi). This improvement in the fatigue strength was suggested as due to the reduced exposure to atmospheric carbon dioxide in the total immersion environment.

As with SCC the effects of the environment on corrosion fatigue have been found to be mitigated by painting the components with a suitable organic coating [4,19,42].

## SENSITIVITY TO ENVIRONMENTAL FACTORS

### Acidity/Alkalinity

The chemical resistance of magnesium and magnesium alloys is typically considered opposite to that of aluminum and

its alloys. Magnesium resists attack by alkaline substances, but is attacked by acids, while aluminum is attacked by alkalis but has reasonable resistance to attack by mild acids. There are two notable exceptions to magnesium's lack of resistance to acids, and these are chromic ( $\text{H}_2\text{CrO}_4$ ) and hydrofluoric (HF) acids. In both cases the resistance is the result of the formation of insoluble protective films. Consequently, both acids are employed in formulations for pretreatments for painting and surface anodize treatments [19,42]. While pure chromic acid has a very limited affinity for metallic magnesium, it will readily dissolve magnesium hydroxide corrosion products. Consequently, a boiling solution of 20 % chromic acid is commonly used for the removal of magnesium corrosion products for refinishing parts as well as for establishing weight loss corrosion rates in the laboratory.

The strong alkalinity of the natural hydroxide film on magnesium means there is little tendency for the compound to give up a proton to strong alkalis; consequently, the film provides excellent protection even in strong hot alkali solutions that would readily attack aluminum or zinc alloys. Hot 10 % caustic or caustic plus alkali metal phosphate solutions maintained at a pH of 11–13 or more are the preferred cleaning solutions for magnesium castings and extrusions [19,42]. The protective capacity of the magnesium hydroxide film at high pH apparently overwhelms the effects of impurities in both the metal and aqueous media. Loose [5] points out that the measured corrosion rate for magnesium in 4 % aqueous NaCl solution is 0.31–0.62 mm/yr (12–50 mpy) at 35°C, while in 48 % caustic solution with the same 4 % NaCl content the corrosion is only 0.02–0.04 mm/yr (0.8–1.2 mpy). Magnesium's resistance to alkali attack combined with the metal's light weight has made it the preferred material for cement finishing tools for many years.

### Specific Ions/Salts

Salt solutions vary in their corrosivity to magnesium. Alkali metal or alkaline-earth metal (chromates, fluorides, phosphates, silicates, vanadates, or nitrates) cause little or no corrosion. Chromates, fluorides, phosphates, and silicates in particular are frequently used in the chemical treatment and anodizes for magnesium surfaces, due to their ability to form somewhat protective films [19,42–44]. Alkali or alkaline-earth metal (chlorides, bromides, iodides, and sulfates) will normally accelerate the corrosion of magnesium in aqueous solutions. Ammonium salts usually show greater activity than the alkali metal salts, apparently due to the somewhat high acidity of these salts. Practically all heavy metal salts are likely to cause corrosion, since magnesium will normally displace heavy metals from solution due to its high chemical activity. Such displaced metals may tend to plate on the magnesium surface and provide cathodic sites for galvanic corrosion [5,19]. There is at least one notable exception to this anticipated activity of heavy metal salts and that is iron phosphate solutions. Iron phosphates react to form surfaces suitable for paint application. Even parts treated or baked at elevated temperatures (300–400°F) show no evidence of active heavy metal deposits, even on high purity alloys [42,43]. This is consistent, however, with the ability of phosphate systems to sequester or strongly complex metal ions at moderate to high pHs.

## Elevated Temperature

Magnesium's corrosion performance in pure water is strongly dependent on temperature. In distilled water the corrosion rate of AZ61 alloy is reported to increase from less than 1 mm/yr to 20 mm/yr (<1 mpy to 20 mpy) at the boiling point. This trend is typical of the commercial magnesium-aluminum and magnesium-aluminum-zinc alloys, and these are reported to be among the best alloys for their resistance to aqueous corrosion environments [4,5,19]. Pure magnesium in distilled water is reported to corrode at 16 mm/yr (640 mpy) at the boiling point. Fluoride ion has been reported to be an effective inhibitor for the corrosion of magnesium in water, while sodium carbonate, sodium silicate, and sodium phosphate are not. Thus, A3A alloy (magnesium-3 % aluminum-0.2 % manganese) when boiled for 31 days in a 0.025 N  $\text{NH}_4\text{F}$  solution showed no discernible attack, while the corrosion rate in pure distilled water was reported to be 1.0 mm/yr (38 mpy) [4].

Magnesium corrosion resistance is typically considered to be good in dry air to about 400°C and to about 350°C in moist air. Magnesium with small alloy additions of zirconium or beryllium has been used in gas cooled nuclear reactors in England and France where operating temperatures exceed 350°C. These alloys are reported to have adequate corrosion resistance in wet  $\text{CO}_2$  and wet air at temperatures to 500°C [4,45].

## Organic Compounds

Organic compounds, with a few exceptions, have little effect on magnesium and its alloys. Reference 46 contains a large tabular summary of specific organic and inorganic substances with their compatibility, or incompatibility, appropriately noted. Magnesium is usable in contact with aromatic and aliphatic hydrocarbons, ketones, esters, ethers, glycols, phenols, amines, aldehydes, oils, and higher alcohols. Ethanol causes slight attack, but anhydrous methanol causes severe attack unless significant water content is introduced. Gasoline-methanol fuel blends in which the water content equals or exceeds about 0.25 % of the methanol content were found not to attack magnesium [46]. At room temperature ethylene glycol solutions produce negligible corrosion of magnesium alone or in galvanic couple with steel. At elevated temperatures such as 115°C (240°F), however, the rate raises and, unless an effective inhibitor level is maintained, significant corrosion will develop.

Most dry chlorinated hydrocarbons cause little attack on magnesium up to their boiling points. Chlorinated solvents have been used for years to degrease magnesium components without incident. (Parts that have been so cleaned, however, should be thoroughly baked to ensure that entrapped solvent is driven off, since it may cause degradation of subsequently applied coatings.) In the presence of water, particularly at high temperatures, chlorinated hydrocarbons may hydrolyze to form hydrochloric acid, causing corrosive attack of the magnesium [4,19].

Magnesium forms a highly stable fluoride film and, consequently, has good resistance to hot fluorine gas, HF solutions, and fluorinated hydrocarbons, such as refrigerants. Hydrofluorocarbons have recently been found to not only be noncorrosive at room and elevated temperatures, but very

effective oxidation inhibitors at a few tenths percent in air over molten metal at temperatures up to 700°C, and above [4,20,25,47].

In acidic foodstuffs, such as fruit juices and carbonated beverages, attack of magnesium is slow but measurable. Milk causes attack, particularly when souring. Continuous poultices of wet organic matter have also been noted to cause corrosive attack, as has continuous contact of wet wood products. In both cases the presence of organic acids produced by the decay process has been assumed to be the cause of the attack.

## Galvanic Corrosion

The severe corrosive attack suffered by magnesium components in salt water environments can generally be attributed to two basic causes: (1) poor alloy quality due to the lack of control of heavy metal contamination, and (2) poor design and assembly practices that can lead to severe galvanic corrosion attack on the magnesium components. The introduction of high-purity alloys in the 1980s (e.g., AZ91D, AM60B, AS41B, WE43A, and AE42) has done much to address the first basic cause of saltwater corrosion failures; however, these alloys offer no defense against the threat of galvanic corrosion. Because magnesium is anodic to all other engineering metals, the need for protective measures has long been recognized and measures to minimize such attack have been defined [4,19,48,49]. If the improved performance of high purity alloys is to be realized in completed assemblies, it is critical that these measures are understood and carefully applied. Recent evaluations of material selection and assembly practices in galvanic couples with magnesium have been based on weight loss and depth of penetration measurements following ASTM B 117 exposures [48,49].

Galvanic corrosion is an electrochemical process with four fundamental requirements:

1. An anode (with magnesium assemblies this is the magnesium),
2. A cathode (e.g., a steel, brass, or graphite component),
3. Direct anode to cathode electrical contact, and
4. An electrolyte bridge at the anode and cathode interface (e.g., salt water bridging the adjacent surfaces of steel and magnesium components).

If any one of these is lacking, the process will not occur. The severity of the attack is determined by the galvanic current, which flows in the completed circuit. This can be expressed as

$$I_{\text{galv}} = (E_{\text{pc}} - E_{\text{pa}})/(R_{\text{m}} + R_{\text{e}}) \quad (2)$$

where  $E_{\text{pc}}$  and  $E_{\text{pa}}$  are the polarized potentials of the cathode and anode, respectively, and  $R_{\text{m}}$  and  $R_{\text{e}}$  are the resistance of the metal-metal contact and the electrolyte, respectively. The chemical process associated with the attack is normally summarized as follows:

The combined equation is the equivalent of that for general corrosion, described in Eq 1; however, due to the

**TABLE 4**—Compatibility of metals in galvanic couple with magnesium alloys AZ31B and AZ61A at Kure Beach, NC [6].

(Most Compatible)				(Least Compatible)
Group 1	Group 2	Group 3	Group 4	Group 5
Aluminum 5052	Aluminum 6063	AlClad 2024	Zinc Plated Steel	Carbon Steel
Aluminum 5056	AlClad 7075	Aluminum 2017	Cad. Plated Steel	Stainless Steel
Aluminum 6061	Aluminum 3003	Aluminum 2024	...	Monel
...	Aluminum 7075	Zinc	...	Titanium
...	...	...	...	Lead
...	...	...	...	Copper
...	...	...	...	Brass

electrochemical driving force involved, the product here is not protective and does not limit the process. Instead, the process continues indefinitely at a high rate typically causing severe pitting attack on the magnesium component at its interface with the cathodic component [4,19].

The most common means of controlling galvanic attack on magnesium is through minimizing the potential difference between the magnesium and the dissimilar metal,  $E_{pc} - E_{pa}$ . Because magnesium shows little, if any, tendency toward anodic polarization, the cathodic materials coupled with magnesium must be selected for their compatibility in the saltwater environment. In one evaluation of various metals with magnesium, the dissimilar metals were coupled to magnesium AZ31 and AZ61 alloy sheet and exposed to the marine environment of Kure Beach, NC. Based on the damage produced during the exposure, the metals were divided into five groups as summarized in Table 4 [4,19].

On steel fasteners, tin, cadmium, and zinc electroplates have long been recognized for their ability to reduce the galvanic attack induced by the fastener when compared to bare steel. The relative effectiveness of these electroplates has generally been accepted to be in descending order as listed. This is consistent with salt spray data presented by Hawke and summarized in Fig. 3. The data are based on the relative weight loss induced by similar fasteners coated with each of these electroplates and a number of alternative

fastener coatings. In addition to the correlation with past evaluations of electroplates, the data highlight two additional points of interest:

1. Certain proprietary zinc and aluminum filled polymers and some ion vapor deposited aluminum coatings, applied to steel fasteners may actually produce more damage than the untreated steel fastener itself. This was attributed to two possible causes: either the high surface area involved with each of the particulate coatings or the contamination of the particulate surface with active cathodic contaminants such as iron, nickel, or graphite;
2. A simple inorganic chromate treatment applied to a cadmium electroplate to preserve its brightness was as effective in further retarding the galvanic attack on magnesium, as was a coating of epoxy resin. (This is consistent with the known inhibitive effects of chromate on the cathodic reduction process and has been observed with other fastener coatings as well) [48,49].

As suggested by Eq 2 an alternate approach to controlling the galvanic corrosion activity in magnesium assemblies is to maximize the circuit resistance  $R_m + R_e$ , thus minimizing the current. There are several practical methods that may be employed depending on the demands of the application.

1. Electrically isolate the magnesium component from the cathodic material. In many applications, however, this is not a practical alternative due to the mechanical, electrical, or cost requirements.
2. Paint the cathodic material. This provides a barrier against electrolyte contact with the cathode; however, this is not simply accomplished in many cases due to the permeability of coatings by moisture combined with the generation of hydrogen and hydroxyl ion on the cathode surface. The combined effect is to strip all but the most alkali-resistant coatings.
3. Design to prevent pooling of the electrolyte in critical areas of fasteners and interfaces with other cathodic components. This is an effective method of control, since it limits both the electrolyte resistance and the period of its presence at the interface, since thin films of an electrolyte have reduced conductivity and higher rates of drying when compared to pools.
4. Use compatible shims or washers in association with fayed joints and fasteners. This control technique works well where exposure to the electrolyte is again intermittent and surfaces are well-drained. By using a shim or washer that extends 3–6 mm (1/8–1/4 in.) beyond the interface of the cathodic material with the magnesium surface, the electrolyte path is extended to a range where the resistance of typical aqueous saltwater electrolytes is

**FIG. 3**—Relative weight loss associated with dissimilar metal fasteners in AZ91 alloy exposed to ASTM salt spray [51,52].

sufficiently high to retard significantly the electrochemical activity. This compatible material may be a nonconductive ceramic, a polymeric material, or a compatible metal, such as an aluminum 5052 or 6061 alloy (Table 4). The use of an aluminum washer beneath the head of a steel fastener that extends 3–6 mm beyond the radius of the bolt head is a simple, effective method of control of the galvanic attack associated with fasteners in magnesium.

## METHODS OF EVALUATION OF CORROSION DAMAGE

Structural magnesium components may experience environmental exposures ranging from the clean, dry indoor atmospheres of computer disk drives and electronic components to the intermittent salt splash associated with automotive applications. Allowable corrosion in these applications may range from submicron attack in disk drives, to substantial attack of several millimeters for some automotive castings, which are judged on their functional performance over a defined period of time. High-purity magnesium alloys have demonstrated their ability to withstand the demands of these environments when components are properly designed, produced, and assembled.

Because magnesium corrosion studies have been limited and spread over several decades, there are few standard practices specific to the material. Perhaps the most commonly used accelerated corrosion test is the salt spray exposure defined in ASTM B 117. This, combined with automotive proving ground tests, has been instrumental in defining the metal quality and galvanic assembly practices required for the recent growth in automotive applications both in North America and Europe over the past decade [3,8,9,11,43,48]. Salt spray has also found a place in the qualification tests for aerospace applications of magnesium castings [50].

Unlike ferrous and aluminum alloys, electrochemical studies of magnesium corrosion have been very limited and as yet are not widely used in the predictive evaluation of its corrosion performance [20].

### Gravimetric Corrosion Rates

In ASTM B 117, salt spray testing exposure periods of seven or ten days are commonly used to evaluate the effects of trace contaminants within the alloy microstructure, as well as on surfaces of untreated and uncoated parts. The cleaning method used for the removal of corrosion products in determining weight loss corrosion rates consists of immersion in a hot (95–100°C) chromic acid solution (20 %  $\text{CrO}_3$  in water) for 1–2 min (or for 15 min at 25°C). The addition of approximately 1 %  $\text{AgCr}_2\text{O}_7$  prevents the accumulation of chlorides, which can lead to magnesium attack (see ASTM G 1, Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens).

Two frequent alternatives to ASTM B 117 testing used in the evaluation of general and galvanic corrosion performance have been (1) alternate immersion testing (30 s immersion in 3 % NaCl followed by 2 min in air [4,5,7], or (2) continuous immersion in 3 or 5 % NaCl for a period of three

to seven days or more. In recent years, continuous immersion testing has been employed most often in Europe. A limited comparison of the test using 3 % NaCl as defined in ASTM G 31, Practice for Laboratory Immersion Corrosion Testing of Metals, suggests a reasonable correlation with salt spray performance; however, the measured weight loss corrosion rates typically run two or three times those measured in ASTM B 117 salt spray for the high-purity alloys.

The correlation of accelerated salt spray test results with real world atmospheric results have been very limited to date. Figure 4 represents one of the few direct comparisons published. The two-year marine atmospheric exposure was conducted at the ASTM Brazos River Test Site on the Texas Gulf Coast southwest of Galveston [19,51,52]. Duplicate panels of controlled-purity magnesium alloy AZ91 were employed in the atmospheric tests and in ASTM B117 salt spray. Although the salt spray corrosion scale is approximately 200 times higher than the atmospheric scale, some interesting correlations remain.

1. The break points, or tolerance limits, are the same in both exposures for the nickel and copper contaminants (about 50 and 500 ppm, respectively).
2. The corrosion rates, with respect to increasing iron content, remain low in both exposures throughout the range covered, confirming that the critical iron/manganese ratio was not significantly exceeded.

FIG. 4—AZ91 die cast alloy performance versus contaminant level: salt spray (ASTM B 117) versus two-year marine atmosphere (ASTM G 50) performance [19,55].

3. High-purity AZ91 clearly possesses lower overall corrosion rates than either cold rolled carbon steel or 380 die cast aluminum. But also noticeable are some significant contrasts: the relative effects of the nickel and copper contaminants in the atmospheric versus salt spray exposure are reversed, and the effect of both contaminants is mild in the atmospheric exposure when compared to their effects on the salt spray performance of AZ91 versus the carbon steel panels common to both tests.

### Painted Corrosion Performance

The evaluation of coatings and pretreatments for relative coating adhesion has been successfully evaluated in salt spray testing using ASTM D 1654, Test Method for Evaluation of Painted or Coated Specimens Subjected to Corrosive Environments, which employs the ASTM B 117 exposure for the acceleration of corrosive disbonding of the organic coating from the metal substrate. While the test is very effective in establishing the relative effectiveness of metal pretreatments and coatings, the correlation with real-world exposures suggests a test period of 28 days is significantly more severe than a five-year atmospheric exposure [43,53].

### Humidity Tests

Humidity testing is a common alternative to saltwater immersion and salt spray testing for evaluation of indoor corrosion performance and for the evaluation of potential flux contamination. Magnesium melts have traditionally been processed using molten eutectic salt mixtures, consisting principally of KCl and  $MgCl_2$ , as a protective barrier against excessive oxidation or burning during casting operations. Entrapment of these salts in association with unsettled oxides has been a common contributing factor to the poor corrosion performance of cast and extruded products. The introduction of protective gas mixtures ( $SF_6$ , HFC 134a,  $SO_2$ , or Novec™ 612—in a dilute blend with air, or air/ $CO_2$ ) [24,25,59,60] has dramatically reduced the frequency with which these problems are encountered; however, some foundries continue to use the traditional salt fluxes in casting operations today [22,23]. The exposure of a freshly machined surface to an atmosphere of 60–80 % relative humidity at 20–30°C will reveal the presence of flux inclusions within 24–48 h. E. F. Emley's *Principles of Magnesium Technology* describes a simple test chamber employing a saturated solution of sodium thiosulfate as a controlled source of 70 % relative humidity. Alternately, the corrosion product, suspected to be the result of flux inclusions, can be tested by dissolving a sample of the corrosion product in dilute nitric acid and then adding a small amount of a silver nitrate solution to verify the presence of chloride contamination via the readily visible precipitation of silver chloride. This procedure is again summarized by Emley [54].

# Aluminum (and Alloys)

*Bernard W. Lifka*<sup>1</sup>

## OVERVIEW OF DOMINANT FACTORS

FOUR FACTORS SHOULD be considered in selecting corrosion tests for aluminum and aluminum alloys. These are: (1) the expected service environment, (2) the type of corrosion expected in service, (3) the primary material requirements of the application which should not be excessively degraded by corrosion, and (4) whether the material requires surface protection for use in the intended environment. Some form of surface protection is almost always necessary for the high-strength 2xxx and 7xxx series alloys.

Accelerated tests should produce the types of corrosion, pitting, or intergranular corrosion (IGC) that occur in service, and contain at least the major contaminants and environmental variables expected. Engineering requirements generally dictate the type of corrosion of most concern and the most significant method of evaluation. For example, for liquid containers the primary concern may simply be to avoid perforation and leaking. Depth of corrosion is the major concern. However, if the liquid is under pressure, the type of corrosion can be of importance as this can affect burst strength.

Tests of the bare, unprotected metal are useful to establish a minimum basis of performance and comparative ranking. However, the applicability to the end use and prediction of service life require evaluation of the protective coatings and maintenance procedures to be used in service.

## NATURE OF THE METAL

### Natural Protective Films

Aluminum is a highly reactive metal that has a high resistance to corrosion in many environments because of the presence of a thin, highly adherent film of aluminum oxide. When a fresh surface of aluminum is exposed to air or water, a surface film of aluminum oxide immediately begins to form and grow rapidly. The stable film thickness in air is about 5 nm (50 Å). The film is thickened when grown in the presence of water and oxygen at elevated temperatures. Pourbaix diagrams show aluminum oxide film is stable in the pH range of 4.0 to 9.0 [1]. In this pH range aluminum and its alloys normally undergo localized corrosion rather

than uniform corrosion. Outside this pH range, the aluminum oxide film dissolves rapidly in strong acids and bases, and the aluminum is then attacked uniformly. Notable exceptions are stability of the film in concentrated nitric acid and glacial acetic acid at pH 1 and lower; and in concentrated ammonium hydroxide and sodium disilicate at pH 11 to 13.

### Effect of Alloying (Composition)

Very high-purity aluminum, 99.99 % or purer, is highly resistant to pitting. Any alloying addition will reduce resistance to pitting corrosion. The 5xxx Al-Mg alloys and the 3xxx Al-Mn alloys resist pitting corrosion almost as well. The pure metal and the 3xxx, 5xxx, and 6xxx series alloys are resistant to the more damaging forms of localized corrosion, exfoliation, and stress-corrosion cracking (SCC). However, cold-worked 5xxx alloys containing magnesium in excess of the solid solubility limit (above 3 % magnesium) can become susceptible to exfoliation and SCC when heated for long times at temperatures of about 80–175°C [2,3].

Higher strength alloys are produced by the addition of magnesium and silicon (6xxx series); and by the addition of copper plus silicon, or copper plus magnesium and silicon (2xxx series). The highest strength alloys are produced by the addition of zinc plus magnesium, or magnesium and copper. The additions of these elements change the electrochemical potential of the alloy, which affects corrosion resistance even when the elements are in solid solution. Zinc and magnesium tend to shift the potential markedly in the anodic direction, while silicon has a minor anodic effect. Copper additions cause marked cathodic shifts. This results in local anodic and cathodic sites in the metal that affect the type and rate of corrosion.

### Effect of Metallurgical and Mechanical Treatments

Metallurgical and mechanical treatments often are interactive with regard to producing chemical-microstructural features in aluminum alloys, such as dislocations, precipitates, and the microstructural morphology (grain size and shape). For simplicity these two effects are discussed separately.

### Effect of Metallurgical Treatments

Variations in thermal treatments such as solution heat treatment, quenching, and precipitation heat treatment (aging)

<sup>1</sup>Former Technical Consultant, Alcoa Technical Center, Alloy Technology Division, Alcoa Center, PA 15069-0001; retired 3/1/93, contact at 724-337-8130.

can have marked effects on the local chemistry and hence the local corrosion resistance of high-strength, heat-treatable aluminum alloys [3]. Ideally, all the alloying elements should be fully dissolved and the quench cooling rate should be rapid enough to keep them in solid solution. The first objective usually is achieved, except when alloying elements exceed the solid solubility limit, e.g., alloy 2219; but a sufficiently rapid quench often is not obtained, either because of the physical cooling limitations, or the need for slower quenching to reduce residual stresses and distortion. Generally, practices that result in a nonuniform microstructure will lower corrosion resistance, especially if the microstructural effect is localized.

Precipitation treatment (aging) is conducted primarily to increase strength. Some precipitation treatments go beyond the maximum strength condition (T6 temper) to markedly improve resistance to IGC, exfoliation, and SCC through the formation of randomly distributed, incoherent precipitates (T7 tempers). This diminishes the adverse effect of highly localized precipitation at grain boundaries resulting from slow-quenching, underaging, or aging to peak strengths.

### Effect of Mechanical Treatments

Mechanical working influences the grain morphology and the distribution of alloy constituent particles. Both of these factors can affect the type and rate of localized corrosion.

Cast aluminum products normally have an equi-axed grain structure. Special processing routes can be taken to produce fine, equi-axed grains in thin rolled sheet and certain extruded shapes, but most wrought products (rolled, forged, drawn, or extruded products) normally have a highly directional, anisotropic grain structure. Rectangular products have a three-dimensional (3-D) grain structure. Figure 1 shows the three-directional Longitudinal (principal working direction), Long-Transverse, and Short-Transverse grain structure typically present in rolled plate and the two-directional grain structure of rolled rod. These directional structures markedly affect resistance to SCC and to exfoliation of high-strength alloy products (see ASTM G 34, Test Method for Exfoliation Corrosion Susceptibility in 2xxx and 7xxx Series Aluminum Alloys (EXCO Test)).

Most die forgings and many extrusions with irregular, complex cross sections have a metal flow that varies with the product contour. An example is shown in Fig. 2. Evaluation of such products requires knowledge of the metal flow pattern through either prior experience or macroetching. The grain structure and resultant corrosion behavior also vary from surface to center in products with appreciable thickness. This factor begins to be important at a thickness of about 12 mm. Almost all forms of corrosion, even pitting, are affected to some degree by this grain directionality. However, highly localized forms of corrosion, such as exfoliation and SCC, which proceed along grain boundaries, are highly affected by grain structure. Long, wide, and very thin pancake-shaped grains are virtually a prerequisite for a high degree of susceptibility to exfoliation. The photomicrograph shown in Fig. 2 of ASTM G 34 is an example of a highly laminated grain structure and the severe exfoliation corrosion that can occur.

Since SCC in aluminum alloys characteristically is intergranular, susceptible alloys and tempers are most prone to

SCC when the tensile stress acts in the short-transverse, or thickness direction, so that the crack propagates along the aligned grain structure. The same material, e.g., 7075-T651 plate, will show a much higher resistance to stress acting in the longitudinal direction, parallel to the principal grain flow. In this case the intergranular crack must follow a very meandering path and usually does not propagate to any major extent. Special agings to various, highly resistant T7 tempers have been developed to counteract this adverse effect of directional grain structure. Figure 3 [4] shows a

FIG. 1—(a) Three-dimensional grain structure of rolled plate, and (b) two-dimensional grain structure of rolled rod. Original magnification was 100 diameters. (Photographs courtesy of J. J. Liput, Alcoa Technical Center.)

FIG. 2—Transverse slice showing the variable grain structure in a die forging. (Photograph courtesy of J. J. Liput, Alcoa Technical Center.)

FIG. 3—Bar graph comparing tensile yield strength and the highest surviving SCC test stress for 7075-T6 and T73 in the L, LT, ST directions of plate and the Land T directions of rod. The SCC results are representative of tests in ASTM G 44 and in seacoast atmosphere at Point Judith, RI.

comparison of strength and SCC resistance for the principal grain directions in 7075 plate and rod in both the T651 and T7351 tempers. Various artificially aged tempers are available for both 2xxx and 7xxx alloys that provide a range of compromise choices between maximum strength and maximum resistance to exfoliation and SCC [5].

### Mill and Foundry Products

Cast aluminum products are produced by sand cast, die cast, and permanent mold casting methods. The alloys and tempers used are unique to castings, and their performance differs significantly from wrought products.

The most basic form of cast aluminum product is large ingot produced for subsequent fabrication into a wrought

product. Commercial ingots are cast by continual processes as rounds or rectangles, hence they can be of various lengths and as thick as 915 mm diameter or 619 mm thick. Corrosion tests are rarely made for products still in the ingot stage, but the homogenization (preheating) and hot- and cold-working processes given to ingot will affect the metallurgical structure and corrosion resistance of the final product. One has to establish, therefore, whether changes in ingot casting or processing affect the corrosion performance of the finished product.

Wrought aluminum products are produced by all of the standard hot- and cold-working processes. In general, the commercial alloys and tempers cross product lines. As such the main effect of various products on corrosion is that attributable to variations in grain structure, as discussed in the previous section.

### Role of Hydrogen

Hydrogen will dissolve in aluminum alloys in the molten state and during thermal treatments at temperatures close to the melting point in atmospheres containing water vapor or hydrocarbons. Upon solidification, this causes porosity and surface blistering.

Recent literature surveys [6,7] show there still is considerable dispute as to how much, if at all, high-strength aluminum alloys are embrittled by hydrogen. There is evidence that hydrogen evolving from anodic dissolution at a crack tip can dissolve into the metal at the grain boundary ahead of the crack tip, and thus be a factor in SCC of some 7xxx and possibly 2xxx alloys. Hydrogen embrittlement, however, has not restricted the commercialization of high-strength aluminum alloys.

### Protective Coatings

As mentioned earlier, pure aluminum, the 3xxx, 5xxx, and most 6xxx series alloys, are sufficiently resistant to be used in industrial atmospheres and waters without any protective coatings. Examples of this are cookware, boats, and building products. Generally, coatings are used to enhance an alloy's resistance and protection is considered necessary for the higher strength 6xxx alloys, such as alloy 6013, and for all 2xxx and 7xxx alloys.

One of the principal methods of protection is to enhance the thickness and quality of the natural oxide by prefilming in hot water, which can thicken the surface oxide by about a factor of 10. The film can be thickened even more (to 1000 or more times the natural thickness) by anodizing in special acid (e.g., sulfuric or chromic) electrolytes. Chemical conversion treatments also provide protection, but to a much lesser degree and are primarily used as a substrate for the subsequent application of organic films. A discussion of the effective use of organic coatings is beyond the scope of this chapter.

A protective measure unique to aluminum is the use of alclad, in which a thin layer of high-purity aluminum, or a special alloy designed to be sufficiently anodic, is metallurgically bonded to a less resistant alloy having more desirable engineering properties such as strength, toughness, or fatigue endurance. The cladding thickness is on the order of

2.5–5 % of the total product. Alclad sheet for the aerospace industry is the primary example, and almost all commercial airplanes currently use Alclad 2024-T3 sheet in the fuselage. A major advantage of alclad over other protective measures is that it provides both a protective barrier and electrochemical (cathodic) protection since the cladding alloy, by design, is anodic to the core alloy. This enables the cladding to continue to provide protection, even in the event of an intentional or inadvertent breach in the cladding, such as drilled holes and cut edges or accidental scratches or dings. The mechanism of alclad protection is analogous to that of the familiar galvanized steel, except the thin protective aluminum surface layer is applied by a fabrication process (generally hot-rolling or extrusion), whereas the zinc surface on steel is applied by a hot dip or plating process.

## SENSITIVITY TO PARTICULAR ENVIRONMENTAL FACTORS

### Acidity/Alkalinity

The aluminum oxide film generally is stable in the pH range of 4 to 9, but is readily dissolved in strong acids and alkalis, with some notable exceptions as mentioned in the section on Natural Protective Films. The rate of corrosion cannot be predicted solely by the pH, but depends on the specific ions present, their concentration, and the temperature. For example, the dissolution rate of aluminum in sulfuric acid becomes appreciable between 50–100 % concentration, with the maximum rate occurring at 70–90 % concentration. Furthermore, the corrosion rate at 50°C can be as much as four times more rapid than at 25°C [8–10].

A saturated solution of aluminum chloride ( $\text{AlCl}_3$ ) has a pH of 3.0–3.5 just into the range where the natural oxide is unstable. A saturated concentration can occur when aluminum corrodes in a chloride-containing solution under conditions where the electrolyte cannot be readily replenished, such as crevices, deep pits, and cracks. It also occurs in cyclic wet-dry environments, where the solution gradually evaporates and becomes concentrated. This tends to keep corrosion active at such a site, as opposed to the usual self-limiting effect.

Currently there is appreciable public concern over the effect of acidic precipitation (“acid rain”) on all materials of construction. Typically the pH ranges from 4–5.5 and rarely is less than 3.5. As such acidic precipitation does not cause severe damage to aluminum and its alloys from the standpoint of structural integrity. However, acid rain can cause cosmetic problems, such as dark brown to black stains.

### Specific Ions

Corrosion of aluminum requires the presence of moisture and oxygen. Aeration and oxygenating conditions will accelerate corrosion. Conversely, deaeration will retard corrosion. The amount of water may be minuscule, and present as isolated droplets or a continuous film. Soft waters tend to be less corrosive than hard waters. At ambient temperatures aluminum initially reacts with high-purity water, but this ceases after a few days as a result of the development of

a more protective oxide film [3]. A small amount of water can drastically affect resistance to certain anhydrous organic solutions, particularly halogenated hydrocarbons. Water vapor in the air is sufficient to cause staining upon condensation, and to support SCC.

Unlike steel, aluminum is resistant to steam, and steam or boiling water treatments can actually increase the protective oxide.

Halides, particularly the chloride ion, are corrosive to aluminum. Various mechanisms have been proposed, the most probable being localized breakdown and penetration of the oxide film. The corrosiveness of the chloride ion is a major concern because the ion is ubiquitous. Potable water and well water often are used to make up processing solutions and these normally contain small amounts of chlorides.

Small concentrations of heavy metals in solution (particularly copper, iron, lead, and even trace amounts of mercury) can plate out on the aluminum surface and can cause rapid localized pitting. Interactive effects can also occur, for example, the rate of pitting as a function of chloride content is highly accelerated by the addition of a few ppm of copper ions [3]. Consequently, the composition of etchants and other process solutions should be monitored and renewed on a regular basis. The depth of pitting occurring in such operations may be shallow, but can be adverse for cosmetic reasons, or as a site for subsequent corrosion.

Some ions are inhibitors and will reduce either the anodic or cathodic reactions that occur during the corrosion of aluminum. Examples are chromates (an anodic inhibitor) and phosphates (a cathodic inhibitor). Inhibition of circulating water systems is complex and professional consultation is recommended for the design of water treatment systems.

Corrosion rates tend to decrease as the electrolyte becomes spent and saturated with aluminum ions. Consequently, a greater amount of corrosion can be expected for conditions that prevent this, such as high flow rates, and a low ratio of area of metal surface to volume of solution. Contamination of a pure solution can increase, or decrease, the corrosion rate. Therefore, predictions of the corrosion performance should be obtained from Refs 8–10 or by experimentation.

### Elevated Temperature

In general, corrosion rates increase with increasing temperatures. In some cases this effect can be very marked, as noted previously for sulfuric acid.

In contrast to ambient temperature, high-purity water at high temperatures of 200 to 300°C can cause rapid disintegration of pure aluminum. Aluminum-nickel-iron alloys have been developed for use at such temperatures [11].

In atmospheric corrosion, slightly elevated temperatures can be beneficial by reducing the time of wetness. An example is electrical conductors that operate slightly above ambient temperatures and which usually incur little corrosion because the elevated operating temperature keeps them dry.

In addition to affecting the corrosion reactions, elevated temperatures can cause additional precipitation and changes in the metallurgical structure of the metal. The

2xxx and 7xxx alloys are affected beginning at temperatures of about 120°C. This effect initially is adverse, but with continued heating past peak strength conditions, a reversal and improved resistance can occur. The 5xxx series alloys containing more than 3 % magnesium are sensitized by exposure to temperatures on the order of 80 to 175°C. Exposure of these 5xxx alloys to even higher temperatures results in a coarsening of the precipitate, producing discontinuous grain boundary precipitation which reduces, or eliminates, the sensitization effect [12].

### Liquid Metals

Mercury is the primary liquid metal that degrades aluminum. Liquid mercury does not wet an aluminum oxide surface, but if the natural oxide film is penetrated aluminum dissolves in the mercury to form an amalgam starting a very rapid reaction. The dissolved aluminum oxidizes immediately in the presence of moisture and more aluminum dissolves. This reaction is assisted by the presence of halides. The mercury penetration tends to proceed along grain boundaries, and if tensile stresses are present in the metal, drastic splitting and the exposure of further film free metal occurs. Mercury can plate out of aqueous solutions to produce this effect. A mercury content of greater than 0.01 ppm is cause for concern. Detection of even lesser amounts of mercury may indicate a problem, since mercury tends to evaporate and low levels are difficult to analyze. Common sources of mercury are broken thermometers and mercury vapor bulbs, or mercury manometers that have been over-pressurized.

### Chemicals

Aluminum is suited for containment and production of many chemicals and foods. References 8–10 should be consulted to determine compatibility with specific chemicals. Caution is advised concerning compatibility with a specific chemical that has become contaminated. For liquid chemicals, especially with the use of closed aluminum containers, the resistance of the aluminum container can differ in the liquid and vapor phases and at the liquid-vapor interface. If the corrosion performance is unknown, all three conditions should be investigated.

### Galvanic Couples

Galvanic corrosion and the factors affecting it have been discussed in Chapter 20. However, a few precautionary comments are in order for aluminum, since it is anodic to most common materials of construction, with the exception of magnesium and zinc. In the presence of a good electrolyte, as little as 15 mV difference in corrosion potential of the two metals can have an effect, and if the difference is 30 mV or greater the anodic material will definitely corrode sacrificially to protect the contacting cathodic metal. A recently revised report on galvanic corrosion, with emphasis on automotive applications is available [13].

It is generally recognized that protection must be provided if aluminum and aluminum alloys contact copper, copper alloys, iron, or steel. Aluminum alloys are quite

anodic to these metals and an alloy change will have little effect. An exception is 2xxx series aluminum alloys containing 2 % or more copper in the solution heat-treated T3 or T4 tempers. These alloys can approach the corrosion potential of mild steel.

Designers often want to use aluminum in contact with stainless steel and titanium. Both these materials are quite cathodic to aluminum, but the effect of the couple depends to a large extent on whether or not the stainless steel or titanium passivates or stays active. If these metals passivate, such a couple often is tolerable, but one cannot assume passivity. The designer really needs to determine the expected environmental conditions and establish the performance of stainless steel and titanium. Conditions such as crevices, acidity, and oxygen availability are important.

Many users do not recognize that aluminum alloys themselves span a range of about 400 mV in their respective corrosion potentials. In aerated sodium chloride solutions, pure aluminum, 3xxx alloys, and many other alloys have a potential of about –740 mV when measured with a saturated calomel reference electrode (SCE). Aluminum alloys with high magnesium or zinc contents will be more anodic by as much as 260 mV, while high copper content alloys will be more cathodic up to about 140 mV. Care must be taken therefore, that all alloys and tempers are compatible, even in an all aluminum structure.

### Crevice

If an electrolyte can enter the crevice formed by the faying surfaces of two aluminum surfaces an oxygen concentration, and subsequently chemical concentration, cell can form and cause accelerated localized attack. As such, corrosion protection often is required in joints, even when not needed on the freely exposed aluminum. The severity of crevice corrosion depends on the electrolyte and how readily it is replenished. It also is influenced by the geometric shape of the crevice, and the ratio of active crevice cathode area to the adjacent external cathode area. The best protective measures are to design so that crevices will drain, and to effectively seal crevices to prevent ingress of the electrolyte.

## METHODS OF EVALUATION OF CORROSION DAMAGE

The various types of corrosion that occur in metals were covered in Section IV of this manual, Testing for Corrosion Types. Additional information also can be found in Refs 2, 3, and 14–16. This paragraph covers considerations more or less unique to aluminum. A brief summary of analytical methods used with aluminum is given in Table 1, listing the forms of corrosion in the order most prevalent in aluminum alloys.

Regardless of the type of corrosion, the initial, basic evaluation should be a visual inspection in the “as-corroded” condition, assisted by low-power (3 to 10×) magnification. A written description should be kept, preferably documented with photographs. If the sample is disassembled or cleaned, the visual/photographic inspection should be repeated. Cleaning in concentrated nitric acid, method

**TABLE 1**—Methods of evaluation of corrosion damage.

Type of Corrosion	Methods of Evaluation
Pitting Corrosion	Visual examination including low magnification, photographs, measurement of depth, assessment of size and number of pits, ASTM G 46. Determination of effect on mechanical properties.
Intergranular Corrosion	Metallographic determination of extent and depth of attack, ASTM G 110. Determination of effect on mechanical properties.
Exfoliation Corrosion	Visual and metallographic examination, photographs, photomicrographs, ASTM G 34 and G 66.
Stress-Corrosion Cracking	Determination of minimum stress level required for failure, number of failures, time to failure (log normal distribution), probability of percent survival (or failure) versus time, crack propagation rate and threshold stress intensity. Refer to Chapter 25.
Filiform Corrosion	Visual and metallographic examination. Photographs.
Staining	Visual examination and photographs. Measurement of reflectivity or image clarity.
Uniform Etching Corrosion	Rarely occurs, except in certain highly acidic or alkaline corrodents. Gravimetric methods in ASTM G 1.

C.1.2 in ASTM G 1, Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens, is the procedure normally used for aluminum because it is simple and effectively removes most corrosion products.

Likewise, metallographic examination is performed in all but the most elementary evaluations. Typically this begins with optical microscopy at magnifications of 50–500 diameters to determine the type, depth, and extent of corrosion. Both pitting and intergranular corrosion of aluminum tend to be localized and nonuniform over the surface. Visual examination usually can define areas of most severe corrosion and metallographic examination generally is limited to such regions. Both forms of corrosion tend to develop in hemispherical shaped sites, and several (typically three) random metallographic sections of about 20 mm in length are examined to ensure a better chance of the plane of polish being at the deepest portion of the hemisphere. Repetitive polishing and measurement of the metallographic sections provide another means of assuring the maximum depth of penetration has been measured. The average depth of corrosion often provides a more repeatable assessment of the “overall” corrosion damage, which is useful for statistical evaluations. However, maximum depth is of prime importance in applications where service failure results from the penetration of the wall of a tube or vessel, or when corrosion sites act as initiation sites for other forms of metal damage, such as fatigue cracks.

Examination by scanning electron microscopy (SEM) permits examination of the actual corroded surface, with excellent resolution at high magnifications. Investigators often employ a mechanical test (tension or fatigue test) of a

corroded specimen, which inherently fractures at the deepest corrosion site. The fractured surface then is examined to measure the depth of corrosion at the fracture initiation site. Jones et al. [17] showed that, for more than half of their samples, the depth of corrosion measured by SEM examination of pre-corroded fatigue specimens was greater than that determined by optical microscopy.

Techniques involving probe instruments, sometimes used for ferrous alloys, are not reliable for measuring of the depth of narrow pits or IGC in aluminum.

### Pitting Corrosion

Pitting corrosion is normally encountered on all aluminum alloys and in all environments, i.e., laboratory tests, field tests, and service applications. It occurs randomly, but not necessarily uniformly, over the entire surface. The depth and frequency of pitting depend on the alloy and environment. Pitting can be locally accelerated by crevices and contact with dissimilar metals. Pitting in aluminum tends to be self-stopping, following a polynomial [14], or power function [16] depending on the environment. Because pitting tends to be nonuniform, the “Pitting Factor” (ratio of maximum to average penetration) discussed in paragraph 7.3.2. of ASTM G 46, Practice for Examination and Evaluation of Pitting Corrosion is not useful for aluminum.

### Intergranular Corrosion (IGC)

Intergranular (intercrystalline) corrosion also occurs randomly, over the entire surface, but corrosion is limited to the immediate grain boundary region and often is not apparent visually. This localization results from compositional differences between precipitates on the boundaries, the solute depleted grain margins, and the higher (normal) solute grain interior. IGC penetrates more quickly than does pitting corrosion, but it too reaches a self-limiting depth. This is due to limiting transport of oxygen and the corrodent down the narrow corrosion path. When the limiting depth has been reached, intergranular attack spreads laterally. If IGC results in splitting or exfoliation, the corrosion will not be self-limiting [18]. IGC has much sharper tips than pitting corrosion, hence it is a more drastic stress riser and has a more damaging contribution to corrosion fatigue.

### Exfoliation Corrosion

Exfoliation corrosion occurs in products having highly directional grain structure, such as that shown for plate in Fig. 1. The corrosion begins as lateral intergranular corrosion on subsurface grain boundaries parallel to the metal surface, but entrapped corrosion products produce internal stresses that tend to lift off the overlying metal. This spalling off of the metal creates fresh metal surfaces for continued corrosion. Consequently exfoliation corrosion does not become self limiting. Photographs of exfoliation can be found in Figs. 2–6 of ASTM G 34, and Figs. 1 and 2 of ASTM G 66, Method for Visual Assessment of Exfoliation Corrosion Susceptibility of 5xxx Series Aluminum Alloys (ASSET Test). These figures can also be found in Chapter 22 of this manual.

Highly cold-worked tempers of certain 3xxx and 5xxx alloys can incur a less aggressive form of exfoliation that proceeds in a transgranular mode, following selective precipitation along slip bands [16].

## STRESS CORROSION CRACKING (SCC)

Resistance to SCC is of prime importance in structural, load bearing applications. Considerable testing is performed to ensure adequate resistance because failure by this corrosion mode could be catastrophic, and because of the uncertainty of the time to initiate a failure.

SCC in aluminum alloys is typically intergranular, although transgranular SCC has been observed for a few alloys under highly specific environmental conditions [16,19] and may be part of the propagation mechanism in some 7xxx alloys. SCC requires the interaction of a metallurgically susceptible material, a corrosive environment (water vapor may be sufficient) and sustained (but not necessarily continuous) tensile stress.

Generally there is a threshold stress that must be exceeded in order for SCC to initiate, but this is dependent on the environment, the test specimen or part configuration, and the method of loading, (bending, direct extension, constant load, etc.). The initiation period increases as the applied stress is decreased and can vary from a few hours to many years. Once cracking has begun, the crack grows linearly at a constant velocity independent of the applied stress. This continues until either unstable crack growth occurs, leading to rapid failure, or the applied stress falls below the threshold required for crack propagation. Precracked, fracture toughness type specimens have been developed that can measure the crack growth rate, plateau velocity, and the threshold level of stress-intensity.

The use of precracked SCC specimens is necessary for some metals in which an SCC flaw will not initiate, but in which other types of flaws such as weld cracks can propagate by SCC. This is not necessary for aluminum alloys, which will initiate a SCC flaw on an unflawed, smooth specimen. Most SCC testing of aluminum has been done using smooth specimens because these specimens and test methods are faster and less expensive. Although the data from the two types of testing are not interchangeable, both methods tend to rank aluminum alloys in the same relative order of increasing resistance to SCC [20].

The most significant type of SCC data is determination of the safe stress level below which failure will not occur. Other data forms are time to failure, number of failures, and percent failure (or survival). SCC failure times are not normally distributed, but the logarithm of failure times tend to have a normal distribution. This permits probability plots of cumulative percent failure (or survival) versus exposure time. Refer to Chapter 25.

## FILIFORM CORROSION

Filiform corrosion is selective worm-track pitting corrosion of the surface of the metal beneath a pliable film. An example is shown in Fig. 4. This type of corrosion usually

**FIG. 4—Photograph of filiform corrosion that occurred on a medicinal “Uni-dose” cup during compatibility tests with various pharmaceuticals. The cup was formed from 0.15 mm aluminum foil coated with a clear lacquer. Corrosion did not perforate the cup but resulted in contamination of the liquid. (Photograph courtesy of F. S. Bovard, Alcoa Technical Center.)**

penetrates only a few hundredths of a millimeter; hence the concern generally is aesthetic appearance, except in the case of thin foils where perforation can occur, or where the packaged contents can be contaminated.

Resistance to filiform corrosion depends more on factors such as the environment, the type and thickness of coating, metal surface preparation, and coating application procedures than on the metal itself. However, there is evidence that higher copper content aluminum alloys are more susceptible. Primary environmental factors are the presence of moisture and chloride ions. An acidic electrolyte has an accelerating effect.

## UNIFORM CORROSION

Uniform corrosion of aluminum is rare, except in special, highly acidic, or alkaline corrodents, e.g., the preparation of specimens for exposure per paragraph 12.1 of ASTM G 66 by etching for 1 min in 5 % by weight sodium hydroxide at 80°C.

Under controlled conditions, the rate of dissolution is quite uniform and linear, depending primarily on the chemical concentration and temperature of the electrolyte. Several industrial processes use this principle to electrochemically machine or size parts. Thickness measuring devices, or gravimetric procedures, can be used in such cases.

## STAINING CORROSION

Bright aluminum surfaces incur staining in certain aqueous solutions. Frequently stains result from a roughening and thickening of the aluminum oxide, which causes a change in the refraction of incident light. This is important

in applications such as bright trim and reflector sheet. Assessment of damage is by visual inspection, photographs, and measurement of reflectivity or image clarity.

## TESTS FOR SPECIFIC TYPES OF CORROSION

The purpose of this section is to introduce standard test methods, practices and guides for evaluation of the various type of corrosion that occur in aluminum. Refer also to Section IV for additional information.

### General Pitting Corrosion

Pitting corrosion will occur in most environments, particularly those containing the chloride ion. Pitting can be evaluated on virtually any specimen, but flat panels usually are used when this is the principal purpose of the test. ASTM G 1 describes surface preparation of specimens for pitting tests, while ASTM G 46 covers specimen evaluation after test.

Specific tests frequently used are: (a) neutral 5 % Sodium Chloride salt spray (ASTM B 117, Test Method of Salt Spray (Fog) Testing), (b) 3.5 % Sodium Chloride by alternate immersion (ASTM G 44, Practice for Evaluating Stress Corrosion Cracking Resistance of Metals in 3.5 % Sodium Chloride Solution), and (c) exposure to various outdoor atmospheres. Guidelines for outdoor exposure are contained in ASTM G 50, Practice for Conducting Atmospheric Corrosion Tests on Metals. Generic types of atmospheres used are seacoast, industrial, urban, and rural. Sometimes specific geographical locations or local chemical conditions are important because they can produce unique results [21].

### Intergranular (Intercrystalline) Corrosion

Susceptibility to intergranular corrosion depends primarily on the type of alloy and fabrication process and can occur in most environments. The six-hour ASTM G 110 test (Practice for Evaluating Intergranular Corrosion Resistance of Heat Treatable Aluminum Alloys by Immersion in Sodium Chloride + Hydrogen Peroxide Solution) is most often used to determine inherent susceptibility to this form of corrosion. However, users are cautioned that the degree of susceptibility in this accelerated test may not be representative of performance in outdoor atmospheres [22].

A rather unique mass loss test method, ASTM G 67 (Test Method for Determining the Susceptibility of Intergranular Corrosion of 5xxx Series Aluminum Alloys by Mass Loss After Exposure to Nitric Acid [NAML Test]) has been developed to provide a quantitative measure of the intergranular susceptibility of 5xxx series Al-Mg and Al-Mg-Mn alloys. The technique is useful to determine whether material has become sensitized by exposure to elevated temperature. Development of the test is reported in Ref 23.

### Exfoliation

Exfoliation corrosion occurs only for certain tempers and alloys, but resistance to this form of corrosion should be

known, because the resultant damage can be quite severe. Also, protective coatings do little to prevent this type of corrosion.

ASTM standards have been prepared for several short time laboratory tests that range from one day to two weeks of exposure; namely, ASTM G 34 for 2xxx and 7xxx alloys, ASTM G 66 for 5xxx alloys, and three methods of Salt Spray (Fog) Testing, ASTM G 85 (Practice for Modified Salt Spray [Fog] Testing), Annexes A2, A3, and A4. The background of the development of these and other tests are contained in Refs 24–28. In addition ASTM G 112, Guide for Conducting Exfoliation Corrosion Tests in Aluminum Alloys, provides guidelines regarding specimen preparation, significant exposure periods, and inspection and evaluation techniques. The degree of susceptibility to exfoliation of some materials will vary in the different accelerated tests. Performance in seacoast atmosphere is generally regarded as the baseline against which the appropriateness of any accelerated test should be judged. Two years of exposure at the seacoast is considered the minimum exposure period for this purpose, and longer seacoast experience of four or more years is desirable [27,28] (see also Chapter 22).

### Stress Corrosion Cracking (SCC)

SCC tests differ from others corrosion tests in that specific types of specimens and loading methods are required to stress the specimens. Care must be taken to electrically insulate the specimen from any metallic loading fixtures.

### Smooth Specimens

Smooth specimens can be stressed by a constant load, by constant strain rate, or by constant deflection, which is the usual procedure. Typical specimens are (a) direct tension specimens, (b) C-ring specimens, (c) U-bend specimens, (d) bent beam specimens, and special techniques for weldments (see ASTM G 49, Practice for Preparation and Use of Direct Tension Stress-Corrosion Test Specimens; ASTM G 38, Practices for Making and Using C-Ring Stress-Corrosion Test Specimen; ASTM G 30, Practice for Making and Using U-Bend Stress-Corrosion Test Specimens; ASTM G 39, Practice for Preparation and Use of Bent-Beam Stress-Corrosion Test Specimens; and ASTM G 58, Practice for the Preparation of Stress-Corrosion Test Specimens for Weldments, respectively).

The most frequently used accelerated test is the 3.5 % NaCl alternate immersion test ASTM G 44 following procedures given in ASTM G 47, Test Method for Determining Susceptibility to Stress-Corrosion Cracking of High-Strength Aluminum Alloy Products. For 7xxx series alloys containing less than 0.25 % copper ASTM G 103, Test Method for Performing a Stress-Corrosion Test for Low Copper Containing Al-Zn-Mg Alloys in Boiling 6 % Sodium Chloride Solution is used.

Successful completion of any of these tests only assures a specific level of resistance and does not imply immunity to SCC. Field tests in outdoor atmospheres, especially seacoast and industrial atmospheres, are the primary baseline for determination of long-term service performance.

SCC tests involving constant strain rate loading are rarely used in the United States; however, a procedure for this type

of test is contained in the International Standards document ISO 7539-7 and in ASTM G 129, Practice for Slow Strain Rate Testing to Evaluate the Susceptibility of Metallic Materials to Environmentally Assisted Cracking (EAC).

A new technique for use with constant deflection specimens is the determination of the residual "breaking strength" (load carrying ability) after short exposures to an environment such as ASTM G 44, rather than use of pass/fail data. Both unstressed and stressed specimens are exposed, providing a measure of the effect of applied stress on corrosion and on resistance to SCC. An adequate number of replicate specimens (typically five), two or more stress levels (one being no stress), and three or more exposure periods (one being no exposure) are required. Such a method is in use for high-strength aluminum alloys [29] and the results of an ASTM round robin are contained in Ref 30. An expanded report version of Ref 30 containing all the tabular data is on file with ASTM. The advantages of the method are considerably shorter exposure periods and statistical analysis of results.

### Precracked Specimens

Tests involving precracked specimens are rarely used for aluminum alloys (except for mechanistic studies) because they require longer exposure and more expensive specimens. Specimens are loaded to a percentage of the fracture toughness and the loading method can result in a constant, an increasing, or a decreasing level of stress-intensity as the crack progresses. The last method is the usual one, using the double-cantilever notched, precracked specimens of the type shown in Ref 20. The data measured are crack lengths, from which crack velocity and the limiting stress-intensity

for crack growth can be calculated. The international standard ISO 7539-6 exists on this subject.

### Galvanic Corrosion

Electrochemical methods, such as anodic polarization curves electrochemical impedance spectroscopy (EIS), and measurement of the corrosion potential (open circuit or rest potential) are primarily laboratory tests. They require experience in interpretation of the results, but have the advantage of very short test times. As such, they are important in mechanistic studies, but certain commercial uses also exist.

ASTM electrochemical standards include ASTM G 3, Practice for Conventions Applicable to Electrochemical Measurements in Corrosion Testing; ASTM G 5, Standard Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements; ASTM G 69, Practice for Measurement of Corrosion Potentials of Aluminum Alloys; and ASTM G 82, Guide for Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance. The corrosion potential (ASTM G 69) often is used for metallurgical purposes, i.e., determination of the amount of material in solid solution, heat-affected areas from welding, and the validity of thermal treatments.

### Filiform Corrosion

To date there is no standardized filiform corrosion test, but it appears that chloride ions and high humidity are required for initiation and propagation. Laboratory tests that have been used are the 3.5 % NaCl alternate immersion test, ASTM G 44, or exposure to hydrochloric acid vapors

TABLE 2—Relative general corrosion and SCC ratings.

Ratings:<sup>a</sup>

- (1) *General Corrosion*: Relative ratings from A through D are in decreasing order of merit. Material rated A or B can be used in some applications without protection.
- (2) *SCC*: Ratings apply to the short transverse direction of products with a critical directional grain structure. Relative ratings from 1 through 5 are in decreasing order of merit. Material rating 1 is not susceptible to SCC, rating 2 is resistant at stresses up to 75% Y.S., rating 3 is resistant at stresses up to 50% Y.S., rating 4 is resistant at low stresses, 105 to 170 MPa, while rating 5 has incurred some failures even at the lowest stress level tested, 48 MPa.

Wrought, Strain-Hardened Alloys					
Type of Alloy	Commercial Examples	General Corrosion		Stress-Corrosion Cracking	
		Temper	Rating (1)	Temper	Rating (2)
Unalloyed Al	1100, 1230	All	A	All	1
Al-Mn	3003, 3004	All	A	All	1
Al-Mg	5052, 5454	All	A	All	1
Al-Mg-Mn	5083, 5456	All	A <sup>b</sup>	All	1 <sup>b</sup>
Wrought, Heat-Treated Alloys					
Al-Mg-Si	6061, 6013	T6	B	T6	2
Al-Cu	2024, 2324	T3, T39	C or D <sup>c</sup>	T3, T39	5
Al-Cu	2024, 2219	T8	C	T8	2
Al-Zn-Mg	7005	T6	B	T6	5
Al-Zn-Mg-Cu	7075	T6	C or D <sup>c</sup>	T6	5
Al-Zn-Mg-Cu	7075	T73	C	T73	2
Al-Zn-Mg-Cu	7050	T74	C	T74	3
Al-Zn-Mg-Cu	7075, 7150	T76	C	T76	4
Al-Zn-Mg-Cu	7150, 7055	T77	C	T77	4

<sup>a</sup>See Refs 34, 35, and ASTM G 64 for more detailed comparison, including other alloys.

<sup>b</sup>Ratings will be lower if material in a non-stabilized temper is heated at 80 to 175°C.

<sup>c</sup>The D rating applies to thick products susceptible to intergranular corrosion and exfoliation.

for 24 h followed by prolonged exposure to high humidity at slightly elevated temperatures of about 50–65°C [31].

Publications on filiform test methodology are anticipated in the near future due to the current interest in aluminum for auto body sheet, together with the need to maintain an aesthetically pleasing painted surface. This form of corrosion can occur during exposure to seacoast atmosphere, and it has been developed at inland atmospheric exposure sites by spraying the specimens periodically (about three times per week) with a 3–5 % solution of sodium chloride.

### Protective Coatings

Evaluation of the protective ability of coatings generally is made in salt spray cabinets, such as those covered in ASTM B 117 and G 85 or in the 3.5 % NaCl alternate immersion test (G 44).

Recent investigations, primarily on steel, have established the desirability of including ultraviolet (UV) light as part of the exposure cycle since UV light has a degrading effect on paints and other organic coatings. The significance of such tests on coated aluminum has not yet been fully established.

Furthermore, there is considerable interest in potentiodynamic polarization techniques to rapidly assess the durability of coated aluminum surfaces that have been painted or given various polymeric or anodic surface treatments [32,33]. Refer also to Chapter 56 in this section of the manual.

### RELATIVE COMPARISON OF CORROSION BEHAVIOR

A brief relative comparison of wrought, strain-hardened, and heat-treated alloys is given in Table 2. More detailed comparisons can be found in the following three references: Comparison of the general and the stress-corrosion resistance of registered alloys [34], Classification of SCC resistance of high-strength alloys (see ASTM G 64), and Comparison of the general corrosion resistance of weldments [35].

# Steels

*M. E. Komp<sup>1</sup>, D. L. Jordan,<sup>2</sup> and R. Baboian<sup>3</sup>*

IN MOST INSTANCES, corrosion test methods for plain carbon steels, high-strength low-alloy steels, and alloy steels do not differ greatly. Therefore, these steels are grouped together for the purposes of this chapter. (Alloy steels here refers to heat treatable constructional and automotive steels, and does not include the stainless steels or other high alloys.) There are some differences in the corrosion test methods used for different mill products of this group of steels, and these will be discussed. The steels covered in this chapter are defined below.

Carbon steels are basically alloys of iron and carbon, with only small amounts of other elements present. For most of the steels discussed here, the carbon content ranges up to 1 %. However, there are some specialty steels in which carbon content may range up to 2 %. Carbon steels always contain some manganese, silicon, phosphorus, and sulfur; minor amounts of other elements may also be present. The American Iron and Steel Institute (AISI) specifies that carbon steel may contain up to 1.65 % manganese, 0.6 % silicon, and 0.6 % copper [1].

High-strength low-alloy (HSLA) steels contain additional alloying elements (up to a total of 3–4 %), which increase strength and, in some grades, improve atmospheric corrosion resistance. Usually they are supplied in the as-rolled or normalized condition, although some can be supplied in the quench-and-tempered condition. Alloying elements commonly present in HSLA steels include nickel, chromium, copper, silicon, phosphorus, columbium, vanadium, and titanium. Typical HSLA steels are described in the following specifications:

- ASTM A 242, Specification for High-Strength Low-Alloy Structural Steel
- ASTM A 572, Specification for High-Strength Low-Alloy Columbium-Vanadium Steels of Structural Quality
- ASTM A 588, Specification for High-Strength Low-Alloy Structural Steel with 50 ksi (345 MPa) Minimum Yield Point to 4 in. (100 mm) Thick
- ASTM A 606, Specification for Steel, Sheet and Strip, High-Strength, Low-Alloy, Hot-Rolled and Cold-Rolled, with Improved Atmospheric Corrosion Resistance

<sup>1</sup>Deceased, formerly with USS, a Division of USX Corporation, Monroeville, PA 15146.

<sup>2</sup>Formerly Staff Engineer, Inland Steel Flat Products Company, a Subsidiary of Inland Steel Industries, East Chicago, IN 46312.

<sup>3</sup>RB Corrosion Service, Greenville, RI 02828.

- ASTM A 852, Specification for Quenched and Tempered Low-Alloy Structural Steel Plate with 70 ksi (485 MPa) Minimum Yield Strength to 4 in. (100 mm) Thick

Minimum yield strengths for HSLA steels range from 40 000 to 70 000 psi (275–485 MPa.)

Alloy steels include the constructional alloy steels, which are normally supplied in the quenched-and-tempered condition with yield strengths of 100 000 psi (690 MPa) or higher, as described in the following specifications:

- ASTM A 514, Specification for High-Yield-Strength, Quenched and Tempered Alloy Steel Plate, Suitable for Welding
- ASTM A 517, Specification for Pressure Vessel Plates, Alloy Steel, High-Strength, Quenched and Tempered

Also included are the heat treatable constructional alloy steels identified in the Unified Numbering System (UNS) as designations between G13XXX and G94XXX, inclusive. These latter steels are also referred to as SAE-AISI alloy steels. The alloy steels generally contain somewhat higher carbon and alloy content than the HSLA steels (up to a total of about 5 %.) Stainless steels and other high alloys are not included in this category; they are covered in other chapters in this section. Mill products available in carbon, HSLA, and alloy steels include bar, plates, structural shapes, sheet, strip, tubular products, and wire.

## METALLURGICAL EFFECTS ON CORROSION

### Composition

Small amounts of alloying elements in steel can have a significant beneficial effect on corrosion in the atmosphere. Copper-bearing steels (0.2 % copper, minimum) have long been used for this purpose. In the HSLA weathering steels, small additions of elements such as chromium, silicon, copper, nickel, and phosphorus are used to achieve even greater resistance to atmospheric corrosion.

Under immersed conditions in natural waters, in neutral or alkaline solutions, or when buried in soil, the chemical composition of carbon, HSLA, and alloy steels has little effect on corrosion rates. In acid solutions, however, the composition can have a pronounced effect on corrosion. Rates of corrosion in acid increase with increasing carbon and nitrogen content of the steel. Sulfur and phosphorus

also increase the rate of attack, whereas copper additions counteract this effect.

### Microstructure

The microstructure of these steels has little effect on corrosion in the atmosphere or in neutral or alkaline solutions. In acids, however, microstructure can have a significant effect because the carbide morphology affects the hydrogen discharge reaction. Untempered martensitic and pearlitic structures generally show the lowest rates of attack in acids, whereas tempered martensite and spheroidized structures show much higher rates [2].

## ENVIRONMENTAL EFFECTS ON CORROSION

### Atmospheric

The main environmental factors that govern the corrosion rate of steel in the atmosphere are temperature, time-of-wetness, and type and amount of chemical contamination. Time-of-wetness includes not only time when the steel is wet from precipitation or dew, but also time above a certain "critical humidity," which can vary from about 50–70 % relative humidity, depending upon the contaminants present in the air [3]. For most inland sites, the most important chemical contaminant affecting atmospheric corrosion of steel is sulfur dioxide. At coastal sites, and locations where de-icing salts are used, chloride content is most important.

### Aqueous

In natural waters and other aqueous environments, corrosion of steel is controlled by the concentration of dissolved oxygen, temperature, acidity (pH), dissolved salts, and flow velocity. Corrosion rate is relatively constant between pH 4 and pH 10. At pH < 4, acid attack with hydrogen evolution generally occurs. In some acidic environments, particularly those containing sulfides or cyanides, or both, the hydrogen generated can diffuse into the steel and can result in blistering of low-strength steels and cracking of high-strength steels. Above pH 10, corrosion rate decreases. Dissolved salts generally increase corrosion rates because they increase the conductivity of the solution. However, in natural waters some calcium and magnesium salts (present in "hard" water) can be beneficial because they form insoluble protective films on the steel.

### Soils

Corrosion of steel buried in soil is largely controlled by moisture content, conductivity (dissolved salts), degree of aeration, and acidity (pH) of the soil. The effects of these factors are much the same as for immersed conditions in water. Corrosion caused by bacteria also may be important in soils. For example, under anaerobic (oxygen-free) conditions, sulfate-reducing bacteria in soil can form hydrogen sulfide, which attacks steel. Aerobic organisms can also cause corrosion. This entire subject is referred to as MIC (microbiologically influenced corrosion) [4].

### High Temperatures

The high temperature oxidation rate of carbon steels in air, steam, and other oxidizing gases is generally considered to be negligible below about 1000°F (540°C). For HSLA and alloy steels, the maximum temperature can be somewhat higher, depending primarily on the chromium, silicon, and aluminum contents of the steel. In reducing gases, the presence of sulfur and halogen compounds can create a much more aggressive environment and may preclude the use of these steels at elevated temperatures.

High-temperature hydrogen environments can cause severe damage to carbon steel at temperatures above about 425°F (220°C). Hydrogen diffuses into the steel and reacts with iron carbides to form methane. The resulting high internal pressures in the steel can result in cracking failures. Hydrogen damage in steel is effectively inhibited by alloying with strong carbide formers such as chromium, molybdenum, titanium, and vanadium. Diagrams showing the safe operating limits for carbon and alloy steels in high temperature hydrogen environments are available in the literature [5,6].

Some liquid metals can severely corrode carbon and low-alloy steels, usually by intergranular attack, and can also result in embrittlement and cracking failures. Molten lead-tin solder, brass, bronze, copper, and zinc are among the metals that reportedly can cause these problems under certain conditions [7].

## GENERAL CORROSION TESTING CONSIDERATIONS

In selecting a corrosion test method for steels, a number of issues must be considered and resolved. The purpose of the test must be carefully stated. Corrosion tests meant to predict long-term durability differ from those used to rank material performance in an idealized environment, which, in turn, differ from tests geared toward understanding why materials behave the way they do. The tests noted in this chapter are outlined in detail in standards published by ASTM, NACE International (formerly National Association of Corrosion Engineers), Society of Automotive Engineers (SAE), International Organization for Standardization (ISO), and German Standards Institution (DIN), and focus on long-term performance and ranking. Specialized tests for mechanism studies will not be addressed, since such tests are often developed specifically for a particular, sometimes unique, situation. Specialized tests are under constant refinement and are reported regularly in technical and scholarly journals. Corrosion testing of steels with metallic and organic coatings is covered in another chapter in this section. Details concerning mechanisms associated with the various corrosion types are discussed in another section of this manual.

The performance characteristic to be determined, e.g., mass loss, thickness loss, or strength loss, must be specified before selecting and performing the corrosion test. The environment must be specified, and a decision on whether or not to test in that specific environment (i.e., an in-plant or in-service test) or in a simulated environment (i.e., in a laboratory test) must be made. Any deviations from the actual

in-service conditions may make the testing simpler to accomplish, but will invariably introduce uncertainties into the data and resulting conclusions.

Before embarking on any corrosion testing program, the recommendations of the following documents should be read and understood:

- ASTM G 1, Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens
- ASTM G 15, Definitions of Terms Relating to Corrosion and Corrosion Testing
- ASTM G 16, Practice for Applying Statistics to Analysis of Corrosion Data
- NACE Recommended Practice-Collection and Identification of Corrosion Products (RP0173)

Chemical cleaning of corroded iron and steel often involves hazardous chemicals, so recognition of the safety considerations listed in ASTM G 1 is mandatory.

Of particular interest to users of iron and steel is the presence of the passive film. The passive film and its breakdown are major controllers of iron and steel corrosion, so factors that influence the film (e.g., chloride ion, atmospheric oxygen, abrasion) must be carefully considered during test selection, sample preparation, and test execution.

## CORROSION TEST METHODS APPLICABLE TO ALL MILL PRODUCTS

### Uniform Corrosion

Uniform corrosion is responsible for the largest amount of corrosion damage, on a tonnage basis, of any type of corrosion. It is characterized by attack that occurs uniformly over the metal, with no concentrations in localized areas. Fortunately, methods are available to predict the corrosion rate, the extent of subsequent metal thinning, and the probable failure time, based on accurate knowledge of the metal and environment. This chapter will briefly describe the use of standard tests for uniform corrosion and will indicate possible testing pitfalls specifically associated with iron and steel.

In-service or in-plant tests are particularly useful in estimating the service life of steel, since the exposure conditions are considered to be realistic. The following documents clearly outline procedures to obtain meaningful corrosion rates for steels in their respective applications and environments:

- ASTM G 4, Guide for Conducting Corrosion Coupon Tests in Field Applications
- NACE Recommended Practice-Preparation and Installation of Corrosion Coupons and Interpretation of Test Data in Oil Production Practice (RP0775)
- SAE Recommended Practice for Undervehicle Coupon Corrosion Tests (J1293)
- ASTM G 52, Practice for Exposing and Evaluating Metals and Alloys in Surface Seawater

Care should be taken to prepare test materials with precisely the same processing history as those expected to be in service, since surface and bulk characteristics of the steel can dramatically influence the corrosion rate. Chemical

**TABLE 1**—Relative corrosivity of atmospheric corrosion test sites.<sup>a,b</sup>

Site	No. of Years			
	1	2	4	8
State College, PA (rural)	1.0	1.0	1.0	1.0
South Bend, PA (semi-rural)	1.5	1.5	1.6	1.7

<sup>b</sup>From Ref 8.

cleaning, temper rolling, shot peening, or specialized heat treatments must be considered in that regard.

ASTM G 50, Practice for Conducting Atmospheric Corrosion Tests on Metals, is widely used, but care must be taken to interpret the results as being applicable only to the selected test site. Atmospheric corrosion testing involves exposing specimens of the test material to given environments for fixed periods of time. The typical measured response is mass loss, which can be converted to depth of penetration per unit time. Such a conversion assumes that the corrosion proceeds uniformly over the metal surface; localized corrosion is not considered in the treatment. It is common to test sheet or plate materials, due to their easily controllable geometry and placement in the corrosion environment. Shapes such as bolts, formed sheet, and fabricated parts, while often useful for product evaluation, complicate corrosion evaluation procedures. Different locations on irregular samples experience different exposure conditions; partially sheltered portions, skyward surfaces, groundward surfaces, and various angles from horizontal cannot be expected to experience the same corrosion rates. Table 1 shows that the measured corrosion rate for mild steel in one geographic location may differ significantly from that in another location [8]. Likewise, rankings of related materials may be different for different exposure locations. Clearly, selection of an atmospheric test location that adequately simulates the expected service environment is of utmost importance. Useful methods to determine and classify the corrosivities of different atmospheres are given in the following standards:

- ASTM G 92, Practice for Characterization of Atmospheric Test Sites
- ISO Standard-Corrosion of Metals and Alloys-Corrosivity of Atmospheres-Classification (9223)
- ISO Standard-Corrosion of Metals and Alloys-Corrosivity of Atmospheres-Guiding Values for the Corrosivity Categories (9224)

When it is impractical to test in service, laboratory simulations of the corrosive exposures may be necessary. Immersion tests, cabinet tests, and electrochemical measurements are in widespread use, but do not necessarily provide results that correlate with service exposures. However, relative rankings of selected materials under controlled testing conditions can be useful in materials development.

Guidelines for determining mass loss of a metal exposed in an apparatus that contains a solution of interest are provided in the following standards:

- ASTM G 31, Standard Practice for Laboratory Immersion Testing of Metals
- NACE Standard Test Method-Laboratory Corrosion Testing of Metals for the Process Industries (TM0169)

The apparatus may control temperature, aeration, agitation, or other parameters, depending on the service conditions that are to be simulated.

Guidelines for specialized cases of immersion testing of metals, including steels, are provided in the following standards:

- NACE Standard Test Method-Method of Conducting Controlled Velocity Laboratory Corrosion Tests (TM0270)
- NACE Standard Test Method-Autoclave Corrosion Testing of Metals in High Temperature Water (TM0171)
- NACE Standard Test Method-Dynamic Corrosion Testing of Metals in High Temperature Water (TM0274)
- ASTM G 129, Practice for Slow Strain Rate Testing to Evaluate the Susceptibility of Metallic Materials to Environmentally Assisted Cracking (EAC)

Many so-called cabinet tests are used to detect lot-to-lot variation of materials. Cabinet tests involve exposure of a material to an aqueous fog that may contain a variety of corrosive species (e.g., chlorides, sulfates), either singly or in combination. The exposure conditions (e.g., temperature, solution pH, solution specific gravity, fog delivery rate, position of specimens) are carefully specified and controlled. However, extensive efforts to correlate cabinet test results with those of service performance tests for many materials, including steel, have failed. The inability of the cabinet to reproduce the exposure conditions experienced in service is the primary contributor to that limitation. The unique interplay of the environment with the relatively fragile passive film on steel makes proper selection of exposure conditions mandatory. Standardized cabinet tests that could be adapted for quality control of uncoated steel are described in the following standards:

- ASTM B 117, Method of Salt Spray (Fog) Testing
- ASTM G 60, Test Method for Conducting Cyclic Humidity Tests
- ASTM G 85, Practice for Modified Salt Spray (Fog) Testing
- ASTM G 87, Practice for Conducting Moist SO<sub>2</sub> Tests

The electrochemical nature of corrosion may be studied effectively by a wide variety of electrochemical tests. Many of the tests require sophisticated instrumentation and expert interpretation and, therefore, have not been standardized. However, general guidelines for testing are described in the following standards:

- ASTM G 5, Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements
- ASTM G 59, Practice for Conducting Potentiodynamic Polarization Resistance Measurements

It should be noted that many electrochemical measurements cause forced dissolution of the test material, and the actual corrosion rates of the material in service may have little or no correlation with the electrochemical results.

### Pitting Corrosion

Pitting is a type of localized corrosion where the corrosion rate differs at adjacent sites on the metal. Pits are frequently encountered during standard corrosion tests, expected to result in uniform corrosion. In those cases, only the interpretation of the results differs.

Testing for pitting corrosion is difficult, due to the probabilistic nature of its occurrence and the frequent difficulty of detecting the attack. Catastrophic perforation of the metal is often the first detectable manifestation of pitting.

The highly localized nature of pitting makes mass loss and mechanical property measurements meaningless. Pitting is usually characterized by measuring the maximum pit depth in a given area; measurements of average pit depth will not give an accurate indication of impending perforation.

ASTM G 46, Practice for Examination and Evaluation of Pitting Corrosion, recommends that pitting corrosion be quantified by destructive methods (metallographic or by machining) or by nondestructive methods (micrometer or microscopical measurements). A standard rating chart for pits is included in ASTM G 46.

ASTM G 61, Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, and Cobalt-Based Alloys, outlines an electrochemical procedure to screen and rank the pitting susceptibility of various metals. However, the electrochemical measurement does not necessarily correlate with pitting rates actually encountered in service.

### Crevice Corrosion

Crevice corrosion is associated with small amounts of stagnant electrolyte and frequently appears in lap joints, under bolt heads, or in other areas shielded from the surrounding environment. Many of the techniques used to characterize pitting corrosion are applicable to crevice corrosion.

### Galvanic Corrosion

Galvanic corrosion of a metal occurs as a result of electrical contact with a more noble conductor in a corrosive electrolyte. It is often called "dissimilar metal" corrosion. Galvanic corrosion can often be avoided by disconnecting the point of electrical contact. In cases where electrical isolation is not possible, proper material selection can help minimize the effect.

The primary detrimental effect of galvanic corrosion is electrochemical dissolution of the less noble member of the couple and is manifested in increased mass loss of that member. Therefore, techniques specified in ASTM G 1, ASTM G 15, and ASTM G 16 are applicable. In some instances, the more noble member of the couple can be adversely affected by cathodic reaction products OH<sup>-</sup>, H<sub>2</sub>, or H<sub>2</sub>.

ASTM G 71, Guide for Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes, outlines recommended procedures and possible pitfalls in performing galvanic corrosion tests. Specimen geometry is the primary difference between galvanic corrosion testing and testing for uniform corrosion, due in part to its effect on current flow. Several useful sample geometries include wire-on-bolt, stacked washers, and stacked plates [9]. ASTM G 116, Practice for Conducting Wire-on-Bolt Test for Atmospheric Galvanic Corrosion, provides practical details for testing anodic metals.

### Stress Corrosion Cracking

SCC occurs in susceptible alloys and products under the simultaneous application of tensile stress and corrosive

environment. Methods of applying the test environment for SCC susceptibility screening tests for all mill products are described in the following standards:

- ASTM G 41, Test Method for Determining Cracking Susceptibility of Metals Exposed Under Stress to a Hot Salt Environment
- ASTM G 44, Practice for Evaluating Stress Corrosion Cracking Resistance of Metals and Alloys by Alternate Immersion in 3.5 % Sodium Chloride Solution

The atmospheric exposure outlined in ASTM G 50 may also be useful for SCC testing. Recommended exposure conditions, including solution composition, temperature, and drying cycles are listed. The time to first appearance of cracking is recorded. The stress state to be tested depends in large part on the geometry of the actual part, and methods to apply particular stress states to test specimens will be described in later paragraphs.

Slow strain-rate tests, in which standard tension test specimens are subjected to a constant extension rate of 10–4 to 10–6 m/s while being exposed to a corrosive environment, provide a relatively quick method for SCC screening of metals. Such methods are described in the following standards:

- ISO Standard-Corrosion of Metals and Alloys-Stress-Corrosion Testing-Part 7: Slow Strain-Rate Testing (7539-7)
- Proposed NACE Standard Test Method-Slow Strain Rate Test Method for Screening Corrosion Resistant Alloys (CRAs) for Stress Corrosion Cracking in Sour Oilfield Service (Task Group T-1F-9)

The methods are also discussed in detail in Ref 10.

The above methods for SCC testing are not widely used for carbon and low-alloy steels.

## CORROSION TEST METHODS APPLICABLE TO SPECIFIC MILL PRODUCTS

### Sheet and Strip

Nearly all of the standard test methods mentioned previously are applicable to sheet and strip. An important test that is best run on flat specimens is ASTM F 1113, Test Method for Electrochemical Measurement of Diffusible Hydrogen in Steels (Barnacle Electrode). This test measures the amount of diffusible (atomic) hydrogen in a steel sample by electrochemically oxidizing the atomic H to H<sup>+</sup>, which then combines with hydroxyl ions (OH<sup>-</sup>) in the electrolyte to form water. The atomic H can cause hydrogen embrittlement, a condition that reduces the ductility of a metal and results in cracking. Much of the testing for hydrogen embrittlement is associated with electroplated steels and is covered elsewhere in this section.

Procedures for making flat SCC specimens with specific stress states are outlined in the following standards:

- ASTM G 30, Practice for Making and Using U-Bend Stress-Corrosion Test Specimens
- ASTM G 39, Practice for Preparation and Use of Bent-Beam Stress-Corrosion Test Specimens
- ASTM G 49, Practice for Preparation and Use of Direct Tension Stress Corrosion Test Specimens

The specimens may then be tested by methods outlined in ASTM G 36, ASTM G 41, ASTM G 44, or ASTM G 50. A constant strain condition is maintained in the U-bend geometry specified in ASTM G 30; varying the bend radius controls the strain level. ASTM G 39 describes the bent beam SCC test specimen, which is similar in concept to the U-bend specimen, but is subject only to elastic strain. Axial loaded SCC test specimens are covered in ASTM G 49 and can be tested under constant strain, constant load, or varying strain rates. All of the SCC specimen preparation procedures for sheet and strip require careful sampling, due to the anisotropy introduced by rolling; specification of rolling direction on each specimen is mandatory.

### Bar, Plate, and Structural Shapes

Many applications for bar, plate, and structural steel require use of painting or other protective measures; therefore, there is not a great need for corrosion testing of the bare metal. An important exception to this, however, is the use of weathering steels, such as those specified in ASTM A 242, ASTM A 588, and ASTM A 852 in atmospheric exposure. The corrosion resistance of these steels is such that they can be used in the unpainted condition for many applications, depending on the environmental conditions. For these applications, there is a need for atmospheric corrosion testing to determine the suitability of bare weathering steels in specific locations.

The general recommendations given in ASTM G 50 can be followed for testing of weathering steels. Corrosion penetration calculated from mass loss after removal of corrosion products (per ASTM G 1) is the main criterion used, although pit depth and appearance are also used. However, it should be recognized that the corrosion rate of relatively small test panels of steel in the atmosphere may be substantially different than that of a massive structure, such as a bridge or large building. A large structure acts as a greater heat sink and has fewer temperature fluctuations, as compared to that of a small test panel; thus, time-of-wetness can be appreciably different. As indicated earlier, time-of-wetness is a significant factor in determining atmospheric corrosion rates.

For specific applications of bare weathering steel, it is desirable to test a mock-up containing the type of bolted and/or welded joints that will be used in the intended structure, and also the orientation conditions that the bare steel will encounter in the structure (e.g., horizontal, vertical facing north, 30° to the horizontal facing south, etc.). In addition to giving information on appearance and general corrosion rates in the specific environment, the mock-up can provide information on certain design details that should be avoided to prevent excessive localized corrosion.

ASTM G 101, Guide for Estimating the Atmospheric Corrosion Resistance of Low-Alloy Steels, presents two methods for use in estimating the performance of weathering steels in the atmosphere. The first method utilizes linear extrapolation of logarithmic plots of short-term atmospheric corrosion data to predict long-term performance. Examples of such predictions, taken from ASTM G 101, for ASTM A 242 and ASTM A 588 steels in industrial environments, are shown in Fig. 1.

FIG. 1—Projected corrosion penetration of ASTM A 588 and ASTM A 242 Type 1 steels in industrial environments in the U.K. and the U.S. (see Table 2 for identification of lines). From ASTM G 101.

The specific locations from which these data were obtained are given in Table 2 (ASTM G 101).

The second method of ASTM G 101 uses a predictive equation, based on the chemical composition of the steel, to calculate a corrosion resistance index. If the index for a specific steel composition falls within the range normally expected for weathering steel, the indication is that the steel in question contains sufficient alloying elements (in the proper proportion) such that it should perform as a weathering steel. Averages and ranges of corrosion resistance indices, taken from ASTM G 101, for ASTM A 242 and ASTM A 588 steels, are shown in Table 3.

Additional tests that are used for bar and plate steels include those for sulfide stress cracking (SSC) and hydrogen-induced cracking (HIC), for applications involving exposure to oilfield environments containing hydrogen sulfide ( $H_2S$ ), and for applications in the petroleum refining industry. These tests are described in the subsection Tubular Products, which follows.

TABLE 2—Identification of penetration lines for industrial exposures, shown in Fig. 1.<sup>a</sup>

Line No.	Type of Steel	Exposure Site
1	A588 Grade A	Tinsley, U.K.
2	A588 Grade A	Teeside, U.K.
3	A588 Grade A	Battersea, U.K.
4	A588 Grade A	Middlesbrough, U.K.
5	A588 Grade A	Portishead, U.K.
6	A588 Grade B	Bethlehem, PA
7	A588 Grade B	Newark, NJ
8	A242 Type 1	Teeside, U.K.
9	A242 Type 1	Battersea, U.K.
10	A242 Type 1	Pittsburgh, PA
11	A242 Type 1	Pittsburgh, PA
12	A242 Type 1	Bethlehem, PA
13	A242 Type 1	Newark, NJ

<sup>a</sup>From ASTM G 101.

Because of the extensive use of steel reinforcing bars in concrete, corrosion tests of steel embedded in concrete are of interest. Procedures in the following standards are useful in this regard:

- ASTM C 876, Test Method for Half-Cell Potentials of Uncoated Reinforcing Steel in Concrete
- ASTM G 109, Test Method for Determining the Effects of Chemical Admixtures on the Corrosion of Embedded Steel Reinforcement in Concrete Exposed to Chloride Environments

Also, NACE Standard Recommended Practice-Design Considerations for Corrosion Control of Reinforcing Steel in Concrete (RP0187) contains recommendations for corrosion monitoring systems for steel in concrete.

### Tubular Products

Corrosion tests specifically applicable to tubular products involve primarily oil country goods exposed to sour ( $H_2S$ -containing) oil and brines. These test methods were developed and are published by NACE International.

NACE Standard Test Method for Testing of Metals for Resistance to Sulfide Stress Cracking in  $H_2S$  Environments (TM0177) describes four test methods in which specimens stressed in tension are exposed to acidified brine saturated with  $H_2S$ . In Method A of this test, standard tension test specimens are used and the tensile stress is applied by either

TABLE 3—Atmospheric corrosion indices calculated from a modified Legault-Leckie equation for an industrial atmosphere<sup>a</sup> (36 heats of each steel).

Steel	Atmospheric Corrosion Index (1) <sup>b</sup>	
	Avg.	Range
A242 Type 1	8.5	7.9–9.1
A588 Grade A	6.8	6.4–7.0

<sup>a</sup>From ASTM G 101.

<sup>b</sup>The higher the index, the greater the corrosion resistance.

$$\text{Crack Sensivity Ratio, CSR} = \frac{\sum(a \times b)}{W \times T} \times 100\%$$

$$\text{Crack Length Ratio, CLR} = \frac{\sum a}{W} \times 100\%$$

$$\text{Crack Thickness Ratio, CTR} = \frac{\sum b}{T} \times 100\%$$

Where: a = crack length  
 b = crack thickness  
 W = section width  
 T = specimen thickness

FIG. 2—Schematic illustrating method of determination of CSR, CLR, and CTR in NACE TM0284. (© Copyright 1987 by NACE International. All Rights Reserved by NACE; reprinted by permission.)

a constant-load or a sustained-load device, per ASTM G 49. Method B uses bent-beam specimens stressed with a constant-deflection device employing three-point bending of the specimen. Method C uses C-ring specimens in accordance with ASTM G 38, Practice for Making and Using C-Ring Stress-Corrosion Test Specimens, and is intended primarily for transverse tests of pipe or tubing. Method D uses a double cantilever beam (DCB) specimen, in accordance with ISO Standard-Corrosion of Metals and Alloys-Stress Corrosion Testing-Part 6: Preparation and Use of Pre-Cracked Specimens (7539-6). This method is a crack arrest type of fracture mechanics test, and measures resistance of the steel to crack propagation by SSC in terms of critical stress intensity  $K_{Isc}$ .

NACE Test Method for Evaluation of Pipeline Steels for Resistance to Stepwise Cracking (TM0284) consists of exposing unstressed specimens to synthetic seawater saturated with  $H_2S$ , and subsequently examining polished cross sections of the specimens at magnifications up to 100× to determine the extent of internal cracking. This method is commonly referred to as the HIC (hydrogen-induced cracking) test. It is intended primarily to evaluate the resistance of pipeline steels to stepwise cracking caused by hydrogen absorption. "Stepwise" cracking refers to linking up of cracks on adjacent planes through the wall of the pipe, which can reduce the effective wall thickness and lead to overstressing and rupture. Three criteria are used to evaluate cracking in the steels: Crack Sensivity Ratio (CSR), which

is the summation of the crack areas divided by the area of the examined section; Crack Length Ratio (CLR), which is the summation of the crack lengths divided by the section width; and Crack Thickness Ratio (CTR), which is the summation of crack thicknesses divided by the specimen thickness. The determination of these ratios is shown schematically in Fig. 2, taken from NACE TM0284. The ratios are all multiplied by 100 to convert them to percent. The NACE test standard does not include acceptable values for these ratios; this is a matter of negotiation between the buyer and the producer.

For evaluation of the effect of flow velocity on corrosion in pipelines, NACE Standard Test Method of Conducting Controlled Velocity Laboratory Corrosion Tests (TM0270) can be used to evaluate several steel samples at one time, at velocities up to 8 ft/s (244 cm/s).

## Wire

In addition to the standard tests noted previously for uniform corrosion in the atmosphere and in aqueous electrolytes, two SCC tests specifically developed for wire must be noted. DNA Standard-Testing the Resistance of Aluminum Wrought Alloy Against Stress Corrosion (DIN 50908) outlines the Fry test, which consists of applying a bending load to a wire immersed in an appropriate test electrolyte and noting the time to fracture. Recognizing that bending loads are not always experienced by wire in service (e.g., concrete reinforcement) de Bondt developed a similar test that employs an axial load [11].

# Copper (and Alloys)

Arthur Cohen<sup>1</sup>

COPPER AND COPPER ALLOYS are produced in various mill-product forms such as bar, pipe, rod, tube, plate, sheet, wire and as castings. They are used widely because of their excellent corrosion resistance particularly when combined with their other properties, including outstanding electrical and thermal conductivities and ease of fabrication and joining. The copper alloys also possess superior resistance to biofouling.

## NATURE OF PROTECTIVE FILM

Copper and its alloys are unique in that their superior performance is associated with two factors. The first is that in accordance with the electromotive force (or galvanic) series, they display noble potentials. Second, they form a cuprous oxide ( $\text{Cu}_2\text{O}$ ) product film that is responsible for their protection. This  $\text{Cu}_2\text{O}$  film is tenaciously adherent.

For any corrosion reaction to proceed, copper ions and electrons must migrate through the  $\text{Cu}_2\text{O}$  film. Reducing the ionic or electronic conductivity of this film by doping the alloy with divalent or trivalent cations further improves corrosion resistance. In practice, alloying additions of aluminum, zinc, tin, iron, beryllium, and nickel are used to dope the corrosion product films, which lead to significant corrosion rate reduction.

## EFFECT OF ALLOY COMPOSITIONS

The various wrought and cast copper and copper alloy families are listed in Table 1 [1]. The corrosion performance of these alloy families has been widely reported [1–4].

### Copper and High Copper Alloys

These alloys possess similar corrosion resistance. They have excellent resistance to seawater corrosion and biofouling but are susceptible to erosion-corrosion at high water velocities. The high-copper alloys are used primarily in applications that require enhanced mechanical performance, often at slightly elevated temperature, with good thermal or electrical conductivity. Processing for increased strength in the high-copper alloys generally improves their resistance to erosion-corrosion.

<sup>1</sup>Formerly, Arthur Cohen & Associates, Albuquerque, New Mexico. Now deceased.

TABLE 1—Generic classification of copper alloys.

Generic Name	UNS Numbers	Composition
<b>Wrought Alloys</b>		
Coppers	C10100-C15760	>99% Cu
High-copper alloys	C16200-C19600	>96% Cu
Copper Beryllium	C17000-C17600	Cu-Be-Co-Ni
Brasses	C20500-C28580	Cu-Zn
Leaded brasses	C31200-C38590	Cu-Zn-Pb
Tin brasses	C40400-C49080	Cu-Zn-Sn-Pb
Phosphor bronzes	C50100-C52400	Cu-Sn-P
Leaded phosphor bronzes	C53200-C54800	Cu-Sn-Pb-P
Copper-phosphorus and copper-silver-phosphorus alloys	C55180-C55284	Cu-P-Ag
Aluminum bronzes	C60600-C64400	Cu-Al-Ni-Fe-Si-Sn
Silicon bronzes	C64700-C66100	Cu-Si-Sn
Other copper-zinc alloys	C66400-C69900	—
Copper nickels	C70000-C79900	Cu-Ni-Fe
Nickel silvers	C73200-C79900	Cu-Ni-Zn
<b>Cast Alloys</b>		
Coppers	C80100-C81100	>99% Cu
High-copper alloys	C81300-C82800	>94% Cu
Red and leaded red brasses	C83300-C85800	Cu-Zn-Sn-Pb (75–89% Cu)
Yellow and leaded yellow brasses	C85200-C85800	Cu-Zn-Sn-Pb (57–74% Cu)
Manganese and leaded manganese bronzes	C86100-C86800	Cu-Zn-Mn-Fe-Pb
Silicon bronzes, silicon brasses	C87300-C87900	Cu-Zn-Si
Copper-bismuth and copper-bismuth-selenium	C88000-C89999	(Cu-Zn-Sn-Bi) (64–91% Cu)
Tin bronzes and leaded tin bronzes	C90200-C94500	Cu-Sn-Zn-Pb
Nickel-tin bronze	C94700-C94900	Cu-Ni-Sn-Zn-Pb
Aluminum bronzes	C95200-C95810	Cu-Al-Fe-Ni
Copper-nickels	C96200-C96800	Cu-Ni-Fe
Nickel silvers	C97300-C97800	Cu-Ni-Zn-Pb-Sn
Leaded coppers	C98200-C98800	Cu-Pb
Miscellaneous alloys	C99300-C99750	—

### Brasses

The most widely used group of copper alloys is the brasses, which are basically copper-zinc alloys. The resistance of brasses to corrosion by aqueous solutions does not change markedly as long as the zinc content does not exceed about 15 %; above 15 % zinc, dezincification (or dealloying) may occur. Selective removal of zinc leaves a relatively porous and weak layer of copper.

Dezincification may be either plug-type (Fig. 1) or layer-type (Fig. 2) as exhibited.

FIG. 1—Plug-type dezincification (cross section) in a yellow brass (alloy C26000) tube (magnification 15 $\times$ ).

By contrast, the resistance to pitting is almost total when the zinc content exceeds 15 %. But the brasses that resist pitting are severely degraded by dezincification, which causes them to lose much of their strength [2] as illustrated in Fig. 3.

Quiescent or slowly moving saline solutions, brackish waters and mildly acidic solutions are environments that often lead to the dezincification of unmodified brasses.

Brasses containing the highest amounts of zinc have the best resistance where exposure to sulfur compounds is involved. Susceptibility to stress corrosion cracking (SCC) is affected significantly by the zinc content; alloys containing more zinc are more susceptible with resistance to SCC increasing substantially as zinc content decreases from 15 % to zero.

Elements such as lead or tellurium have no effect on the corrosion-resistant properties of copper or the binary copper-zinc alloys as they are added only to enhance the property of machinability.

### Tin Brasses

Tin additions significantly increase the corrosion resistance of some brasses, especially dezincification. Uninhibited Admiralty metal is a variation of Cartridge brass (alloy C26000), which is produced by the addition of 1 % tin to

FIG. 2—Layer-type dezincification (cross section) in a yellow brass (alloy C26000) threaded fastener (magnification 15 $\times$ ).

the basic 70Cu-30Zn composition. Its use as a heat exchanger tube has been replaced completely by the inhibited Admiralty alloys C44300-C44500. Uninhibited Naval brass is the alloy resulting from the addition of 0.75 % tin to the basic 60Cu-40Zn composition of Muntz metal (alloy C28000), which is widely used in tube sheet applications.

Cast brasses for marine use also are modified by the addition of tin, lead and sometimes nickel. The cast marine brasses are used for plumbing goods in moderate-performance seawater piping systems or in deck hardware for which they subsequently are chrome plated.

### Aluminum Brass

Aluminum oxide ( $\text{Al}_2\text{O}_3$ ) is an important constituent of the corrosion product film on this brass. Its presence markedly increases resistance to impingement attack in turbulent high velocity saline water. Arsenical aluminum brass (alloy C68700) tube used to be widely specified for marine condensers and heat exchangers in which impingement attack was likely to pose a serious problem. This alloy is susceptible to dezincification unless it is inhibited with a small amount of arsenic.

FIG. 3—Effect of zinc content on corrosion of brasses. Brass strip, 0.8 mm (0.032 in.) thick, was immersed for 60 days in 0.01M  $\text{NH}_4\text{Cl}$  solution at 45°C (113°F).

### Inhibited Alloys

The addition of arsenic, antimony, or phosphorus (typically 0.05 %) to Admiralty metal, Naval brass or aluminum brass produces high resistance to dezincification and SCC.

### Phosphor Bronzes

Additions of tin and phosphorus to copper produce alloys having good resistance to flowing seawater and to most non-oxidizing acids except hydrochloric. Alloys containing 8 to 10 % tin have high resistance to impingement attack. Phosphor bronzes are much less susceptible to SCC than bronzes and are similar to copper in their resistance to sulfur attack.

Tin bronzes tend to be used primarily in the cast form in which they are modified by further alloy additions of lead, zinc, and nickel. Contemporary uses include pumps, valves, gears, and bushings. This group of alloys has fair resistance to impingement and good resistance to biofouling.

### Copper Nickels

Alloy C71500 (70Cu-30Ni) has the best general resistance to aqueous corrosion of all the commercially important copper alloys, but C70600 (90Cu-10Ni) often is selected because it offers good resistance at lower cost. These alloys are used widely as condenser and heat exchanger tubes in recirculating steam systems in the chemical industry and are superior to copper and other copper alloys in resisting acid solutions and are highly resistant to impingement and SCC. They tend to be less resistant to pitting and crevice corrosion than the high copper alloys under certain conditions.

### Nickel Silvers

Alloy C75200 (nickel silver, 65-18) and C77000 (nickel silver 55-18), the two most common alloys in this family, have superior resistance to dezincification in both fresh and salt water over bronzes of similar copper content, chiefly because of their relatively high nickel contents.

### Copper-Silicon Alloys

These alloys generally have the same corrosion resistance as copper, but higher mechanical properties and superior weldability. They are somewhat better than the common bronzes in their resistance to SCC. However, evidence of their susceptibility to embrittlement by high-pressure steam makes them unsatisfactory in this application.

### Copper-Beryllium Alloys

As with other copper alloys used in electronics, beryllium copper can be supplied with solderability shelf life of 18 months or more. The alloys are essentially immune to cracking in sodium, potassium, magnesium, and mixed chloride salt solutions. They show no loss of ductility or strength under severe hydrogen charging conditions. Superior corrosion resistance and high hardness has led to their long successful service as undersea components, mold materials for plastic component manufacture, and instrument housings for oil and gas well drilling.

### Aluminum Bronzes

These alloys containing 5 to 12 % aluminum have excellent resistance to impingement corrosion and high-temperature oxidation. The corrosion characteristics of aluminum bronzes are related primarily to aluminum content. Alloys with up to 8 % aluminum have face-centered cubic alpha structures and good resistance to corrosion attack.

When the aluminum content exceeds 8 %, the alpha-beta duplex structures appear. The beta phase is a high-temperature phase retained at room temperature on fast cooling from 565°C (1050°F) or above. Slow cooling or long exposure at temperatures from 320 to 565°C (610 to 1050°F) tends to decompose the beta phase into a brittle alpha + gamma-2 eutectoid having either a lamellar or modular structure. The beta phase is less resistant to corrosion than the alpha phase, and eutectoid structures are even more susceptible to attack.

A corrosion mechanism similar to brass dezincification, known as dealuminification, can occur to the beta phase or eutectoid structure depending on environmental conditions. Proper quench and temper treatments produce a tempered beta structure with reprecipitated acicular alpha crystals, a combination often superior in corrosion resistance to the normal annealed structure. The nickel component in the more complex nickel aluminum bronzes alters the corrosion characteristics of the beta phase because of the nickel additive and gives greater resistance to dealloying and cavitation-erosion in most liquids.

### Cast Copper-Bismuth and Copper-Bismuth-Selenium

These cast alloys utilize bismuth and bismuth-selenium as a substitute for lead to facilitate machinability and pressure tightness in fluid carrying applications. Lead is not added intentionally to these alloys to minimize the amount that may leach in potable water systems and in other applications such as dairy product processing.

## SELECTION OF COPPER AND COPPER ALLOYS FOR SPECIFIC ENVIRONMENTS

In the following broad classifications, copper and copper alloys have demonstrated superior corrosion performance:

- Atmospheric exposure such as roofing and other architectural applications.
- Plumbing systems with superior corrosion resistance to both potable waters and soils.
- Marine applications involving supply lines, heat exchangers, and hardware where resistance to seawater and bio-fouling are mandatory.
- Industrial and chemical plant process equipment involving exposure to a wide variety of organic and inorganic chemicals.

While much corrosion performance data have been compiled by organizations such as the Copper Development Association (CDA) and the National Association of Corrosion Engineers (NACE), experience and field or laboratory

tests still remain the best criteria and are the most reliable guides for alloy selection for specific environments.

### Atmospheric Exposure

Copper and copper alloys perform well in industrial, marine, and rural atmospheres except in atmospheres containing ammonia which have been observed to cause SCC in brasses containing over 20 % zinc. Alloy C11000 (ETP copper) is the most widely used, particularly for roofing, flashing, gutters, and downspouts with alloys C22000 (commercial bronze), C23000 (red brass), C38500 (architectural bronze), and C75200 (65-12 nickel silver) accounting for much of the remainder.

### Water and Soils

The largest single application of copper tube is for hot and cold water distribution lines in building construction, with smaller amounts for heating and drainage lines and fire safety systems. Copper protects itself by forming a protective film, the degree of protection depending on mineral, oxygen, and carbon dioxide contents.

The brasses also perform well in unpolluted freshwaters but may experience dezincification in stagnant or slowly moving brackish or slightly acidic waters. The copper-nickels, silicon and aluminum bronzes display excellent resistance to corrosion.

Copper exhibits high resistance to corrosion in most soil types found throughout the United States. On the rare occasion where local soil conditions are unusually corrosive, some means of protection such as cathodic protection, neutralizing backfill (e.g., limestone), protective coatings, or wrappings may be helpful.

Studies on samples exposed underground have shown that tough pitch coppers, deoxidized coppers, silicon bronzes, and low-zinc brasses behave essentially alike. Soils containing cinders with high concentrations of sulfides, chlorides, or hydrogen ions corrode these materials. In this type of contaminated soil, alloys containing more than 22 % zinc experience dezincification. In soils that contain only sulfides, corrosion rates of the brasses decrease with increasing zinc content and no dezincification occurs.

For underground copper electric cables, the highest corrosion rate observed was in soils of lowest resistivity.

Due to the formation of a somewhat protective film, the corrosion rate of copper in quiescent ground waters tends to decrease with time, the rate depending on the amount of dissolved oxygen present.

### Steam

Copper and copper alloys resist attack by pure steam, but if carbon dioxide, oxygen, or ammonia is present, the condensate is corrosive.

### Steam Condensate

When the boiler feedwater is treated chemically to make the steam condensate relatively free of noncondensable gases, copper and copper alloys essentially are unattacked. The

presence of dissolved carbon dioxide, oxygen or both significantly increases the rate of attack.

Modern power utility boiler feedwater treatments commonly include the addition of organic amines to inhibit the corrosion of iron components of the system by scavenging oxygen and increasing the pH of the feedwater. These chemicals such as morpholine and hydrazine decompose in service to yield ammonia, which can be corrosive to some copper alloys. However, elevated oxygen levels are generally more deleterious than elevated ammonia levels.

### Salt Water

The superior performance of the inhibited admiralties, aluminum brass, aluminum bronzes, and copper-nickels over copper results from the combination of their corrosion product insolubility in seawater, erosion, and biofouling resistance.

Both alloys C70600 and C71500 display excellent resistance to pitting in seawater. The corrosion resistance of copper alloys in flowing seawater depends on the growth and maintenance of a protective film or corrosion product layers. The more adherent and protective the film on a particular alloy, the higher the velocity at which there is a transition from low- to high-corrosion rate and the greater its resistance to impingement attack or erosion-corrosion.

In general, the copper-base alloys are galvanically compatible with one another in seawater. While the copper-nickel alloys are slightly cathodic (noble) to the nickel-free copper base alloys, the small differences in corrosion potential generally do not lead to serious galvanic effects unless unusually adverse anodic/cathodic area ratios are involved.

### Polluted Cooling Waters

The primary causes of accelerated attack of copper alloys by polluted seawater are: (1) the action of sulfate-reducing bacteria under anaerobic conditions (bottom muds and sediments) on the natural sulfates in seawater in coastal harbors and estuaries, and (2) the putrefaction of organic sulfur compounds from decaying plant and animal matter within seawater systems during periods of extended shutdown.

### Biofouling

The copper alloys long have been recognized for their inherent resistance to marine fouling. Fouling resistance is a result of corrosion of the alloy. If galvanic effects or impressed cathodic protection suppresses the corrosion, the antifouling character will not be promoted.

### Acids

In general, copper alloys are used successfully with non-oxidizing acids as long as the concentration of oxidizing agents, such as dissolved oxygen (air), and ferric ( $\text{Fe}^{+3}$ ) or dichromate ( $\text{Cr}_2\text{O}_7$ )<sup>-2</sup> ions is low.

Acids that are oxidizing agents in themselves, such as nitric, cannot be handled in equipment made of copper or its alloys. Successful applications of copper and its alloys are in phosphoric, acetic, tartaric, formic, oxalic, malic, and other organic acids that react in a manner similar to sulfuric acid.

## Alkalies and Ammonia

Copper and its alloys resist alkaline solutions, except those containing ammonium hydroxide, or compounds that hydrolyze to ammonium hydroxide or cyanides. Ammonium hydroxide reacts with copper to form the soluble complex copper-ammonium compound  $\text{Cu}(\text{NH}_3)_4^{+2}$ .

Ammonium hydroxide solutions also attack copper-zinc alloys. Alloys containing more than 15 % zinc are susceptible to SCC when stressed and exposed to ammonium hydroxide, although it also is experienced by the copper-beryllium alloys which are zinc-free. The stress may be due to applied tensile service loads or to unrelieved residual tensile stresses.

## Salts

Copper metals are used widely in equipment for handling various kinds of salt solutions including the nitrates, sulfates, and chlorides of sodium and potassium. Chlorides usually are more corrosive than the other salts especially in strongly agitated aerated solutions.

Neutral salt solutions can be handled successfully by copper alloys. Hence, these alloys are selected for heat exchanger and condenser equipment exposed to seawater.

While alkaline sodium salts such as silicate, phosphate, and carbonate attack copper alloys at low rates, alkaline cyanide is aggressive and attacks copper alloys fairly rapidly because of the formation of the soluble complex copper cyanide anion  $\text{Cu}(\text{CN})_2^{-2}$ .

## Oxidizing Salts

Copper metals should not be used with oxidizing saline solutions except those that are very dilute. Temperature and acidity adversely affect the rate of attack.

## Liquid Metal Embrittlement

Intergranular cracking may be caused by liquid metal embrittlement if the alloy is under tensile stress, either residual or applied. While mercury embrittles copper, the severity increases when alloyed with aluminum or zinc. This embrittlement occurs in both tension and fatigue and varies with grain size and strain rate. Other alloying elements such as lithium, sodium, bismuth, gallium, and indium also affect embrittlement.

## Organic Compounds

Copper and many of its alloys resist corrosive attack by most organic compounds such as amines, alkanolamines, esters, glycols, ethers, ketones, alcohols, aldehydes, naphtha, gasoline, and most organic solvents.

Corrosion rates of copper and copper alloys in alkanolamines and amines, while low, can be increased significantly if these compounds are contaminated with water, acids, alkalies, salts or combinations of these impurities, particularly at high temperatures.

## CORROSION TESTS

### Mercurous Nitrate Test

The mercurous nitrate test (ASTM B 154, Method for Mercurous Nitrate Test for Copper and Copper Alloys) probably has been the most important and widely used accelerated test for detecting the presence of residual (internal) stresses in tension, which might result in failure of individual parts in storage or in service due to SCC.

The test method is not intended for assemblies under applied stress. If used for that purpose, it shall be for information only and not a cause for rejection of the assembly, its component parts, or the original mill product.

Basically, the procedure involves degreasing the test specimen in a suitable alkaline degreasing solution or organic solvent. If necessary, the specimen shall be immersed totally in an aqueous solution of sulfuric acid (15 vol %) or nitric acid (40 vol %) until all oxides are removed completely from its surface or pickle in such solutions as may be prescribed in the specification for the material being tested. Remove the specimen from the pickling solution and rinse it immediately in running water. Drain the specimen free of excess water and totally immerse it at room temperature into the mercurous nitrate solution for 30 min and rinse again in running water. Visual examination for cracks then takes place.

Test specimens are mercury-contaminated and may not be recycled for remelting or machined into product.

Because of mercury's health hazard and problems associated with the disposal of the test specimens and the mercurous nitrate test solutions, a substitute test based on an ISO ammonia test (see following) was adopted after modification to ASTM format.

### Ammonia Test

In response to the request from the U.S. Coast Guard and ASME's Boiler and Pressure Vessel Code for a replacement test for ASTM B154, ASTM B05 Committee undertook the effort. ASTM B858 (Method for Determination of Susceptibility to Stress Corrosion Cracking in Copper Alloys Using an Ammonia Vapor Test) was created in 1995. This test method is a conversion of ISO 6957 [5], Ammonia Test for Stress Corrosion Resistance with additional input from DIN 50916 [6] Stress Corrosion Cracking Test Using Ammonia, Research work performed by Mattson et al. [7] validates the technical integrity of the test method.

The test method uses an ammonia atmosphere to simulate service conditions under which stress corrosion cracking may occur. This test method is suitable only for products fabricated from copper alloys that are known to be susceptible to stress corrosion cracking in ammonia vapor atmospheres. It is intended to create an environmental condition of reproducible severity, but it is well known that the critical step in the cracking mechanism is the development of an environment in the condensate film that occurs on the test specimen, which is rich in complex copper ions.

This test method is an accelerated test to determine if a copper alloy product in a specific stress condition will be susceptible to stress corrosion cracking when exposed to a particular atmosphere condition during service with the appropriate risk

**TABLE 2**—Guidance for choice of the pH-value of the test solution [7,8].

Corrosiveness of Atmosphere	pH-value Safety Requirement	
	Low	High
<b>Low</b>		
Indoor atmosphere under dry conditions	9.3	9.5
<b>Moderate</b>		
Indoor atmosphere with risk of formation of condensation	9.5	10.0
Outdoor atmosphere, temperate climate	9.5	10.0
<b>High</b>		
Atmosphere with ammoniacal pollution, for example in stables	10.0	10.5

level (Table 2). Changing the pH value of the solution producing the ammoniacal atmosphere can regulate severity.

This test method generally is intended to determine if a copper alloy product will crack because of internal stresses when subjected to the test, and is not intended for testing assemblies under applied stress. If used for this purpose, it shall be for information only and not a cause for rejection of the assembly, its component parts, or the original mill product.

Detailed solution composition, test media, and procedure are illustrated in ASTM B 858. The major deficiency of this test method is that the exposure time is 24 h versus 30 min in the mercurous nitrate solution.

Also, the question arises as to how a crack is defined. Cracks can be very short, and the rim of the base, particularly at high magnification (10× or more) is not absolutely smooth. Distinguishing between an irregularity or a mark from the drawing die and the beginnings of a true crack becomes very difficult. The decision reached by IEC [9] was that if the "defect," however small, had characteristics that suggested a crack, it was called a crack.

Because a crack can become filled or covered with corrosion products, an acid dip or buffing frequently is necessary to clean the surface in order to verify that a crack exists beneath.

### Stress Corrosion Cracking Testing in Mattsson's Solution

ASTM G 37 (Practice for Use of Mattsson's Solution of pH 7.2 to Evaluate the Stress Corrosion Cracking Susceptibility of Copper-Zinc Alloys) is an accelerated stress corrosion cracking test environment for brasses (copper-zinc alloys). The use of this test environment is not recommended for other copper alloys since the results may be erroneous, providing completely misleading rankings. This is particularly true of alloys containing aluminum or nickel as deliberate alloying additions.

This practice is intended primarily where the test objective is to determine the relative stress corrosion cracking susceptibility of different brasses under the same or different stress conditions or to determine the absolute degree of stress corrosion susceptibility, if any, of a particular brass or brass component under one or more specific stress conditions. The tensile stresses may be known or unknown, applied or residual.

The practice may be applied to wrought brass products or components, brass castings, brass weldments, and to all brasses. Strict environmental conditions are mandatory.

There are no restrictions as to surface preparation or finish nor are particular stress corrosion test specimen configurations or methods of applying the stress recommended.

The practice consists of completely and continuously immersing a stressed test specimen in an aqueous solution containing 0.05 g-atom/L of  $\text{Cu}^{++}$  and 1 g-mol/L of  $\text{NH}_4^+$  and of pH 7.2. The copper is added as  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  and the  $\text{NH}_4^+$  as mixture of  $\text{NH}_4\text{OH}$  and  $(\text{NH}_4)_2\text{SO}_4$ . The ratio of these latter two compounds is adjusted to give the desired pH. Exposure time, criterion of failure are variable and are not specifically recommended.

The test environment correlates the service ranking for different brasses in environments that cause SCC, which are due to the combined presence of traces of moisture and ammonia vapor.

Linkage of the SCC of brasses to environments containing corroders other than ammonia is unknown. These alternate environments include marine atmosphere (chloride), severe industrial atmosphere (predominantly sulfur dioxide), or superheated ammonia-free steam.

Metallographic examination is necessary to distinguish between true SCC and mechanically induced cracking. The most widely used SCC agent for copper and copper alloys is ammonia ( $\text{NH}_3$ ). The  $\text{NH}_4^+$  ion does not appear to cause cracking in a stable salt such as ammonium sulfate whereas cracking will occur in a salt that disassociates (such as ammonium carbonate) to form ammonia.

For SCC of copper alloys to occur, however, the presence of air, oxygen, or an oxidizing agent along with the presence of moisture are essential, because cracking may appear to be caused by the presence of a condensed moisture film.

Detailed solution composition, test media, and procedure are illustrated in ASTM G 37.

### Salt Spray Test

Metal coatings are intended in most cases as corrosion protection barriers. In accelerated tests, the time required for corrosion should be reduced preferably by exposing the specimens continuously to conditions, which in service would arise only intermittently. At the same time, the conditions used should cause no damage of types other than that which would arise under conditions of natural exposure.

Early salt spray tests intended to reflect the rapid testing of metal coatings in an atmosphere comparable to that encountered at seacoasts were unsatisfactory because of the multiple variables involved [10].

The current salt spray test, in which the plated specimen is exposed to a spray or fog of sodium chloride solution, is the most widely used accelerated corrosion test for coatings, and various procedures have acceptance tests in standard specifications in numerous countries. Over the years, the procedure has employed sodium chloride solutions of concentrations between 3 and 20 %, sometimes with the addition of hydrochloric acid or hydrogen peroxide. The salt spray test [ASTM B 117, Test Method of Salt Spray (Fog) Testing] has largely fallen into disrepute because of the recognition that its reproducibility and correlation with outdoor exposure were often poor. Cyclic salt spray testing as well as alternate electrolytes such as the "prohesion" test solution have been found to produce more realistic results.

Detailed apparatus, test specimens, position of specimens during exposure, salt solution, air supply, conditions in the salt spray chamber, continuity and period of exposure and cleaning of tested specimens are illustrated in ASTM B 117.

The procedures of ASTM B 117 and a modified version of ASTM G 44 were employed to study the behavior of solid brass fittings with that of coated and zinc-plated steel fittings. While G 44 was developed originally as an accelerated test for determining the chloride stress corrosion cracking resistance of aluminum and ferrous alloys, the concept of the alternate wet and dry cycling was considered relevant.

G 44 can be used for both stressed and unstressed specimens. Historically, it has been used for stress corrosion cracking testing, but often is used for other forms of corrosion, such as uniform, pitting, intergranular, and galvanic. It uses a 1-h cycle that includes a 10-min period in a aqueous solution of 3.5 % sodium chloride (NaCl) followed by a 50-min period out of the solution, during which the specimens are allowed to dry. This 1-h cycle is continued 24 h/day for the total number of days for the particular alloy being tested.

### Modified Salt Spray (Fog) Testing

The addition of acetic acid to the salt solution used in the salt spray tests was introduced first in 1945 and is currently Annex A1 of ASTM G 85 [Practice for Modified Salt Spray (Fog) Testing]. The acidified test is much more corrosive than the normal salt spray test and is capable of producing a pattern of attack similar to that developed in outdoor service for decorative chromium plate on steel or zinc. It is much slower than the copper-accelerated acetic acid-salt spray (CASS) test in ASTM B 368 [Method for Copper-Accelerated Acetic Acid-Salt Spray (Fog) Testing (CASS Test)], [11] which resembles it in effect.

An improved salt spray test employed a mixture of sodium chloride and acetic acid. A solution containing 50 g/L of sodium chloride in distilled water is adjusted to a pH value between 3.2 and 3.4 (electrometric) with glacial acetic acid. The solution is sprayed through a small aperture atomizing nozzle and mixed with a compressed air stream. The solution usually is heated to 95 to 100°F (35 to 38°C). Failure under this test is assessed visually, and results generally are obtained within 48 to 72 h, depending on the coating system.

Additional information on salt spray testing can be found in Section III of this manual. Detailed information on apparatus, test solution, air supply, test specimens, procedure, and evaluation of results are illustrated in ASTM B 368.

### CASS [13,14] and Corrodokote Tests

[ASTM B 380 (Method of Corrosion Testing of Decorative Electrodeposited Coatings by the Corrodokote Procedure)].

The CASS test and Corrodokote procedure are employed primarily for testing decorative chromium systems, with the CASS test also being useful for testing anodized aluminum. These tests were developed to give a more rapid indication of corrosion resistance and a better correlation with service performance. They have come into prominence as the most widely used modifications of the salt spray test because of their greater speed. Both tests employ cupric ion in the corrodant

**TABLE 3**—Compositions of CASS and Corrodokote electrolytes.

CASS			Corrodokote		
	g/L	Moles/L		g/L	Moles/L
NaCl	50.0	0.86	NH <sub>4</sub> Cl	20.0	0.4
CuCl <sub>2</sub> ·2H <sub>2</sub> O	0.26	0.0015	FeCl <sub>3</sub> ·6H <sub>2</sub> O	3.3	0.012
			Cu(NO <sub>3</sub> ) <sub>2</sub> ·3H <sub>2</sub> O	0.7	0.005
	pH 3.1 (Acetic Acid)			pH 2.4	
	Temperature 124°F (51.1°C)			Temperature 100°F (37.8°C)	

solution. In the CASS test, a solution containing copper chloride, sodium chloride, and acetic acid is sprayed into a chamber like that employed in the neutral salt spray.

Specimens are cleaned by rubbing with a paste of magnesium oxide and water so that they become free from water breaks after rinsing. Articles then are exposed to the salt fog for 16 to 18 h, then washed in warm running water to remove salt deposits before being dried and inspected. Compositions of these electrolytes are given in Table 3.

The tests fairly accurately reproduce the corrosion pattern produced in outdoor exposure, although there is sometimes excessive spreading of corrosion product.

One important ingredient of the Corrodokote slurry is the application of a paste-containing copper nitrate and ferric and ammonium chlorides in a clay-water matrix to the specimen surface, followed by exposure in a high-humidity non-condensing atmosphere.

It had been established previously that the Annex A1 of ASTM G 85, applied to copper-nickel-chromium plated zinc castings, would produce the type of failure experienced on such articles in service. However, the 16 to 20 h required to produce such failure were considered by many to be undesirably long.

Detailed information on apparatus, procedure, and valuation of results is illustrated in ASTM B 380.

### The Salt Droplet Test

In the normal salt spray test, direct spraying is avoided and a fine mist envelops the specimens. The salt droplet test by contrast involves spraying the salt solution directly onto the test specimens.

The specimens are sprayed manually with a spray bottle once daily five times a week with an artificial seawater, the droplet size and distribution being required in the specification along with exposure time.

This test has the advantage over the salt spray test in that it excludes the effect of specimen shape and suspension method. In addition, it is possible to directly determine and control the droplet size. Moreover, effects due to the size and shape of the test chamber are excluded.

### Hydrochloric Acid Spray Test

It was reported that the early salt spray tests (ASTM B 117) did not yield useful results when applied to chromium-plated brass specimens, while the results of a hydrochloric acid spray test were claimed to be in good agreement with the behavior of this material during weathering [10].

A solution of 1.7 to 2.0 % hydrochloric acid is sprayed for 5 h at room temperature with the test specimens left in the test chamber for an additional 10 h without spraying.

Corrosion defects developed are similar to those observed on weathering (blisters, pits, cracks, flaking).

### Testing in Potable Water [12]

The corrosion of metals and alloys in potable water varies greatly depending on the water's composition. Among the factors that are most influential are: oxygen content, pH, temporary hardness, chloride, sulfate, total dissolved solids (TDS), and conductivity. Temporary hardness is sometimes referred to as carbonate hardness and is removed easily by boiling.

Testing frequently must take place in a combination of field and laboratory tests, possibly using electrochemical methods.

### Testing in Seawater [13,14]

Reverse osmosis (RO) desalination technology has become established over a number of years for producing potable water from various natural waters, including seawater. While some RO systems utilize nonmetallic construction materials for the pressure vessels to contain the membrane cartridges, metallic materials are desired where higher pressures and/or enhanced fire resistance are required.

Corrosion resistance is essential to the operation of RO systems constructed of metallic materials. This is because localized corrosion cannot be tolerated at the critical pressure seals which separate feedwater, brine, and the product water (permeate). Secondly, there is little tolerance for the generation of corrosion products, which can affect RO membrane performance.

Because of the extensive use of copper-nickel in shipboard piping, the potential corrosivity of RO ultrapure water on these systems is considered important, ASTM G 4 (Standard Guide for Conducting Corrosion Coupon Tests in Field Application) covers in-plant testing of metals and alloys without regard to alloy type, family, or class and generates test results by exposure of the materials to filtered seawater (RO feed stock), an intermediate-pass brine by-product, and ultrapure product water.

ASTM G 78 is employed specifically for crevice corrosion testing of iron and nickel-base type alloys. If susceptible, these materials exhibit attack within the crevice area. Other "nonstainless-type" alloys such as copper-nickels often tend to suffer localized corrosion just outside the crevice rather than within it. Traditional crevice corrosion test are performed routinely on Cu-Ni alloys.

Overall, the two ASTM Standard Guides (G 04 and G 78) provide valuable information applicable to the design and interpretation of these natural water corrosion tests.

While seawater is a ubiquitous environment and quite similar in terms of chloride content and pH, the corrosivity is site-specific, and likely to be influenced by a myriad of other factors such as temperature, dissolved oxygen concentration, flow, degree of fouling, bacterial activity, and pollution. All of these factors often are interrelated. The test program followed the guidelines provided in ASTM G 52 (Standard Practice for Conducting Surface Seawater Exposure Tests on Metals and Alloys).

Enhanced corrosion in seawater has been shown to be associated with sulfide contamination. Copper-nickel alloys

also have been shown to be susceptible to impingement attack in unpolluted but more so in polluted seawater. The corrosion behavior of copper-nickel alloys C70600 and C71500, respectively, under aerated static, aerated stirred, and under impingement attack in sulfide polluted seawater has been studied by Cyclic Current Reversal Chronopotentiometry (CRC) [15].

The application of this technique for evaluating the long-term corrosion behavior of copper-nickel alloys in sulfide-polluted and unpolluted seawaters employed an intentional abrupt change of current between anodic and cathodic values to determine the feasibility of using the CRC method.

Electrochemical corrosion measurements were conducted in a modified corrosion testing cell where a combination of a circulating pump and a jet nozzle simulated jet-impingement attack as shown in Figure 4.

The principle of the CRC technique is illustrated in Figure 5.

### Statistical Analysis of Pitting Corrosion in Condenser Tubes [16]

Corrosion performance is often the key to proper selection of tube alloy for steam surface condensers, particularly for those cooled by seawater and brackish water. Contamination of the working fluid will lower the steam quality, thus decreasing overall power generation efficiency.

One or more types of corrosion can cause condenser tube failures in seawater service. These corrosion types include turbulence/velocity stimulated corrosion at inlet ends or at partial tube blockages, galvanic-induced corrosion caused by a mismatch between tube and tubesheet/waterbox alloys, and selective corrosion attack caused by microstructural differences resulting from improper welding or fabrication techniques.

Pitting-type corrosion frequently causes condenser tube failures. Prediction of a particular alloy's propensity for pitting corrosion can involve some special problems. Sometimes, pitting corrosion becomes a problem in real-life service conditions even when laboratory studies indicate pitting immunity.

A statistical technique known as extreme value analysis for assessing pitting corrosion in condenser tubing is broadly

FIG. 4—The electrochemical cell used to simulate impingement attack.

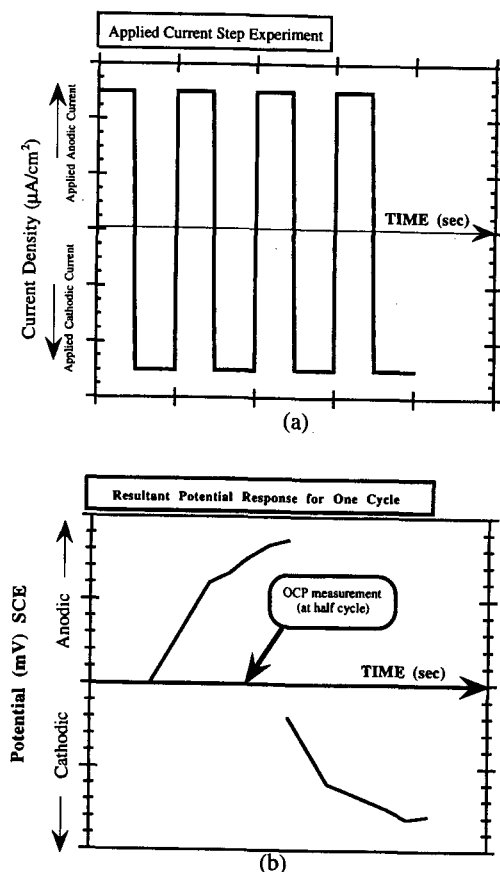

FIG. 5—A schematic diagram showing (a) the input applied current steps, and (b) the resultant potential response from a single current cycle for the cyclic current reversal chronopotentiometric experiment.

applicable to condition assessment, design problems, and applied research.

The normal probability relationship and its familiar bell-shaped curve represent a totality of data, all of the scores on a test, average soil resistivities, or all pit depths form the basis for the curve. Application of the cumulative probability function for an exponential extreme value distribution of a standard variate to practical situations requires statistically valid collection of data. A practical and consistent sample size must be selected and enough samples must be taken to attain reliable results.

The most important pit in piping systems where leakage is a concern is the deepest pit. This pit causes the first tubing wall penetration and the first leak. The time between the first tube failure and subsequent failures depends upon the statistical distribution of these pits and the rate at which corrosion continues.

### BNF Jet Test (Copper and Copper Alloy Deposits)

The apparatus consists of a separating funnel that is filled with the reagent solution to be used for attacking and gradually penetrating the plated coating. A rubber tube connects

the top of the funnel with a jet constructed to specified dimensions. A thermometer is immersed in the solution through a rubber plug at the top of the funnel.

The part to be tested is cleaned by wiping with magnesium oxide, rinsed, and wiped dry. It then is clamped in such a way that the surface is at an angle of  $45^\circ$  to the horizontal and  $1/4$  in. (6.35 mm) below the nozzle. When the tap is opened, a stopwatch is started simultaneously and the solution is permitted to flow until the coating is penetrated. The solution for testing copper or bronze deposits and multiple coatings of copper with nickel contains:

Ferric Chloride	300 g/L	(48 oz/gal)
Copper Sulfate	100 g/L	(16 oz/gal)

Calibration charts provided with the instrument give the relationship between penetrating time and plating thickness for various coatings.

The endpoint for copper on zinc-base or aluminum alloys is marked by the appearance of a black spot, and on nickel by a white spot. When testing copper on steel, the endpoint is detected as a black spot by placing with a pipette two drops of a 1 % antimony oxide solution in 50 % concentrated hydrochloric acid on the test area at intervals during the test. It is not required for bronze on steel.

When copper under nickel coatings are tested, the first endpoint (a copper spot) gives the thickness of nickel, after which the test is continued to the endpoint for copper as described previously.

### Cavitation Tests [17]

Cavitation is the dynamic phenomenon of repeated growth and collapse of bubbles in a liquid. It produces shock-like stresses in any solid in its vicinity. These stresses are not applied uniformly as the stress in a conventional test. Hence, no simple correlation exists between the cavitation erosion resistance of metals and alloys and any of their bulk mechanical properties.

Instead, the local modes of deformation in the metal play a major role in determining (1) the ability of the metal to absorb the impact energy, and (2) the mechanisms of subsequent material removal.

In one such test, the alloys studied were subjected to cavitation produced ultrasonically in distilled water by the piezoelectric device shown in Fig. 6. The damage produced then is evaluated metallographically and by microhardness measurements.

### Electrical Resistance Tests [18]

In a description of the methods summarizing soldering flux corrosivity, it was concluded that a quantitative method to replace the qualitative visual assessments was needed.

This short duration test method allows the corrosivity of liquid flux residues after wave soldering to be assessed and employed as a screening test prior to employment of the more time-consuming procedures.

The procedure to assess the corrosivity of flux residues towards a copper cable under controlled conditions of time, temperature, and humidity at an applied potential of 250 V

FIG. 6—Schematic representation of the vibratory cavitation probe.

DC involves measuring the changes in the strength of the copper cable.

The cable test piece consists of ten untwisted strands of bare copper wire mounted on a glass fiber-filled epoxy substrate with holes to allow flux residues to pass from the underside of the board to contaminate the cables on the topside during wave soldering. A DC power supply polarizes the test pieces anodically with respect to the copper conductor track on the laminate.

The environmental test chamber is maintained at 21°C with a relative humidity of 95 to 100 % using a reservoir of distilled or deionized water.

The strength is expressed in terms of all ten wires, even if some are broken, before the tensile strength of the cable is determined.

The increasing availability and reliability of digital equipment [19], both for performing analog-to-digital data conversion and for data reduction, analysis and digital filtering has become more widely used. The Fast Fourier Transform (FFT) techniques in performing digital faradaic impedance measurements (DFIM) on copper corrosion in acidic environments offers some advantages that make it appropriate for corrosion applications.

The measurement system consists of a calculator with a memory that controls data acquisition, data averaging, data storage, and data transmission to a large scale computer. These multifrequency impedance measurements are rapid and provide a rather complete description of the corrosion behavior in a very short time.

### Erosion-Corrosion Tests [20]

The repeated impact of liquid against a solid surface using an intermittent jet at sufficiently high speeds leads to a form of erosion. At impact, a liquid drop produces a very high compressive stress in the vicinity of the area of contact, and this is followed by outward, radial flow of liquid at very high speed which shears and erodes the surface. Erosion-corrosion in alpha-brass comprises two parts. The initial progressive plastic indentation is followed by the formation of an annulus where pits gradually form.

With the fastest jet of 218 m/s, an impression is made during the first impact. It consists of a flat circular region, approximately two thirds of the projected diameter of the jet, tapering at the outside up to the original surface of the specimen as indicated in Fig. 7.

Thereafter it remains constant throughout the remainder of the erosion process. The grains in the crater are marked clearly with many sliplines or extrusions, and during its deepening, the inner diameter of the depression does not change and the outer diameter alters only marginally. A central conical hole forms that is approximately twice the depth of the depression and this deepens with the number of impacts. However, the conical hole continues after the outer compressed region has reached its maximum depth; in fact,

FIG. 7—Development of impact impression in alpha brass during the no-mass-loss stage of erosion.

FIG. 8—Increase in depth of impression with number of impacts in alpha-brass. Water jet velocities (m/s): • is 218; ◇ is 161; \* is 110.

it deepens rapidly to about 20× the final depth of the compressed region. The central hole develops as the deepest part of the erosion crater.

In general, fluid velocity has two effects on corrosion: the mass transfer effect and the surface shear stress effect.

At low velocities, the rate of corrosion is completely or partially controlled by the rate of mass transfer. The effect of increasing velocity is to increase the surface concentration of the corrodent or to decrease the surface concentration of the corrosion product. Therefore, the rate of corrosion increases with increasing velocity. At higher velocities, the rate of mass transfer is much faster than the rate of charge transfer reaction at the metal surface. As a result, activation control of the overall corrosion process is observed. In this region, the corrosion rate is independent of fluid velocity and, in principle, also of the geometry involved. At still higher velocities, erosion-corrosion may occur if the surface shear stress is high enough to strip the protective film from the surface.

### Galvanic Corrosion Tests [21,22]

Components suffer most in areas where crevice-type conditions prevail. Thus, dealloyed nuts and bolts are common, with the influence of stagnant versus flowing fluid conditions playing a major role.

FIG. 9—Cross section of the metal-metal connection in a galvanic couple.

Dissimilar metal or galvanic couplings are created by firmly pressing the components together by means of an insulated bolt. Details of the arrangement are shown in Fig. 9.

In the specimens with the larger surface area, a hole is drilled. The galvanic couples and the uncoupled reference specimens are mounted in duplicate on wooden planks by means of an insulated bolt passing through the hole. PTFE washers insulate the test specimens from the plank and the bolt head.

Immediately before and after the exposure, the contact resistance between the metals in each galvanic couple is checked with an ohmmeter. Following exposure, initial cleaning of marine growth is done with a plastic scraper and nylon brush, then transferred to the laboratory for final cleaning.

Copper alloys are cleaned by immersion (15-s cycles) in 10 % sulfuric acid containing 4 % hydrogen peroxide at ambient temperature followed by scraping and brushing under flowing water several times until clean. After weighing, the specimens were studied under a stereomicroscope at 20×. For metallographic examination, etching was done in a 10 % solution of peroxodisulfate for 30 s at 20°C.

Additional information on galvanic corrosion tests may be found in Section IV of this manual.

The general effect of coupling dissimilar metals in a corrosive environment is that one metal will corrode more and the other less than would be expected from a consideration of the individual corrosion rates.

A popular practice has been to use a galvanic series in which the metals are arranged according to their potentials measured in a particular environment.

Several factors such as the formation of films on the surface, potential variation with time, and variation of polarizability of metals with environment can lead to drawbacks in the use of potential measurements and the galvanic series.

Connection of the multiple couples with the ammeter and voltmeter was made through a high-speed scanner with the galvanic cell and recirculating flow system as shown in Fig. 10.

Corrosion rates of uncoupled brass and bronze were determined both by potentiodynamic polarization and by weight loss and dezincification weight loss depth measurements.

### Oxidation Test [23]

Candidate container materials for high level nuclear wastes were evaluated as bare metal specimens exposed to an air atmosphere containing 12 % moisture in chambers maintained at temperatures of 150°C, 200°C, 250°C, and 300°C. Air was pumped through evaporators maintained at 50°C and then through the test chambers.

In the short-term testing with packing material, specimens were placed in the chambers in aluminum capsules packed with basalt-bentonite packing materials.

All specimens were polished through 600-grit abrasive before testing. Synthetic ground water used in these tests was prepared according to GR-4 specifications. The packing material used consisted of 75 % fine basalt and 25 % bentonite [24].

Penetration results were derived by calculating the weight loss per unit area from the weight change and dimensional measurements, then dividing by the density of the material.

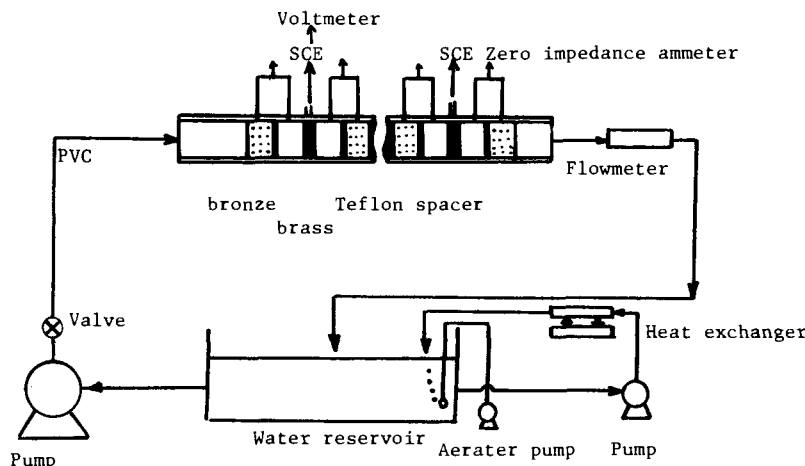

FIG. 10—Flow loop and galvanic cells.

### Potentiostatic Tests

Extensive cold water pitting corrosion was encountered in copper plumbing systems in the late 1940s and into the 1950s in the United Kingdom during the reconstruction of war-damaged housing [25]. The cause was circumstantially associated with carbon film residues resulting from the breakdown of drawing lubricants during bright annealing in the manufacturing process.

The BNF or the VTR tests for visual carbon have been recognized as being unsatisfactory because these simulated service tests are not reproducible between laboratories and take far too long. Also, they do not differentiate between acceptable and unacceptable tube in borderline cases.

This potentiostatic test method involves the monitoring and analysis of electrochemical current noise signals emitted by copper tubes immersed in a water that is linked to cold water pitting corrosion. It is claimed that the method provides a rapid and reliable means to distinguish between satisfactory and unsatisfactory tubes, especially in the borderline region.

Tubes with artificially controlled and produced levels of carbon films were produced by exposure to butane passing through the copper tubes when the traveling furnace heated them. Rates of flow of the gases and the temperature were varied to lay down different quantities of carbon film.

The synthetic pitting solution simulates a potable water composition known to cause cold water pitting [26]. It was prepared by bubbling carbon dioxide through a rapidly stirred suspension of calcium carbonate in distilled water to produce a solution of calcium hydrogen carbonate. Sodium sulfate (133 mg/L) and sodium chloride (49 mg/L) were dissolved in the solution and air then was bubbled through to adjust the pH to within the range of 7.0 to 7.5.

A pair of identical specimens was immersed in a container of synthetic pitting water, which was recirculated slowly and continuously throughout the test, generally 50 to 60 h, although some were extended to several hundred hours. This cell then was placed inside a grounded metallic drum, which acted as a Faraday cage. A zero resistance ammeter, programmable switch box, and high-resolution voltmeter were used to measure the current noise between these apparently identical specimens.

The current data were collected as a series of discrete time "windows" throughout the test. Typically, current-time windows were recorded once per hour during the early part of a test and at increasing intervals as the total test duration increased.

### Measuring the Corrosion of Metals in Soil [27,28]

Advances in technology have allowed measurements to be extended to field situations. Improved performance of electronic components, miniaturization of equipment, and development of portable computers and high impedance digital voltmeters are an important result of these advances.

Corrosion rate and galvanic current are the two measurement categories. Polarization measurements have shown that induced alternating current increases the corrosion rate of copper concentric neutrals compared to copper neutrals without alternating current. Galvanic current measurements provide valuable information on the behavior of galvanically coupled materials enabling the comparison of the corrosivity of soil environments.

The corrosiveness of a soil depends on a number of factors including resistivity, pH, aeration, moisture, and chemical contents. It is highly location-dependent and is influenced further by the presence of alternating current as well as galvanic couples with other buried metals.

Corrosion of copper shielding conforms to the mechanism of uniform corrosion. It is inherently resistant to differential aeration and only uniform corrosion of exposed areas occurs.

Copper is a relatively noble metal and is usually cathodic to other metals.

Losses in weight and maximum pit depths of copper and copper alloys are slight with the following exceptions: (1) in cinders; (2) in soils having high concentrations of sulfides; (3) in acid soils; and (4) in soils containing chlorides.

### Accelerated Corrosion Testing of Automotive Radiators

Automotive radiators have been made of copper and brass since the first water-cooled engines were produced. They

consist of an assembly of fluid-carrying tubes, which are joined either by heat conducting fins or by plates common to all tubes or groups of tubes or by corrugated conduction fins inserted between adjacent lines of tubes.

Radiators are composed of copper fins, tubes which until recently were soldered with a lead-tin solder. Currently, soldering with zinc and brazing are being studied.

Corrosion testing of radiators involves exposure of test pieces to a corrosive environment and determination of the corrosion effect arising during the exposure [29]. While field tests expose test pieces to the type of corrosive environment, where the material will be used, accelerated corrosion tests permits the corrosion rate to be increased through moderate changes such as temperature, the time of wetness or the contents of corrosion species. The changes, however, must not be so great that the corrosion mechanism or the corrosion products become significantly different from those in the service case. This increase of the corrosion rate can be expressed in terms of an acceleration factor.

Laboratory tests have many advantages over field and service tests as the exposure conditions can be controlled and the exposure time may be shortened.

The airside of the radiator, including the fins and the outside of the tubes, is exposed to the road climate. The atmospheric corrosion of radiators is influenced by the following parameters [28]: the time of wetness as corrosion of practical importance generally will take place only when the metal surface is covered with a moisture film; the types and contents of air pollutants from urban and industrial sources; splashing from the road.

Applicable test methods include [28]: Continuous Salt Spray Tests (ASTM B 117), Neutral Salt Spray Test (ASTM B 117), Acetic Acid Salt Spray Test, Copper-Accelerated Salt Spray Test (CASS) (ASTM B 368), Cyclic Salt Spray Tests, the Copper Development Association (CDA) Test, the Hitachi Salt Spray Test, Climate Tests, The Humidity Test, The International Electrotechnical Commission/International Organization for Standardization (IEC/ISO) Test and Mud Test.

Evaluation of corrosive effects arising during the exposure can be evaluated by visual inspection, metallographic examination of cross section under microscope with respect to pits, cracks, intergranular attack, and dezincification (of brass); and determination of loss in heat transmission capacity, a method which has direct relation to the function of automotive radiators.

An intensive study conducted for the Copper Development Association and reported by Beal [30] reported on two new soldered cup specimens that had been developed to evaluate blooming corrosion effects of solder and soldering parameters using ASTM D 1384 (Corrosion Tests for Engine Coolants in Glassware). Critical examination of the original test revealed wide variations in results in appearance and weight loss so that differences in solder alloy corrosion were difficult to interpret.

A new stressed solder specimen was shown to be sensitive to coolant conditions with experimental work confirming the validity of the new specimens by identifying the influences of the chosen test variables. In descending order of importance, antifreeze formula, flux, solder composition, and processing parameters were found to affect blooming corrosion.

## Microbiologically Influenced Corrosion Testing

Microbiologically influenced corrosion (MIC) is used to designate corrosion resulting from the presence and activities of microorganisms within biofilms on a material surface. Such microorganisms can accelerate and control corrosion reactions by several mechanisms: formation of differential or concentration cells, formation of metabolites, such as sulfides and organic and inorganic acids; metal oxidation and reduction, and deactivation of corrosion inhibitors.

Iron-oxidizing, sulfur-oxidizing, iron-reducing, sulfate-reducing, acid-producing, slime-producing, ammonia producing, and hydrogen-producing bacteria have been implicated in the corrosion of metals and alloys. Sulfate-reducing bacteria (SRB) are found commonly to be responsible for MIC in anaerobic environments through the production of  $H_2S$ . Metal-depositing bacteria, especially iron-oxidizing genera, form dense deposits of cells and metal ions, creating oxygen concentration cells and under-deposit corrosion. Acidic bacterial exopolymers can bind metal ions from the aqueous phase, increasing corrosion rates by providing an additional cathodic reaction [30].

While microorganisms attach to all engineering materials in contact with natural waters and colonize films to produce biofilms, these films are varied in composition, but usually include bacteria, algae, and fungi, in addition to exopolymeric material that provides attachment and structural integrity. A large fraction of the biofilm is adsorbed and entraps materials such as solutes, heavy metals, and inorganic particulates in addition to cellular constituents. Cells with biofilms grow, reproduce, and form colonies that are physical anomalies on a metal surface; local anodes and cathodes and differential aeration cells result as illustrated in Fig. 11.

Under aerobic conditions, areas under respiring colonies can become anodic and surrounding areas cathodic. A thick biofilm can prevent diffusion of oxygen to cathodic sites and diffusion of aggressive anions, such as chlorides to anodic sites. Outward diffusion of metabolites and corrosion products also is impeded. If areas within the biofilm become anaerobic, the cathodic mechanism can change to reduction of water or microbiologically produced  $H_2S$ .

Examination of a corrosion system experiencing MIC should include (1) metal composition; (2) macroscopic examination, (a) visible fouling, (b) localized corrosion, (1) forms, (2) location, (3) material within pits, and (c) corrosion products. Factors of interest in evaluating the environment of a corroding system include the following: (1) presence, absence, cycles of light, (2) aqueous medium, (a) temperature,

FIG. 11—Differential aeration cell resulting from microbial colony on metal surface.

(b) salinity, (c) dissolved oxygen, (d) water chemistries, (e) water microbiology, (f) direction, and velocity of flow, (3) system relationship to upstream industry, and (4) operating history of corroding system.

Additional laboratory and field procedures for evaluating microbiologically influenced corrosion resulting particularly from the sulfiding action of consortia are reported in Ref 31–34.

### Refractories in Copper Smelting [35]

Because of the high temperature corrosion resistance and thermal stability exhibited by magnesium-chromium oxide refractories in copper smelting, converting and fire refining furnaces, little research has been conducted on other refractory families. However, the concern for hexavalent chromium ( $\text{Cr}^{+6}$ ) as a potentially hazardous waste in spent refractories from copper production furnaces has prompted the recognition that a more environmentally acceptable material is needed for the copper industry.

Various chrome-free refractory materials have been studied by dip testing of these refractories in ferrous silicate and calcium ferrite slags typical of those used in copper production furnaces. More recently, a rotating sample test procedure has been employed.

A refractory sample exposed to a temperature of  $1300^{\circ}\text{C}$  was mounted on a stainless steel shaft with a section of stainless steel tubing placed around the shaft which in turn served as a high temperature “sacrificial anode.” Corrosion tests were conducted at rotation speeds of 60 and 120 rpm, along with a few under-static conditions.

The slag used for testing was a fayalite-based slag (70 %  $\text{FeO}$ ), produced using precipitated silica, reagent-grade hematite, and iron powders. The test durations were two and four hours.

However, the relatively mediocre corrosion resistance of the magnesia-based refractories suggests that its high temperature bonding strength is not sufficient, and that application of this material to copper smelting systems would be effective only under relatively static conditions, such as the bottom of stationary anode furnaces.

# Nickel (and Alloys)

*Edward L. Hibner<sup>1</sup>*

THIS CHAPTER HIGHLIGHTS the corrosion resistance of nickel and its alloys and identifies relevant ASTM standards associated with their evaluation. The test technique selected ultimately will depend upon the specific alloy involved, the type of corrosion in question, or the end application, or a combination thereof. The following discussions will deal primarily with aqueous corrosion and the nickel-base (greater than about 30 % nickel) alloys designed for aqueous corrosion resistance. High-temperature gaseous corrosion will be addressed in other sections.

For assistance in understanding corrosion terminology, please refer to ASTM G 15, Terminology Relating to Corrosion and Corrosion Testing.

## INHERENT CORROSION RESISTANCE OF NICKEL AND NICKEL ALLOYS

Nickel and its alloys spontaneously form passive oxide films upon exposure to the atmosphere at ambient temperature. This film helps to provide very useful corrosion resistance in a variety of environments. The protective nature of this film can be enhanced by specific alloying additions.

### Effects of Alloying (Composition) and Metallurgical Factors

Commercially pure nickel, e.g., alloy 200 (UNS N02200), is resistant to general corrosion and stress-corrosion cracking (SCC) in strong caustic solutions and in many mildly reducing environments. Nickel can be alloyed with high percentages of many elements for enhanced corrosion resistance while maintaining a stable austenitic structure.

The first practical alloying of nickel for enhanced corrosion resistance was the addition of copper to make the 70Ni-30Cu alloy commonly known as alloy 400 (UNS N04400). This provided improved general corrosion resistance in reducing environments. The addition of chromium to improve corrosion resistance in oxidizing environments such as nitric acid is demonstrated by the development of many Ni-Fe-Cr or Ni-Cr-Fe alloys. The presence of iron in these alloys is usually for economy, not necessarily corrosion resistance. Molybdenum improves corrosion resistance to strongly reducing environments such as hot concentrated hydrochloric acid, e.g. alloy B-2 (UNS N10665).

Molybdenum, and sometimes tungsten, are also added to Ni-Cr-Fe alloys for improved localized corrosion (pitting and crevice corrosion) resistance. An example is alloy C-276 (UNS N10276), which contains about 57Ni-15.5Cr-15.5Mo-4W-5Fe and is one of the most pit-resistant nickel-base alloys available.

Though these alloying additions are quite effective in improving resistance to a particular environment, the resulting alloy can be susceptible to other forms of corrosion such as intergranular attack (IGA). Heat treatment in the 650°C to 870°C (1200° to 1600°F) range, such as in the heat affected zone of a weld joint, can cause intergranular sensitization. This sensitization, resulting from grain boundary chromium depletion, makes the grain boundary area susceptible to IGA by highly oxidizing solutions. Additions of titanium or niobium are used for stabilization against the intergranular sensitization. A stabilizing anneal at about 940°C (1724°F) is used for these stabilized alloys. Unstabilized materials like alloy 600 (UNS N06600) are annealed at various temperatures required to achieve desired properties, but specific use of the 940°C (1724°F) temperature is ineffective without the required titanium or niobium additions.

Certain nickel alloys are age-hardened by additions of aluminum, titanium, and/or niobium in amounts greater than that used for stabilization against IGA (see above). The aging mechanism can adversely affect the SCC resistance of these alloys, making them more susceptible to chloride and caustic cracking than their nonagehardenable counterparts. Nevertheless, materials like the age-hardened alloy K-500 (UNS N05500) have performed successfully in many seawater applications even though it is susceptible to SCC in the very severe boiling magnesium chloride test, ASTM G 36 (Recommended Practice for Performing Stress-Corrosion Cracking Tests in Boiling Magnesium Chloride Solution).

### Microstructural Effects

The most common microstructural effect on the corrosion resistance of nickel alloys is intergranular sensitization, as previously mentioned. This is the result of chromium carbide precipitation in many Ni-Fe-Cr alloys but can result from intermetallic Mu-phase precipitation in low-carbon highly alloyed materials such as alloy C-276 (UNS N10276). Several standard IGA tests (discussed in the Intergranular Corrosion section) are available for determining (1) if stabilized alloys have been properly annealed to prevent subsequent sensitization, and (2) if nonstabilized alloys are free from significant sensitization as produced.

<sup>1</sup>Senior Metallurgist, Code Manager, and Specification Coordinator for Special Metals Corporation, Inc., Huntington, WV 25705.

Nickel-base alloys with at least about 30 % nickel are very resistant to SCC in chloride and caustic solutions. Increasing nickel content usually provides increasing SCC resistance. Many different specimen designs are used to provide the stress necessary for evaluating the SCC resistance of a material (see SCC section).

Grain orientation has little effect on corrosion resistance in nickel-base alloys, though preferential end grain or edge attack can occur due to attack of nonmetallic inclusions, which are elongated in the rolling direction. In general, there is little difference in the corrosion resistance of the various available mill product forms when in the same final condition. Heavily cold-worked or age-hardened material, with high yield strength, will be less resistant to SCC than annealed material. Standard tests will apply to all products such as sheet, plate, tubing, and rod.

## SENSITIVITY TO PARTICULAR ENVIRONMENTAL FACTORS

### Aqueous Solution Variables

Minor changes in acidity or alkalinity can have a significant effect on pitting and crevice corrosion resistance. High chloride concentrations may be tolerated at a neutral pH but cause severe pitting as the solution becomes more acidic. Acid-chloride solutions are the most common cause of localized corrosion (pitting and crevice corrosion) failures of nickel alloys. Though nickel-base alloys with greater than about 30 % nickel normally resist chloride SCC, exposure to concentrated caustic at elevated temperatures, 260° to 350°C (500° to 662°F), can result in intergranular SCC. Ni-Cr-Fe alloys 600 (UNS N06600) and age-hardened alloys X-750 (UNS N07750) and 718 (UNS N07718) have also failed by SCC in high-purity water at these temperatures. Alloy 690 (UNS N06690), with a higher chromium content, is resistant to this failure mechanism.

### Liquid Metals and Hydrogen

Ni-Cu alloy 400 (UNS N04400) is susceptible to intergranular cracking in mercury at ambient temperature or in molten bismuth. Other than this, nickel alloys are normally resistant to liquid metals at temperatures up to about 540°C (1000°F). Nickel alloys are susceptible to hydrogen embrittlement but are much more resistant than steels or titanium alloys. Of the nickel alloys, the age-hardened materials are the most susceptible. Hydrogen can diffuse into nickel alloys from low-temperature gaseous environments or in aqueous solutions under cathodic charging. The degree of damage is determined by measurement of mechanical properties or alloy hydrogen content, or both [1].

## METHODS OF EVALUATION OF CORROSION DAMAGE

### Gravimetric

The most common method of evaluating uniform corrosion damage is by measurement of mass loss per unit area and

time. These parameters, along with material density, are used to calculate a uniform rate of corrosion penetration in mm/y or other similar units. This procedure is described in detail in ASTM G 31, Recommended Practice for Laboratory Immersion Corrosion Testing of Metals. In addition to uniform corrosion, many intergranular corrosion tests rely upon mass loss measurements to calculate a corrosion rate. Though an overall rate is used, most of the mass loss occurs at grain boundaries. This is especially true for sensitized specimens that exhibit a high corrosion rate. Thus, an accurate measure of grain boundary attack is obtained from the overall mass loss measurement. In extreme cases, accelerated mass loss can be the result of actual grain removal (grain dropping) due to intergranular attack.

While mass loss may be used to quantify the overall corrosion damage due to pitting, corrosion rates based on mass loss should not be used to predict the rate of pitting.

### Depth of Attack

Depth of attack measurements are most often used to quantify the extent of localized corrosion due to pitting or crevice attack. ASTM G 46, Recommended Practice for Examination and Evaluation of Pitting Corrosion, describes various techniques for pit depth measurement and pit characterization. Pit depths are most often measured with a pointed needle depth gage or micrometer or by use of a focusing microscope with a calibrated eyepiece. In commercially pure nickel, alloy 200 (UNS N02200), and nickel alloys without chromium, such as alloy 400 (UNS N04400), pits are usually broad and shallow. In some aggressive high-chloride, low-pH media, nickel alloys containing chromium, such as alloy 800 (UNS N08800), may exhibit deep undercut pits with relatively small openings at the surface. Pit depth, which causes component perforation, is the most important measurement, but pit density is also measured. ASTM G 46 provides detailed procedures for pit depth and density measurement. In some cases, where pit density is high, a change in mechanical properties may result.

Depth of attack measurements are often used to characterize the severity of SCC. Sectioning of the sample is usually necessary to obtain an accurate measurement. Also, in some IGA tests the presence of cracking after an exposed specimen is bent indicates susceptibility to IGA.

## TESTS FOR SPECIFIC CORROSION TYPES

### Uniform Corrosion Testing

As with many other materials, nickel and nickel alloys can be evaluated for uniform corrosion resistance according to guidelines in ASTM G 31. Due to the active/passive nature of many nickel alloys, the length of the test exposure can affect test results and reproducibility. In a short test lasting only a few hours, duplicate specimens can provide very different corrosion rates in some environments, like sulfuric acid. It is not unusual for one sample to show active behavior and another passive behavior over short time periods. Thus, extended test periods of about 100–200 h often provide more accurate results than shorter tests. The following

**TABLE 1**—General corrosion rates for alloy 725 (UNS N07725), 0.125 in. (0.32 cm) sheet testing in acid environments for varied exposure times as specified in Ref 2.

Environment	Temp., °C	Corrosion Rate, mm/y		
		0–96 h	96–192 h	0–192 h
0.2 % HCl	Boiling	<0.01	<0.01	<0.01
1.0 % HCl	Boiling	0.12	0.05	0.26
1.0 % HCl	90	0.64	0.05	0.05
5.0 % HCl	70	4.92	5.16	4.31
5.0 % HCl	50	1.34	1.33	1.14
5.0 % HCl	30	0.24	0.17	0.18
10.0 % H <sub>2</sub> SO <sub>4</sub>	Boiling	0.25	0.55	0.12
60.0 % H <sub>2</sub> SO <sub>4</sub>	70	0.65	0.65	0.41
60.0 % H <sub>2</sub> SO <sub>4</sub>	50	0.59	0.02	0.74
60.0 % H <sub>2</sub> SO <sub>4</sub>	30	0.04	0.03	0.18
95.0 % H <sub>2</sub> SO <sub>4</sub>	70	1.68	1.71	1.07
95.0 % H <sub>2</sub> SO <sub>4</sub>	50	1.84	1.27	0.58
95.0 % H <sub>2</sub> SO <sub>4</sub>	30	0.28	0.34	0.33
85.0 % H <sub>3</sub> PO <sub>4</sub>	Boiling	0.78	0.79	1.47
85.0 % H <sub>3</sub> PO <sub>4</sub>	90	0.01	0.01	0.01

NOTES: Unpublished data developed by Inco Alloys International, Inc., by the test method specified in Ref 2.

equation gives a suggested test duration when expected corrosion rates are low to moderate (see ASTM G 31):

$$\text{Hours} = \frac{2000}{(\text{anticipated corrosion rate in mpy})}$$

(This method of estimating test duration is useful only as an aid in deciding, after a test has been made, whether or not it is desirable to repeat the test for a longer period. The most common testing periods are 48–168 h.)

The test exposure intervals specified in the Materials Technology Institute Manual No. 3 [2], for instance, are 96 and 192 h for immersion testing. Examples of corrosion rates determined for these time intervals are shown in Table 1. Even with these relatively long test periods, some variation in test results can be seen, especially in sulfuric acid.

Because variations in corrosion rates can result from different surface finishes, greater reproducibility can often be obtained if a common surface is used on all specimens. A common surface produced by wet grinding with 120 grit abrasive, e.g., SiC, or pickling will provide a better estimate of the inherent corrosion resistance of a material, though it is sometimes desired to evaluate a particular commercial surface.

### Intergranular Corrosion

Intergranular precipitation can occur in nickel alloys when exposed to temperatures in the range of 649–871°C (1200–1600°F) during some fabrication and welding operations. The resulting depletion of chromium or segregation of other elements can cause the material to become susceptible to IGA in highly oxidizing environments, SCC under certain conditions, and possibly accelerated localized corrosion.

Thus standard accelerated intergranular corrosion tests have been developed as a quality control test. They are designed to:

1. Determine if a stabilized alloy, such as alloy 825 (UNS N08825), has received a proper stabilizing anneal. In this case a 677°C (1250°F)/1 h sensitization heat treatment

will be applied to the mill annealed material prior to testing to determine if the material is resistant to intergranular sensitization caused by precipitation of chromium carbide at 677°C (1250°F).

2. Determine if an unstabilized material, such as alloy C-276 (UNS N10276), has received an adequate solution anneal that has effectively removed all Mu or other intergranular phases that may have been precipitated during earlier processing. A sensitization heat treatment is not applied in this case because the material is not stable after prolonged exposures at intermediate temperatures (though short exposures during welding can be tolerated). ASTM G 28 (Method for Detecting Susceptibility to Intergranular Attack in Wrought Nickel-Rich, Chromium-Bearing Alloys, Practice A) is an example of a test that can be used for either of the above alloys, though ASTM A 262 (Practices for Detecting Susceptibility to Intergranular Attack in Austenitic Stainless Steels, Practice C) is usually specified for alloy 825 (UNS N08825).

The most common intergranular corrosion tests are outlined in ASTM A 262 and G 28. Most of these test solutions are strong oxidizing acids or acids with added oxidizers that maintain the specimen at a stable electrochemical potential where accelerated intergranular corrosion will occur in a susceptible material. The test duration is typically 24–120 h, depending on the alloy. Recommended exposure periods for various nickel-base alloys are listed in ASTM G 28 but not in ASTM A 262. Though only austenitic stainless steels are listed in ASTM A 262, some of the test methods are used for nickel-base alloys. It is important to note that ASTM A 262, Practice A, the oxalic acid etch test, is recommended for stainless steels. It is not normally used for nickel-base alloys.

The corrosion rates determined in the various tests will vary greatly depending on the alloy being evaluated. Acceptance corrosion rates are not specified in the ASTM test procedures. They must be agreed upon by the supplier and user. Examples of typical acceptable corrosion rates determined for various alloys in ASTM G 28, Practice A are listed in Table 2 [3]. Due to test and material variations, the maximum acceptable rate will be somewhat higher than this nominal number.

In this oxidizing environment the corrosion rate of unsensitized, properly annealed material is determined primarily by the chromium content. Thus, the base rate for alloy C-276 (UNS N10276) with lower chromium content, for example, is higher than the other alloys. The relative suitability of an alloy for a particular application is sometimes mistakenly related to the annealed base corrosion rate in the IGA test. This concept is an error. The test is designed to flag out improperly produced material exhibiting a rate above the normal base corrosion rate (Table 2), not a rate higher than some other alloy.

**TABLE 2**—Typical corrosion rates for annealed nickel alloys in ASTM G 28, Practice A.

Alloy	Corrosion Rate, mm/y
C-276 (UNS N10276)	6.35
622 (UNS N06022)	1.02
C-22 (UNS N06022)	0.89
316 (UNS S31600)	0.51
625 (UNS N06625)	0.36

### Localized Corrosion (Pitting and Crevice Corrosion)

Factors affecting localized corrosion of nickel-base alloys are chloride concentration, pH, temperature, crevice geometry (depth and tightness), and crevice former material (non-metallic or similar or dissimilar metal, metal surface condition, area ratio of exposed to shielded metal). A wide range of results can be obtained as these factors are varied.

ASTM G 48, Test Method for Pitting and Crevice Corrosion Resistance of Stainless Steels and Related Alloys by the Use of Ferric Chloride Solution, covers procedures for determination of the resistance of stainless steels and related alloys to pitting and crevice corrosion when exposed to an oxidizing chloride environment (6 % FeCl<sub>3</sub>). Four procedures are identified as Methods A, B, C, and D.

- Method A—Ferric chloride pitting test.
- Method B—Ferric chloride crevice test.
- Method C—Critical pitting temperature test.
- Method D—Critical crevice temperature test.

Method A is designed to determine the relative pitting resistance of stainless steel and nickel-base, chromium bearing alloys, whereas Method B can be used for determining both the pitting and the crevice corrosion resistance of these alloys. Methods C and D allow for a ranking of alloys by minimum (critical) temperature to cause initiation of pitting and crevice corrosion, respectively, of stainless steels, nickel-alloy, chrome bearing alloys in a standard ferric chloride solution (acidified 6 % FeCl<sub>3</sub>). These tests may be used to determine the effect of alloying additives, heat treatment, and surface finishes on pitting and crevice corrosion resistance. Though the critical temperature cannot be extrapolated to other environments, the relative order of resistance of various materials to pitting or crevice corrosion in other acid chloride environments should be similar. These ferric chloride test procedures are not capable of producing pitting attack in nickel alloys containing more than about 13 % molybdenum, though crevice corrosion can usually be produced at elevated temperatures [up to about 85°C (185°F)].

ASTM G 78, Guide for Crevice Corrosion Testing of Iron Base and Nickel Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environment, describes the use of multiple crevice assemblies and other devices applicable to nickel alloy testing in chloride environments. These procedures can be used to identify conditions most likely to result in crevice corrosion and provide a basis for assessing the relative resistance of various alloys to crevice corrosion under certain specified conditions.

Localized corrosion propagation rates are highly variable and not normally measured unless the time to initiation of attack is determined visually or by electrochemical monitoring. Pits in nickel alloys such as alloy 400 (UNS N04400), which are usually of the broad and shallow variety, tend to propagate much more slowly than the narrow undercut types found in chromium-bearing nickel alloys. Electrochemical tests are useful to predict pit initiation, while immersion tests evaluate initiation and also provide some indication of the possibility of severe pit propagation.

Weld metal is usually attacked by localized corrosion to a greater extent than the base metal because of the dendritic

structure and segregation present in weld metal. All weld metal or combination weld metal/base metal samples can be evaluated in pitting or crevice corrosion tests. For some crevice corrosion tests, however, the weld must be machined flat prior to attaching the crevice assembly (designed for a flat surface). It should be recognized that significant weld metal removal may cause inaccurate results since final surface weld passes may exhibit different corrosion resistance than initial weld passes exposed by machining. Alternatively, a surface contouring type crevice-forming device or any applied coating such as epoxy (now described in ASTM G 78) may be employed.

### Stress Corrosion Cracking

SCC testing of nickel alloys is conducted using the same specimen designs and test solutions as for many other alloy systems. One of the most commonly used specimen designs is the simple U-bend specimen; see ASTM G 30, Practice for Making and Using U-Bend Stress Corrosion Test Specimens. This is a severe screening test used to determine if a material is susceptible to SCC in a specific environment. For determination of critical stress levels required to produce SCC, bent beam (ASTM G 39, Practice for Preparation and Use of Bent-Beam Stress-Corrosion Specimens) or C-ring (ASTM G 38, Practices for Making and Using C-Ring Stress Corrosion Cracking Test Specimen) specimen designs may be used.

One notable caution is in the use of precracked wedge open loaded (WOL) specimens. Nickel alloys are usually so ductile that a very thick specimen is required to obtain a plane strain stress state at the tip of the precrack. The minimum thickness required can be calculated from the following equation

$$B \geq 2.5(KIc/\sigma_{ys})^2$$

where B = thickness and  $\sigma_{ys}$  = yield strength of the material [4].

Nickel alloys also do not show a strong directional effect as in aluminum alloys. SCC resistance of most nickel alloys is nearly the same in the short transverse direction as in the longitudinal direction.

Because of their very good resistance to chloride SCC, nickel alloys are often tested in the severe boiling magnesium chloride test, ASTM G 36, rather than the alternate immersion sodium chloride test, ASTM G 44, Practice for Alternate Immersion Stress Corrosion Testing in 3.5 % Sodium Chloride Solution, or the recently developed ASTM G 123, Test Method for Evaluating Stress-Corrosion Cracking of Stainless Alloys with Different Nickel Content in a Boiling Acidified Sodium Chloride Solution acidified sodium chloride test. These sodium chloride tests, which cause cracking of stainless steels, usually do not cause failure of nickel alloys containing about 30 % or more nickel.

Though nickel alloys are more resistant to chloride and caustic SCC than stainless steels, they are equally susceptible to cracking in polythionic acid (PTA) when in the sensitized condition. See ASTM G 35, Practice for Determining the Susceptibility of Stainless Steels and Related Nickel-Chromium-Iron Alloys to Stress Corrosion Cracking in Polythionic Acids, for test details.

### Electrochemical Testing

Nickel-base alloys respond well to most electrochemical test techniques and show active-passive behavior in many environments. Due to their rapid repassivation, however, the results obtained with potentiodynamic techniques can sometimes be affected by scan rate and immersion time prior to starting the test [5,6]. Electrochemical techniques are useful for investigating localized corrosion resistance, ASTM G 61, Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-Based Alloys, and general corrosion resistance, ASTM G 59, Practice for Conducting Potentiodynamic Polarization Resistance Measurements of nickel alloys. Electrochemical impedance measurement techniques have not been extensively applied to nickel alloys.

### COMPARISON OF CORROSION BEHAVIOR

The corrosion resistance of nickel alloys can be either very good or very poor depending on the alloy/environment combination. Each of the various alloys, by chance or design, has very good resistance to certain environments, while exposure to other environments may be highly detrimental (i.e., without failure). Alloying additions that increase resistance to one form of corrosion may decrease resistance to another form of corrosion. The design of alloys for various applications was discussed in the preceding section on Nature of Nickel and Nickel Alloys.

The limiting variable for usable corrosion resistance of nickel alloys, like many other alloys, is often temperature. Many nickel alloys, for instance, have good resistance to ambient temperature sulfuric or hydrochloric acid at all concentrations. As the temperature increases, the number of alloys withstanding severe attack diminishes rapidly. Other than certain limitations such as this, most aqueous

corrosion applications can be handled by nickel or some nickel alloy.

New nickel-base alloys such as alloy G-30 (N06030), alloy 59 (N06059), and alloy 686 (N06686) have been developed with higher levels of chromium or molybdenum, or both, for increased resistance to localized or general corrosion in severe environments. These materials are being included in test procedures such as ASTM G 28.

Cast equivalents are available for many nickel-base alloys. Some test procedures, such as ASTM G 28, do not apply to cast materials. In most cases, castings should be expected to have lower corrosion resistance than wrought materials of similar composition. Also, selective phase attack may be confused with other corrosion mechanisms such as pitting.

# Stainless Steels

*James W. Martin<sup>1</sup>*

## NATURE OF STAINLESS STEELS

### Natural Protective Film

STAINLESS STEELS ARE iron-based alloys containing at least 10 % chromium [1]. Although iron may corrode in an ordinary rural environment, the chromium gives stainless steel its ability to form a protective or passive film that resists corrosion. It is this ability to resist the formation of rust that led to the name "stainless steel." Generally, it is thought that the passive film consists of hydrated chromium oxide. Other alloy elements such as iron, molybdenum, silicon, etc., have also been detected in the passive film. The passive film also tends to incorporate anions and cations that may be present in the environment in which the film forms. Stainless steels are aut passivating in the sense that the passive film is formed spontaneously upon exposure to air, moisture, or an oxidizing acid. When stainless steel is exposed to such an environment, its corrosion resistance approaches that of noble metals; however, when exposed to an environment that damages, reduces, or inhibits the formation of the passive film, corrosion resistance of the alloy is compromised.

The presence of exogenous surface contamination, including dirt, grease, or free iron from contact with steel tooling, may interfere with formation of a continuous passive film. The cleaning of these contaminants from stainless steel will facilitate spontaneous passivation by allowing uniform access of oxygen to the steel surface. The passive film may be augmented by chemical treatment that provides an oxidizing environment for the stainless steel surface.

Methods for cleaning and passivating stainless steels are presented in ASTM A 380, Practice for Cleaning, Descaling, and Passivation of Stainless Steel Parts, Equipment, and Systems and ASTM A 967, Specification for Chemical Passivation Treatments for Stainless Steel Parts.

### Effects of Alloying

Chromium is the main element that provides stainless steel with its corrosion resistance. However, several other

elements can be added to stainless steel to enhance corrosion resistance under various conditions.

### Aluminum

Additions of aluminum enhance high temperature oxidation resistance. Aside from corrosion performance, this element is added to some precipitation-hardening stainless steels to promote age hardening (e.g., S13800). In contrast, a small amount of aluminum is present in Type 405 stainless (S40500) to prevent hardening by stabilizing the ferrite phase.

### Niobium (Columbium)

Niobium is used to combine with carbon and nitrogen, thus reducing the formation of chromium carbonitrides. This reduces the possibility of intergranular corrosion when stainless is welded or heat-treated. Niobium also contributes to age hardening in some precipitation-hardening stainless grades.

### Copper

In austenitic stainless steels, copper can be added to provide corrosion resistance to sulfuric acid. Copper also is used as an age-hardening agent in precipitation-hardenable stainless steels, such as 15Cr-5Ni stainless (S15500). However, copper can be detrimental to stress-corrosion cracking resistance in some ferritic alloys.

### Nickel

Nickel is the primary element that stabilizes the austenite phase and provides stainless steels with resistance to corrosion in reducing environments.

### Nitrogen

Provides increased resistance to pitting and crevice corrosion, especially in the presence of molybdenum. Nitrogen is a strong austenite-stabilizing element.

### Manganese

Stabilizes austenite and can be used to replace nickel in some stainless steels. Manganese also increases nitrogen solubility.

<sup>1</sup>Specialist, Stainless Alloy R&D, Carpenter Specialty Alloys, Reading PA 19612. Original text authored by Mark J. Johnson—Research associate, Allegheny Ludlum Corp., Brackenridge, PA 15014.

## Molybdenum

Pitting and crevice corrosion resistance as well as resistance to reducing environments are enhanced by the addition of molybdenum.

## Silicon

In some alloys silicon is added for high temperature oxidation resistance. Silicon has also been shown to provide resistance to stress corrosion cracking, as well as resistance to corrosion by oxidizing acids.

## Titanium

Titanium can serve a similar purpose as niobium relative to carbonitride stabilization. Titanium is added to some precipitation-hardening stainless steels (e.g., S46500) as an age-hardening agent.

## Microstructure

There are more than 170 different basic compositions of stainless steel [2]. They may be divided into five families: (1) austenitic, (2) ferritic, (3) martensitic, (4) precipitation-hardening, and (5) duplex. Each family has some unique physical and mechanical properties; however, within each family there is a range of corrosion resistance that is achieved by varying the alloying elements. This allows for the substitution of an alloy from one family for that of another and thus takes advantage of these properties. UNS (Unified Numbering System) grade designations currently are assigned as a joint activity of SAE and ASTM. Heat and corrosion resistant (stainless) steels are assigned identities within the range of S00001 through S99999. Austenitic chromium-nickel-manganese steels typically are assigned as S2xxxx designations; austenitic chromium-nickel grades and duplex stainless steels typically are listed as S3xxxx. Ferritic and martensitic grades are normally categorized using S4xxxx designations. This system generally follows previous AISI-type grade designations. The precipitation-hardening stainless grades are unique in that they are grouped within the S1xxxx, S4xxxx or S6xxxx series.

## Austenitics

In this family, the alloys have a face centered cubic structure, are not hardenable by heat treatment, have excellent formability and weldability, and have a wide range of corrosion resistance. UNS S30400 (Type 304), or "18-8" as it was commonly known, is probably the most widely used stainless steel. Modifications of S30400 are the stabilized S32100 (Type 321—stabilized with titanium) and S34700 (Type 347—stabilized with niobium) grades. When improved corrosion resistance is needed, alloys with higher chromium, nickel or molybdenum content, or both, such as S31600, S31700, and the 4 and 6 % molybdenum alloys are used. For high temperature applications, the higher chromium S30900 and S31000 are used.

The 200 series alloys are also austenitic. In this group of alloys, the nickel content has been reduced and replaced

with manganese and nitrogen additions to stabilize the austenitic microstructure. Common alloys in this group are S20100 and S20430, which, in most environments, have corrosion resistance similar to S30400, and S20910, which compares favorably to S31600 in corrosion resistance.

The austenitic alloys are not hardenable by heat-treating, but they can be hardened by cold work. S20100 and S30100 are particularly amenable to such hardening. Various levels of strength and hardness can be produced by controlled cold reductions of strip or wire. Such processing can produce deformation-induced martensitic transformation in some of the lower alloy content (metastable) grades. Other austenitic grades are more stable and, thus, do not exhibit martensitic transformation after severe cold working. Such alloys are used when low magnetic permeability is critical to the intended application.

These alloys may be made sensitive to intergranular corrosion by some environments if they are improperly heat-treated or sensitized during welding. During heat-treating, if the alloy is held in the temperature range of about 550–850°C, chromium carbides will form at the grain boundaries, resulting in a chromium depleted envelope around individual grains. This envelope, having lower chromium content, will be less resistant to corrosion and may be attacked in certain environments. This type of corrosion is referred to as intergranular corrosion. The same sensitization can occur during welding. In this case, only a narrow band on either side of the weld is usually affected. This is where the temperature has remained between about 550 and 850°C for an extended period. Sensitization can be eliminated by annealing the alloy, or avoided by using the low carbon alloys (S30403, S31603, etc.) or the stabilized alloys (S32100, S34700). Sensitization does not significantly affect the mechanical properties of the stainless nor can it be readily observed visually. However, it may be detected by conducting corrosion tests, as outlined in ASTM A 262, Practices for Detecting Susceptibility to Inter-granular Attack in Austenitic Stainless Steels.

Some of the higher-alloyed austenitic stainless steels (S31600 and alloys with more chromium or molybdenum, or both, as well as the stabilized alloys) may form sigma or chi precipitates at temperatures between about 900 and 990°C. These precipitates are enriched with chromium and molybdenum and leave an envelope surrounding the grains depleted in these elements. ASTM A 262 describes testing methods to determine if an alloy has been subjected to precipitation of these phases.

The austenitic alloys are particularly susceptible to stress corrosion cracking (SCC) in hot chloride environments. This form of corrosion can be minimized by increasing the amount of nickel in the alloy.

## Ferritics

The ferritic alloys have a body centered cubic structure, are mildly hardenable by cold work, have good formability (particularly drawability), and have a range of corrosion resistance. The ferritic alloys are particularly noted for their SCC resistance. A widely used alloy in this group is S43000 (Type 430), which contains 16 % chromium. The S409xx series are 11 % chromium alloys stabilized with titanium,

niobium, or a combination of titanium and niobium that are commonly used for automotive applications. For improved pitting and general corrosion resistance, alloys with higher chromium and molybdenum should be chosen. There are ferritic alloys, known as superferritics, with chromium as high as 30 %, and molybdenum as high as 4 %. Such alloys provide excellent resistance to pitting, crevice, and general corrosion, but are somewhat limited in terms of maximum product section size.

The ferritic alloys are also susceptible to sensitization. They are sensitized by heating to temperatures above about 900°C where the carbon and nitrogen are in solution. Upon cooling to about 400 to 700°C, the solubility of these elements is lowered and they precipitate as chromium carbides and nitrides, thus causing chromium depletion. This sensitization can be corrected by heating the ferritic stainless steel to 800°C. At this temperature, chromium will rediffuse back into the depleted areas. ASTM A 763, Practices for Detecting Susceptibility to Intergranular Attack in Ferritic Stainless Steels, may be used for testing for the sensitization of these stainless steels.

### Martensitic

The alloys in this family have a body centered tetragonal structure. The most common alloy in this group is S41000 (Type 410) with about 11.5 % chromium. These alloys are hardenable by heat treatment but have the least corrosion resistance of the five stainless steel families. They are used primarily for their high strength and hardness. Other common alloys in this group include S42000 (Type 420) and S440xx (Type 440 grades). The carbon and chromium contents in these alloys are higher, which help produce a hard, wear-resistant martensitic structure.

### Precipitation-hardening Alloys

These alloys are used for their combination of strength, hardness, and corrosion resistance. By controlling alloying elements and heat-treatment processes to manipulate the balance between austenite, ferrite, martensite, and second phase precipitation, a wide range of properties can be produced. The precipitation-hardenable alloys can be classified as martensitic, austenitic, or semi-austenitic. In the latter case, the alloys are predominately austenitic in the solution-annealed condition for ease of forming, but are subsequently transformed to a martensitic structure to produce higher strength capability. Semi-austenitic alloys may be magnetic if they are martensitic, or nonmagnetic if they are fully austenitic. Precipitation-hardenable alloys are characterized by their ability to be aged to high strength levels. They may also be cold worked before age hardening to achieve even greater strength levels. Alloys representative of the martensitic, austenitic and semi-austenitic precipitation-hardenable stainless steel classifications are S17400, S66286, and S35500, respectively.

The precipitation-hardenable alloys do not have the range of corrosion resistance offered by some of the austenitic or ferritic alloys; however, they provide substantially higher strength and are not restricted by product form.

### Duplex

Duplex stainless steels represent a comparatively small, but growing, family of alloys. As the name suggests, the compositions of duplex stainless steels are balanced to contain two phases, austenite and ferrite. The resultant duplex microstructure exhibits higher strength and improved stress-corrosion cracking resistance compared with many austenitic grades, yet provides greater toughness and ductility than ferritic stainless steels. However, toughness and corrosion resistance can be impaired significantly by the precipitation of intermetallic phases. ASTM A 923, Test Methods for Detecting Detrimental Intermetallic Phase in Wrought Duplex Austenitic/Ferritic Stainless Steels, was developed to allow detection of such phases in certain duplex grades.

Traditional alloys, such as S32900, contain about 15–20 % austenite in a ferritic matrix. Modern duplex stainless steels (e.g., S32950, S32550, S32205) are alloyed with nitrogen to increase the austenite volume fraction to about 30–50 %. Because of their ferrite content, duplex stainless steels are magnetic.

### Mill Products

Stainless steels are versatile materials. They are manufactured into a wide variety of product forms including bar, wire, strip, sheet, plate, tubing, pipe, and castings. Stainless steels may be drawn, formed, spun, extruded, welded, and electropolished. Section sizes may range from fine surgical needle wire to large structural forgings.

Many finishes can be applied to stainless steels. They range from dull, to satin, to mirror. Pattern and other textured finishes may also be applied. Because of this diversity, stainless steels are frequently used for decorative purposes on automobiles, buildings and storefronts, and even for statues. The cleanability and corrosion resistance of stainless steels makes them ideal for use where stringent sanitary and health conditions are of utmost importance. The pharmaceutical, food processing, dairy, wine, brewing, and many other industries, as well as hospitals, restaurants, hotels, and the home, are some of the places where stainless steel equipment is found. Precipitation-hardening stainless steels are found in aerospace applications requiring a combination of good corrosion resistance with high strength and fracture toughness.

### Sensitivity to Particular Environments

#### Acids

The effect of pure acids on stainless steels depends on whether the acid is reducing or oxidizing. If the acid has low oxidizing strength, the stainless will corrode rapidly. If, however, the oxidizing strength of the acid is sufficiently high, the stainless steels will resist corrosion.

Hydrochloric acid is a good example of a reducing acid with very little oxidizing capacity. Stainless steels will readily corrode in this acid in all but the very low concentrations. The form of corrosion that will occur will be general corrosion. The stainless steels with higher nickel and molybdenum concentrations will perform better in reducing acids.

Nitric acid has a high oxidizing capacity and stainless steels will remain passive in nitric acid solutions. Although sulfuric acid is corrosive to stainless steels, it may be innocuous in low concentrations and in the presence of aeration. Similar performance can be expected in phosphoric acid and in many of the organic acids.

Stainless steels with higher chromium concentrations tend to have more corrosion resistance in oxidizing environments.

Metal salts, such as ferric and cupric sulfate, are oxidizing and will passivate stainless steel when added to sulfuric acid. The salt concentration may be controlled so that passivity will occur at a specific chromium concentration. Stainless steels or areas of a stainless surface (such as sensitized grain boundary areas) with lower chromium content will not be passivated. This is the basis for the intergranular corrosion tests for stainless steels.

### *Alkalies*

Generally, the stainless steels are not corroded by alkalies such as sodium and ammonium hydroxide at solution temperatures below 100°C. At higher temperatures the austenitics such as S30400 may corrode excessively and may also exhibit SCC. The higher chromium ferritics and duplex stainless steels (26 % chromium) resist corrosion by alkalies up to about 150°C.

### *Salts*

Stainless steels are resistant to corrosion by most salts. The exceptions are the halide salts that cause pitting, crevice corrosion, and SCC. Of these salts, those containing chlorides are the most corrosive, followed by fluoride, bromide, and iodide salts. Stainless steels with higher chromium, molybdenum, and nitrogen concentrations will resist pitting and crevice corrosion more effectively. Austenitic stainless steels with higher molybdenum and nickel, ferritic stainless steels with no nickel or copper, and duplex stainless steels will resist SCC.

### *Liquid Metals*

Low melting metal such as aluminum, cadmium, copper, magnesium, zinc, etc., will corrode stainless steels at or above their melting point. In mercury, the lower chromium ferritics are much more resistant than the higher alloyed stainless steels.

### *Outdoor Atmospheres*

The stainless steels have excellent corrosion resistance in outdoor environments. They will suffer some rust staining when exposed to chlorides (seacoast, deicing salts) and/or acid industrial fumes. The higher the alloy content of the stainless steel, particularly chromium, molybdenum, and nitrogen, the better the performance.

## **METHODS OF EVALUATION**

As with most metals, stainless steels are susceptible to most forms of corrosion. However, the most frequently encountered forms of corrosion are: general, intergranular, pitting, crevice, and SCC. Methods for evaluating stainless

steels for susceptibility to these forms of corrosion are described in the ASTM standards as outlined in this section.

## **Tests for Susceptibility to Forms of Corrosion**

In order to obtain accurate and consistent test results the specimens must be properly prepared before corrosion tests are conducted. Following ASTM G 1, Practice for Preparing, Cleaning and Evaluating Corrosion Test Specimens, will provide better reproducibility and will afford a commonality for comparing results compiled in the same laboratory at different times to results obtained at another laboratory.

### *General Corrosion*

General corrosion is the overall wastage of the material. This is a manageable form of corrosion in that the corrosion rate can be established, and an item may be built to last the length of time needed by selecting the correct thickness. The corrosion can be monitored and the life of the item can be estimated. Thus, no unexpected failures will occur. To test for susceptibility to this form of corrosion, samples may be exposed to the corrosive medium at the anticipated use temperature and a corrosion rate established. ASTM G 31, Practice for Laboratory Immersion Corrosion Testing of Metals, is an excellent guide for conducting such tests. Atmospheric corrosion tests may be conducted by following ASTM G 50, Practice for Conducting Atmospheric Corrosion Tests on Metals. The following electrochemical tests may also be used for establishing the relative corrosion resistance of stainless steels: ASTM G 3, Practice for Conventions Applicable to Electrochemical Measurements in Corrosion Testing; ASTM G 5, Standard Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements; ASTM G 59, Test Method for Conducting Potentiodynamic Polarization Resistance Measurements; and ASTM G 102, Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Measurements.

### *Intergranular Corrosion*

As described before, intergranular corrosion of stainless steels occurs when the material is sensitized. This condition produces a chromium-depleted envelope around each grain, which is less corrosion-resistant. This results in intergranular corrosion of the stainless steel in certain environments. The two ASTM standards that describe how to test stainless steels for susceptibility to this form of corrosion are ASTM A 262 and A 763. A third standard, G 28, is applicable to nickel-rich, chromium-bearing alloys.

### *Pitting Corrosion*

This is a localized type of corrosion. There could be only one or two pits on the surface of a tank containing a liquid and this very slight, highly localized corrosion could render that tank useless. Pitting of stainless steel usually starts as a small opening on the surface and then may spread like a balloon beneath it. Pitting can require an extended incubation period, and therefore short test periods may not provide useful data. A very high percentage of pitting of stainless steels is caused by chloride ions. The other halides

may also cause pitting, as will some sulfur species. Pitting susceptibility is usually established using chloride-containing solutions. Acid and oxidizing conditions tend to accelerate pitting. Alkaline conditions, on the other hand, tend to suppress pitting corrosion of the stainless steels. ASTM G 48, Test Methods for Pitting and Crevice Corrosion Resistance of Stainless Steels and Related Alloys by the Use of Ferric Chloride Solution, is used for testing pit susceptibility. ASTM G 46, Guide for Examination and Evaluation of Pitting Corrosion, may be used for evaluating the results of the tests. ASTM G 150, Test Method for Electrochemical Critical Pitting Temperature Testing of Stainless Steels, offers an electrochemical technique for evaluating relative susceptibility to pitting corrosion.

As previously mentioned, stainless steels with higher chromium, molybdenum, and nitrogen concentrations typically will resist pitting and crevice corrosion more effectively. Empirical formulas have been derived to express the relationship of chromium, molybdenum, and nitrogen concentrations to pitting and crevice corrosion resistance. For example, Eq 1 has been applied to austenitic stainless steels to define Pitting Resistance Equivalent or PRE number [3]. Elemental coefficients may differ depending upon the specific alloy family. For example, Eq 2 has been associated with duplex stainless steels. Results of such formulas are relative and should be used only as a guideline.

$$\text{PRE} = \% \text{Cr} + 3.3x\% \text{Mo} + 30x\% \text{N} \quad (1)$$

where elemental concentrations are expressed mass percent.

$$\text{PRE} = \% \text{Cr} + 3.3x\% \text{Mo} + 16x\% \text{N} \quad (2)$$

where elemental concentrations are expressed mass percent.

### Crevice Corrosion

This form of corrosion is very much like pitting corrosion. The only difference is that the attack occurs in a crevice such as lap joints, gaskets, bolts, rivets, dirt deposits, under disbonded paint, corrosion products, scale, etc. Everything stated above about pitting corrosion of stainless steel applies to crevice corrosion as well. There is an incubation period just like in pitting corrosion. The attack occurs, in this instance, on the surface of the stainless, immediately below the crevice former. As with pitting, metal dissolution can be very rapid once the passive film breaks down and attack has initiated. Corrosive ions, such as chlorides, tend to migrate to the crevice and concentrate, thus accelerating corrosion. The acidity of the solution in the crevice is also increased, which further accelerates corrosion. Given similar conditions, crevice corrosion will occur before pitting initiates.

ASTM G 48 is also used to evaluate stainless steels for crevice corrosion susceptibility. ASTM G 78, Guide for Crevice Corrosion Testing of Iron-Base and Nickel-Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environments, should be consulted prior to crevice corrosion testing.

### Stress Corrosion Cracking (SCC)

This form of corrosion is caused by the joint action of tensile stresses and corrosion. Almost all metals have some alloy systems that are susceptible to SCC. However, there are specific environments that cause cracking in each material.

A primary agent causing most stainless steel SCC failures is the chloride ion. The stainless steels that are most susceptible to this form of corrosion are the approximately 8–10 % nickel austenitic grades. However, as the nickel content of the austenitic steels increase beyond this level, the resistance to SCC increases. The ferritic stainless steels, with no nickel or copper, are resistant to this form of corrosion. However, ferritic grades are more prone to hydrogen-induced cracking or embrittlement.

Three factors are considered necessary to cause SCC in a susceptible austenitic stainless steel: (1) presence of chlorides, (2) elevated temperatures, and (3) tensile stresses. If any one of these is reduced or eliminated, the likelihood of SCC occurring is reduced.

SCC of the austenitic stainless steels has a characteristic morphology. The cracks are branching and transgranular in nature, unless the alloy is sensitized. In sensitized material the cracking will take an intergranular path. This form of corrosion also has an incubation period. Depending on the chloride ion concentration, the temperature, and the magnitude of tensile stresses, the failure can occur within hours or after many years.

The following ASTM standards may be used for testing susceptibility to SCC:

- G 30, Practice for Making and Using U-Bend Stress-Corrosion Test Specimens
- G 35, Practice for Determining the Susceptibility of Stainless Steels and Related Nickel-Chromium-Iron Alloys to Stress-Corrosion Cracking in Polythionic Acids
- G 36, Practice for Evaluating Stress-Corrosion Cracking Resistance of Metals and Alloys in a Boiling Magnesium Chloride Solution
- G 38, Practice for Making and Using C-Ring Stress-Corrosion Test Specimens
- G 39, Practice for Preparation and Use of Bent-Beam Stress-Corrosion Test Specimens
- G 41, Practice for Determining Cracking Susceptibility of Metals Exposed Under Stress to a Hot Salt Environment
- G 44, Practice for Exposure of Metals and Alloys by Alternate Immersion in Neutral in 3.5% Sodium Chloride Solution
- G 49, Practice for Preparation and Use of Direct Tension Stress-Corrosion Test Specimens
- G 58, Practice for Preparation of Stress-Corrosion Test Specimens for Weldments
- G 123, Test Method for Evaluating Stress-Corrosion Cracking of Stainless Alloys with Different Nickel Content in Boiling Acidified Sodium Chloride Solution
- G 129, Practice for Slow Strain Rate Testing to Evaluate the Susceptibility of Metallic Materials to Environmentally Assisted Cracking
- G 168, Practice for Making and Using Precracked Double Beam Stress Corrosion Specimens.

Refer to Chapter 25 for more information on testing for susceptibility to SCC.

# Cobalt-Base Alloys

P. Crook<sup>1</sup>

## THE NATURE OF COBALT AND ITS ALLOYS

COBALT OCCURS IN two atomic forms: a low temperature stable hexagonal close packed (hcp) form and a high temperature stable face centered cubic (fcc) form. The transformation temperature of pure cobalt is 417°C. Alloying elements such as nickel, iron, and carbon (within its soluble range) are known as fcc stabilizers, and suppress the transformation temperature. Chromium, molybdenum, and tungsten, on the other hand, are hcp stabilizers and have the opposite effect.

In reality, the transformation is extremely sluggish, and most cobalt-base alloys exhibit a (metastable) fcc structure at room temperature, even if their transformation temperatures are considerably higher. Partial transformation (from fcc to hcp) of most cobalt-based alloys is, however, easily induced at room temperature by plastic deformation (under the action of mechanical stress), the extent of the transformation being related to the composition (in particular the ratio of hcp stabilizers to fcc stabilizers). The transformation under stress is believed to progress by the creation of wide stacking faults (the fcc form of these alloys having very low stacking fault energies) and by subsequent coalescence. Extensive microtwinning is also observed in plastically-deformed, cobalt-based alloys.

By virtue of these crystallographic features, the cobalt-based alloys are inherently resistant to those forms of wear that involve a microfatigue constituent, namely sliding wear, fretting, cavitation erosion, and liquid droplet erosion [1].

From a corrosion standpoint, the roles of various alloying elements in the cobalt-base alloys parallel those seen in the nickel-base alloys. Chromium, molybdenum, and tungsten, for example, are highly soluble in both atomic forms of cobalt. Chromium is added to most of the commercially important alloys, and provides passivity over a wide range of potentials. Molybdenum and tungsten enhance resistance to corrosion within the active regime.

The cobalt-base alloys fall generally into two categories. Alloys in the first category contain low levels of carbon, and are intended for use in severely corrosive environments, at high temperatures, or where ductility is an important consideration. Alloys within the second category have high carbon contents; they exhibit high hardnesses and provide resistance to low stress abrasion (in addition to other forms of wear), but exhibit low ductilities and poorer corrosion resistance. Compositions from both categories are listed in Table 1.

Most of the low-carbon, cobalt-base alloys are available in the form of wrought products (plates, sheets, bars, etc.), from which industrial components can be fabricated. Some of these alloys are common in cast and weld overlay form also. The high-carbon alloys are not easily produced in wrought product form; they are therefore used mostly in cast or weld overlay form. From a microstructural standpoint, not only is there a large difference between the wrought and cast versions of certain cobalt-base alloys, but there is also an enormous microstructural difference

between the high- and low-carbon alloys [2]. During solidification, large quantities of carbide form in the microstructures of the high-carbon, cobalt-base alloys. At a carbon level of 2.4 wt% (STELLITE 3), for example, the carbides constitute about 30 wt% of the material [3]. These are of the  $M_7C_3$  (chromium-rich primary) and  $M_6C$  (tungsten-rich eutectic) types, where M represents the metal component (e.g.,  $M_7C_3$  corresponds to  $Cr_7C_3$ ). At 1 wt% carbon (UNS R30006), the carbides constitute about 13 wt% of the material, these being predominantly chromium-rich eutectic carbides of the  $M_7C_3$  type [3].

Carbides are much less abundant in the low-carbon alloys, and absent from the wrought, annealed microstructure of UNS R31233. In some of these low-carbon alloys, they play an important role. The  $M_6C$  precipitates in UNS R30605, for example, are important to its high-temperature, mechanical properties, partially because they restrict grain growth [4].

Microstructures of several cobalt-based alloys are presented in Fig. 1. From these, the influence of carbon content on the nature and volume fraction of carbide precipitates is evident.

With regard to corrosion resistance, carbide precipitates are very important in that they tie up critical alloying elements, and create, within the segregated cast microstructures at least, networks prone to preferential attack. Even in quenched, wrought microstructures, grain boundary sensitization due to carbide precipitation is common. In reviewing the high-carbon, cobalt-base alloy compositions, it should be appreciated that the (effective) solid solution chromium, molybdenum, and tungsten levels are relatively low, and that, in cast components and weld overlays, compositional inhomogeneity within the solid solution is to be expected.

## THE AQUEOUS CORROSION TESTING OF COBALT-BASE ALLOYS

Several tests are used to assess the suitability of the cobalt-base alloys for use in corrosive media. The most common is the immersion test, performed according to the procedures defined in ASTM G 31, Practice for Laboratory Immersion Corrosion Testing of Metals.

In special cases, such as UNS R31233, when general usage of the alloy in the chemical processing industries is anticipated, many immersion tests are performed in certain media, and isocorrosion curves generated. Comparative curves for UNS R31233 and UNS N06022 are shown in Fig. 2. These curves represent the concentrations and temperatures (in sulfuric, hydrochloric, nitric, and phosphoric acids) at which corrosion rates of 0.13 mm/y (5 mpy) and 0.51 mm/y (20 mpy) were encountered. At lower concentrations and temperatures, lower corrosion rates were measured. All of the immersion tests used to construct these curves were performed in duplicate, using samples of dimensions 25.4 by 12.7 by 3.2 mm and 1 L of solution per duplicate pair. The samples were each tested for four 24-h periods, with a new solution every period. Weights were measured after every test period.

Given the chromium and molybdenum levels that exist in UNS R31233, these curves suggest that the two elements are at least as effective in cobalt-base alloys as they are in the

iron- and nickel-based alloys, provided they remain in solution (i.e., do not partition to primary or secondary precipitates).

To evaluate the susceptibility of the cobalt-based alloys to localized attack, the procedures described in ASTM G 48, Test Method for Pitting and Crevice Corrosion Resistance of Stainless Steels and Related Alloys by the Use of Ferric Chloride Solution can be used. When tested in 6 % ferric chloride, for example, at a temperature of 65°C, the pit densities and depths for samples of UNS R31233 were less than those for UNS N10276.

The mode of degradation under which the nickel-base alloys are inherently superior to the cobalt-based materials is stress corrosion cracking. This is a result of their respective crystallographic characteristics. On the one hand, the nickel-base alloys possess stable fcc structures with high stacking fault energies, in which cross-slip is easily accomplished during plastic deformation. On the other hand, the cobalt-base alloys possess, in general, metastable fcc structures with low stacking fault energies, in which slip is predominantly planar. Such crystallographic characteristics are known to promote transgranular stress corrosion cracking [6].

Relative to the austenitic stainless steels, however, the low-carbon cobalt-base appear to exhibit reasonable resistance to stress corrosion cracking (equivalent to that of the high nickel grades). Although it has not been possible to differentiate between UNS R31233 and high-nickel stainless steels such as UNS N08020 by testing U-bend samples, prepared in accordance with ASTM G 30, Practice for Making and Using U-Bend Stress-Corrosion Test Specimens, in a boiling magnesium chloride solution (ASTM G 36, Practice for Performing Stress-Corrosion Cracking Tests in a Boiling Magnesium Chloride Solution), four-point bend tests at stresses within the elastic ranges of the materials have allowed the ranking of UNS R31233 relative to UNS N08020 and UNS S31603. The results of this test, which was performed in 30 % magnesium chloride at 118°C, are illustrated in Fig. 3.

Immersion testing according to the ASTM G 31 procedures can be used to evaluate the relative performance of the high- and low- carbon alloys. The data in Table 2 illustrate the difference in corrosion resistance between UNS R31233 (0.06 wt% carbon) and UNS R30006 (1 wt% carbon), when used in the cast form. All samples were prepared from investment castings. For comparison, data are presented also for investment castings of UNS R30605, CF-3M (the cast equivalent of UNS S31603 stainless steel), CW-12MW (equivalent to UNS N10276), and CX-2MW (equivalent to UNS N06022). The three cobalt-based alloys were tested in the as-cast condition (since castings of these alloys are not normally annealed); the stainless steel and nickel-base alloys were tested in the solution annealed condition.

These test media may be grouped into those that are oxidizing in nature (ASTM G 28A solution [Test Methods for Detecting Susceptibility to Intergranular Attack in Wrought Nickel-Rich, Chromium Bearing Alloys],  $P_2O_5$ , and  $HNO_3$ ), those that are non-oxidizing (HCl,  $H_2SO_4$ , and HF), and those that promote pitting (ASTM G 28B solution and  $FeCl_3$ ). For those in the oxidizing category, the chromium content of the alloy is critical in that it controls the

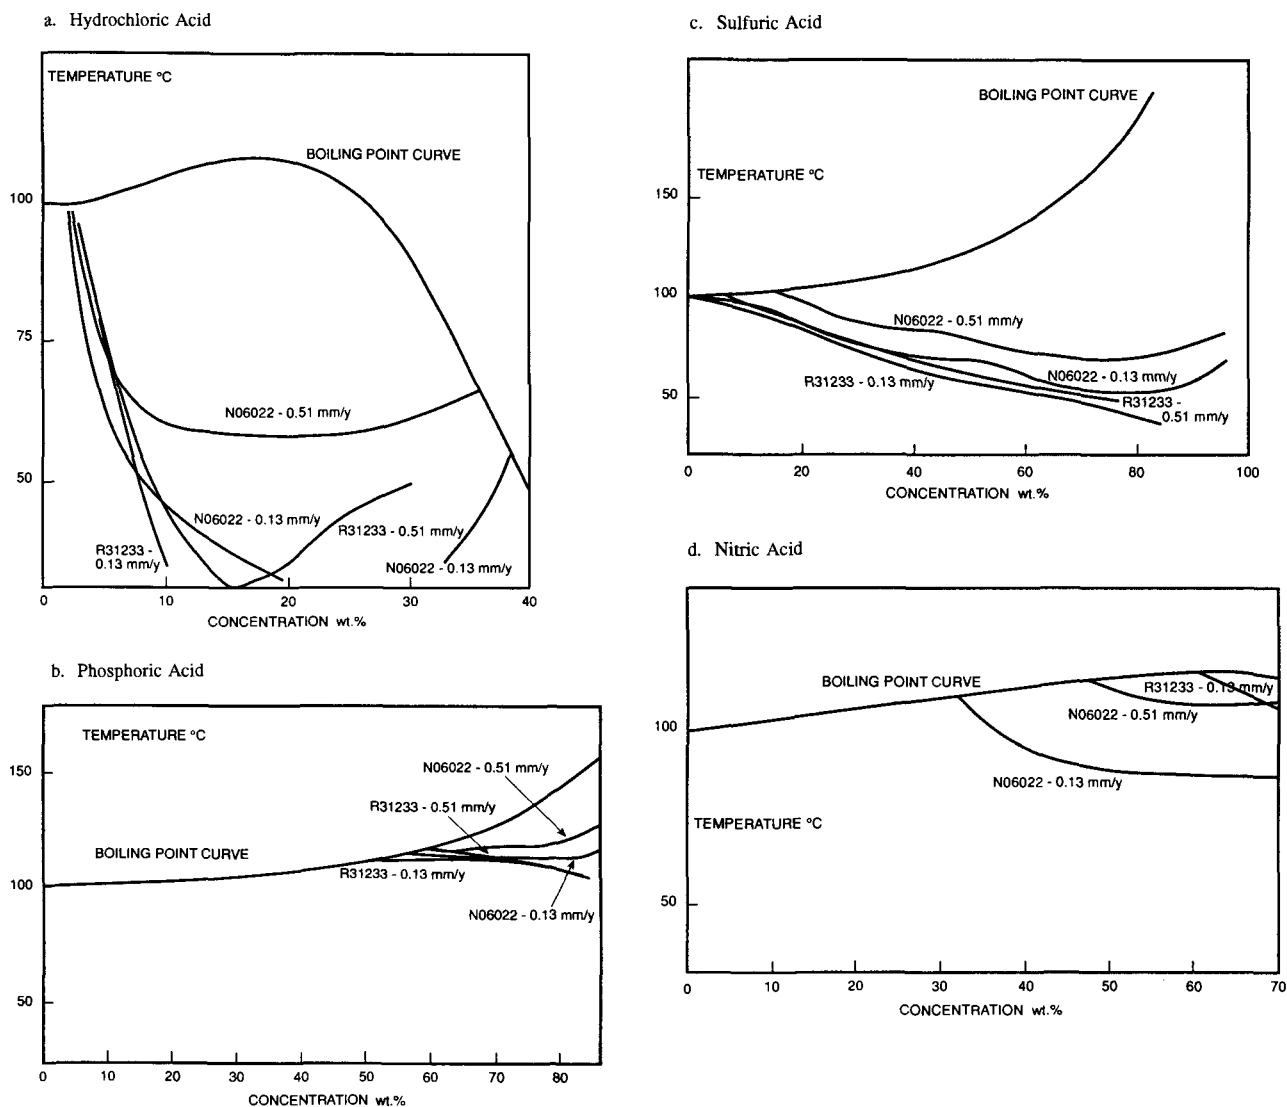

FIG. 2—Isocorrosion curves for UNS R31233.

FIG. 3—Stress corrosion cracking data in 30 % magnesium chloride at 118°C.

active-passive behavior. In the case of multiphase alloys, it is important how the chromium partitions to the individual phases. In the case of castings, the distribution of chromium within each phase is critical also.

As discussed, a substantial proportion of the chromium in UNS R30006 partitions to the carbide phase. This explains the poor performance of UNS R30006 relative to UNS R31233 in the three oxidizing media.

For the non-oxidizing media, molybdenum and tungsten appear to be the most influential elements in cobalt-, nickel-, and iron-base alloys. Here the poorer performance of UNS R30006 can be explained by the atomic weight differences between molybdenum and tungsten (1 wt% of molybdenum being approximately equivalent to 2 wt% tungsten, in atomic terms), and the presence of the chemically-active carbides in the microstructure. Higher tungsten contents in the cobalt-base alloys are only effective when carbon

contents are low, because of partitioning of the tungsten to the carbides.

For those media that promote localized attack (pitting and crevice corrosion), the combination of chromium and molybdenum appears to be important. Again, the distribution of these elements in the microstructure is believed to be important, as are second phases, which can act as initiation sites.

Since the cobalt-base alloys are widely used in weld overlay form, it is important to establish the effects of dilution (intermixing with the substrate material) by immersion testing, according to ASTM G 31 procedures. By means of such tests, it has been shown that intermixing of the cobalt-base alloys with either carbon steel or stainless steel is detrimental [7]. The extent to which dilution influences the corrosion resistance of UNS R31233, in selected oxidizing and non-oxidizing media, is illustrated in Fig. 4. These results may be attributed to the lower chromium and molybdenum levels in the diluted overlays; iron appears to degrade the corrosion resistance of the cobalt-base alloys also [7].

With regard to the use of corrosion tests for the quality control testing of cobalt-base alloys, only UNS R31233 appears to be subject to this. In this case, each wrought product (i.e., every thickness of plate, bar, and sheet from a given heat) is subjected to the ASTM G 28A (50 % H<sub>2</sub>SO<sub>4</sub> + 42 g/l Fe<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>, boiling) test prior to sale. A corrosion rate of less than 0.25 mm/y is necessary for release of the material. The test duration is 120 h.

## WEAR TESTING OF COBALT-BASE ALLOYS

The chief industrial attribute of the cobalt-base alloys is their resistance to wear. They hold a unique position in that they are also corrosion-resistant (when the carbon content is low), and maintain their strengths and wear resistance at high temperatures, by virtue of reasonable microstructural stability (relative to, say, the austenitic manganese steels, the tool steels, and the high-silicon stainless steels).

In evaluating the cobalt-base alloys in a wear sense, several ASTM standards, most involving room temperature tests, have been employed. Among these are:

- ASTM G 32, Test Method for Cavitation Erosion Using Vibratory Apparatus
- ASTM G 65, Test Method for Measuring Abrasion Using the Dry Sand/Rubber Wheel Apparatus
- ASTM G 98, Test Method for Galling Resistance of Materials

To illustrate the benefits of the cobalt-base alloys as compared to other alloys of moderate and high corrosion resistance, data generated using the ASTM G 32 and G 65 (Procedure B) tests are presented in Figs. 5 and 6. With regard to galling resistance, data are presented in Table 3.

The galling test used to generate the information in Table 3 was a modification of the ASTM G 98 procedure. It involved:

- (a) cyclic motion of the test pin through an arc of 120°,
- (b) application of the load by means of a Riehle Mechanical Tester (in the load holding mode), and

FIG. 5—Comparative cavitation erosion data (ASTM G 32 test).

(c) quantitative interpretation of the test scars by surface profilometry.

The cylindrical pins (of diameter 15.9 mm) and the counterface blocks (of dimensions 76.2 by 25.4 by 12.7 mm) were surface ground prior to test. During test, the pins were subjected to five rotational cycles (i.e., they were turned back and forth through ten arcs of 120°) by means of a wrench, at loads of 1361, 2722, and 4082 kg.

In visual terms, the cylindrical pins and the counterface blocks appeared to suffer the same degree of damage in each test. The blocks, therefore, were used in the quantitative determination of damage, since they were more amenable to profilometry, allowing travel of the stylus to and beyond the circumference of the scar. For accuracy, the stylus was passed twice over each scar (one pass along the diameter parallel to the sides of the block; the other along the diameter perpendicular to it). Measurement involved appreciable overlap of the adjacent unworn regions, to enable calculation of the initial peak-to-valley amplitude. By considering each radius as a distinct region of the scar, four values of final peak-to-valley amplitude were measured per scar. The

average of these four values was used to determine the degree of damage incurred, by subtracting the average of four values of initial peak-to-valley amplitude.

With regard to the effects of dilution upon the wear properties of cobalt-base alloy weld overlays, tests have been performed on all-weld-metal samples made from admixtures of UNS R31233 and UNS G10400 (carbon steel) and of UNS R30006 and UNS G10400. The influence of dilution upon the resistance to cavitation erosion and galling of these two cobalt-base alloys was not strong, but both were affected markedly with regard to low stress abrasion, as measured using the ASTM G 65 procedure. The abrasion test results are presented graphically in Fig. 7.

## HOT CORROSION AND OXIDATION TESTING OF COBALT-BASE ALLOYS

As has been stated, the cobalt-base alloys are relatively strong and wear-resistant at elevated temperatures. Indeed, many applications of the alloys involve temperatures in the range of 500–1000°C. One of the important factors in their commercial success for high temperature applications is their excellent resistance to gaseous sulfidation. Data relating to this property are presented in Table 4. These data were generated by use of the test procedures described in Ref 8. Also of importance in high temperature applications is their good oxidation resistance. In particular, UNS R30188, which has an addition of the rare-earth lanthanum, is equal to the chromia-forming nickel-base superalloys from an oxidation standpoint, and is favored for many flying gas turbine parts because of its higher strength. With regard to other cobalt-based alloys, the wrought forms of UNS R30006 and UNS R31233 have been found to possess excellent resistance to oxidation under static conditions up to approximately 1000°C.

Temperature: 871°C.

## SUMMARY

In summary, by corrosion and wear testing the cobalt-base alloys according to the procedures described in ASTM standards G 31, G 32, G 36, G 48, G 65, and G 98, it is possible to determine their suitability for many industrial situations. In general, the alloys are characterized by their carbon contents, the low-carbon alloys being generally much more corrosion-resistant and ductile than the high-carbon alloys.

# Titanium

Ronald W. Schutz<sup>1</sup>

APPLICATION OF TITANIUM and its alloys in aerospace, marine, energy chemical process, and other industrial sectors continues to expand. This has been motivated, in part, by trends in decreasing cost and increasing commercial availability of titanium mill products, improved designer and user knowledge and familiarity, and titanium's unique, attractive combination of engineering properties. These properties include, but are not limited to, relatively low density, low modulus, a wide range of strength, and exceptional corrosion resistance over a very wide span of environmental conditions [1,2].

Growing application of titanium and its alloys has stimulated increased laboratory and in-process (in situ) corrosion testing for the purpose of evaluation and service qualification. Although titanium alloys are evaluated via the same basic test methodologies used for other passive, film-forming CRAs (corrosion resistant alloys), its unique metallurgy, windows of susceptibility, and properties can require additional consideration toward or adjustments in certain testing details. This chapter overviews relevant corrosion test methods, and provides detailed guidelines to help ensure proper, meaningful evaluation of titanium alloy corrosion resistance and behavior.

## COMMERCIAL TITANIUM ALLOYS

The designations and nominal compositions of various commercial aerospace and industrial titanium alloys are listed in Table 1. The first eleven alloys listed are titanium alloys primarily used in chemical or industrial applications in which corrosion resistance is the main design consideration. These alloys consist of single alpha ( $\alpha$ ) phase (hexagonal close-packed crystal structure), or near-alpha alloys containing relatively small amounts of beta ( $\beta$ ) phase (body-centered cubic crystal structure) in an alpha phase matrix. The remaining alloys exhibit significantly higher strength and were developed for aerospace service, although several are rapidly finding applications in industrial service. Alloy strengthening is achieved via solid-solution alloying and stabilization of two-phase structures. These alpha-beta and beta alloys contain varying amounts of stabilized beta phase, and may be heat-treated (aged) to higher strength levels. Further

details on the metallurgy and mechanical/physical properties of titanium alloys can be found elsewhere [3–8].

## MECHANISM OF CORROSION RESISTANCE

The excellent corrosion resistance of titanium alloys results from the formation of very stable, continuous, highly adherent, and protective oxide films on the metal surfaces. Because titanium metal itself is highly reactive and has an extremely high affinity for oxygen, these beneficial surface oxide films form spontaneously and instantly when fresh metal surfaces are exposed to air or moisture, or both. In fact, a damaged oxide film can generally heal itself instantaneously if at least traces (that is, parts per million) of oxygen or water (moisture) are present in the environment. However, anhydrous conditions in the absence of a source of oxygen may result in titanium corrosion, because the protective film may not be regenerated if damaged.

The nature, composition, and thickness of the protective surface oxides that form on titanium alloys depend on environmental conditions. In most aqueous environments, the oxide is typically  $\text{TiO}_2$ , but may consist of mixtures of other titanium oxides, including  $\text{TiO}_2$ ,  $\text{Ti}_2\text{O}_3$ , and  $\text{TiO}$  [9]. High-temperature oxidation tends to promote the formation of the chemically resistant, highly crystalline form of  $\text{TiO}_2$ , known as rutile. Lower temperatures, oxidizing aqueous media, and anodizing favor generation of a less crystalline form of anatase  $\text{TiO}_2$ , or a mixture of rutile and anatase [9,10]. These naturally formed films are typically less than 10–30 nm thick and are invisible to the eye. The  $\text{TiO}_2$  oxide itself is highly chemical-resistant and is attacked by very few substances, including hot, concentrated  $\text{HCl}$ ,  $\text{H}_2\text{SO}_4$ ,  $\text{NaOH}$ , and (most notably)  $\text{HF}$ . This thin surface oxide is also a highly effective barrier to atomic and molecular hydrogen. With this hard, rehealable (ceramic-like) oxide film, titanium alloys exhibit elevated resistance to erosion, erosion-corrosion, and cavitation damage under high velocity, turbulent flow conditions [1].

The  $\text{TiO}_2$  film, being an n-type semiconductor, is electronically conductive. As a cathode, titanium permits electrochemical reduction of ions in an aqueous electrolyte. On the other hand, very high resistance to anodic current flow through the passive oxide film (i.e., significant anodic polarization) can be expected in most aqueous solutions. Elevated anodic pitting (breakdown and repassivation) potentials can also be expected with many titanium alloys.

Passivity and good corrosion resistance of titanium can be expected under conditions where these protective surface oxides are thermodynamically stable. Pourbaix (potential-pH) diagrams for the titanium-water system [1,11] reveal that oxide film stability occurs over a wide range of potentials, from highly oxidizing to mildly reducing conditions. As a result, titanium alloys can be expected to resist all natural waters (including seawater) and common salt solutions of halides (i.e., chlorides), sulfates, silicates, phosphates, nitrates, carbonates, etc., over the pH range of 3–12. However, oxide film breakdown and resultant corrosion of titanium occurs under moderate to strong reducing acid conditions. Thus, severe general corrosion is possible in strong uninhibited reducing acids such as HCl, HBr, H<sub>2</sub>SO<sub>4</sub>, or H<sub>3</sub>PO<sub>4</sub> solutions, particularly as acid concentration or temperature, or both, increases [1,2]. An especially severe attack of titanium occurs in acid fluoride (HF) solutions, even at relatively low concentrations (>10 to 15 ppm free fluorides) and temperatures. Titanium hydride formation is predicted under strongly reducing aqueous conditions (highly cathodic potentials) and is dependent on solution pH.

## FACTORS AFFECTING PASSIVITY IN AQUEOUS MEDIA

The passivation of titanium is favored and can be expanded in aqueous reducing acid media by any factor that shifts the alloy potential in the noble (positive) direction where oxide film stability is promoted. This beneficial ennobling influence may result from several factors including:

1. An increased surface oxide film thickness by anodizing or thermal oxidation;
2. Anodic polarization of the alloy by impressed anodic current, or galvanic coupling to a more noble metal (i.e., precious metals);
3. The presence of dissolved oxidizing species in the environment acting as cathodic depolarizers;
4. The presence of certain alloying elements in titanium that decreases the cathodic (hydrogen) overvoltage, thereby depolarizing the cathodic process.

The last two factors listed are most commonly encountered and can dramatically influence titanium alloy performance in reducing acid solutions. Dissolved reducible (oxidizing) species in solutions are common in many chemical process streams, whether intentionally added or present as minor background contaminants. Some common oxidizing inhibiting species in reducing acid solutions include Fe<sup>+3</sup>, Cu<sup>+2</sup>, Ni<sup>+2</sup>, Ti<sup>+4</sup>, Cr<sub>2</sub>O<sub>7</sub><sup>-2</sup>, O<sub>2</sub>, Cl<sub>2</sub>, and NO<sub>3</sub><sup>-2</sup>. For example, it is not uncommon for upstream steel corrosion to produce ferric corrosion products (i.e., Fe<sup>+3</sup> ions), which contaminate process streams. Several ppm concentrations or more of any of these species may partially or fully passivate titanium alloys in reducing aqueous media depending on acid concentration and temperature, and should be taken into account when evaluating alloy corrosion resistance.

These same oxidizing species can also stimulate and aggravate crevice corrosion of titanium in hot salt solutions. By depolarizing the cathodic process on open metal surfaces exposed to bulk solution, they effectively increase the potential difference between creviced and uncreviced metal surfaces, thereby driving the crevice cell [1,12,13]. This is why hot FeCl<sub>3</sub> solutions, Cl<sub>2</sub>-saturated solutions, or oxygenated brines are often selected as test media for accelerated test screening of alloy crevice corrosion resistance. Again, it is vital that these often minor background species

be accounted for in any crevice corrosion tests involving simulated laboratory environments.

The last factor listed addresses certain alloying element additions to titanium that may also enhance passivation in reducing acid solutions via cathodic depolarization (reduced hydrogen overvoltage on metal surfaces). This simultaneously enhances the alloy's resistance to crevice corrosion in hot salt solutions, since the solutions within an active crevice are essentially deaerated reducing acids. Alloying elements commonly added to commercial titanium alloys to achieve these improvements include the precious metals (i.e.,  $\geq 0.04$  wt % palladium or  $\geq 0.08$  wt % ruthenium), nickel ( $\geq 0.5$  wt %), and/or molybdenum ( $\geq 3.5$  wt %). Alloys incorporating these alloying additions for corrosion resistance enhancement in Table 1 include titanium Grades 7, 11, 12, 16, 17, 18, 19, 21, 26, 27, 28, and 29, and the Ti-6-2-4-6 alloy.

### Other Metallurgical Factors in Aqueous Media

The nature of the oxide film on titanium alloys basically remains unaltered in the presence of minor alloying constituents; thus, small additions ( $< 3$  %) of most commercially used alloying elements, or variations in trace alloy impurities (i.e., oxygen, nitrogen, carbon, and iron) generally have little effect on the general corrosion resistance of titanium in passivating environments. However, under active conditions (i.e., in strong reducing acids) in which titanium exhibits significant general corrosion, certain alloying elements such as iron or sulfur, or both, may accelerate corrosion. Thus, minor variations in alloy chemistry may only be of significance under conditions where the passivity of titanium is borderline or when the metal is fully active. Increasing aluminum content generally diminishes alloy corrosion resistance in strongly reducing or oxidizing acid media. Higher vanadium content can also result in higher corrosion rate in strong oxidizing acids, especially as temperature increases.

Weldments and castings of the first eleven titanium alloys listed in Table 1 generally exhibit corrosion resistance similar to that of their unwelded, wrought counterparts [1]. These titanium alloys contain so little alloy content and second phase that metallurgical instability and thermal effects are not significant. Protected by the same surface oxide film, titanium weldments and associated heat-affected zones will exhibit passive behavior (insignificant corrosion) for the same conditions under which the wrought base metal is passive. However, under marginal or active corrosion conditions (for corrosion rates  $\geq 0.10$  mm/yr, or 4 mils/yr), weldments may experience accelerated corrosion attack relative to the base metal, depending on alloy composition [14,15]. Microstructural and crystallographic texture, which often exists in many commercial titanium products, generally produces little or no effect on general or crevice corrosion test results. Thus, sample orientation and/or end-on (edge) grain texture effects are generally minor or insignificant in these two test modes. Unlike many metals, the introduction of severe cold work (plastic deformation/damage) has little impact on passivity and does not alter the basic corrosion resistance of titanium alloys.

Although little effect of heat treatment or annealing is observed with the leaner-alloy industrial titanium alloys (first eleven listed in Table 1), certain heat treatments (i.e., aging) may affect the corrosion resistance of higher strength  $\alpha$ - $\beta$  and  $\beta$  titanium alloys in reducing acid environments.

Evaluation of stress corrosion cracking (SCC) resistance of titanium alloys, on the other hand, does require attention to, and can be highly dependent on, alloy composition, heat treatment, microstructure, product processing, crystallographic texture, and orientation. Although the leaner industrial alloys (first eleven in Table 1) are generally SCC-resistant in aqueous environments, most higher strength titanium alloys generally exhibit SCC susceptibility in the form of  $K_{IC}$  or  $K_C$  reduction (i.e.,  $K_{ISCC}$  or  $K_{SCC}$ ) and/or increased environmental crack growth rates. With the exception of a few alloys in sensitized conditions (i.e., Ti-13-11-3 and Ti-8-1-1 alloys), most alloys will not exhibit SCC in stressed smooth or notched sample or component configurations when exposed to aqueous media. It is for this reason that aqueous SCC testing of titanium alloys is often conducted via precracked fracture mechanics or slow strain rate tests. Titanium alloying elements that decrease SCC susceptibility include molybdenum, vanadium, niobium, and tantalum, and precious metals (palladium and ruthenium) in high-temperature halide media. Detrimental effects may stem from increasing aluminum ( $\geq 5$  %), silicon, chromium, and manganese content in these alloys, as well as oxygen ( $\geq 0.2$  % in unalloyed Ti, or  $> 0.13$  % in higher strength alloys) and other interstitials. The influence of these metallurgical factors on titanium alloy SCC behavior is discussed in detail elsewhere [1,16-19].

It should be noted that titanium alloys are generally not susceptible to sulfide stress cracking (SSC) in  $H_2S$ -rich, sulfides, and/or sulfur containing environments (e.g., sour gas/oil well fluids). This inherent SSC resistance stems from the fact that formation of titanium sulfide corrosion products is not thermodynamically favored, such that stability of titanium's protective oxide surface film will prevail even at higher service temperatures. In these hot sour brine service environments, resistance to chloride-induced SCC is a more relevant issue for titanium alloys.

Due to the protective oxide film, titanium alloys generally exhibit anodic pitting (breakdown and repassivation) potential values that are elevated, and well above those of most corrosion engineering metals (i.e.,  $>> +1$  V). For example, pitting potentials in sulfate and phosphate solutions exceed  $+80$  V (versus SCE), and are typically in the  $+2$  to  $+10$  V range in chloride media depending on alloy composition, brine pH, and temperature. As a result, spontaneous pitting of titanium alloys in most aqueous environments does not occur and is usually not of engineering concern in the majority of applications. However, relatively low anodic pitting potential values near or just below  $+1.0$  V, which decrease with increasing temperature and acidity, may be observed in pure bromide or iodide salt solutions. Studies [20] have shown that increasing almost any alloying element reduces anodic repassivation potential values in titanium, whereas molybdenum, niobium, and zirconium generally have neutral and/or slightly beneficial influences. Unlike the intrinsic, conservative anodic repassivation potential value, the extrinsic anodic breakdown pitting potential is highly

dependent on metal surface condition. Roughened, mechanically damaged, ground, and sandblasted surfaces reduce values, whereas well-pickled, thermally-oxidized, and anodized surfaces elevate alloy anodic breakdown potentials [1].

## ROLE OF HYDROGEN

Titanium alloys are generally highly resistant to penetration by gaseous (diatomic) hydrogen and nascent (atomic) hydrogen due to the surface oxide barrier film. In hydrogen gas exposures, traces of moisture or oxygen are sufficient to maintain this protective film, whereas anhydrous gas can lead to hydrogen absorption, particularly as hydrogen gas pressures and temperature increase. Excessive cathodic charging of atomic hydrogen on titanium metal surfaces via galvanic coupling with active metals or impressed cathodic currents may induce excessive hydrogen uptake, depending on solution pH and temperature. Active corrosion of titanium in reducing acids, within active crevices, or exposure to high-temperature, strongly alkaline solutions, in which the oxide film is compromised, can also result in significant hydrogen pickup. Metallic iron embedded or galled into titanium metal surfaces can provide “windows” for enhanced penetration of hydrogen. On the other hand, surface treatments that increase oxide film thickness, such as anodizing and thermal oxidation, tend to thwart hydrogen absorption.

In  $\alpha$  and  $\alpha$ - $\beta$  alloys, excessive hydrogen uptake can induce the precipitation of titanium hydride phase in the  $\alpha$  phase. These acicular-appearing (needle-like) hydride platelets, shown in Fig. 1, are a relatively brittle phase. In most cases, small amounts of hydride precipitates are not detrimental from an engineering standpoint, but can cause severe reduction in alloy ductility and toughness when present in greater amounts. For example, hydride precipitates can be observed in Grade 2 titanium microstructures at hydrogen concentrations above approximately 40–100 ppm at 25°C, depending on the amount of  $\beta$  phase and interstitials

present. These precipitates do not result in gross embrittlement of Grade 2 titanium until hydrogen levels in excess of 500–600 ppm are reached. Since hydrogen solubility increases dramatically with temperature, hydride embrittlement may not be observed at higher temperatures. If significant absorption has occurred, embrittlement may manifest upon cooling as the hydride phase precipitates. Hydrogen solubility and tolerance generally increase with increasing volume% beta phase in  $\alpha$ - $\beta$  alloys. In Ti-6Al-4V, for example, hydride precipitates are not formed below hydrogen levels of 400–800 ppm, depending on product microstructure.

Although uniaxial tensile properties may experience little effect from increasing hydrogen levels, biaxial or triaxial stress properties, such as bend ductility, cold-drawing, and impact toughness in  $\alpha$  and near- $\alpha$  alloys may be very sensitive to hydrogen levels [21–24]. In  $\alpha$  and especially  $\alpha$ - $\beta$  alloys, hydrogen contents above critical levels (i.e., >80–120 ppm) can result in sustained-load cracking, which dramatically reduces useful maximum service loads in notched or cracked components under slow strain rate or constant tensile load situations [21–25].

Beta titanium alloys have a very high solubility for hydrogen. Therefore, embrittlement is generally not associated with hydride precipitation. Significant losses in ductility or formability do not occur below hydrogen levels of several thousand parts per million, although the tolerance to hydrogen decreases somewhat in the aged (high-strength) condition. In addition, hydrogen atom diffusivity (mobility) within the beta alloy is typically several orders of magnitude above that in alpha titanium.

## FORMS OF CORROSION AND RELEVANT TEST METHODS

It is important to know where titanium might exhibit susceptibility to corrosion attack in order to establish which corrosion test methods may be applicable or relevant to titanium alloys. Table 2 presents a list of specific environments where some form of corrosion susceptibility has been observed on titanium alloys in laboratory tests or service experience. The table indicates the relevant mode of corrosion degradation that can be expected, general scope of titanium alloys susceptible, and comments on critical factors that strongly influence each corrosion phenomenon.

Based on Table 2, the general forms of corrosion and corresponding test methods relevant to titanium alloys include: general corrosion, crevice corrosion, anodic pitting, SCC, hydrogen absorption/embrittlement, ignition/burning, and oxidation. The following sections will provide methods and guidelines for testing and evaluation of these seven basic forms of titanium alloy corrosion damage.

## TEST METHODS FOR EVALUATION OF CORROSION DAMAGE

### General Corrosion Testing

General corrosion rates for titanium alloys can be determined from weight loss data, dimensional changes, and

**FIG. 1—Photomicrograph of severely hydrided unalloyed titanium at 200 $\times$ . Note the acicular (needle-like) titanium hydride precipitate.**

TABLE 2—Environments where corrosion susceptibility of titanium alloys has been observed.

Environment	Corrosion Mode of Concern	Potentially Susceptible Ti Alloys	Comments
Strong Reducing Acids (HCl, HBr, HI, H <sub>2</sub> SO <sub>4</sub> , H <sub>3</sub> PO <sub>4</sub> , and especially HF)	general corrosion	all	Dependent on alloy composition, acid conc. and temp., and presence of inhibitive oxidizing species.
High-temp Halide and Sulfate Solutions	crevice corrosion	non-Pd or Ru alloys, or alloys with <3.5 % Mo or <0.6 % Ni	Dependent on alloy composition, brine pH and temp. Requires severe crevices.
Pure Bromide/Iodide Solutions	anodic pitting	all	Dependent on alloy composition and surface, and pH and temp.
High-temp Strongly Alkaline Solutions	hydrogen absorption	all	Occurs at pH >12 and >75°C.
High-temp Sour Brine (sulfide/H <sub>2</sub> S-rich)	galvanically induced hydrogen absorption	all	Requires galvanic couple to an active metal/alloy and >75°C.
Anhydrous Hydrogen Gas	hydrogen absorption	all	Occurs at higher temps. and gas pressures if water- or oxygen-free.
Anhydrous Methanol	stress corrosion cracking	all	Occurs when water content is below 2–3 wt %.
Red-fuming Nitric Acid or Nitrogen Tetroxide	stress corrosion cracking and/or pyrophoric reaction	all	Dependent on water and/or oxygen content.
Halide Salt Residues at High Temperatures (>230°C)	hot salt stress corrosion cracking	higher strength $\alpha/\beta$ and $\beta$ alloys	Dependent on alloy composition, stress load, temp., and exposure time.
Chlorinated Hydrocarbons	stress corrosion cracking	higher strength $\alpha/\beta$ and $\beta$ alloys	Dependent on alloy composition and condition.
Halide Salt Solutions	stress corrosion cracking	higher strength $\alpha/\beta$ and $\beta$ alloys	Dependent on alloy composition and condition, brine pH and temp., and test method.
Liquid Cadmium and Mercury, and Solid Silver (>230°C) and Cadmium	liquid or solid metal embrittlement	all	Requires direct, intimate contact with fresh unfilmed metal under high stress.
Dry Chlorine Gas	general corrosion and/or ignition/burning	all	Occurs when water content is below 0.5–1.0 wt % depending on temp.
Pure Oxygen Gas	ignition/burning	all	Dependent on alloy composition, component thermal mass, and gas pressure.
Warm Alkaline Peroxide Solutions	general corrosion	all	Dependent on peroxide solution composition, pH, and temp.
High-temp Air or Oxygen-containing Gas Exposures (>600°C)	metal oxidation, wastage, and/or embrittlement	all	Dependent on alloy composition, temp., and exposure time.

electrochemical methods. Electrochemical anodic and cathodic polarization testing is often used to supplement weight loss testing. Polarization testing can identify whether the alloy is truly fully passive or possibly metastable; this is often not discernible from weight loss tests alone. The immersion test procedures described in ASTM G 1 (Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens) and G 31 (Practice for Laboratory Immersion Corrosion Testing of Metals) apply, provided several modifications are observed [1,26]. These modifications focus on test sample surface preparation and post-test sample-cleaning procedures. A typical laboratory test apparatus for weight-loss immersion testing in acid solutions at or below the boiling point is shown in Fig. 2.

The type of sample surface finish tested should resemble the one expected in service. For titanium alloys, this is frequently the pickled finish, although sandblasted, ground, or machined surfaces are also common. The initial degreasing of test samples should avoid chlorinated organic solvents (with higher-strength titanium alloys), anhydrous methanol, or hot alkaline cleaners. Acceptable cleaning solvents include methyl ethyl ketone (MEK), acetone, most alcohols, benzene, and most detergent solutions. The pickled finish

can be prepared by pickling the metal in a 35 vol % HNO<sub>3</sub>-5 vol % HF solution (based on 48 wt % HF and 70 wt % HNO<sub>3</sub> stock acid solutions, with the balance being water) at 20–55°C for 0.5–5 min or more. Typically, 0.005–0.05 mm (0.2–2 mils) of sample surface is removed in this process, depending on surface requirements. More dilute solutions, such as 12 vol % HNO<sub>3</sub>-1 vol % HF, can also be used if slower pickling rates are desired. In any case, a minimum 7:1 HNO<sub>3</sub>:HF stock acid vol % ratio should be maintained to avoid excessive uptake of hydrogen in titanium alloys during pickling. After pickling, a quick rinse in deionized water and air drying leaves a shiny gray specimen that is ready for weighing. The abraded surface finish can be obtained by wet grinding with fine grit SiC or Al<sub>2</sub>O<sub>3</sub> abrasive paper after the cleaning step. A final deionized water rinse and drying would prepare the specimens for weighing and testing. Prepared and weighed titanium samples may be stored in open air prior to exposure for several days without significantly affecting sample weight.

A mechanically abraded or polished coupon surface finish is highly recommended over pickled finishes when corrosion testing titanium alloys containing readily reducible (noble) alloying elements. These alloys include those containing

**FIG. 2—Typical Huey test apparatus with water-cooled condenser for conducting sample general corrosion (weight-loss) tests up to the solution boiling point. Samples are typically suspended in the solution by Teflon® string or glass rods.**

platinum group metals (Pd, Ru, Pt) and other metals (Ni, Cu), which may readily plate back in pure form onto titanium coupon surfaces during the pickling process. These plated metal residues can ennoble coupon test surfaces, and may not represent the most conservative test methodology.

Consideration should be given to the presence of certain test solution contaminants that may significantly affect the corrosion rate. More specifically, contamination of acid media with transition metal ions, such as ferric, nickel, cupric, and chromic ions, and other oxidizing species should be avoided because these ions act as cathodic depolarizers and inhibit corrosion in most acid media. In nitric acid testing, dissolved silicon,  $\text{Ti}^{+4}$ ,  $\text{Fe}^{+3}$ , and most precious metal ions are fairly effective inhibitors and will lower corrosion rates. In strong nitric acid media, it is best to avoid prolonged testing in glass, and the accumulation of dissolved  $\text{Ti}^{+4}$  corrosion product, which inhibits corrosion. This can be counteracted by frequent solution change or refreshment. In most reducing acids, such as HCl,  $\text{H}_2\text{SO}_4$ , or  $\text{H}_3\text{PO}_4$  (but not HF), testing in glass flasks is acceptable. The  $\text{Ti}^{+3}$  ion corrosion product normally formed and dissolved in a reducing acid medium does not appear to affect corrosion

significantly except at near-saturated concentrations, but mild oxidizing agents mentioned earlier, such as the transition metal ions (particularly those in higher oxidation states) may inhibit corrosion at concentrations above several ppm. It is recommended that the solution be constantly refreshed or changed at least every 24 h in corrosion tests where foreign ions are generated from corrosion processes in order to minimize their effects. It is also critical that the degree of aeration (dissolved  $\text{O}_2$  level) and other background chemistry variables in the test media that influence titanium passivity be taken into account to achieve valid and relevant test results.

The presence of surface corrosion products on titanium after testing depends on the environment to which the titanium was exposed. Removal of these products, when formed, is necessary for obtaining the proper weight loss data, and the correct corrosion rate. In media where the titanium has remained essentially passive, such as near-neutral brines, the original shiny metal luster will usually still exist, and the specimens need only be rinsed in distilled water before their final weighing. Most deposits from the medium that adhere to the specimen surface and are nontitanium corrosion products may be cleaned off in a warm ( $\leq 65^\circ\text{C}$ ) 25 vol %  $\text{HNO}_3$ -25 vol % HCl solution or a 50 vol %  $\text{HNO}_3$  solution. Other compatible post-test acid cleaning solutions include  $\leq 10$  wt % HCl or  $\text{H}_2\text{SO}_4$  inhibited with a minimum of 1000 ppm ferric ( $\text{Fe}^{+3}$ ), cupric ( $\text{Cu}^{+2}$ ), chromate ( $\text{Cr}^{+6}$ ), or molybdate ( $\text{Mo}^{+6}$ ) ions up to  $70^\circ\text{C}$ . Note that amine-type corrosion inhibitors are not effective for titanium. Siliceous scales may be removed in warm ( $< 65^\circ\text{C}$ ) solutions containing  $\leq 20$  % NaOH inhibited with 1 wt %  $\text{NaNO}_3$ , NaOCl,  $\text{NaCrO}_3$ , or  $\text{Na}_2\text{MoO}_4$ . The use of strong, uninhibited mineral acids such as HCl,  $\text{H}_2\text{SO}_4$ ,  $\text{H}_3\text{PO}_4$ , and especially HF are not recommended for cleaning, since they will corrode the metal samples; this also explains why the electrolytic cleaning method mentioned in ASTM G 1 is not used.

In media where the titanium does have a low but finite corrosion rate and where the dissolving titanium hydrolyzes back onto the surface of the specimen (such as dilute, hot reducing acids) or in very strongly oxidizing media (such as boiling concentrated  $\text{HNO}_3$ ), a titanium oxide-hydroxide corrosion product may build up slowly on the surface. This oxide film or deposit is not soluble in common mineral acids and cleaning solutions. The more desirable means of cleaning the specimen of titanium corrosion product or even stubborn nontitanium deposits is a fine grit- or glass bead-blasting procedure. Tests run in the laboratory suggest that the use of 120 or finer grit silica or alumina sand to lightly blast off titanium surfaces results in acceptably small weight losses in sample coupons. Weight losses in the  $10^{-4}$  g range may be incurred when light sandblasting ( $\leq 5$  s exposure) is used, and these can be corrected for by exposing an untested titanium specimen to the same blasting procedure and correcting for its weight loss. A final rinse in distilled water after sandblasting leaves the dried specimen ready for weighing. Titanium specimens that have been exposed to hot, strong reducing acids in which the corrosion rate is quite high generally exhibit chemically roughened matte-gray hydrided metal surfaces, which may not require surface cleaning.

Immersion testing will generate weight loss data, or corrosion current measurements can be obtained from standard electrochemical polarization tests (see ASTM G 5, Standard Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements; see also Ref 27). Corrosion rates in millimeters per year (mpy) for titanium alloys can be calculated from sample weight loss data as follows:

$$\text{Corrosion rate (mm/y)} = \frac{(8.76 \times 10^4)(W)}{(d)(A)(t)}$$

where:

$d$  = alloy density in g/cm<sup>3</sup>,  
 $A$  = sample surface area in cm<sup>2</sup>,  
 $t$  = exposure time in h,  
 $W$  = weight change in g.

Corrosion rates in mpy (thousandths of an inch per year) can be derived using the formula:

$$\text{Corrosion rate (mpy)} = \frac{(534,700)(W)}{(d)(A)(t)}$$

where:

$W$  = weight change in g,  
 $d$  = alloy density in g/cm<sup>3</sup>,  
 $A$  = sample surface area in in.<sup>2</sup>,  
 $t$  = exposure time in h.

A list of density values for common commercial titanium alloys is given in Table 3.

Corrosion rates in mm/y can be calculated from electrochemical measurements by using the formula:

$$\text{Corrosion rate (mm/y)} = \frac{(3.3)(i_{\text{corr}})(EW)}{d}$$

where:

$i_{\text{corr}}$  = the measured corrosion current in mA per cm<sup>2</sup>,  
 $d$  = alloy density in g/cm<sup>3</sup>,  
 $EW$  = the equivalent weight (at. wt./valence state) for titanium.

**TABLE 3**—Room temperature density values for some commercial titanium alloys.

Alloy	Density, g/cm <sup>3</sup>
Ti Gr.1, 2, or 3	4.51
Ti Gr.7, 11, 16, 17, 26, or 27	4.51
Ti Gr.12	4.52
Ti Gr.9, 18, or 28	4.48
Ti Gr.5, 23, or 29	4.42
Ti-6-2-4-6	4.68
Ti-10-2-3	4.64
Ti-15-3-3-3	4.78
Ti-3-8-6-4-4 (Ti Gr.19)	4.82
Ti Gr.21	4.93

<sup>2</sup>ASTM Standard G 30, Practice for Making and Using U-Bend Stress-Corrosion Test Specimens; G 35, Practice for Determining the Susceptibility of Stainless Steels and Related Nickel-Chromium-Iron Alloys to Stress Corrosion Cracking in Polythionic Acids; G 36, Practice for Performing Stress-Corrosion Cracking Tests in a Boiling Magnesium Chloride Solution; G 47, Test Method for Determining Susceptibility to Stress-Corrosion Cracking of High-Strength Aluminum Alloy Products.

The equivalent weight for titanium is 16 g per equivalent under reducing acid conditions (Ti→Ti<sup>+3</sup>), and 12 g per equivalent under oxidizing conditions (Ti→Ti<sup>+4</sup>). The value of  $i_{\text{corr}}$  is typically determined from Tafel slope extrapolation or linear polarization methods [27–29].

## Crevice Corrosion Testing

Crevice corrosion is a form of localized attack of titanium alloys that may occur in higher temperature (>70°C) chloride, bromide, iodide, fluoride, and/or sulfate-containing solutions; its occurrence is highly dependent on alloy composition, solution pH, and temperature. Crevice attack on titanium requires the presence of large and very severe (tight) crevices, such as gasket-to-metal flange joints or seals, tube-to-tubesheet joints, metal-to-metal joints, or adherent process stream deposit/scale crevice formers found in service. Attack typically takes the form of irregularly shaped craters or pits, with voluminous, off-white, light gray, or sometimes black corrosion product caps as pictured in Fig. 3. Metal surfaces adjacent to active crevices may sometimes display vivid oxide film coloration from hydrolyzed acidic crevice solutions. The mechanism for titanium alloy crevice corrosion is generally similar to that for stainless steel and nickel alloys, in which oxygen-depleted reducing acid conditions develop within tight crevices as detailed elsewhere [1,30].

Crevice corrosion testing of titanium alloys generally aims at determining go/no-go performance information. The rate of crevice corrosion is of little practical interest, because crevice attack is generally insidious and very rapid. Thus, crevice corrosion cannot be tolerated in any form. Many crevice test assemblies have been used, including the multiple-crevice (serrated) washer (ASTM G 78, Guide for Crevice Corrosion Testing of Iron Base and Nickel Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environments), the Dutchman or spool rack (ASTM G 4, Method for Conducting Corrosion Coupon Tests on Plant Equipment) assembly, and the sheet sandwich-type assembly. The multiple-crevice (serrated) washer is generally not a conservative test and not recommended, since titanium is highly crevice-resistant and requires a relatively large creviced surface area for crevice corrosion initiation. The larger creviced surface area and depth of the sheet sandwich-type assembly, illustrated in Fig. 4, dramatically increases susceptibility to attack and is most commonly used. This method uses a test assembly in which thin gasket sheets (typically TFE, FEP, or other gasket material of interest) are interspersed between flat metal sheet or plate coupons to produce the desired number of metal-to-metal and/or metal-to-gasket crevices, or both. In some cases, even curable polymeric sealants (i.e., EPDM or polymethylacrylate) are applied to coupon surfaces prior to assembly. Coupons are typically 1 in. by 1 in. (25 mm by 25 mm) or larger to create large, deep creviced surfaces. Each test assembly is fastened together with a centerline titanium bolt and nut and tightened down to a torque of 25–90 in.·lb (2.8–10.1 m·N) to create tight, severe crevices. The titanium assembly bolts and nuts may be of the same titanium alloy being tested, or covered with an insulating, PTFE sleeve or tape wrap to avoid galvanic interferences.

It is important that coupon surfaces be flat and, especially, as smooth as possible (low RMS roughness) to minimize crevice gap and volume and, thereby, stimulate initiation. Highly roughened sandblasted or ground surfaces exhibit reduced crevice corrosion susceptibility. Although a 240 grit wet-ground coupon surface finish may be considered a minimum requirement, a 400 grit finish or finer is recommended for most conservative test results. Preparation of crevice test coupons follows the same procedures as that for general corrosion test coupons. Note that it is also vital that only the virgin grade of fluoropolymer gaskets (e.g., PTFE, FEP, or Viton) be used in these tests, since nonvirgin (reprocessed) grades may release fluorine compounds during test exposures that may falsely stimulate localized attack.

Laboratory crevice testing is usually conducted in glass flasks and vessels, titanium alloy autoclaves, or other resistant alloy autoclaves. The minor presence of background and/or contaminating metal ion species or other oxidizing species may aggravate crevice attack. Thus, it is also vital that suitable test vessels be selected and that the representative degree of aeration, pH, and other aspects of background solution chemistry be controlled and simulated. Although crevice corrosion can initiate within the first several hours of exposure, a minimum test duration of 30 days is recommended in order to develop a sufficient degree of attack for detection and measurement purposes.

Post-test evaluation of crevice test coupons may require removal of titanium oxide/hydroxide corrosion products (see Fig. 3) if crevice attack has occurred. Common mineral acids and reagents will not dissolve these tenacious deposits. A light ( $\leq 120$  grit and  $< 5$ – $8$  s) sandblasting or glass-bead blasting of coupon surfaces will readily remove these scales and facilitate visual examination of pitted surfaces (per ASTM G 46, Practice for Examination and Evaluation of Pitting Corrosion), and permit sample weighing after water rinsing. Creviced coupon surfaces are often highly colored after hot aqueous exposures, but reveal no visible pits after sandblasting. This is indicative of the very slight growth of a protective surface titanium oxide film, which is considered quite normal and acceptable from a performance standpoint. Slight coupon weight gain is often measured in this situation. In addition to visual examination and weight change measurements, monitoring of creviced specimen potential [31,32] and current [33] has been used to a limited extent to identify the initiation of crevice corrosion. Examination of polished and etched metallurgical sections through pitted areas of creviced coupons may also provide additional information concerning depth of attack and mechanisms of crevice initiation and propagation.

**FIG. 3—Typical example of crevice corrosion of titanium in hot chloride brines. (a) Irregularly-shaped crevice corrosion attack on Grade 2 titanium tubing. (b) Photomicrograph of cross section through crevice corrosion site in Grade 2 titanium showing the titanium oxide corrosion product cap and irregular attack profile (100 $\times$  magnification).**

**FIG. 4—Typical crevice test assembly for crevice corrosion testing of titanium alloy sheet or plate coupons. Sequence of coupons and gasket sheets can be modified to form gasket-to-metal and/or metal-to-metal crevices.**

### Pitting Potential Testing

The susceptibility of an alloy to pitting on openly exposed surfaces (in the absence of crevices) in a given solution and fixed temperature is normally assessed by determination of anodic pitting potential values. The two pitting potentials of interest are (1) the extrinsic, surface-dependent anodic breakdown potential ( $E_b$ ), and (2) the conservative, intrinsic anodic repassivation potential (or protection potential ( $E_{prot}$ )) that defines the minimum potential at which pitting is possible in the test environment.

The anodic breakdown potential of titanium alloys is typically determined by the potentiodynamic (potential scan) technique (ASTM G 3, Practices for Conventions Applicable to Electrochemical Measurements in Corrosion Testing, and ASTM G 5) at slow scan rates ( $\leq 0.5$  mV/s). Since this value is sensitive to sample surface condition, it is vital that the representative metal surface anticipated in service be tested. Titanium alloy repassivation potential, on the other hand, may be measured by a galvanostatic method [34], the constant potential-surface scratch test [27,29,34], or reverse scan potentiodynamic method. The galvanostatic method is quick, easy, and generally preferred, and involves impressing a constant anodic current density of approximately  $+200$  mA/cm<sup>2</sup> on the specimen for at least several minutes before measuring the sample polarization potential relative to a reference electrode. This potential, once stabilized and corrected for electrolyte IR drop, represents the anodic repassivation potential. The constant potential-scratch method is more tedious and time-consuming, involving trial iterations for bracketing the critical potential. Potentiodynamic scan reversal (ASTM G 3 and G 5) after scanning anodically to induce breakdown pitting may produce ambiguous results with nonreproducible, scan rate dependent repassivation potential values.

The exceptionally high anodic pitting potentials of titanium alloys in most aqueous solutions means that: (1) oxidizing acid solutions such as FeCl<sub>3</sub> or Fe<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> solutions (ASTM G 28, Test Methods for Detecting Susceptibility to Intergranular Attack in Wrought Nickel-Rich Chromium-Bearing Alloys, and G 48, Test Method for Pitting and Crevice Corrosion Resistance of Stainless Steels and Related Alloys by the Use of Ferric Chloride Solution) cannot be used to identify critical pitting parameters, and (2) potential range and/or power requirements for potentiostats/galvanostats are greater than that for most other common metals and alloys. In chloride solutions, for example, a potentiostat or galvanostat with an impressed sample potential output range as high as  $+10$  to  $+12$  V may be required for pitting potential determinations. Practical counter-electrodes for these electrochemical techniques include glassy carbon and platinum.

### Stress Corrosion Cracking Testing

SCC test methods commonly used for metals [35] are all applicable to titanium alloys, as long as relevant mechanical and physical properties are accounted for. This means formulating applied stresses based on alloy strength and/or elastic modulus values for the appropriate sample orientation, which is corrected for test temperature when appropriate. The smaller spread between yield and ultimate strength and lower plastic strain limits exhibited by titanium alloys compared to most other CRAs also means limiting applied sample stresses values to  $\leq 105$  % yield strength in static- or deflection-loaded tests. Since many titanium alloy products can exhibit significant crystallographic texture depending on alloy type and processing history, it is advisable that SCC susceptibility be evaluated with regard to sample orientation as well. In  $\alpha$  and  $\alpha$ - $\beta$  alloy mill products, for example, greater susceptibility is often associated with the direction along hcp basal plane intensification (e.g., T-L direction in unidirectional processed products.)

Test methods for assessing the SCC resistance of titanium alloys can be grouped into three basic categories:

*Category 1* tests use smooth, statically loaded specimens, such as U-bend, C-ring, bent beam, and dead-loaded tension specimens (described in ASTM G 30, G 35, G 36, G 38, G 49, and G 472).

*Category 2* tests are fracture mechanics tests that use notched and precracked specimens that are statically or dynamically loaded, such as cantilever beam, compact tension, and double cantilever beam specimens, and are conducted per ASTM E 399, Test Method for Plane-Strain Fracture Toughness of Metallic Materials.

*Category 3* tests use smooth or notched tension specimens that are dynamically loaded at very low strain rates; the slow strain rate test (SSRT) is the primary example.

Selection of a suitable SCC test method for titanium alloys is primarily determined by the nature of the stress cracking data or design information desired and by the chemical nature of the test environment relative to titanium alloy passivation. For simple go/no-go assessment of SCC with no quantitative cracking parameters, the least costly Category 1 tests may be adequate if SCC initiation (incubation) periods are not too long. The data are typically considered in terms of sample stress versus time to failure, as shown in Fig. 5a. SSRT results are generally assessed as comparisons or ratios of test sample ductility and/or time-to-failure values to those from a reference (control) sample (tested in air or inert gas), providing some sense of relative SCC susceptibility. However, confirmation of SCC occurrence must also entail examination of SSRT sample fracture surfaces for indications of SCC (i.e., cleavage, intergranular cracking, and/or secondary cracking).

If fracture mechanics design information (i.e.,  $K_{ISCC}$  or Stage I or II crack growth parameters) is required, then the more sophisticated, costly Category 2 tests are the obvious choice (Figs. 5b and 5c).  $K_{ISCC}$  results for titanium alloys are stress- and time-dependent, such that  $K_{ISCC}$  values may be plotted as a function of time to failure to reveal true, conservative  $K_{ISCC}$  values. Sufficient test periods (typically 1–10 h) at each stress-intensity level tested should be allowed to ensure that the “plateau” shown in Fig. 5b has been reached.

Slow-strain-rate testing (SSR) is a highly sensitive, rapid, most discriminating, and conservative SCC test method for titanium alloys. In some cases, it is too conservative from a design/use standpoint because the surface-oxide film is continuously being broken during straining to failure. This method is particularly useful for rapid alloy screening and sorting, and provides a relative and/or semiquantitative sense of alloy SCC susceptibility. Discriminating strain rates for titanium alloys in aqueous and methanolic solutions lie within the  $10^{-5}$  to  $10^{-7}$  s<sup>-1</sup> window.

Selection of an appropriate SCC test method for titanium alloys may also be based on the particular type of environment to be tested. In environments where alloy repassivation (oxide film formation) is favored, and where Stage I subcritical cracking is generally not observed, Categories 2 and 3 tests are more severe and discriminating than Category 1 tests. This is the case for aqueous media, including salt water and brines, and chlorinated organic solvents in

FIG. 5—Various types of SCC test data presentation: (a) typical for Category 1 tests, (b) and (c) typical for Category 2 tests.

which cracking failure of Category 1 specimens is generally not observed at near-ambient temperatures. One must provide initial or continued local oxide film breakdown, such as in Categories 2 and 3 tests, to expeditiously initiate and manifest potential SCC tendencies in these alloys. Exceptions to this rule are those very few titanium alloys that may exist in highly sensitized metallurgical conditions. For example, alloys susceptible to SCC in ambient neutral salt water in smooth or notched samples include step-cooled Ti-8Al-1Mo-1V and Ti-13V-11Cr-3Al alloys. Highly stressed Category 1 test specimens may also be applicable for testing in hot aqueous halides or chlorinated solvents, where higher temperatures may overcome SCC activation barriers in certain alloys after sufficient exposure periods.

For environments where Stage I subcritical cracking behavior occurs and repassivation is not favored, Category 1 tests are often preferred over Categories 2 and 3 tests for practical reasons. These environments include methanol, red-fuming nitric acid,  $N_2O_4$ , liquid/solid metals, molten salts, and hot salt. Note that Category 2 testing is not physically applicable to the evaluation of solid metal embrittlement and hot salt SCC in these alloys. Also, note that hot salt SCC testing of titanium follows the guidelines and procedures provided in ASTM G 41, Practice for Determining Cracking Susceptibility of Metals Exposed Under Stress to a Hot Salt Environment.

### Hydrogen Testing

Testing to determine the susceptibility of a titanium alloy to hydrogen uptake and embrittlement should simulate conditions expected in service. In hydrogen gas atmospheres, simple coupon exposures for as long as is deemed practical are recommended to ensure significant uptake, if it occurs. The gas atmosphere must duplicate exact gas chemistry, particularly with respect to water and oxygen content. Mere traces of moisture, for example, will effectively inhibit hydrogen absorption by titanium in dry hydrogen gas and possibly cause test interference.

Galvanic coupling tests or cathodic charging tests can also be conducted to evaluate susceptibility to hydrogen uptake. For a given environment and temperature, an active metal (iron, aluminum, etc.) sample is galvanically coupled to the titanium alloy sample, such that a specific anode-to-cathode surface area is tested. Impressed cathodic charging tests are performed in electrolytic cells containing a specific electrolyte. A power supply (potentiostat or galvanostat) impresses a constant potential or current on the cell, such that the titanium is cathodic relative to an inert counter-electrode such as graphite or platinum. A reference electrode can also be used to control or to measure the polarization potential of the test cathode. There are no standardized test methods or setups for cathodic charging studies; therefore, they are designed to best simulate conditions anticipated in service. Two examples of typical laboratory charging cell setups are depicted in Figs. 6a and 6b. Note the presence of a porous diaphragm in these cells to minimize unwanted intermixing of cathode/anode by-products and catholyte contamination. Catholyte refreshment should also be considered to maintain representative electrolyte composition and pH.

The surface condition of the test sample is a critical variable in all hydrogen uptake tests. Studies have shown that abraded or sandblasted surfaces absorb hydrogen more readily than as-pickled surfaces [7]. Thickening of the surface oxide film by anodizing or thermal oxidation further retards absorption. The actual surface finish anticipated in service should be evaluated.

After test exposure, sample evaluation for hydrogen may include tensile, notched tensile, bend, ductility (for example, drawn cup), and/or impact Charpy tests, hydrogen analysis, or cross-sectional microstructural examination, or a combination thereof. Uniaxial, smooth-specimen tension testing is generally of little value in diagnosing the subtle embrittling effects of hydrogen. Titanium alloys tend to

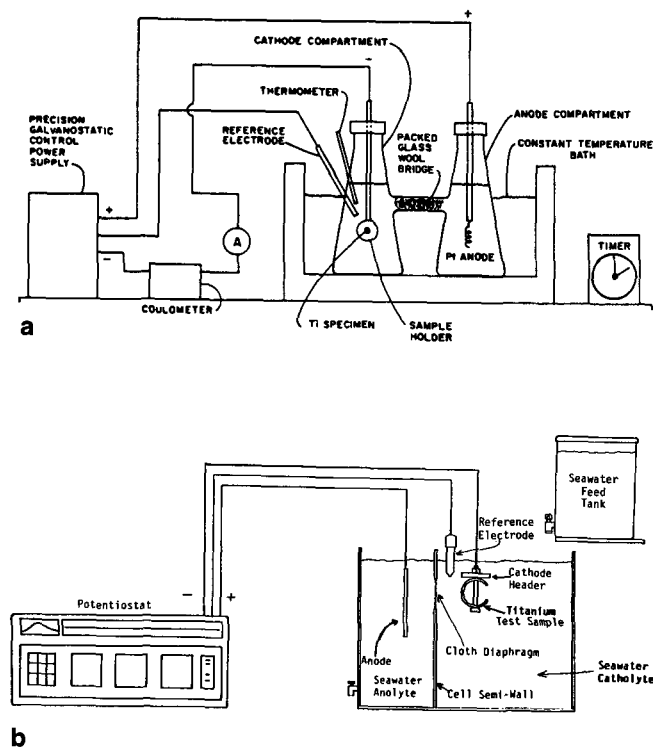

FIG. 6—Typical examples of laboratory cell setups for cathodic charging tests on titanium alloys. (a) Typical cell setup for short-term cathodic charging of titanium samples at constant current in hot acidic electrolytes. (b) Typical cell setup for longer-term cathodic charging of titanium samples at constant potential in seawater and brines.

exhibit susceptibility under biaxial or triaxial stress states; therefore, bend tests, cup tests, or notched tension tests are generally more sensitive to hydrogen effects. Impact toughness testing can be an especially sensitive indicator of hydrogen effects in  $\alpha$  alloys, whereas slow strain rate methods are very suitable for  $\alpha$ - $\beta$  alloys [21,22,25]. Because hydrogen content has relatively little effect on alloy hardness, hardness testing is generally of little use.

Some titanium alloys may be susceptible to sustained load cracking (SLC), also known as delayed cracking. This can occur on  $\alpha$ ,  $\alpha$ - $\beta$ , and aged  $\beta$  alloys that are highly stressed in tension for sustained periods. SLC susceptibility increases with increasing hydrogen content, alloy aluminum- or oxygen-equivalency, decreasing strain rate, and increasing stress intensity [23,36]. Highest susceptibility generally occurs at or somewhat below room temperature [23], and diminishes at higher temperatures.

SLC test severity increases (to the right) according to the following types of test specimens: smooth tensile << notched tensile << loaded pre-cracked specimen. Typical  $K_{ISLC}$  data dependence with test time (i.e., time-to-failure) is depicted in Fig. 7 with respect to  $K_{IC}$  (air) and  $K_{ISCC}$  (salt water). Approximate test time scale typically ranges anywhere from a few to 20 h [23,36]. Since alloy microstructure and, especially, product crystallographic texture strongly influence SLC susceptibility, it is important to consider the

FIG. 7—Generalized test time dependence of  $K_{ISLC}$  values measured for high strength titanium alloys, as compared to their  $K_{IC}$  and  $K_{ISCC}$  values.

sample orientation of interest for testing. Examination of post-test specimen fracture surfaces should reveal low-energy facets of quasi-cleavage under high magnification SEM examination if SLC has occurred.

Hydrogen analysis of coupons is performed by the hot vacuum extraction method. In the hot vacuum extraction apparatus, a small sample is heated to between 1100 and 1400°C for several minutes within a chamber to reversibly release the absorbed hydrogen, which is subsequently measured. LECO Hydrogen Analyzers offer measurement resolution on the order of  $\pm 5$  ppm at sample hydrogen levels below 200 ppm. It is critical to note that the analyzed hydrogen content may be directly dependent on the test sample thickness tested if a nonhomogeneous distribution (i.e., hydrogen gradient or surface film) of absorbed hydrogen exists within the sample. If the hydrogen is uniformly distributed or diffused through the sample cross section (which is often not the case), no sample thickness dependence exists and the hydrogen content may be directly used to predict or correlate with metal behavior and properties.

Since hydrogen chemical analysis only provides the total hydrogen present in a given sample cross section, test samples are often metallurgically sectioned and examined for hydride phase to determine the hydrogen distribution. This technique, which is only useful in  $\alpha$ , near- $\alpha$ , and leaner  $\alpha$ - $\beta$  titanium alloys, involves wet-abrasive wheel- or saw-cutting through the sample cross section, wet-grinding down below any worked or heat-affected metal, and hand-polishing down through abrasive papers and slurry/cloth wheels down to 0.05  $\mu\text{m}$  alumina. Sample edge retention is vital in this hand-polishing technique. Final light etching with an HF/HNO<sub>3</sub> type etch (i.e., Kroll or Oxalic etches) should reveal the acicular hydride precipitates (Fig. 1), if present, which tend to etch out first. Intermediate electropolishing followed by etching may also be employed if sample edge (surface) retention is not critical or of interest. Basic guidelines and procedures for preparation of titanium alloy samples for metallographic examination can be found in Ref 37.

Microscopic examination of hydride phase precipitates is typically conducted at magnifications of 200 to 1000 $\times$ , depending on hydride size and quantity.

### Ignition Testing

Titanium alloys can be susceptible to ignition or burning, or both, in very few special gas environments, such as pure gaseous or liquid oxygen, oxygen-enriched gas mixtures, and dry chlorine gas [1]. These highly exothermic reactions generally increase with increasing gas pressure, concentration, flow rate, and temperature. Normally, the nonreactive, protective surface oxide film on titanium must be removed, damaged, or penetrated for ignition and reaction to occur. In the case of oxygen gas, burning is sustained only if the local metal surface temperature remains at or above the alloy's melting point, above which formation of the protective oxide film is not possible. Any factor that removes local heat generated, such as increased metal thermal conductivity and/or section thickness (i.e., increased thermal mass), will inhibit or diminish ignition and burning tendencies.

Although no standard metal ignition tests exist, testing has traditionally been aimed at identifying ignition and sustained burning thresholds of a metal as a function of gas pressure, concentration, and temperature. Ignition and burning tests may be categorized as either static or dynamic, depending on whether the reaction gas is nonflowing (static) or continuously flowing past the test sample through a test chamber. Since increased gas flow rate exacerbates metal ignition and burning, the dynamic tests tend to produce more conservative thresholds.

Ignition tests must incorporate a means of breaking or removing the surface oxide film and exposing fresh metal surface on the sample. This can be achieved by a variety of methods [38], including tensile straining to fracture, puncture, impact, severe surface abrasion or scratching, severe plastic straining, explosive shock, or high-energy beams (i.e., laser) [39] or electric sparks focused on the metal test sample. Tensile rupture of test samples within pressurized test vessels has been most commonly employed for testing in oxygen-rich gas mixtures [40–42] and dry chlorine gas [43]. A typical ignition test setup using tensile rupture is

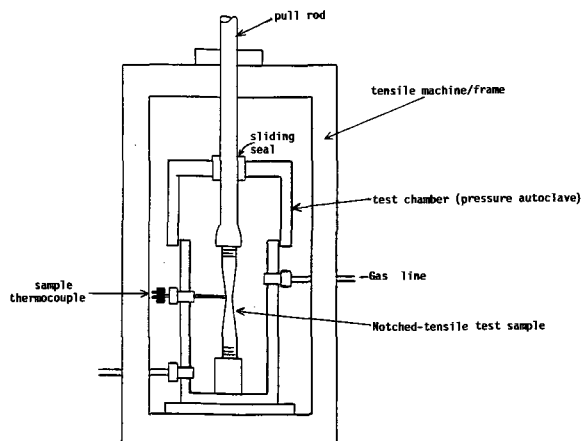

FIG. 8—Typical ignition test setup for titanium samples using tensile rupture.

depicted in Fig. 8. Continuous measurement of gas pressure and test sample temperature can provide an indirect means of assessing ignition occurrence. Go/no-go assessment of ignition is usually based on post-test visual examination of sample fracture surfaces for melting or oxide scaling, or both. More sophisticated burn testers may incorporate continuous video monitoring and pyrometers, or other heat sensors to track the ignition/burn event.

Burning or sustained combustion testing of titanium alloys typically involves intentional localized heating of a test sample at one end or location to a temperature above its melting point. This localized focused sample heating can be achieved by laser, electron beam, electric arc, electrical resistance, or plasma arc methods. Once sample ignition is induced, the ignition heating source is removed, and duration and extent of sustained sample burn is measured. One commonly used burn test uses a 4-in. (102-mm) long, 0.125-in. (3.18-mm) diameter test sample (rod) that is ignited on one end by electric arc. The rod length remaining after the test is measured and used to rate alloy burn susceptibility. Design details and setup of static and flow (dynamic) burn testers are presented in Figs. 9 and 10, and are discussed in more detail in Ref 44. Note that test sample size, geometry, and section thickness directly influence burn susceptibility, and must be standardized for comparative tests and specified in all cases.

FIG. 9—Static burn tester using promoted metal sample ignition [42].

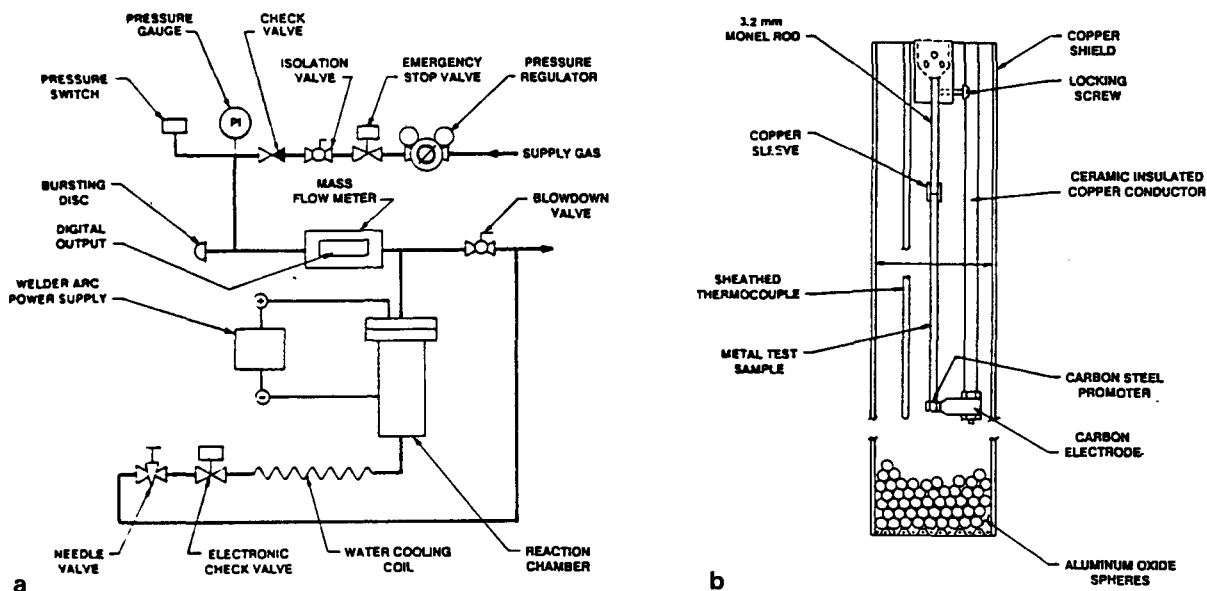

FIG. 10—Photomicrograph (400 $\times$ ) illustrating example of a hard oxygen-rich surface layer (alpha case) on  $\alpha/\beta$  and  $\beta$  titanium alloys after high-temperature air exposure.

### Oxidation Tests

Although titanium alloys are highly resistant to oxidation up to moderate temperatures, colored protective surface oxide films form in air at 370–595°C. Depending on exposure time at temperature and alloy composition, oxide film or scale growth may become excessive and unacceptable for engineering purposes above ~620°C. In terms of titanium alloy content, increasing vanadium, manganese, and zirconium concentrations are generally detrimental, whereas increasing molybdenum, niobium, silicon, and chromium concentrations tend to retard oxidation. Elevated aluminum content, as in the titanium aluminide intermetallics, markedly enhances oxidation resistance, elevating titanium alloy use windows by a few hundred degrees.

In addition to oxide film or scale formation at elevated temperatures, titanium alloys can also experience oxygen enrichment of metal surfaces beneath the oxide scale. These hard, brittle metal surface layers, known as “alpha case,” result from diffusion of oxygen or nitrogen interstitials, or both, into the metal. This time/temperature-dependent phenomenon becomes significant above ~540–590°C depending on alloy type, and severely reduces metal formability, ductility, and fatigue life, particularly as metal section thickness is reduced. Typical examples of an alpha case in  $\alpha/\beta$  and  $\beta$  titanium alloys are shown in Fig. 11.

Simple static oxidation testing of titanium alloys can be conducted per ASTM G 54, Practice for Simple Static Oxidation Testing, with a few unique considerations relative to post-test evaluation. Descaling of titanium samples after test exposure may employ mechanical scale removal or hot alkaline solution descaling. A light fine sand grit or glass-bead blast for several seconds are good mechanical descale methods if a procedure is prequalified to ensure insignificant substrate metal weight loss. Several high-temperature alkaline descale solutions based on concentrated KOH solutions

are available commercially for titanium alloys. Again, prequalification of the chemical descale procedure (i.e., exposure time and temperature) is recommended to avoid substrate metal corrosion. Conventional strong reducing acids will not dissolve heavy oxide films or scales on titanium and will attack the metal substrate and should, therefore, be avoided.

Metallographic examination offers valuable information once the sample is sectioned, mounted, hand-polished, and Kroll etched per recommended procedures outlined in Ref 37. The remaining metal sample thickness and the alpha-case layer thickness along the sample surface can be determined from the cross-sectioned mount. This alpha-stabilized layer is not visually discernable in  $\alpha$  alloys, but should be readily apparent when heavier than a few tenths of a mil in  $\alpha/\beta$  and  $\beta$  alloys (see Fig. 11). Subscale or

FIG. 11—Photomicrograph (400 $\times$ ) illustrating example of a hard oxygen-rich surface layer (alpha case) on  $\alpha/\beta$  and  $\beta$  titanium alloys after high-temperature air exposure.

internal oxidation attack is not typically observed with titanium alloys. Mechanical testing of samples after thermal exposure (i.e., tensile, bends, etc.) may also be of interest to assess extent of oxidation wastage and diffused interstitial embrittlement. Knoop or Vickers microhardness profiles of mounted and polished sample cross sections may also be useful in identifying heavy alpha case layers, since these oxygen-rich layers are substantially harder than the metal matrix.

# Zirconium and Hafnium

*Te-Lin Yau*<sup>1</sup>

## GENERAL CONSIDERATIONS

THE CHEMICAL PROCESS industry presents a complex set of materials selection challenges. Conducting corrosion testing of candidate materials under simulated or actual service conditions is widely used in the process of materials selection. ASTM G 4, Guide for Conducting Corrosion Tests in Field Applications and G 31, Practice for Laboratory Immersion Corrosion Testing of Metals, and NACE Standard TM-01-69, Laboratory Corrosion Testing of Metals are the general guides for conducting corrosion tests. While these standards can be very useful in making a preliminary list of the best candidate materials, they are designed primarily for the more common metals and alloys such as steel, aluminum alloys, and copper alloys. Certain portions of these procedures, e.g., cleaning methods, are not applicable to zirconium, hafnium, and their alloys. Although ASTM G 2 is designated specifically for zirconium, hafnium, and their alloys, it is a specific practice used in the nuclear industry. Therefore, a tailored practice for conducting corrosion specimen tests on zirconium, hafnium, and their alloys in chemical environments is needed. The use of test standards that have not been modified for zirconium or hafnium may lead to erroneous or invalid results.

For example, when field tests were conducted on zirconium and other materials in acetic acid environments, zirconium was the only metal tested to exhibit excellent corrosion resistance under most conditions [1]. However, severe general corrosion and pitting occurred in acetic acid when the acid contained both acetic anhydride and copper ions. The presence of copper ions was the result of the corrosion of copper specimens, which were tested at the same time. Zirconium resists attack by a wide range of acetic acid and anhydride environments when certain contaminants, such as copper ions, are avoided [2].

Standard practices must be modified for conducting laboratory or field tests on zirconium, hafnium, and their alloys. Emphasis must be placed on specimen quality and preparation, galvanic corrosion, test duration, contamination resulting from the corrosion of other metals, and handling of corroded specimens. The procedures recommended herein should be used in conjunction with the applicable ASTM and NACE standards previously mentioned. Additional information is available in Ref 3.

Zirconium and its alloys are susceptible to stress corrosion cracking (SCC) in such environments as  $\text{Fe}^{3+}$ - or  $\text{Cu}^{2+}$ -containing chloride solution,  $\text{CH}_3\text{OH}$  + halides, concentrated  $\text{HNO}_3$ , halogen vapors, and liquid mercury or cesium [4,5]. Common test methods, e.g., U-bend, C-ring, split ring, direct tension, double cantilever, and slow strain rate tension, have been used to determine zirconium's susceptibility to SCC.

## SPECIMEN IDENTITY

Zirconium ores generally contain a few percent of hafnium. Zirconium and hafnium are similar chemically and metallurgically but differ markedly in their nuclear properties. Zirconium is almost transparent to thermal neutrons and hafnium is highly opaque to thermal neutrons. As a result, there are nuclear and nonnuclear grades of zirconium, hafnium, and their alloys. The nuclear grades of zirconium materials are essentially hafnium-free, and the nonnuclear grades may contain up to 4.5 % hafnium. The alloy names Zircaloy, Zr-2.5Nb, and Zr1Nb apply to nuclear grade materials. Zircaloy is the general term for a series of zirconium-tin alloys containing minor amounts of iron, chromium, and nickel that were developed by the U.S. Navy Nuclear Propulsion Program. Only Zircaloy-2 and Zircaloy-4 are still in common usage. For commercial applications, ASTM specifications list three grades, namely, UNS R60702 (Grade 702), UNS R60704 (Grade 704), and UNS R60705 (Grade 705). Grade 702 is commercially pure zirconium, and Grades 704 and 705 are similar to Zircaloy-4 and Zr-2.5Nb, respectively.

For hafnium, Grade R1 materials, which are low in zirconium content, are for nuclear applications, and Grade R3 materials, which may contain a higher zirconium content, are intended for nonnuclear applications.

The first step in corrosion testing is to correctly identify corrosion specimens. When corrosion specimens need an identifying mark, a vibrating tool can be used.

## SPECIMEN QUALITY

Chemical composition and metallurgical condition are essential factors in determining corrosion properties. All specimens should be of known composition and metallurgical condition. Furthermore, each specimen should be examined

<sup>1</sup>Consultant, 1445 Belmont Avenue SW, Albany, OR 97321-3765.

**TABLE 1**—Results of EDX analyses of contaminated surface areas of untested specimens of Grade 702 zirconium from different sources.

Zn	—	—	—	—	—	3.61	—	—	16.37	—

visually for irregularities such as stains, scratches, foreign particles, etc. Unusual features should be recorded. Surface condition is very important in corrosion resistance.

Corrosion specimens may be unacceptable if they are not prepared properly. One of the major problems is cross contamination during specimen fabrication. Examples of contaminated surface areas of several Grade 702 zirconium specimens from different suppliers are given in Table 1. The specimen preparation can contaminate specimen surface as well when certain operations, such as bending and grinding, are employed. Tools should be clean in specimen-making processes. Surface condition plays an important role in corrosion and is particularly important to zirconium.

## PRECAUTIONS

Hazardous chemicals are frequently used in making and testing specimens of zirconium, hafnium, and their alloys. Detailed information on safe handling of involved chemicals should be obtained from competent sources.

## PREPARATION OF CORROSION SPECIMENS

### Corrosion Specimens

The size and shape of corrosion specimens are affected by several factors and cannot be rigidly defined. All convenient sizes are acceptable. Preferably, the edges of corrosion specimens should be machined in order to remove cold-worked metal. When the application demands, the specimens should include welds, cold-worked areas, and other features of the intended service.

### Cleaning

Usually corrosion specimens with as-manufactured surfaces are tested without further surface treatment other than cleaning. Corrosion specimens should be cleaned in a cleaner such as 5–10 % aqueous ammonia. An ultrasonic device can be used if available. Because of tightening regulation, organic solvents became undesirable cleaning agents recently. Use

a nylon brush or other nonmetallic brush if required. Rinse cleaned specimens in running cold water for five minutes. Then, specimens may be air-dried, wiped dry with a clean, lint-free cloth, or blown with clean, dry air. Handle cleaned specimens only with clean, lint-free gloves or forceps. When not being processed, enclose the specimens in a clean container or wrap in cloth, plastic, or clean heavy paper that will not affect weight or appearance.

### Pickling

Pickling is often applied to corrosion specimens to assure that the surfaces are free of surface contamination and uniform in nature. It is necessary if one of the following situations exists:

1. The surface of specimens is embedded with impurities.
2. The effects of pickling are being studied.
3. Specimens will be subsequently treated to form thick oxide films in air, water, steam, or molten salts.

Detailed procedures for pickling are given in ASTM G 2, Test Method for Corrosion Testing of Products of Zirconium, Hafnium, and Their Alloys in Water at 680°F or in Steam at 750°F.

### Dimensions, Weight, and Inspection

Measure and weigh each clean, dry specimen. Dimensions determined to the third significant figure and mass determined to an accuracy of 0.1 mg are suggested. Do not weigh specimens until they are thoroughly dry and at the same temperature as the balance. Examine each specimen for folds, cracks, blisters, foreign material, luster, brown acid stain, etc. Reject or reprepare any unacceptable specimen or record any significant observations prior to testing.

## CORROSION TESTING

### Specimen Mounting and Test Rack Installation

In laboratory testing, zirconium or hafnium specimens should not be placed in the same vessel with specimens of

other metals. The supporting device and vessel should also not cause contamination of the test solution.

In field testing, zirconium or hafnium specimens should be placed nearest the inlet of the process solution when other metals are also being tested. It is desirable to have the specimen or test rack securely fixed in place. Eliminate the possibility of galvanic effects resulting from metal-to-metal contact by using an insulating material.

A note should be made about the location and position of test specimens in the testing unit. Preferably, corrosion specimens should be placed so that any flow of liquid will be against the edges of the specimens. The same condition of agitation of the liquid should then be encountered by all specimens.

Tape, tube, and washers made of virgin fluorocarbon polymers can be used to prevent the galvanic coupling. Avoid insulated materials made of reprocessed fluorocarbon polymers, since free hydrofluoric acid may be formed from released fluoride ions. Properly oxidized zirconium or Zircaloy materials can also be used for this purpose. Zirconium oxide is an excellent insulating material.

### Test Solutions

Test solutions should be prepared accurately from chemicals conforming to the specifications of the committee on Analytical Reagents of the American Chemical Society and distilled water per ASTM D 1193 (Standard Specification for Reagent Water), unless they are naturally occurring solutions or plant solutions. The pH and specific gravity of fresh and tested solutions should be measured and recorded. Minor constituents should not be overlooked because they often affect corrosion rates. If there is any doubt, the composition of the test solutions should be checked by analysis. In corrosion testing, one should always expect the unexpected. For example, significant amounts of chloride and fluoride have been found in reagent grade nitric and sulfuric acids [6].

### Temperature of Solution

Temperature of the test solutions should be controlled within 2°C and the temperature must be reported with the test results.

### Aeration of Solution

Unless specified, the test solutions should not be aerated. Most tests related to process equipment should be run with the natural atmosphere inherent in the process, such as the vapors of the test solutions.

If aeration is required, test specimens should not be located in the direct oxygen or air stream from the sparger. Unrelated effects can be encountered if the gas stream impinges on the specimens.

If exclusion of dissolved oxygen is necessary, specific techniques are required, such as prior heating of the test solutions and sparging with an inert gas (usually nitrogen). A liquid atmospheric seal is required on the test vessel to prevent further contamination.

Tests at the boiling point should be conducted with the minimum possible heat input, and boiling chips should be

used to avoid excessive turbulence and bubble impingement. Cleaning may be needed to remove trace amounts of impurities in boiling chips before their usage. For example, amphoteric alundum granules, which may have some fluoride contamination, should be cleaned in boiling 20 % sulfuric acid for 24 h, rinsed in water, cleaned in boiling 40 % nitric acid for 24 h, rinsed in water, and dried.

### Duration of Test

Zirconium, hafnium, and their alloys can be either highly reactive or highly corrosion-resistant. In an incompatible environment, corrosion may occur within a short period of time, i.e., a few hours to a few days. On the other hand, in a compatible environment, there may be little change in mass (gain or loss) for years. Consequently, the commonly suggested test duration in hours, which is 50 divided by the corrosion rate in mm/y or 2000 divided by the corrosion rate in mpy, may be excessive and impractical. For example, if the corrosion rate determined from a short-term test is 0.0025 mm/y (0.01 mpy), the suggested test duration would be 20 000 h!

An often-used test schedule in testing zirconium or hafnium is the 2-4-2 day cycle. This schedule gives some indication about the time effect on the corrosivity of the test solution and the corrodibility of the test specimen.

Nevertheless, the duration of any test should be determined by the nature and purpose of the test. In studying the effects of a minor impurity, the duration of test can be 1 h or shorter, depending on the time required to measure an effect. In a confirmation test, the duration of the test can be 14 days to a year.

During the test, frequent checks should be made, if possible, at the test vessel for changes in solution color, temperature, pressure, bubbling, etc.

### Removal of Specimens from Test

The condition and appearance of the holder and specimens after removal from test should be noted and recorded. It is desirable to photograph the holder and specimens. Specimens should then be rinsed in water and dried. They can be cleaned with a nylon brush or other nonmetallic brush as required. In removing the specimens, care should be taken to keep them in proper order relative to each other so that any specimen may be identified from the original record of its position on the holder. This is important if corrosion has been so severe that identification marks have been removed. Tested specimens should be handled by forceps.

Specimens of zirconium and its alloys can be covered with a layer of pyrophoric film when they are tested under certain specific conditions, e.g., a stagnant solution of 77.5 % sulfuric acid and 200 ppm ferric ion at 80°C for ten days [7]. Treating in hot air or steam can eliminate this pyrophoric tendency. This takes 20 to 30 min at 250°C. It should be noted that most corroded specimens do not have a pyrophoric layer. The formation of pyrophoric films is possible, but not guaranteed when both the following conditions exist:

1. The test solution is stagnant or there are stagnant areas (e.g., under a gasket) on the test specimens.

2. The test solution can cause localized corrosion on a macroscale.

To clean exposed specimens, a nonmetallic brush or rubber stopper can be used if necessary. There is no applicable chemical or electrolytic cleaning method for zirconium, hafnium, and their alloys since their oxides and most of the other compounds are very inert.

### Interpretation and Calculation of Results

After exposed specimens have been cleaned, they should be reweighed with accuracy corresponding to that of the original weighing. The mass change during the test period can be the principal measure of corrosion. It should be noted that specimens of zirconium and hafnium may show weight gains after testing in certain oxidizing media, such as nitric acid, which result in the formation of insoluble oxide films.

The pH and specific gravity of spent solutions should be measured and recorded. Spent solutions should be saved for a reasonable period of time. They should be analyzed if test results are inexplicable.

Each tested specimen should be examined carefully for the presence of any pits or unusual marks. If there are any pits, the average and maximum depths of pits are determined with a pit gage or a calibrated microscope (refer to ASTM G 46, Practice for Examination and Evaluation of Pitting Corrosion).

If tested specimens are suspected of being subject to intergranular attack or hydrogen embrittlement, a cross section of the specimens should be metallographically examined for evidence of such attack.

Tested specimens may be subjected to simple bending tests to determine whether any embrittlement has occurred.

For corrosion-rate calculation, densities of Zr 702, Zr 704, Zr 705, and Hf are 6.50, 6.50, 6.53, and 13.1 g/cm<sup>3</sup>, respectively.

### REPORT

It is important to report all data as completely as possible. Expansion of the testing program in the future or correlating the results with other test results will be possible only if all pertinent information is properly recorded. The following checklist is a recommended guide for reporting all important information and data:

- Name of personnel and laboratory involved
- Date
- Identification of specimen material and number
- Form and metallurgical conditions of specimens
- Treatment used to prepare specimens
- Visual appearance remarks of each specimen before and after the corrosion testing
- Weights and dimensions of specimens before and after the corrosion testing
- Corrosive media and concentration (and any changes during test)
- Volume of test solution
- The color, pH and specific gravity of the test solution before and after the corrosion testing
- Temperature (maximum, minimum, and average)
- Aeration (describe conditions or technique)
- Agitation (describe conditions or technique)
- Type of apparatus used for test
- Duration of each test
- Number of specimens of each material tested, and whether specimens were tested separately or which specimens were tested in the same container
- Method used to clean specimens after exposure and the extent of any error expected by this treatment
- Evaluation of attack if other than general, such as crevice corrosion under support rod, pit depth and distribution, and results of microscopical examination or bend tests
- Corrosion rates for each specimen
- Minor occurrences or deviations from the proposed test program often can have significant effects and should be reported if known

# Tantalum and Niobium Alloys

E. B. Hinshaw<sup>1</sup> and K. D. Moser<sup>2</sup>

## TANTALUM

### General

A MAJOR FACTOR IN determining the specific applications of tantalum for corrosion-resistant equipment is its price. The cost of tantalum metal is about 15 times that of nickel-copper, nickel, or titanium and about 50 to 100 times that of the stainless steels. Accordingly, the service requirements for tantalum components are to have practically no corrosion degradation over time periods of years—virtually indefinite life. This means that the use of tantalum is limited to a relatively small number of the most severe media and conditions in relatively thin cross sections or as lining compared to other materials of construction. Selection of tantalum for use is based on large, not moderate, improvements of performance over other materials. Therefore, testing data do not need to be highly quantified. If corrosion rates greater than 0.051 mm/yr. (2 mpy) are indicated the application very likely is not recommended [1].

### Nature of the Metal

#### Electrochemical Behavior

The corrosion resistance of tantalum is due to a naturally occurring oxide film. The film is dielectric and electronically rectifying. It is amorphous rather than crystalline. The integrity of the film can be breached at temperatures above 175 to 190°C (350–375°F) depending on the media composition. It is characteristic of tantalum that when the film loses effectiveness the very reactive metal is exposed and reaction can be vigorous. Accordingly, if tantalum is not highly resistant to media conditions it generally will be attacked rapidly and severely. In view of this behavior, and because only a slight amount of corrosive attack is tolerated in tantalum equipment, the practical evaluation of its corrosion characteristics can be relatively simple. In general, the preferred procedure is to do testing by exposure to the actual service conditions.

#### Alloys

Tantalum is similar in nature to the other passivating reactive-refractory metals (titanium, zirconium, and niobium)

but it is highly resistant to more species of chemicals and is susceptible to fewer types of attack. Alloys with these elements that have been evaluated have increased reactive tendencies in rough proportion to their compositional content as might be expected with solid solution alloys. Like all reactive metals tantalum and its alloys are susceptible to corrosion attack by fluoride ion or fluoride compound such as hydrogen fluoride at all temperatures. Caustic has a similar effect and readily attacks tantalum; however, tantalum is resistant to caustic corrosion at low concentrations <10 wt. % and temperatures <(38°C) 100°F, which is adequate for rinsing cycles in batch processing and continuous processing lines [2].

The only tantalum alloys of commercial importance are with tungsten. The Ta-2.5 % W alloy has corrosion resistance equivalent to that of the pure metal. The Ta-10 % W alloy has slightly less resistance in general but provides higher mechanical strengths.

### Sensitivity to Particular Environments

#### Hydrogen

Tantalum can be embrittled by exposure to hydrogen. It has a large solubility for hydrogen and embrittlement can occur without detectable formation of a hydride phase. Loss of ductility can range from moderate to extreme glass-like behavior. Embrittlement can be detected by a decrease in the normally high elongation or reduction of area values obtained in tension tests. When specimen size and shape selection are limited flex-bend tests and biaxial cup stretch tests are good indicators [3]. Successful NDE methods to determine hydrogen embrittlement could use *in-situ* hardness testing to detect increases in hardness of the material or determine the change in electrical conductivity by measuring the changes in the impedance [4]. In service tantalum normally assumes a cathodic potential when galvanically coupled and embrittlement can occur readily. Accordingly, evaluation for corrosive applications always should consider the possibility of embrittlement.

The use of platinum-plated spots on the chemical side of the tantalum surface at a surface ratio of 1/1000 to 1/10 000 can be effective in preventing hydrogen embrittlement in corrosive media [5].

#### Other Relevant Environments

Corrosive attack of tantalum is usually by uniform mass loss. No observations of stress-corrosion cracking (SCC) or of crevice corrosion have been reported in industrial service.

<sup>1</sup>CPI-Product Manager, H. C. Starck, Inc., 45 Industrial Place, Newton, MA 02161-1951.

<sup>2</sup>Senior Metallurgist, H. C. Starck, Inc., 45 Industrial Place, Newton, MA 02161-1951.

Pitting-type attack is rare and the mechanism is not understood. Extremely anhydrous or oxygen deficient conditions in association with halogen species have caused pitting [6].

Tantalum's major usage in corrosion resistant equipment is for the processing of primary chemicals, especially highly concentrated acids at elevated temperatures ( $>100^{\circ}\text{C}$ ). It can withstand moderately basic conditions, but caution is necessary for exposure in strong alkaline media. Two severe environments in which tantalum has been shown to be not susceptible to corrosion or cracking are:

1. NACE sulfide test [7,8] compositions at high temperature and pressure ( $250^{\circ}\text{C}$ –7 bar) ( $490^{\circ}\text{F}$ –100 psi).
2. Extended use in the production of 98 to 99 % fuming nitric acid [9].

No observations in industrial use have been reported wherein tantalum has been affected by increased anodic potential due to oxidizing ions (transpassive behavior). Neither microstructural-dependent attack nor interactive/selective attack involving welds and adjacent nonwelded metal has been observed.

Tantalum is unaffected by contact with most liquid metals at temperatures below  $600^{\circ}\text{C}$  ( $450^{\circ}\text{C}$  for zinc, tin) and up to  $1000^{\circ}\text{C}$  for some. Resistance to the alkali metals is dependent on maintaining very low levels of oxygen in the system [10].

No common organic compositions affect tantalum at temperatures below about  $200^{\circ}\text{C}$  except in compounds that have decomposition products of fluorine, sulfur trioxide, or strong alkalis. However, there is uncertainty about the effects of some complex species under highly anhydrous or oxygen-deficient conditions.

## NIOBIUM

### General

A major factor in determining the specific applications of niobium for corrosion-resistant equipment is its price. The cost of niobium metal is about 7 times that of nickel-copper, nickel, or titanium and about 25 to 50 times that of the stainless steels. Accordingly, the service requirements for niobium components are to have practically no corrosion degradation over time periods of years—virtually indefinite life. This means that the use of niobium is limited to a relatively small number of the most severe media and conditions in relatively thin cross sections or as lining compared to other materials of construction. Selection of niobium for use is based on large, not moderate, improvements of performance over other materials. Therefore, testing data do not need to be highly quantified. If corrosion rates greater than 2 mpy are indicated the application very likely is not recommended.

### Nature of the Metal

#### Electrochemical Behavior

The corrosion resistance of niobium is due to a naturally occurring oxide film. The film is dielectric and electronically rectifying. It is amorphous rather than crystalline.

The integrity of the film can be breached at temperatures above  $175$  to  $190^{\circ}\text{C}$  ( $350$ – $375^{\circ}\text{F}$ ) depending on the media composition. It is characteristic of niobium that when the film loses effectiveness the very reactive metal is exposed and reaction can be vigorous. Accordingly, if niobium is not highly resistant to media conditions it generally will be attacked rapidly and severely. In view of this behavior, and because only a slight amount of corrosive attack is tolerated in niobium equipment, the practical evaluation of its corrosion characteristics can be relatively simple. In general, the preferred procedure is to do testing by exposure to the actual service conditions.

### Alloys

Niobium is similar in nature to the other passivating reactive-refractory metals (titanium, zirconium, and tantalum) and has an inherent resistance to a wide range of chemicals. In general, compared to Zr and Ti, Nb has better corrosion properties in acids with small amounts of metal or organic contaminants. Niobium alloys with alloying elements such as Zr and Ti have been evaluated and have shown increased reactive tendencies in rough proportion to their compositional content as might be expected with solid solution alloys.

Commercially pure niobium (grade 1) is used commonly in nuclear reactors whereas niobium (grade 2) is used commonly for its corrosion resistance for lining of chemical equipment and as barrier shields in X-ray environments. The only niobium alloys of significant commercial importance are: the Nb with 1 % Zr for sodium vapor lamps, Nb with 55 % Ti for use in high purity oxygen injection parts/piping, Nb-Ti, Nb-Ti-Sn and Nb-Sn alloys for superconducting wires and magnets, and for extremely high temperature rocket nozzles which use the Nb-10 % Hf-1 % Ti alloy.

## Sensitivity to Particular Environments

### Hydrogen

Niobium can be embrittled by exposure to hydrogen. It has a large solubility for hydrogen and embrittlement can occur without detectable formation of a hydride phase. Loss of ductility can range from moderate to extreme glass-like behavior. Embrittlement can be detected by a decrease in the normally high elongation or reduction of area values obtained in tension tests. When specimen size and shape selection are limited, flex-bend tests and biaxial cup stretch tests are good indicators [3]. Successful NDE methods to determine hydrogen embrittlement could use *in-situ* hardness testing to detect increases in hardness of the material. In service niobium normally assumes a cathodic potential when galvanically coupled and embrittlement can occur readily. Accordingly, evaluation for corrosive applications always should consider the possibility of embrittlement.

### Other Relevant Environments

Corrosive attack of niobium is usually by uniform mass loss. No observations of stress-corrosion cracking (SCC) or of crevice corrosion have been reported in industrial service. Pitting type attack is rare and the mechanism is not understood. Extremely anhydrous or oxygen deficient conditions in association with halogen species have caused pitting [6].

Niobium's major usage in corrosion resistant equipment is for the processing of primary chemicals, especially in concentrating nitric acid at elevated temperatures  $>100^{\circ}\text{C}$  [11]. Niobium also has been used in chromic acid plating baths even with trace amounts of fluorine or fluoride-containing compounds; otherwise, niobium should not be considered in environments containing any amount of fluoride or fluoride compounds [12]. It can withstand moderately basic conditions, but caution is necessary for exposure in strong alkaline. Oxide scale formation and hydrogen absorption may occur in alkaline concentrations greater than about 10 % at ambient temperatures.

No observations in industrial use have been reported wherein niobium has been affected by increased anodic potential due to oxidizing ions (transpassive behavior). Neither microstructural dependent attack or interactive/selective attack involving welds and adjacent nonwelded metal have been observed.

Niobium has good resistance to most liquid metals but is not as resistant as tantalum.

Organic compositions do not affect niobium at temperatures at and below their boiling points except in compounds that have decomposition products of fluorine, sulfur trioxide, or strong alkalis.

However, there is uncertainty about the effects of some complex species under highly anhydrous or oxygen-deficient conditions.

## TANTALUM AND NIOBIUM

The most used chemical process industry equipment components made with tantalum and niobium are tanks/vessels, heat exchangers (tubing), immersion probes, and devices for instrumentation, valves, and glass lining repair assemblies [12].

### Recommended Corrosion Testing Procedures

The preferred procedure for corrosion testing tantalum and niobium materials, as stated previously, is to test by exposure to actual service conditions. However, in situations when this is not possible and it is necessary to obtain corrosion test data under simulated service conditions in the laboratory, guidance can be obtained from the following ASTM standards contained in the ASTM Annual Book of Standards Volume 03.02:

- G 4 Method for Conducting Corrosion Coupon Tests in Plant Equipment

- G 31 Practice for Laboratory Immersion Corrosion Testing of Metals
- G 1 Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens
- G 46 Practice for Examination and Evaluation of Pitting Corrosion

Additional information on these standards can be obtained by referring to the index in this manual.

ASTM tantalum and niobium mill product specifications can be located in ASTM Annual Book of Standards, Section 2, Nonferrous Metal Products, and Volume 2.04 (ASTM Standards for Nb; B 898, B 391, B 391, B 394, B 393 and Ta Standards; B 898, B 364, B 365, B 521, B 708) and are also available through the ASTM website [www.astm.org](http://www.astm.org).

# Metallic Coatings on Steel

*T. C. Simpson<sup>1</sup> and H. E. Townsend<sup>2</sup>*

## ENGINEERING PROPERTIES OF STEEL

EACH YEAR IN the United States, roughly 100 million tons ( $9.1 \times 10^{10}$  kg) of steel are consumed for a wide variety of applications. This enormous use results from a unique and favorable combination of characteristics that includes outstanding mechanical, physical, and magnetic properties, excellent manufacturability, low cost, availability, and ease of recycling. Because of its susceptibility to corrosion, steel is almost always used with a protective coating. The types of coatings and the kinds of corrosion test methods that are employed are as widely varied as the many end-uses [1–4].

## FUNCTIONS OF PROTECTIVE COATINGS

Protective metallic coatings are typically applied to metallic substrates for one of three reasons: to aid in corrosion resistance, to furnish high-temperature oxidation resistance, and/or to provide a base for painting. Although metallic coatings could also be applied for other user-specific reasons, such as appearance, to achieve the desired end-use product, the intent of this chapter is to focus on application of coatings to provide protection to the underlying substrate.

One very common reason for the application of metallic coatings to steel is to provide corrosion resistance. Metallic coatings can provide corrosion protection by one or more of several mechanisms including, barrier, sacrificial, or inhibitive protection. The details of these mechanisms of protection will be reviewed later in this chapter.

Metallic coatings can also be used to provide high-temperature oxidation resistance for specific applications. Aluminum and aluminum-zinc coatings are well suited for high-temperature applications (up to 675°C).

One additional attribute of metallic coatings, although not typically the only reason for their use, is their suitability to the application of paints. Metallic coatings, such as the iron-zinc coating galvalume, have a high degree of surface texture, which enhances paint adhesion compared to a relatively smooth steel surface.

This chapter will review the basic types of metallic coatings that are applied to steel substrates, the methods by which the coatings are applied, the mechanisms by which they protect the underlying substrate, and the common methods used to test metallic coatings on steel. In addition, a discussion of the important considerations in selecting/designing a corrosion test program for coatings on steel is included.

## COATING PROCESSES AND ALLOYS

The following two sections were designed to introduce the reader to the types of metallic coatings commonly applied to steel and the coating processes used to prepare them. The reader is also referred to a number of review articles that describe coating microstructure, preparation, and properties in further detail [2,26–30,57,58].

## COATING PROCESSES

### Hot Dip Coating

Hot dipping is the most widely used process to apply metallic coatings to steel. The hot dip process consists of immersion of clean steel into a molten bath of the material to be deposited. In the continuous hot dip process the material exits the bath and coating weight is controlled using a low pressure [typically, 50 psi (344.7 kPa) or less] gas wiping system prior to solidification. Hot dip coatings applied in the continuous process typically have coating thicknesses ranging from 6–20  $\mu\text{m}$ . Hot dip coatings can also be applied in a batch mode. Coating weight control for batch applications is controlled by letting the item drain, or bump, after application and/or by centrifugation. Hot dip coatings applied in a batch mode typically have coating thicknesses ranging from 50–130  $\mu\text{m}$ . Hot dip coatings are limited to use with metals having melting points  $\leq 732^\circ\text{C}$  (1350°F). The most common hot dip coatings are zinc, aluminum, and zinc-aluminum alloys [1,4,5,57].

### Electroplating

Another common method for coating application is electroplating. In electroplating, negatively charged steel sheet is immersed in a plating bath next to positively charged anodes.

<sup>1</sup>Research Supervisor, International Steel Group Inc., 116 Research Drive, Bethlehem, PA 18015.

<sup>2</sup>President, Townsend Corrosion Consultants, Inc., 3155 Balsam Road, Center Valley, PA 18034.

Metallic ions in an electrolyte bath are reduced and plated on the surface of the steel sheet forming the coating. Typical electroplated coating thicknesses range from 4–13  $\mu\text{m}$ . The bath composition, electrolyte velocity, current density, and temperature determine the chemistry and properties of the metallic/alloy coating. Typical electroplating baths are composed of aqueous salts of the ions to be deposited. Electroplating of highly electronegative metals such as aluminum, however, requires the use of molten salt or aprotic solvent plating baths, or both. Common coatings applied by electroplating are zinc, zinc-nickel, zinc-iron, tin, chromium, nickel, cadmium, and copper [6–8,58].

### Diffusion

Diffusion, also known as cementation, coatings are formed by heating the steel substrate in contact with the coating metal, usually in the form of powder at high temperature for sufficient time for interdiffusion to occur [9]. In Sheradizing, one of the oldest and most widely used cementation processes, zinc dust and steel parts are rotated in a drum at 370°C for several hours to form an iron-zinc alloy coating containing 8–10 % iron with thicknesses on the order of 50–100  $\mu\text{m}$ . Aluminum (calorized or Alonized) and chromium (chromized) coatings are also applied to steel as diffusion coatings for protection against high-temperature oxidation.

Diffusion coating is also done using a gaseous source of coating metal. For example, silicon diffusion coatings are applied by heating steel in the presence of hydrogen and silicon tetrachloride.

### Thermal Spray

In the most common type of thermal spray, also known as flame spray or metallizing, metal in the form of wire or powder is fed to an oxyacetylene flame [10]. Droplets of molten or semimolten metal are propelled toward the substrate by the flame where they splatter and form a coating. This method is most often used to coat large structures after they have been fabricated in the field. Zinc and aluminum are the most common coating metals applied by thermal spray and the coatings are usually applied in thicknesses on the order of 100  $\mu\text{m}$ . Because the coatings tend to be porous, they are generally used in conjunction with an organic topcoat.

Thermal spraying of small components is often done in an enclosed chamber with a reduced pressure or inert gas background. This technique facilitates safe containment of toxic or pyrophoric materials and minimizes oxidation.

Electric arc and plasma-arc thermal spraying are used when higher temperatures are required for improved bonding and coating density, or to liquefy higher melting point coating materials.

### Physical Vapor Deposition

In its simplest form, physical vapor deposition (PVD) is the evaporation of a coating metal source and condensation of the vapors on the substrate [11–13]. The process is carried out at low pressure, typically  $10^{-1}$  Pa, in order to avoid

oxidation of the metallic vapor. Virtually any coating metal can be applied by PVD and environmental concerns associated with liquid wastes can be avoided. Coatings up to about 10  $\mu\text{m}$  are deposited, and deposition rates are controlled by the rate of heat input used to vaporize the coating-metal source. Resistance and induction heating methods are often used, but the highest rates are obtained with electron beam heating.

Application of PVD coatings to coils of steel sheet in a continuous process was studied extensively in the United States during the 1970s, but the process was found to be more costly relative to other coating methods, such as electroplating and hot dipping. More recently, efforts are underway in Japan and Europe to further develop such a process.

Other types of PVD include ion-beam assisted deposition (IBAD), ion plating, and sputtering.

With the IBAD process, the coating surface is simultaneously bombarded with inert gas ions from an auxiliary source during coating deposition in order to improve adhesion and density of the PVD coating.

In ion plating, a negative bias, typically 3000–4000 V, is applied to the substrate, and the background pressure is increased with argon in order to create a glow discharge. Evaporated metal atoms are ionized and accelerated to the substrate with a resultant improvement in adhesion and density.

With sputtering, a target of coating metal is bombarded with argon ions in order to produce multiatomic fragments, which are then deposited on a substrate. Sputtering rates are generally less than that of ordinary PVD.

### Chemical Vapor Deposition

In chemical vapor deposition (CVD), a gas containing the coating metal is thermally decomposed on a heated substrate surface to form a deposit [14]. Typical coating thicknesses cover a very wide range (up to 100  $\mu\text{m}$ ) depending on the specific coating applied. Owing to the generally high temperatures required for thermal decomposition, CVD deposits usually have good adhesion and density. Gases used include halides, hydrides, carbonyls, and organometallics. Nickel, tungsten, and chromium are the most commonly applied CVD metal coatings. As an example, CVD tungsten coatings can be applied to steel by heating to 700–900°C in a mixture of tungsten hexachloride and hydrogen. Recent developments include the use of laser, microwave, or plasma energy in order to reduce the amount of substrate heating.

### Mechanical Coating

Mechanical coatings [15] are formed on steel surfaces by peening simultaneously with glass beads and metal powder, as described in ASTM B 695, Specification for Coatings of Zinc Mechanically Deposited on Iron and Steel, and ASTM B 696, Specification for Coatings of Cadmium Mechanically Deposited. A coating is built up by the cold-welding of successive layers of coating particles. The process is usually carried out by tumbling a barrel containing the substrate, coating metal powder, glass beads, and a proprietary

aqueous solution. It has been used primarily to coat fasteners and small hardware made of high-strength steel with zinc when it is desirable to avoid either the adverse effects of high temperatures in hot dipping on mechanical properties, or the possibility of hydrogen embrittlement in electroplating. Cadmium, tin, copper, lead, indium, and mixtures thereof have also been applied by mechanical coating. Coatings are typically in the range 5–25  $\mu\text{m}$  thick.

## COATING ALLOYS (COMPOSITIONS, APPLICATIONS, TYPICAL WEIGHTS, MICROSTRUCTURE)

### Zinc

Pure zinc coatings are usually applied to steel using the hot dip or electroplating methods. The hot dip process produces a predominately zinc coating containing an intermetallic layer at the zinc:steel interface. Hot dip zinc coatings are typically 6–20  $\mu\text{m}$  (40–140  $\text{g}/\text{m}^2$ ) thick. Electroplated zinc coatings consist of a single phase  $\alpha$  zinc coating. Electroplated zinc coatings applied at coating thicknesses of 4–13  $\mu\text{m}$  (20–90  $\text{g}/\text{m}^2$ ) are typically more uniform than hot dip zinc coatings. Hot dip coatings are typically less expensive than electroplated zinc coatings, particularly for heavier coatings and thinner steel sheet. Pure zinc coatings are used widely in the automotive and construction industries.

### Zinc Alloys (ZnAl, ZnNi, Zn-Fe)

Zinc alloy coatings are applied to steel by the hot dip or electroplating processes. Hot dip zinc-iron coatings are produced by heating zinc-coated strip just after it leaves the wiping dies. The extent of alloying is controlled by the time and temperature of the thermal process and by the addition of a small amount of aluminum to the zinc bath. Hot dip zinc-iron coatings, called galvaneal, typically contain 8–12 % iron and are 6–11  $\mu\text{m}$  (40–80  $\text{g}/\text{m}^2$ ). Hot dip zinc-iron coatings contain a microstructure consisting of several phases. A typical zinc-iron hot dip coating could have a zinc-rich zeta phase at the surface and progressively more iron-rich delta and gamma phases as one moves closer to the steel substrate. Electroplated zinc-iron coatings may contain 8–18 % iron and are applied at thicknesses up to 7  $\mu\text{m}$  per side. Similar to pure zinc coatings, zinc-iron hot dip coatings have the advantage of being less expensive and zinc-iron electroplated coatings have the advantage of being more uniform. Both coatings have the advantages of better weldability, and better paint adhesion (due to the microporous surface) than pure zinc coatings. Zinc-iron coatings are used primarily for automotive applications as body panels and other parts.

Zinc-nickel coatings contain 10–14 % nickel and are typically applied by electroplating at coating thicknesses ranging from 3–6  $\mu\text{m}$ . Zinc-nickel coatings are also commonly used by the automotive industry for exposed and unexposed panels because of their superior weldability (over pure zinc coatings) and good formability [16].

Zinc-aluminum coatings containing 5 % aluminum and small amounts of other elements are also commercially

available. One common 5 % aluminum coating also contains about 0.1 % mischmetal (cerium and lanthanum) to increase wettability of the bath and reduce the incidence of bare spots. Another contains 0.1 % magnesium to counteract the adverse effects of lead and tin impurities on intergranular corrosion and paint adhesion. These coatings can be used for enhanced corrosion properties over an equal thickness pure zinc coating in severe marine environments. In moderate marine, industrial, and rural environments, however, these coatings perform no better than pure zinc [17,18].

These 5 % aluminum coatings have no added lead and no spangle. As a result, they are free of spangle cracking and have better resistance to cracking during forming than ordinary spangled hot dip zinc coatings. The microstructure of a typical 5 % aluminum-zinc alloy coating is characterized by a matrix of 5 % aluminum eutectic and scattered regions of primary zinc. No intermetallic layer is visible on steel sheet coated with the eutectic alloy because the bath temperature is lower, and the aluminum content is higher, than with ordinary galvanized.

Enhancements of zinc alloy coatings are also commercially available. Zinc-nickel composite coatings are prepared by applying a chromium pretreatment followed by a thin (1–2  $\text{g}/\text{m}^2$ ) silicate containing organic topcoat to the zinc-nickel surface. The organic coating is typically applied to one side of the zinc-nickel, the side that will be the interior of the final panel. This provides additional protection to the areas where phosphating and priming may be inadequate after assembly. The other side of the steel sheet will typically contain zinc-nickel, but can be coated or uncoated. Perforation corrosion resistance is significantly enhanced in zinc-nickel composite coatings over conventional zinc-nickel coatings.

Plating of a thin iron-phosphorous (Fe-P) layer (2  $\text{g}/\text{m}^2$ ) or iron-zinc (3  $\text{g}/\text{m}^2$ ) layer on the surface of iron-zinc hot dip or electroplated coatings is also used for automotive applications. The thin electroplated layer is designed to improve formability and to reduce electrocoat cratering tendencies of the iron-zinc alloy coating.

### Aluminum and Aluminum Alloys

Aluminum coated steel sheet is produced in coil form by continuous hot dipping in a molten aluminum bath. The resultant coating consists of an iron-aluminum intermetallic layer and an aluminum overlay with a total thickness of 20–40  $\mu\text{m}$ . The product, referred to as Type 2 aluminum coated, is used mostly for light construction, e.g., metal buildings, silos, and highway culvert.

Another continuously coated steel sheet product, Type 1 aluminum-coated, is made by hot dipping in a molten bath of aluminum containing 5–11 % silicon [19]. Type 1 coatings are thinner, typically 10–20  $\mu\text{m}$ , and are more formable than Type 2 coatings. This product is widely used in high-temperature applications (up to 675°C), particularly for automobile tailpipes and mufflers.

Batch coating of steel hardware with aluminum to form aluminum-iron alloy coatings is also done by hot dipping or cementation. Pure aluminum coatings are applied on a batch basis by thermal spray, ion plating, and electroplating from nonaqueous solvents.

Aluminum-zinc alloy coatings are prepared by the hot dip process using a bath containing 55 % aluminum, 43.5 % zinc, and 1.5 % silicon. The coating consists of an aluminum/zinc matrix containing zinc-rich interdendritic areas. Coatings are typically 20–25  $\mu\text{m}$  (150 g/m<sup>2</sup>) thick. Aluminum-zinc coatings are most commonly used in the metal building industry. These coatings also provide high temperature resistance (up to 675°C) and are used by the automotive industry for heat shields, gas tank shields, mufflers, etc.<sup>3</sup>

### **Terne**

Terne is steel sheet that is hot dip coated with a lead-tin alloy [20]. Because lead does not readily wet steel, 2–25 % tin is added in order to ensure wetting and bonding of the coating to the substrate. Typical coating thicknesses are in the range of 5–15  $\mu\text{m}$ . The product has good weldability, solderability, and formability. Largest applications have been in the automobile industry, particularly for fuel tanks.

### **Tinplate**

Historically, tin was applied to individual cut lengths of steel sheet by fluxing and hot dipping [21]. Today, virtually all tin is electrolytically applied to steel sheet in continuous coil form for use in food containers. The tin serves as a base for protective organic coatings. Because of its favorably low frictional characteristic, tin also improves the formability of the steel substrate. Coating thicknesses are typically in the range of 0.4–1.6  $\mu\text{m}$ . As-deposited electrolytic tin coatings have a dull, matte appearance and normal practice is to brighten the deposit by melting it with in-line induction heating. This results in the formation of a thin iron-tin alloy layer at the coating-steel interface.

### **Chromium**

Chromium coatings [22–24] are batch-applied to steel components by diffusion, vacuum deposition, chemical vapor deposition, and most often by electrodeposition. Electroplated chromium coatings can be of two general types. Hard (also called industrial, functional, or engineering) coatings are applied in thicknesses of up to hundreds of  $\mu\text{m}$  in order to build up worn or improperly machined surfaces. Decorative chromium coatings, used for appearance purposes, are generally less than 2  $\mu\text{m}$  in thickness, and are applied as the outer layer of a multilayer system involving inner layers of electrodeposited nickel and copper. The chromium layer is often deliberately deposited in the crazed or microcracked condition in order to enhance corrosion resistance by minimizing adverse galvanic effects between the cathodic chromium and the anodic nickel. Automotive bumpers and trim are typical applications of decorative chromium coatings.

Although not truly metallic, a type of chromium coating is continuously applied to steel sheet in the production of “tin-free” steel (TFS). TFS was developed as an alternative to tinplate for the container industry. A mixture of chromium

oxide and metallic chromium is electrolytically applied in thickness on the order of 0.1  $\mu\text{m}$  or less. The TFS coating is an excellent base for coil-line applied organic coatings which, in turn, impart favorable forming and corrosion characteristics to the steel.

### **Cadmium**

Electrolytic cadmium coatings [25] have been widely used to protect fasteners, particularly for exposure in chloride environments. The lubricity of cadmium coatings aids in uniformly tightening threaded fasteners. However, use of cadmium is declining because of toxicity and environmental concerns.

## **CORROSION RESISTANCE**

### **Mechanisms**

Metallic coatings provide corrosion protection through one or more of the following mechanisms:

#### *Barrier*

In the barrier mechanism, the coating serves to isolate the underlying metal from the corrosive environment. The barrier mechanism is effective as long as the coating is continuous. Continuity is particularly important with noble coatings so that localized pitting due to galvanic attack is avoided. Barrier coatings should also corrode at a slower rate than the substrate.

#### *Galvanic*

In the galvanic mechanism, the coating is less noble than the underlying substrate, so that it corrodes preferentially and provides galvanic protection to any substrate that may be exposed at pores or cut edges.

#### *Inhibition*

In the inhibition mechanism, corrosion products from a sacrificial coating are deposited on the cathodic substrate where they act as a barrier to further corrosion.

In general, passive metals or noble metals provide only barrier protection to steel.

Studies of the corrosion mechanisms occurring in laboratory tests are often conducted in order to ensure that real-world conditions are being simulated, and to increase confidence in the test results [31]. Visual and microscopic examination is used to characterize the mode of attack, and a variety of analytical methods, including X-ray diffraction and fluorescence; and Raman, infrared, and Mossbauer spectroscopies are employed to identify corrosion products.

### **Specific Systems**

Tin coatings may be sacrificial or nonsacrificial, depending on the environment. In neutral, aerated solutions, tin acts cathodically to steel, resulting in pitting attack at coating pores. However, in deaerated, acid solutions, such as fruit juice within a closed container, tin behaves sacrificially and protects steel exposed at pores.

<sup>3</sup> In order to avoid embrittlement of the steel sheet during prolonged heating in the temperature range of 370–510°C, a phosphorus containing (>0.04 % P) steel substrate must be specified.

Aluminum coatings are passive in most environments where they provide only barrier protection. However, in chloride environments, aluminum may become active and provide sacrificial protection to steel.

Cadmium provides sacrificial protection to steel.

Zinc and zinc-alloy coatings can combine all three of the above protection mechanisms, a fact that forms the basis for their effectiveness and widespread use in protecting steel. As an example, consider electroplated zinc-alloy coatings containing approximately 13 % nickel. In order to explain why Zn-Ni alloy coatings perform remarkably well in salt-containing environments, such as the environment used for ASTM B 117, Test Method of Salt Spray (Fog) Testing, a detailed mechanistic study was conducted [32]. This work revealed how each of the three mechanisms comes into play during various stages during the lifetime of the coating (Fig. 1). As deposited, the Zn-12 % Ni alloy coating is composed of a uniform layer of gamma phase, a complex cubic structure  $\text{Ni}_5\text{Zn}_{21}$  intermetallic compound, which initially acts as a barrier. At this time, the coating corrodes at a potential that is anodic to steel, so that small areas of exposed substrate are galvanically protected. As the coating continues to corrode, zinc is preferentially dissolved, leaving behind a layer that becomes enriched in nickel and increasingly less sacrificial. At the same time, large tensile stresses are developed within the coating because of volume shrinkage associated with the loss of zinc. Eventually, cracks are formed as the shrinkage stresses exceed the tensile strength of the coating. Steel exposed at the base of the cracks at first is protected by the galvanic mechanism. Dissolved zinc cations are attracted to the cathodic sites where the steel is exposed and precipitate there because of the increased pH associated with the cathodic reactions. With further loss of zinc, the potential of the coating approaches that of the steel substrate, and sacrificial protection ceases. At that point, the coating consists of a cracked, nickel-rich layer with zinc corrosion products filling the cracks, and it acts only as an inert barrier. The superior performance of Zn-Ni alloy coatings compared to pure zinc coatings is attributed to the ability of the fine cracks to mechanically trap and retain zinc corrosion products.

FIG. 1—Schematic of the corrosion mechanism of Zn-Ni alloy coatings [32].

## CORROSION TESTING

Testing of metallic coatings on steel will vary depending on the available resources and the desired degree of reliability. In the following list of test alternatives, the most reliable are at the top, but these are generally the most costly and time-consuming as well:

- Actual Field Service
- Simulated Field Service
- Static Atmospheric Testing
- Cabinet Testing
- Electrochemical Testing
- Service/Atmospheric Tests

Consider the cosmetic corrosion testing of coated steel sheet for autobody panels as an example [29]. The most reliable performance data are obtained by field surveys of vehicles in parking lots and junkyards after years of actual service. However, the time, effort, and sample-size requirements place practical limits on this approach.

The Society of Automotive Engineer's Automotive Corrosion and Prevention Committee (SAE/ACAP) has been publishing the results of parking lot surveys of five- to six-year-old vehicles randomly selected in parking lots [33,59,60]. Figure 2 shows survey results for cars manufactured from 1980 to 1993. The increases in automobile corrosion resistance that occurred during that time are believed to be the results of improvements in design, advances in pretreatment and paint technology, and increasing use of metallic-coated steel sheet.

Another approach to in-service testing is to monitor the behavior of the materials in a fleet of captive vehicles. This enables better control and recording of the exposure and driving conditions. The use of fleet vehicles also makes it possible to test coupons representing a wider range of materials. Coupons mounted on pickup trucks operated in Montreal, Quebec, and St. John's, Newfoundland for up to five years served as the real-world standard of performance in a laboratory test development by SAE/ACAP and The American Iron and Steel Institute's Corrosion Task Force. The materials being used in these tests are described in Table 1 and results after five years of testing at these sites are shown in Fig. 3 [64].

Automotive steel sheet coupons and components are usually tested in the painted condition. For evaluation of exterior cosmetic corrosion resistance, this includes application of phosphate, cathaphoretic primer, and one or more topcoats. Intentional damage to the paint system, usually in the form of a scribe that extends through the paint system and any metallic coating to the base steel, is an essential part of these tests. A number of practices for scribing are possible, using tungsten carbide engraving pencils, razors, and tungsten carbide lathe tools [34]. ASTM D 1654, Test Method for Evaluation of Painted or Coated Specimens Subjected to Corrosion Environments, and GM 9102P, Corrosion Creepback Test Method, describe a standardized scribing procedure. Other forms of intentional paint damage have been employed, including shot blasting, stone chipping, and diamond shot pecking. Results are generally reported in terms of the amount of underfilm delamination of the paint film (scribe creep), the degree of red rust at the scribe, and sometimes the extent of penetration of the steel substrate at the scribe.

### Simulated Service

Field service can be simulated at automotive proving grounds. Major automobile manufacturers operate proving ground test facilities that are intended to compress many years of service into a period of months. At these locations, production and prototype vehicles are repeatedly subjected to salt-water splash or spray, driven over rough roads, and

**GMPG Exposure - 10 Year Cosmetic****Total Width Creepback at Scribe (Ave. of 5 Measurements Per Panel)****FIG. 4**—Results of proving ground tests of AISI materials (see Table 1 for material identification codes) [35]. (Reprinted with permission, from SAE paper 912283, © 1991, Society of Automotive Engineers, Inc.).

parked in high humidity conditions. Small test coupons or individual components are also mounted on vehicles or trailers driven on the proving-ground circuit. Results of ten years of simulated road driving at an automotive proving ground are shown in Fig. 4 for the AISI/SAE test materials [35]. The data are plotted, similar to Fig. 3, as averages of total creepback from a scribe line with 95 % confidence limits shown. The main drawbacks to proving ground testing are that very few organizations have this type of resource, and there is a lack of uniform procedures practices. SAE J1950 is a guide to Proving Ground Vehicle Corrosion Testing.

Field service has also been simulated by mounting test coupons on a trailer that is towed over public roads and periodically sprayed with salt-water.

### Static Atmospheric Testing

Static atmospheric testing as described in ASTM G 50, Practice for Conducting Atmospheric Corrosion Tests on Metals, and ASTM G 1, Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens, is used to test coated sheet steels intended for a variety of outdoor applications. In the case of automotive steel sheet, the practice has been modified to include a twice-weekly application of salt spray. Figure 5 shows the results of a 15-month exposure of the coated steel sheet products in the AISI/SAE test program [36]. The data are plotted as averages of total creepback from a scribe line and 95 % confidence intervals are shown in the figure.

In the case of metallic-coated steels intended for general outdoor applications such as metal buildings, normal testing practice is to expose multiple 100 by 150 mm coupons for determination of coating mass loss as a function of time. Several test locations should be employed in order to characterize performance in a range of representative environments, including marine, rural, and industrial atmospheres. Typical results for steel sheets coated with zinc, aluminum, and 55 % Al-Zn alloy are shown in Fig. 6, which gives the loss of coating thickness as calculated from mass loss during 13 years of testing at the marine site located 250 m from the ocean at the LaQue Corrosion Technology Center in Kure

**FIG. 5—Results of modified atmospheric tests of AISI materials (see Table 1 for material identification codes) [36].**

Beach, NC [37]. The same data are plotted on a logarithmic scale in Fig. 6, where they fall on a straight line and can be easily fitted to an equation of the form

$$\log C = \log A + t \log B$$

where

$C$  is the corrosion loss,  $t$  is the exposure time, and  $A$  and  $B$  are constants.

This relationship facilitates extrapolation of the results in order to estimate coating life.

The above equation can also be written in exponential form,

$$C = A t^B$$

and differentiated with respect to time in order to conveniently calculate corrosion rate,  $dC/dt$ , as a function of time

$$dC/dt = A B t^{(B-1)}$$

as plotted in Fig. 6.

Another approach taken in atmospheric testing of metallic-coated steels is to monitor the appearance of test specimens during long-term exposure. Figure 7 shows how the life of zinc coatings on galvanized sheet increases with coating mass as determined by recording the percentage of rust on the surface of the test specimens in an industrial environment [38].

The visual approach is often used in the atmospheric testing of painted, metallic-coated sheet. Extent of paint blistering, paint undercutting, and appearance of corrosion products at edges, scribes, and formed areas are typically observed and recorded.

## Cabinet Tests

### Continuous Exposure Tests

Several tests are used to evaluate the performance of coated steel substrates that involve continuous exposure to

**FIG. 6—Quantitative test results for coated steel sheet in marine atmosphere (250-m lot at Kure Beach, NC) [39]; top: thickness loss versus time (linear scale); middle: thickness loss versus time (logarithmic scale); bottom: thickness loss rate versus time.**

one environment. ASTM B 117 (also GM 4298-P) involves continuous exposure to 5 % NaCl at elevated temperature (35°C). Some common continuous exposure tests include the Humidity Test, GM 4465P; the Cleveland condensation test (ASTM D 2247, Practice for Testing Water Resistance of Coatings in 100% Relative Humidity), the Kesternich/Moist SO<sub>2</sub> Test, (ASTM G 87, Practice for Conducting Moist SO<sub>2</sub> Tests), and the wet-storage stain test. The wet-storage stain test is commonly used for zinc and aluminum/zinc coated

FIG. 7—Visual test results for zinc coatings of various masses in industrial atmosphere (Brunot Island, Pennsylvania) [9].

steel [39]. This test consists of stacking wet panels of the test material to simulate conditions that these materials may encounter during field storage. The test is often used to evaluate the quality of the passivation applied to the materials. Continuous exposure tests tend to be quite good at simulating a specific environment, but care must be taken in using them for the prediction of service life performance. For example, it has been clearly demonstrated that ASTM B 117 does not accurately predict the cosmetic corrosion performance of an automotive environment using the AISI/SAE materials [31].

### Cyclic Tests

Accelerated laboratory tests that have gained increasing support over the last several years typically combine several conditions into a cycle, and materials undergo repeated exposures to this cyclic environment. These tests are designed to take all potentially corrosive components of an exposure environment into consideration. The automotive industry has been using cyclic tests for a number of years as predictors of field performance and several other industries have recently begun investigating them as well. Some examples of cyclic tests are shown in Table 2. The first two tests shown in Table 2 are automotive tests that were developed by General Motors. The third test is a test used by investigators at the Sherwin Williams Company in recent years and combines aggressive exposure with accelerated weathering [40]. The Society of Automotive Engineers (SAE) has published an information report (SAE J1563) that provides guidelines including suggested control limits for test chambers, information about panel preparation, etc., to be used when running a cyclic test. In addition, the Automotive Applications Committee of the American Iron and Steel Institute (AISI) in cooperation with the Society of Automotive Engineers' Automotive Corrosion and Prevention (SAE/ACAP) Committee have developed a new cyclic cosmetic corrosion test. This test has is now designated as SAE J2334. Efforts are underway to develop a perforation corrosion test [62]. To date, the SAE J2334 also looks promising in predicting perforation corrosion behavior [65].

### Electrochemical Tests

Corrosion of metallic substances is an electrochemical process. An alternate approach to field or other accelerated tests in understanding and predicting metallic corrosion is the use of electrochemical parameters/tests. Electrochemical

TABLE 2

A. Test 1: GM 9511P-August 1989 SCAB Corrosion Creepback of Paint Systems on Metal Substrates	
Monday Only:	1 h 60C in air circulating oven 30 min cold cabinet (-25C) 15 min 5% NaCl immersion 21 h humidity cabinet (60C, 85% RH)
Tuesday Through Friday:	15 min 5% NaCl Immersion 1 h 15 min room temperature 22 h 30 min humidity cabinet (60C, 85% RH)
Saturday and Sunday:	humidity cabinet (60C, 85% RH)
Cycle is typically repeated to complete 20 cycles: One day of Monday through Friday exposure constitutes one cycle.	

B. Test 2: GM 9540P-May 1992 Accelerated Corrosion Test	
Monday Through Friday:	Salt mist applications in ambient environment (25C +/- 3C, 40-50% RH) every 1.5 hours (4 applications total for a total time of 4.5 hours)  Salt consists of: 0.9 % NaCl 0.1 % CaCl <sub>2</sub> 0.25 % NaHCO <sub>3</sub>  pH = 6-8  8 h humidity cabinet (49C, 95-100% RH) 8 h dry (60C +/- 2C, <30% RH) 8 h ambient (25C +/- 3C; 40-50% RH)
Saturday and Sunday:	ambient (25C +/- 3C; 40-50% RH)
Test is typically repeated for 40 cycles. One day of Monday through Friday exposure constitutes 1 cycle.	

C. Test 3: Combined Corrosion/Weathering Test	
Week 1	4 h UV light (UVA-340 bulbs), 60C 4 h H <sub>2</sub> O condensation, 50C
Week 2	1 h spray (0.35% (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> + 0.05 wt% NaCl, ambient temperature) 1 h forced air dry, 35C
Test is repeated for 6 cycles. (One cycle consists of completion of week 1 and week 2 of exposure.)	

tests often complement other test methods by providing kinetic and mechanistic data that would be otherwise difficult to obtain. Electrochemical tests are typically grouped as DC or AC methods based on the type of perturbation signal that is applied in making the measurements. A number of investigators have used DC and AC electrochemical methods for the examination of metallic corrosion over the last several decades. This chapter will highlight a few sample applications of electrochemical methods to monitoring/examining metallic corrosion of coated sheet materials. These applications are provided for illustrative purposes only and the reader should not feel restricted to these applications. It is suggested that the reader consult the following review books/symposia proceedings and references contained within to see a much broader sampling of the ways electrochemical methods have been applied to study metallic corrosion, particularly corrosion of coated sheet products with or without organic coatings [41-46].

The simplest DC electrochemical method is the measurement of the electrochemical potential. Electrochemical potential measurements can be used to estimate the relative activity of a material in a particular environment and/or to compare materials in a particular environment. Tracking electrochemical potential as a function of time in a particular environment can provide information on how the corrosion process is proceeding. Investigators have used electrochemical potential/mixed potential measurements for numerous studies throughout the last several years. Efforts at Bethlehem Steel's Research Laboratories have used electrochemical potential monitoring to track the dissolution of active phases from zinc/aluminum alloy coatings on steel. Figure 8 is a representative plot of the potential change as a function of time in an aggressive environment for one of these alloy coatings. Regions of this curve have been labeled to indicate the dissolution expected to be taking place within each region. This monitoring method has been used to track the extent of dissolution of active phases from these coatings as a method of pre-exposure of these samples prior to field exposure. This method allows a significant decrease in the time involved in a field exposure to enable evaluation of effects of process/composition changes on performance of the material [47].

Other DC methods that are quite simple to use and provide important information to the corrosion scientist include polarization resistance (ASTM G 59, Practice for Conducting Potentiodynamic Polarization Resistance Measurements), potentiostatic and potentiodynamic polarization measurements (ASTM G 5, Standard Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements), cyclic polarization measurements (ASTM G 61, Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-based Alloys), and galvanic current monitoring. These DC techniques can be used to estimate the reactivity of a material in a particular environment, to determine the corrosion rate of a material in a particular environment, and/or to determine the susceptibility of a material to localized corrosion.

FIG. 8—Typical electrochemically monitored etching curve for zinc/aluminum alloy coatings on steel. Potential regions are labeled to indicate the dissolution occurring within each region [47].

Potentiodynamic polarization measurements are quite appropriate for determination of the pitting susceptibility of aluminum coatings, and/or the corrosion current density/corrosion rate of coated steel products in general. ASTM G 102, Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Measurements, describes the calculation of corrosion rates and other information from electrochemical measurements. Another example of the use of DC electrochemical methods to examine the corrosion performance of coated sheet materials is a study by D. A. Jones et al. [48]. The study used polarization resistance measurements to examine the mechanism of steel and coated sheet degradation under conditions of alternate immersion. Jones compared the polarization resistance of samples of low-carbon steel, unpainted galvanized, aluminum-coated, and Zn-Ni alloy coated steel during continuous immersion and alternate immersion. Alternate immersion cyclic exposure produced a thick oxide that led to significant underfilm attack. Jones found that phosphate pretreatment tends to increase the resistance of these materials to underfilm attack. This study is an excellent example of the way electrochemical measurements can be used as a complement to other techniques to elucidate mechanistic information.

Additional electrochemical methods that involve some component of an AC signal include electrochemical impedance spectroscopy (ASTM G 106, Practice for Verification of Algorithm and Equipment for Electrochemical Impedance Measurements), galvanostatic staircase polarization (ASTM G 100, Method for Conducting Cyclic Galvanostaircase Polarization), and electrochemical noise monitoring. Efforts at the Research Laboratories of Bethlehem Steel have used electrochemical impedance spectroscopy (EIS) to evaluate phosphate coverage/stability on galvaneal [49]. Phosphate coatings are applied to coated steel products to enhance paint adhesion and alkaline stability of the painted system. A good correlation was observed between the near DC impedance value and the phosphate coating weight (determined gravimetrically) after exposure in a highly alkaline environment. A trend was also observed between the phosphate coating weight and near DC impedance value prior to any aggressive exposure. The value of using EIS in these types of studies is that EIS measurements can be nondestructive and gravimetric coating weight measurements are always destructive.

Another application of EIS to evaluation of metallic coatings on steel was reported by Ruiz and Davidson [50]. Samples of painted cold-rolled steel, electrogalvanized steel, and electrogalvanealed steel were evaluated by EIS, in a laboratory cyclic corrosion test (Chrysler Chipping Test) and in a cyclic corrosion test that is conducted outdoors (Volvo test). Prior to conducting EIS measurements, a gravelometer was used to intentionally damage the paint coatings. The laboratory cyclic corrosion test employed similar paint damage prior to test. EIS measurements were sensitive to the pretreatment type and substrate type. EIS data correlated well with the accelerated corrosion test conducted outdoors (Volvo test).

A relatively new application area for electrochemical techniques to corrosion studies that has gained considerable interest over the last several years is the use of electrochemical current and potential noise measurements. Skerry was one

of the early investigators to apply this technique to steel substrates [51,52]. Skerry found good relationships between the electrochemical noise parameters and performance data for a series of organic coatings on steel. Although these studies were not completed on coated steel substrates, the methods might be directly applicable to coated steel substrates.

## **SUMMARY: SELECTING CORROSION TESTS FOR COATED SHEET MATERIALS**

There are a number of factors to consider when selecting corrosion tests for coated sheet materials. The investigator must have a clear understanding of the materials to be tested, the exposure environments these materials are likely to encounter, and the levels/durations of these exposures. The most appropriate corrosion test(s) for a particular study can sometimes change based on the goal of the study. If the goal is to rank the corrosion performance of materials, or to select the best material for exposure in a specific environment, or both, field exposure data for those materials in that environment are the ideal. When time constraints prevent this type of data from being practical, accelerated test methods are often a reasonable alternative. Proving ground tests, laboratory cabinet tests, and/or other accelerated tests may be appropriate in these cases. One key in choosing an accelerated test to model performance is a good understanding of the exposure environment being simulated. Many investigators have been misled by accelerated tests because test conditions did not match the conditions of the exposure environment that the test was supposed to simulate. For example, it does not make sense to use a salt-spray test, for example, to simulate performance of materials in most natural environments, which involve alternating cycles of wetting and drying. By the same token, it may not make sense to use the Kesternich test to simulate performance of many of these materials either, since the conditions of this test may be too severe for an accurate simulation.

If the goal is a mechanistic/kinetic investigation of the corrosion process, again examination of samples after field exposure in the environment of interest may be the ideal. When this is not possible or practical, accelerated test methods should be used. If possible, these accelerated methods should have been previously verified to result in the same extent and mechanism of degradation as actual field exposure. Electrochemical methods can often provide important mechanistic/kinetic information about a corrosion process. Surface analytical, metallographic, or spectroscopic methods, or a combination thereof, can also be important components of any mechanistic study of metallic corrosion.

A second key to choosing an accelerated test is a good understanding of the material/materials being tested. In the subsection titled Specific Systems, a discussion of the way in which several coated sheet products provide corrosion protection was presented. Selection of a cyclic test that will yield good predictive information must take these factors into account. If the material of interest is known to provide barrier protection due to the formation of a passive film on the coating surface in the exposure environment of concern,

then it does not make sense to expose it in an accelerated test environment that results in rapid anodic dissolution of the coating. A viable approach to selection of a predictive accelerated test is to use the test or series of tests on materials of known field performance that are as similar as possible to the materials that require evaluation. If the accelerated test results in similar types (mechanisms) and extents of corrosion damage on known materials, then it is likely to be predictive on the test materials. The reader is referred to Refs 53 and 54 for additional information on test methods for coated sheet products.

Throughout the field of corrosion research, efforts have been ongoing to find better corrosion tests. For several years investigators have been aware of the current limitations in both continuous exposure and cyclic tests. Most laboratories have coped with these limitations by developing their own cyclic test, testing it on their own materials to determine performance correlations, and then using this test for further studies. Although this may work well in some instances, it leads to each laboratory having their own "preferred" test method and restricts interlaboratory- and/or industry-wide understanding of data, acceptance of results, etc. It also often leads to one laboratory having to test its material using many different cyclic tests to satisfy its customers. Not only does this result in added cost and time, but can often yield results that are not meaningful if the customer-preferred test is not appropriate for the material under study.

An approach to combating these problems is to unify the test methods used by different laboratories by finding/creating tests that are predictive of field performance and that are acceptable to a wide variety of users. Two industries, automotive and metal building, have taken the approach of trying to unify cyclic test methods for coated sheet products. In each case, committees have been formed with the charge of determining the most predictive cyclic tests for coated sheet products on steel. The formation of such committees is an important milestone in the testing of coated sheet products and for the field of corrosion research as well. These committees contain representatives from metal/coated sheet producers, paint and pretreatment companies, automotive companies, and other end-users. The impact of having such diverse representation of these committees is that committee consensus has the likelihood of changing the way testing is conducted throughout the entire industry rather than only at one company or in one supply group. Such groups have the added advantage of combining the expertise of personnel throughout each industry rather than being limited to one area of expertise. This should be a significant advantage in both designing the programs and in interpreting the results.

An excellent example of such a program was the one conducted by the automotive industry sponsored by the AISI's Corrosion Task Force in cooperation with SAE/ACAP that was described earlier in this chapter. In this study, ten materials (see Table 1) were placed on vehicles operated in the corrosive environments of Montreal, Quebec and St. John's, Newfoundland to determine a performance ranking for cosmetic (outside-in) corrosion resistance. These same materials were also exposed in a series of accelerated laboratory tests, at proving grounds, and at other exposure sites.

Correlation of the test methods to actual field performance is forming the basis of selection of the most predictive accelerated tests. This work led to the development of SAE J2334, a new standard accelerated laboratory cyclic corrosion test that accurately predicts the cosmetic corrosion performance of automotive coated steel sheet. The results of this study are described in a series of publications [31,35,36,55].

A similar program also conducted by the automotive industry is also a collaborative effort between AISI's Corrosion Task Force and SAE/ACAP led to the determination of appropriate test methods for predicting perforation (inside-out) corrosion on automotive coated sheet products. Development/determination of appropriate test methods for predicting perforation corrosion on coated sheet products [56,62,65].

A similar program began in the metal building industry through ASTM Subcommittee D01.27.31 on Corrosion Testing (Nonautomotive) and AISI CC-89 Task Force on Accelerated Test Methods for Coil Coated Steel for Construction. Materials were placed in field exposure at four sites for the AISI program during the summer of 1991. Details on the design of this program and the preliminary results were recently published [63]. Laboratory testing of these materials and evaluations are in progress. It is expected that once the work of these committees has been completed, significant improvements will occur in the cyclic tests that these industries use. Due to efforts like these, the next several years should yield important advances in the way that we test the corrosion behavior of coated steel products.

This chapter has attempted to give the reader some basic information about the types of coated steel products that are in common use, the methods by which they are prepared, the mechanisms by which they undergo corrosion, and the types of test methods that can be used to evaluate these corrosion processes. It is important for the investigator to use information obtained about the exposure environment, and the performance/corrosion properties or problems of the material in question to select an appropriate corrosion test. It is also important for the investigator to have a clear understanding of the goal of the test program. Only through careful evaluation of all of the information at the disposal of the investigator can the best test for a particular situation be selected.

# Nonmetallic Coatings

*Richard D. Granata*<sup>1</sup>

## SCOPE

A LARGE NUMBER OF tests exist for establishing the reliability of nonmetallic protective coatings on metal substrates. Definitions, fundamentals, methodology, and practical examples are offered for a better understanding of tests for protective coatings and to demonstrate that well defined tests alone are not adequate without rational application and interpretation.

## Focus of Testing

Materials tests and standards of nonmetallic organic and inorganic coatings systems on corrodible substrates are described. Coatings systems may provide many properties in addition to corrosion resistance, e.g., appearance, insulation, and tack. Although test methods exist for a wide variety of coatings characteristics, the primary nonmetallic coatings tests addressed herein evaluate corrosion resistance, adhesion, and physical/chemical durability.

## Nonmetallic Coatings Materials

Two broad groups of nonmetallic coatings materials are considered:

1. Organic, including formulations containing dispersed inorganic or metallic materials. Examples: clear coatings, typical paints, metal flake coatings, organic-based galvanic (zinc-rich) coatings.
2. Inorganic, which may be modified by organic and metallic materials. Examples: phosphates, anodic coatings, oxides, carbides, nitrides, borides, silicides, inorganic-based galvanic (zinc-rich) coatings. Most of these inorganic coatings are applied. Some, such as anodic coatings, are formed by reaction on the surface.

Additional types of coatings exist, which are hybrids of these groups, and may be appropriately classified as metallic coatings or composite materials.

## Coatings and Coatings Systems

The term "coatings" implies that there is a supporting structure or substrate—an obvious point sometimes overlooked. The failure of otherwise acceptable coatings may be

due to the substrate. The machined, molded, or polished substrate may contain defects or trapped impurities that affect performance of the coatings system. A coatings test may assess the substrate properties. Likewise, the cleaning, surface preparation, and pretreatment methods influence the coatings system performance. Use of the term coatings system is intended to emphasize these interdependent properties. Most tests evaluate whole coatings systems, with emphasis on a particular component or processing step. (Conversely, the term film is appropriate when a coatings material can be evaluated independent of the substrate.)

## FUNDAMENTALS

### Tests/Standards, Application/Selection and Specifications

Tests and standards are intended to provide a means for determining the appropriateness of materials for the users' purposes. Example: The user requires excellent performance at low cost. The requirement must be translated to a set of tests and standards, collectively known as specifications, agreeable to supplier and user, often on a contractual basis. Achieving an agreement accrues benefits to both supplier and user; an efficient and effective agreement yields a competitive result. The major specification or objective in the context of corrosion testing is service life. Tests and standards must be selected and applied to satisfy user specifications (service and lifetime requirements). A difficulty is the often unsatisfactory relationship between long-term field service results to laboratory tests and standards results. Application and interpretation of tests for nonmetallic corrosion protective coatings is a dynamic, evolving process of satisfying specifications, including both short-term tests and long-term service performance. It is important to understand the limitations of tests and standards results.

### Electrochemical Mechanism of Corrosion

A typical corrosion process, the reaction of iron with hydrochloric acid (HCl) under anaerobic conditions, is represented by the equation

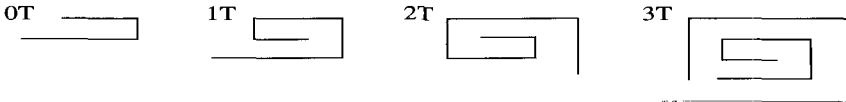

A more accurate representation is

<sup>1</sup>Florida Atlantic University, Boca Raton, FL.

TABLE 1—Brief descriptions of selected tests.

Test	Description and Remarks
Salt Spray (ASTM B 117)	Most widely specified test. Atomized 5 % sodium chloride, neutral pH, 35°C*, follow details of ASTM B 117, Appendix X1. Emphasizes wet surfaces (nondrying), high oxygen availability, neutral pH, and warm conditions. Control or comparative specimens should be run simultaneously. Corrosivity consistency should be checked as described in ASTM B 117, Appendix X3. Notes: May be the most widely misused test. Requires correlation to service tests for useful results. Do not assume correlation exists.
100 % Relative Humidity (ASTM D 2247)	Widely used test. Condensing humidity, 100 % RH, 38°C. Emphasizes sensitivity to water exposure.
Acetic Acid-Salt Spray ASTM G 85, A 1 (formerly ASTM B 287)	Widely used test. Atomized 5 % sodium chloride, pH 3.2 using acetic acid, 35°C. More severe than ASTM B 117. The lower pH and the presence of acetate affect the solubility of corrosion products on and under the protective coatings.
Sulfur Dioxide-Salt Spray (ASTM G 85, A 4)	Atomized 5 % sodium chloride, collected solution pH = 2.5–3.2, 35°C, SO <sub>2</sub> metered (60 min × 35 cm <sup>3</sup> /min per m <sup>3</sup> cabinet volume) 4 times per day.
CASS(copper accelerated salt spray), (ASTM B 368)	Atomized 5 % sodium chloride, pH 3.2 with acetic acid, 0.025 % cupric chloride-dihydrate, 35°C. Galvanic coupling due to copper salt reduction to copper metal. More severe than ASTM B 117.
FACT(formely ASTM B 538)	Testing anodized aluminum specimens. Electrolyte as in salt-spray or CASS test. Specimen is made the cathode to generate high pH at defects.
Accelerated Weathering	Exposure of coated specimens to effects of UV radiation experienced in outdoor sunlight conditions which may be combined with other exposures such as moisture and erosion. Exposure cabinets use carbon arc (ASTM D 822), xenon lamp (ASTM G 26) or fluorescent lamp (ASTM G 53).
Lactic Acid	On substrates of brass and copper alloys, determines coatings porosity and resistance to handling (perspiration). Consists of immersion in 85 % lactic acid solution, drying and incubating above acetic acid vapors for 20 h to reveal discoloration spots at failure points or delaminations.
Acidified Synthetic Seawater Testing (SWAAT), ASTM G 85, A 3 (formerly ASTM G 43)	Atomized synthetic seawater (ASTM D 1141) with 10 mL glacial acetic acid per L of solution, pH 2.8 to 3.0, 35°C. More severe than ASTM B 117. The lower pH and the presence of acetate affect the solubility of corrosion products on and under the protective coatings.
Electrographic and Chemical Porosity Tests	Pores and active defects in nonmetallic coatings can be revealed by color indication or deposit formation. On nickel substrates, dimethylglyoxime, or steel, potassium ferricyanide (ferroxyl test) indicator can be applied to surface on filter paper while substrate is made the anode. Alternatively, a substrate immersed in acidic copper sulfate can be made the cathode to form copper nodules at conductive coatings defects.
Adhesion ASTM D 3359-02	Knife and fingernail test consists of cutting through the coating with knife or awl and dislodging coating with thumbnail or fingernail (pass/fail). The ASTM D 3359 test consists of “X” scribes or parallel cross-hatches followed by adhesive tape stripping of loosened coating.
T-Bend Adhesion ASTM D 4145	Combined flexibility and adhesion test consists of clamping end of coated flat metal panel in vise or similar tool, bending (convex) through 90°, reclamping to bend through 180° to give “0T” bend (where “T” is panel thickness and # (zero, 1, 2, ...) is the number of panel thicknesses). Rebending over the 180° bend gives a “1T” bend. Adhesive tape is pressed down along edge of bend and any loose coating stripped off.
	
Scab Test	Cyclic testing consisting of short salt exposure, short drying period, and long period of high humidity. Undercutting from scribe is measured.
Exterior Exposure ASTM D 1014	Method for conducting exterior exposure tests of paints on steel. Well-defined exposure setup, not necessarily equivalent to service tests.
Service Test/Data	Performance data of coatings systems under use conditions. Slowest evaluation method: provides tangible results.

\*Note that dissolved CO<sub>2</sub> concentration at 0°C is three times that of concentration at 35°C and can affect corrosion.

which indicates that the acid reactant and the ferrous chloride (FeCl<sub>2</sub>) corrosion product exist largely in the ionic state in aqueous solution. The probability of this reaction occurring by the mechanism implied in the equation is very low because too many species must meet simultaneously. We may, however, conceive of this reaction occurring in two independent steps

In the two reactions, electron loss occurs at one site and electron gain occurs at another with the electrons linking the reactive sites through the conductive metal phase (Fe<sup>0</sup>).

The overall reaction takes place at a rate determined by the more difficult of these two steps. This simple concept, independent anodic and cathodic half-reactions, is the basis of the electrochemical mechanism of corrosion. The mechanism has profound effects on the corrosion protective properties of nonmetallic coatings materials. Some tests exploit the electrochemical mechanism to determine specific corrosion susceptibilities of coatings systems such as cathodic disbondment and pinhole detection. Coatings that are permeable to oxygen may be vulnerable to damage due to an alternative cathodic reaction

capable of causing high local pH and chemical degradation of the polymer or adhesive bonds. Thermodynamically this cathodic (reduction) reaction takes precedence over the hydrogen ion reduction reaction whenever oxygen is present at the cathodic reaction site.

### Corrosive Environmental Exposure

Corrosion occurs when all components of the process are present and capable of reaction (see preceding section). Basic test conditions include exposure of the coatings systems to an electrolyte containing reducible species (typically oxygen or hydrogen ion). More sophisticated testing would include closely replicating known corrosive conditions such as wet/dry cycles and multicomponent and multiphase chemical environments. Immersion, salt spray, and a partial pressure of sulfur dioxide corrosion tests correspond to water tank, marine, and combustion exhaust service environments, respectively. An important relationship exists between the corrosive environment used in the test procedures and the product's intended service use.

### Corrosion Effects

Distinction should be made between degradation due to corrosion and/or other processes. Corrosion can cause loss of coatings adhesion such as occurs with cathodic disbondment, blistering, or undercutting. Although adequate adhesion is necessary, greater adherence does not correspond to greater corrosion resistance. Exposing a coatings system to water can reduce the adhesion (wet adhesion), which is regained upon drying. Unless permanent damage occurs during the low adhesion period, no corrosion degradation results. The same may be true for other properties such as flexibility. Initial properties and property changes due to a corrosion environment may relate to corrosion protective properties. Clearly defining the relationship between measured properties and the intended use of the protective coatings is important.

### Noncorrosive Effects

There are many tests for coatings systems that provide useful information related to service requirements involving salts, fogs, immersion, scribes, radiation, heat, chemical, cold, and pressure transients. Whether such tests are applicable to the service intended for the coatings must be established and the test results must be interpreted in the context of corrosion protection performance. Ultraviolet (UV) resistance is not a useful property for the interior of water storage tanks. Long-term 100 % relative humidity and water immersion resistances are not necessarily appropriate for outdoor desert or climate-controlled indoor environments. Selecting tests without regard for the coatings' use may be detrimental to the development or qualification of a satisfactory coatings system.

## TESTS AND STANDARDS: SELECTION, APPLICATION, AND INTERPRETATION

### Available Tests and Standards

New and existing tests and standards are under continuous development and revision. ASTM is a leader of tests and

standards; other contributors, with various emphasis on specifications, are the federal government with Federal Test Method Standard 141C,<sup>2</sup> state government agencies, NACE International, Society of Automotive Engineers (SAE), Steel Structures Painting Council (SSPC), National Coil Coaters Association (NCCA), International Standards Organization (ISO), foreign systems (DIN), and commercial (e.g., automotive, architectural, electronics), proprietary, and military organizations. A comprehensive listing of these tests and standards is not the intent of this document.

Gaynes [1] and Munger [2] give descriptions and the framework for effective use of tests and standards. Gaynes [1] provides detailed descriptions including photographs, cross-listing ASTM to federal tests and a broader perspective encompassing the federal standard, miscellaneous tests, and some caveats of traditional testing. Munger [2] offers practical material directed towards large structures and provides a listing based on ASTM standards. Altmayer [3] compiled a table of 13 applicable corrosion tests for 30 metallic, inorganic, and organic coating/substrate combinations. The most commonly used tests are salt spray (ASTM B 117), acetic acid salt spray (ASTM G 85, Annex A1, formerly ASTM B 287), and the 100 % humidity (ASTM D 2247). A condensed listing with brief descriptions of tests selected from Altmayer [3], Mazia [4], ASM International [5], and others is given in Table 1. Additional tests are listed in Table 2, an edited and revised listing by Munger [2]. Hess [6] provides a very important auxiliary reference aiding in identifying the causes of paint film defects.

### Methods Selection

The large number of tests and methods makes selection difficult. Suppliers, users, and testers/researchers have different perspectives to help narrow the selection process. Obtaining corrosion resistance information enables a better focus. To aid in the selection process where no universal methodology exists, engage one or more from the following sections: (1) survey of practices; (2) specific practice by a successful coatings industry participant; (3) service life testing philosophy; and/or (4) a useful practical example involving cooperative efforts through better understanding (methodology).

#### Survey of Practices

A survey commissioned by the Federation of Societies for Coatings Technology (FSCT) was performed by Steel Structures Painting Council (SSPC) [7]. The full report [8] is available from FSCT and contains useful details including nonstandard tests and analyses. One portion of the report is particularly relevant to methods selections; a compilation of 102 coatings test users' responses is shown in Table 3, from which two conclusions are drawn: (1) most respondents used only one or two tests; and (2) the most prevalent test was salt spray. Salt spray testing is a crude approximation to highway environments involving deicing compounds [8] (see also fourth account below, Cooperative Practice Yielding Better Understanding) and is more useful for marine systems [8]. Coatings users may approach quality assurance with fewer tests than formulators [8]. Liu [9] presents a considerate case describing salt spray test usefulness or

<sup>2</sup> Standard 141C supersedes 141A and 141B.

uselessness based on years of experience. (See other chapters in this Manual on “Cabinet Tests” and “Automotive.”)

### A Specific Practice

The following tests constitute a generic test plan used by one industrial service company for coated metal in laboratory performance testing. A 4 in. by 12 in. (10.2 cm by 30.5 cm) coated panel is the preferred configuration. Before accelerated corrosion tests (ASTM B 117, G 85-A1, B 368, and G 85-A3), a scribe is introduced using ASTM D 3359,

Method A or D 1654, Section 5. Exposure times are 240–1000 h, depending on test and substrate. Additional corrosion tests (unscribed and ASTM D 714 evaluation) include hot humidity (ASTM D 2247, 100°F/100 % RH), condensing humidity (ASTM D 4585, 140°F), condensing humidity/UV (ASTM G 53, 150°F), water soak (ASTM D 870), and detergent soak (ASTM D 2248, 72 h). Scribed samples are prepared for ASTM D 1654 evaluation by scrape/rinse/dry, rinse/blow-off or 3M's #610 tape pull-off. Other noncorrosion tests (mainly adhesion) are also performed including T-Bend, Wedge Bend, Conical Mandrel, Impact (Direct/Reverse), MEK rub

<sup>a</sup> Multiple tests used (total greater than 100%).

(cure test), Olsen Cup, Gravelometer, Pencil Hardness, Cross-Hatch, Dry Film Thickness, and Loss of Gloss. This battery of tests provides generous information about the coatings system, without establishing a direct link to service data. The test battery is necessarily extensive because the intent is to determine possible causes for service problems. A clear relationship between service and test data is necessary for problem resolution.

### Service Life Testing Methodology

In the example in the preceding paragraph, no rationale is given for the selection or application of the tests. Experience provides an important gauge for developing a useful set of tests. Dickie [10] suggested that a methodology be developed to provide rational guidance for service life testing, and proposed a general framework integrating laboratory experiments, field exposure history, and theoretical and empirical models. The central role of physical and chemical models of degradation processes in service life prediction was examined [10] and represents an important philosophical contribution for coatings testing. The methodology was first presented in a somewhat different form at an informal meeting of experts discussing coatings failure mechanisms [11]. (Correlation of test results with service life is discussed in several chapters in the section on Testing in Industries in this manual.)

### Cooperative Practice Yielding Better Understanding

AISI [12–14] has taken a leadership role to develop and evaluate methodology based on laboratory experiments, field exposure history, and theoretical and empirical models through an open forum of all interested parties (mainly North American automotive and steel industries), organized as the Corrosion Task Force of the AISI. The task force developed an improved laboratory-accelerated test for ranking the cosmetic corrosion resistance of coated automotive steel sheet products. This approach serves as a model for methodology development in areas of nonmetallic coatings corrosion testing.

### SUMMARY

- Many tests are available for evaluation of corrosion protective properties necessitating a test selection process.

- Understanding the protective mechanisms of coatings systems aids in developing methodologies for systems having long lives.
- The interpretation of the test results requires adequate correlation to service life data.
- Service results validation is difficult and often requires constrictively long times.
- Successful case histories and experiences provide the best means for useful evaluations until functional methodologies are devised.

# Metal-Matrix Composites

*L. H. Hihara*<sup>1</sup>

METAL MATRIX COMPOSITES (MMCs) are metals that are reinforced with fibers or particles that usually are stiff, strong, and lightweight. The fibers and particles can be metal (e.g., tungsten), nonmetal (e.g., carbon or boron), or ceramic (e.g., silicon carbide (SiC) or (alumina)  $\text{Al}_2\text{O}_3$ ). The purpose for reinforcing metals with fibers or particles is to create composites that have properties more useful than that of the individual constituents. For example, fibers and particles are used in MMCs to increase stiffness [1], strength [1], and thermal conductivity [2], and to reduce weight [1], thermal expansion [3], friction [4], and wear [5].

Selection of the matrix metal and reinforcement constituent is usually based on how well the combination interacts to achieve desired properties. Interaction of the MMC with the environment is normally a secondary consideration; therefore, it is not uncommon for MMCs to have low resistance to corrosion. It is also not uncommon for MMCs to have corrosion behavior significantly different from what might be expected, based on the normal corrosion behavior of the MMC constituents. The corrosion resistance of the MMC is usually inferior to that of its monolithic matrix alloy, due to one or more of the following reasons:

1. Galvanic coupling of reinforcement constituent and matrix;
2. Formation of an interphase between the reinforcement constituent and matrix;
3. Microstructural contaminants and processing residuals in the MMC; and
4. Microstructural changes caused by the presence of the reinforcement constituents.

The corrosion behavior of aluminum, magnesium, lead, depleted uranium, stainless steel, titanium, copper, and zinc MMCs will be reviewed. Reinforcement constituents used in the aforementioned MMCs include boron, graphite, SiC,  $\text{Al}_2\text{O}_3$ , mica, quartz, tungsten, yttria, and zircon. The reinforcement constituents usually range from 10 to 60 vol. %. This review focuses on the corrosion properties of bulk MMCs and does not cover corrosion protection of MMCs, surface modification of MMCs, or MMCs used as coatings. Other reviews on corrosion of various types of MMC are available [6–12]. Methods and tests that can be used in a corrosion testing program to assess corrosion damage, determine corrosion mechanisms, and study specific types of corrosion will be discussed.

## CORROSION SUSCEPTIBILITY OF MMCS

The effect of different types of reinforcement constituents on MMC corrosion behavior is discussed below. Due to the limited amount of information on MMC corrosion behavior, it is not feasible to have separate sections for effects of alloying elements, effects of microstructure, sensitivity to acidity/alkalinity, etc. MMCs are relatively new and specialized materials; therefore, only a limited number of corrosion studies have been conducted. Most studies relate the effects of the reinforcement constituents to overall MMC corrosion behavior.

### Aluminum MMCs

Corrosion research has focused primarily on aluminum MMCs, which is the only type of MMC that has become widely available [3]. Aluminum has relatively good corrosion resistance and is lightweight. Its density is  $2.7 \text{ g/cm}^3$ . Corrosion studies have been conducted on aluminum MMCs reinforced with boron, graphite, SiC,  $\text{Al}_2\text{O}_3$ , and mica. Corrosion of diffusion bonds, stress corrosion, and corrosion fatigue will also be discussed.

#### *Effect of Boron*

The primary use of boron/aluminum (B/Al) MMCs has been tubular struts in the mid-fuselage structure of the space shuttle. The use of B/Al MMCs instead of aluminum alloys (as planned in the original design) resulted in a 44 % savings in weight [13].

Boron filaments (BFs) consist of polycrystalline boron with a core of tungsten and tungsten borides, which form during processing [14]. B/Al MMCs are usually fabricated by diffusion bonding BFs between aluminum foils [15]. Aluminum borides (i.e.,  $\text{AlB}_{12}$  and  $\text{AlB}_2$ ) have been found at BF-matrix interfaces [16].

Crystalline boron has good chemical resistance and is not attacked by strong acids and bases, even though it is thermodynamically unstable in water [17]. Accordingly, BFs are relatively inert in aqueous solutions. No observable degradation of the BFs was observed after exposure to boiling, saturated, nickel chloride solutions for 16 s [18], or to 3 % NaCl solutions containing 0.1 % hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) [19].

Pure boron (99.999 %) [20], as-manufactured (referred to as "virgin") BF with tungsten core shielded [20,21], virgin BF with tungsten core exposed [21], and BF extracted from aluminum matrices (not specified if tungsten core exposed)

FIG. 1—Micrograph of Gr/6061-T6 Al MMC. Graphite fiber volume fraction is approximately 50 %.

[22] are noble to aluminum in NaCl solutions. Therefore, galvanic corrosion of aluminum coupled to pure boron or BF is thermodynamically possible. Pure boron, however, is an insulator and cannot support electrical currents under normal conditions. Cathodic and anodic currents were unmeasurable on pure boron (99.999 %) electrodes in aerated NaCl solutions [20]. The conductivity of BFs is many orders of magnitude greater than that of pure boron, due to tungsten and tungsten borides in the core [14]. Galvanic currents, however, were also unmeasurable between virgin BF and 2024 aluminum or 6061 aluminum in 3.5 % NaCl solutions [22]. It was not specified whether solutions were aerated or deaerated and whether the tungsten core of the BFs was exposed. Galvanic currents were measurable between the aluminum alloys and BFs that were extracted from the matrix [22]. The extracted BFs were enveloped by a 4- $\mu\text{m}$ -thick layer of aluminum boride, which could not be positively identified as  $\text{AlB}_2$  or  $\text{AlB}_{12}$ . Galvanic currents measured between the aluminum alloys and aluminum boride (boride species not specified) were similar to those between the alloys and the extracted BFs. When the layer of aluminum boride was removed from the extracted BFs, the galvanic current ceased, indicating that the aluminum boride interphase is necessary for galvanic corrosion. In addition, B/Al MMCs were noble to the matrix alloy and active to the extracted BF and aluminum boride, which coincides with the mixed-potential theory. The corrosion rate of B/Al MMCs also increased when the BF content was increased from 18 to 46 vol. %, suggesting that corrosion rates increase as aluminum-boride cathodic sites increase. It was also noted that BF-matrix interface regions were preferentially corroded, but it was not determined if matrix near the interphase or the interphase itself was attacked. Others [19,20] have found that diffusion bonds in B/Al MMCs have been major sources

of corrosion. This is discussed in the subsection below entitled, *Effect of Diffusion Bonds and Microstructural Contaminants*.

#### *Effect of Graphite*

Continuous fiber Gr/Al MMCs (Fig. 1) are known to have high specific tensile strength and stiffness in the direction of the fiber axis. Limitations of shear, compression, and transverse strengths of the MMCs, however, have restricted their use [3]. Particulate Gr/Al MMCs have also been developed for potential use in tribological applications due to good resistance to wear and seizure [23,24].

In the presence of water, carbon has a small domain of thermodynamic stability in potential-pH space [25]. At active potentials, it is thermodynamically possible to form methane ( $\text{CH}_4$ ) by the reaction

but this has not been confirmed [25]. No  $\text{CH}_4$  was detected or visual fiber degradation observed when pitch-based graphite fibers were cathodically polarized [26]. At noble potentials, various carbon compounds may form during carbon oxidation [25], but carbon dioxide ( $\text{CO}_2$ ) and carbon monoxide ( $\text{CO}$ ) are believed to be the dominant reaction products [27]. During anodic polarization, pitch-based graphite fibers are oxidized to  $\text{CO}_2$  and  $\text{CO}$  with crevice formation [26]. Graphite compounds also form by the intercalation of ions between graphite planes during polarization [27]. In the open-circuit condition or when coupled to aluminum, however, graphite fibers do not usually exhibit visual degradation.

Graphite, which is an electrical conductor, can serve as an efficient cathode during galvanic corrosion in Gr/Al MMCs. Czyrklis [28] and others [29–31] have found that the

FIG. 2—Anodic polarization diagrams of ultrapure aluminum and 6061-T6 aluminum in deaerated 3.15 wt % NaCl plotted with the cathodic polarization diagrams of pitch-based graphite fibers (cross section exposed) in deaerated and aerated 3.15 wt % NaCl at 30°C. Scan rate = 0.1 mV/s.

open-circuit potential of a Gr/Al MMC is noble to the matrix alloy in deaerated NaCl solutions [28]. The open-circuit potential of a particulate Gr/Al MMC, however, was reported to be more active than the matrix material for a case in which the presence of graphite particles caused a large increase in the anodic currents [32]. Dull et al. [33] conducted polarization experiments on various Gr/Al MMCs in NaCl solutions, and found that dissolved oxygen greatly increases the corrosion rate, indicating that the main driving force for galvanic corrosion is oxygen rather than proton reduction in aerated solutions. Using the zero-resistance ammeter (ZRA) technique [34], Dash [35] showed that the galvanic-corrosion current density ( $i_{\text{GALV}}$ ) of a galvanic couple with a 5-to-1 area ratio of pure aluminum to pitch-based graphite fiber increased from less than  $1 \times 10^{-8}$  A/cm<sup>2</sup> in deaerated 3.5 wt % NaCl to  $1.5 \times 10^{-6}$  A/cm<sup>2</sup> in aerated 3.5 wt % NaCl. Hihara and Latanision [36] also found that  $i_{\text{GALV}}$  of galvanic couples consisting of equal areas of 6061-T6 aluminum and pitch-based graphite fiber was about 60 times greater in aerated 3.15 wt % NaCl solutions compared to deaerated solutions where  $i_{\text{GALV}}$  was equal to about  $3 \times 10^{-6}$  A/cm<sup>2</sup>. The galvanic effect has also been reported in particulate Gr/Al MMCs [37,38].

Figure 2 shows the anodic polarization diagrams of ultrapure aluminum (99.999 %) and 6061-T6 aluminum in deaerated 3.15 wt % NaCl with the cathodic polarization diagrams of pitch-based graphite fibers in deaerated and aerated 3.15 wt % NaCl. As shown in the figure, proton reduction on graphite will polarize aluminum to noble potentials that are less than the pitting potential  $E_{\text{PIT}}$ , explaining the negligible galvanic-corrosion rates in deaerated solutions. Oxygen reduction on graphite, however, polarizes aluminum into the pitting regime, which causes high galvanic-corrosion rates in aerated, chloride-containing solutions. Figure 3 shows  $i_{\text{GALV}}$  of 6061-T6 aluminum and ultrapure aluminum as a function of the area fraction of pitch-based graphite fiber (cross section exposed) in aerated 3.15 wt % NaCl [36]. Both ultrapure aluminum and 6061-T6 aluminum are represented by the same curve, since they have similar galvanic-corrosion behavior. Relatively new, nonequilibrium aluminum alloys containing approximately 20 at. % molybdenum or 26 at. % tungsten, with marked higher pitting

FIG. 3—Graphs showing  $i_{\text{GALV}}$  of ultrapure aluminum and 6061-T6 aluminum as a function of area fraction  $X_c$  of graphite fiber and SiC in aerated 3.15 wt % NaCl at 30°C.

potential (i.e., in excess of 1 V compared to pure aluminum) in chloride solutions, have been studied as potential new alloys for Gr/Al MMCs [39,40]. The results have been promising, as graphite fibers in aerated chloride solutions were incapable of polarizing the alloys to their pitting potentials, resulting in galvanic corrosion rates between the fibers and alloys up to three orders of magnitude lower than that with pure aluminum [39,40].

Another cause of degradation in Gr/Al MMCs is the presence of  $\text{Al}_4\text{C}_3$ . An aluminum carbide interphase forms by the reaction of aluminum and carbon [41]. In Gr/Al MMCs, the formation of  $\text{Al}_4\text{C}_3$  becomes substantial during processing at temperatures much higher than the liquidus temperature [42]. Portnoi et al. [43] showed that  $\text{Al}_4\text{C}_3$  in Gr/Al MMCs readily decomposes in water, producing  $\text{CH}_4$  and aluminum hydroxide  $\text{Al}(\text{OH})_3$ :

The hydrolysis rate of hot-pressed  $\text{Al}_4\text{C}_3$  (78 % theoretical density) was measured to be approximately 1 %/hr [44].

Aylor and Moran [45], who conducted polarization experiments on Gr/Al MMCs in seawater, also hypothesized that diffusion of carbon into aluminum could lower the integrity of the passive film, rendering it more susceptible to breakdown. Wielage [46] reported that the pitting potentials of various squeeze-cast Gr/Al MMCs were approximately 20 mV more active than that of the pure aluminum matrix material in a chloride solution. Aluminum carbide was found at the Gr fiber-matrix interfaces. Shimizu et al. [31], however, found that pitting potentials of a squeeze-cast, short fiber Gr/6061 Al MMC had pitting potentials similar to that of monolithic 6061 Al in a chloride solution.

#### Effect of Silicon Carbide

The SiC/aluminum (SiC/Al) MMCs are reinforced with SiC particles (P) (Fig. 4), whiskers (W), fibers, or monofilament (MF). In 1988, an aluminum tube in the catamaran *Stars and Stripes* '88 was replaced by a lighter SiC<sub>p</sub>/Al MMC tube having a 30.5-cm outer diameter [3]. Lightweight mirrors for telescopes have also been fabricated from SiC<sub>p</sub>/Al MMC foam [47].

The electrical resistivity of SiC depends on its purity. It ranges from about  $10^{13}$  to  $10^{-5}$   $\Omega$  cm [48]. Thus, in the un-pure state, the resistivity of SiC can be rather low. Some

FIG. 4—Micrograph of SiC/6061-T6 Al MMC. SiC volume fraction is 13 %.

SiC<sub>MF</sub> also have carbon cores and carbon-rich surfaces [49], with resistivities on the order of  $10^{-2} \Omega \text{ cm}$  [44]. Consequently, in aqueous solutions, SiC can serve as an inert electrode for proton and oxygen reduction. Depending on the type of SiC, galvanic corrosion with aluminum is possible.

In deaerated, chloride-containing solutions, SiC/Al MMCs and their matrix alloys passivate in the open-circuit condition [45,50]. Proton reduction alone cannot polarize the composites or the matrix alloys to  $E_{\text{PIT}}$ , since oxygen reduction is required for this. Accordingly, in aerated, chloride-containing solutions, the open-circuit potentials of SiC/Al MMCs and their matrix alloys are nearly equal to pitting potentials [50].

Galvanic corrosion between aluminum and SiC is possible in aerated chloride-containing environments. The degree of galvanic corrosion is strongly dependent on the type of SiC reinforcement. Figure 5 shows the anodic polarization diagrams of ultrapure aluminum and 6061-T6 aluminum in deaerated 3.15 wt % NaCl with the cathodic polarization diagrams of hot-pressed SiC, SiC<sub>MF</sub> (configurations with either carbon cores or carbon-rich surface exposed), pitch-based graphite fiber, and 6061-T6 aluminum in aerated 3.15 wt % NaCl. The figure shows that  $i_{\text{GALV}}$  of 6061-T6 aluminum coupled to hot-pressed SiC (of equal surface area) is about twice the normal corrosion current density ( $i_{\text{CORR}}$ ) of 6061-T6 aluminum. When 6061-T6 aluminum is coupled to SiC<sub>MF</sub> (of equal surface area),  $i_{\text{GALV}}$  is about 25 times greater than  $i_{\text{CORR}}$  of 6061-T6 aluminum. The influence of the carbon core and carbon-rich surface of the SiC<sub>MF</sub> is clearly seen in Fig. 5 where the polarization diagram of the SiC<sub>MF</sub> has a stronger resemblance to that of pitch-based graphite than that of hot-pressed SiC [44]. Galvanic current between Nicalon SiC fibers and an aluminum alloy was also measured in an aerated NaCl solution [29]. The galvanic current was 72  $\mu\text{A}$

(specimen areas not given) and 15 % of that between carbon fiber and the aluminum alloy.

For particulate SiC/Al MMCs, the galvanic corrosion behavior is likely to be more accurately represented by comparison to the hot-pressed SiC data, as opposed to the SiC<sub>MF</sub> and Nicalon SiC fiber data. From the polarization data in Fig. 5, galvanic-corrosion rates were calculated for ultrapure aluminum and 6061-T6 aluminum coupled to hot-pressed SiC exposed to aerated 3.15 wt % NaCl [36]. Figure 3 graphically shows  $i_{\text{GALV}}$  as a function of hot-pressed SiC area fraction. Galvanic corrosion between hot-pressed SiC and 6061-T6 Al would not exceed the normal corrosion rate of 6061-T6 Al in aerated 3.15 wt % NaCl until the SiC volume fraction exceeds approximately 0.3. Hence, based on

FIG. 5—Anodic polarization diagrams of ultrapure aluminum and 6061-T6 aluminum in deaerated 3.15 wt % NaCl plotted with the cathodic polarization diagrams of pitch-based graphite fiber, SiC<sub>MF</sub>, hot-pressed SiC, and 6061-T6 aluminum in aerated 3.15 wt % NaCl at 30°C. CS = cross section exposed. FS = fiber surface exposed. Scan rate = 0.1 mV/s.

Fig. 3, galvanic corrosion of particulate SiC/Al MMCs would increase with SiC content and become relatively noticeable only at higher SiC volume fractions; for example, in the electronic grade MMCs with 35–55 vol. % SiC.

Experimental results have generally indicated that the corrosion rate of particulate and whisker SiC/Al MMCs increase with SiC content in aerated, chloride-containing environments. Lore and Wolf [51] found that the degree of corrosion in SiC<sub>w</sub>/6061 Al MMCs exposed to chloride-containing solutions is proportional to the SiC content. Metzger and Fishman [6] reported the results of DeJarnette and Crowe who exposed 20 vol. % SiC<sub>p</sub>/2024 Al MMCs and monolithic 2024-T4 Al to aerated 3.5 wt % NaCl. The composite corroded about 40 % faster than the matrix alloy. Sun et al. [52] and Modi et al. [53] have also reported that corrosion rates of SiC<sub>p</sub>/Al MMCs were higher than that of the matrix alloys. Griffiths and Turnbull [54], however, found no evidence of galvanic corrosion in SiC/6061 aluminum MMCs with 20–30 wt % (17–27 vol. %, respectively) SiC particles. Rather, they showed that diffusion-limited oxygen reduction on SiC/Al MMCs in an NaCl solution was significantly greater than that of the monolithic alloy, which could not be attributed to the SiC content, but could be attributed to the increase in intermetallic particles in the MMC. Hence, it is possible that the increase in corrosion rates of the MMCs in comparison to the monolithic alloys could be the result of oxygen reduction on intermetallics. Observations contrary to that of Griffiths and Turnbull, however, have been made. Sun et al. [52] reported that the degree of corrosion increased with SiC particle content, but the intermetallic content was relatively constant.

Silicon carbide particles in SiC/Al MMCs have little effect on passive currents. In a chloride-free, sodium tetraborate-boric acid solution of pH 8.4, the passive current of a SiC<sub>w</sub>/6061 Al MMC was only slightly greater than that of monolithic 6061 aluminum [55]. In deaerated 0.1 N NaCl, the passive current densities (at potentials less than  $E_{PT}$ ) of 20 % SiC<sub>w</sub>/2024 Al and 20 % SiC<sub>w</sub>/6061 Al MMCs were actually slightly less than that of their monolithic matrix alloys. The passive current densities were on the order of  $10^{-5}$  A/cm<sup>2</sup> [50].

Silicon carbide also has little effect on  $E_{PT}$  [29,31,45, 50,54,56–59] indicating that the presence of SiC particles does not degrade the pitting resistance of passive films on aluminum. The pitting potential of a 20 vol. % SiC<sub>w</sub>/2024 Al MMC, however, was depressed by about 0.1 V [50]. Contrary to the relatively invariable behavior of  $E_{PT}$ , pit morphology is indirectly affected by the presence of SiC particles. Trzaskoma [60] found that pits on SiC<sub>w</sub>/Al MMCs were notably more numerous and much smaller in size, compared to pits on wrought and powder-compacted monolithic alloys during anodic polarization in 0.1 N NaCl. The pits nucleated at intermetallic particles (not SiC), which are smaller and more numerous in the MMCs than in the monolithic matrix alloys [60]. Apparently, SiC whiskers [60] and particles [54] enhance the precipitation of the intermetallic phases. The presence of SiC, therefore, may increase the number of intermetallic pit-nucleation sites but does not weaken the resistance of the passive film, as gaged by pitting potentials. Others have also observed pit nucleation at dendrite cores [61], near eutectic silicon [58,62] and intermetallic particles [62] in various SiC/Al MMCs.

The corrosion behavior of particulate SiC/Al MMCs is also sensitive to processing. The SiC particles have an indirect effect on corrosion behavior by altering the condition of the matrix metal. Processing conditions and the presence of SiC particles can affect void content [63], dislocation density [64], and the precipitation of active phases [65] in aluminum matrices. Paciej and Agarwala [63] found that certain solution heat treatments and high extrusion ratios improved corrosion resistance of a 20 % SiC<sub>p</sub>/7091 Al MMC. Bhat et al. [66] reported that extrusion improved the corrosion resistance of cast MMCs by reducing the amount of pores and agglomerates of SiC particles; and Ahmad and Abdul [67] found that the T4 temper improved corrosion resistance over O and F tempers due to a finer, more homogenous distribution of secondary phases. It has been suggested that corrosion near the SiC-Al interface could be caused by high dislocation density due to a mismatch of the coefficient of thermal expansion between SiC and aluminum [44,68,69], segregation of alloying elements to the SiC-Al interface [70], or the formation of Al<sub>4</sub>C<sub>3</sub>, which hydrolyzes in water. Silicon carbide reacts with molten aluminum to form Al<sub>4</sub>C<sub>3</sub> if the silicon activity is low [71]. Aluminum carbide has been identified as a source of corrosion for MMCs reinforced with particles [72] and SiC Nicalon fibers [29].

### *Effect of Alumina*

Particles and both short and continuous Al<sub>2</sub>O<sub>3</sub> fibers have been used to reinforce aluminum alloys. A short type of Al<sub>2</sub>O<sub>3</sub> fiber has been used to reinforce diesel-engine pistons [73].

The resistivity of Al<sub>2</sub>O<sub>3</sub> (99.7 % pure) is greater than about  $10^{14}$  Ω·cm [74], and therefore, galvanic corrosion between Al<sub>2</sub>O<sub>3</sub> fibers and aluminum is unlikely. In alkali and acidic solutions, Al<sub>2</sub>O<sub>3</sub> is thermodynamically unstable [75]; however, the short type of Al<sub>2</sub>O<sub>3</sub> fibers are resistant to hot concentrated alkalis and most hot acids [76]. It can be assumed for practical purposes that Al<sub>2</sub>O<sub>3</sub> fibers are inert in aqueous solutions to which Al<sub>2</sub>O<sub>3</sub>/Al MMCs are likely to be exposed.

The Al<sub>2</sub>O<sub>3</sub> reinforcements usually do not have significant effects on pitting potentials in chloride solutions [29,31, 56–58,77], although passive current densities below the pitting potential have been reported to increase with Al<sub>2</sub>O<sub>3</sub> content [77]. Microbial corrosion was also more significant on particulate MMCs in comparison to the monolithic alloy, indicating that the Al<sub>2</sub>O<sub>3</sub>/Al matrix interface may have aided biofilm formation [78].

Formation of interphases incorporating aluminum, oxygen, and alloying elements has been observed in some Al<sub>2</sub>O<sub>3</sub>/Al MMCs. Preferential corrosion near fibers and particles is sometimes noticed.

Continuous Al<sub>2</sub>O<sub>3</sub> fibers in an aluminum (2 % Li) MMC (containing 50 vol % of fibers) [79] were enveloped by a 2 to 3 μm thick Li<sub>2</sub>O·5Al<sub>2</sub>O<sub>3</sub> interphase, which formed during processing of the composite [6]. The corrosion resistance of the Al<sub>2</sub>O<sub>3</sub>/Al (2 % Li) MMC was compared to that of 6061-T6 aluminum and 2219-T87 aluminum in eight accelerated-corrosion tests that are often used for wrought aluminum alloys. Most of the test environments contained chlorides. In most cases, weight-loss data showed that the corrosion rate of Al<sub>2</sub>O<sub>3</sub>/Al (2 % Li) MMCs was slightly higher than that of 6061-T6 aluminum, but significantly lower than that of 2219-T87 aluminum. No severe interfacial corrosion was observed.

Continuous fibers in an aluminum (2 % magnesium) MMC [80] were enveloped by a thin layer of  $\text{MgAl}_2\text{O}_4$  through which bonding between fiber and matrix was made. Near the fibers, iron was detected and magnesium concentrations reached levels of about 10 %, suggesting that  $\text{Mg}_2\text{Al}_3$  clusters were present. Pits were found near the fibers after the composites were exposed to NaCl solutions containing  $\text{H}_2\text{O}_2$ . Yang and Metzger [80] attributed the pits to corrosion of  $\text{Mg}_2\text{Al}_3$ , which is rapidly attacked at low potentials. No attack of the  $\text{MgAl}_2\text{O}_4$  interphase was observed.

Preferential corrosion in the proximity of an unspecified type of  $\text{Al}_2\text{O}_3$  fiber in a 6061-T6 aluminum MMC was observed by Agarwala [81]. The MMC was exposed to 3.5 wt % NaCl (deaeration or aeration was not specified) for a 500-h period. No correlation was made between the microstructure and the region of corrosion.

Selective attack in the vicinity of  $\text{Al}_2\text{O}_3$  particles has been observed during anodic polarization [82] and in the open-circuit condition [58] in chloride solutions.

### *Effect of Mica*

Mica/aluminum (mica/Al) MMCs have been developed for potential use in applications where good antifriction, seizure resistance, and high-damping capacity are required [83].

Muscovite ( $\text{KAl}_3\text{Si}_3\text{O}_{10}(\text{OH})_2$ ) mica particles that are less than about 70  $\mu\text{m}$  in size are used in mica MMCs [84]. Galvanic corrosion between aluminum and muscovite should not be a problem, since muscovite is an insulator with resistivities that range from about  $10^{13}$  to  $10^{17} \Omega\cdot\text{cm}$  [85]. Muscovite is insoluble in cold water [86]; however, it has been reported that muscovite particles have a tendency to absorb moisture and then swell [87].

Mica particles were cast in various aluminum alloys [87, 88]. In 3.5 wt % NaCl solutions, the presence of mica particles depressed pitting potentials by approximately 20–30 mV, in comparison to the monolithic matrix alloys, suggesting that the presence of mica particles may slightly weaken the passive aluminum film. Corrosion behavior was also affected by the precipitation of secondary phases. In some cases, precipitates were preferentially attacked. Pits around and away from mica particles, interfacial corrosion of the mica-matrix interface, and exfoliation of mica particles were also observed.

Values of  $i_{\text{CORR}}$  (extrapolated from polarization diagrams) for nondeaerated 3.5 wt % NaCl ranged from about 3 to 10  $\mu\text{A}/\text{cm}^2$ , which was slightly less than that of the monolithic matrix alloys. Weight-loss data that were measured over a 32-day period showed that the MMCs corroded at higher rates than that of the alloys, contradicting trends observed in  $i_{\text{CORR}}$  data. The mica MMCs corroded at rates ranging from approximately 3.0 to 5.5  $\text{mg}\cdot\text{dm}^{-2}\cdot\text{day}^{-1}$ , which was approximately 1.5–2.0 times that of the monolithic alloys. The discrepancy in the trends of the weight-loss and  $i_{\text{CORR}}$  data could have resulted from several possibilities. Some of the weight loss could be due to nonelectrochemical reactions, such as the dissolution of dissolvable phases and the exfoliation of mica particles. The values of  $i_{\text{CORR}}$  were extrapolated from polarization curves that were generated after relatively short exposure times; whereas, the weight loss was assessed over a 32-day period.

### *Effect of Diffusion Bonds and Microstructural Contaminants*

B/Al and Gr/Al MMCs have been fabricated using techniques where aluminum foils, filaments, and precursor wires have been consolidated by diffusion bonding. The diffusion bonds, if of low integrity or if contaminated, may cause severe corrosion damage.

Sedriks et al. [20] and Bakulin et al. [19] found that  $E_{\text{CORR}}$  of B/Al MMCs was active to that of their monolithic matrix alloys in aerated NaCl solutions. That behavior does not appear to comply with the mixed-potential theory. Bakulin et al. [19], however, found that hot-pressed stacks of aluminum foil processed in the same way as the MMC (but without the BFs) have  $E_{\text{CORR}}$  values that are active to the MMCs. The only difference between the monolithic aluminum and the hot-pressed stacks of aluminum foil was crevices in the diffusion bonds between adjacent foils. The crevices, which are sources of additional anodic sites, can polarize the stacks to active potentials. Thus, the B/Al MMCs are actually noble to the matrix material processed in the same way, and the  $E_{\text{CORR}}$  values actually coincide with the mixed-potential theory. Sedriks et al. [20] found that increasing the volume fraction of BF caused anodic current densities (w.r.t. matrix area) to increase. This implies that BF-matrix interfaces, which increase with BF content, were also sources of anodic sites. Evans and Braddick [89] also reported that BF-matrix interface regions were severely attacked in an oxygenated NaCl solution. These reports indicate that the BF-matrix and foil-foil interfaces are major causes of corrosion.

Gr/Al MMCs that were fabricated by the Ti-B vapor deposit method [90] go through a processing sequence where a tow of graphite fibers is infiltrated with molten aluminum and solidified as a precursor composite wire. Bunches of wires are then diffusion bonded to consolidate larger components, such as plates and bars. Some of these composites have been susceptible to exfoliation (Fig. 6), which is the disbonding of precursor wires and aluminum foils caused by localized corrosion along wire-wire and wire-foil diffusion bonds. This form of corrosion is severe because composite plates can be rendered useless, even though corrosion in the bulk of the foils and precursor wires may not be severe. There have been some reports [91,92] of preferential corrosion of diffusion-bonded regions in marine environments. In severe cases of exfoliation, precursor wires are expelled from the sides of MMC plates [93].

The cause of exfoliation has been attributed [94] to residual microstructural chloride [95] that is trapped in the diffusion-bonded regions. The residual chloride originates from the Ti-B vapor deposit method, which uses titanium tetrachloride ( $\text{TiCl}_4$ ) and boron trichloride ( $\text{BCl}_3$ ) gases. The chloride is deposited on the skin of the precursor wires as the wires are extracted from the aluminum melt. Experiments have shown that in sodium sulfate solutions, where aluminum should be passive, the chloride-contaminated diffusion bonds corrode vigorously [94] (see subsection **Determination of Dissolution Behavior Using Polarization Techniques**.)

### *Effect of Reinforcement Constituents on Stress Corrosion in Al MMCs*

Stress corrosion studies have been conducted on continuous-fiber reinforced and particle-reinforced Al MMCs.

**FIG. 6—Exfoliation of Gr/6061-T6 Al MMC. MMC exposed to indoor environment.**

Studies have been conducted on unidirectional, continuous-fiber Gr/6061 Al [96], BF/2024 Al [20], BORSIC/2024 Al, BORSIC/6061 Al [97], and Nextel ( $\text{Al}_2\text{O}_3$ ,  $\text{SiO}_2$ ,  $\text{B}_2\text{O}_3$ )/6061 Al [98] MMCs. Stresses were applied either parallel or perpendicular to the fiber axis of unnotched specimens. The Gr/6061 Al MMCs were stressed parallel to the fiber axis in natural seawater. At high stresses, failure was stress-dependent and occurred in less than 100 h. At lower stresses, failure was primarily caused by extensive corrosion, and therefore, was relatively stress-independent. BF/2024 Al MMCs stressed parallel to the fiber axis at 80 % fracture strength in an NaCl solution did not fail in 1000 h, but failed after 500 h when  $\text{H}_2\text{O}_2$  was added to the NaCl solution. Extensive intergranular matrix corrosion and broken filaments at random sites were observed. The monolithic matrix alloy failed within 10 h under similar conditions. For BF/2024 Al MMCs stressed perpendicular to the fiber axis at 90 % yield strength in the NaCl and NaCl with  $\text{H}_2\text{O}_2$  solutions, failure occurred by intergranular matrix corrosion and separation at diffusion-bonded, fiber-matrix interfaces. Failure times decreased with increasing BF content. BORSIC/Al MMCs were stressed to 689 MPa along the fiber axis by three-point bending and exposed to synthetic sea-salt spray at 95°C and nearly 100 % relative humidity. The 6061 Al MMCs showed general corrosion attack without preference to tensile regions; whereas, the 2024 Al MMCs showed about a 2-to-1 depth-of-attack ratio comparing the tensile to the compressive surfaces, which may have been related to specimen orientation. Unlike the 6061 Al MMCs, the corrosion resistance of the 2024 Al MMC was sensitive to heat treatment. In the Nextel fiber MMC, the prevailing mode of failure was

attributed to extensive corrosion along the fiber-matrix interface and not stress-corrosion cracking in a pH 2 NaCl solution [98].

The stress corrosion behavior of particulate  $\text{Al}_2\text{O}_3$ /2014 [99],  $\text{SiC}_w$ /6061 [99],  $\text{SiC}_p$ /6061 [99], and  $\text{SiC}_p$ /2024 [100,101] MMCs were investigated in NaCl solutions. The  $\text{Al}_2\text{O}_3$ /2014 MMC was susceptible to stress corrosion cracking while subjected to three-point beam bending and alternate exposure and continuous immersions in an NaCl solution [99]. Under the same conditions, however, the 6061 Al MMCs reinforced with  $\text{SiC}_p$  and  $\text{SiC}_w$  were not susceptible to stress corrosion cracking [99]. Similarly,  $\text{SiC}_p$ /2024 MMCs were not prone to stress-corrosion cracking under constant strain at 75 % of ultimate tensile strength while exposed to an aerated NaCl solution [100]. Slow strain rate tension testing of  $\text{SiC}_p$ /2024 MMCs in an NaCl solution in the open-circuit condition indicated that the MMC lost up to 10 % of failure strength compared to exposure in air [101].

#### *Effect of Reinforcement Constituents on Corrosion Fatigue in Al MMCs*

Corrosion-fatigue studies have been conducted on Al MMCs reinforced with graphite fibers [96],  $\text{SiC}_w$  [102–105], and  $\text{SiC}_p$  [103,106]. Processing conditions and type of reinforcement affect corrosion-fatigue behavior. Unnotched Gr/6061 Al MMCs were exposed to natural seawater and stressed parallel to the fiber axis. The MMCs were processed with either silica ( $\text{SiO}_2$ )-coated or Ti-B-coated graphite fibers. For a given stress amplitude, the Ti-B type MMC had the longest corrosion-fatigue life, followed by the  $\text{SiO}_2$  type, and the monolithic matrix alloy. At low stress amplitudes

corresponding to longer exposure times, the  $\text{SiO}_2$  type MMC suffered premature failure due to extensive corrosion. In SiC/Al MMCs, fatigue crack rates of compact tension specimens are usually higher in NaCl solutions as compared to air [102] or argon [106]. Loading frequency affects corrosion-fatigue crack rates [106], but no consistent trends were observed. Fatigue [102] and corrosion-fatigue [106] crack rates are influenced by loading and extrusion or rolling direction. The nucleation of a crack was also observed at the bottom of a corrosion pit [105]. The shape of the reinforcement constituent may also have significant effects. Jones [104] developed a model based on crack-tip strain rate that is applicable to stress corrosion and corrosion fatigue. The model is relatively insensitive to slight variations in reinforcement volume fraction. The model predicts that crack rates are reduced by increasing the reinforcement constituent 1-to-d ratio, implying that MMCs reinforced with whiskers are more resistant to stress corrosion and corrosion fatigue than those reinforced with particles. This is in agreement with results of Hasson et al. [103] who found that  $\text{SiC}_w/6061$  Al MMCs have longer corrosion-fatigue lives than  $\text{SiC}_p/6061$  Al MMCs in salt-laden moist air.

### Magnesium MMCs

Very light composites can be fabricated from magnesium, which is one of the lightest structural metals. Its density is only  $1.7 \text{ g/cm}^3$ . Magnesium, however, is the most active structural metal in the electromotive series [107], which means that it has a very high tendency to corrode. Since magnesium is a very active metal, it is particularly susceptible to galvanic corrosion when in contact with noble reinforcement constituents. Corrosion studies have been conducted on magnesium MMCs reinforced with BF, graphite fibers,  $\text{SiC}_{MF}$ , and  $\text{Al}_2\text{O}_3$  fibers. Stress-corrosion behavior of an  $\text{Al}_2\text{O}_3/\text{Mg}$  MMC is included in the  $\text{Al}_2\text{O}_3$  section.

#### Effect of Boron

The general properties of BFs given in the subsection *Effect of Boron* (for **Aluminum MMCs**) also apply here. Pure boron is an insulator and a very poor cathode. Galvanic currents were unmeasurable between pure boron and magnesium in 0.005 N NaCl solutions [21,108] (it was not specified if solutions were deaerated or aerated). Galvanic currents, however, were measurable between virgin tungsten-core BF (cores either shielded or exposed) coupled to magnesium [108] and an MA2-1 magnesium alloy [21]. Galvanic currents were higher when tungsten cores were exposed [21,108]. This is not unexpected since pure tungsten was shown to be an effective cathode [21]. Since galvanic currents were unmeasurable between magnesium and pure boron, but measurable between magnesium and virgin BF (with tungsten cores shielded), it was suspected that the outer layer of BFs consisted of tungsten boride and not of pure boron [108]. It was also found that BF extracted from the matrix supported cathodic-current densities that were about five times that of virgin BFs [21]. The corrosion rates of actual BF/MA2-1 MMCs in 0.005 N and 0.5 N NaCl solutions were  $12.49 \text{ g/m}^2\text{day}$  and  $81.72 \text{ g/m}^2\text{day}$ , respectively, which were about six times the values of the monolithic matrix alloy in respective environments.

FIG. 7—Anodic polarization diagrams of pure magnesium and ZE41A magnesium in deaerated 3.15 wt % NaCl plotted with the cathodic polarization diagrams of pitch-based graphite fiber (cross section exposed) in deaerated and aerated 3.15 wt % NaCl at 30°C. Scan rate = 0.1 mV/s.

#### Effect of Graphite

The general properties of graphite given in the subsection *Effect of Graphite* (for **Aluminum MMCs**) also apply here. Figure 7 shows the cathodic polarization diagrams of pitch-based graphite (cross section exposed) in deaerated and aerated 3.15 wt % NaCl with the anodic polarization diagrams of pure magnesium and ZE41A magnesium in deaerated 3.15 wt % NaCl. Figure 7 reveals that galvanic-corrosion rates increase in aerated solutions. It should be noted that both anodic and cathodic curves of pure magnesium and ZE41A magnesium are practically insensitive to solution aeration, indicating that normal corrosion rates are virtually unaffected by dissolved oxygen. Figure 7 shows that galvanic corrosion of magnesium is not anodically controlled, and therefore galvanic-corrosion rates should increase with increasing area fraction of cathodic reinforcement material. Trzaskoma [109] showed that galvanic-corrosion current densities increased from about  $0.3 \times 10^{-3}$  to  $0.6 \times 10^{-3} \text{ A/cm}^2$  (based on magnesium area) as the graphite-to-magnesium area ratio was increased from 0.25 to 0.44. The galvanic couples consisted of AZ31B magnesium alloy and pitch-based graphite fiber with fiber ends and circumferential fiber surface exposed to an aerated, borated-boric acid solution of 8.4 pH containing 1000 ppm NaCl. Actual MMCs immersed in air-exposed 0.001 N NaCl suffered severe degradation within five days.

Czyrkliś [28] showed electrochemical evidence of galvanic corrosion in actual graphite/magnesium (Gr/Mg) MMCs. He measured open-circuit potentials and calculated corrosion current densities (by Tafel extrapolation) of a 40 % Gr/Mg MMC and its matrix alloy that were exposed to a deaerated 50 ppm-chloride solution. The open-circuit potential of the composite ( $-1.127 \text{ V}_{SCE}$ ) was about 0.3 V noble to that of the matrix alloy, and  $i_{CORR}$  of the composite ( $178 \text{ } \mu\text{A/cm}^2$ ) was about 40 times greater than that of the matrix alloy at 25°C. Czyrkliś also reported severe degradation of Gr/AZ91C Mg MMCs that were exposed to 50 ppm-chloride solutions and 95 % relative humidity atmospheres. Composite degradation was attributed to galvanic corrosion and to selective attack of  $\text{Mg}_{17}\text{Al}_{12}$  precipitates in the magnesium matrix.

Interphase formation of  $\text{Al}_4\text{C}_3$  was observed in a Gr/Mg (1 % aluminum) MMC produced by squeeze casting. The  $\text{Al}_4\text{C}_3$

FIG. 8—Anodic polarization diagrams of pure magnesium and ZE41A magnesium plotted with cathodic polarization diagrams of hot-pressed SiC, SiC<sub>MF</sub>, and pitch-based graphite fibers in deaerated 0.5 M NaNO<sub>3</sub> at 30°C. Scan rate = 0.1 mV/s. CS = cross section exposed. FS = fiber surface exposed.

formation resulted from heat treatments at 500°C [110]. Degradation of these MMCs could be accelerated by both galvanic corrosion and Al<sub>4</sub>C<sub>3</sub> hydrolysis.

#### Effect of Silicon Carbide

The general properties of SiC given in the subsection **Aluminum MMCs** also apply here. Galvanic corrosion between magnesium and SiC depends to a large degree on the type of SiC reinforcement and on the presence of dissolved oxygen in solution. Figures 8 and 9 show anodic polarization diagrams of pure magnesium and ZE41A magnesium with cathodic polarization diagrams of hot-pressed SiC, SiC<sub>MF</sub> (with either carbon core or carbon-rich surface exposed) in deaerated and oxygenated 0.5 M sodium nitrate (NaNO<sub>3</sub>) solutions, respectively. Galvanic-corrosion rates (as determined by the mixed-potential theory) are greater in oxygenated solutions due to oxygen reduction occurring on the reinforcement materials (compare Figs. 8 and 9). Galvanic-corrosion rates are lowest between magnesium and hot-pressed SiC and highest between magnesium and SiC<sub>MF</sub> (with core exposed) [111]. The carbon-core and the carbon-rich surface appear to have a dominant effect on cathodic behavior of the SiC<sub>MF</sub>. The curves of SiC<sub>MF</sub> have a stronger resemblance to pitch-based graphite fiber (cross section exposed) than to hot-pressed SiC (Figs. 8 and 9). Similar

FIG. 9—Similar to Fig. 8, except the 0.5 M NaNO<sub>3</sub> solution is oxygenated.

results were obtained for sodium sulfate (Na<sub>2</sub>SO<sub>4</sub>) and NaCl solutions [112]. Nunez-Lopez et. al [113] conducted studies on particulate ZC71 magnesium alloy reinforced with 12 vol. % SiC particles ranging in size up to approximately 20 μm. Specimens exposed to salt spray tests did not show signs of galvanic coupling between the matrix and SiC particles. Preferential attack between SiC particles and the matrix was not observed. Instead, macroscopic anodic and cathodic regions developed. Corrosion spread over the MMC surface much more rapidly than on the monolithic alloy, but the local corrosion rates were approximately only three times greater on the MMC. The authors [113] speculated that the higher corrosion rates on the MMCs could have been caused by iron contamination of the magnesium matrix during processing in a steel crucible. Studies on a model MMC consisting of high-purity magnesium and well-separated SiC particles exposed to 3.5 wt % NaCl also did not show evidence of galvanic corrosion between the particles and matrix [114].

#### Effect of Alumina

The general properties given for Al<sub>2</sub>O<sub>3</sub> in the previous subsection of the same title (for aluminum MMCs) also apply here. Galvanic corrosion should not be expected in Al<sub>2</sub>O<sub>3</sub>/magnesium (Al<sub>2</sub>O<sub>3</sub>/Mg) MMCs, since Al<sub>2</sub>O<sub>3</sub> is an insulator. However, Levy and Czyrkis [115] found that continuous-fiber Al<sub>2</sub>O<sub>3</sub>/AZ91C MMCs were much more susceptible to corrosion in chloride-containing solutions compared to the matrix alloy. They did not specify if the solutions were deaerated. In a 50 ppm Cl<sup>-</sup> solution at 25°C, the corrosion rate of the composite was 0.78 mm/y compared to only 0.10 mm/y for the alloy. When the temperature was increased to 66°C, the corrosion rate of the composite dramatically increased to about 150 mm/y, while that of the alloy increased to only 0.13 mm/y. Corrosion rates were highest in 3.5 wt % NaCl at 25°C, where the composite corroded at an astronomical rate of about 350 mm/y compared to 3.6 mm/y for the alloy. In chloride-free environments, the composite showed equivalent or greater resistance to corrosion than the alloy. In distilled water at 25°C and 95 % relative-humidity environments at 25°C and 66°C, the corrosion rate of the composite and matrix alloy was less than 0.25 mm/y. The tremendously higher corrosion rates of the composites in the chloride-containing environments appear to be caused by the presence of the Al<sub>2</sub>O<sub>3</sub> fibers. It is unlikely that galvanic corrosion between the matrix and Al<sub>2</sub>O<sub>3</sub> fibers can take place, since Al<sub>2</sub>O<sub>3</sub> is an insulator. However, galvanic corrosion could be possible between the matrix and an interphase or precipitates, which potentially could form due to the presence of the Al<sub>2</sub>O<sub>3</sub> fibers. Czyrkis [116] reported that  $E_{CORR}$  of 35 % continuous-fiber Al<sub>2</sub>O<sub>3</sub>/AZ91C MMCs was more noble than that of the matrix alloy in 50 ppm Cl<sup>-</sup> solutions, indicating that galvanic corrosion is a possibility. It was not specified if the solutions were deaerated.

Evans [117] studied the stress-corrosion behavior of continuous-fiber Al<sub>2</sub>O<sub>3</sub>/ZE41A Mg MMC in an NaCl-potassium chromate (K<sub>2</sub>CrO<sub>4</sub>) solution. Unnotched and notched specimens stressed parallel to the fiber axis and exposed for approximately 100–1000 h in the NaCl-K<sub>2</sub>CrO<sub>4</sub> solution retained approximately 90 % of the strength in air. The matrix alloy and the MMC with the stress aligned perpendicular to the fiber axis retained only approximately 40–60 % of the strength in air.

## Lead MMCs

Lead is a relatively heavy metal with a density of  $11.4 \text{ g/cm}^3$ . Lead MMCs, therefore, are normally developed for applications where a combination of its structural, physical, and chemical properties are important. The corrosion behavior of pure lead MMCs in simulated, lead-acid battery environments has been studied to assess the feasibility of using these composites as positive electrode grids in place of conventional lead-based alloy grid materials. Lead can be alloyed with elements such as arsenic, antimony, or calcium to increase strength and stiffness. These elements, however, reduce corrosion resistance. Monolithic pure lead has very good corrosion resistance in lead-acid battery environments (which consists of sulfuric acid solutions), but is heavy and lacks sufficient mechanical strength. Pure lead, therefore, has been reinforced with strong, lightweight fibers in hopes of achieving the goals of increasing strength, reducing weight, and retaining the corrosion resistance of pure lead [118–120]. More recently, a study on the corrosion behavior of particulate lead-antimony alloy MMCs exposed in sodium chloride solutions has been conducted [121].

### Effect of Fibers

To simulate corrosion in lead-acid battery environments, Dacres et al. [118] and others [119,120] anodically polarized test materials at 1.226 V (versus mercury/mercurous sulfate reference electrode) in sulfuric acid solutions (of 1.285 specific gravity) at 50, 60, and/or 70°C. At 1.226 V, lead and water are oxidized to lead dioxide ( $\text{PbO}_2$ ) and molecular oxygen ( $\text{O}_2$ ), respectively [122,123]. About one third of the total anodic current is consumed in the oxidation of lead under these conditions [120].

$\text{Al}_2\text{O}_3$ , carbon, SiC, and glass-quartz fibers of various volume percents have been used in lead MMCs. Fabrication methods as well as fiber type may have significant effects on corrosion resistance. Several types of continuous-fiber  $\text{Al}_2\text{O}_3$ /lead ( $\text{Al}_2\text{O}_3/\text{Pb}$ ) MMCs [118,120] were examined. MMCs containing 5 % [120] and 7.5 % [118]  $\text{Al}_2\text{O}_3$  fibers showed good corrosion resistance. The 5 %  $\text{Al}_2\text{O}_3$  fiber MMC had gravimetric and Faradaic corrosion rates of 0.033 mm/y and 0.10 mm/y, respectively.  $\text{Al}_2\text{O}_3/\text{Pb}$  MMCs having 6 % [118], 10 % [120], 15 % [120], and 25 % [118]  $\text{Al}_2\text{O}_3$  fibers did not have acceptable corrosion resistance. Poor bonding between  $\text{Al}_2\text{O}_3$  fibers and the matrix allowed the electrolyte to diffuse into fiber-matrix interfaces, leading to accelerated corrosion [118] and swelling of the composite due to corrosion-product buildup [120].

Composites reinforced with carbon or graphite fiber were not resistant to corrosion [118,120]. Viala et al. [119] reported that the graphite fibers were oxidized. SiC fiber/Pb MMCs also did not have good corrosion resistance [119,120]. Viala et al. [119] reported that composites were destroyed by swelling due to formation of  $\text{PbO}_2$  in the bulk of the composites. The SiC fibers (which do not have carbon cores) were stable. The corrosion resistance of glass-quartz/Pb MMCs having 9.5 % fiber was not satisfactory, and gravimetric and Faradaic corrosion rates were 0.24 and 0.62 mm/yr, respectively [120]. Lead alloys containing calcium and tin had gravimetric and Faradaic corrosion rates of 0.49 and 1.35 mm/yr, respectively, also showing unsatisfactory corrosion

resistance [118,120]. The studies [118–120] have indicated that the penetration of electrolyte into the bulk of the composites, possibly through poorly bonded fiber-matrix interfaces or by oxidation of fibers, is a major factor governing degradation properties.

### Effect of Particles

A commercially available lead (80 %)-antimony (20 %) alloy was reinforced with 1, 3, and 5 wt % zircon ( $\text{ZrSiO}_4$ ) particles [121] and exposed to a 1 N NaCl solution. The particles should not induce galvanic corrosion. Weight loss measurements, made over a 72 h period, showed that weight loss of the lead MMCs increased with increasing zircon content. Heat treatment of the  $\text{ZrSiO}_4/\text{Pb-Sn}$  MMC at 200°C also improved resistance to weight loss.

## Depleted Uranium MMCs

Tungsten fiber/depleted uranium (W/DU) MMCs are the antithesis of the lightweight MMCs. W/DU MMCs were developed to create high-density materials. Uranium has a density of  $18.9 \text{ g/cm}^3$ .

DU corrodes galvanically when coupled to tungsten fibers in air-exposed 3.5 wt % NaCl solutions at room temperature [124]. The open-circuit potential of tungsten fiber ( $-0.25 \text{ V}_{\text{SCE}}$ ) is noble to that of the DU alloy ( $-0.80 \text{ V}_{\text{SCE}}$ ). The open-circuit potentials of the W/DU MMC and galvanic couples consisting of tungsten fiber and DU alloy of equal areas are  $-0.78 \text{ V}_{\text{SCE}}$  and  $-0.77 \text{ V}_{\text{SCE}}$ , respectively. These potentials fall between those of tungsten fibers and the DU alloy, which is consistent with the mixed-potential theory. The galvanic-corrosion current density measured between equal areas of tungsten fibers and the DU alloy was equal to about  $4 \times 10^{-5} \text{ A/cm}^2$ . In a 30-day exposure test in the NaCl solution, the W/DU MMC lost  $43.56 \text{ mg/cm}^2$ , which was about 1.3 times that of the DU alloy.

## Stainless Steel MMCs

Sintered, particulate composites consisting of ferritic 434L stainless steel and  $\text{Al}_2\text{O}_3$  particles have been developed for potential application in chemical processing plants, turbine blades, and heat exchanger tubes [125–127]. Austenitic 316L stainless steels reinforced with  $\text{Al}_2\text{O}_3$  and  $\text{Y}_2\text{O}_3$  have also been investigated for enhanced strength and wear resistance [128].

### Effect of Alumina

The corrosion behavior of sintered  $\text{Al}_2\text{O}_3/434\text{L}$  MMCs and sintered 434L alloy without  $\text{Al}_2\text{O}_3$  particles was examined [125–127]. The volume fraction of  $\text{Al}_2\text{O}_3$  particles in these materials ranged from 0 to 8 %. The effect of small amounts of titanium and niobium alloying elements on corrosion resistance was also investigated. Galvanic corrosion between 434L stainless steel and  $\text{Al}_2\text{O}_3$  should not occur since the latter is an insulator. Experiments were conducted in 1 N sulfuric acid ( $\text{H}_2\text{SO}_4$ ) [125–127] and 5 wt % NaCl [125] solutions at room temperature. It was not mentioned if solutions were deaerated. In 1 N  $\text{H}_2\text{SO}_4$  [125–127], there was no strong correlation between  $\text{Al}_2\text{O}_3$  content and corrosion behavior. The  $E_{\text{CORR}}$  and  $i_{\text{CORR}}$  values varied between materials,

**FIG. 10—Micrograph of SiC<sub>MF</sub>/Ti-15-3-3-3 MMC. Monofilament volume fraction is approximately 40 %.**

but clear trends relating  $E_{CORR}$  and  $i_{CORR}$  to  $Al_2O_3$  content or alloy composition were not conspicuous. One of the few generalities that could be made was that passive-current densities were within an order of magnitude of  $1 \text{ mA/cm}^2$  for almost all materials. Alloying with titanium and niobium tended to increase passive current densities. In the 5 wt % NaCl solutions,  $i_{CORR}$  of the MMCs was less than  $10 \text{ } \mu\text{A/cm}^2$  [125]. Upon polarization, all materials displayed active corrosion behavior in the NaCl solutions.

Particulate 316L stainless steel MMCs [128], fabricated using powder metallurgy, were reinforced with 3, 4, and 5 wt %  $Al_2O_3$  and additions of 2 wt % chromium diboride ( $B_2Cr$ ) or 1 wt % boron nitride (BN) for sintering aids. The density of the MMCs ranged from 86 to 96 % of the theoretical value. Unreinforced 316L specimens were also fabricated using powder metallurgy without sintering aids, resulting in 85 % of theoretical density. The test samples were immersed in 10 % sulfuric acid ( $H_2SO_4$ ) at room temperature for 24 h, 1 % hydrochloric acid (HCl) at room temperature for 24 h, and boiling 10 % nitric acid ( $HNO_3$ ) for 8 h. The pure, unreinforced 316L specimens passivated in the 10 %  $H_2SO_4$  solution; whereas, the corrosion rate of the MMC generally increased with increasing  $Al_2O_3$  content to a maximum value of approximately 4 mm/yr. Specimens with the BN sintering aids corroded at higher rates as compared to those with the  $B_2Cr$  sintering aids. The authors correlated this behavior to the local depletion of chromium in the matrix due to matrix reactions with BN, as compared to reactions with chromium-rich  $B_2Cr$ . The MMC performed better than the unreinforced 316L specimen in the 1 wt % HCl solution, but worse than the unreinforced specimen in the boiling nitric acid solution. There was no strong correlation between  $Al_2O_3$  content in the MMCs and the corrosion rates in 1 wt % HCl and boiling 10 wt %  $HNO_3$  solutions.

### *Effect of Yttria*

Yttria ( $Y_2O_3$ ) is an insulator and galvanic effects are not expected. The 316L stainless steel specimens discussed above [128] were also reinforced with 3, 4, and 5 wt %  $Y_2O_3$  and additions of 2 wt % chromium diboride ( $B_2Cr$ ) or 1 wt % boron nitride (BN) for sintering aids. In all solutions (i.e., sulfuric, hydrochloric, and nitric acid solutions), the  $Y_2O_3$  reinforced MMCs exhibited reduced corrosion resistance as compare to the  $Al_2O_3$  reinforced MMCs. The  $Y_2O_3$  MMCs were sintered to 88–96 % of theoretical density, and the  $Al_2O_3$  MMCs were sintered to 86–92 % of theoretical density. The  $Y_2O_3$  particles also showed better bonding to the matrix, probably forming a complex  $YCrO_3$  oxide, as compared to the  $Al_2O_3$  particles. It is possible that the formation of the reaction layer around the  $Y_2O_3$  particles may have depleted chromium from the matrix, resulting in reduced corrosion resistance, as compared to the  $Al_2O_3$ -reinforced MMCs.

### **Titanium MMCs**

Titanium MMCs have been developed for aerospace applications, as well as potential surgical implant materials. Silicon carbide MF/titanium ( $SiC_{MF}/Ti$ ) MMCs (Fig. 10) have utility in high-temperature applications requiring strong, lightweight materials. Titanium has a density of  $4.5 \text{ g/cm}^3$ . Structural  $SiC_{MF}/Ti$  MMCs have been used in prototype drive shafts, turbine-engine discs, compressor discs, and hollow fan blades; they are also candidate materials for the skin of the National Aerospace Plane [129]. Porous, particulate Ti MMCs have potential use as surgical implant materials, owing to the compatibility of titanium and bone growth [130]. Porous titanium is a good surgical implant material, because

bone growth is enhanced by the relatively low elastic modulus of titanium, and bone ingrowth is allowed by the porous structure. Porous titanium, however, has poor tribological properties and, therefore, MMCs that incorporate graphite to reduce friction, and incorporate titanium carbide to improve wear resistance are of interest [130].

#### *Effect of Graphite*

Porous titanium/graphite MMCs were processed and heat-treated to fabricate a porous titanium/graphite/titanium carbide (TiC) MMC [130]. Polarization tests were conducted in 0.9 wt % NaCl and lactated Ringer's solution for in vitro use. The  $E_{CORR}$  values of the Ti/graphite/TiC MMCs were more noble than that of pure Ti, as expected due to the presence of graphite and TiC. The anodic polarization current densities of the MMCs were significantly higher than that of pure monolithic titanium, which passivated. The authors attributed the higher corrosion rates of the Ti/graphite/TiC MMC to its porosity, which may have prevented complete passivation of the titanium matrix. Another possibility for the higher current densities could be the oxidation of graphite particles, and not dissolution of the titanium matrix (see subsection below).

#### *Effect of Silicon Carbide*

Corrosion studies on titanium alloy Ti-15-3-3-3 (15 wt % vanadium, 3 wt % chromium, 3 wt % tin, 3 wt % aluminum, balance titanium) [131] and titanium aluminide  $\alpha_2$ -Ti<sub>3</sub>Al (14 wt % aluminum, 21 wt % niobium, balance titanium) [132] reinforced with SiC<sub>MF</sub> have been conducted. The corrosion behavior of Ti-15-3-3-3/SiC<sub>MF</sub> MMC was investigated in 3.15 wt % NaCl. There was excellent agreement in the polarization diagrams of the actual MMC and that of a model utilizing the polarization diagrams of the individual constituents and the mixed-potential theory (see subsection **Determination of Dissolution Behavior Using Polarization Techniques**), indicating that the fabrication processing did not affect the dissolution behavior of the MMC constituents. The matrix passivated and the carbon cores and carbon-rich outer surface of the SiC<sub>MF</sub> oxidized. During anodic polarization, graphite oxidizes to CO<sub>2</sub> [94]. Zero-resistance ammeter studies showed that galvanic currents between the Ti-15-3-3-3 matrix and SiC<sub>MF</sub> were negligible. Based on the polarization diagrams, the galvanic current density cannot exceed that of the passive current density of Ti-15-3-3-3. The corrosion behavior of the  $\alpha_2$ -Ti<sub>3</sub>Al/SiC<sub>MF</sub> [132] was somewhat similar to that of the Ti-15-3-3-3/SiC<sub>MF</sub> MMC [131], with the exception that the  $\alpha_2$ -Ti<sub>3</sub>Al matrix is less resistant to pitting. During anodic polarization, the  $\alpha_2$ -Ti<sub>3</sub>Al/SiC<sub>MF</sub> pitted at approximately 1 V<sub>SCE</sub> in 0.5 N NaCl, which was approximately 0.5 V less than that of the monolithic matrix alloy. Some matrix pitting and crevice corrosion around the SiC<sub>MF</sub> were also observed after anodic polarization. The galvanic current density of the  $\alpha_2$ -Ti<sub>3</sub>Al/SiC<sub>MF</sub> MMC was negligible and limited to the passive current density of the  $\alpha_2$ -Ti<sub>3</sub>Al matrix [132].

#### **Copper MMCs**

Copper MMCs have been investigated for use in marine, electronic, and thermal applications. Copper is relatively heavy, with a density of 8.96 g/cm<sup>3</sup>. Reinforcements are

typically chosen to impart strength and stiffness, reduce weight, enhance thermal and electrical properties, improve machinability, and enhance wear resistance. Initial studies [7] were conducted on a wide variety of experimental copper and copper alloy MMCs for marine applications. The MMCs generally showed corrosion behavior that was similar to that of the monolithic alloys, although corrosion rates were higher for some of the MMCs. More recent corrosion studies have also added additional insight to corrosion mechanisms of copper MMCs.

#### *Effect of Graphite*

Copper MMCs have been reinforced with graphite particles and fibers. The particulate MMCs have been developed for sliding electrical contact materials [133], and improved machinability for lead-free copper alloys [134]. Fiber reinforced MMCs have been developed for applications requiring reduced-weight and high thermal conductivity [135]. Highly graphitized fibers have very high thermal conductivity, exceeding that of silver [3].

Sun et al. [136] examined the corrosion behavior of pure copper MMCs with 1.2, 5, 15, 25, and 40 vol % graphite particles and fiber-reinforced pure copper MMCs with 50 vol % graphite fibers in deaerated and aerated 3.5 wt % NaCl solutions. The corrosion potential of the particulate reinforced MMCs became more noble with increasing graphite content in both the deaerated and aerated solutions, as would be expected by increasing the content of the noble graphite particles. Polarization resistance generally decreased, with a few exceptions, with increasing graphite content in both deaerated and aerated solutions. This indicated that corrosion rates generally increased with graphite content, assuming that cathodic and anodic Tafel slopes remained relatively constant for the different MMC specimens (i.e., 1.2–40 vol % graphite). The corrosion rate is a function of both the polarization resistance and Tafel slopes. The 6 % porosity of the MMCs may have also been a factor regarding corrosion behavior. The corrosion potential of the fiber-reinforced MMC (50 vol % graphite fiber) was approximately as noble as the particulate MMC with 40 vol % graphite in the aerated solution, but was significantly more active than the particulate composite in the deaerated solution. This finding could be expected if the hydrogen evolution kinetics on the graphite fiber were significantly different from that of the graphite particles.

Rohatgi et al. [134] studied C90300 copper alloy reinforced with approximately 1–10 vol % graphite particles and 1 wt % Ti, added to enhance wettability of the graphite. The corrosion potentials of the MMCs increased with increasing graphite content in an aqueous solution containing ferric chloride, copper sulfate, and hydrochloric acid. Gravimetric measurements were made on specimens immersed for one year in an aqueous solution containing sodium bicarbonate, magnesium chloride, calcium chloride, sodium sulfate, and sodium chloride. The results showed insignificant weight gain (<0.25 %), indicating that the MMCs were resistant to corrosion in the test solution.

#### *Effect of Silicon Carbide*

Lee et al. [137] examined the corrosion behavior of pure copper MMCs reinforced with 0, 5, 10, and 20 vol % SiC particles

in a 5 wt % NaCl solution. The porosity of the materials ranged from 2.2 to 3.5 %, and generally increased with increasing SiC content. Corrosion potentials became more active, and corrosion current densities increased with increasing SiC content. The corrosion morphology indicated that there was significant corrosion at SiC-copper interfaces. Voids caused by porosity and SiC-copper interfaces both increased with increasing SiC content. Hence, the decrease in  $E_{CORR}$  with increasing SiC content is likely to have been caused by an increase in anodic currents from voids and SiC-copper interfaces. The SiC particles could also serve as cathodes, but due to their relatively high electrical resistivity, they are not as effective, for example, as graphite. Hence, any increases in cathodic currents with the increase in SiC content may not have been sufficient to shift  $E_{CORR}$  to positive values and overcome the effect of the higher anodic currents.

#### *Effect of Alumina*

A copper MMC reinforced with 2.7 vol %  $Al_2O_3$  was studied by Sun and Wheat [138] in deaerated and aerated 3.5 wt % NaCl. The corrosion potentials of the MMC were slightly more active (i.e., 0.01–0.02 V) than monolithic pure copper. The corrosion rates of the MMCs were comparable to monolithic copper. A galvanic effect with  $Al_2O_3$  is not expected due to its insulative nature.

#### **Zinc MMCs**

Zinc MMCs have been developed [139] for potential use as bearing materials. Zinc has a density of 7.14 g/cm<sup>3</sup>. An MMC with a ZA-27 zinc alloy matrix was cast with 1, 3, and 5 wt % graphite particles ranging in sizes from 100 to 150  $\mu$ m. Zinc alloys are known to have excellent wear and bearing characteristics [140]. Gravimetric corrosion tests were conducted at 23°C in:

1. SAE 40 grade lubricating oil that had been in service for six months in an internal combustion engine, and
2. 1 N hydrochloric acid (HCl).

The MMCs did not corrode in the previously-used lubricating oil. Interestingly, in the 1 N HCl, corrosion rates decreased with higher content of graphite, which is a noble conductor that can induce galvanic corrosion. Several hypotheses were made [139], such as the presence of the graphite network hindering the reaction between HCl and the matrix. Another possibility is that zinc ions in solution, acting as a cathodic inhibitor [141], may have eventually precipitated as zinc hydroxide on the cathodic graphite particles if the local pH resided in the correct range. This would also explain the decreasing corrosion rates with time that was observed. Similar behavior was noticed in graphite-aluminum couples in solutions containing zinc chloride [142].

### **METHODS FOR EVALUATING CORROSION DAMAGE**

Tests to evaluate corrosion damage of conventional monolithic alloys are not always applicable to MMCs. Under some circumstances, the reinforcement constituents that are left

in relief after matrix corrosion may interfere with measurements. There have been relatively few studies on MMC corrosion in comparison to monolithic metals. Tests that have been more commonly used for MMCs are gravimetric, and also those that assess loss of mechanical properties. The researcher should be able to use other tests that have been developed for monolithic alloys; however, data must be analyzed carefully to ensure that test results are valid since special problems are sometimes associated with MMCs. Further details regarding corrosion analysis of MMCs are provided below.

#### **Depth of Attack**

Depth of attack can be used to assess corrosion damage in MMCs. It may be more difficult, however, to assess the penetration depth in MMCs compared to that in monolithic metals because reinforcement constituents that are left in relief can prevent a depth gage from contacting the matrix surface, and thus, prevent the true depth of penetration from being measured. In particulate MMCs, the interference may be attenuated since reinforcement particles are free to detach from the matrix as they are undercut by corrosion. When reinforcements interfere with mechanical measurements, depth of penetration can be assessed metallographically. Samples may be mounted and polished, and penetration measurements can be made with a microscope and a calibrated eyepiece. Details for determining penetration depth are available in ASTM G 46, Recommended Practice for Examination and Evaluation of Pitting Corrosion.

#### **Gravimetric**

Gravimetric evaluation is often used to assess corrosion damage. Special problems, however, can be encountered when using gravimetric evaluation for MMCs. Results obtained from MMCs can be misleading, since corrosion is sometimes accompanied by weight gain. MMC samples can experience weight gain when corrosion products and moisture are trapped in composite microstructures, resulting in swelling of the MMC. Swelling of MMCs appears to be more troublesome with fiber-reinforced composites, as opposed to particulate composites. For details on gravimetric measurements, reference should be made to ASTM G 1, Recommended Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens. This standard addresses metal alloys, and references should be followed for the matrix alloy in the MMC.

#### **Loss in Mechanical Properties**

Corrosion damage of MMCs is sometimes assessed by measuring a loss in strength. Changes in strength are measured before and after exposure to corrosion environments. These tests can be very useful for assessing corrosion damage in MMCs when corrosion appears to be mild on the surface, but penetrates deep into the bulk along diffusion bonds or reinforcement-matrix interfaces. Test specimens may take on various shapes and sizes, depending on the form of the stock material (e.g., wire, sheet, rod, etc.). Reference should be made to ASTM G 1 (7.3.2) and G 46 (7.5).

## TESTS FOR SPECIFIC CORROSION TYPES

Various tests can be performed on MMCs to obtain specific information on corrosion behavior. Tests used for monolithic metals can be applied to MMCs with some success. However, since MMCs may have properties significantly different from those of monolithic metals, conventional tests developed for monolithic metals may not always produce sought-after results when used to test MMCs.

### Determination of Dissolution Behavior Using Polarization Techniques

Dissolution behavior of MMCs can be determined by anodic polarization measurements. To ensure that the polarization setup is working properly, it should be checked against ASTM G 5, Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements. The dissolution behavior of MMCs in specific environments can be determined by generating anodic polarization diagrams of the MMC. To determine the extent of matrix dissolution versus that of reinforcement dissolution, polarization diagrams of monolithic matrix metal and reinforcement constituents should be generated separately. The individual diagrams of the MMC constituents are then used to generate a polarization diagram of the MMC (here called a mixed-electrode diagram) using the mixed-potential theory. If good correlation exists between the polarization diagram of the actual MMC and the mixed-electrode diagram, the fraction of dissolution current originating from the matrix and from the reinforcement constituents can be determined. The results can be verified by examining the corrosion morphology of the MMC. For example, the anodic polarization diagrams of an actual  $\text{SiC}_{\text{MF}}$  (40 vol %)/Ti-15-3-3-3 MMC and that generated using the MMC constituents and the mixed-potential theory corresponding to a 3.15 wt % NaCl solution were in very good agreement (Fig. 11). Corrosion morphology studies confirmed that the high anodic currents measured on the MMC corresponded to oxidation of the carbon cores and carbon-rich surface of the  $\text{SiC}_{\text{MF}}$  [131].

FIG. 11—Anodic polarization diagrams of SiC monofilament (cross section exposed), monolithic Ti-15-3-3-3, and  $\text{SiC}_{\text{MF}}$  (40 vol. %)/Ti-15-3-3-3 MMC exposed to deaerated 3.15 wt % NaCl at 30°C. Scan rate = 0.1 mV/s. A diagram for a composite consisting of 40 vol. % SiC monofilament was generated on the basis of the mixed-potential theory.

If there is poor correlation between the polarization diagram of the actual MMC and the mixed-electrode diagram, the discrepancy in dissolution behavior might be caused by formation of interphases or contaminants introduced in the MMC microstructure during processing. For example [94], Fig. 12 shows an anodic, mixed-electrode diagram generated from polarization diagrams of graphite fiber and 6061-T6 aluminum exposed to 0.5 M  $\text{Na}_2\text{SO}_4$ . The mixed-electrode diagram shows that 6061-T6 aluminum passivates during the anodic scan. The anodic polarization diagram of an actual Gr(50 vol %)/6061-T6 Al MMC, however, exposed to the same solution shows that pitting is induced at approximately  $-0.6 V_{\text{SCE}}$  (Fig. 12). The unexpected pitting was found to be caused by residual microstructural chloride [94] that was unintentionally introduced into the microstructure during processing [95]. Buonanno [143] later verified that the anodic polarization diagram of chloride-free Gr/Al MMCs traces the mixed-electrode diagram.

### Galvanic Corrosion between Matrix and Reinforcement Constituents under Immersed Conditions

Galvanic corrosion between the matrix and reinforcement constituents can be determined by several methods. The mixed-potential theory can be used with polarization data of the matrix metal and reinforcement constituents to estimate galvanic-corrosion currents and potentials. The intersection of the anodic polarization curve of the matrix metal with the cathodic polarization curve of a noble reinforcement constituent gives the galvanic-corrosion current and potential (refer to appendix of ASTM G 82, Guide for Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance). When using this method, it should be noted that changes in electrochemical behavior of MMC constituents caused by MMC processing cannot be taken into consideration if virgin MMC constituents are used to obtain polarization data. The behavior predicted using virgin MMC constituents could be quite different compared to that of the actual MMC. Timonova et al. [21] showed that BF<sub>3</sub>

FIG. 12—Anodic polarization diagrams of pitch-based graphite fiber (cross section exposed), monolithic 6061-T6 aluminum, and Gr(50 vol. %)/6061-T6 Al MMC plate exposed to deaerated 0.5 M  $\text{Na}_2\text{SO}_4$  at 30°C. Scan rate = 0.1 mV/s. A diagram for a composite consisting of 50 vol. % graphite and 6061-T6 aluminum was generated on the basis of the mixed-potential theory.

extracted from a magnesium matrix supported cathodic-current densities that were about five times that of virgin BFs (see subsection *Effect of Boron* in **Magnesium MMCs**).

The galvanic-corrosion rate can also be determined from the open-circuit corrosion current of actual MMCs. To obtain the galvanic-corrosion current density, the local-corrosion current density [144] should be subtracted from the open-circuit current (of the MMC) that has been normalized with respect to matrix area. One difficulty would be to obtain an accurate estimation of the local-corrosion current density.

The zero-resistance ammeter technique (ASTM G 71, Practice for Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes) can be used to measure galvanic-corrosion currents between monolithic pieces of the matrix metal and reinforcement constituents. One advantage of this technique is that galvanic-corrosion currents can be measured over long periods of time. If virgin MMC constituents are used, changes due to processing cannot be accounted for. Pohlman [22] showed that galvanic-corrosion currents between aluminum alloys and BFs extracted from an aluminum MMC were significantly greater than currents between aluminum alloys and virgin BFs. Aluminum borides that formed on the BFs during MMC processing were responsible for increasing galvanic-corrosion currents (see subsection *Effect of Boron* in **Aluminum MMCs**).

The three methods discussed above can be used to estimate galvanic-corrosion behavior. Advantages and disadvantages are associated with each method. Some comparisons between these methods have been made for Gr/Al [36] and SiC/Mg MMCs [111].

### Uniform Corrosion

Uniform corrosion of MMC matrices can be expected in environments that attack the matrix metal uniformly. In continuous-fiber MMCs, however, fibers will be left in relief as the matrix corrodes, whereas, in particulate MMCs, reinforcement particles fall free as they are undercut. Uniform corrosion rates of MMCs may be greater than that of the monolithic matrix alloys, due to galvanic action between the matrix and reinforcement constituents.

MMCs should be exposed to environments of interest and then inspected. If corrosion is uniform, corrosion rates can be assessed using recommendations in ASTM G 1. Electrochemical measurements can also be used to determine uniform corrosion rates. Refer to ASTM G 102, Calculation of Corrosion Rates and Related Information from Electrochemical Measurements. Note that when determining matrix corrosion rates, the corrosion current should be normalized with respect to the matrix area if reinforcements are inert.

### Pitting Corrosion

MMCs are susceptible to pitting in environments that induce pitting in the matrix metal. These environments usually contain halides and are oxidizing. In MMCs that have noble reinforcement constituents, galvanic corrosion between reinforcement constituent and matrix can accelerate pitting compared to the monolithic matrix alloy. The presence of the reinforcement constituents may also influence pitting by altering MMC microstructures. In SiC<sub>w</sub>/Al MMCs,

for example, pits were more numerous and much smaller in size compared to pits on monolithic alloys [60]. Apparently, the SiC whiskers enhance the precipitation of the intermetallic particles upon which pits nucleate [60] (see subsection *Effect of Silicon Carbide* in **Aluminum MMCs**).

MMC specimens should be exposed to environments of interest. The degree of pitting can be assessed using ASTM G 46. Pitting potentials may be obtained by generating anodic polarization diagrams of the MMCs. Refer to ASTM G 5 to ensure that the electrochemical setup is working properly. Electrochemical impedance spectroscopy has also been used to detect the onset of pitting in some MMCs [145].

### Stress Corrosion

Studies on stress-corrosion behavior of MMCs have been limited. Results for some aluminum and magnesium MMCs are summarized in the subsections on *Effect of Reinforcement Constituents on Stress Corrosion in Al MMCs*, and *Effect of Alumina* in Magnesium MMCs respectively. The type of tests that can be used will depend to some degree on the form in which the MMC is produced and whether or not the MMC can be precracked. Some types of MMCs are produced only in the form of relatively thin panels (e.g., less than about 0.25 cm), whereas other types are available in bars or tubes. It is sometimes impossible to properly precrack unidirectional, continuous-fiber MMCs because cracks do not always grow perpendicular to the direction of applied stress [146].

A variety of stress-corrosion testing methods, using unnotched, notched, and precracked specimens, have been well documented [147]. The following ASTM standards are also helpful in developing a stress-corrosion testing program: ASTM E 399, Test Method for Plane-Strain Fracture Toughness of Metallic Materials; G 30, Practice for Making and Using U-Bend Stress-Corrosion Test Specimens; G 38, Practice for Making and Using C-Ring Stress-Corrosion Test Specimens; G 39, Practice for Preparation and Use of Bent-Beam Stress-Corrosion Test Specimens; and G 49, Recommended Practice for Preparation and Use of Direct Tension Stress-Corrosion Test Specimens.

### Corrosion Fatigue

Relatively few studies on corrosion fatigue of MMCs have been conducted. Results for Gr/Al and SiC/Al MMCs are summarized in the subsection *Effect of Reinforcement Constituents on Corrosion Fatigue in Al MMCs*. An appropriate testing program will depend on the form of the MMC and the ability to precrack specimens, which is a problem in some MMCs. The practices for fatigue testing in ASTM Metals Test Methods and Analytical Procedures, Volume 03.01, should be helpful in selecting a testing scheme. Annex A.1 in ASTM E 647, Test Method for Measurement of Fatigue Crack Growth Rates, is particularly useful when doing corrosion-fatigue tests in aqueous environments.

## COMPARISON OF CORROSION BEHAVIOR BETWEEN MMCs

To some degree, the corrosion resistance of MMCs can be ranked based on the intrinsic corrosion resistance of the

matrix alloy. Within an MMC group, corrosion resistance can be further ranked based on the type of reinforcement constituent. For example, MMCs reinforced with graphite would have less resistance to corrosion than those reinforced with  $\text{Al}_2\text{O}_3$ , due to the degree of galvanic corrosion between reinforcement and matrix. It should be emphasized, however, that ranking by generalities may be misleading, since MMC corrosion properties can be highly sensitive to the effects of processing conditions. The formation of interphases, presence of microstructural contaminants, and microstructural changes in the matrix metal caused by reinforcement constituents may significantly deteriorate corrosion resistance. Two identical types of MMCs, but fabricated by different methods, may have very different corrosion resistances.

In the most general terms, titanium MMCs have the best resistance to corrosion due to the general and localized corrosion resistance of titanium. Aluminum MMCs reinforced with semi-conductors or insulators (i.e., SiC,  $\text{Al}_2\text{O}_3$ , and mica) were ranked next due to lack of significant galvanic action between reinforcement and matrix. Aluminum MMCs reinforced with conductors (i.e., graphite, carbon-coated  $\text{SiC}_{\text{MF}}$ ) are more susceptible to corrosion due to galvanic coupling with the reinforcements. Magnesium MMCs were ranked the least resistant due to the highly reactive magnesium matrix. Lead, and depleted uranium, stainless steel, copper, and zinc MMCs were not ranked since these MMCs and/or testing conditions were very specialized or limited. The above assessment is general and exceptions are likely.

# Electrodeposits

*T. P. Moffat*<sup>1</sup>

ELECTRODEPOSITION OF METALLIC coatings has been extensively used as a means of corrosion control. In general, coatings are designed according to one of three different schemes. Electrodeposited coatings may be devised to act as corrosion-resistant barrier layers that separate the substrate from the aggressive environment. Alternatively, the well-known galvanic effects that arise from electrically coupling dissimilar metals may be used to provide active porous coatings, which cathodically or anodically protect the substrate. Electroplating a base metal with a barrier layer of gold is an example of the first strategy. Electrogalvanizing, or depositing zinc on steel, is an example of a sacrificial coating, while thin, porous, noble metal coatings such as palladium or platinum, which catalyze the proton-hydrogen reaction, may be used to anodically protect stainless steels.

In discussing the corrosion resistance of electrodeposited coatings, we are interested not only in the intrinsic chemical properties of the deposit, but must also give close attention to possible galvanic interactions between the coating and the substrate. This results from simultaneous exposure of the electrodeposited coating and the substrate due to either processing-related porosity or selective removal of the coating by mechanical or chemical means. Consequently, to be successfully implemented, the electrodeposited coating and substrate should be viewed as a composite system.

## INTRINSIC CORROSION RESISTANCE OF ELECTRODEPOSITED MATERIALS

In the simple case of free-standing electrodeposits, or deposits that completely cover the substrate, the corrosion behavior may be characterized by the standard procedures described in Sections III and IV of this manual. As with materials produced by other means, the corrosion performance of the deposit may be expected to be a sensitive function of the composition and microstructure, which are determined by the processing conditions. Interestingly, electrochemical deposition may be used to generate a variety of novel metastable materials. The deposition of certain metallic glasses or supersaturated single-phase materials offers the promise of remarkable corrosion resistance. For example, electrodeposited  $\text{Ni}_{51}\text{Cr}_{23}\text{P}_{26}$  metallic glass has been shown to exhibit corrosion characteristics superior to Hastelloy C-276 (Fig. 1) [1]. The nature of the passive film formed on Ni-Cr-P metallic

glasses has been investigated by X-ray photoelectron spectroscopy [2]. Oxidized phosphorus is found in the passive film as  $\text{CrPO}_4$  while phosphorus is enriched at the metal/film interface [2]. Thus, phosphorus chemistry in combination with the underlying homogeneous single-phase solid is responsible for the observed corrosion resistance. It is important to note that these single-phase materials cannot be made by traditional thermomechanical processing. In a similar fashion, much work has been performed concerning the corrosion resistance of  $\text{Ni}_{1-x}\text{P}_x$  alloys, which may be synthesized by electrolytic or electroless deposition [3]. Nonaqueous and molten salt electrolytes have also been used to produce a variety of interesting materials, ranging from photomagnetic cobalt-gadolinium films [4] to corrosion-resistant single phase aluminum-transition metal alloys [5]. Potentiodynamic polarization measurements of electrodeposited aluminum-manganese alloys in chloride media enable the pitting resistance of the materials to be assessed (Fig. 2) [6]. The unanticipated beneficial effect of manganese additions is revealed by the increase in the pitting potential for supersaturated solid solution  $\text{Al}^{97}\text{Mn}_3$  and glassy  $\text{Al}^{74}\text{Mn}^{26}$ . These results demonstrate that standard electrochemical techniques may be fruitfully employed to characterize the intrinsic behavior of electrodeposited materials. However, as noted earlier, electrodeposited coatings are often porous, or alternatively, the coating may be selectively removed by abrasion or scratching events. Galvanic corrosion processes, which may then occur at the discontinuities, must be carefully considered.

FIG. 1—The potentiodynamic *i*-*E* characteristics of electrodeposited  $\text{Ni}_{51}\text{Cr}_{23}\text{P}_{26}$  metallic glass compared to some conventional materials in 1 M HCl [1].

FIG. 2—The potentiodynamic  $i$ - $E$  characteristics of electrodeposited  $\text{Al}_{97}\text{Mn}_3$  and  $\text{Al}_{74}\text{Mn}_{26}$  compared to aluminum and manganese in 0.1 M NaCl, pH = 10, 0.2 mV/s. The enhanced pitting resistance of the Al-Mn alloys is revealed by the more positive pitting or breakdown potential [6].

## MECHANISMS OF CORROSION OF ELECTRODEPOSITED COATINGS

The electrochemical state of a corroding metal may be characterized by a mixed potential or free corrosion potential, and a corrosion rate or current density [7–9]. Both of these parameters are the result of the interaction of at least two partial processes, metal dissolution and the reduction of some oxidant, typically oxygen or protons. When there are two electrically conductive materials, which in general have different corrosion potentials and are electrically connected, the possibility for galvanic corrosion exists. This may be described using mixed potential or Evan's diagrams (Fig. 3) [7]. The figure shows the corrosion rate of Metals M and N before and after coupling. Before coupling, Metal M has a relatively positive corrosion potential and a low corrosion rate,  $i_{\text{corr}}(\text{M})$ , while Metal N corrodes at a higher rate,  $i_{\text{corr}}(\text{N})$ , at a more negative corrosion potential. When equal areas of these two metals are coupled (in a cell designed to ensure a homogeneous potential distribution), a mixed potential for the systems is established,  $E_{\text{couple}}$ , where the total oxidation rate equals the total reduction rate, i.e., conservation of charge. Thus, coupling results in a decrease of the corrosion rate of the metal, M, with the more positive corrosion potential, while the corrosion rate of the metal, N, with the more negative corrosion potential, is accelerated. The well-known galvanic series for metals and alloys immersed in a variety of media corresponds to a listing of the measured corrosion potentials and is often used to predict the effects of coupling two different materials. However, a more accurate assessment of galvanic effects may be obtained by measuring the current flow between coupled electrodes by using a zero-resistance ammeter (ZRA). If the individual potential-current characteristics of the coupled materials are known, then

FIG. 3—A schematic Evan's diagram of cathodic protection of metal M (iron) that might be expected to occur due to the coupling with a more active metal N (zinc) [7].

sound predictions of galvanic corrosion effects may be generated and tested by using a ZRA. Further details on this particular method may be found in Section III of this manual.

From the preceding discussion, it is clear that an electrodeposited coating such as zinc may be used to protect substrates with a more positive corrosion potential such as iron. Thus, cathodic protection is implemented by the sacrificial coatings. Nonetheless, it is important to note that the zinc overlayer itself offers a degree of protection as a barrier coating, in addition to its action as a sacrificial anode. For example, in moist air zinc generally forms a thin, protective film of corrosion products, while bare steel rusts rapidly without protection. However, when zinc-coated steel is scratched exposing the iron substrate to an aqueous chloride solution, sacrificial dissolution of zinc protects the iron (Fig. 3). In contrast to the benefits of coating iron with zinc, electroplating a porous layer of corrosion-resistant metal, such as platinum, on a base metal substrate like zinc or iron leads to an acceleration of substrate dissolution, as shown in Fig. 4. This effect is accentuated due to the effects of geometry; namely, a large cathode to anode area ratio drives the anodic reaction at a higher rate. When two dissimilar materials are electrically connected in a cell with a homogeneous potential distribution, the corrosion rate of the anode is proportional to the area of the cathode. Table 1 demonstrates this effect from the coupling of two materials, chromium and "bright"

FIG. 4—A schematic Evan's diagram of accelerated substrate corrosion due to coupling of the base metal with a porous noble metal coating. The dramatic effect of the geometry, cathode/anode area ratio, is demonstrated [7].

TABLE 1—The influence of area ratio on the corrosion rate of bright nickel in contact with chromium in model rain water (pH 2.5).

nickel, which are relevant to the finishing of automobile bumpers [9].

It is important to note that the geometry associated with porous electroplated coatings can result in significant deviation from the uniform potential distribution associated with the simple mixed potential model described above [9]. In reality, the distributed nature of the pores may yield a highly nonuniform potential distribution. Furthermore, the occluded geometry of the pores, like that associated with pitting corrosion, may result in local solution chemistry markedly different from that of the bulk electrolyte. Likewise, the conductivity of the electrolytic medium is also

FIG. 5—Profiles of electrode potential, referred to the rest potential of zinc, at the surface of a rod shaped zinc/platinum/zinc short-circuited cell in acidic chloride media. The dashed lines represent platinum electrodes of varying length [9].

known to affect the potential distribution of an active galvanic cell. These effects are synonymous with the issue of controlling the throwing power in an externally driven electrolysis cell. Not surprisingly, the anodic current density is accentuated at regions adjacent to the cathode. The actual distribution is a sensitive function of the flaw, or pore size and distribution. This is demonstrated by using a scanning reference electrode to measure the potential distribution for a rod shaped zinc/variable length platinum/zinc short-circuited galvanic cell (Fig. 5). If the electrochemical parameters of the individual electrodes are known, it is possible to predict the corrosion rate from the measured potential distribution. However, as the dimensions of the flaw decrease, the potential field becomes more difficult to measure.

A major impediment to the extensive application of highly corrosion-resistant barrier coatings is the rapid pitting or perforation of the substrate that occurs at flaws in the coating (Fig. 4). The severity of the localized corrosion occurring at such pores may be reduced by appropriately designed multilayer electrodeposits. A coating system often used in automotive finishing provides an excellent example of this design philosophy (Fig. 6) [10]. The top layer of chromium has numerous microcracks that result in galvanic coupling with the "bright" nickel layer, which is sacrificial to the "semibright" nickel layer. The reactivity difference between

FIG. 6—Corrosion scheme for duplex nickel composite showing lateral penetration in the bright nickel layer, which helps prevent perforation of the substrate [10].

the respective nickel layers leads to enhanced lateral corrosion in the active bright nickel layer and retarded penetration of the semibright nickel layer. The potential difference between the nickel layers arises from the incorporation of sulfur in the bright nickel layer. The magnitude of the potential difference between the nickel layers is a sensitive function of the sulfur concentration. If the potential difference is too low,  $\approx$  less than 100 mV, enhanced lateral penetration may not occur. Consequently, controlling the activity of the organosulfur additives in the electrolytic bath is very important for maintaining good corrosion resistance. Likewise, the microcrack density in the chromium layer is an important parameter. Typically, finer dispersions of microcracks result in superior corrosion performance [11].

An interesting variation of the effect of galvanic coupling occurs with metals that exhibit active-passive transitions. When noble metals such as platinum, which are good catalysts for hydrogen reduction, are coupled to a metal with an active-passive transition below the reversible proton-hydrogen potential, spontaneous passivation may ensue (Fig. 7). Thus, a porous coating of noble metal on titanium, chromium, or stainless steels will result in anodic protection of the substrate.

In a similar fashion, care must be taken with sacrificial coatings to be sure that they will not be passivated in the application environment. For example, the position of zinc and iron in the galvanic series may be reversed in domestic water at temperatures above 71°C. The reversal is the result of the temperature dependence of the stability of the passivating corrosion product formed on zinc [12].

### Coating Porosity

From the preceding discussion, it is clear that coating porosity plays a central role in the corrosion behavior of electrodeposited coatings. This is particularly true for noble metal coatings that are designed to isolate the substrate from the aggressive environment. While a variety of means may be used to measure and control porosity, in electroplating practice coating thickness is the most frequently used parameter. For thin films, porosity is a sensitive function of the deposition parameters and substrate preparation, while

FIG. 7—Spontaneous passivation of an active-passive metal, such as titanium, by galvanically coupling to a noble metal such as platinum. The noble metal has a high rate constant for the proton-hydrogen reaction; thus, the corrosion potential of the system is near to the reversible potential for this reaction [7].

at greater thicknesses, it is controlled by the coating thickness [13–15]. A list of recommended thickness values for effective coverage of zinc, cadmium, and bright nickel/chromium coatings is available [16,17]. Likewise, a variety of destructive and nondestructive methods (see ASTM B 659, Guide for Measuring Thickness of Metallic and Inorganic Coatings, in Ref 18) are established for assessing coating thickness.

Several chemical staining methods exist for delineating the active pores in a coating [15,18]. Typically, the test involves using an indicator to reveal corrosion products that result from dissolution of the substrate at coating flaws or alternatively react with the substrate to highlight the flaws. Paper electrography, the ferroxyl, and the nitric acid vapor test are representative of the general methodology [15,18]. The electrographic technique involves making the substrate the anode in a two-electrode cell with filter paper soaked in a suitable electrolyte sandwiched between the electrodes. In the case of a corrosion-resistant coating on steel, flaws are identified by treating the filter paper with an indicator such as potassium ferrocyanide, which causes the precipitation of the iron dissolution products in the filter paper matrix, thus yielding an imprint of the defect population of the coating. Further details on this and other staining techniques may be found in the literature (ASTM B 765<sup>2</sup>) [18]. However, it must be remembered that porosity tests do not necessarily assess the pertinent corrosion performance, since this will depend on the actual service conditions.

### CORROSION TESTING OF ELECTRODEPOSITED COATING

Corrosion tests typically vary from simple exposure to the operational environment to laboratory-based accelerated exposure tests or more sophisticated electrochemical tests described in Sections III and VII of this manual. The corrosion

<sup>2</sup>Guide to the Selection of Porosity Test for Electrodeposits and Related Metallic Coatings.

testing of electrodeposits in microelectronic devices has been treated elsewhere [19], and a related chapter may be found in Section VII of this manual.

### Exposure Test

Salt spray-fog testing, ASTM B 117, Test Method of Salt Spray (Fog) Testing [18,20], has often been used to characterize the corrosion behavior of electrodeposited coatings. A copper-accelerated acetic acid salt spray (CASS) test (ASTM B 368<sup>3</sup>) [18] has been developed specifically for examining decorative copper/nickel/chromium composite coatings [18,20]. A similar test (Corrodokote) involving the application of a salt slurry followed by exposure to a humid environment has also been described (ASTM B 380<sup>4</sup>) [18,20]. The electrochemical basis of the CASS and Corrodokote test has been investigated [21]. A rating procedure exists for assessing the damage caused by these tests (ASTM B 537<sup>5</sup>), and a related test method is used specifically for quantifying the corrosion sites on copper-nickel-chromium multilayer deposits (ASTM B 651<sup>6</sup>) [18].

### Electrochemical Tests

A variety of standard electrochemical methods may be used to probe the corrosion behavior of electroplated coatings with a particular focus on assessing the effects of galvanic coupling between the coating and the substrate (ASTM G 5<sup>7</sup>, G 59<sup>8</sup>, G 61<sup>9</sup>, G 82<sup>10</sup>, G 102<sup>11</sup>, and G 106<sup>12</sup>) [22]. In accordance with the mixed potential treatment of galvanic corrosion, the corrosion potential and polarization resistance are expected to be a sensitive function of the anode/cathode area, i.e., porosity [13,14,20,23].

### Corrosion Potential Measurements

Measurement of the rest potential of a corrosion-resistant barrier coating on an active substrate provides a rapid and essential nondestructive means of assessing coating integrity. Mixed potential theory predicts that the corrosion potential

FIG. 8—Comparison between corrosion potential and polarization resistance measurements of the porosity of simulated tinplates [17].

will be a logarithmic function of the exposed substrate area,  $A^N$ . With an appropriate choice of electrolytes, the effect of the pores can be exaggerated by differential polarization, with a resultant increase in sensitivity and precision. A quantitative relationship [23] requires independent knowledge of the corrosion potential  $E_{\text{corr}}$ , corrosion rate  $i_{\text{corr}}$ , and the anodic  $b_a$  and cathodic  $b_c$  transfer coefficients of the Anodic A and Cathodic C electrode ( $A = N$  and  $C = M$ ) in

$$E_{\text{corr}} = C' - \frac{b_a^A b_c^C}{b_a^A + b_c^C} \log \frac{A^A}{A^C}$$

and

$$C' = \frac{E_{\text{corr}}^C b_a^A + E_{\text{corr}}^A b_c^C + b_a^A b_c^C \log i_{\text{corr}}^C / i_{\text{corr}}^A}{b_a^A + b_c^C}$$

(Fig. 3). This relationship has been demonstrated for a variety of systems ranging from gold coatings on copper [13,14] to tin overlayers on steel [23] (Fig. 8). However, there remains some uncertainty regarding the role of current distribution for systems with very high cathode/anode area ratios, i.e., high anodic current densities [20]. In practice, the dependence of the corrosion potential on the area of exposed substrate material may also be estimated by independent measurements of the exposed area, thus allowing a calibration curve to be obtained.

Corrosion potential measurements may also be used as an active probe of the effectiveness of a coating in service. An interesting example is the intergranular stress corrosion cracking (IGSCC) of 304 stainless steel piping in boiling water reactors, which represents a serious threat to operational longevity. The corrosion potential is the single most important environmental parameter in these systems. IGSCC of 304 SS only occurs at potentials above some critical value  $E_{\text{IGSCC}}$  (typically about  $-0.23$  SHE in high-temperature water) [24]. Consequently, a great deal of effort has been expended to displace the corrosion potentials below this value. Mixed potential theory predicts that the potential of a system may be dominated by coupling a metal with a particularly fast redox reaction. Noble metals are well-known catalysts for the hydrogen-proton reaction, which has a reversible potential below that of  $E_{\text{IGSCC}}$ . Thus, a porous noble metal coating on stainless steel will act to maintain the

<sup>12</sup>Practice for Verification of Algorithm and Equipment for Electrochemical Impedance Measurements.

corrosion potential near the hydrogen-proton reversible potential (Fig. 7). The effective control of the corrosion potential of 316 SS, via an electrodeposited coating of palladium, has been demonstrated [25].

### Polarization Resistance Measurements

Mixed potential theory also allows predictions of the dependence of the polarization resistance on the exposed area of a galvanically active substrate. With due consideration for the influence of the total specimen area, as well as the surface roughness, an expression for the polarization resistance may be derived:

$$\frac{1}{A} \left( \frac{\Delta I}{\Delta E} \right) = K' + \frac{b_A}{b_A + b_c} \log \frac{A^A}{A} + \frac{b_c}{b_A + b_c} \log \frac{A^c}{A}$$

where

$$K' = \frac{E_{\text{corr}}^c - E_{\text{corr}}^A + b_c \log i_{\text{corr}}^c + b_A \log i_{\text{corr}}^A}{b_A + b_c} - \log \frac{b_A b_c}{2.3(b_A b_c)}$$

A recent publication [23] presents a summary of the systems that have been investigated to date. However, the influence of potential distribution is not considered in this model [9,20]. As with corrosion potential measurements, an independent calibration method demonstrates that with the appropriate electrolyte the polarization resistance is proportional to the exposed substrate area. For tin-coated steel tested in thiocyanate solution, favorable agreement is found between polarization resistance and corrosion potential measurements (Fig. 8).

### Chronopotentiometry

Chronopotentiometry, where the electrode potential is monitored as a function of time during galvanostatic polarization, is a particularly useful technique for characterizing the thickness and phase structure of electrodeposited multilayers. The corrosion performance of copper/semibright nickel/bright nickel/microcracked chromium composite coatings is a strong function of thickness of the various layers, as well the potential difference between the semibright and the sulfur containing bright nickel layer [10,11]. The potential difference must be sufficient to cause the bright nickel to corrode preferentially and sacrificially with respect to the semibright nickel. Chronopotentiometry may be used to assess effectively the thickness as well as the potential difference between the nickel layers. If a chromium layer is present, it is typically first removed with concentrated hydrochloric acid. The sample is then placed in the electrolyte under a constant galvanostatic imposed anodic current. A sharp transition in the potential occurs after the bright nickel layer has dissolved to expose the semibright nickel layer, which proceeds to dissolve until the copper substrate is exposed (Fig. 9). Assuming 100 % current efficiency, a coulometric analysis, according to Faraday's law, may be used to transform the time axis to an appropriate thickness scale. This test has been formalized as an ASTM standard known as the STEP Test (ASTM B 764<sup>13</sup>) [18].

<sup>13</sup>Test Method for Simultaneous Thickness and Electrochemical Potential Determination of Individual Layers in Multilayer Nickel Deposit.

FIG. 9—Results of galvanostatic stripping of a duplex nickel deposit from a copper substrate (taken from ASTM B 764 [16]).

Chronopotentiometry has also been used to analyze the effects of different processing methods on the phase structure of coatings. The potential response of a variety of galvanostatically dissolved zinc-coated steel samples is highly sensitive to the presence of intermetallic layers that form at elevated temperatures [12].

### The EC Test

The EC Test (ASTM B 627<sup>14</sup>) [18,20,26] uses a combination of chronoamperometry and constant current coulometry to perform accelerated corrosion testing of copper/nickel/microcracked chromium multilayer electrodeposits on steel or zinc-based die castings. The test was designed to simulate the actual corrosion service expected for automotive trim in a metropolitan area such as Detroit [26]. The current-potential behavior for the individual constituents (Fig. 10) demonstrates that at potentials more positive than +0.1 V SCE, the dissolution rate is consistent with the anticipated ordering based on the Galvanic series. In the EC Test, the specimen is held potentiostatically at 0.3 V SCE, which preferentially initiates attack on the bright nickel layer. As the attack progresses, the measured current increases as the area of exposed nickel increases. When the current reaches a specific value, typically 3.3 mA/cm<sup>2</sup> (projected geometrical area), the regulation of the experiment is converted to galvanostatic control, thereby simulating corrosion control by the cathodic partial process (i.e., oxygen and proton reduction on microcracked chromium). The time of galvanostatic regulation corresponds to length of service. Penetration of the coating is ascertained by using chemical indicators, either in the electrolyte or after removal from the electrolyte, to reveal dissolution products emanating from the steel or zinc substrate. The test was found to be over 400 times faster than the CASS exposure test, and the mode of corrosion is found to be more representative of that observed in service [26].

<sup>14</sup>Test Method for Electrolytic Corrosion Testing.

FIG. 10—Potentiostatic *i*-*E* curves for the constituents of the composite coating shown in Fig. 6 [20].

### In-Situ Imaging and Nondestructive Evaluation of Electrodeposited Coatings

During the last decade, significant developments have occurred that enable the in situ mapping of the potential distribution on a corroding surface. Both the scanning reference electrode (SRET) and, more recently, the scanning vibrating electrode technique (SVET) have been described [27]. In both techniques, a fine capillary tip electrode, which is rastered across the surface, is used to sense potential gradients. These methods may be used to image the sites of localized corrosion and related heterogeneities on surfaces and to determine their polarization characteristics. The SVET is currently able to resolve features down to 40  $\mu\text{m}$ , and a discussion of the limitations of the technique is available [27]. Defects in aluminized steel have been imaged in borate solution as shown in Fig. 11. The figure shows the result of repeated scanning of a single line in the X direction, which crosses over active sites, while the substrate potential was decreased from 1.1 to  $-0.9$  V. The polarization behavior of three specific sites may be compared. The two adjacent high current density sites at 1.1 V show a decrease in current density with decreasing potential. At negative potentials, the cathodic currents remained low at the two adjacent sites, while the cathodic currents observed from the third site increased. These results demonstrate that this technique allows the identification and examination of the character of different surface defects.

FIG. 11—A scanning vibrating electrode (SVET) image used to characterize the nature of defects in an aluminum-coated steel substrate as function of potential in a buffered borate solution [29].

Several other scanning probe techniques are under development, which may be used to examine the character of electrodeposited coatings. The scanning electrochemical microscope (SECM) is used to create a map of the chemical reactivity of a surface [28]. The technique involves using a redox couple to mediate the interaction between a rastered microelectrode probe and the substrate. This technique may be particularly useful for examining the character of thin noble metal coatings. For example, patches of gold on a glassy carbon electrode have been successfully imaged [28]. The resolution of this technique appears to be limited by the diameter of the probing microelectrode.

Other techniques such as magnetic force microscopy or SQUID magnetometry [29] may also find application in assessing the quality of electrodeposited materials. However, limitations on the sensitivity and spatial resolution of these methods need to be assessed.

## CONCLUSIONS

Electrodeposition enables the production of many novel corrosion-resistant alloys that may not be produced by conventional thermomechanical means. A variety of standard electrochemical methods may be used to examine the corrosion resistance of the electrodeposited material itself. However, the corrosion behavior of an electrodeposited coating must be viewed as a composite system due to possible galvanic interactions between the coating and substrate. An assortment of techniques is available for examining the corrosion behavior of these systems. Invariably, these methods all focus on the effects of coating porosity. It is important for the investigator to have a clear understanding of the goal of the test program (e.g., ranking of materials, quality control, study of mechanisms, etc.). Only through careful evaluation of all of the information can the most appropriate test for a particular situation be selected.

# Powder Metallurgy (P/M) Materials

*Erhard Klar<sup>1</sup> and Prasan K. Samal<sup>2</sup>*

A POWDER METALLURGY part is conventionally made by compacting a lubricated metal powder in a die to the desired shape followed by sintering in a protective atmosphere. Simple and complex parts with densities typically ranging between 80 and 90 % of theoretical and having the finished dimensions are produced at high production rates. The P/M process uses raw materials and energy efficiently and, hence, is cost effective.

The P/M materials developed during the first four decades of the 20th century included cemented carbides, composite electrical contacts, self-lubricating bronze bearings, and composite friction materials. The service lives of these materials were in general not limited by their corrosion resistances. With the sharp increase of iron-based sintered steel parts in the 1940s, however, corrosion resistance became of increasing importance. This culminated in the development of sintered stainless steels in the 1950s.

The bulk of sintered P/M carbon-, copper-, nickel-, and low-alloy steel parts are used without any further treatment for additional corrosion protection. The reason for this is that about 70 % of all P/M parts manufactured in North America are used in the automotive industry [1], and that a large majority of these parts are internal components of the automotive transmission, the engine, and the steering gears, where corrosion is not a problem. Farm, lawn and garden equipment, hardware, appliances, and business machines also contain many carbon- and low-alloy steel parts that sometimes require additional treatments for corrosion protection. A very simple treatment for corrosion protection consists of dipping the P/M parts in an oil. Alternately, P/M parts may be painted or coated mechanically (mechanical plating) [2]. Steam treatment [3,4] is an economical process applied to small iron and steel parts to improve their hardness, compressive strength, and corrosion resistance. It involves controlled oxidation with superheated steam. The parts become coated with a tightly adhering dark blue or black oxide ( $\text{FeO}$  and  $\text{Fe}_3\text{O}_4$ ), which is acceptable as final finish. Some sintered parts are impregnated with a resin, followed by plating with copper, nickel, cadmium, zinc, or chromium. More recently, a special coating process, called Dacronizing [5], was developed for the corrosion protection of ferrous P/M sensor rings used in anti-lock brake systems. It consists of a combination of steam treating, coating with

zinc flake and chromic acid, followed by impregnation and overcoating with a silicate slurry.

Sintered stainless steel parts are used generally in more severe corrosive environments. Due to their large surface areas and the presence of pores, these require special processing precautions to ensure good corrosion resistance. During the past ten years, the complex fundamental requirements for good corrosion resistance of sintered stainless steels have been described [6] and the industry is presently acquiring the know-how for mastering the practical aspects of these requirements. With appropriate process control and some modification of composition, it is now possible to manufacture sintered stainless steel parts passing the widely specified 100 h salt spray test (ASTM B 117, Test Method of Salt Spray/Fog Testing), and to even approach the corrosion resistances of wrought stainless steels [7,8].

Table 1 is a partial listing of the compositions of the common porous sintered P/M materials. Selected compositions of P/M materials possessing near theoretical full density (>99 %), sometimes called "full dense" or high-performance P/M materials, are shown in Table 2 [2,9]. Full dense P/M parts are made by liquid phase sintering, powder injection molding, extrusion, or hot isostatic pressing. Important full dense P/M materials include P/M superalloys, P/M tool steels, several P/M aluminum alloys, and many P/M specialty alloys. Owing to their refined microstructure and greater homogeneity, full dense P/M materials offer superior mechanical properties with equal or superior corrosion resistance, compared to their wrought or cast counterparts.

## CORROSION TESTING AND EVALUATION

Corrosion testing procedures and standards established for wrought alloys are generally applicable to full dense P/M materials. They are discussed in other chapters in this section. Among the porous P/M materials, sintered stainless steels are by far the most important materials whose corrosion testing is of commercial interest [6]. Only a very limited number of reports are published on the corrosion behavior of any other types of porous P/M materials. Therefore, the following discussion will be focused principally on sintered stainless steels. Details relating to the P/M process are covered only to the extent that they are relevant to corrosion resistance. For additional information, the reader is referred to other publications [2,10,11].

At present, there exists only one standard on corrosion testing and evaluation of sintered P/M parts, although many of the methods employed for wrought metals are used for sintered P/M parts with minor modification. In addition, a few nonstandardized tests are available.

## Atmospheric Testing

Many P/M parts are used in the equipment and machinery exposed to the atmosphere. However, systematic investigations into their corrosion resistances under atmospheric conditions, as they are known for many wrought metals, are not available for P/M parts. In most investigations, surface appearance and/or weight changes after certain length of exposure are reported [12], and occasionally changes in mechanical properties are reported. Recommendations in ASTM G 50, Practice for Conducting Atmospheric Corrosion Tests on Metals, are useful for this type of testing. One should keep in mind, however, that weight changes in sintered materials may be more difficult to interpret because of the presence of pores. The loss in weight due to the actual loss of material on the surface of the part may be undesirably compensated by the weight gain that occurs due to buildup of products of corrosion and moisture in the interior of the pores.

## Immersion Tests

Corrosion testing of P/M parts by immersion is useful for comparing the performance of various alloys, for optimization of P/M processing, and, with the mutual agreement

between the parties involved, as a criterion for acceptable quality.

## Immersion Tests with Mass Loss

ASTM G 31, Practice for Laboratory Immersion Corrosion Testing of Metals, may be followed for P/M parts where a loss in mass results due to reaction with the test solution. In comparison to wrought materials, the preparation of specimens or sintered parts for corrosion testing is usually minimal. In most cases the actual parts or specimens are tested in their as-sintered, or “secondary” treated, conditions. In fact, it would be counterproductive in most cases to clean the surfaces by mechanical means since this may result in material removal, and the new surfaces may differ in their compositions and structures from the original surface. The composition and structure of only the as-produced original surface has the most relevance to the corrosion resistance and the service life of the part. Cleaning by simply degreasing the P/M parts with an organic solvent is usually sufficient.

Corrosion rates of sintered steels have been reported for immersion testing in nitric [13], sulfuric [14–16], and acetic [17] acids. Compared to their wrought counterparts, the P/M parts exhibited much greater weight losses. In a more recent study, the authors reported a hydrogen sintered Nb-stabilized 444L stainless steel that was fully resistant in 2 % H<sub>2</sub>SO<sub>4</sub> [18].

## Immersion Tests without Mass Loss

Immersion testing without a resultant mass loss includes testing in neutral salt solutions. Developed by the authors,

a salt solution immersion test has now been standardized (ASTM B 895-99) and is widely used for sintered stainless steels. The procedure is simple, inexpensive, and flexible so that P/M parts producers also can use it in-house for optimizing their sintering process for stainless steels.

Each test is based on five or more pressed and sintered replicate specimens, which are exposed to a 5 % NaCl solution in individual jars at room temperature. The standardized test prescribes that the jars must be closed with lids, while the earlier version of the test was based on open jars or beakers. The specimens are examined visually at predetermined time intervals, for onset of staining or rusting, and thereafter for an estimation of the percentage of surface area covered by stain or rust, in accordance with the following four rating classes:

- A—sample free from any corrosion.
- B—up to 1 % of surface covered by stain or rust.
- C—1 to 25 % of surface covered by stain or rust.
- D—>25 % of surface covered by stain or rust.

A chart containing photographs of a series of specimens for each of the four rating classes is referred to, for maintaining accuracy of rating (Fig. 1). The time intervals between inspections are short at the beginning of the test, and are increased gradually as the test progresses. Table 3 shows a typical record of test data. Figure 2 shows a typical plot for the set of data listed in Table 3. From this plot, the mean lives (in hours) for the specified degrees of surface corrosion (on set, 1 % and 25 %) are obtained as the intersection points of the respective rating curves with the horizontal line at 50 %. If the specimens are not fabricated properly or handled carefully (such as affected by contaminations, wide variations in oxygen, nitrogen, or carbon contents, density variations, etc.), the scatter of the test data will increase.

With immersion testing in 5 % NaCl, corrosion resistances up to a C-rating (<25 % rust) usually have little effect on the mechanical properties of a P/M stainless steel part. At these levels of rusting, weight loss measurements are unreliable,

as some of the rust, as well as salt, may penetrate the pores and cause weight gains instead of weight losses. For applications that can tolerate larger amounts of corrosion, the determination of the amount of surface rust is often insufficient for part qualification. In cases of pitting, determination of number and depth of pits in porous materials is complex and their effects on mechanical properties are less severe in porous P/M parts than in wrought steel. In such cases it is often useful to remove surface rust (for instance, by sandblasting) and to provide photographic evidence of pitting in combination with relevant mechanical properties in accordance with Section 7.5 of ASTM G 46, Practice for Examination and Evaluation of Pitting Corrosion. Most of the other aspects of ASTM G 46 cannot be used readily for sintered materials because the size and shape of corrosion pits can be quite similar to those of the pores in sintered materials. Electrochemical testing (see subsection on *Electrochemical Tests*) appears to be the best technique for identifying pitting corrosion in sintered stainless steels.

### Salt Spray Tests

Salt spray testing in accordance with ASTM B 117 is being increasingly used in the P/M industry in recent years for qualifying new stainless steel parts or P/M substitutes for wrought parts. It may also be used for alloy development and process optimization. The neutral salt spray test is more aggressive than the neutral salt immersion test. The visual rating system described in the subsection on *Immersion Tests without Mass Loss* may also be used for salt spray testing. An extensive discussion of the corrosion resistances of sintered austenitic stainless steels processed under varying conditions is given in Refs 19 and 20. Testing and evaluation included electrochemical and neutral salt spray methods in accordance with ISO 3768 [21] and a visual rating scale from 10 to 0 in accordance with ISO 4540 [22]. In Ref 23 the neutral salt spray test is used on sintered 410L sensor rings for antilock brake systems.

### Electrochemical Tests

Electrochemical anodic polarization tests (ASTM G 5<sup>2</sup> and G 61<sup>3</sup>) are useful corrosion test methods for alloy and process development work on P/M materials. Reference 23 describes the application of potentiostatic anodic polarization to steam-treated P/M carbon steel in neutral salt and acidic environments. References 13 and 19 describe the application of potentiodynamic polarization to sintered austenitic stainless steels. These test methods are very effective in revealing metallurgical weaknesses of sintered stainless steels. Sintered stainless steels, due to their large surface areas, exhibit large corrosion currents, compared to the wrought stainless steels, and frequently the current rises with increasing potential. Furthermore, sintered stainless steels do not always exhibit a pronounced transition from

the active to the passive state. As a result, the differences between initial passivation current,  $I_{\text{peak}}$ , and passive current,  $I_{\text{pass}}$ , may be smaller, and, at times,  $I_{\text{pass}}$  may be higher than  $I_{\text{peak}}$ . Also, sintered materials often show smaller differences between critical passivation current,  $I_{\text{peak}}$ , and passive current,  $I_{\text{pass}}$ . Metallurgical weaknesses show up as higher values of  $I_{\text{peak}}$  and  $I_{\text{pass}}$ , and lower values of the critical potential,  $E_{\text{pit}}$ . A larger critical passivation current means that the material is more difficult to passivate or remain passive. A higher passive current signifies a higher corrosion rate in the passive region. A lower critical potential signifies reduced pitting resistance.

Figure 3 shows potentiodynamic curves for three P/M 316L stainless steel specimens sintered under three different conditions. These curves do not exhibit a pronounced transition from active to passive state, but do exhibit increase in corrosion current with increasing potential. Defining  $I_{\text{pass}}$  as the corrosion current in the passive region just before pitting initiates, it may be noted that the lowest  $I_{\text{pass}}$  is obtained with the specimen sintered at the highest sintering temperature (1350°C), in a 100 %  $\text{H}_2$  atmosphere and cooled rapidly.  $I_{\text{pass}}$  is higher for the specimens sintered in the nitrogen bearing atmosphere and for the lower sintering temperature in this atmosphere; both of these conditions increase the nitrogen content in the sintered stainless steels and cause precipitation of  $\text{Cr}_2\text{N}$  with attendant depletion of chromium in the grain boundaries and loss of corrosion resistance.

Table 4 summarizes electrochemical test data for 316L sintered in hydrogen and under vacuum [24]. In these examples, inferior corrosion resistance, documented also by neutral salt spray data, can be attributed to greater degrees of reoxidation of the surface of a specimen during cooling

in a higher dewpoint environment. Mathiesen and Maahn [19] have pointed out that in order to obtain qualitative correlation with neutral salt spray testing of sintered stainless steels of various densities, stepwise polarization must be employed. The slower polarization rate in stepwise polarization apparently enables the time-consuming buildup of localized attack in the pores, analogous to the mechanism of crevice corrosion.

### Ferroxyl Test

The ferroxyl test is mentioned in ASTM A 380, Practice for Cleaning and Descaling Stainless Steel Parts, Equipment, and Systems. It has recently been adapted as a rapid and simple corrosion test for sintered austenitic stainless steels [25] and for the detection of contamination of stainless steel powder with iron or low-alloy steel powders [26]. This test uses hexacyanoferrate (II/III) solutions with different chloride contents. Immersion of a sintered stainless steel part into such a solution develops, usually within minutes, a blue precipitate known as Turnbull's blue in accordance with

This test can reveal metallurgical weaknesses due to improper sintering conditions or due to contamination with iron. Agreement with salt spray testing and electrochemical

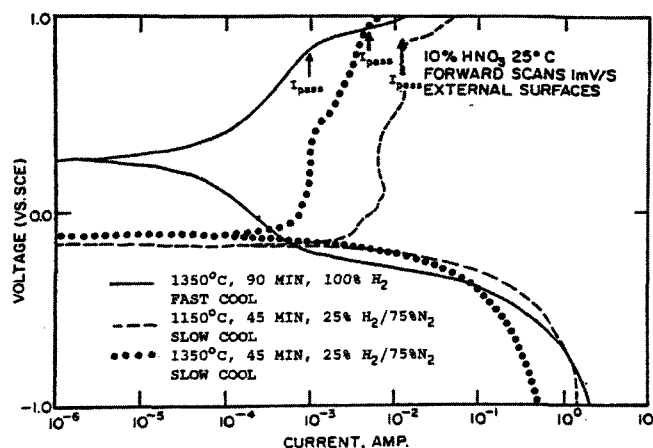

FIG. 2—Plot of percentage of replicate specimens with a given rating versus immersion time.

FIG. 3—Forward scan potentiodynamic corrosion curves for external surfaces of three sintered type 316L stainless steel samples in 10 %  $\text{HNO}_3$  at 25°C [13].  $I_{\text{pass}}$  increases with sintering in a nitrogen containing atmosphere, decreasing sintering temperature, and decreasing cooling rate.

measurements is moderate. However, this test is superior to the earlier established Copper Sulfate Test (ASTM A 380-88) for detecting less noble metal particles such as iron or low-alloy steel in austenitic stainless steel powders. Such particles, unless very fine, do not become alloyed or dissolved in the stainless steel during sintering and, therefore, give rise to galvanic corrosion. In the copper sulfate test the powder sample is covered with a saturated aqueous solution of copper sulfate, whereby the less noble contaminant particles become coated with metallic copper, and are thus readily identifiable under a low magnification stereo microscope. However, the copper sulfate test does not work with lubricated powders or green parts, whereas the ferroxyl test is not affected by presence of lubricant on powder surfaces. Also, unlike the copper sulfate test, in the ferroxyl test the blue precipitates formed in the interior of a green part or the powder mass grow rapidly in size, thus making it easy to examine. The high sensitivity of the ferroxyl test is commensurate with the fact that even traces of iron or low-alloy steel contamination can ruin the corrosion resistance of sintered stainless steel parts. Recommended test solutions and development times for the blue precipitate are shown in Table 5.

## PROCESSING AND QUALITY CONTROL OF SINTERED STAINLESS STEELS

This section briefly describes the critical process parameters that affect the corrosion resistance of sintered stainless steels in a chloride environment. The authors have observed that the most frequent processing problems in the stainless

steel parts producing industry are related to improper delubrication, excessive dewpoints in sintering furnaces, slow cooling rates after sintering, and contamination with iron or low-alloy steel powders. Improper delubrication can lead to high residual carbon or oxygen contents, or both, which in turn can cause intergranular and pitting corrosion. Excessive dewpoints of the sintering atmosphere most often result in the oxidation of the surface layers of the sintered parts during cooling. The amount of absorbed oxygen is usually too small to be identified by conventional oxygen analysis or to be noticed as discoloration of the surface. This condition produces low pitting resistance. Slow cooling rates may cause precipitation of carbides at the grain boundaries, in the same manner as sensitization occurs in wrought stainless steels. Slow-cooling in a nitrogen bearing atmosphere can lead to absorption of nitrogen on the surface of the part, forming chromium nitrides which will also impair corrosion resistance. Contamination with less noble metal powders produces galvanic corrosion.

A practical approach to process improvement for achieving good corrosion resistance in sintered stainless steels includes the following steps:

1. Testing of powders and pressed parts to assure freedom from contamination (Ferroxyl test).
2. Corrosion testing of sintered parts in accordance with the section on Corrosion Testing and Evaluation.
3. Comparison of corrosion resistance with published corrosion data.
4. Analysis of cause of inferior corrosion resistance, including analysis of samples for nitrogen, oxygen, and carbon contents, and examination of microstructure for presence of nitrides, oxides, and carbides.
5. Process modification to eliminate cause of inferior corrosion resistance as identified under (4).

Table 6 summarizes chloride corrosion resistances for various sintered and wrought stainless steels. These data were generated for a broad range of sintering conditions employed in the P/M industry. In all cases, processing was controlled to eliminate contamination of the specimens with less noble powders, to avoid or minimize precipitation of chromium carbides and chromium nitrides as well as loss of chromium during vacuum sintering [6,19,20]. Table 6 can be used by stainless steel parts producers to gage their

progress regarding process optimization for maximizing corrosion resistance. The data also show that it is possible to obtain satisfactory corrosion resistances in all three sintering atmospheres used by the P/M industry.

FIG. 4—Effect of sintered density upon corrosion resistance of pressed, sintered, repressed and annealed 317L [27].

Chemical analysis and metallographic examination can identify the causes of inferior corrosion resistance in many cases [6,19,20]. Quantitative data for intergranular corrosion in accordance with ASTM A 262, Practices for Detecting Susceptibility to Intergranular Attack in Austenitic Stainless Steels, are not available for sintered porous stainless steels.

For the lower alloyed austenitic stainless steels, say 18-8 and lower, after control of the metallurgical factors, there remains the detrimental effect of porosity giving rise to crevice corrosion. Crevice corrosion may be determined in accordance with ASTM G 48, Test Method for Pitting and Crevice Corrosion Resistance of Stainless Steels and Related Alloys by the Use of Ferric Chloride Solution. As shown in Fig. 4, for 317L type alloys, in the density range from about 6.6 to 7.4 g/cm<sup>3</sup>, the chloride corrosion resistance decreases with decreasing porosity reaching a minimum at around 7.2 g/cm<sup>3</sup>, and thereafter it increases as full density is approached. In these tests, the high densities were obtained by the use of a liquid phase sintering additive. To the left of the minimum, corrosion resistance decreases with decreasing pore size. To the right of the minimum, corrosion resistance improves as pores become increasingly closed-off or inaccessible to the surface. This type of crevice corrosion can be reduced or overcome by impregnation of the pores with a resin, metallurgical modification of the pore surfaces, or the use of higher alloyed stainless steels, particularly those containing higher concentrations of molybdenum.

## INTRODUCTION

THE AUTOMOTIVE INDUSTRY has become one of the key sectors of the economy throughout the world. In industrialized countries it is estimated that between 10 and 16 % of the working population is employed in activities related to the automotive sector.

Passenger car production starts with the input of sheet metal, generally in coil form. The metal is cut and formed into 300–500 pieces, which are welded to form the body. It then passes through a paint line to the final assembly line where the assembled components (seats, carpets glass, engines, transmissions, suspensions, electrics, wheels, tires, brakes, etc.) are fitted to produce the finished vehicle.

Over the past 25 years, strategies to improve quality and reliability while reducing manufacturing costs and improve profit margins, have brought about considerable change in the industry. New designs, improved processing and new and/or improved materials and components have been developed to meet these challenges. The resulting improvements in corrosion resistance have led to extended warranties, which are currently 6–10 years for perforation and 1–5 years for cosmetic corrosion. Corrosion testing, such as laboratory accelerated tests, and the use of corrosion test track vehicles, has played a major role in the development of corrosion resistant vehicles. Today, the cost of conducting a corrosion test track study is estimated to be \$200,000 per vehicle. Therefore, the automotive industry has started to rely on other corrosion tests to determine performance characteristics of vehicles and components in service environments. This chapter addresses all of the testing technology used in the development of corrosion resistant vehicles.

## AUTOMOTIVE MATERIALS

The automobile has evolved into a complex multimaterial system that is exposed to a highly aggressive and wide range of environments. Its design includes auto-body and structural materials; hardware such as trim, bumpers, and brackets; engine; drive train and exhaust systems; electrical systems and systems incorporating liquid passages and reservoirs such as heat exchangers; hydraulic brake lines, fuel lines and tanks; and oil and transmission fluid reservoirs. Thus, the variety of materials used is extremely large. Table 1a

lists some of the metallic materials used in various automotive systems. Metallic and nonmetallic coatings used in the automotive industry are listed in Table 1b. Choice of these materials is determined by the specific application and nature of the environment.

The most significant changes that have occurred over the past three decades has been the transition from bare steel to pre-coated sheet steels such as galvanized steel. Other important changes include the increased use of aluminum alloys and of plastics and plastic composites. Also, use of lightweight magnesium has increased in recent years

## PROCESSING

Significant improvements in processing have been made over the past two decades. The most important are the steps in finishing the vehicle. Included here are the cleaning/phosphate processes, the electrocoat primer application, body sealing and wax augmentation coatings, and application of the topcoat. Other processing improvements include techniques to remove residual chemicals from components, improved electrodeposition processes and control of thickness, surface characteristics, chemistry, and metallurgy of metallic materials.

## DESIGN

Design improvements have played a major role in the development of corrosion resistant vehicles. Areas of entrapment, where salt, poultice and other materials could build up and provide a corrosive environment, have been eliminated to enhance corrosion resistance in vehicles. For example, wheel wells are now designed to have a sloping configuration so that corrosives can be washed or will drain out. Drain holes have been incorporated in areas so that corrosive liquid cannot accumulate. Sealers are used to eliminate crevices and joints where corrosives can build up. And, attempts have been made to reduce galvanic corrosion by avoiding dissimilar metal contact.

## AUTOMOTIVE ENVIRONMENT

The automotive environment can be categorized as (1) external exposure, (2) internal combustion exposure,

<sup>1</sup>RB Corrosion Service, Greenville, RI 02828.

**TABLE 1**—(a) Metallic materials used in the automotive industry.

Body Panels	Steel, coated steel (zinc, zinc-iron, zinc-nickel, aluminum), aluminum
Chassis	Steel, HSLA steel, coated steel (zinc, zinc-aluminum, aluminum), aluminum
Trim and Hardware	Chrome plated steel, stainless steel, aluminum, chrome plated zinc, stainless steel clad aluminum (bimetal), magnesium
Exhaust System	Steel, coated steel (zinc, zinc-aluminum, aluminum), stainless steel, Monel
Engine and Components	Iron, steel, aluminum, magnesium
Transmission	Steel, stainless steels, copper and alloys, nickel and alloys, aluminum
Fasteners	Steel, coated steel (wide range of metallic and nonmetallic coatings) aluminum
Cooling System	Copper and alloys, aluminum, steel, stainless steel, solder (lead-tin, tin, zinc) braze alloy (aluminum, copper)
Fuel System	Steel, coated steel (zinc, zinc-aluminum, zinc-nickel, aluminum, lead-tin, tin)
Brake System	Steel, coated steel (zinc, zinc-aluminum, lead-tin, tin) stainless steel cupro-nickel alloy
Electrical and Electronics	Aluminum, copper and alloys, coated steel (cadmium, chromium, nickel, copper, tin, lead) solder, beryllium, gold, silver stainless steels, magnesium

## (b) Coatings used in the automotive industry.

Precoated Steels	
Hot Dip	Zinc, zinc-iron, aluminum, aluminum (55%)-zinc, zinc-aluminum (5%), terne (lead-tin), nickel terne (nickel/lead-tin)
Electroplated	Zinc, zinc-iron, zinc-nickel, tin plate, tin free (chrome)
Organic/Precoat	Zinc-rich organic primer
Post-Applied (Protective and Decorative)	
Metallic	Cadmium, zinc, lead, copper, copper/nickel/chromium, nickel/chromium, chromium (microdiscontinuous), chrome flash, hard chromium, nickel-iron
Chemical Conversion Coatings	
Inorganic	Zinc phosphate, manganese phosphate, iron phosphate, black oxide, anodic oxide (aluminum), oxide/chromate, magnesium oxide
Organic Primers and Topcoats	
Organic Base	Epoxies, epoxy esters, polyesters, alkyds, vinyls, acrylics, oils, urethanes, cellulose
Pigments	Molybdates, lead, zinc, coloring
Other Organics	
Sealers	Asphaltic, rubber, vinyl, hot melts

and (3) internal functional liquids. Of these, the environment most investigated is external exposure.

### External Exposure

The severity of external automotive corrosion varies considerably throughout the world, due to differences in the chemistry of the environment [1–3]. The severest corrosion environments are in the snowbelt areas where deicing salts are used and along coastal areas where warm, humid, salt atmospheres exist. During the 20th century, the chemistry of the environment changed drastically. As a result of those changes, the corrosivity of the automobile environment increased.

To design automobiles for corrosion resistance, it is necessary to understand the nature of the environment and how materials react in that environment. Rain and snow are important to providing moisture to the environment. Atmospheric moisture and the conditions that produce fog and dew are also important. However, extensive studies and historic data have shown that moisture alone does not cause serious corrosion problems on automobiles.

Aggressive corrosive constituents include chlorides and pollutants. Marine environments are corrosive because of dissolved chlorides. A typical seawater composition has a sodium chloride content of about 3.5 %. However, this content will vary depending on location, such as that near tidal rivers or oceans. Splash and spray, which causes atmospheric redistribution of seawater, is extremely important in

marine environments. Larger seawater droplets fall out rapidly closer to the source. Smaller droplets distribute over a wide area while evaporating to an equilibrium size and deposit according to local weather conditions.

The data in Fig. 1 compiled by the Salt Institute (Washington, D.C.) on annual use of road salts in the United States show that use of sodium chloride and calcium chloride for ice and snow removal began to increase during the late 1950s. At that time, only one million tons per year of salt were used in the United States. By 1965, four million tons were used, and in 1979 usage peaked at twelve million tons. During the 1970s and 1980s, annual usage leveled at about ten million tons. During the 1990s, usage peaked at almost 20 million tons per year but varied in the range of 10–20 million tons. (See Fig. 1.) Approximately 5 % of the total usage is calcium chloride.

The rapid increase in the use of road salts during the 1960s was attributed to salt replacing abrasives. Further increase during the 1970s was attributed to changes in highway maintenance policy. Public awareness of the damaging effects of road salts during the 1980s may have prevented further increases. This pattern of road salt use has occurred throughout a large part of the industrialized world. Recent variations in usage have been attributed to variations in snowfall.

Atmospheric pollutants, such as sulfur dioxide, nitrogen oxides, hydrogen sulfide, ammonia ( $\text{SO}_2$ ,  $\text{NO}_x$ ,  $\text{H}_2\text{S}$ ,  $\text{NH}_3$ , respectively), and particulate matter, are known to have an effect on corrosion of metals [4]. The presence of  $\text{SO}_2$  in the

FIG. 1—Annual emissions and road salt usage in the United States.

atmosphere and its effect on corrosion has been studied very extensively. The complex reaction involves the SO<sub>2</sub> molecule striking a steel surface and converting to sulfuric acid as a result of oxidation and hydrolysis. This introduces reactive ions, increased conductivity, and a lower pH. The presence of hygroscopic sulfate corrosion products also lowers the critical humidity for corrosion reaction.

Study of the behavior of NO<sub>x</sub> has led to the conclusion that nitric acid forms on a steel surface. The conversion of SO<sub>2</sub> to sulfuric acid is enhanced in the presence of NO<sub>2</sub>, according to the reaction [5].

Increased corrosion rates have been measured for steel in the presence of both SO<sub>2</sub> and NO<sub>x</sub>. This synergistic effect may be important in the automobile environment because automobile emissions contain NO<sub>x</sub>.

Data in Fig. 1 compiled by the National Acid Precipitation Assessment Program (Washington, D.C.) on SO<sub>2</sub> and NO<sub>x</sub> emissions show that annual emissions have risen steadily in the United States peaking at 30 million tons for SO<sub>2</sub> in 1970 and 20 million tons of NO<sub>x</sub> in 1978 [6]. Although emissions have decreased during the 1980s and 1990s for SO<sub>2</sub>, the levels for NO<sub>x</sub> emissions increased. The current levels for both still remain quite high.

Atmospheric oxides of sulfur and nitrogen are emitted from both natural and anthropogenic sources. Examples of natural sources include volcanic activity and decomposition of organic materials (such as emissions from salt marshes). Anthropogenic sources are concentrated in the heavily industrialized zones. These emissions may be transported over great distances, because they are usually discharged from tall smokestacks. Thus, the long distance movement of air pollutants can affect areas remote from industry. Studies have shown that oxidation and hydrolysis reactions of SO<sub>2</sub> and NO<sub>x</sub> occur in the atmosphere yielding H<sub>2</sub>SO<sub>4</sub> and HNO<sub>3</sub>. (The residence time of SO<sub>2</sub> in the atmosphere is

estimated to be two to four days.) The resulting acid deposition in the form of acid rain, acid snow, acid fog, acid dew, and dry acid deposits is distributed over large areas.

The synergistic effect of road salts and acid deposition on corrosion has been investigated [1–4]. The combined effect of the chloride (a film disruptor on metals) and acids (which provide reducible hydrogen ions) can be much worse than the added separate effects. Thus, geographical areas that are subjected to both road salts and acid deposition are likely to be the most corrosive to automobiles.

Another important factor is the highly corrosive environment produced by the accumulation of dirt, vegetation, and other debris in metallic entrapment areas [7]. These areas remain wet almost continuously due to the presence of this poultice and produce a stationary electrolyte environment. The result is a concentrating effect of salts and acids similar to the phenomena observed in crevices. When steels are exposed to this poultice environment, the corrosion process becomes autocatalytic leading to rapid deterioration.

### Internal Combustion Exposure

Internal combustion produces water vapor and exhaust gases, which can condense in internal areas such as the exhaust system of automobiles [8,9]. This condensate chemistry includes sulfate, sulfite, nitrate, ammonium, carbonate, bicarbonate, and chloride ions. The acidity of the condensate is high due to the presence of nitric, hydrochloric, sulfuric, and sulfurous acids. Nitric acid is formed from atmospheric nitrogen, which is converted to oxides in the engine and then to the acid. Sulfuric and sulfurous acids are formed because fuels and lubricatory oils contain sulfur, which converts to sulfur dioxide and then reacts with water vapor to form these acids. In addition, catalytic converters are designed to convert SO<sub>2</sub> to SO<sub>3</sub> yielding acids. Chloride additives to fuels yield hydrochloric acid.

The temperature of the system is of great importance. If the system does not become hot enough (above the dew point), the condensate remains and concentrates. Thus, vehicles, which are driven for short distances are more susceptible to corrosion by exhaust gas condensates, sometimes referred to as cold-condensate corrosion [8]. Deterioration is also accelerated by stress (both cyclic and static) and by design configurations (such as at joints and welds).

Direct exhaust-gas impingement (erosion corrosion) can occur due to the high-velocity exhaust gas stream on the internal surfaces of the exhaust system. This effect is important at sharp bends and surfaces normal to the gas flow. The combination of particulate matter with hot corrosive gas produces this type of attack.

High-temperature oxidation of exhaust system components is governed mainly by the temperature encountered, as well as exhaust gas composition. Temperatures measured near the exhaust-manifold typically range up to 800°C and the skin temperature of metal components in this area can reach 600°C.

### Internal Functional Liquids

Internal functional liquids include engine coolants, engine oil, transmission fluid, hydraulic brake line fluid, fuels, etc.

The requirement of engine coolants is to transfer heat from the engine to the radiator where it is dissipated. Properties must include high specific heat, good thermal conductivity, low freezing point, high boiling point, chemical stability, and noncorrosivity. Since ethylene glycol provides a fairly good overall balance of these properties, it is used almost universally for automobile engine coolant in aqueous solution [10]. Typically, an ethylene glycol concentrate will also include a small amount of other glycols, chemical inhibitors, buffer or neutralizer, foam suppresser, dye, and a small quantity of water to dissolve the additives (ASTM D 3585, Specification for ASTM Reference Coolant, is a typical example of a formulated coolant). The concentrate is generally mixed with water for automotive service. The nature of the water used to dilute the ethylene glycol concentrate, and the type and length of service of the coolant will determine its corrosivity. Chloride-containing water, for example, can override the effect of inhibitors in the coolant and therefore will cause corrosion damage. Inhibitor depletion, and glycol breakdown to form acids, are also mechanisms whereby the coolant can become corrosive [11]. Metals and alloys exposed to engine coolants are copper, solder, brass, steel, cast iron, stainless steels, and aluminum.

Basic functions of engine oil are to provide lubricity, heat removal, and containment of contaminants [12]. The composition is about 75–90 % base stock (such as mineral oil) and 10–25 % additives such as viscosity index (VI) improvers, antioxidants, corrosion inhibitors, detergents, dispersants, and others such as antifoam agents. The aging of engine oil, as determined by the type of driving, can result in an aggressive liquid. Examples include oxidized oil due to exposure to heat and oxygen, loss of buffer when it is used up in neutralizing acids, and contamination by coolant, gasoline, and engine exhaust gases. Prolonged use of aged engine oil can lead to general corrosion, fretting, and erosion corrosion.

Automatic transmission fluid (ATF) performs many functions including lubrication, power transfer, hydraulic control, and cooling [13]. This fluid is extremely complex consisting of a base mineral oil (consisting of paraffinic, naphthenic, and aromatic hydrocarbons) and an additive package. Newer ATF compositions consist of synthetic base materials. The additives prevent fluid oxidation, corrosion, loss of lubricity, and foaming. Even though antioxidants, inhibitors, and stabilizers are added to the ATF, the base oil

can react with oxygen to form organic acids. The acidity is quantitatively measured as the total acid number (TAN). In addition, some additives such as organothiophosphates are reactive to some metals.

Hydraulic brake line fluids are usually polyglycols or silicones. Commercial brake fluids are hygroscopic and absorb moisture when exposed to humid atmosphere. Water contamination can also occur from atmospheric condensation. The result of this water contamination is a liquid with various degrees of corrosivity towards brake cylinders, the master cylinder, hydraulic brake line tubing, and other brake system components [14].

## CORROSION MECHANISMS

Corrosion mechanisms on automobiles are dependent on factors such as physical and chemical properties of the environment, materials, and the specific application. Table 2 is a summary of corrosion mechanisms according to specific application.

The most visible part of the automobile is the exterior body panel structure. Corrosion degradation is generally classified into structural (inside-out) and cosmetic (outside-in) corrosion. Structural corrosion in the auto-body leads to perforation, generally from the inside out (Fig. 2). This corrosion occurs at crevices and other entrapment areas where poulitice can build up and at failed coatings. Cosmetic corrosion is usually associated with painted auto-body panels (Fig. 3). Therefore, the quality and nature of the paint/metal system is very important. Paint coating failure can occur from a wide range of mechanisms including differential cells, cathodic disbondment, filiform corrosion, galvanic (bimetallic) effects, and fretting, and can occur at crevice geometries [1,2,15–27].

The chassis and undervehicle is most susceptible to mechanical damage because of its proximity to external road conditions [24] (Fig. 4). Usual corrosion mechanisms apply such as those due to the effect of stone impingement and crevice and uniform corrosion. Coatings failure can enhance deterioration as can poulitice built up in entrapment areas.

Trim and hardware are used for a number of reasons including styling, hiding welds, and protection from mechanical damage [28]. Trim materials such as stainless steel and anodized aluminum are susceptible to pitting, crevice corrosion,

TABLE 2—Corrosion mechanisms in automobile applications.

Body Panels—Structural	<b>Uniform</b> , pitting, <b>crevice</b> , fretting, <b>coating failure</b> , <b>poulitice</b>
Body Panels—Cosmetic	<b>Crevice</b> , <b>galvanic</b> , fretting, <b>coating failure</b>
Chassis	Uniform, pitting, <b>crevice</b> , fretting, stress cracking, coating failure, <b>poulitice</b>
Trim and Hardware	Uniform, <b>pitting</b> , <b>crevice</b> , <b>galvanic</b> , dealloying, intergranular, <b>coating failure</b>
Exhaust System	<b>Uniform</b> , pitting, crevice, dealloying, erosion, fretting, <b>intergranular</b> , stress cracking, <b>coating failure</b> , <b>high temperature oxidation</b>
Engine and Components	Uniform, pitting, crevice, galvanic, dealloying, <b>fretting</b> , intergranular, stress cracking, high temperature oxidation

\*Primary mechanisms are in boldface.

FIG. 2—Structural corrosion (inside-out perforation) on automobile body.

and discoloration. Stainless steel trim materials can cause galvanic corrosion of painted auto-body steel. On the other hand, some trim materials such as aluminum and zinc die cast are anodic to auto-body steel and corrode sacrificially.

The exhaust system and engine are exposed to a dual (external and exhaust gas) environment. Therefore, the materials must be chosen to perform in more complex service conditions. High temperatures are important along with the chemistry of the exhaust gas condensate. Corrosion mechanisms include those normal in the external environment with the additional temperature factor [8,9].

Electrical and electronic systems are extremely susceptible to corrosion by the aggressive automobile environment [29–31]. Pitting, crevice and galvanic corrosion, and corrosion product creep are all important mechanisms, and in many cases these mechanisms are accelerated by leakage currents, which impose a potential bias on the materials. Fretting and coatings failure are also failure mechanisms.

## CONTROLLING AUTOMOTIVE CORROSION

### Exterior Exposure

The severe corrosivity of the automobile environment due to road salts and acid deposition has made it necessary for the industry to improve corrosion protection through (1) proper design, (2) choice of corrosion-resistant materials, (3) use of coatings and sealants, and (4) proper consumer maintenance [32–36].

Proper design has been recognized as an important aspect of automobile corrosion resistance. Thus, elimination of entrapment areas where moisture and poultice can be trapped, minimization of crevice configurations, elimination of unnecessary holes in body panels, provision of drainage holes, access for complete pretreatment and primer coverage, and elimination of dissimilar metal crevices are common practices in the design of automobiles.

Advancements in materials have been one of the most important factors in the development of corrosion-resistant automobiles. For automobile body and chassis parts, use of precoated sheet steel in critical areas, as demonstrated in Fig. 5, is one of the most effective methods of combating corrosion. Early on, hot dip galvanized steel and Zincrometal coated steel were used to prevent perforation corrosion from the inside out in auto-body applications. Today a wide range of materials is used including hot dip and electrodeposited zinc, zinc-iron, zinc-nickel, and zinc-nickel/organic composite coated steel. Other materials include aluminum and aluminum-zinc coated steels for exhaust systems and some structural components,terne (tin-lead) coated steel for fuel tanks, and tin coated steel [23–25].

Materials systems are used quite widely on automobiles for corrosion protection. For example, clad metals are commonly used in applications such as exterior trim and bumpers (stainless steel clad aluminum), windshield wiper socket (copper/steel/bronze), transition materials to join aluminum to steel (aluminum clad steel), and hydraulic brake line tubing (steel/SS/steel) [37]. A wide range of metallic coatings are produced by spraying, chemical vapor deposition, physical vapor deposition, electrodeposition, and electroless deposition [23–25].

FIG. 3—Cosmetic corrosion (outside-in) with red rust at painted auto-body steel.

FIG. 4—Severe undervehicle corrosion.

**FIG. 5—Critical areas and use of galvanized steel on automobile designed for corrosion resistance (courtesy of L. L. Peipho, General Motors Corporation, Milford Proving Grounds).**

New alloys have been introduced for specific automobile applications including type 434 stainless steel for exterior trim, type 409 and 430 stainless steels for exhaust systems, and 6XXX and 7XXX aluminum alloys for auto body and structural parts. Use of aluminum for body panels such as hoods and deck lids has prompted the development of new processing techniques for this material.

A wide range of inorganic and organic coatings and sealants is used to provide supplemental corrosion protection to automobiles [23–25]. Included are conversion coatings formed by interaction of the metal surface with constituents in solution to form an inert inorganic film. Some of these are phosphate, chromate, and various anodized and oxide coatings. Organic coatings are also used extensively and function as a barrier between the metal surface and the environment. These include primers, waxes, seam sealers, barriers to mechanical damage, and petroleum-based rust preventives.

The automobile paint system involves several different coatings [24,25]. Typically, a conversion coating such as phosphate is applied to a clean metal surface to improve corrosion protection and ensure good adhesion. Then, an epoxy primer is applied by dipping, spraying, or by electrodeposition. The most important advances in epoxy primer deposition have been in electrophoretic systems variously called electrocoating, E-Coat, or ELPO [2]. In this process, the metal substrate is immersed in an aqueous bath and coated with a charged organic primer under the influence of an electric field. The advantages here include uniform coverage, edge protection, penetration into enclosed areas, and full automation. In recent years, the industry has shifted from anodic to cathodic electrocoating [38]. The next step is usually a primer surfacer or guide coat for sealing and enhanced appearance. Finally, the topcoat is applied, usually in two or more steps including a base coat and a clear coat. These are generally enamels and urethanes. The performance of these complex painted auto-body materials in the aggressive automobile environment is understandably dependent on a number of factors.

Sealers play an important role in automobile corrosion protection by preventing water and contaminants from entering crevices and joints. They are usually rubber, vinyl, asphaltic, or hot melt or wax compounds [24,25]. The choice depends on the specific application such as at door hem flanges, brackets, fasteners, and body joints. Structural adhesives are also used to bond assemblies such as doors, decklids, and hoods, thereby sealing crevices and eliminating welds.

Consumer maintenance has become an important part of automobile corrosion protection. Automobile manufacturers have provided recommendations for maintenance in order to prevent deterioration from corrosion. The first defense is regular washing to remove road salts and other corrosive agents, and poultice. The procedure should ensure that mud and dirt is removed from entrapment areas underneath the vehicle. Drain holes should be cleaned out. The second defense includes repair of paint damage to avoid propagation of corrosion in these areas. Precautions should be taken to exclude corrosive agents from the interior such as driving in or splashing seawater or road deicing salt puddles on the vehicle.

### Internal Combustion

The service life of exhaust systems has been greatly extended through the use of more corrosion-resistant materials [8]. These include stainless steels (types 409 and 430), aluminum coated steels, and aluminum-zinc coated steels [39]. The use of catalytic converters presents some special problems because of the catalyzed oxidation reactions that take place in the exhaust gas stream. The converter itself must be highly corrosion-resistant because of its location near the exhaust manifold and the reaction to form acids such as sulfuric acid. Stainless steel is therefore widely used for the catalytic converter canister. More corrosion-resistant materials are also being used downstream from the converter.

### Liquid Passages and Reservoirs

Internal functional liquids generally have inhibitors in the formulation to minimize degradation due to corrosion. These inhibitors provide the necessary protection as long as they are present in the required concentration.

However, inhibitor depletion and acidity buildup due to decomposition of base organics can occur depending on the nature of vehicle use and maintenance practice. For example, engine coolant formulations contain a complex inhibitor package providing protection to component metals such as copper, steel, aluminum, solder, etc. [40,41]. When inhibitor depletion occurs, failure of an aluminum water pump due to corrosion can result but this component is easily replaced. When a transmission component fails due to corrosion, replacement is more costly and therefore more corrosion-resistant materials are generally used. For example, copper and brass may corrode in used automatic transmission fluid while steels and stainless steels are generally resistant in that environment. A proper maintenance schedule of replacement of these fluids is very important in maintaining corrosion protection within liquid passages and reservoirs.

## Electrical and Electronic Systems

Use of electrical and electronic components on automobiles has increased dramatically so that corrosion protection is important. The primary method is to minimize exposure to the environment by locating wiring and other components within the passenger compartment, by shielding or providing good drainage, and by sealing and coating [29,30]. Proper design, manufacturing, and quality are a precursor. However, failure can occur in electrical and electronic systems if proper precautions are not taken. For example, residual fluxes can cause corrosion problems because they can contain chlorides and may be hygroscopic. Examples of critical systems are connectors, switches, terminals, large housings and electrical connections, sensors, integrated circuits, and other electronic control devices. Various organic and inorganic coatings are used to exclude air, moisture, and chemical contaminants and to increase lubricity and reduce thermal degradation. These include paint, primer, varnish, resin, silicone compounds, oil, and greases. A wide range of sealed connectors has been developed for use on automobiles because even the best selection of base materials and plating cannot provide the necessary termination protection in the severe automotive environment. The problems associated with leakage currents (bias) have been addressed by ensuring that proper barrier coatings, sealing, and design are used.

## TEST METHODS

Corrosion testing has played a major role in the development of corrosion-resistant automobiles. The tests are generally classified as laboratory tests or field tests. The difference involves the nature of the environment. Laboratory tests simulate the environment, while field tests are conducted in the natural environment. Some tests combine a simulated environment and the natural environment. Although laboratory test results are obtained in shorter times, field test results are more reliable because they are conducted in the actual environment. The design and interpretation of laboratory tests are important in order to obtain useful information [1,42].

Test parameters are categorized according to chemical and physical effects. Chemical parameters involve the composition of the environment, i.e., concentration of constituents, pH, dissolved gases, etc. The complexity of the

automobile environment has been described above. The physical conditions include temperature, static or flowing solution or vapor, liquid or atmospheric volume, and mechanical factors such as stress and impingement. Finally, the duration of the test and exposure periods must be chosen carefully so that under- or over-exposure will not lead to incorrect design. Table 3 lists methods and guidelines that are used in the automobile industry for design and interpretation of corrosion tests.

## Laboratory Tests—External Exposure

Categories of laboratory (accelerated) tests are: electrochemical, immersion, cabinet, cyclic, and proving grounds. These accelerated tests require (1) selection of environmental and physical conditions representative of service exposure, (2) accelerated corrosion rates without a change in the mechanism, (3) reproducibility of results, and (4) acceleration factors which relate to service performance.

Electrochemical tests are rapid techniques to determine mechanisms, determine the effect of various parameters on corrosion rate, and screen out a large number of materials [43]. They usually involve measurement of corrosion potentials, corrosion currents, polarization curves, and electrochemical impedance. They are used to evaluate metals and alloys and the behavior of metallic, inorganic, and organic coatings. The simplest test involves the measurement of the corrosion potential and its use in conjunction with other measurements. A zero resistance ammeter (ZRA) is commonly used to measure corrosion currents between dissimilar metals and alloys. Controlled potential tests and anodic and cathodic polarization curves using potentiostats are the most commonly used electrochemical tests. These are powerful tools for investigating the effect of various parameters on corrosion behavior. These incorporate the use of cyclic polarization and polarization resistance for localized corrosion and corrosion rate measurements. Table 4 lists electrochemical tests that can be used for corrosion tests in the automobile industry.

Immersion tests are listed in Table 5 and consist of specimens immersed in a fluid of interest. Variations of the test can be used to enhance certain types of exposure such as partial immersion to create oxygen concentration cells, and alternate (cyclic) immersion to produce wetting and drying effects. The latter test, along with the ferric chloride spot test is used to determine the behavior of exterior stainless steel trim materials.

Cabinet tests are the most commonly used laboratory tests in the automobile industry. These have been developed to simulate the effects of atmospheric corrosion [44]. Normally, a test chamber is used and the desired environment is introduced under controlled conditions. A list of these tests is given in Table 6. The simplest of these is the humidity test whereby the temperature and relative humidity within a chamber are controlled. A condensing humidity chamber, which operates at 100 % relative humidity and 38°C, provides

an environment whereby condensation occurs continuously on the specimens. The moist SO<sub>2</sub> test (Kesternich test, ASTM G 87) is a modification of the humidity test but is much more aggressive due to the presence of sulfur dioxide which converts to sulfuric acid. Another modification commonly referred to as the mixed flowing gas test (ASTM B 827) uses extremely low quantities of pollutants such as H<sub>2</sub>S, SO<sub>2</sub>, NO<sub>x</sub>, Cl<sub>2</sub>, and HCl with humidity to duplicate environments within the passenger compartment. This test is especially useful for electrical and electronic systems [45].

The most widely used cabinet test is the neutral salt spray (Fog) test (ASTM B 117), which consists of a fog of 5 % sodium chloride within the chamber at 35°C [46]. Controversy exists over the validity of B 117 as a performance test because corrosion mechanisms are not always the same as those observed in automobile service. Also, not all materials can be successfully evaluated in the test. However, the value of the salt spray test as a quality assurance test is well documented [46]. Several modifications to the salt spray test have been developed including acetic acid salt spray (ASTM G 85, Annex 1), copper accelerated acetic acid salt spray (ASTM B 368), acidified synthetic seawater fog (ASTM G 43, Method of Acidified Synthetic Seawater (Fog) Testing), and modified salt spray (ASTM G 85). ASTM G 85 also includes cyclic tests.

Cyclic corrosion tests have been developed to more accurately duplicate corrosion behavior observed in service [47–50]. They simulate the automobile environment by introducing a combination of conditions that exist in service. Testing consists of exposing specimens to at least two different environmental conditions and cycling from one environment to the other. There are a number of cyclic tests that have been developed specifically for determining the behavior of painted auto-body materials. In some cases, these tests are conducted in cabinets or in and out of cabinets. In other cases, the tests are not conducted within a cabinet. The various environmental conditions that have been used include salt spray, salt mist, aqueous immersion, temperature variation, humidity variations, ultraviolet (UV) light exposure, poultice, gravel or shot blasting, and drying. Cyclic tests are listed in Table 7.

A typical test developed by one of the automobile manufacturers and used widely, GM9540P, includes two accelerated

laboratory methods to evaluate assemblies and components. The test procedures provide a combination of cyclic conditions (salt solution ( $\text{NaCl}$ ,  $\text{CaCl}_2$  and  $\text{NaHCO}_3$ ), various temperatures, humidity and ambient environment) to accelerate metallic corrosion. The procedures are effective in evaluating a variety of mechanisms including galvanic, crevice, etc. [49].

One of the improved laboratory cyclic test procedures for cosmetic corrosion was developed during the 1990s by a joint Task Group of AISI and SAE. The extensive work of this Task Group resulted in the standard test SAE J 2334. The procedure is based on field correlated laboratory tests. The test has been shown to give an excellent correlation with five-year on vehicle tests in the aggressive environments such as Montreal, and also shows promise for perforation corrosion [51]. The test cycle consists of three stages; (1) humid stage-50°C, and 100 % RH, 6 hours duration; (2) salt application stage ( $\text{NaCl}$ ,  $\text{CaCl}_2$ , and  $\text{NaHCO}_3$  by immersion or misting)-15 minutes duration at ambient conditions; (3) dry stage-60°C and 50 % RH, 17 hours and 45 minutes in duration. Typically, J 2334 is conducted for 60–80 cycles when evaluating coated products.

Proving grounds tests (Table 8) include the operation of an automobile in a controlled environment to evaluate the performance of a fully assembled vehicle [52]. The test schedule varies from one facility to another but generally includes a driving schedule over various roads including highway travel, salt highway, gravel road, mud trough, and salt trough (Fig. 6). Also included are exposure to rain, snow, drying, elevated temperature, and controlled humidity. The period of time required to complete one set of exposure is termed a cycle, and usually a number of cycles is related to years of automotive service. One method to provide correlation to service performance is by use of coupons with known service behavior mounted on the test vehicle.

These are evaluated periodically to determine acceleration factors during the proving grounds test. Because these tests simulate service exposure but still represent accelerated conditions, considerable expertise is required for evaluation and interpretation of results. Some novel developments in proving ground testing include the use of specimens (including panels, parts, and components) mounted on trailers, which are pulled throughout the test schedule. A large amount of information can be obtained through this test procedure.

### Field Tests—External Exposure

When products or materials are exposed to the natural environment, they are considered field or service tests. Included in this category are atmospheric exposure, mobil test racks, fleet tests, and field surveys (Table 8).

Atmospheric exposure consists of placing specimens such as coupons, parts, components, on racks at stationary test sites [53]. The example in Fig. 7 shows bumpers under test at the marine splash and spray facility of the LaQue Center for Corrosion Technology at Wrightsville Beach, North Carolina. The nature of the site varies depending on geographic area and specific location within an area. Factors such as environmental chemistry (chlorides, pollutants,

FIG. 6—Proving ground test vehicle driven on salted highway strip.

FIG. 7—Marine splash and spray exposure test on vehicle bumpers.

etc.), time of wetness, temperature, humidity, hours of sunlight, and seasonal changes have an important effect on the corrosion rate and mechanism and, therefore, many atmospheric test sites for automobile materials are chosen based on these conditions. A warm, humid, marine site will be more aggressive than a rural site. The combination of marine chemistry with acid deposition is most aggressive. Frequently, test sites are located close to roads where deicing salts are used to obtain the desired automotive environment. Alternatively, the Volvo test consists of outdoor atmospheric exposure with periodic spraying with 5 % sodium chloride (Table 7). The more useful information from atmospheric corrosion tests is obtained when climatic and chemical information is available for the site.

Mobil test racks or plates are mounted on vehicles or trailers, which are subjected to normal driving conditions. They are mounted on various locations on vehicles such as the undervehicle as described in SAE J1293. However, these racks or plates are also mounted on bumpers, grilles, and truck trailers (Fig. 8). Panels, coupons, parts, and components are attached to these racks and are therefore exposed to driving conditions in the natural environment. Direct

FIG. 8—Corrosion test plate mounted on the front bumper of an automobile.

comparisons can therefore be made on the corrosion behavior of these materials.

Fleet tests are extremely valuable in providing direct information on corrosion behavior in specific locations. Groups of cars that are typically used for these tests are taxicabs, rental cars, municipally owned cars, and sales fleet cars. Because the operating parameters can be recorded through fleet record keeping, this type of test is probably the most reliable of all for automobile corrosion performance.

Field surveys are valuable because of the large number of vehicles that can be visually inspected over a short period of time [54]. In general, a location and time of year is chosen and a team of evaluators survey parking lots, streets, dealerships, etc., with survey sheets. Therefore, corrosion performance is based on inspection and evaluation of actual standard production vehicles exposed to natural environments and normal operating conditions. One drawback to field surveys is that actual driving conditions for each vehicle cannot be determined unless each owner is interrogated. However, the vehicle identification number (VIN) and odometer reading does provide important information.

Testing—Internal Combustion

The complex exhaust system environment including internal condensate corrosion, high-temperature oxidation, and exhaust-gas impingement makes it very difficult to obtain meaningful accelerated corrosion test results. Laboratory tests are generally based on exposure to synthetic exhaust gas condensate. A common test is the Walker Standard Accelerated Corrosion Test, which uses alternate immersion in hot synthetic muffler condensate [55]. Variations of this test are used depending on the particular components being considered [1,8,16]. The hottest area in the exhaust system exists from the catalytic converter back to the engine. Beyond the catalytic converter the temperature drops off but that area becomes susceptible to exhaust-gas condensation. Various test temperatures, immersion times, and condensate chemistries are used depending on the specific component and manufacturers' requirements (Table 9).

Controlled engine laboratory tests are valuable for evaluating internal exhaust system deterioration. These tests are conducted with actual engines to produce the exhaust gas, which is directed through the appropriate materials to be tested. This can be a coupon exposed to the exhaust stream or an actual exhaust system depending on the test design. The dew point temperature can be controlled such that condensation occurs within a temperature range. This control provides an acceleration factor for the test.

Fleet tests and surveys provide the most accurate information on exhaust system durability [39]. However, since this type of testing is not accelerated, long time periods are required to obtain meaningful results.

### Testing—Liquid Passages and Reservoirs

Laboratory tests to determine the behavior of materials and corrosivity of automotive fluids such as engine coolants, engine oils, automatic transmission fluids, and fuels involve exposure to the actual fluid as close to operating conditions as possible. In most cases, aging of the fluids due to their functional use produces a more corrosive liquid; therefore it is important that the test be conducted on used liquids or that aging of the fluid occur in-situ. Simple immersion tests can be used if chemical and physical environmental effects are introduced. This is not always possible and therefore simulated service tests have been developed. These laboratory bench tests simulate more

closely actual service conditions by using a model of a particular automobile function. Field service tests are the most reliable but also most time consuming and costly.

Corrosion testing of engine coolants is the most advanced in this group. These are divided into three categories including (1) laboratory tests, (2) engine tests, and (3) field service tests [10]. Tests under these categories are listed in Table 10. Laboratory tests have been the primary means for evaluating the corrosive effects of engine coolants and the effectiveness of the coolant inhibitor formulation. The most important of these is the Laboratory Glassware Test (ASTM D 1384). However, a wide range of other tests is used including electrochemical techniques. A simulated service test for engine coolants (ASTM D 2570) is also used quite widely and includes the use of a pump, radiator, thermostat housing, and a large pot to house test coupons. An extension of this test includes an actual operating engine, which is referred to as a no-load engine test (ASTM D 2758). Field service tests evaluate materials and inhibitor systems under actual vehicle operating conditions and are the most reliable. The test is described in ASTM D 2847.

The behavior of automatic transmission fluid (ATF) and its effect on materials has been a recent subject of investigation. Several tests are used to determine the behavior and include "bench" tests, laboratory motor-driven transmission tests, and field service tests [13,56]. These are listed in Table 11.

Laboratory tests for ATF include the copper corrosion test (ASTM D 130), rust test (ASTM D 665), the humidity cabinet test (ASTM D 1748), and a variety of glassware oxidation tests. Various bench tests are used by manufacturers to determine automatic transmission fluid oxidation stability. Important results obtained in these tests are the behavior of materials and corrosivity of the used fluids. Bench tests include the Chrysler CBOT (Chrysler Bench Oxidation Test), Ford's Mecromatic Test and its Thermal Stability Test, and General Motor's Turbo-Hydro-matic Cycling Test (THCT). The CBOT and Ford Thermal Stability test are glassware tests while the THOT, THCT, and Mercomatic involve transmissions mounted on test beds. These tests are designed

to deliberately oxidize the ATF under controlled conditions and the effects on materials and extent of oxidation are measured. In the latter tests, transmissions are run under cycling conditions to simulate those in actual driving. The behavior of copper wire, strip, or components is frequently used as a standard for corrosion resistance in the tests. Visual examination of copper content in the ATF are methods used for evaluation.

The most reliable information on ATF testing is obtained from lengthy and costly vehicle fleet tests. Taxicab service is generally chosen because shifting occurs more often with this type of service. In general, taxicabs are operated in large cities [approximately 6000 miles (966 km) per month] and ATF samples are taken every 10 000 miles (16 093 km). These are evaluated for physical and chemical characteristics (such as for copper). At the end of the test, the transmission is disassembled and evaluated for deterioration due to corrosion.

A laboratory immersion test for corrosion in hydraulic brake line fluid is described in Motor Vehicle Brake Fluid SAE J1703. This test includes the use of standard metal coupons for mass change and visual examination after immersion at 100°C in the brake fluid. Other tests are used to evaluate specific components in the braking system such as that described in SAE J1047 for hydraulic brake line tubing. Internal corrosion is not considered as important as external corrosion of the braking system and therefore only simple tests are used outside of on vehicle service tests.

Corrosion tests for hydraulic brake line fluid, as well as for motor oil, grease, and lubricants, are listed in Table 12. In addition, the effects of various fuels on materials have been of importance due to the effect of small amounts of water, which can become trapped in areas such as the fuel tank [57]. Various additives to fuels can prevent corrosion effects and include inhibitor packages and small amounts of alcohol and aromatics. Recently, corrosion testing of ethanol fuels has been of interest because small amounts of water as well as other contaminants (chlorides) cause severe corrosion to occur [58]. Tests for fuels include electrochemical polarization and immersion tests (Table 12).

### Testing—Electrical and Electronic Systems

Corrosion testing of electrical and electronic systems has generally followed the guidelines used for testing in external environments. A large degree of evaluation is performed in cabinet tests although the most accurate of these is the mixed flowing gas test. These are listed in Table 6. In addition, electrochemical tests (Table 4), immersion tests (Table 5), and various cyclic tests (Table 7) are used for laboratory purposes. Specific tests for these systems are listed in Table 13. Proving grounds and field tests are the most reliable but these are lengthy and costly procedures.

## TEST STANDARDS

Automobiles consist of a wide range of materials fabricated into various components and exposed to complex environments including external driving conditions and functional internal fluids and exhaust gas. Therefore, a wide range of corrosion tests is required in order to determine the corrosion behavior of materials in service. Corrosion standards are developed to ensure that results are reproducible and consistent. Several reviews have been published on this subject [59,60].

The wide range of standards used in the automobile industry is demonstrated in Table 14 by the long list for corrosion testing of body, chassis, trim, and hardware materials. These ASTM and SAE standards are prepared by volunteers representing various sectors of the industry including users, suppliers, and general interest participants. Tables 9 through 13 list standards used for other automotive systems including the exhaust system, cooling system, transmission system, brake system, electrical, and electronic systems.

Automotive companies develop their own standards if proprietary technology is involved or when suitable standards (ASTM, SAE, NACE, etc.) do not exist. These company standards become more valuable when they become the basis of a standards writing organization standard. Therefore, cooperative efforts to prepare automotive materials related standards at organizations such as ASTM, NACE, and SAE are extremely strong and active.

# Commercial Aircraft

A. A. Adjorlolo<sup>1</sup> and J. A. Marceau<sup>2</sup>

CORROSION OF AIRCRAFT STRUCTURE has plagued the airline industry since the use of metals in aircraft manufacture. It is costly both in unscheduled downtime and man-hours required for repair. The International Air Transport Association (IATA) reported in 1983 that corrosion cost the airlines between \$8 and \$20 per flight hour [1]. These numbers do not reflect the unscheduled downtime, both at the main bases and route stations, nor the additional corrosion inspections of aging airplanes recently mandated by the regulatory agencies. In fact, unlike fatigue damage, corrosion is extremely difficult to predict, i.e., when and where it will start, how fast it will progress, or how much damage it will cause. Because of this unpredictability, corrosion inspections are an integral part of an airline's maintenance program, and make up a significant part of its cost.

Corrosion problems on commercial aircraft are the result of combinations of factors whose causes can be found in the basic design, manufacturing, and operations of the aircraft. Some of these factors are summarized in Table 1 (manufacturer), and Table 2 (operator and service environment). These present unique problems to the manufacturer who must make the best design, materials, and process choices that are compatible with structural requirements and the economics of building and operating an airplane. In order to achieve these ends, corrosion testing must help establish requirements for structural materials and compatible finish systems, as well as a host of manufacturing aids, interior materials, and operational maintenance fluids that will

**TABLE 1**—Contributing causes of corrosion—manufacturer related.

Causes	Factors
Basic Design	<ul style="list-style-type: none"> <li>• Drainage</li> <li>• Crevices</li> <li>• Dissimilar metals</li> <li>• Finish system</li> <li>• Materials selection</li> <li>• Process selection</li> <li>• Access to structure</li> <li>• Pockets, cavities</li> </ul>

Accidental Contamination	<ul style="list-style-type: none"> <li>• Lavatory spills</li> <li>• Galley spills</li> <li>• Cargo spills</li> <li>• Chemical spills</li> <li>• Mercury</li> <li>• Fire smoke and extinguisher residues</li> </ul>
Operational Environment	<ul style="list-style-type: none"> <li>• Seacoast</li> <li>• Tropical environment</li> <li>• Humidity</li> <li>• Industrial environment</li> <li>• Ground-air ground cycle</li> </ul>
Maintenance Problem Areas	<ul style="list-style-type: none"> <li>• Neglect</li> <li>• Improper repairs</li> <li>• Inadequate corrosion control program or lack of implementation</li> <li>• Inadequate training</li> <li>• Ignorance of corrosion</li> <li>• Plugged drain systems</li> </ul>

ensure the structural integrity of the aircraft during its useful life. In addition, anticipation and consideration of factors whose presence may at times be accidental in the operation of the airplane is necessary to the selection of the appropriate standardized corrosion tests. Sometimes test modifications, which account for these factors, are necessary. With over 44 years of service history on commercial jet aircraft, corrosion problems are being addressed systematically. Many improvements that are being incorporated into today's new aircraft would not have been possible without laboratory and outdoor corrosion tests.

## SERVICE ENVIRONMENTS

Environmental conditions inside and outside an airplane vary considerably from one operator to another. Factors

that determine environments include airplane interior configuration, an airline's geographic location, route structure, and world climatic conditions. The commercial jet airplane is designed to be a self-contained pressurized vessel, in order to create a comfortable living environment for flight durations of less than 1/2 h to longer than 12 h. Inside the fuselage, the air is conditioned for the comfort of passengers. Galleys (food stations) are provided for food and drink, and lavatories are provided for the needs of passengers.

Creating this comfortable environment also creates localized environments that are quite unique and very aggressive to structural components if these are not properly protected. For instance, fluids from food and drink spillage in galleys can migrate under floor panels. Trapped between the floor panels and the underlying structure, these fluids fester and cause corrosion of the structural component parts. The same is true for lavatory fluids, which can leak and become trapped between the flooring and floor structure. Further, excess fluids from galleys and lavatories will flow into the bilge, potentially creating further problems. In addition, entryways, e.g., passenger, service, and cargo, are exposed to the weather and occasional spills, which also add to the corrosive environment of the floor structure and bilge.

The rest of the fuselage interior is constantly exposed to condensing humidity caused by colder temperatures that result from the ground-air-ground flight cycle. This condensate is fairly benign compared to the fluids encountered under galleys and lavatories. However, this only means that corrosion will take longer to manifest itself.

The exterior surfaces of airplanes are always exposed to the elements, and are, hence, affected by world and local climatic conditions, e.g., rain, humidity, airborne industrial pollutants, hot and/or cold temperatures, dust, runway dirt, and spray from the oceans and seas. Corrosive contaminants trapped in exterior cavities and cove areas, e.g., wheel wells, wing front and rear spar cove areas, and fairing areas, are not washed off by rain in contrast to aerodynamic surfaces, thereby compounding potential corrosion problems.

## TECHNIQUES USED FOR CONTROLLING CORROSION

The primary defense for corrosion control of the airplane structure is the finish system. As a result, corrosion testing of metals and compatible finish systems is a significant factor in their selection. The tests for evaluating these materials and finishes depend on the function and the anticipated environmental exposure of the component parts. These same finishes are also used during repairs. It must be demonstrated that they can be applied locally over surface preparations accomplished in the field under less than optimum conditions. Techniques available to the airlines for controlling corrosion involve (1) maintaining drain holes open for proper drainage of condensed moisture, (2) restoring of the finish, and (3) applying corrosion inhibiting compound to protect further the paint in problem areas, and dislodge trapped moisture from joints and crevices.

Many of the corrosion tests described in the section titled **Use of Test Methods to Evaluate Corrosion** are routinely used in the aircraft industry to evaluate materials and finish systems. The tests specifically determine their performance during long-term service, usually relative to a current material finish or process. However, because laboratory tests represent relatively short-term exposures compared to the life of an airplane and cannot always simulate in-service airplane conditions, the rationale used to establish test duration and conditions must be relevant.

## In-Service Monitoring

Despite the obvious economic advantage of allowing airlines the ability to disassemble a structure for repairs only when corrosion is known to exist in certain areas, in situ monitoring of corrosion is not practiced in the industry. The resulting monitoring system's complexity, added weight, and future certification issues are certainly negative factors. The authors are aware of only one instance of experimentation with sensors in U.S. commercial aviation to detect the presence of moisture in certain areas prone to corrosion, such as floor support structure. A system using an optical fiber-based sensor and data acquisition system is being field-tested. This system has been described in a recent Aging Airplane conference [3].

Currently, in-service monitoring of corrosion on commercial airplanes is accomplished by inspection during routine maintenance checks. Although most airlines have corrosion control programs implemented in their maintenance programs, the regulatory agencies have recently required mandatory corrosion inspections based on calendar time rather than airplanes cumulative flight hours, as well as defining the specific areas to be inspected and at what frequency. For instance, a known problem area, such as the fuselage bilge, is inspected much more frequently than the crown (ceiling) area. These directed inspections, such as FAA-mandated Corrosion Prevention and Control Program (CPCP), assign levels of 1, 2, and 3 to corrosion findings. These levels relate to the amount of material blend-out required to remove the corrosion occurring between repeat inspections (level 1 or 2), and whether airworthiness concerns exist (level 3) with particular corrosion findings.

## Inspection

Inspection for corrosion is primarily by visual method, requiring very good access to the structure and the ability to recognize various forms of corrosion, their early signs in different metallic structures, or conditions leading to corrosion, such as finish damage and blocked drains. Other difficult to access areas may require borescope inspection. In some cases of hidden structure, such as lap joints, non-destructive inspection (NDI) techniques such as eddy current, or X-ray (radiography) may be used. Ultrasonic inspection has the advantage of detecting small cracks that may appear in corroded locations. Because some of these techniques may require significant amounts of material loss for detection, may be complex, and require high technician skills, visual observation of a partially opened lap joint is necessary to determine the full extent of the corrosion.

## SPECIFIC PROBLEM AREAS

Most corrosion problems on commercial aircraft are associated with aluminum alloys. This is consistent with the large use of corrosion-susceptible, high-strength or high-toughness alloys (approximately 78 %) in making the structure. Furthermore, all of the high-strength alloys used are susceptible to corrosion and must be protected appropriately. Corrosion protection of these alloys relies entirely on the protection systems used, i.e., anodizing, conversion coatings, primers, sealants etc. Most failures in the protection system occur at joints, faying surfaces, or crevices where water and aggressive electrolytes can become trapped for long periods of time. Crevices can be created by many conditions, e.g., joints, poorly adhering paint, insulation blankets against structure in wet areas, etc. When they exist in the highly corrosive areas described in the previous section, **Service Environments**, corrosion problems are greatly compounded. Other potentially corrosive conditions would include dissimilar metal couples, e.g., an aluminum-nickel-bronze bushing in an aluminum alloy housing, or an aluminum hinge fitting attached to a carbon fiber reinforced plastic control surface (e.g., elevator, aileron, etc.). Some of these conditions are unavoidable; therefore, it is extremely important that the proper finish protection schemes be incorporated.

## USE OF TEST METHODS TO EVALUATE CORROSION

The foregoing discussions on airplane corrosion problems, service environments, techniques for corrosion control, and problem areas underscore the need for comprehensive corrosion testing, including both sound rationale and methods. Table 3 summarizes the corrosion tests used in the commercial airplane industry. Shown are the names of the tests, how they are used, the type of information sought, and the type of comparative control used. These tests primarily address alloys, coatings, manufacturing aids or process evaluation, and also service conditions. The tests, particularly those from ASTM, lend themselves to multiple applications (for instance, there are many uses of the salt spray test—ASTM B 117, Test Method of Salt Spray (Fog) Testing). Alternately, there are multiple tests available to evaluate a particular corrosion issue (for instance, pitting can be evaluated using many different tests). The following is a more detailed discussion on why some of these tests are used in the selection of materials and processes.

### Materials Selection

The desirability of light structures for increasing payloads in commercial aircraft design dictates the use of materials with high strength-to-weight ratios. High-strength aluminum alloys, 7XXX series and 2XXX series, and their tempers, are evaluated for their integrity in environments likely to cause exfoliation and stress corrosion cracking (SCC). Steels must demonstrate that they are no more susceptible to hydrogen embrittlement and SCC than conventional high-strength, low-alloy (HSLA) steels. These represent

most commonly used alloys, and also the ones most susceptible to hydrogen embrittlement.

### Aluminum Alloy/Heat-Treat Evaluation

Exfoliation corrosion is the leaf-like degradation of high-strength aluminum alloys, due to corrosion product forming along the elongated grain paths of sheets, forgings, or extrusions. Susceptibility to exfoliation corrosion is predicted by testing in accordance with ASTM G 34, Test Method for Exfoliation Corrosion Susceptibility in 2XXX and 7XXX Series Aluminum Alloys [Exco Test], and ASTM G 85, Practice for Modified Salt Spray [Fog] Testing, Annex A2. However, exfoliation corrosion experienced in service by 7150-T6511 extruded alloys demonstrated, despite extensive prior testing, an important limitation of these accelerated tests. Exfoliation corrosion of this material, it was found, can initiate after a long incubation period detectable only after long natural outdoors exposure. This and all the other environmental factors responsible for exfoliation are difficult to assemble into one laboratory test, and ideally one would like to test in an outdoors environment for at least several years.

Several test methods are currently used for the testing of SCC in aluminum alloys: ASTM G 47, Test Method for Determining Susceptibility to Stress-Corrosion Cracking of High-Strength Aluminum Alloy Products, in conjunction with ASTM G 44, Practice for Evaluating Stress-Corrosion Cracking Resistance of Metals in 3.5 % Sodium Chloride Solution. The double cantilever beam test [2], and the breaking load test using ASTM G 139, Standard Test Method for Determining Stress-Corrosion Cracking Resistance of Heat-Treatable Aluminum Alloy Products Using Breaking Load Method, have also been used to that effect. The contrasting performance of stress corrosion resistant 7075-T73 aluminum alloy, the current standard, against that of 7079-T6, replaced by more SCC-resistant alloys in the late 1960s, is a reflection of the implementation of these two test methods.

### Testing of High-Strength Steels

Since most high-strength steels have requirements for chromium, low-embrittlement cadmium, or cadmium-titanium plating, their selection is dictated by their ability to be processed in a way that avoids the hydrogen-embrittling effects of these processes. Requirements for avoiding hydrogen embrittlement in AISI 4340 steel establish a baseline that must be met by any new alloy. A notch tensile test is generally performed using AISI 4340 as control material and evaluated according to ASTM F 519, Method for Mechanical Hydrogen Embrittlement Testing of Plating Processes and Aircraft Maintenance Chemicals.

### Paint Evaluation

Paints are used on a wide variety of materials and parts as a means of protecting the underlying metal and are generally the first line of defense. The paint itself must adhere to the substrate under dry, humid, or wet conditions, a requirement that underscores the critical nature of a base

TABLE 3—Corrosion tests conducted in the commercial airplanes industry.

General Test Name	Where Used (Alternate Test Name)	Information Sought	Control
EXCO (ASTM G 34)	Alloy evaluation	Resistance to exfoliation corrosion after 48 h immersion in test solution	Conventional alloy and/or thermomechanical treatment
Modified ASTM Acetic Acid Salt Intermittent Spray-MASTMAASIS (ASTM G 85)	Alloy evaluation	Resistance to exfoliation corrosion after 28 days exposure	Conventional alloy and/or thermomechanical treatment
3.5% NaCl Alternate Immersion (ASTM G 44)	Alloy evaluation	SCC resistance per ASTM G 47	Conventional alloy
Double Cantilever Beam	Alloy evaluation	Resistance to pitting of unstressed specimens	
Electrochemical Tests	Alloy evaluation	SCC growth rate, threshold $K_{ISCC}$	Conventional alloy
		Passivation characteristics (ASTM G 5)	Conventional alloy
		Corrosion rates	
		Pitting/protection potentials (ASTM G 61)	
		Corrosion potential (ASTM G 69)	
		Polarization resistance	
		Galvanic corrosion	
Notched Tension Test (ASTM F 519)	Paint/Coating evaluation	Impedance spectrum (ASTM G 106)	Conventional paint/coating
	Alloy evaluation	Resistance to hydrogen embrittlement	Conventional alloy
	Maintenance fluid evaluation	Potential to cause hydrogen embrittlement on AISI 4340 steel per ASTM F 519 Section 7.2	Conventional fluid
	Plating process evaluation	Resistance to hydrogen embrittlement of plated AISI 4340 per ASTM F 519 Section 7.3	Specification requirement per ASTM F 519, Sec. 7.3
Intergranular Attack/End Grain Pitting (IGA/EGP)	Manufacturing aid evaluation (deoxidizer/cleaner)	Potential to cause end grain pitting or intergranular attack in excess of recommended limits	Aluminum alloys 7178-T6514, 7075-T6511
Filiform Corrosion Test (ASTM D 2803)	Metal surface preparation processes and paint evaluation	Resistance to filiform corrosion $\frac{1}{8}$ in. (3.2 mm) beyond line scribed on a painted panel specimen preexposed to HCl vapor and held at 104 F at 80 % RH for 1000 h	Conventional organic coatings
Salt (Fog) Spray (ASTM B 117)	Alloy evaluation	General corrosion, pitting resistance after 30 days, 90 days, or 1 year exposure	Conventional alloy
or Modified Salt Spray (Fog) Test (ASTM G 85)	Chemical conversion coating/process evaluation	Resistance to pitting after 168 h exposure period (ASTM B 117 only per specification)	Conventional chemical coating/qualified process
or Outdoor Environmental Exposures	Anodizing/process evaluation	Resistance to pitting after 336 h exposure period (ASTM B 117 only per specification)	Conventional chemical coating/qualified process
	Paint/alloy evaluation (scribed line test)	Resistance of scribed line to corrosion after predetermined exposure period; loss of adhesion; blistering	Paint over conventional alloys or conventional paint over alloy
	Paint/alloy evaluation (fastener insulation test)	Resistance to corrosion around fastener heads; rating per ASTM D 1654	Paint over conventional alloys or conventional paint over alloy
	Paint/alloy evaluation (Al/CRES or CFRP coupling)	Resistance to corrosion aided by galvanic coupling; rating per ASTM D 1654	Paint over conventional alloys or conventional paint over alloy
	All adhesive bonding process evaluation (metal/metal) (Lap Shear Corrosion Test)	Reduction in lap shear strength after exposure for predetermined period	Qualified adhesive/primer over recommended surface preparation
	All adhesive bonding process evaluation (metal/metal) (Wedge Corrosion Test)	Crack growth rate after exposure to salt spray for 30, 60, and 90 days, or longer	Same as above
	All adhesive bonding process evaluation (metal/metal) (Double Cantilever Test)	Crack growth after exposure to neutral salt spray for 1 year or longer; Resistance to galvanic corr	Same as above
Titanium Compatibility Test	Manufacturing aids evaluation (lubricants/coolant)	Potential of fluid considered to cause pitting, cracking, or rough etching on titanium	Currently qualified material

TABLE 3—Corrosion tests conducted in the commercial airplanes industry. (continued)

General Test Name	Where Used (Alternate Test Name)	Information Sought	Control
Evaporation Corrosion Test	Manufacturing aids evaluation (lubricants/coolant)	Potential for pitting caused by fluid left to evaporate on machined alloy after 7 days	Currently qualified fluid
	Interior materials (silicone rubber-coated fabric, floor covering, carpet and underlay, thermal/acoustical insulation, flame-resistant polymer-coated fabric, Nomex felt, etc.)	Assessment of the corrosivity of water leachable species from tested materials left to evaporate on 2024-T3 aluminum after 7 days	Deionized or distilled water
	R & D (evaluation of corrosion inhibitors; maintenance fluids, and various extracts)	General corrosivity and pitting caused by water soluble extract from material of interest left to evaporate on 2024-T3 aluminum after 7 days.	Deionized, 3.5% NaCl, or distilled water
	Manufacturing aids evaluation (lubricants and coolants)	Resistance to general corrosion or staining caused by fluid entrapment on 7075-T6, 2024-T3 bare or clad Al alloys	Deionized, distilled water, or conventional fluid
	Maintenance fluids evaluation	Resistance to general corrosion or staining caused by fluid entrapment on 7075-T6, 2024-T3 bare or clad Al alloys	Deionized, distilled water, or conventional fluid
Immersion Test (ASTM F 483)	Manufacturing aids (lubricants and coolants) evaluation	Resistance to weight loss of AISI 4130 and 2024-T3, 7075-T6 Al alloys in fluid of interest	None—Allowable weight loss table
	Maintenance fluids evaluation	Resistance of selected aerospace aluminum, steel, titanium, and magnesium alloys, cadmium plate, to weight loss in fluid of interest; Resistance to galvanic corr.	None—Allowable weight loss table
Galvanic Entrapment	Manufacturing aids (cuttings fluids and greases) evaluation	Resistance to crevice corrosion caused by test fluid entrapment between drilled and fastened Al/Cad plated steel/Ti stackup	Deionized water, conventional fluid
Stress Corrosion Test	Manufacturing aids evaluation (lubricants and coolants)	Resistance to corrosion crack growth, pitting on precracked, 50 ksi (in.) <sup>a</sup> prestressed specimens immersed for 24 h in test fluid, and in ambient environment for 76 h minimum	Conventional fluid
Drip Test	Titanium/coating evaluation	Resistance to hydraulic fluid of coating and substrate at various temperatures (usually 450°F)	Bare 6Al-4V titanium specimen

surface preparation. The ability of the paint to protect against corrosion is evaluated using ASTM G 85 and ASTM B 117 for a test duration of 1000–3000 h on scribed surfaces, with fasteners installed, or on specimens galvanically coupled to a more noble metal. These tests are all designed to simulate accidental scratch marks, corrosion prone areas, or conditions that accelerate corrosion.

### Surface Finishes Evaluation

ASTM B 117 is the standard test used for evaluating the corrosion resistance of unpainted aluminum alloy surfaces when treated by anodizing, conversion coating, and for plating processes. Aluminum surfaces, which are anodized and then sealed for corrosion protection, must resist the salt spray environment for at least 336 h without pitting. Conversion

coated surfaces must resist at least 168 h. Cadmium plate on ferrous or copper alloys must also resist this environment for 96 h without showing base metal or cadmium corrosion. Although it is generally agreed in industry that the salt spray test is used too broadly, individual pass/fail criteria developed for each process have helped monitor process problems. Alternate testing methods (e.g., electrochemical tests) are under development, and have found limited use to aid in the evaluation of alloys and finishes.

### GENERAL REMARKS

The multiplicity of external environments, the unpredictability of various spillage inside an airplane, the influence of environmental and loading cycles on material and finishes,

and the long design life of an airplane account for the main difficulties encountered in performing the right laboratory corrosion test in commercial airplanes manufacturing. As a large amount of data from the commercial airplane fleet has become available, service history has emerged as the most important criterion in validating design choices, modifying the corrosion tests themselves, and developing better test acceptance criteria.

The history of airplane corrosion testing includes many successful tests that are now performed routinely, e.g., ASTM G 85 Annex A2 and ASTM G 44. Some other successful tests, such as the wedge test (ASTM D 3762, Test Method for Adhesive-Bonded Surface Durability of Aluminum), discovered as a result of bond line corrosion problems on airplanes, are not described here because they are not strictly corrosion tests. Many of the tests described here are ASTM standards. With others, standardization is being pursued, e.g., electrochemical impedance, or ANCIT (Aluminum-Nitrate Chloride Immersion Test), to replace EXCO [4]. Corrosion may never be totally eliminated from an airplane; however, further refinements in corrosion testing, made

possible by a better understanding of the fundamental interaction between environmental factors and dynamic loads, will take the airplane industry close to that goal.

# Military Aircraft and Associated Equipment\*

*Earl C. Groshart<sup>1</sup>*

THIS CHAPTER DISCUSSES the reasons for running various corrosion tests on military equipment including airplanes and missiles, and the equipment needed to support them.

Military airplanes, missiles, space equipment, and the supporting equipment must be designed to operate for long periods of time in the most extremes of environment, from the Arctic Circle to the equator, from water to space. This defines ground temperatures from very cold [ $-60^{\circ}\text{F}$  ( $-51^{\circ}\text{C}$ )] to very hot [ $140^{\circ}\text{F}$  ( $60^{\circ}\text{C}$ )] and humidities from very low to saturated. The ambient air can have high levels of salt, industrial pollution, sand, and dust.

The life cycle management of military hardware requires that the various conditions of exposure of the hardware be determined. The many environments to which the hardware may be exposed must be determined, and a test program then must be designed to determine the acceptability of the hardware to those environments. The environments in question may range from transportation, storage, mission theater, and include spending time on aircraft carriers, air bases, or in hangers.

## SHIPPING/TRANSPORTATION OF EQUIPMENT

During this phase of the life of the aircraft, missiles, and equipment, it may be assumed that these items will be transported by truck, rail, airplane, or ship. These methods of transport will expose the hardware to high and low temperatures, high and low humidity, rain/hail, sand/dust, salt fog, temporary immersion, and reduced pressure. Corrosion tests to simulate shipping/transportation can be designed but usually are deferred to the more severe operational environmental tests.

## STORAGE/LOGISTIC SUPPLY

During this phase it can be assumed that equipment, parts, aircraft, and missiles are stored in either of two extremes: in environmentally controlled warehouses or sitting in the open on a dock or runway. Military space, office, computer, etc., equipment usually will be stored under conditions of

controlled humidity and temperature, but most other military equipment will likely see conditions of high and even condensing humidity, low and high temperature, conditions allowing fungus growth, and even those allowing chemical attack, (i.e., ground equipment moved to a warfare front). Because of mechanical damage, equipment in shipping crates and with packaging cannot be assumed to remain packaged during logistic supply and transport life phase. It therefore requires testing to withstand these environments. Testing is described later.

## THE MISSION

During its mission, military hardware is likely to be exposed to many extreme environments: high and low weather temperatures [ $-60^{\circ}\text{F}$  to  $140^{\circ}\text{F}$  ( $-51.1$  to  $60^{\circ}\text{C}$ )], fully wet conditions of rain and condensing humidity, including morning dew, blowing and settling sand and dust; salt fog, and chemical and biological attack.

## ENVIRONMENTAL TESTING

Testing to withstand the environments listed previously for the various life phases of military hardware involves not only testing of construction materials to help the designer find the best material for the job, but testing the unit after construction to see how well it can function after being placed into the various test environments. Only the equipment tests are crucial here since materials testing is covered fully in other areas.

### Humidity Testing

It is not enough to place an assembled hardware item into a chamber of high humidity. This will cause condensation of water onto the outside with some penetration into the inside through openings. The test is to cause moisture to penetrate into the hardware by raising and lowering the temperature while holding to relative humidity at 95 %. A common cycle is to start at room temperature (RT), the relative humidity (RH) at 95 %, raise the temperature to  $160^{\circ}\text{F}$  ( $71.1^{\circ}\text{C}$ ) within the next four hours, and add enough water to keep the humidity at 95 %. Hold the temperature under these conditions for 12 hours and then lower it back to RT while maintaining the 95 % RH in the next eight hours.

\* This chapter has been revised by Section VII Editor, S. W. Dean and Editor, R. Baboian.

<sup>1</sup> The Boeing Company, Seattle, WA 98124-2499.

Condensation will occur, but by removing water it can be held to a minimum. The test would consist of ten cycles, and at the end of the test the equipment is to be operated. A dry-out of some time may be allowed, and the severity of equipment damage is judged by any loss of operating efficiency. Other cycles can be used; for instance, to simulate the constant high humidity found in tropics, Mil-Std-810 has an "Aggravated Temperature-Humidity Cycle," where the temperature varies between 85 and 140°F (29.4 and 60°C), and the RH varies between 85 % for eight hours and 95 % for 16 hours; ten cycles usually are run and dry-out times are not allowed for equipment functioning tests.

### Temperature Shock

The purpose of the test is to determine if material in the assembled condition can withstand sudden changes of the temperature in the surrounding atmosphere without experiencing physical damage or detriment in performance.

As a result of exposure to extremes in temperature, operating equipment may bind, stick or have a slackening in tightness of moving parts, glass may shatter, and electrical part functions may change.

The test is conducted by starting at room temperature, raising it to a high temperature, say 160°F (71.1°C), and then lowering it to the low temperature, say -65°F (-53.9°C). Time should be allowed between the temperature changes, but the materials temperature should not reach equilibrium. The idea of this test is to see if the equipment can withstand air transport and be dropped in a cold environment to function without loss of efficiency and without broken or warped parts.

Variations of the test would hold the high temperature or the low temperature to see its effect on the equipment. The humidity can be varied during the entire test procedure. Effectiveness of the test is to operate without loss of efficiency at any temperature.

### Fungus

Equipment used in hot, humid environments is subject to fungus attack whether the material is fungus-resistant or not. This happens because organic contamination [fingerprints, oils, cleaning agents (soaps)] left on the hardware will support fungus growth. The tests are run to evaluate effects on performance of hardware that may or may not become contaminated with a fungus growth.

The test is conducted by inoculating the hardware with a selected group of fungus spores that have been cultured in an agar solution. After the culture has been sprayed onto the hardware sample, it is maintained in a warm, humid environment for 21 to 30 days. Evaluation of the test is to check on the viability of the spores. They should not live on the prepared agar for more than 18 to 20 days; if they do live they are probably living off contamination or nonfungus-resistant materials such as sleeving, wiring insulation, etc. Any loss of equipment efficiency also will be interpreted as test failure. Fungus tests are described in both Mil-Std-810 and in a number of ASTM tests such as ASTM D 3273 (Test Method for Resistance to Growth of Mold on the Surface of Interior Coatings in an Environmental Chamber). While

they are generally similar, the Mil-Std-810 test is conducted for military hardware.

### Salt Fog

Equipment salt fog tests are run to determine if conducting salts will cause malfunctioning of equipment. Salt fog tests may cause some corrosion of equipment which may cause the malfunction; however, if the equipment is known to require salt fog resistance it is more common to require that the materials of construction with their attendant finish system pass the tests for longer test times. The tests of equipment not intended for salt-containing environments are rarely run for longer than 48 h. Materials tests for equipment intended to resist salt environments are run in a neutral, 5 % salt fog exposure commonly at 500, 1000, and 5000 h. Tests are conducted according to ASTM B 117 [Test Method of Salt Spray (Fog) Testing] using a 5 % sodium chloride solution at a neutral pH. To simulate shipboard or seacoast operations, ASTM B 368 [Method for Copper-Accelerated Acetic Acid-Salt Spray (Fog) Testing (CASS Test)], which uses a copper ion and acetic acid as additives to the salt fog is used. In addition, ASTM G 85 [Standard Practice for Modified Salt Spray (Fog) Testing] is used. Annex 1 through 4 of this standard are used widely for this purpose.

After the equipment is exposed to the salt fog test it is required to operate without malfunctions. Drying out time may or may not be allowed.

### Low Pressure

Transportation of military equipment in unpressurized aircraft exposes hardware to a low-pressure environment that it was not designed to withstand. Low-pressure tests are therefore conducted on assembled equipment to check for pressure leaks, fluid leaks, evaporation of lubricants, failure of hermetic seals, etc. These types of failures may or may not lead to corrosion problems, but they certainly will lead to erratic operation or malfunction, or both. Missiles and space equipment are required to operate in low-pressure environments; however, low-pressure tests have caused sparks and corona that did not (or would not) show up at a lower altitude or higher-pressure environment. The tests are conducted by lowering the pressure in the chamber, allowing the equipment to outgas and come to equilibrium before it is operated. The conditions usually are optimized at ambient temperatures and the low pressures held for at least an hour. The equipment then may be operated either at low pressure or returned to ambient pressure and then operated.

### Solar Radiation—Sunshine

Military equipment may be subjected to long periods of time in areas of no protection from solar radiation. The heating effects of solar radiation differ from those of high air temperature alone in that the amount of heat absorbed or reflected depends on the roughness and color of the surface on which the radiation is incident. In addition to the differential expansion between dissimilar materials, changes in the intensity of solar radiation may cause components

to expand or contract at different rates, which can lead to severe stresses and loss of structural integrity. Long-term aging, especially of polymeric materials, also will be a problem. Mil-Std-810 Method 505.3 testing is used. For solar radiation effects (only) a minimum of 7–24 h cycles is suggested, for long-term aging, a minimum of 10–24 h cycles (Procedure 2, Method 505.3) for equipment occasionally exposed, and as much as 56 cycles for equipment continuously exposed is suggested.

### Rain

Rain tests are conducted to see if the hardware can function after it has been exposed to rain or complete wetting. Tests may be tailored as to the amount of rain and the duration of the exposure. The criteria for the test may be to check for leakage and, if leakage is allowed, determine if the operation will be affected. Mil-Std-810 Method 506.2 Procedure I is a convenient “blowing rain” test. This test is performed by allowing the rain to impinge on the test article for 30 min. The equipment can be operated during the last 15 min of the cycle. The equipment is rotated and the rain cycle repeated until all possible angles have been exposed. Less severe tests such as allowing a steady drip on equipment for a period of time (one week for example) also may be conducted according to Mil-Std-810.

### Sand and Dust

An airborne sand and dust environment, associated most often with the hot-dry regions of Earth, exist seasonally in other regions. Naturally occurring sand and dust storms are an important factor in the deployment of material, but with the increased mechanization of military operations, these cause less of a problem than do sand and dust associated with man’s activities. Consequently, this type of testing is important even when equipment may not be employed in hot-dry regions.

Some of the problems caused by sand and dust include abrasion and erosion of surfaces and finishes (generally paint finishes), penetration of seals, degradation of switch relays, contaminations of lubricated bearings and bushings, etc.

This test method is divided into two procedures. The small-particle procedure (dust, fine sand) is performed to ascertain the ability of equipment to resist the effects of dust particles that may penetrate into cracks, crevices, bearings, and joints. The test is run for 6 h at room temperature followed by 6 h at the high storage or high operating temperature. The second procedure, the blowing sand test, is performed to determine whether material can be stored and operated under blowing sand (149 to 850  $\mu\text{m}$  particle size) conditions without experiencing degradation of its performance, effectiveness, reliability, and maintainability due to the abrasion (erosion) or clogging effect of large, sharp-edged particles. The test duration is 90 min per face.

## STANDARDS AND SPECIFICATIONS

Up until recently, military specifications and standards (commonly known as Mil-Specs) dictated many aspects of system procurement to program offices and contractors.

Between 1994 and 2000, Acquisition Reform radically changed the way that military equipment was procured. During that period, the Department of Defense (DOD) reviewed over 29 000 detailed military specifications and standards in order to eliminate those that were no longer needed or replace them with nongovernment standards or performance specifications. While Mil-Spec reform did not eliminate the need for DOD military specifications and standards, it did dramatically shift the balance towards more commercial and performance-based specifications and standards [1].

One of the challenges of the reformed system is to identify and obtain copies of specifications and standards dealing with corrosion control [2]. The Acquisition Streamlining and Standardization Information System (ASSIST) database addresses this challenge. ASSIST provides a search capability for military, federal, and adopted nongovernment specifications and standards at the web site <http://assist.daps.dla.mil/online/start/>. One can use the ASSIST Quicksearch at the web site, <http://assist.daps.dla.mil/quicksearch/>, to view documents online. Information about other standards, specifications, and automated tools offered by the Defense Standardization Program Office can be obtained from the web site [www.dsp.dla.mil](http://www.dsp.dla.mil).

## CONCLUSION

Military equipment is exposed to every extreme of environment and is expected to function whenever called upon after long periods of exposure and nonfunctioning. It is because of these conditions that the specifications to which the equipment is built requires testing of the materials of construction for such materials properties as general corrosion resistance, susceptibility to stress corrosion cracking (SCC), and hydrogen embrittlement, as well as the severe testing of the equipment as delimited here. These tests are flexible as has been indicated, but should reflect the conditions under which the equipment must operate. The tests in detail as applied to military equipment are contained in Ref 3. ASTM tests are described in ASTM B 117, B 368, G 60, G 85, and D 4587 (Practice for Conducting Tests on Paint and Related Coatings and Materials Using a Fluorescent UV-Condensation Light- and Water-Exposure Apparatus). SAE tests are described in Ref 4. A search for standards and specifications by the military in dealing with corrosion control can be conducted at the web site in Ref 5.

# Pipeline

*Paul S. Rothman<sup>1</sup> and Walter T. Young<sup>2</sup>*

CORROSION TESTING OF pipelines is done for several reasons. One is to evaluate the pipeline condition to determine whether or not it is safe to operate. If repairs are needed, testing is performed to determine if repair is feasible or if replacement is needed. Testing is performed to track the pipe condition so that repair or replacement can be budgeted. Another reason for testing pipes is to evaluate the effectiveness of corrosion control measures, such as inhibitors for internal pipe surfaces or cathodic protection for internal or external surfaces. This chapter provides information on test techniques that can be applied to metallic pipes above ground or buried in an aqueous environment. Prior to discussing test techniques, the chapter will discuss briefly the materials and corrosion issues affecting pipelines. This chapter is by no means a detailed text on corrosion of pipelines, and the reader is encouraged to consult the references for further detail.

## PIPELINE MATERIALS

### Steel

Carbon and low-alloy steels are probably the most commonly used materials for pipes handling water, petroleum products, and some chemicals. Reference 1 provides a summary of the different specifications used for pipelines. Steel tends to corrode by both pitting and uniform surface deterioration [2]. Steel must usually be protected from corrosion both on the inside from the material being carried and on the outside from corrosion by the atmosphere, soil, or water that surrounds the pipe. External corrosion protection is provided by material selection, selective backfill, barrier coatings, stray current control, and cathodic protection. Internal corrosion protection can be provided by inhibitors, coatings, design process control, and materials selection.

### Stainless Steel

Stainless steel pipe is used primarily where corrosion products from carbon steel would cause unacceptable contamination of the product. Examples include jet fuel piping, food handling and other piping requiring FDA approval,

and chemical piping. There are many different variations of stainless steel alloys [3]. In general, stainless steels tend to corrode in a localized manner, resulting in pitting, crevice corrosion, stress corrosion cracking (SCC), and intergranular corrosion [4,5]. Corrosion will occur in any environment where access of the steel surface to oxygen is limited or uneven. Accelerated corrosion can occur in clay soils, soils containing chlorides, bacteria, marshy soils, and where stray currents are present. Stainless steel, under many conditions, requires protection from corrosion in the form of coatings and cathodic protection.

### Cast Iron and Ductile Iron

Cast (gray) iron and ductile iron are different in both chemical composition and metallurgy by virtue of the shape that the graphite takes in their microstructure [6]. Cast and ductile iron are used as wastewater piping and potable water piping. Alloyed cast iron is used to transport chemicals. Cast and ductile iron (other than the alloyed variety) corrode by pitting and uniform corrosion in water and in soils [2,3,7]. Gray cast iron, because of the interconnecting network of flake graphite, tends to retain its shape, but not its strength, even when severely corroded. This makes evaluation of the condition of gray cast iron difficult and requires that the "graphitized" layer be removed to perform a meaningful evaluation. The graphite in ductile iron is in the shape of nodules and does not have an interconnecting network. Ductile iron corrodes more like steel; however, graphite and corrosion products can also be difficult to evaluate without removing the corrosion products. Cast and ductile iron should be protected from corrosion when in a severely corrosive environment by using coatings, linings, and cathodic protection. Cast and ductile iron water piping are commonly lined with cement mortar [8]. Cast and ductile iron pipe also require protection against stray current corrosion.

### Galvanized Steel

Galvanized steel is carbon steel with either a hot dipped coating of zinc or a deposited layer of zinc (mechanically or electrolytically applied). The advantage of the zinc coating is that it provides increased corrosion resistance and some local cathodic protection to the steel if the layer is damaged. Galvanized steel is primarily used to transport water. The coating on hot dipped galvanized steel is primarily

<sup>1</sup>Principal Corrosion Engineer, The Port Authority of NY and NJ, New York, NY.

<sup>2</sup>Principal Engineer, Corpro Companies, West Chester, PA 19380.

a combination of several iron-zinc alloy layers [9]. This affects its ability to protect the steel by cathodic protection [10]. Galvanized steel will experience accelerated corrosion when buried in soils containing cinders, chlorides, and in alkaline ( $\text{pH} > 9$ ) or acidic ( $\text{pH} < 5$ ) soils. Therefore, galvanized steel is not recommended for buried applications without additional corrosion protection.

### Aluminum and Aluminum Alloys

Aluminum pipe is used where contamination of the contents with corrosion products is unacceptable, such as in jet fuel piping or alcohol. Aluminum pipe corrodes by pitting, intergranular corrosion, and uniform corrosion in soils and water [2]. In addition, aluminum is anodic (will corrode) when connected to most common engineering metals (bimetallic corrosion). Aluminum is also amphoteric; that is, it will corrode in either acidic or alkaline environments, i.e., below  $\text{pH} 4$  or above about  $\text{pH} 8.5$  [2,11]. Aluminum is corroded by copper or mercury in contaminated soils [12,13]. Aluminum is also corroded in tidal marsh, muck, and soils containing chlorides or cinders. Aluminum should be protected from corrosion by the use of coatings, linings, careful use of cathodic protection (because of possible deterioration in the alkaline environment created by cathodic protection), and by dielectric isolation from less active metals [14].

### Copper and Copper Alloys

Copper pipe is used primarily to transport water. Copper corrodes externally by pitting, crevice, uniform corrosion, and sometimes SCC. Copper can be corroded in soils containing cinders, chlorides, nitrogen compounds, inorganic and organic acids, cyanides, sulfides, and in salt tidal marsh soils [2,15]. Copper can also corrode internally due to the presence of high  $\text{CO}_2$  concentrations, high velocity at fittings and other flow restrictions, and by galvanic action resulting from bimetallic corrosion and corrosive flux in soldered joints.

## CORROSION ENVIRONMENTS

Factors affecting the corrosion of pipe include: soil resistivity, moisture content of the soil,  $\text{pH}$ , permeability of soil to moisture and air, soluble ion content of the soil, oxygen content, and the presence of corrosion-activating bacteria.

### Soil Resistivity

Resistivity is a measure of the soil's ability to conduct electrical current and is used as a guide in determining the corrosivity of the soil. Generally, soils with lower resistivity are more corrosive. Neither resistivity nor  $\text{pH}$  (described below) by themselves can be used to describe completely the corrosivity of the environment around the pipe. This is because other factors, such as aeration, drainage, and moisture levels have a significant impact on the corrosivity of soil. Very general resistivity guidelines are as follows:

<1000 $\Omega\text{-cm}$	Severely corrosive
1100–3000 $\Omega\text{-cm}$	Moderately corrosive
3100–10 000 $\Omega\text{-cm}$	Mildly corrosive
>10 000 $\Omega\text{-cm}$	Progressively less corrosive

It must be noted that the above guidelines are very qualitative and do not provide specific information as to corrosion rate, nor do they make distinctions about the performance of different materials, or the effect of bimetallic or other galvanic corrosion cells. For more information, the reader is referred to Refs 2, 16, and 17.

Lower resistivity soils can conduct more current and, therefore, tend to be more corrosive. The resistivity of a given soil can vary with the amount of moisture in the soil. Variations in resistivity can affect corrosion, because differential soil conditions create galvanic corrosion cells (e.g., oxygen concentration differential cells). Soil resistivity measurements are conducted according to ASTM G 57<sup>3</sup>, either in situ using the four-pin method or in the laboratory with a soil box. Of the two methods, field testing is preferable since it represents the actual conditions affecting the structure. Soil tested with a soil box should be measured with both the sample as-received and with the sample saturated with distilled water. Several soil measurements should always be taken, particularly when using the soil box, because soil characteristics are statistically distributed and resistivity will follow a normal probability function [18]. This fact can often be used to advantage, since it is only necessary to obtain representative data, which can be analyzed using normal and extreme value statistics [18,19].

### Moisture Content

Moisture is almost always found in soil. There is no critical moisture content for corrosion to occur, but greater quantities of water will increase the corrosivity of soil by increasing the amount of dissolved ions in the soil. Increasing water content will cause the resistivity to decrease, thus increasing the soil's conductivity and its ability to conduct corrosion current. Moisture content is measured by comparing the weight of the soil as-received with the weight after oven drying. A method to conduct this test is provided in ASTM D 2216<sup>4</sup>.

### Soil pH

Soil  $\text{pH}$  is a measure of the acidity or alkalinity of the soil, according to the following criteria [2]:

<4.5	extremely acid
4.5–5.0	very strongly acid
5.1–5.5	strongly acid
5.6–6.0	medium acid
6.1–6.5	slightly acid
6.6–7.3	neutral
7.4–7.8	mildly alkaline
7.9–8.4	moderately alkaline
8.5–9.0	strongly alkaline
>9.1	very strongly alkaline

It is generally considered that the corrosion of ferrous pipe in soil, where oxygen reduction is the cathodic reaction, is unaffected by  $\text{pH}$  unless the  $\text{pH}$  is below 4 or above 10. In

<sup>3</sup>Method for Field Measurement of Soil Resistivity Using the Wenner Four Electrode Method.

<sup>4</sup>Test Method for Laboratory Determination of Water (Moisture) Content of Soil and Rock.

soil with a pH below 4, the corrosion rate of iron increases above that found in neutral soils. The corrosion rate of iron in soil with pH above 10 decreases below that in more neutral soil. Variations in pH, even in the 4–10 range, cause corrosion by creating galvanic corrosion cells (called a pH differential corrosion cell). Corrosion rates of amphoteric metals, such as aluminum, are accelerated in soils with either strongly acidic or alkaline pH values. Soil pH is measured according to ASTM G 51.<sup>5</sup> The soil should be tested within 24 h of sampling. The soil pH is measured directly with pH and reference electrodes without adding any water.

### Permeability of Soil to Moisture and Air

Corrosion reactions depend on the presence of both moisture and oxygen. In general, soils that prevent the movement of either water or oxygen to the pipe surface will not be as corrosive as those that permit the ready movement of these items. Soil in the pipe ditch is generally more permeable than natural undisturbed soil.

### Soluble Ion Content

Significant ions include chlorides and sulfates. The higher the content of these ions, the more corrosive the soil. The amount of corrosion that occurs will depend on the quantity of moisture in the soil. Very dry soils are less corrosive than wet soils, even though both might contain high concentrations of dissolved salts. The soluble chloride and sulfate ion content of the soil can be measured by taking a water extract of the soil, measuring the chloride concentration of the extract, then calculating the chloride ion concentration in the original soil volume. The true concentration in parts per million (ppm) is given by

$$\frac{\text{Measured concentration of extract (mg/L)} \times \text{Mixed volume (L)} \times 10^6}{\text{Initial weight of solid sample (g)} \times 1000}$$

ASTM D 512<sup>6</sup> provides a method for measuring the chloride ion concentration of water. The sulfate ion content is measured in much the same way as the chloride ion test. ASTM D 516<sup>7</sup> provides a method of measuring the sulfate ion concentration in water. Titration methods and water testing kits can also be used. Soil chlorides can be found naturally in soils, or can be introduced by deicing salts and in a seacoast environment.

### Oxygen Content

Oxygen is essential for corrosion to occur in the pH range commonly found in soils. Soils such as clays restrict oxygen movement; therefore, these soils are prone to anaerobic conditions. Often, however, soils such as clays tend to promote galvanic corrosion cells that are caused by differences in oxygen concentration (differential concentration cell corrosion). Bacterial corrosion often occurs in clay soils because anaerobic conditions and organic matter promote bacterial growth. A common type of bacteria that causes

corrosion in soils is *desulfovibrio desulfuricans* anaerobic sulfate reducing bacteria.

The oxidation-reduction behavior of a soil is not frequently measured, because it is difficult to obtain reliable data in the field. Extraction of soil samples for laboratory analysis is likely to introduce oxygen into the sample that will adversely affect the accuracy of the data. Accurate data can be obtained with the soil in situ, but special probes are required. The use of redox potentials in evaluating the corrosivity of soils is discussed in Refs 20 and 21.

### Corrosion-Activating Bacteria

The presence of some forms of aerobic or anaerobic bacteria promotes corrosion, called microbiologically induced corrosion (MIC). The most common type of bacteria causing corrosion in soil is anaerobic sulfate reducing bacteria (SRB). Bacteria can cause the corrosion of ferrous and non-ferrous pipe. Identification and measurement of MIC can be accomplished by either laboratory analysis or by using several commercially available test kits.

For additional discussion on the relevance of soil characteristics, the reader is referred to ASTM STP 1013 and STP 1000 [22,23].

## CORROSION CONTROL

### Resistant Alloys

An acceptable life for underground pipelines can sometimes be realized through the use of corrosion-resistant piping. Copper, aluminum, and stainless steel piping are sometimes used for this purpose. All three alloys can have greater corrosion resistance than carbon steel or cast iron. However, they are not immune to corrosion and are often more susceptible to localized corrosion such as pitting, crevice corrosion, and SCC than carbon steel or cast iron. Further, corrosion protection in the form of coatings and cathodic protection are frequently used.

### Coatings and Linings

The purpose of a coating is to provide a barrier between the environment and the metal surface in order to prevent the corrosion cell from occurring. If the coating were a perfect barrier, then this would be satisfactory; however, experience has shown that coatings are rarely perfect barriers. Coatings contain defects that allow moisture to get through to the metal. Coatings are not always sufficiently bonded to the metal, due to contaminants on the metal surface or inadequate surface preparation or application. This allows osmotic transfer of moisture with subsequent blistering of the coating. Coatings can be damaged from soil stresses and mishandling and poor workmanship sometimes occurs, resulting in missed spots on the pipeline. If the pipe is not critical and if leaks are not a hazard or an economic problem, then coating alone might be justified; but normally, coating should be supplemented with cathodic protection.

Coatings are applied to carbon steel piping in atmospheric exposure, as this type of material is subject to general corrosion. Pitting attack can also occur on steel piping where

<sup>5</sup>Test Method for pH of Soil for Use in Corrosion Testing.

<sup>6</sup>Test Methods for Chloride Ion in Water.

<sup>7</sup>Test Methods for Sulfate Ion in Water.

conditions result in nonuniform collection of water and other aggressive contaminants. Coating of the piping in these areas is critical for the elimination of this form of accelerated corrosion attack. Coatings should also be applied to carbon steel, stainless steel, and ductile iron piping installed underground. The corrosion of all three of these ferrous materials can be of the pitting type, due to the inhomogeneity of the environment. Stainless steel, normally protected from corrosion by the formation of a passive oxide film, can corrode in a concentrated manner when buried in soil due to the inability to form a uniform oxide film. Therefore, the same corrosion resistance as that provided in above grade and internal exposure is not guaranteed when this material is buried. The same applies for aluminum piping. The application of coatings is generally part of a unified corrosion control program consisting of coatings and cathodic protection, so it is extremely important to select coatings systems that are compatible with the application of cathodic protection.

### Cathodic Protection

Cathodic protection is a very effective method of controlling corrosion on the exterior surfaces of metallic piping systems, including carbon steel, stainless steel, and ductile iron. It is most cost-effective when a quality coating system has been applied to the exterior surfaces of the pipe. Cathodic protection is of two types, galvanic anode and impressed current. The galvanic anode type uses metal ingots of a material more electrochemically active than the metal to be protected, to overcome the galvanic corrosion cells that exist on the pipe surface. This type of system usually requires that the pipe to be protected be electrically isolated from other metallic structures, such as copper water lines and grounding systems. In this manner, minimal current is required to achieve corrosion protection, and this current can be applied economically with a galvanic anode type system. If electrical isolation and effective coating do not exist, an impressed current type system is employed to produce the larger quantity of current required to achieve protection. The impressed current system uses inert anodes that serve as earth contact electrodes to supply the protective current to the protected structure. The current is generated by an external source of direct current, typically known as a "rectifier." The rectifier is an adjustable output current source that can deliver variable amounts of current based on the specific needs of the structure to be protected. The difference in operation between the two systems involves the consumption of the respective anodes. The galvanic anodes are consumed at a rate dependent on the current output and the consumption rate of the particular alloy. The consumption rate of typical impressed current anodes is much lower per ampere of current delivered. For example, a magnesium anode is consumed at a rate of 17 lb (7.7 kg) per ampere per year. A typical high silicon cast iron impressed current anode is consumed at a rate of 1 lb (0.45 kg) per ampere per year. Precious metal (platinized niobium and titanium) and mixed metal oxide coated titanium anodes have even lower consumption rates (on the order of milligrams per ampere per year of current discharge.) For more information, consult Refs 24 or 25.

### Stray Current Control

Stray currents are electrical currents on a pipeline caused by external sources. Examples of stray currents include: d-c or a-c powered transit systems, electric welding operations, currents from mining operations, and interference from cathodic protection systems on other structures. Stray current can cause corrosion where it discharges from the surface of the pipeline. For example, one ampere of d-c stray current causes the loss of 20 lb (9.1 kg) of iron per year. A-C stray current has about 1% of the effect of d-c strays on iron pipe, but a-c strays have a detrimental effect on aluminum [25]. Note that a-c stray current is not necessarily the same as induced a-c sometimes found on pipelines near a-c power transmission lines.

Corrosion by stray current is the result of the flow of current in other than intended paths. For example, in a d-c powered transit system, current that is intended to flow back to its source (the traction power substation) follows another path, exiting the rails, flowing into the ground, and is accumulated on a metallic structure such as a pipeline. The current flows along the pipeline, which acts as a low resistance conductor, until another low resistance path back to its source becomes available. The current discharges from the metallic structure into the soil and to its intended destination, the traction power substation negative bus. The problem involves the loss of metal at the point of discharge; for example, 20 lb (9.1 kg) of iron per year for every ampere of current discharging to earth.

The control of corrosion caused by stray current involves either reduction of the amount of current at the source or safe removal of the current from the corroding structure. The removal of the current from the structure involves the creation of a metallic path for the current to flow, rather than the electrolytic (soil) path. In order to create this metallic path, first the exact point of current discharge must be located through tests, and the quantity of current involved must be determined. The metallic path is provided after determining the quantity of current that must be "drained," and the characteristics that the drainage circuit must have. The resistance of the wire, its ampacity, and the exact point to which the current must be drained are examples of the characteristics that must be determined.

Standard tests for evaluating stray currents are rare. ASTM G 165, Practice for Determining Rail-to-Earth Resistance, provides a test method for measuring the resistance-to-earth of the running rails, which are used as the conductors for returning the train operating current to the substation in electric mass transit systems. For more information, consult Refs 25, 26, and 48.

### Above-Ground Installation

In some cases, external corrosion of buried structures can be eliminated by installing these structures above grade, rather than burying them. This has become common practice in plants, where space is available to relocate the underground facilities to above ground. This practice results in elimination of the invisible corrosion of the formerly buried structures, and replacement with a condition in which the structure can be seen and maintained. However, there

still remain corrosion control requirements. The structure must still be protected from atmospheric corrosion through the application and continual maintenance of corrosion coatings. A continuing program of visual inspection and maintenance of the coatings must be carried out to prevent the deterioration of the coating and the structure itself.

## Inhibitors

Chemicals can be added to the product in pipelines to control corrosion. These chemicals are called inhibitors. They control corrosion by forming barriers to isolate the metal surface from the environment or by controlling the anodic or cathodic corrosion reactions. Inhibitors are used to control corrosion by water (either condensed from the gas carrier or water being carried by the pipe) and salts (brine in petroleum pipelines, gathering pipelines, and oil wells). Inhibitors include oxygen scavengers, filming inhibitors, biocides, and passivating agents. For more information, see Ref 15.

## PROBLEM AREAS

### Welds and Mechanical Joints

Welds and mechanical joints can be areas where accelerated corrosion occurs for several reasons. Field coatings applied to joints are sometimes not of the same quality as shop-applied coatings on the remainder of the pipeline. This can lead to the environment penetrating to the metal and the formation of corrosion cells. Mechanical joints and rough welds can lead to crevice corrosion. Weld metallurgy also plays a role in corrosion. Welds containing high levels of sulfide inclusions can lead to localized corrosion of the weld metal.

### Mechanical Damage

Mechanical damage to the pipe can result in localized corrosion where the surface is scratched or dented, due to the formation of differential stress electrochemical corrosion cells. Corrosion can also occur if local damage occurs to the protective oxide film on the metal surface, resulting in an electrochemical corrosion cell between the clean metal and corroded metal. In the case of active-passive alloys, such as stainless steel, local damage to the protective oxide layer can result in an electrochemical corrosion cell.

### Bimetallic Couples

Corrosion caused by the connection of two or more different metals also occurs underground. This electrochemical corrosion cell is commonly referred to as bimetallic or galvanic corrosion. Typical examples include: brass or bronze valves connected to steel or cast iron pipes and stainless steel fasteners connected to steel or cast iron. These couplings of dissimilar metals will locally affect the corrosion rate. Aluminum can be severely corroded if directly connected to most other engineering alloys, such as steel, iron, copper, or stainless steel—dielectric isolation must be used.

## Stress Differences

Stress differences can result in localized electrochemical corrosion cells. An example is bolts used on joint fittings. The head and threaded areas of the bolt corrode at a faster rate than the body that is at a lower stress level.

## Environmental Cracking

### Hydrogen Damage

Atomic hydrogen generated at the surface by cathodic protection will diffuse into the metal. This atomic hydrogen can cause blistering of the metal, the formation of hydrides (in the case of titanium) that embrittle the titanium, and the embrittlement of steel (particularly high strength steel), martensitic stainless steel, high strength aluminum alloys (particularly 7000 series), and prestressed concrete. The embrittlement of the metal can cause cracks to form, which can grow and cause the structure to fail.

The prevention of hydrogen embrittlement depends on keeping the potential below the hydrogen evolution potential, which depends on the pH. In general, hydrogen is generated in neutral environments at  $-1044$  mV CSE. The lower the pH, the lower the hydrogen evolution potential. For aluminum, the polarized potential must be kept below  $-1200$  mV (CSE) to avoid alkali corrosion. For titanium, the maximum potential is  $-700$  mV (silver-silver chloride) to prevent hydriding. Overprotection levels are discussed in some cathodic protection criteria documents and might differ from these somewhat. For prestressed concrete, polarized potentials more negative than  $-1000$  mV CSE should be avoided.

### Stress Corrosion Cracking

Stress corrosion cracking is the cracking of a metal under an applied tensile stress in the presence of a corrosive environment. Many metals, including high strength steel, aluminum (2000 and 7000 series alloys), stainless steels, and brass alloys are susceptible to stress corrosion cracking. Cathodic protection generally reduces or eliminates stress corrosion cracking, because it stops the corrosion process. However, stress corrosion cracking of high strength pipeline steels caused by cathodic protection has occurred. This type of cracking occurs in a narrow potential range ( $-525$  to  $-725$  mV CSE) at a pH between 8 and 10.5, and is more likely at higher temperatures. The cracking occurs because of the formation of carbonates and bicarbonates at the steel surface. See Refs 27–30.

## CORROSION TEST METHODS

### Visual

Field evaluations consist of documenting both visual observations and measurements of corrosion on pipe sections. Evaluation of the environment also provides valuable information in the analysis of pipe corrosion. Visual methods are difficult to use on underground pipes because the pipe must be excavated to be examined; however, this is often the best way to evaluate the condition of a pipe. Carefully

obtained corrosion measurements can be analyzed using normal probability and extreme value statistics. There are no standards for performing this type of test. It is suggested that the locations for visual measurements be carefully selected from leak records, tapping excavation reports, close-interval survey test results (to be discussed), or soil corrosivity measurements (resistivity, pH, soil chemistry).

It is often difficult to evaluate the condition of a pipe by simple examination in the ditch because of the presence of corrosion products and deposits. Uncoated pipe should be thoroughly cleaned to remove all corrosion product and foreign matter (as in the evaluation of any corrosion, samples of the corrosion product should be retained for further analysis if the cause of the corrosion is unknown). This can be particularly true of gray cast iron, because the graphite matrix retains its shape and must be removed to reveal the remaining iron surface. Cleaning is often best accomplished using abrasive blasting. Care must be taken when using grit blasting not to erode away the pipe material itself, and grit blasting should not be used on thin pipes such as copper. For example, cast iron is harder than graphite and will not erode quickly, but if the blast nozzle is held in one place too long, the iron will erode. The graphite will be black in color and the cast iron a gray color.

Irregular surfaces and hard brownish deposits on the pipe are indicators that corrosion has occurred. Black or whitish deposits are indicators of possible anaerobic sulfate-reducing bacteria. Other visual methods rely on preparation of the pipe surface to remove graphite.

Visual inspection of the pipe in the ditch before pipe preparation includes the following steps:

- Clean the pipe surface to remove soil and debris.
- Document any obvious areas of corrosion or corrosion product accumulation.
- Evaluate black or whitish deposits for sulfate-reducing bacteria (SRB). A quick qualitative determination can be made using a 10 % hydrochloric acid solution in water. Place a drop of the solution on the deposit. An aroma of hydrogen sulfide (rotten eggs) indicates that SRB are present. Significant corrosion of the pipe might have occurred and further investigation is warranted. Wear safety glasses and gloves when handling the acid, and observe all necessary safety precautions. Commercial test kits are available that can provide a quantitative determination of the type and quantity of bacteria present.
- Obtain a general idea of the condition of gray cast iron pipe, especially when severely graphitized, by sounding the pipe with a hammer. A dull thud suggests extensive graphitization.
- Document all observations on data sheets and with photographs.

Further pipe evaluation is performed either by removing a sample from the pipe or cleaning a section of pipe for in situ measurements. Cleaning and measuring a section of pipe in the ditch provides the most accurate information, and the data are usable for statistical analysis. Extending the data from a single pipe section to the entire pipe run is not recommended beyond 1000 ft (305 m) or where the environment is known to vary significantly from that in the excavation.

## Pipe Coupon

Cut a coupon from the pipe using a pipe tapping tool, or cut a full circumferential coupon. Retain the coupon for further testing in the laboratory. Mark the sample to show the orientation of the sample on the pipe (top, side, bottom) and direction of flow. The full sample length should be at least 1 ft (30.5 cm). If possible, remove a 3-ft (0.9-m) length. The longer length will provide better information for statistical analysis. Put the sample in a plastic bag, seal the bag, and send it to the laboratory for further testing.

## Clean Pipe Section (In-Place Measurement)

Repair and safety equipment must be on-hand for any leak that might occur during the excavation or as a result of the cleaning procedure.

- Excavate a 10-ft (3-m) section of pipe, exposing the entire circumference of the pipe so that the entire pipe can be reached for examination.
- Document the condition of the pipe in writing and photographically before cleaning. Save samples of corrosion product before the pipe is cleaned for analysis.
- Sandblast the surface to remove all corrosion products. CAUTION: This can be hazardous! If the pipe shows extensive corrosion, extreme care must be exercised to avoid penetrating the pipe wall. Stop the cleaning operation if a wall penetration appears likely. The pipe surface after sandblasting should be a silver gray.
- Mark the cleaned surface into segments, each 1-ft (30.5-cm) long.
- Measure the depth of corrosion in each section, ensuring that the deepest corrosion is measured.
- Apply two coats of coal tar mastic coating to the pipe surface. Attach a sacrificial anode to the pipe section that was cleaned. This is necessary because the cleaned surface and old corroded surface form a galvanic corrosion cell. The clean pipe will corrode faster than the uncleaned pipe.

Coated pipe is somewhat more difficult to evaluate, because corrosion only occurs at coating holidays and sometimes under disbonded coating. Coating defects must be carefully examined and the condition of the pipe documented.

## Ultrasonic Inspection

Ultrasonic measurements can be used to supplement mechanical pit depth measurements and can be used in areas where the internal condition of the pipe must be determined. Ultrasonic measurements can be analyzed, using the same statistical approach as mechanical measurements. Additional information for ultrasonic inspection is found in ASTM E 212<sup>8</sup> and Ref 31.

There are several important considerations relative to ultrasonic measurements. One is the doubling effect of some digital gages when the thickness limitation of the transducer is reached. Another is the effect of coatings on the readings. Most pulse-echo instruments will provide inaccurate

<sup>8</sup>Practice for Ultrasonic Examination of Metal Pipe and Tubing.

information when the tester tries to read through an organic coating on the pipe. Coatings must be removed unless the equipment used compensates for the presence of the coating. The surface roughness of the pipe, both internal and external, plays an important role in the accuracy of the data. The surface must be relatively smooth. Roughness can make it either difficult or impossible to obtain accurate thickness data. It is sometimes necessary to grind the surface just enough to allow the transducer a flat surface. One very important consideration is the nature of the internal corrosion. Internal pitting that consists of narrow or widely scattered pits might be difficult to find with ultrasonics, because the probability of the transducer being immediately above a pit can be low. In that case, a scanning approach should be used to cover the widest area possible. A visual inspection of the pipe is a good idea if at all possible to determine the type of corrosion present.

### Instrumented Pigs

Instrumented or "smart pigs" using ultrasonic, eddy current, or mechanical measuring instrumentation can be effectively used to measure corrosion from the inside of the pipe. Instrumented pigs contain sensing devices that scan the pipe wall searching for defects. Ultrasonic devices work by measuring the time that it takes a high-frequency sound wave to travel across the pipe thickness and back to the transducer. The instrument is calibrated to measure this time as thickness of the pipe wall. Magnetic or eddy current devices work by sensing deviations in a magnetic flux field caused by corrosion pits or other defects that distort the flux field. For more information, consult Refs 32–34.

Magnetic flux inspection using pigs has been applied to small diameter cast iron and ductile iron water pipe as a means of measuring the internal and external corrosion of that pipe. Pipe up to 8 in. (200 mm) has been inspected using this technique [35].

### Statistical Evaluation

Corrosion, particularly pitting corrosion, tends to be distributed in a nonuniform manner. The depth of pits on a surface can be described by a normal probability curve. This can be used to advantage when evaluating a pipeline, because it is only necessary to measure a few representative areas and use statistics to determine the condition of the entire pipe. There are no standard test methods, but ASTM G 16<sup>9</sup> does describe statistical approaches to laboratory data, and applicable references can be found in Refs 36 and 37.

The corrosion data collected in the above-mentioned test provide information about the samples tested, but not necessarily about the pipe as a whole. That is why it is important not only to select sampling locations that represent the condition of the pipe run as a whole, but also include the worst case conditions. Whatever areas are selected, it is possible that more severe corrosion exists. Statistical analysis is a method that uses known data to predict the range of corrosion.

In order for a statistical analysis to provide useful results, the data must be taken in a systematic fashion. The corrosion measurements for both the field and laboratory evaluation, as described above, provide corrosion data at known and consistent intervals along the pipe sample. This provides usable data for the statistical analysis.

The statistical analysis procedure most useful in evaluating corrosion on pipes is the extreme value statistical method. The referenced publications provide details on extreme value statistics and their application to pipeline corrosion. The extreme value statistical approach analyzes the maximum pit depth (or minimum wall thickness) per unit length to estimate the range of corrosion data for the pipe. The results, of course, assume that the pipe run is in the same condition as the sample tested. The more samples tested, the greater the accuracy of the result.

Normal probability and extreme value statistics have already been discussed as means of evaluating corrosion and soil resistivity. Statistical methods have been applied to determine when steel tanks will fail [38]. Individual soil characteristics, such as resistivity, pH, and soluble ion content, are unsatisfactory methods of predicting the corrosion behavior of a structure in a particular soil. The statistical method is based on a regression analysis of all of the soil characteristics that affect corrosion as compared to actual corrosion of structures found in those soils. This method yields a mean time to corrosion failure (MTCF) as opposed to an actual corrosion rate. Its validity for structures other than steel tanks has not been demonstrated.

### Electrochemical Methods

#### *Polarization Techniques*

Polarization refers to the change in corrosion potential of a metal as an external current is applied. Plots of potential versus applied current are called polarization curves; these can be used to measure the corrosion rate of pipelines. ASTM G 59<sup>10</sup> and G 102<sup>11</sup>, normally used in the laboratory, are not directly usable on pipelines. Polarization curves to measure Tafel slopes (E-log I plots) have been used for years to measure corrosion currents and cathodic protection current requirements. Standard laboratory techniques must be modified to fit field conditions, since we are dealing with large working electrodes<sup>12</sup> rather than small electrodes as in a laboratory setting. Also, several factors are often present that are not found in the laboratory, such as the working electrode being coated and the possible presence of galvanic and stray currents. These factors make interpreting polarization data to determine corrosion rate difficult. Since all coatings contain defects (called holidays), the total area of pipe exposed and size and distribution of the holidays are often unpredictable and will affect the corrosion rate; i.e., one cannot use the total area of the pipe in the corrosion current density calculation. Concentration

<sup>10</sup>Practice for Conducting Potentiodynamic Polarization Resistance Measurements.

<sup>11</sup>Practice for Calculating the Corrosion Rates and Related Information from Electrochemical Measurements.

<sup>12</sup>The pipe is called the "working electrode" in electrochemical terminology.

<sup>9</sup>Guide for Applying Statistics to Analysis of Corrosion Data.

polarization effects on a large structure often affect the observation of the Tafel slope, thus making the measurements unreliable.

One method of getting around these problems is to use a small working electrode coupon connected to the pipe. The size of the electrode is based on a reasonable estimate of the holiday sizes on the pipe. The polarization curve is obtained by observing the potential on the known electrode. Such data must be evaluated carefully, since it represents only one point. On a long pipeline, several test locations should be evaluated. For more details on electrochemical polarization, the reader is advised to consult Refs 39 to 41 and 42.

### Potential Measurements

Corrosion testing often involves determining the relative level of electrical activity of various structures such as pipelines, storage tanks, and the like in the environment in which they are installed. These environments may be soil, water, or concrete, to name a few. In each case, the environment in which the structure is installed is the electrolyte that can and will support corrosion activity. Structure-to-electrolyte potential measurements may be used at various stages in the corrosion evaluation to determine the existence of corrosion activity. This is accomplished by measuring the "native" or "natural" potential of the structure. This involves using the circuit shown in Fig. 1. The measurements taken will indicate the electrical characteristics exhibited by the structure in its natural state. For example, for a pipeline installed in soil, the potential with respect to the soil by means of a standard reference electrode, taken at regular intervals along the pipeline will indicate the corrosion patterns affecting the pipeline, as described in the next section.

Once the potential pattern has been measured for a structure, potential measurements can also be used to evaluate the effects of the application of cathodic protection current. While a measured quantity of current is applied to a structure,

potential measurements are taken at locations where native potential measurements had been taken. The shift in potential as well as polarization effects due to the application of the current can be measured. These data can be used to determine the quantity of current required to achieve cathodic protection of the structure.

Potential measurements are also used to gage the effectiveness of a cathodic protection system, after it has been installed and is operating, in mitigating the corrosion activity detected by the native potential profile. The pipe-to-soil potential measurement has been established by corrosion engineers as a standard for determining the degree of cathodic protection on underground metallic structures. Various criteria have been promulgated; the three currently in use for steel structures are: (a) the achievement of a pipe-to-soil potential of  $-850$  mV referenced to a copper-copper sulfate electrode with cathodic protection current applied, (b) the achievement of a polarized potential of  $-850$  mV, and (c) the achievement of a  $100$  mV shift in potential due to cathodic polarization.<sup>13</sup> These measurements can be taken at distinct points along a structure, or continuously, as in the case of a close interval potential survey (see next section).

### Close Interval Survey

As discussed above, corrosion activity can be detected through the measurement of native structure-to-electrolyte potentials at regular intervals along a pipeline or similar structure. Techniques have been developed using sophisticated computerized data loggers to record the large numbers of potential readings that can be encountered during the course of such a survey. These data loggers in conjunction with personal computers can provide a continuous profile of the potential along miles of pipeline traversing all types of terrain. Some instrumentation can be linked to global positioning systems (GPS) synchronization software.

Figure 2 shows a typical pipe-to-soil potential profile on a pipe experiencing galvanic corrosion activity. This profile consists of a series of measurements with one reference electrode moved directly over the pipe, and a second reference electrode moved at a lateral distance remote from the pipe. In general, anodic areas exist at locations where the "over-the-pipe" potentials are more negative than "off-the-pipe" potentials. The anodic areas are at locations where the over-the-pipe potentials are of higher negative values than those measured in the cathodic areas. In the case of stray current interference, current is picked up on the pipeline, increasing the potential in the negative (cathodic) direction. At the point of stray current discharge, the potential is depressed (less negative). Therefore, the anodic areas in the case of interference currents are at locations where the potentials (both "over" and "off" the pipe) are of lower negative values than those at the cathodic areas. Figure 3 illustrates the typical profile for a stray current interference condition. Other types of corrosion conditions can be detected through the use of close interval potential surveys. These include the effects of coating damage, shorts to bare or grounded structures, and very aggressive soil environments [43].

## Coupons

Coupons are relatively small pieces of metal, the same composition as the structure being evaluated, that are buried in the soil next to the structure. They are intended to measure the corrosivity of the soil where the structure is buried or is intended to be placed. If the structure already exists, the coupon should be connected to the structure in order to expose it to galvanic and stray currents, as well as the soil. Coupons can be evaluated after a period of time using mass loss (ASTM G 112) or polarization as previously discussed. Coupons should be large enough for pitting to develop. All coupons should be evaluated visually after exposure.

Commercially available coupon systems are available for measurement of cathodic protection data, and some are available for measurement of both polarization and corrosion rate data. Care must be exercised when using these methods to ensure that the coupons are installed in an area representative of the pipe and that the coupon size is representative of the coating holidays on the pipe. NACE International has published a state-of-the art report on the

application and interpretation of data from external coupons [44]. For additional information, see Refs 45 and 46.

NACE International has a series of test methods that are applicable to in situ testing. These are:

1. Standard Recommended Practice RP0189, On-Line Monitoring of Cooling Waters,
2. Standard Recommended Practice RP0775, Preparation, Installation, Analysis, and Interpretation of Corrosion Coupons in Oilfield Operations,
3. Standard Test Method TM0172, Determining Corrosive Properties of Cargoes in Petroleum Product Pipelines,
4. Standard Test Method TM0299, Corrosion Control and Monitoring in Seawater Injection Systems.

## Remote Monitoring

Recent advances in digital measurement systems and microprocessor-based monitoring and control systems have made the monitoring of cathodic protection systems for pipelines and complex piping networks more economical and accurate. Cathodic protection systems can be monitored on a continuous basis, and operational malfunctions such as power loss to impressed current rectifiers, lightning damage, and other component failure can be detected and alarms can be sent to owners and operators of these systems. The technology also includes the capability to perform detailed test protocols to evaluate the effectiveness of cathodic protection systems at critical locations, without the need for personnel to visit the locations. The testing can include anything from simple routine testing, such as pipe-to-soil potential at a test point, to simultaneous interruption of multiple rectifier units and the measurement of depolarization decay at selected test points. The outputs of the rectifier units and individual anodes can be both monitored and remotely adjusted. Additional information is contained in Ref 47.

# Highways, Tunnels, and Bridges

James B. Bushman<sup>1</sup> and Victor Chaker<sup>2</sup>

TRANSPORTATION IN THE UNITED STATES is essential to the physical and economic well-being of the country. In general, the transportation infrastructure in the United States has stood up well, leading to a false sense of security and to our taking it for granted. We are currently faced with the need to maintain, repair, and reconstruct the existing systems to extend their life expectancies, or to develop new technologies to replace them with more efficient and effective systems. To understand these challenges, an overview of the current material and testing procedures has been prepared.

## MATERIALS OF CONSTRUCTION

### Highways [1]

Highway design and construction use numerous materials, both metallic and nonmetallic. Most of the materials are controlled by standards adopted by the American Association of State Highway and Transportation Officials (AASHTO).

Metallic materials include but are not limited to the following:

- Steel forgings, carbon and alloy, for general use.
- Steel castings, carbon, for general application.
- Gray and ductile iron castings.
- High-strength steel bolts for structural steel joints.
- Carbon steel bars, cold-finished, standard quality.
- Structural steel.
- Steel sheet piling.
- Standard strength steel wire ropes and sockets for conventional catenary cable suspension bridges.
- Carbon steel reinforcing bars.
- Epoxy coated carbon steel reinforcing bars
- Stainless steel reinforcing bars.
- Stainless steel clad carbon steel reinforcing bars.
- Medium and ultra-high strength bar, rod, and cable in prestressed and post-tensioned concrete components.
- Ultra-high strength steel cables for cable stay suspension bridges.

Nonmetallic materials include but are not limited to the following:

- Fiberglass reinforced plastic (FRP) reinforcing bars.
- Timber, pressure-treated, and wood products.
- Portland cement concrete.

- Fly ash, silica fume, and ground granulated blast furnace slag.
- Corrosion inhibitors
- Bituminous material for paving
- Granulated rubber from used tires.

### Tunnels [2]

Steel, cast iron, or precast lining rings are installed in tunnels to support the ground. Tunnels in loose, noncohesive, or soft ground are generally driven by means of a steel shield, most often circular in shape, either in free air or under compressed air. The shield permits the excavation of soil and erection of primary lining under safe conditions and must be used in subaqueous tunnels. Some of the notable shield-driven tunnels include the Hudson River tunnels, which became part of the Hudson-Manhattan Railroad. The Holland Tunnel under the Hudson River began in 1922, followed by the three Lincoln Tunnels and the Midtown Tunnel under the East River.

All shield tunnels must have a primary lining to support the ground and take the thrust of the shove jacks. Traditionally, segmental cast iron liners have been used; other methods are ribs and lagging, fabricated steel liners, pressed steel liner plates, and precast concrete segmental liners.

#### Ribs and Wood Lagging

In tunnels that require a secondary lining for interior finish or smooth surface, steel ribs and wood lagging have been used in firm and relatively dry ground.

#### Precast Concrete Lining

Precast concrete liners have not yet found great use in the United States, except for the O'Rourke block used in a number of tunnels in Detroit. They are not watertight and require a secondary lining. Precast concrete segments were designed for a test section of the Baltimore subway tunnels, but were not competitive with steel liners.

In subway construction, concrete segmental liners generally do not receive a secondary lining, since slight seepage is tolerated.

#### Secondary Lining

A secondary lining is required if the primary lining consists of ribs and lagging or O'Rourke blocks, or if the tunnel interior needs a finish (as in highway tunnels). Rail tunnels with segmental metal or precast concrete usually do not receive a secondary lining.

<sup>1</sup>Principal Corrosion Engineer, Bushman & Associates, Inc., Corrosion Consultants, P.O. Box 425, Medina, OH 44256.

<sup>2</sup>Former Author, retired from Port Authority of NY/NJ.

Secondary linings are usually applied after primary linings have been in place for a period during which they have adjusted to the soil pressure and deformation, so that they have to absorb only long time secondary settlements.

In subaqueous tunnels, the thickness of the secondary lining may be governed by the requirement that its weight together with that of the rest of the structure be sufficient to counterbalance the buoyancy forces.

### *Poured Concrete Lining*

Generally used in highway tunnels, which receive a tile finish or other light reflecting surface, poured concrete lining will be of a minimum practical thickness for pouring and enclosure of conduits, fixtures for lighting, and other recessed equipment. The concrete is poured behind steel forms, starting at the invert. In tunnels with no watertight primary lining, the concrete secondary lining is placed as close to the face as possible.

Sprayed linings of cement mortar may be used to protect the interior of the steel primary linings. Acoustical lining may be sprayed directly to the primary lining or on a sprayed mortar lining for the reduction of train noise in rapid transit tunnels, particularly adjacent to the stations.

## **Bridges [1]**

### *Foundation*

Selection of foundation type must be based on an assessment of the magnitude and direction of loading, depth of suitable bearing materials, seismic activity, evidence of previous flooding, potential for liquid action, undermining or scour, swelling potential, frost depth, and ease and cost of construction.

Piling may be considered when footings cannot be founded on rock or on granular or stiff cohesive soils within a reasonable depth. Piles may be structural steel sections, steel pipe, precast concrete, cast-in-place concrete, prestressed concrete, timber, or a combination of materials. A steel foundation design must consider the possibility of corrosion, particularly in fill soil, low pH soil, and marine environment. Methods of protecting steel and steel reinforced concrete piling in corrosive environments include coating, wrapping, and cathodic protection.

A steel reinforced concrete pile foundation must consider the effect of sulfates, ground water or seawater, chlorides in soils, chemical waste, acidic ground water, and organic acids.

A timber pile foundation must consider the effect of decay from wetting and drying cycles and marine borers.

### *Retaining Walls*

Rigid gravity and semigravity walls can be constructed of reinforced concrete, while gravity walls can also be constructed of stone masonry or unreinforced concrete, or both.

Vertical wall elements may consist of discrete vertical elements and support retained soil with facing elements. Discrete vertical elements may include piles, caissons, drilled shafts, or augured cast piles. Structural facing may include wood, precast or cast-in-place concrete panels, wire or fiber-reinforced shotcrete, or metal elements such as sheet piles.

Mechanically stabilized earth systems may employ metallic strips or polymeric tensile reinforcements in the soil mass, and a discrete precast concrete facing.

Prefabricated modular wall systems generally employ interlocking soil filled reinforced concrete or steel modules or bins, which resist earth pressures by acting as gravity-retaining walls.

### *Super Structures and Fasteners*

Structural steels of all grades are selected with a modulus of elasticity of 200 000 kPa (29 000 000 psi) and a coefficient of linear expansion of 0.0000118 per °C (0.0000065 per °F).

Steel for pins, rollers, and expansion rockers may be carbon cold-finished standard quality, and steel forgings, carbon and alloy, for general industrial use.

Fasteners may be carbon steel bolts, power driven rivets, or high-strength bolts.

Weld metal should conform to the current requirements of the ANSI/AASHTO/AWS D1.5 Bridge Welding Code.

Cast steel should conform to AASHTO specifications for Steel Castings for Highway Bridges; Mild to Medium Strength Carbon Steel Castings for General Application; and corrosion-resistant Iron Chromium, Iron Chromium Nickel-based Alloy Castings for general application.

## **CORROSIVE ENVIRONMENTS**

Most of the materials used in transportation construction are exposed to one or more environments including atmospheric, soil, and water. The following section will outline the corrosive nature of each environment.

### **Atmospheric [3,15]**

Atmospheric corrosion is considered that which occurs from exposure of metals to atmospheric conditions, including precipitation and dew. Atmospheric corrosion damage includes general attack, cracking, and localized corrosion.

Although atmospheric corrosion has been recognized as a major cause of metal degradation for many years, it has been an ongoing challenge to make accurate predictions of the rate of atmospheric corrosion and the effectiveness of preventive measures.

Initial work done in this field showed that outdoor environments vary greatly in their corrosivity, that urban and industrial areas have substantially higher corrosion rates for most engineering materials than rural areas, and furthermore, that marine environments and locations within a mile or two of the ocean surf also suffer significantly higher corrosion rates than other inland areas.

It has been determined that sulfur dioxide and carbon dioxide from combustion of fossil fuels is the primary corrodent that differentiates industrial areas, and that chlorides from sea salt accelerated the corrosion in marine environments. In general, the acceleration of corrosion that occurs in marine atmospheres is different from that which occurred in industrial atmospheres in that it tends to cause localized corrosion in many alloys.

Recent atmospheric cleanup has caused the average sulfur dioxide concentration at the industrial ASTM Newark/Kearny

atmospheric exposure site to be lower than the rural ASTM State College site. Consequently, evaluation of the airborne contaminants from similar sites will enable engineers to select knowledgeably the appropriate material(s) and corrosion protection systems.

### Soils [4]

The characteristics of the soil are determined by the physical and mineralogical composition of the parent material, the contamination of the material over time by airborne salts and chemicals applied to the soil surfaces, and the natural processes of plant and animal life on and in the soil.

Chemical analyses of soils for corrosion purposes are usually limited to determination of the elements that are soluble in water. The base-forming elements are usually sodium, potassium, calcium, and magnesium. The acid-forming elements are carbonate, bicarbonate, chloride, nitrate, and sulfate. The nature and amount of soluble salts, together with the moisture content of the soil, generally determine the conductivity and corrosivity of the soil. The development of acidity in soils is a result of the natural processes of weathering and decay under humid conditions.

Bacteria may affect the chemical properties of soils. Certain types of bacteria are capable of fixing atmospheric nitrogen and converting nitrogenous material in the soil to a form useful for plant life. Other bacteria convert sulfur and sulfides to sulfates, and still others accomplish the reverse reaction.

The physical properties of soils important in corrosion are mainly those that determine the permeability of the soil to oxygen or air and to water. The particle size distribution of the soil is an important factor with respect to aeration and moisture content. In coarse texture soils such as sands and gravel, where there is free circulation of air, corrosion approaches the atmospheric type. Clay and silty soils are characterized in general by fine texture, high water-holding capacity, and by poor aeration and poor drainage. Variations in these characteristics within the same soil environment lead to higher corrosion rates compared to that experienced by atmospherically exposed materials.

#### *Factors Affecting Corrosion in Soils*

Since corrosion is an electrochemical process, it requires a potential difference between two points electrically connected and immersed in an electrolyte. Electrons flow from the anodic area through the metallic path to the cathodic area to complete the circuit. The anodic area is the most negative in potential and is the area that corrodes through the loss of metal ions to the electrolyte.

The factors affecting corrosion in soils are aeration, electrolyte, stray d-c currents, and miscellaneous:

1. Aeration affects the access of oxygen and moisture to the metal, consequently affecting corrosion. Oxygen causes corrosion by combining with the metal ions to form oxides, hydroxides, or salts of metal. If these corrosion products are soluble or removed from the anodic areas, corrosion proceeds, but if the products accumulate they may act as a protective layer to reduce corrosion or initiate localized corrosion because the corrosion products are more noble than the base metal.

FIG. 1

2. Electrolytes affect the flow of electrons. Moisture in soils helps the flow of electrons, thus promoting the corrosion process. The ions in the electrolyte determine the electrical conductivity as well as the acidity or alkalinity of the electrolyte, and the chemical reaction between the primary products of corrosion and the electrolyte.
3. The principal factor in the corrosion of metals in soils is the variation in potential that exists at different points or areas on the surface of the metal. Potential differences involve both the metal and the electrolyte. It may be affected by local variations in either one. The amount of current that flows through the cell as a result of the potential difference is dependent upon the electrical characteristics of the electrolyte and the polarization of the metal surfaces. The potential difference and the resulting corrosive current are not necessarily constant with time. The relative size of the anode and cathode areas is a factor in determining the rate of corrosion damage. For example, in a given environment, a small anode to large cathode area will always result in the highest penetration rate at the anode area.
4. Some of the miscellaneous factors affecting corrosion in soils are the effect of different soils in contact with the same metallic structure, different compaction and aeration in the case of backfill in a trench, and foreign material or stones in contact with the metal surface; bacterial action is another factor and is associated with aeration and the formation and presence of soluble salts. Porous backfills, such as sand and pea gravel, while giving good mechanical support to the structure, accelerate corrosion of metals buried in them by acting as "French Drains" providing ingress for aggressive surface pollutants such as fertilizers and de-icing salts.

### Waters [5,15]

At ordinary temperatures in neutral or near neutral water, dissolved oxygen is necessary for appreciable corrosion of iron. In air-saturated water, the initial corrosion rate may be high. This rate may diminish over a period of time as the iron oxide film is formed and acts as a barrier to oxygen diffusion. Since the diffusion rate at steady state is proportional to oxygen concentration, it follows that the corrosion rate of iron is also proportional to oxygen concentration.

In the absence of dissolved oxygen, the corrosion rate at room temperature is negligible both for pure iron and for steel.

Although in deaerated water iron does not corrode appreciably, the corrosion rate in some natural deaerated environments is found to be abnormally high. These high rates have been traced to the presence of sulfate-reducing bacteria. The bacteria thrive only under anaerobic conditions in the pH range of about 5.5–8.5. Certain varieties multiply in fresh waters and in soils containing sulfates, others in brackish water and seawater, and others exist in deep soils at temperatures as high as 60–80°C (140–175°F).

Sulfate-reducing bacteria reduce inorganic sulfates to sulfides in presence of hydrogen or organic matter, and are aided in this process by the presence of an iron surface. The aid which iron provides is to supply hydrogen which is normally adsorbed on the metal surface, and which the bacteria make use of in the reduction of  $\text{SO}_4$ . The bacteria therefore act essentially as depolarizers.

When corrosion is accompanied by hydrogen evolution (for example, iron corroding in hydrochloric acid), the corrosion rate doubles for every 10°C (18°F) rise in temperature.

When corrosion is controlled by diffusion of oxygen, the corrosion rate at a given oxygen concentration approximately doubles every 15–30°C (28–55°F) rise in temperature.

Since corrosion of ferrous metals in most environments involves both processes to some degree, in the absence of any other data, temperature is generally assumed to double the rate of corrosion every 10–15°C (18–28°F) below 80°C.

The effect of pH of an aerated pure (or soft) water on corrosion of iron at room temperature is high at the lower or acidic pH up to about pH of 4. It is stable between pH 4 and 10, then drops gradually to pH 14.

Within the range of about pH 4–10, the corrosion rate is independent of pH and depends only on how rapidly oxygen diffuses to the metal surface. The major diffusion barrier of hydrous ferrous oxide is continuously renewed by the corrosion process. Regardless of the pH of water within this range, the surface of iron is always in contact with an alkaline solution of saturated hydrous ferrous oxide, the pH of which is about 9.5. Within the acid region (pH 4), the surface pH falls, and iron is more or less in direct contact with the aqueous environment. The increased rate of reaction is then the sum of both an appreciable rate of hydrogen evolution and oxygen depolarization. Above pH 10, increase in alkalinity of the environment raises the pH of the iron surface. The corrosion rate correspondingly decreases because iron becomes increasingly passive in the presence of alkalis and dissolved oxygen. So long as oxygen diffusion through the oxide layer is controlling, which is the case within pH 4–10, any small variation in composition of a steel and its heat treatment, or whether it is cold-worked or annealed, has no bearing on corrosion properties provided the diffusion-barrier layer remains essentially unchanged. Oxygen concentration, temperature, and velocity of the water alone determine the reaction rate. These facts are important because almost all natural waters fall within the pH range 4–10. This means that whether a high- or low-carbon steel, or similarly a low-alloy steel, wrought iron, cast iron, or cold-rolled mild steel is exposed to fresh or seawater, all the observed corrosion rates in a given environment are essentially the same.

## CORROSION CONTROL TECHNIQUES

Seven primary corrosion prevention methods are available to reduce the corrosion of metals: material selection, electrical isolation, electrical bonding, environmental modification, inhibitors, coatings, and cathodic protection. Corrosion prevention methods are often used in conjunction with one another. Coatings are used to reduce current requirements in cathodic protection. Zinc is used as a cathodic protection system in coatings. The effects of two or more corrosion prevention systems can be synergistic or antisynnergistic. Two effects are synergistic if the combination of the two is more effective than the sum effect of the two.

### Material Selection

Alloying a metal with a noble metal can reduce its tendency to corrode. Alloys with active metals can reduce corrosion through passivity. A metal is considered passive when the potential for corrosion is large and the corrosion rate is small. Passivity is associated with a thin protective layer formed on the metal surface. An example is the use of an appropriate alloy of stainless steel in seawater.

### Electrical Isolation

Electrically separating one metal, which otherwise would be in direct contact with another dissimilar metal, can prevent the adverse effects of bi-metallic corrosion. A typical example is the use of di-electric unions where copper water pipe is connected to the steel tank of a hot water heater.

### Electrical Continuity

Where stray currents from a man-made source of direct current are a potential problem, metallic bonding the structure of concern to the source of the dc is often used to mitigate the corrosion that would otherwise occur. This is a common method of control where pipelines are subject to the adverse effects from stray currents generated by light rail transit systems, d-c welding machines, and impressed current cathodic protection systems installed on other nearby structures.

### Environmental Modification

Modification of the corrosion environment is a common control method. The corrosion environment can be made less damaging by the removal of active materials (oxygen or chemical composition of the electrolyte). The corrosion environment can be made less damaging by removing materials that reduce the extent or rate of formation of protective layers. A common example is the use of electro-chemical chloride removal systems on steel reinforced concrete structures.

### Inhibitors

A corrosion inhibitor is meant to be the addition of a chemical or chemicals to the fluid phase for its effect on the solid surface of the metal. In view of the fact that the corrosion inhibitor must be effective on the metal side of the

FIG. 2

metal/fluid interface, it is clear that a major aspect of corrosion inhibition is concerned with transport of the inhibitor to the interface. Also, the inhibiting particle must reach the solid surface to be effective, whether it is the material originally introduced or a derivative of the added substance. An example of this is the use of calcium nitrite as an admixed material in concrete, which will be exposed to high chloride environments.

### Coatings

Most coatings function by providing a resistive barrier between the metal to be protected and the environment. Common examples include coal tar epoxies, fusion bonded epoxies, and polyurethanes on buried steel pipelines and tanks. Some coatings provide protection by sacrificing themselves to protect the substrate metal. Galvanizing (zinc-coated) steel is an example. This is a form of cathodic protection. Some coating systems provide corrosion resistance by admixing a corrosion inhibitor to the coating prior to application.

### Cathodic Protection

Cathodic protection is an electrochemical polarization process that is widely and effectively used to limit corrosion. Simply stated, it is an electrical system whose energy operates in opposition to the natural electrochemical decomposition process of corrosion. All cathodic protection systems require the artificial development of an alternative corrosion cell with (-) electrons flowing from the artificially installed anode to the structure in the metallic path. It also requires the flow of (+) ions (atoms or molecules carrying electrical charge) from the anode to the structure by the electrolyte path and/or (-) ions in the opposite direction. For a constant current, the level of protection depends on the polarization slope of the cathodic reaction on the structure. Current can be supplied by a galvanic or impressed current system. In a galvanic system, the electrons flow because of the difference in half-cell potential between the metal of the structure and the cathodic protection anode metal, given that the anode metal is more reactive than the metal of concern. In an impressed current system, an

FIG. 3

a-c to d-c converter/power supply forces these electrons and ions to flow in the appropriate direction.

## SPECIFIC PROBLEM AREAS

### Highways

One example of the type of highway corrosion is the deterioration of culvert pipes. One of the materials used extensively is hot dip galvanized corrugated steel pipe. Accelerated corrosion on these culverts occurs on the invert of the pipe when an extremely aggressive water within the pipe is combined with a high flow rate providing an abrasive scouring action called "erosion-corrosion." For such conditions, remediation usually consists of paving the invert area.

### Tunnels

Many tunnel liners are made of cast iron rings. To date there is no known nondestructive method to test for graphitization on the outside surface of a tunnel. Ultrasonic methods were not effective because of the large graphitic grains. In one case, the length of graphitic grains were measured 1.1 mm (40 mils), and the wave length of sound used was 0.5 mm (18 mils) at the lowest frequency of 1 MHz. High scattering makes bistatic ultrasonic inspection methods unreliable, since the scattering within the specimen produces a background which when combined with increased attenuation of the ultrasound can obscure the backwall echo and make detection difficult. In another case, a large variation in sound velocity occurred between samples or between regions of the same sample. Since large variations in sound velocity correspond to large uncertainties in ultrasonic estimates of wall thickness, the observed grain size distribution raised questions about the suitability of ultrasonic methods for assessment of intact wall thickness. It is of interest to mention that the ultrasonically determined thickness consistently overestimated the thickness of the remaining wall thickness, which could lead to a false sense of security about the integrity of the liner section.

## Bridges

### *Deterioration of Concrete Bridges Due to Corrosion*

The primary cause for deterioration of concrete bridge components is the chloride-induced corrosion of the reinforcing steel. Wedging action resulting from the production of voluminous corrosion reaction products causes cracking and delamination at the steel rebar/concrete interface, ultimately leading to spalling of the concrete.

Normally, reinforcing steel is in a passive state due to the formation of a tenacious passive oxide coating called gamma ferric oxide on the steel surface created by the highly alkaline environment ( $\text{pH} > 12.5$ ) of concrete. However, the presence of chloride ions at the concrete/steel interface in excess of the reaction threshold level 0.5 kg to 1.0 kg of chloride ions/meter<sup>3</sup> concrete (1.0–2.0 lb of chloride ions/yard<sup>3</sup>) depassivates the steel, and corrosion will initiate. On bridges, the source of the chloride ion is usually deicing chemicals applied in the snow-belt areas in winter or salt spray with seawater in coastal areas.

### *Lead Paint [6]*

Highway agencies have been using lead-containing bridge paints for several decades. They have proven to be effective systems for protecting against corrosion and also are forgiving of surface preparation and application quality. Consequently, an estimated 70 % of existing highway bridges in the United States are painted with lead-containing systems. Unfortunately, lead compounds, including those used in bridge paint, are toxic to humans and other life forms. They are cumulative poisons that affect the central nervous system and can lead to debilitating illnesses and eventually death.

The major concern has been the potential entry of lead into the environment, and for this reason it has been regulated by the Environmental Protection Agency (EPA). The EPA has established national ambient air quality standards for lead at 1.5  $\mu\text{g}/\text{m}^3$  averaged over a 90-day period. Sand-blasting of paint containing lead frequently will produce airborne concentrations of lead greater than the maximum permissible by the EPA. However, normally these operations do not last as long as 90 days, resulting in a reduced average emission level. Another potential detrimental effect is the formation of silt deposits under the bridges, which can affect spawning grounds of fish. The pollution of soil by lead residues is a problem that tends to be localized, and good housekeeping can minimize this problem.

There is a variety of techniques that may be suitable for containing debris from the paint removal process. These include tarps and drapes, screens, rigid structure containments, dust collectors, vacuum blasting, power tools with vacuum attachment, and wheel blasting devices. The need for and efficiency of these techniques are highly dependent on the environmental conditions, structure configuration, and ability to take part or all of the structure out of service during the restoration process.

Waste disposal is a national problem extending beyond the scope of bridge paints. Procedures developed by other industries may be applicable to lead debris containment. The key to any approach is the economics of the processes. These numbers are often difficult to determine precisely because of the uncertain costs of hazardous waste disposal, and the larger uncertainties of whether a waste is hazardous to begin with.

It is important that the highway community continues to work with environmental agencies and regulators, because these groups usually have the final say in what is acceptable.

## TEST METHODS TO EVALUATE CORROSION

### Material Selection [7]

A large variety of materials, ranging from steel to concrete, is used by the engineer to construct bridges, roadways, tunnels, etc. The corrosion engineer is primarily interested in the chemical properties (corrosion resistance) of materials, but he or she must have knowledge of mechanical, physical, and other properties to assure desired performance. The properties of engineering materials depend upon their physical structure and basic chemical composition.

Selection of material must be done in conjunction with selection of the manufacturing method. It must be assumed that the material will be selected from among those candidate materials that meet all design and engineering requirements with emphasis on corrosion resistance or control, or both. Selecting a material for economy in manufacture involves consideration of several factors:

1. Raw material factors include chemical composition, form of mill product, size of mill product, material condition or temper, surface finish, and quality characteristics.
2. Processing factors include formability, machinability, weldability, response to heat treatment, and coatability.
3. General factors include quantity of material required, availability of grade and product form, plant standardization of grades and sizes, energy consumption, and availability of required processing equipment.

Because these factors are interdependent and strongly influenced by variables in the manufacture of the material and of the component made from it, none should be considered singly. Once all pertinent factors have been assembled, the different options should be evaluated for their effects on total cost. Standard specifications, such as those developed through ASTM, AASHTO, ASME, or NACE, may establish unified requirements for all of the selection factors described.

Corrosion tests are in two broad categories: (1) tests performed in the laboratory under controlled conditions, and (2) tests performed in the field under actual service conditions.

Tests performed in the laboratory give an early indication of what will happen in the field. These tests can be of a comparative nature where results are compared with known environments with known corrosion rates. These relative results can be very definitive. Field tests, on the other hand, take us one step closer to the end use. Some field tests will last from a few hours to a few days, while some ongoing testing/monitoring procedures may use months or even years.

### In-Service Monitoring

Monitoring the performance of materials while in actual service is very important, especially when it can be used to predict the life expectancy or remaining life.

### Atmospheric Environment [8]

One of the sensors used to measure the corrosivity of the atmosphere is the time-of-wetness. This is a moisture sensor that monitors the presence of surface moisture in conjunction with atmospheric corrosion testing. Both types Zn/Au and Cu/Au cells are equally effective. The time-of-wetness of a surface will vary not only from one locality to another and from one month or year to another, but also with type, size, and orientation of a specimen exposed to a given atmosphere.

### Soil and Natural Water Environments

Monitoring corrosion in soil and water extensively often uses reference electrodes. A reference electrode [9] is a pure metal in contact with a solution of known concentration of its own ion, and at a specific temperature develops a potential that is characteristic and reproducible; when coupled with another half-cell, an overall potential develops which is the sum of both half-cells.

Electrochemical sensors and techniques recently have been developed to test the corrosivity of the environment as well

as the corrosion rate of materials in several environments (Fig. 4). They have proven very useful and effective in predicting and controlling the corrosivity of the environment. One means gaining ever increasing use is the burial of small steel coupons of the same metal type as the structure in the same environment. The coupons are electrically connected to the structure and thus behave the same as the pipe itself. Metallic corrosion is usually an electrochemical process [10]. Electrochemical processes require anodes and cathodes in electrical contact and an ionic conduction path through an electrolyte. The electrochemical process includes electron flow between the anodic and cathodic areas, which quantify the rates of the oxidation and reduction reactions that occur at the surfaces. Monitoring this electron flow to or from the coupon provides the capability of assessing the kinetics of the corrosion process, including the continuing metal loss. These same coupons can be subjected to other electrochemical test methods for correlation with the current flow measurements. Finally, the coupons can be selectively retrieved for physical examination throughout the structure life.

Most forms of metallic corrosion, including uniform, localized, galvanic, dealloying, stress corrosion, and hydrogen-induced failure, can be tested by electrochemical techniques. Passivation, cathodic and anodic protection, and performance of barrier and sacrificial coatings on metals can be tested by electrochemical techniques [11]. Some of the more common techniques include Linear, ELogI and Tafel Polarization, Pitting Scans, and Variable Frequency Electrochemical Impedance Spectroscopy.

### Failure Analysis [12]

Failures of materials in service usually are traceable to misapplication resulting from: wrong choice of the material, improper treatment or fabrication of the material, an inadequately controlled environment, or improper design.

The technical literature is very reliable in helping the decision makers to select the appropriate material for the specific application and environment and can narrow the choice of materials to a manageable number of alternatives from which a final choice can be made quickly. Material suppliers are excellent sources of guidance in selection of proper alloys. Major suppliers of materials often maintain a staff of consultants to advise customers on the proper use of their material.

The sources of electrochemical driving force for corrosion reactions merit a special attention. The major causes for developing corrosion currents are given in Table 1.

**FIG. 4—Soil sensor for electrochemical measurements, made of two reference electrodes, two working electrodes, and three counter-electrodes, all connected to their own shielded twisted pair cable. At the terminal box, they can be accessed in various combinations depending on the tests required. It also has two platinized titanium electrodes equally spaced with the reference electrodes to allow for the measurement of the average soil resistivity by the Wenner four-electrode method. The two working electrodes can be designed to represent the different conditions of the structure being monitored.**

SOURCE: Fontana, M. G. and Greene, N. D., *Corrosion Engineering*, McGraw Hill, New York, 1967.

Much can be deduced from examination of materials that have failed in service. It is often possible by visual examination to decide what corrosion mechanisms have been responsible for the material degradation and what corrective measures are required to solve the problem. Fontana and Greene list eight common forms of corrosion based on the physical appearance of a corroded part, given in Table 2.

The corrosion engineer often finds himself confronted with a corroded sample taken from a failed structure. Usually some stopgap action must be taken immediately so that the structure can be placed in service as soon as possible. Then a decision must be made for further action to avoid recurrence of the failure. Often this involves planning and conducting a test program under simulated conditions to determine the factors responsible for the failure [18].

## TEST METHODS

### ASTM [13]

The following standards have been developed by ASTM Committee G 01 on Corrosion of Metals and is annually updated and printed in Volume 03.02, Section 3. They can be used to test materials selected for a transportation application:

- G 33 Practice for Recording Data from Atmospheric Corrosion Tests of Metallic-Coated Steel Specimens.
- G 46 Practice for Examination and Evaluation of Pitting Corrosion.
- G 50 Practice for Conducting Atmospheric Corrosion Tests on Metals.
- G 51 Test Method for pH of Soil for Use in Corrosion Testing.
- G 52 Practice for Exposing and Evaluating Metals and Alloys in Surface Seawater.
- G 57 Method for Field Measurement of Soil Resistivity Using the Wenner-Four Electrode Method.
- G 60 Method for Conducting Cyclic Humidity Tests.
- G 78 Guide for Crevice Corrosion Testing of Iron-Base and Nickel-Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environments.
- G 79 Practice for Evaluation of Metals Exposed to Carbonization Environments.
- G 84 Practice for Measurement of Time-of-Wetness on Surfaces Exposed to Wetting Conditions as in Atmospheric Corrosion Testing.
- G 87 Practice for Conducting Moist SO<sub>2</sub> Tests.
- G 91 Practice for Monitoring Atmospheric SO<sub>2</sub> Using the Sulfation Plate Technique.
- G 101 Guide for Estimating the Atmospheric Corrosion Resistance of Low-Alloy Steels.

- G 104 Test Method for Assessing Galvanic Corrosion Caused by the Atmosphere.
- G 109 Test Method for Determining the Effects of Chemical Admixtures on the Corrosion of Embedded Steel Reinforcement in Concrete Exposed to Chloride Environments.

### NACE Standards [14]

The following standards have been developed by NACE:

- RP0169 Control of External Corrosion on Underground or Submerged Metallic Systems.
- RP0172 Surface Preparation of Steel and Other Hard Materials by Water Blasting Prior to Coating or Recoating.
- RP0281 Method for Conducting Coating (Paint) Panel Evaluation Testing in Atmospheric Exposures.
- RP0187 Design Considerations for Corrosion Control of Reinforcing Steel in Concrete Structures.
- RP0287 Field Measurement of Surface Profile of Abrasive Blast Cleaned Steel Surfaces Using Replica Tape.
- RP0290 Cathodic Protection of Reinforcing Steel in Atmospherically Exposed Concrete Structures.
- RP0390 Maintenance and Rehabilitation Considerations for Corrosion Control of Existing Steel Reinforced Concrete Structures.

### Others

The main organization that develops standards for transportation is the American Association of State Highway and Transportation Officials (AASHTO) [1].

For standard specifications for transportation materials and methods of sampling and testing: Part 1 of the standard is for specifications and Part 2 of the standard is for conducting the tests.

## DISCUSSION

### Unresolved Issues

Many of the existing infrastructures contain elements in need of research to reveal long-term potential problems. This section enumerates two of these issues as an example to stimulate the engineer's thinking.

**Case No. 1:** Many of our infrastructures are built on soils containing aggressive chemical ions and moisture, supported on steel piles. There are no available data on the corrosion rate of such piles exposed to these types of soils, nor the long-term durability of such combinations, nor is there any standard test procedure for evaluating this over the structural life. It should be noted that one set of soldier piles supporting a 60-story office building in a marine environment was recently inspected by basement sidewall excavation. The 27 in. web by 14 in. flange by 75 ft deep piles had suffered more than 15 % web loss in less than three years service.

**Case No. 2:** Many tunnels were built with cast iron rings flanged and bolted together. One surface of the cast iron is exposed to soils and water of various corrosivity. It is

necessary to have a nondestructive method to evaluate that surface, especially to determine the degree of graphitization. Ultrasonic equipment was used unsuccessfully, in some cases, where the graphite fibers were large enough to obstruct the sound signal.

**Case No. 3:** Most bridge decks and substructures constructed or rehabilitated within the last 20 years have been constructed with fusion-bonded epoxy coated reinforcing bars. There are some test data that support the effectiveness of this methodology in solving the chloride induced corrosion activity over the first 20 years of use. These researchers hypothesize that the reduction in corrosion is due both to the coating serving as a barrier between the steel surface and chloride contaminated concrete, and also due to the coating electrically isolating the upper mat rebar from the lower mat rebar eliminating what is commonly called "macro-cell corrosion" [16,17].

On the other hand, other researchers have proposed that while the coating is indeed stopping the corrosion where the coating is intact, that the process will activate after 20–30 years of service when the chlorides permeate the new concrete where coating holidays exist. If this is the case, and presuming accelerated attack occurs, perforation of the bar will occur at a substantially increased rate. The corrosion product may not be of sufficient volume to spall the concrete providing visual warning of the problem, but could result in substantial structural strength degradation over time.

## Outlook for the Future

The advancements in many of the technical fields, especially the computer field, are impacting positively on corrosion testing, detection, design, monitoring, and life prediction. For example, one solution for Case No. 1 could be the design of a sensor and a computerized program to monitor the corrosion rate at different sites and at different depths. The information can be fed to another computer program to project future performance. The model can be updated with the results of the new data collected until the program is perfected. A sketch of such a sensor developed for use in soils is shown in Fig. 1.

Case No. 2 may be resolved by either a technique using magnetic flux leakage, or a technique using time-resolved infrared radiometry.

The principle of the first technique can be understood if a plate is thought of as the "keeper" of an electromagnet of field strength approximately 1000 gauss (tesla). Depending on the permeability of the keeper material and the thickness of the plate, most of the magnetic flux from the magnet will be confined within the plate itself. There is, however, a component of the field exterior to the plate. As the plate thickness changes, so does the exterior leakage field. Correspondingly, if the plate contained a nonmagnetic inclusion or had a part of its backwall replaced with nonmagnetic material, then the leakage flux would increase in the region of anomalous properties. As an extension of the method, if the field of the electromagnet varies sinusoidally, then the degree of flux penetration depends on the frequency of the field variation. In both cases, moving the electromagnet over the plate and measuring the leakage flux permits regions

that have graphite or other magnetic intrusions to be found. It may be possible to determine the degree of graphitization of an entire tunnel plate by varying the field modulation frequency at a fixed position in a single integrated measurement.

The principle of the second technique can be briefly explained as the measurement of surface temperature change of a solid object via infrared radiometry while the object is heated with an external source. The changes in temperature are typically less than 20°C. Since the surface temperature depends on the balance between the rate of heat input from the source and the rate of heat loss into the object, it will change as the rate of heat loss changes. In the case of a plate backed with another material of different thermal properties, the surface temperature changes with time during the heating pulse and then changes again at a time corresponding to the thermal diffusion time through the plate. The sign of the latter change depends on the relative thermal characteristics of the plate and the backing material. By measuring the time at which this second change occurs, the plate thickness can be determined.

Case No. 3 requires additional systematic testing, exhumation, and critical examination of existing structures involving dozens of bridge structures from different regions throughout the U.S. The structures, constructed with fusion bonded epoxy coated bar, must have been in service in high chloride environments for between 20 and 30 years. Part of the structure selection process has to include determination that chlorides have permeated to the rebar mat level at sufficient concentration levels to activate substantial corrosion if the structure were constructed from bare rebar.

If we are expected to resolve some or most of these problems, research funds will have to be budgeted and research programs will have to be developed and encouraged.

# Marine—Piers and Docks

James F. Jenkins<sup>1</sup>

## COMMONLY USED CONSTRUCTION MATERIALS AND SELECTION CRITERIA

THE MOST COMMONLY USED materials for construction of piers and docks are reinforced or prestressed concrete, steel, and timber. Composite materials are used primarily for mechanical applications such as pipe hangers and railings, but the use of composite materials in structural applications such as piling and gratings continues to increase. Other metals, primarily stainless steels and aluminum alloys, are often used for mechanical applications and fasteners. The primary criteria for selection of materials for marine piers and docks are past experience, cost, and availability. However, corrosion testing is used to evaluate candidates for many specific applications. This testing is commonly in the form of the evaluation of either full-scale or subscale components, but direct testing of base materials is also performed in many cases.

### Reinforced and Prestressed Concrete

The interactions between reinforced concrete, prestressed concrete and the marine environment are very complex. From the corrosion standpoint, the primary consideration is protection of the embedded steel from attack by the aggressive marine environment. This protection may rely solely on the ability of the ordinary concrete cover to protect the embedded steel or may be augmented by the addition of corrosion inhibitors to the concrete, by coating of the steel, by cathodic protection, or a combination of one or more of these methods.

While ordinary carbon or alloy steel is used most commonly for reinforcement or prestressing of concrete, stainless steels have been used in construction of piers with special service requirements [1] or in critical areas on other structures [2]. Other materials such as reinforced plastics and nickel-copper alloy 400 have been used also to a limited extent or have been proposed for use as reinforcement for concrete in piers and docks. Stainless steel clad carbon steel is a relatively new development and its use for reinforcement of marine structures currently is being evaluated. Epoxy-coated carbon steel reinforcement also has been used successfully in many marine applications, but some failures have occurred.

### Carbon, Alloy, and Stainless Steel

Carbon and low-alloy steels are the predominant alloys used for construction of waterfront structures. In most applications the steels are protected by protective coatings in the atmospheric, splash, and intertidal zones (including metallic and elastomeric sheathing) and are protected by either cathodic protection alone or by a combination of coatings and cathodic protection in the immersion zone. Use of stainless steels is limited predominantly to mechanical applications rather than structural applications. The use of stainless steel fasteners is common.

### Timber

Timber is used widely in the construction of waterfront facilities. Its durability is limited by biological attack, primarily due to marine boring organisms in the immersion zone and termite and fungus attack in the atmospheric zone. Due to recent success in reducing levels of pollutants in many harbor facilities, marine borer activity has increased greatly in many harbors. In many cases, the life of timber in these locations has decreased to the point that alternative materials are more cost-effective for repair or new construction. In addition, many of the traditional treatments for timber to reduce biological attack are now regulated for environmental reasons, thus either making them unavailable or more costly to use. Thus, although timber continues to be used, it is being supplanted by other materials particularly in the submerged and intertidal zones of many marine structures.

### Other Metals

The use of metals other than steel usually is limited to mechanical rather than structural applications. Aluminum alloys are, however, sometimes used in structural applications, primarily in the atmospheric zone. Copper-nickel and nickel-copper alloys are used also for sheathing of structures in the intertidal and splash/spray zones.

### Composite Materials

Composite materials such as reinforced plastics are used widely in mechanical applications in waterfront structures. They also have been used in the repair of timber structures as structural bracing. Composite pilings have good resistance to environmental deterioration, but their mechanical

<sup>1</sup>P.E., 329 Drake Street, Cambria, CA 93428

properties such as strength and creep resistance have limited their acceptance for marine structures.

### Selection Criteria

The most commonly used criteria for selection of materials for use in waterfront structures are least first-cost and prior experience. This is unfortunate as least first-cost construction usually does not result in least life-cycle costs when maintenance, repair, and facility life are considered. Prior experience also may not be reliable, particularly if the experience is from a different geographical location or from a structure with a different set of service conditions. In addition, differences in materials, changes in the local environment, and differences in corrosion protection and maintenance may limit the applicability of past experience to new construction.

Selection criteria may be based on a required level of corrosion resistance to meet safety and reliability requirements. More likely, selection will be based on economic considerations. Least first-cost usually is not appropriate and some type of evaluation of life-cycle cost is preferred. There are many methods for making such life-cycle cost analyses. The discounted cash flow method is ideally suited to life-cycle cost analyses that consider both first costs and costs for maintenance and repair over the system lifetime [3].

### Cost of Material

The procurement costs of the materials for initial construction are often the easiest cost data to obtain, and too often are used inappropriately as the sole criteria for materials selection. Materials costs based on a price per pound or other quantity usually are very misleading when used in lieu of total system costs to evaluate alternatives. Usually, in order to ensure that actual life-cycle costs are minimized, other cost factors such as maintenance and repair must be considered.

### Cost of Final Structure

All costs of the structure must be considered, such as the cost of materials, transportation of the materials to the construction site, construction, supervision, and inspection. From this information, first costs for the entire structure may be determined and compared for each of the alternative materials being considered. For example, when comparing the relative cost of a structure reinforced with an epoxy-coated steel versus stainless steel, the labor costs associated with the handling and inspection of the epoxy coated steel, along with the labor and materials costs for retouching of the inevitable coating defects and damage prior to pouring the concrete must be considered. In the case of stainless steel, these labor costs are avoided.

### Cost of Maintenance and Repair

Over the projected life of the structure, the total cost of maintaining the structure, including the costs of inspection, maintenance, and repair, easily can exceed the initial cost. Economic analyses such as the discounted cash flow method allow the designer to minimize the annual cost of ownership of a system by balancing the various costs involved. In many cases, reduction in maintenance through

the use of more expensive, but more corrosion-resistant materials in initial construction can reduce life-cycle cost. Economic analysis allows the designer to balance these cost factors properly.

### Strength

Strength alone is a poor criterion for selection of materials for waterfront structures. High-strength materials usually are not only more expensive than lower strength materials, but are often more susceptible to brittle fracture or corrosion. In many designs for marine structures, stiffness rather than strength is the primary structural consideration and low-strength materials used in thicker sections can have an advantage in section stiffness that can compensate for their lower strength.

### Deterioration Resistance

Resistance to deterioration is an important factor, but the cost of corrosion-resistant materials must be balanced against the benefit of their use in terms of extended life or reduced costs of maintenance and repair.

### Constructability

Construction of marine structures requires specialized knowledge and equipment. This knowledge and equipment exists for traditional materials and configurations. Traditional materials and construction techniques have evolved based on successful experience. With changing materials availabilities and costs, as well as changing environmental considerations, costs of maintenance, and other economic factors, these traditional materials and construction techniques may not be the most cost-effective alternatives. Innovative designs and materials that require variations from traditional construction practices may involve considerable extra expense in the development of new construction techniques and equipment. While the extra costs associated with the use of innovative materials or construction techniques may be justified, the costs must be established and evaluated in terms of overall life-cycle costs.

## CORROSIVE ENVIRONMENTS ENCOUNTERED

Waterfront structures are exposed to a variety of marine environments. The resistance of materials to each of these environments may vary considerably, as well as applicability of various forms of corrosion control in mitigating the anticipated corrosion. The waterfront environment can be divided into five exposure zones: sediment, immersion, intertidal, splash/spray, and atmospheric. In most cases, a single type of material will be used for the sediment, immersion, and intertidal zones. In some cases another material may be used for the splash and spray and atmospheric zones of the structure. An example of this would be the use of a reinforced concrete deck over steel pilings. Due to differences in corrosion activity between these zones, the corrosion performance of many materials is substantially different when exposed to two or more of these zones. Figure 1, taken from Ref 4, shows the result of a classical experiment where the corrosion of a continuous strip of

FIG. 1—Variation of corrosion with depth-isolated versus continuous specimens [4].

carbon steel exposed to three marine environment zones is compared to the corrosion of electrically isolated carbon steel panels exposed in the same zones. In this case, corrosion in the intertidal zone on the continuous strip was reduced compared to that of the isolated specimens due to an oxygen concentration cell where the continuously immersed steel was anodic to the steel in the intertidal zone. This effect also is commonly encountered in steel reinforced concrete pilings where the most severe corrosion frequently is encountered just below the intertidal zone where a difference between the highly oxygenated intertidal zone and the lower oxygen immersed zone results in a differential oxygen cell. If the damage is repaired by partial jacketing, the jacket simply drives this differential aeration cell lower on the piling and accelerated corrosion occurs at the bottom of the partial jacket. In other cases, corrosion can be greatly accelerated at the boundary between these zones such as at the mud line.

### Sediment Zone

The sediment zone consists of those portions of the structure that are exposed continuously or intermittently to the bottom sediments. The depth of this zone may vary due to natural sediment movement or to dredging. The sediments usually are characterized by a low oxygen content. In some cases, the conditions are anaerobic and hydrogen sulfide may be present. Cathodic protection can be effective in controlling corrosion of many metals in the sediment zone.

Coatings frequently are used to control the corrosion of steel in the sediment zone by application of the coating prior to emplacement of the structure. *In-situ* coating maintenance usually is not practical.

### Immersion Zone

In this zone the material is exposed continuously to seawater, or in estuarine locations, to brackish or fresh water. Behavior of materials in this zone differs depending upon the geographical location of the structure but is controlled predominantly by the salinity, oxygen content, temperature, and intensity of fouling. Cathodic protection can be effective in controlling corrosion of many metals in the immersion zone. Coating prior to emplacement frequently is used in the immersion zone, but *in-situ* maintenance coating usually is not cost effective due to the high cost of underwater surface preparation and the difficulty of effective coating application.

### Intertidal Zone

Corrosion in the intertidal zone is affected by intermittent immersion conditions. This zone is characterized by the composition of the immersion environment, the composition of the atmospheric environment, and the nature of the tidal variation. When exposed to the air, large amounts of oxygen are available. This affects the corrosion of many metals. For steel exposed to both the immersion and

intertidal zone, corrosion in the intertidal zone may be reduced due to “galvanic coupling” between the steel exposed to both the immersion and intertidal zone. For reinforcing steel in concrete, the intertidal zone is usually the zone of maximum attack. Cathodic protection is effective in mitigating corrosion in this zone and also can mitigate the accelerated attack caused by interzone interactions. Protective coatings, including metallic sheathing, frequently are used to control corrosion in the intertidal zone. Coatings can be maintained either by the use of rapidly curing coatings applied at low tide, coatings that can cure underwater, or preferably by the use of cofferdams that can provide a dry environment for surface preparation, coating application, and curing.

### **Splash and Spray Zone**

The splash and spray zone is often the most aggressive zone on marine structures. In this zone the high availability of oxygen is not offset by galvanic interaction between zones. In many cases, the highest rate of attack is at the boundary between the intertidal and the splash and spray zone. Conventional cathodic protection of steel in this zone generally is not effective, but the steel in reinforced concrete may be protected effectively in this zone using cathodic protection as the concrete is electrically conductive due to entrained water. Coatings frequently are used for corrosion control in the splash and spray zone.

### **Marine Atmosphere Zone**

Above the splash and spray zone, the marine atmospheric environment is characterized by the climatic conditions such as temperature and relative humidity, but is still usually contaminated by salt. Protection of steel in the marine atmosphere zone is primarily through protective coatings. Cathodic protection can be used to protect reinforcing steel in atmospherically exposed concrete.

### **Other Substances Encountered**

The real environment of marine piers and docks contains many potentially corrosive substances. These materials must be considered in the testing and selection of materials. They are of primary importance in the atmospheric zone but also can be of importance in other exposure zones. For example, bird droppings are an inevitable feature of marine pier and dock environments. They can be extremely aggressive toward many materials, particularly the aluminum alloys. Materials handled during loading and unloading operations also can be corrosive and potential contact of these materials with the construction materials must be considered during materials testing and selection.

## **TECHNIQUES USED FOR CORROSION CONTROL**

For permanent installations, few commonly used construction materials have sufficient inherent resistance to corrosion to perform adequately without the use of some

form of corrosion control. In order for the selection of the most cost-effective combination of materials and corrosion control techniques, the efficacy of the corrosion control technique for specific materials must be determined. This normally requires testing. This testing may be performed by accelerated laboratory tests in order to find the most promising alternatives. The most promising alternatives may be compared in field tests.

### **Protective Coatings**

Protective coatings are widely used for controlling corrosion of marine structures. For proper selection of coatings, many factors must be considered including the zone of exposure, degree of shelter, the substrate to be protected, and the potential for recoating. Testing for determination of coating performance must consider all of these pertinent factors in order to provide a valid basis for selection of coatings. While there are no specific standards for coating piers and docks, standards for other marine structures such as NACE RP-0176 (Corrosion Control of Fixed Offshore Platforms Associated with Petroleum Production) contain information that is applicable to marine piers and docks.

### **Cathodic Protection**

Cathodic protection is used widely for the protection of submerged steel in waterfront structures. It also can provide considerable benefit in the intertidal zone and can even reduce the usually high corrosion rate experienced at the boundary between the intertidal zone and the splash and spray zone. Cathodic protection also is used to prevent corrosion of the soil side of steel in marine structures such as sheet steel bulkheads. Cathodic protection also is effective in the control of the corrosion of reinforcing steel in concrete in all exposure zones in waterfront structures. Particularly for impressed current systems, it is important to select materials for the cathodic protection system components such as rectifiers and junction boxes with consideration of the environment to which they will be exposed. When considering cathodic protection, periodic inspection and maintenance is required for proper system operation. The costs for inspection and maintenance must be considered in the overall cost of cathodic protection. While there are no specific standards for cathodic protection of piers and docks, information in NACE RP0176 (Corrosion Control of Fixed Offshore Platforms Associated with Petroleum Production) and NACE RP-0187 (Design Considerations for Corrosion Control of Reinforcing Steel in Concrete) contain information that is applicable to marine piers and docks.

### **Design**

Proper consideration of materials performance in the design process can be the difference between a successful structure and an unsuccessful one. Often simple changes, such as the inversion of structural shapes to provide drainage as shown in Fig. 2, can result in significant improvement in corrosion performance with little or no effect on

FIG. 2—Effect of orientation on drainage.

cost. When selecting materials, the design features that affect the actual environment that will be encountered must be considered. Elimination of crevices and pockets and avoidance of sharp corners and edges where coatings are to be used are other common design features that can improve resistance to deterioration in many structures.

## SPECIFIC PROBLEM AREAS

Rational design and materials selection must be based on an economic analysis of alternatives. In order to determine the actual costs of the alternatives, projected system life and the need for inspection, maintenance, and repair costs must be known. While there is a great deal of information available on the performance of a wide variety of materials in marine environments, these data are difficult to apply to the projection of system life. Most of the quantitative information on corrosion performance is for isolated specimens and does not address the interzone interactions and effect of design features that occur on real structures. Most of the limited amount of published information derived from the evaluation of actual structures is not quantitative and thus is difficult to use in the design of new structures.

## USE OF TEST METHODS TO EVALUATE CORROSION

There are standard test methods that can be used in the corrosion testing of materials in marine environments, but for corrosion testing of components and systems, the applicability of standard methods is predominantly limited to the evaluation of the corrosion that occurs rather than the overall performance of the tests.

### Materials Testing

Techniques and standards for testing of materials for marine structures are described in Chapter 12 of this manual. These techniques and standards generally are suitable for testing in sediment, submerged, and intertidal environments.

Atmospheric testing techniques and standards described in Chapter 11 are applicable to the splash/spray and atmospheric zones. As indicated previously, these tests give useful information for the design of marine structures but in many cases, additional information on the performance of components and component interactions is needed. Full-scale or subscale testing usually is required for the adequate assessment of techniques and materials for maintenance and repair of marine structures. This testing is required not only to determine the performance of the systems but also to derive cost information applicable to the specific application.

## Performance Assessment

Through the inspection of existing marine structures, significant information on the performance of materials and protective systems can be obtained. Routine inspections for condition assessment or maintenance control are seldom adequate for determining material performance. Quantitative performance data are required for assessment of material performance. Many standard methods are available for the assessment of the various forms of materials deterioration and are given in the section on Field Tests in Seawater (Chapter 12) and in other sections of this manual. Nondestructive testing techniques also can be used for quantitative assessment of deterioration of marine structures. ASTM Standards D 610, D 1654, G 40, G 46 and G 56 contain information that can be used to evaluate corrosion on marine structures. ASTM G 15 gives the terminology applicable to the evaluation on many forms of corrosion that commonly occur on marine structures.

For the assessment of the performance of cathodic protection in mitigating corrosion on marine structures, it is important that adequate records are maintained regarding the performance of the cathodic protection system. In many cases, when the performance of cathodic protection systems is being assessed, it is apparent that the cathodic protection system is capable of providing effective corrosion control but has not been operated and maintained properly. This must not be interpreted as an inadequacy of the technology, but only as the inability of the operators to properly apply the technology.

The performance of many systems for maintenance and repair associated with corrosion of marine structures is difficult to assess, as the performance of these systems is highly dependent upon the skill of the maintenance and repair personnel. In evaluation of such systems, it is advisable to evaluate the effect of personnel skill levels on the efficacy of the techniques and material by using the same maintenance and repair technique applied by several individuals or crews. The primary evaluation should be of the ability of the systems to mitigate corrosion, so the corrosion assessment techniques and standards outlined previously can be used.

## TEST METHOD DEVELOPMENT

*In-situ* exposures using actual structures, full-scale structural elements, or subscale structural elements exposed to the appropriate zones at the specific site for the actual

structure are preferred. Similar tests performed at a different test site usually will provide adequate results if the locations have similar environmental conditions.

Environmental simulation is less desirable as many of the actual environmental conditions as well as the interaction between materials exposed to more than one exposure zone are difficult to simulate in the laboratory.

Accelerated testing has little application to the generation of the performance data necessary for the evaluation of systems for marine structures. It is difficult, if not impossible, to quantitatively predict structure life from such tests. Accelerated testing, however, can be useful in screening candidate materials and systems so that the best alternatives can be evaluated in *in-situ* tests.

Standard laboratory type electrochemical tests can be used to establish the mechanisms of corrosion of materials in marine structures but have little application in providing the performance data required for design, maintenance, or repair. Electrochemical techniques such as ASTM G 71 (Guide for Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes) can be used to determine field performance of materials in practical field structures. In addition, many electrochemical techniques can be adapted to field conditions for the assessment of the performance of components and systems in actual or subscale structures. Examples of such techniques are electrochemical techniques for determining the activity of reinforcing steel in concrete in atmospheric exposures (ASTM C 876).

## TEST METHODS/STANDARDS

Other than applicable standards for the evaluation of corrosion of materials and materials testing in surface seawater given in Chapter 12 of this manual, there are few if any industry-wide standards for evaluating the performance of materials or systems for marine structures.

## OUTLOOK

Due to rapid changes in the cost and availability of conventional construction materials used for marine structures, and the development (or increasing acceptance of) newer materials such as stainless steel for concrete reinforcement and composite materials, the economic balance reflected by conventional practice often is no longer valid. The challenge is to realistically evaluate alternative systems in terms of performance and cost so that new construction and the maintenance and repair of existing structures can be accomplished in a manner that adequate service is obtained at the lowest life-cycle cost.

### Need for Testing Standardization

While the lack of standardization of methods for testing of materials and systems has not been a severe impediment in the past, there is an increased need to rely upon evaluation of actual in-service structures to better establish system life for marine structures. It would be highly beneficial if the marine structure industry would develop a cooperative effort to evaluate existing structures using standardized procedures and techniques so that the information could be published in a form that could be used effectively for future design, maintenance, and repair.

# Electric Power

*P. Mayer<sup>1</sup> and A. D. Pellgrini<sup>2</sup>*

CORROSION OF ELECTRIC POWER transmission lines has been a primary cause of in-service equipment degradation. An integral part of the effort to mitigate corrosion processes is the use of standard and nonstandard testing methods for their prevention, correct recognition, and damage extent determination. Corrosion testing also serves multiple functions in equipment design, manufacture, and service life extension.

In the following, a detailed description of all applicable test procedures and devices that have been employed in the corrosion control of power lines will not be attempted. Instead, attention will be directed principally to those corrosion testing methods that are used most frequently in the current practice.

Power transmission is a mature technology that evolved into an optimized system with a very high reliability, based on utilization of traditional low-cost materials and maintenance procedures with a predictable performance. As a result, line equipment can reliably reach the designed operating and asset life with periodic maintenance. Most of the equipment, which has been properly maintained, is in such a good condition at the end of its design life that it is often more economic to refurbish rather than dismantle and build new lines. Consequently, the most frequently employed corrosion tests are those used for quality control during manufacture, performance maintenance scheduling, and condition assessment and service life extension.

## MATERIALS OF CONSTRUCTION AND ENVIRONMENT

The power transmission system in North America consists of equipment that has been built up since the turn of the century. Although the design of individual components has changed, the materials of construction remained virtually the same: steel and cast iron (bare, painted, or galvanized), aluminum alloys and copper alloys, porcelain, glass, and wood. Coatings and inhibitors are used to enhance the corrosion resistance of these materials.

For atmospheric service, zinc dust paints (linseed oil or alkyd) continue to outperform other classes of paints, as

they can be applied directly over some rust with minimal cleaning. For underground service, single component asphaltic and two-compound epoxy mastics are applied most frequently, since a higher degree of surface cleaning, such as abrasive blasting, is feasible. These are, in general, a group of coatings formulated to inhibit corrosion, rather than just provide physical barrier and aesthetic characteristics. In addition, cathodic protection is used to permanently protect the buried steel components. The continued integrity and soundness of the power system components depend mainly on the control of corrosion.

The severity of metal loss and aging process is governed by aggressivity of the environment. Traditionally, the atmospheric environment is classified as industrial, marine, urban, or rural. Recently, efforts have been made to classify the atmospheric corrosivity based on atmospheric data (estimated) or standard panel testing (measured). The atmospheric corrosivity categories range from benign to severely corrosive. This classification is practical for design, scheduling of maintenance, and refurbishment planning.

Corrosion of buried power line components is governed by diffusion of dissolved oxygen in the water entrapped in the soil, resulting in average corrosion rate of zinc and bare steel to be about the same. Copper and lead, which form barrier corrosion films, show lower corrosion rates in the same soils. In marshy and swampy areas, anaerobic sulfate-reducing bacteria (SRB) enhance significantly the corrosion rate of steel. The soils are classified into five classes, which have been found to correlate with the soil resistivity as measured by the Wenner four-pin method. The soil corrosivity range from very low (Resistivity > 10 000  $\Omega\text{cm}$ ), low (Resistivity > 5000 to 10 000  $\Omega\text{cm}$ ), moderate (Resistivity > 2000 to 5000  $\Omega\text{cm}$ ), high (Resistivity > 1000 to 2000  $\Omega\text{cm}$ ), to very high (Resistivity < 1000  $\Omega\text{cm}$ ).

## CORROSION PROBLEMS

Numerous studies have shown that corrosion is the main cause of power line deterioration, and that it affects all components [1].

There are ten broad classes of significant corrosion damages that lead to loss of component function or integrity, or both, if not remedied:

- General corrosion
- Pitting corrosion

<sup>1</sup>Principal Engineer, Kinectrics, 800 Kipling Avenue, Toronto, Ontario, M8Z 5S4, Canada.

<sup>2</sup>President, EP and CC Consulting, 42 Aragon Avenue, Toronto, Ontario, M1T 1X7, Canada.

- Crevice corrosion
- Exfoliation corrosion
- Stress corrosion
- Corrosion fatigue
- Hydrogen embrittlement
- Galvanic corrosion (dissimilar metal, differential, aeration)
- Stray-current corrosion
- Coating damage and deterioration
- Microbial induced corrosion
- Rotting of wood.

## TECHNIQUES FOR CORROSION CONTROL

The main emphasis in power line corrosion control is to select materials resistant to a specific environmental attack and to galvanize ferrous materials (carbon steel and cast iron). This approach is used in the design of new lines and is supplemented by selective use of coatings and cathodic (galvanic) protection. The in-service methods are limited to application of coatings, cathodic protection, and inhibitors.

## NEW POWER LINES

Corrosion testing of new line equipment is often introduced in the product qualification stage and as a part of the quality control during manufacturing. To a lesser degree, corrosion tests are performed to select or screen materials of construction.

For example, connectors used in power equipment and overhead lines are qualification-tested to determine the component resistance to stress corrosion cracking (SCC). Aluminum alloy connectors are subjected to an immersion test [2], in which the connector is attached to the largest conductor for which it is designed and torqued to the reusable stress value, and then immersed in a 7 % NaCl solution for a period of 300 h. For a component to pass, there shall be no visible signs of SCC. This testing is done after the materials were screened using ASTM tests (ASTM G 44<sup>3</sup>, G 47<sup>4</sup>, and G 64<sup>5</sup>) to establish the immunity to SCC. Similarly, copper base alloy connectors [2] are subjected to and shall pass the requirements of the “season cracking” test (ASTM B 154<sup>6</sup>). Attempts have been made in the past to substitute this test with the Mattsson’s solution test (ASTM G 37<sup>7</sup>), due to toxicity and stringent requirements for the disposal of mercurous nitrate.

Other line components, such as conductors, tower steel, and bolts, are not tested routinely for resistance to corrosion, although there is a need for corrosion durability improvements of these components.

<sup>3</sup>Practice for Evaluating Stress-Corrosion Cracking Resistance of Metals in 3.5% Sodium Chloride Solution.

<sup>4</sup>Test Method for Determining Susceptibility to Stress-Corrosion Cracking of High-Strength Aluminum Products.

<sup>5</sup>Classification of Resistance to Stress-Corrosion Cracking of Heat-Treatable Aluminum Alloys.

<sup>6</sup>Method for Mercurous Nitrate Test for Copper and Copper Alloys.

<sup>7</sup>Practice for Use of Mattsson’s Solution of pH 7.2 to Evaluate the Stress-Corrosion Cracking Susceptibility of Copper-Zinc Alloys.

Accelerated weathering tests are being used to develop new long lasting polymeric insulators to replace high-density ceramic and glass.

Tests to determine the aggressivity of environment are used in design of new lines to determine the need for additional corrosion protection of the lines to resist particularly polluted atmosphere, aggressive soil, or water. Coatings and cathodic protection are frequently added to safeguard the lines and to match the service life of other components.

## IN-SERVICE LINES

In recent years, the emphasis of power line operators is on predictive/preventive maintenance to ensure reliable and safe operation. Breakdown maintenance is becoming a thing of the past. Crucial elements of this approach are consistent application of the most up-to-date technological know-how and systematic surveillance of the power lines.

Corrosion tests are an integral part of a wide variety of methods (techniques and tools) employed to establish the condition of overhead lines for maintenance and refurbishment. Although the information needs for maintenance are different from those for refurbishment, the investigation and surveillance methodologies are practically identical. To establish an overall condition of the line for a refurbishment program, a detailed “snapshot in time” is needed. In comparison, a limited periodic survey continuing across the whole system over a long duration is needed to determine maintenance requirements.

The most common method of power line inspection is visual assessment, performed from the ground by foot-patrol or from the air during routine aerial (helicopter) surveillance. This is a very efficient method, but must be used in conjunction with instrumental, chemical, biological, electrical, and electrochemical methods, followed by laboratory failure analysis to obtain a true picture of the line condition.

## FOUNDATIONS

Degradation of foundations enclosed in concrete or grillage-type can be best assessed by excavation. This is the most rigorous method, since it allows the determination of the extent and type of corrosion attack, including possible involvement of microbial induced corrosion. To minimize excavation at every footing, tests to indicate the presence of stray current or a galvanic corrosion, or both, can be used. The stray current and galvanic corrosion can be identified by a potential survey of the footings with a Cu/CuSO<sub>4</sub> half cell reference electrode. The magnitude of the stray current can be measured by using special clip-on d-c ammeters.

New galvanized steel footings, when buried, will exhibit a potential between -0.85 and -1.1 V with reference to Cu/CuSO<sub>4</sub>. After the galvanizing is lost, the newly exposed bare steel surface will have potential between -0.5 and -0.7 V. Corroded steel with a heavy scale will have a potential between -0.3 and -0.5 V. In addition to a potential survey, an electrochemical polarization technique can be used to determine the rate of galvanic corrosion [3]. The device operates by passing a small current between the tower footing

and a probe inserted into the ground nearby. These currents disturb the electrochemical processes at any active corrosion site, and the resulting changes in potential are measured with reference to Cu/CuSO<sub>4</sub> half cell in contact with the ground close to the footing. The level of current required indicates severity of the corrosion process in progress. This instrument provides results that are a useful guide to the relative condition of the footings, but not absolute measure of the metal wastage [3]. For concrete footings, the magnitude of the potential readings is greatly affected by the high resistance of the concrete. Experience and knowledge is required to interpret these readings.

## TOWERS AND TOWER STEEL

Determining correctly the type and extent of power line tower component damage is essential for proper assessment of the structure condition and recommendation for plan of action to ensure safe and reliable operation. Component damage is defined as degradation leading to the loss of the load bearing capacity, which would, if not remedied, lead to tower failure.

The type and extent of the component damage caused by corrosion are determined during field inspection from [4]:

- Detailed visual inspection,
- Measuring loss of cross section and physical shape deformation,
- Measuring protective (galvanizing and/or painted) coating loss, and
- Measuring contamination of surfaces.

During visual inspection, the type of corrosion damage is established at locations where the protective coating was lost. The extent of corrosion damage must be accurately determined to: assess structure's fitness for service condition; estimate the remaining service life; and recommend maintenance, refurbishment, or replacement of the line. The techniques, methods, and instruments used to gage corrosion attack for field or laboratory use, or both, are readily available. These inspection and testing methods are standardized to ensure reproducible results.

The breakdown of protective coating occurs usually by a combination of erosion and physical damage. The extent of erosion (loss of thickness) of an intact coating can be measured by a variety of methods. These include destructive scribing, magnetic pull-off, magnetic flux, eddy current, ultrasonics, etc., gages.

The extent of protective paint loss can be determined using standard methods for evaluating the degree of rusting on steel surfaces (see ASTM D 610<sup>8</sup> and Ref 5) and paint coating degradation (ASTM D 660<sup>9</sup>, D 662<sup>10</sup>, D 714<sup>11</sup>, and D 772<sup>12</sup>).

<sup>8</sup>Test Method for Evaluating Degree of Rusting on Painted Steel Surfaces.

<sup>9</sup>Test Method for Evaluating Degree of Checking of Exterior Paints.

<sup>10</sup>Test Method for Evaluating Degree of Erosion of Exterior Paints.

<sup>11</sup>Test Method for Evaluating Degree of Blistering of Paints.

<sup>12</sup>Test Method for Evaluating Degree of Flaking (Scaling) of Exterior Paints.

Changes in color are an indication of the galvanized coating condition. As galvanizing weathers, it loses its brightness and turns dull gray and becomes progressively darker gray as it gradually erodes. Appearance of yellow and reddish-brown color indicates that the pure zinc coating was lost and the corrosion reddened the zinc-iron amalgam layer. This is the optimal time to paint the structure [6]. When the coating is lost, the surface of the bare steel becomes covered with dark-brown corrosion scale. The galvanizing is considered failed when 5 % of the surface is covered by a dark-brown color. As the percentage of this corroded area increases, higher levels of cleaning are required to remove the corrosion scales, before the paint coating can be applied. If the corrosion is allowed to progress to more than 50 % of the surface area, other corrosion problems, such as hydrogen embrittlement, cracking, pitting, reduced cross section, etc., evolve. Paint coating may no longer be feasible and structure replacement becomes the only option.

The contamination of tower surfaces with aggressive chemicals can lead to enhanced corrosion and deterioration of protective coatings. Although the methods of detection and determination of surface contamination are not standardized, several test methods [7] are accepted by the industry. Surface contamination analysis kits are available [8] to measure pH, chlorides (detection limit 40 ppm) and soluble ferrous ions (detection limit approximately 3 ppm). In most cases, these detection limits are sufficient to establish aggressivity of the operating environment and surface cleanliness before painting.

## WOOD STRUCTURES

Wood pole condition has traditionally been assessed by the sound of an impact on the pole or from the condition of a cored sample of the wood. Recent developments include nondestructive test procedures that offer more refined assessment of wood pole conditions. A device based on the measurement of the passage of ultrasound through the wood was developed [9]. The condition of the pole can be assessed, provided there is an adequate database to calibrate the signal delay time against the measured strength of the particular wood species. The device can only indicate the condition at and above the ground line.

## HARDWARE

Corrosion is a contributing factor to wear damage to hardware caused by aeolian vibration. This damage is very difficult to detect from the ground [10]. Initially, X-ray equipment was taken to the field to enable internal cracks or strand breaks to be detected within clamps or conductors. This was a cumbersome, slow, and costly procedure, and had to be done with the line de-energized. More recently, a line technique using a gamma ray source on hot sticks has been developed that permits detection of the internal damage in a practical manner.

In highly corrosive environments, such as marine, effect of atmospheric corrosion on hardware materials can be

established by using 'CLIMAT' devices [11]. These devices consist of aluminum wires wound tightly around threaded plastic rods. The mass loss of the wire during a 90-day period is measured to indicate the level of corrosion activity and allows mapping of the area in terms of air aggressivity index (Atmospheric Corrosivity Index). These data are valuable to schedule maintenance and evaluate new materials.

## INSULATORS

In marine and highly polluted environments, the steel components of insulators corrode at an accelerated rate. Galvanizing protection is lost early, and the remaining steel forms voluminous oxide scales. The growth of these scales induces large stresses in the ceramic parts leading to cracking, spalling, and failures [12]. The ceramic insulator cracking can be detected by electrical resistance testing.

## OVERHEAD GROUND WIRES

Galvanized steel overhead ground wires age during service, and corrosion is a major contributing factor to this process. A simple technique, based on standard torsional ductility test (ASTM E 558<sup>13</sup>), is being used to determine the remaining life. Based on experience, wire that would break in less than six turns is at the end of the service life and immediate replacement is required. Levels of corrosion and torsional strengths provide planning tools for replacement of the overhead ground wires before in-service failures occur.

## CONDUCTORS

The service life of power lines is limited by the deterioration of the most vulnerable component: the conductor. The deterioration processes include a combination of creep, fatigue, and corrosion. Both traditionally used materials in conductor construction (aluminum alloy and galvanized steel) are prone to corrosion. It was shown [13] that the aluminum alloys suffer from accelerated corrosion in coastal areas, while inland in industrial areas the corrosion attack of the galvanized steel core is most prevalent.

The helicopter borne infrared sensors were employed [14] to inspect power lines for aluminum corrosion. This method is suitable for detection of severe corrosion with many strands distorted and bulging. Early corrosion damage cannot be effectively detected.

The condition of the steel core is a key indicator of the remaining useful life of the conductor. The first step in this assessment is the use of a galvanized steel corrosion detector on in-service lines. Two similar devices have been developed and tested: one based on eddy current technique [15] and the second one using electromagnetic induction [16,17] principle to detect the conductor damage. Following this assessment, samples are removed from the lines and remaining service life is determined using the torsional ductility test (ASTM E 558).

To prioritize maintenance and refurbishment and to select the most suitable materials of construction, the aggressivity of the environment must be established. Passive corrosion tests are the most economical way of mapping large areas accurately. The CLIMAT test [11] and a test [13] comprising of zinc cans and aluminum wire twisted around steel bolts are used most frequently.

## CLOSING REMARKS

Most of the corrosion problems in power transmission can be reliably detected and assessed using conventional and well-established corrosion testing instruments, practices, and methods. The data, from field or laboratory, are essential information for the implementation of ameliorative measures. The corrosion control technology available today can, in a cost-effective way, protect reliability, performance, and safety of transmission lines.

# Nuclear Power

*George J. Licina<sup>1</sup>*

MINIMIZING CORROSION IS a primary objective of nuclear power plant design. Such plants use corrosion-resistant alloys and high purity and well controlled water chemistries in critical systems to achieve that objective. Despite such measures, nuclear plants have experienced localized corrosion and environmentally assisted cracking in several plant components. These corrosion events have had significant ramifications on plant operability due to the extremely stringent requirements on component reliability and containment of radio-nuclides. Standards devoted to assessing susceptibility to localized corrosion and stress-corrosion cracking (SCC) have been used to qualify materials and remedial countermeasures. In many cases, the evolution of nuclear plant designs has required development of new standards.

## BACKGROUND

Nuclear power plants convert heat energy from the fission of uranium ( $^{235}\text{U}$ ) into high-quality steam. The steam is used to run large steam turbines and generate electricity. Large amounts of electric power can be produced inexpensively with very long refueling intervals (nominally 18 months or more) and small operating staffs. These typically large plants (600–1200 MWe) are an excellent source for providing “base load” electricity; however, their large size and the long time from design to commercial operation represent a huge investment of time and resources.

The total quantity of fuel material used and the volume of wastes generated by a nuclear plant per kW is very small; however, the radioactive nature of much of the waste requires that they be contained and closely monitored well beyond the life of the plant. The potential dangers of radioactivity to operating personnel, the general public, and other living creatures dictate designs with multiple barriers to the release of fission and activation products. The reliability of each barrier must meet exacting standards to assure that releases to the environment, including leaks to the air or water supply, do not occur.

Corrosion problems in nuclear plants have almost always been associated with localized corrosion phenomena or environmentally assisted cracking. For example, steam generator tubes in pressurized water reactors (PWRs) have experienced wastage and thinning, SCC, intergranular attack,

pitting corrosion, and “denting.” In boiling water reactors (BWRs), recirculation system piping has been degraded by intergranular stress corrosion cracking (IGSCC), especially at weldments. Irradiation assisted stress corrosion cracking (IASCC) has degraded reactor internal structural components. The zirconium alloys used for fuel cladding have been subject to hydriding, SCC, underdeposit corrosion (for example, under crud), and nodular corrosion. The occurrence of rapid general corrosion, pitting, underdeposit corrosion, and microbiologically influenced corrosion (MIC) have prompted increased attention to nuclear service water systems.

## MATERIALS OF CONSTRUCTION AND SPECIFIC CONCERNS

### General

Reliability is far and away the major concern with components in nuclear power plants. Component reliability must be assured for plant safety and to protect the investment in the plant. The very stringent regulations related to release of radioactivity to the environment drive much of the materials selection, environmental controls, and inspection requirements of nuclear plants. Unlike fossil-fueled plants, where repairs of leaking or flawed components are a routine fact of life, the availability of diverse and redundant systems for containment of radioactivity requires a far greater reliability of systems and components in nuclear systems.

### Materials of Construction

#### Primary Systems

Both BWRs and PWRs use zirconium alloys for fuel cladding. The “neutron economy” afforded by low cross section materials, such as zirconium, is critical for efficient operation of the reactor’s core. Zirconium alloys also exhibit good resistance to corrosion in water/steam environments as well as to the high-temperature fission products (the fission of the uranium produces iodine, cesium, cadmium, etc.). The fuel cladding thus represents the first containment barrier to radioactive products. Fuel cladding is also subject to high heat fluxes. The effects of heat flux and neutron and gamma irradiation can be synergistic with the aggressiveness of the high-temperature water environment, producing corrosion

<sup>1</sup>Associate, Structural Integrity Associates, San Jose, CA 95118.

effects that are more severe than those encountered out-of-reactor or in nonheat transfer applications.

Reactor internals include both fixed and movable components. Examples of such components are control rods (movable), in-core instrumentation (fixed and movable), the core shroud, core plate, jet pumps, top guide, and steam separators and steam dryers (all fixed). Austenitic stainless steels are used for the majority of these components for their corrosion resistance. In other specific applications such as in the control rod drives and jet pumps, precipitation-hardened nickel-base alloys (for example, Alloy X-750, UNS N07750) are used where greater corrosion resistance and strength are required.

### Reactor Coolant Systems

Heat transport system piping in most PWRs (Fig. 1) is fabricated from carbon and low-alloy steels, for strength and economy, and clad with roll bonded or weld deposited corrosion-resistant cladding (either stainless steel or high-nickel alloys).<sup>2</sup> Nickel-base alloys are used extensively as weld fillers for cladding and for joints between alloy steels and stainless steels for their superior corrosion resistance.

The primary coolant in PWRs is circulated through the core, where it absorbs heat, through the reactor coolant piping, and to the steam generators where it transfers its heat to a second, high-purity water loop. The water in the secondary loop is heated to steam. That steam is expanded in the turbine where the thermal energy is converted to mechanical energy in order to generate electricity.

The piping arrangement in a BWR is different from that of a PWR. In the BWR, only a single coolant loop is used (Fig. 2). The same water that is heated in the core to produce steam is expanded in the turbine. The water is further cooled in the condenser and is returned to the core as feedwater. Water is rapidly recirculated through the core at about seven to ten times the mass flow rate of steam, most often using jet pumps. Flow from the recirculation pumps "drives" the jet pumps, which have no moving parts. About a third of the flow from the vessel is returned to the recirculation loop. Water in the recirculation loop (Fig. 3) is pumped through a header, through riser pipes, and discharged to the jet pumps, providing the jet pumps' driving flow. In the jet pumps, water in the downcomer region is accelerated through the jet pump, then discharged into the lower core plenum.

Flow proceeds from the lower plenum, through the core. The steam and water are separated; the steam is then dried and passed to the turbine. Other flow (see above) returns to the recirculation system. Feedwater is introduced to the annulus between the core shroud and reactor vessel (Fig. 4). The recirculation system piping is a primary pressure boundary for the high-pressure, high-temperature reactor coolant. Type 304 stainless steel was selected for recirculation system piping and numerous other auxiliary systems (such as the reactor water cleanup system, residual heat removal system, core spray, and other emergency core cooling systems) for its corrosion resistance and adequate mechanical properties. Failures of weld heat affected zones

<sup>2</sup>Stainless steels, typically Type 304, are used in many PWR plants.

FIG. 1—Diagram of a typical PWR piping arrangement [1].

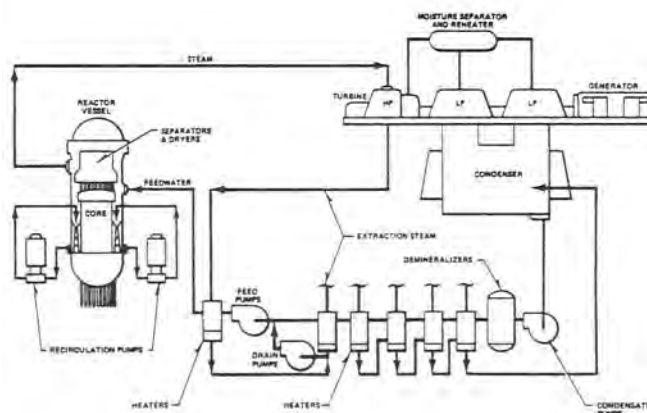

FIG. 2—Diagram of a typical BWR piping arrangement. (Courtesy of GE Nuclear, San Jose, CA.)

(HAZs) by IGSCC in the oxidizing environment resulting from water radiolysis in the core have shown the selection of these stainless steels, at least grades with carbon contents of 0.04 % and above, to have been a poor choice. Remedies, implemented in the most recent designs and in some retrofits, involved the use of special grades with very low carbon contents to avoid sensitization (and higher nitrogen to compensate for decreased mechanical strength), special welding procedures to minimize sensitization, and other remedial procedures to reduce residual stresses at welds. Decreasing the oxidizing power of the high-temperature water environment has also been implemented. This is accomplished by injecting hydrogen into the feedwater to recombine with the oxygen produced by radiolysis.

The BWR also uses some carbon steel and low-alloy steel for steam and other piping (to avoid IGSCC, when corrosion resistance is adequate) and a limited amount of nickel-base alloys (e.g., for reactor vessel/piping safe ends).

### Pressure Vessels and Heat Transfer Components

The key pressure vessels in the PWR system were discussed in the prior section, Reactor Coolant Systems. PWR vessels, including the reactor vessel, steam generator shells,

BWR reactor pressure vessels operate at much lower internal pressures than those of a PWR, of the order of the saturation pressure of steam at reactor operating temperatures (1000 psi/6.89 MPa at 288°C). As a result, BWR reactor vessels (Fig. 6) can be much larger than those of PWRs, which permits much of the equipment (such as jet pumps, steam driers, and steam separators) to be contained within the vessel. These pressure vessels are fabricated from low-alloy steels (SA-533, Grade B; SA-508, Class 2; UNS K12539, K12766) for strength and economy and weld clad with stainless steel for corrosion resistance.

The steam generators in PWRs provide the boundary between the primary (i.e., radioactive) and secondary (non-radioactive) systems. Service experience has proven the steam generator to be a key, if not the key piece of equipment for PWRs. Corrosion problems in the steam generators have been the principal cause of PWR downtime.

Nickel-base alloys (Alloys 600, 690, and 800; UNS N06600, N06690, and N08800) are most commonly selected for steam generator tubes for their good heat transfer properties and excellent resistance to all forms of corrosion. The thin-walled steam generator tubes have no corrosion allowance; hence, essentially any degradation constitutes a failure of the tube.

Like the steam generator shell, tubesheets are fabricated from low-alloy steels for their strength and economy. In some designs, the tubesheets are clad with stainless steel or nickel-base alloys for corrosion resistance.

On the secondary side of the steam generator (i.e., where the steam is actually generated), carbon steel tube support plates have been used (Fig. 7). This selection was based upon economics since the support plates have minimal structural function and represent a small area exposed to the coolant; the amount of iron released to the system from corrosion of the spacers can easily be accommodated by the cleanup system. Selection of carbon steel support plates (for example, SA-515, Grade 6; UNS K02401) proved to be a poor choice. Corrosion of the support plates, especially those with drilled holes, resulted in a thick, adherent magnetite corrosion product. The magnetite buildup caused a significant change in support plate dimensions (a decrease in the size of the holes), producing stresses that were sufficient to deform ("dent") steam generator tubes. Ferritic or martensitic stainless steel tube support plates are used in newer designs.

#### *Power Conversion and Auxiliary Systems*

The power conversion system and the balance of plant components for nuclear plants are similar to those for fossil plants with a few significant differences. First, fossil plants are generally much smaller than nuclear plants; hence, many of the key components in the power conversion system are smaller. Second, fossil plants generally operate at significantly higher temperatures (i.e., steam may be superheated from a few degrees to hundreds of degrees). The requirements on the power conversion system are, therefore, much different. The great emphasis on reliability of nuclear units often affects design and materials selection of power conversion or balance of plant components. Finally, the "diverse and redundant" design philosophy inherent in the design of nuclear plants requires greater numbers of heat exchangers, pumps, and valves, and far more piping in the

**FIG. 3—BWR recirculation loop. (Courtesy of GE Nuclear, San Jose, CA.)**

and pressurizer (Fig. 5), operate at pressures of the order of 2000 psi (13.8 MPa) and temperatures of up to 625°F (330°C). These vessels are fabricated from low-alloy steels (for example ASME SA-302, Grade B; SA-533, Grade B; SA-508, Classes 1, 2, and 3; UNS K12022, K12359, K12042, and K12766) and clad (usually weld clad) with stainless steels or nickel-base alloys. The alloy steel provides adequate strength at a reasonable cost for the thick-walled vessels. The stainless steel cladding provides corrosion resistance.

balance of plant than in a fossil-fired unit of comparable power output. Many of these systems operate very infrequently. The most common operational conditions for many of these systems is a monthly or quarterly demonstration of their operability to assure their functionality in the event of an accident.

Nuclear units use all of the commonly used condenser materials including brass (particularly Admiralty and aluminum brass), copper-nickel (90-10 and 70-30), stainless

steels, and titanium tubes, and Muntz metal and stainless steel tubesheets. Many retubed condensers have used specialty alloys such as titanium or the so-called super ferritic (high chromium; very low carbon; molybdenum contents to 4 %) or super austenitic (basically 20 % Cr-25 %Ni and up to 6 %Mo) or duplex stainless steels to eliminate pitting, SCC, and MIC. Tube replacements, with titanium or super stainless steels, have been performed most often in saline cooling waters; however, the critical nature of some heat

FIG. 7—PWR steam generator tube support plate designs [11].

exchangers and the insidious nature of underdeposit corrosion and MIC have prompted the use of such alloys in freshwater-cooled systems.

Carbon and low-alloy steels are most commonly used in the condensate system for economy and their adequate resistance to corrosion. Austenitic stainless steels have also been used in some systems and in key components. Copper alloys have also been used in some locations, although much less frequently.

Copper alloys (Admiralty, copper-nickel) and austenitic stainless steels are the most commonly used materials for feedwater heater tubing based upon their resistance to general and localized corrosion, erosion-corrosion, and SCC, and adequate heat transfer performance [1,2]. Carbon and low-alloy steels are most often used for the shells of such heaters for economy and availability.

Much of the materials selection for service water systems and closed cooling water systems is dictated by the water source (e.g., carbon steel for fresh waters; coated or lined steel, copper alloys, or stainless steels for saline waters). Coatings, linings, copper alloys, stainless steels, super austenitics, super ferritics, and titanium have been used for replacements.

### Failure Modes

Fine cracks or localized regions of attack, resulting from SCC, corrosion fatigue, or localized corrosion, are the most common corrosion failure modes in nuclear facilities. Small leaks can be a major concern in nuclear power plants where the release of radioactive products to the environment or leakage of extremely expensive materials such as heavy water from CANDU plants must be avoided. The CANDU plants are a type of heavy water moderated process using natural uranium; the name is an acronym for Canadian Deuterium Uranium. The other major concern with small cracks or fine pits is their potential to act as initiation sites for cracks that could lead to large leaks or unstable cracking and loss of coolant events. Almost without exception, the toughness of the alloys used for piping and vessels is sufficiently high that nuclear piping and vessels are structurally

stable, even with such flaws present. This assurance of "leak-before-break" is a critical criterion of nuclear plant reliability.

Radiation buildup, the result of general metal loss to the heat transport system and the deposition of activated corrosion products on metal surfaces, can represent a serious corrosion concern unique to nuclear plants, as radiation levels can limit worker exposure and hinder maintenance. The dissolution of metal and subsequent loss of the metal to the system also has other potential ramifications as maintenance activities such as refueling operations depend upon a high degree of water clarity. Nuclear plants are designed with minimal corrosion allowance on heat transfer surfaces, unlike the large fireside corrosion allowance designed into fossil-fueled plants. The relatively low operating temperatures, high purity water, and the extensive use of corrosion-resistant alloys permit the waterside corrosion allowances to be minimized. This is driven by requirements for water clarity and radiation buildup. Since much of the in-vessel maintenance must be performed using water for shielding, the clarity of the water is extremely important.

### TYPICAL ENVIRONMENTS, METALLURGICAL CONDITIONS, AND CORROSION PROBLEMS

The PWR primary system operates at  $-320^{\circ}\text{C}$  and 13.8 MPa, with a room temperature pH of approximately 10 (6.8 to 7.4 at temperature), and a hydrogen overpressure to suppress radiolysis. Boric acid is added for reactivity control (i.e., higher concentrations early in a fuel cycle; progressively lower as the enriched uranium is depleted). LiOH is added for pH control. The PWR primary system environment is relatively benign, even at the temperatures and pressures at which the system operates. Some components, particularly steam generators and control rod drive mechanism penetrations, have experienced primary water stress corrosion cracking (PWSCC), a phenomenon first discovered by Coriou in the 1960s [3]. Cracking is intergranular and does not appear to be associated with any particular metallurgical anomaly. The major concerns with PWSCC are radioactive contamination of the non-radioactive water/steam environment (e.g., from steam generator leaks) or the potential for a loss of coolant event from cracking in control rod drive mechanism attachments to the reactor vessel head.

PWR steam generators are exposed to the high-pH, hydrogen-rich primary water environment on the tube side (inner side) and high-purity, deoxygenated water on the secondary side. The method for corrosion control in the secondary circuit has evolved from a coordinated phosphate treatment to the all volatile treatment (AVT) that is used presently. Different AVT treatments have included hydrazine and ammonia, hydrazine and morpholine, and the use of alternate amines. Crevices on the secondary side, where impurities can concentrate, and other locations where deposits develop thermal gradients that enhance the concentration of impurities, have produced aggressive local environments (e.g., oxygen concentration cells, both acidic and caustic pH excursions) that have led to pitting, IGA, and SCC [1,2,4]. Figure 8 summarizes steam generator failure history.

**FIG. 8—Steam generator failure history [12].**

The single-cycle BWR historically has used very high purity water (conductivity  $<1\mu\text{S}/\text{cm}$ ) at essentially a neutral pH. More recent experience has shown that control to levels far less than  $1\mu\text{S}/\text{cm}$  ( $\sim 0.10\mu\text{S}/\text{cm}$ ) can be achieved in large operating plants. The radiolytic decomposition of water in the BWR core, however, produces oxidizing species (oxygen and hydrogen peroxide) that make the environment far more aggressive, particularly to the heat affected zones of stainless steel welds. All these factors produce a mildly oxidizing environment that, in concert with the sensitized microstructure and tensile stress, produce IGSCC of austenitic stainless steel.

In both PWRs and BWRs, the carbon steel feedwater train can be susceptible to flow-assisted corrosion and erosion-corrosion effects, especially at extremely low oxygen concentrations. Thinning of this piping, generally at areas of high turbulence, is dependent upon temperature, pH, and oxygen content. Oxygen additions are made to some feedwater lines to assure the formation of a protective magnetite film.

The main heat removal system (for example, the main condenser and associated equipment) and service water systems (which provide cooling for auxiliary equipment such as pumps, room coolers, chillers, etc., fire protection, and reactor heat removal systems used under accident and other shutdown conditions) for both BWRs and PWRs are exposed to environments that are controlled by the site's water source; that is, the cooling water may be seawater, brackish water, or a fresh water (lake, river, or pond). Fresh waters may range from the acidic to the highly alkaline. The pH and concentration of dissolved minerals (particularly calcium and magnesium salts) or metals (manganese or iron) can have a strong influence on the corrosivity of the water. Corrosion under deposits and MIC can result in a variety of such environments. Oxygen and flow rate are key factors in determining the aggressiveness of the environment. Very high flow rates produce flow-assisted corrosion and, eventually, erosion-corrosion, especially on copper alloys and carbon steels. Low flow rates encourage deposition and underdeposit corrosion and MIC.

The importance of corrosion in these balance of plant (BOP) systems increased tremendously for nuclear plant owners in the 1980s. Leakage and functional failures in safety-related and nonsafety-related cooling systems as a result of general corrosion, localized corrosion (especially

underdeposit corrosion), and MIC became critical issues. Several plants in the United States have completely replaced service water system piping, others have initiated planning for such a replacement, and the remainder have been faced with the need for local repairs, often on buried piping that is essentially inaccessible. Utilities are in the process of learning the importance of monitoring for corrosion and deposition and the necessity for early detection and actions to mitigate corrosion. The phenomenon of MIC is even more complex since the presence of living organisms makes it extremely dynamic. Many of the standard approaches to monitoring and control are not applicable. Similarly, the toxicity of many of the standard water treatments for biological control have significant environmental and administrative ramifications on storage and discharge. Most of the methods for testing MIC susceptibility in the laboratory or in service are still under development.

## TESTING FOR CORROSION

### Purpose of Testing and Types of Tests

Corrosion tests are performed for selection or qualification of materials (including materials to be used for repairs or replacements), for monitoring (to assess corrosion or to track process controls such as water treatments), or to supplement and assist with failure analyses.

Streicher [5] has identified five categories of corrosion test methods:

1. Plant service (i.e., how components behave in actual service)
2. Tests in process streams or cooling waters
3. Laboratory tests in plant solutions
4. Laboratory tests with reagent chemicals in place of plant solutions
5. Mechanism tests

Test types 1 or 2 are most useful for monitoring of performance in existing facilities. These test types are most useful for evaluating the performance of existing or candidate replacement materials or for monitoring mitigation treatments. Type 2 tests may include immersion or electrochemical tests. Corrosion (or SCC) may be accelerated by loading the specimen, forming a crevice (using a washer or other means), or by increasing temperature. Test types 3 and 4 have been used and continue to be used to qualify materials for various service environments including those where general corrosion, localized corrosion, or SCC are concerns. The corrosive conditions may be enhanced by using more concentrated solutions, higher temperature, greater aeration or acidity, creviced conditions, applied electrochemical potentials, or stress. Mechanism tests (Type 5) often incorporate environments or loading conditions that have little correspondence to plant conditions; however, they have been formulated to provide a useful indication of a particular characteristic that may be correlated with long-term service exposure. For example, the pitting resistance of stainless steels and nickel-base alloys may be compared by using a ferric chloride solution to determine the critical temperature

above which pitting or crevice corrosion occurs (ASTM G 48, Test Methods for Pitting and Crevice Corrosion Resistance of Stainless Steels and Related Alloys by Use of Ferric Chloride Solution), by determining the key electrochemical potentials for pit initiation and pit growth (hysteresis loop) in chloride solutions (ASTM G 61, Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron, Nickel, or Cobalt-Based Alloys), or using the electrochemical technique for determining the critical pitting temperature (ASTM G 150, Test Method for Electrochemical Critical Pitting Temperature of Stainless Steels) [6,7]. These values are not directly applicable to plant service but provide a useful basis for comparing different alloys.

Similarly, ASTM A 262, Practices for Detecting Susceptibility to Intergranular Attack in Austenitic Stainless Steels, is a mechanism test used to screen alloys for their resistance to intergranular attack (IGA) associated with the precipitation of chromium carbides. This standard has been used to rank alloys and treatments for their relative degree of sensitization and to infer their resistance to IGSCC. ASTM A 262 provides a method for evaluating the sensitization of stainless steels. Both IGA and IGSCC have been shown to be strongly dependent upon sensitization.

## Test Methods

The majority of the corrosion testing done for the initial qualification of materials in the environments encountered in nuclear power plants was based upon that predominant in fossil-fueled power plants and in nuclear-powered submarines where water is the heat transfer fluid. The extensive use of corrosion-resistant alloys, the lower temperatures used in nuclear plants, and the carefully controlled or high-purity environments of nuclear plants suggested that corrosion problems should be at a minimum. Early work, to qualify materials for the first generation of reactors, indicated that localized corrosion and SCC would not be expected in BWR or PWR environments. Those tests showed that control of chlorides and other aggressive anions would avoid corrosion problems. Those tests did not include some of the subtle environmental effects produced in the nuclear plants such as radiolytic decomposition of water in the BWR core to produce hydrogen peroxide and oxygen or the aggressive underdeposit environment in PWR steam generators. Many of the tests used to evaluate SCC resistance of material/environment pairs used deformation-controlled loading conditions (U-bends or C-rings) and test times of the order of thousands of hours. Such methods include:

- ASTM G 30, Practice for Making and Using U-Bend Stress Corrosion Test Specimens
- ASTM G 38, Practices for Making and Using C-Ring Stress Corrosion Test Specimens
- ASTM G 39, Practice for Preparation and Use of Bent-Beam Stress Corrosion Test Specimens
- ASTM G 49, Practice for Preparation and Use of Direct Tension Stress Corrosion Test Specimens
- ASTM G 58, Practice for Preparation of Stress Corrosion Test Specimens for Weldments

The constant deflection methods were, in many cases, inadequate to predict the corrosion effects that would be encountered in long-term service in the various reactor and coolant systems. For example, in constant deflection tests, load relaxation at temperature results in a much lower stress level in the specimen and a less aggressive test.

The slow strain rate test (SSRT) was developed to overcome the deficiencies of deformation-controlled SCC tests. Experience with turbine rotor steels had revealed that U-bends, C-rings, and the like might not crack in environments that would produce cracking in long-term service. Even constant load tests (actively loaded specimens exposed to aggressive environments) would underpredict SCC susceptibility when tests were run for times of the order of (only) thousands of hours. In the SSRT, a tension specimen is actively loaded at a slow, nearly constant, strain rate in the environment of interest. That environment may be the actual plant environment or may be accelerated by using a higher concentration of the species responsible for the attack (e.g., oxygen, chloride, hydroxide) or an applied potential. The slow and continuous strain rate produces deformation at the crack tip that maximizes the interaction of the corrosion and the crack tip strain. That method initiates cracks and causes film rupture events at the tips of existing cracks. Under the proper conditions, the bare metal surfaces (continue to) interact with the environment, resulting in crack advance. Considerable development work has been devoted to establishing optimum strain rates for the test. The SSRT has been used extensively for investigating the cause of IGSCC in BWRs and continues to be used for selection and qualification of replacement materials and remediation processes. The test produces results that look like those from a tensile stress-strain curve (Fig. 9). Like a tension test, the test always produces a failure. Typical test times are of the order of days to a month when extension rates from  $10^{-7}$  to  $10^{-6}$  in./in./s ( $10^{-7}$  to  $10^{-6}$  s $^{-1}$ ) are used. The interpretation of the test results may be compared to the results for the same material exposed to an environment where little or no environmental degradation occurs based upon one or more of the "tensile test" parameters (maximum stress, elongation

FIG. 9—Slow strain rate test, typical curve. (Copyright © 1980. Electric Power Research Institute. EPRI WS-79-174, Volume 1. Reprinted with permission.)

to failure, reduction of area, etc.). There is now a standardized version of this test, ASTM G 129, Practice for Slow Strain Rate Testing to Evaluate the Susceptibility of Metallic Materials to Environmentally Assisted Cracking. While the test is very useful for identifying materials that are susceptible to SCC, assessing the degree of susceptibility to be expected in service is more difficult. Efforts toward standardization of such interpretations continue.

ASTM A 262 is probably the most commonly used mechanism (Type 5) test for corrosion testing in support of nuclear reactor materials. It provides a qualitative measure of the degree of sensitization (DOS). The electrochemical potentiokinetic reactivation (EPR) test [8] provides a rapid method for generating a more quantitative measure of DOS. This test (see ASTM G 108, Test Method for Electrochemical Potentiokinetic Reactivation (EPR) Test Method for Detecting Sensitization of AISI Type 304 and 304L Stainless Steels) involves polarizing a polished sample (including pipe work in the field) at a controlled rate, then reversing the direction of polarization and returning to the open circuit potential. The area under the curve, normalized for the grain boundary area exposed (Fig. 10a), provides a quantitative measure of the degree of sensitization. The "double loop" method is similar, but is less critical regarding specimen preparation and provides the quantitative measure as a relative peak height. See Fig. 10b, and Chapter 7—*Electrochemical Tests*. Standards for the testing and interpretation of results have been under review within ASTM for a number of years.

Other methods that have been, and continue to be used are:

- ASTM G 4, Method for Conducting Corrosion Coupon Tests in Plant Equipment
- ASTM G 61, Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-Based Alloys

FIG. 10—EPR, typical curve (from G DLEPR-XX, G01.08.03 working draft version).

- ASTM G 5, Standard Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements
- ASTM G 2, Test Method for Corrosion Testing of Zirconium, Hafnium, and Their Alloys at 680°F or in Steam at 750°F
- ASTM G 96, Practice for On-Line Monitoring of Corrosion in Plant Equipment (Electrical and Electrochemical Methods)
- ASTM G 111, Guide for Corrosion Tests in High Temperature or High Pressure Environment, or both
- ASTM G 102, Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Methods
- ASTM G 46, Practice for Examination and Evaluation of Pitting Corrosion
- ASTM G 106, Practice for Verification of Algorithm and Equipment for Electrochemical Impedance Measurements.

### Future Outlook

Several unresolved issues remain in the area of corrosion testing for nuclear power plants. These include:

- IGA and IGSCC in PWR steam generator tubing (secondary side). The effect of different, "customized" microstructures such as those for cold-worked nickel-base alloys or (intentionally) heavily twinned materials (to eliminate intergranular crack propagation) on IGA and IGSCC need to be resolved.
- IASCC in BWR environments has been observed in highly irradiated components. Threshold levels of irradiation and methods to assess susceptibility and mitigate IASCC have been defined [9] but require standardization.
- Standard test methods are also required to qualify alternative approaches to environmental controls such as hydrogen water chemistry (HWC). HWC has been shown to be effective for protection of recirculation system piping against IGSCC (at the expense of higher radiation levels); however, the higher levels of hydrogen injection required to protect components in the reactor vessel may not be tolerable from a radiation dose ( $^{16}\text{N}$  carryover in steam) perspective.
- Primary water stress corrosion cracking (PWSCC) has been observed in PWR steam generator tubing, control rod drive mechanism penetrations, and bolting materials. Methods to evaluate susceptibility of components, mechanisms, and methods for qualifying alternate materials for resistance to this specific form of IGSCC are required.
- The nuclear industry has learned the value of on-line monitoring to provide an early warning of corrosion problems. Standard methods for automated and on-line methods (including measurements made at reactor system temperatures and pressures) need to be developed.
- The importance of corrosion effects in balance of plant (BOP) components in nuclear plants increased dramatically in the 1980s. BOP problems such as MIC, pitting, and underdeposit corrosion had a dramatic effect on plant performance. Methods for monitoring and for selecting materials for resistance to pitting and crevice corrosion exist. Additional standard methods for MIC testing are under development [10].

# Steam Generation

Otakar Jonas<sup>1</sup>

THIS CHAPTER COVERS corrosion and corrosion testing for the water side and steam side of utility and industrial steam generation, fossil fuel, and nuclear units. It does not cover primary cycles of nuclear units, fire side in fossil fuel fired steam generators, gas turbines, and cooling water systems.

## INTRODUCTION

The cost of corrosion and scale of steam cycle components in all types of cycles (fossil and nuclear utility, industrial) is still very high [1–3]. Recent studies determined that the total cost of corrosion in the United States is \$276 billion/year, including the \$6.9 billion/year cost to electric utilities [1]. The main cost is for the replacement power or lost production; it is about ten times higher than the cost of repairs. Scale and deposits often reduce the steam generating capacity and thermodynamic efficiency. There are also safety issues, such as stress corrosion of turbine blade attachments, deaerator cracking, and flow accelerated corrosion of piping. The high cost of corrosion led to intensive research into corrosion behavior of the materials used, characterization of the chemistry of corrosive environments, and introduction of corrosion into component design.

### Critical Areas

The following are current critical areas where corrosion dramatically impacts safety and reliability of the steam generating equipment:

- break before leak or before other warnings
- corrosion cracking of carbon steel welds in hot water
- stress corrosion cracking (SCC) in nuclear pressurized water reactor (PWR) and boiling water reactor (BWR) cycles
- corrosion fatigue of turbine blades, boiler tubes, and PWR cycle components
- other corrosion failures of boiler tubes
- corrosion cracking of deaerator welds
- flow accelerated corrosion (FAC) of feedwater and wet steam piping
- corrosion of condenser and feedwater heater tubing

## Corrosion Mechanisms and Root Causes of Problems

All the known corrosion mechanisms active in aqueous environments have been found to be active on the water side and steam side of the steam generation cycles. The most frequently found mechanisms include high-cycle and low-cycle corrosion fatigue, SCC, pitting, general and crevice corrosion (often under deposits), FAC, fretting, oxidation, and exfoliation. The most costly mechanisms are corrosion fatigue and SCC. During the last two decades, FAC received a lot of attention because of several catastrophic failures of carbon steel piping and the effect of the corrosion products generated by FAC on other cycle components, such as boilers and PWR steam generators. The root causes of most of the corrosion problems include design, water chemistry and operation, and material selection. The design root causes include high local steady and vibratory stresses, high flow velocity and turbulence (leading to FAC) and heat transfer conditions which can lead to concentration of corrosive impurities.

Because of the intensive research and application of the research to problem correction, over 90 % of these corrosion problems are understood, the mechanisms and root causes can be identified, and there are engineering solutions to these problems. Major contributions have been made by Electric Power Research Institute, main vendors of equipment, and by technical societies such as ASME [4], the American Society for Materials International (ASM) [5], ASTM, American Nuclear Society (ANS), and the National Association of Corrosion Engineers (NACE).

## Equipment Description

The steam-generating cycles of interest in this chapter include industrial and utility drum boiler cycles, utility once-through boiler cycles (super critical and subcritical), fluidized bed boiler cycles, combined cycles with gas and steam turbines, cogeneration cycles, pressurized water reactor and boiling water reactor cycles, and geothermal steam generation. An example of a utility drum boiler cycle is given in Fig. 1. The figure also indicates major impurity transport mechanisms around the cycle that can dramatically influence impurity concentration on the cycle component surfaces and corrosion. A link in the communication between different engineering disciplines on corrosion and water and steam chemistry is provided by the Mollier Diagram

<sup>1</sup>P.E., Ph.D. consultant, Jonas Inc., Wilmington, DE 19803.

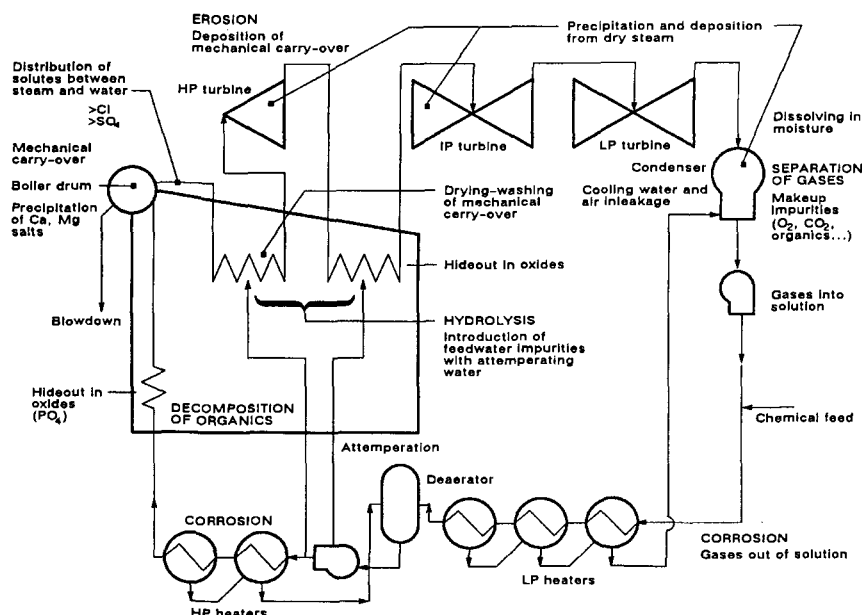

FIG. 1—A typical electric utility drum boiler cycle with sources of chemical impurities and their concentration mechanisms and transport [10,13].

(enthalpy-entropy), which can characterize the steam and water properties as well as impurity behavior and corrosion Fig. 2. Additional information on cycle designs, water chemistry, and corrosion can be found in Refs 4 to 24.

### Objectives of Corrosion Testing

The objectives of corrosion testing and associated monitoring of chemical, stress, and thermodynamic conditions in steam generating cycles are:

- to provide corrosion characteristics of materials for cycle and component design and selection of water treatment
- to provide data for troubleshooting and root cause analysis
- to help in life assessment and failure analysis
- to prevent leaks, breaks before leaks, and other catastrophic failures.

### MATERIALS OF CONSTRUCTION AND SELECTION CRITERIA

The highest proportion of the materials used in steam generation cycles are carbon and low-alloy steels. Austenitic and martensitic stainless steels are used for selected high-duty components such as for turbines blades, pumps, and valves, and there is a small quantity of superalloys used for special applications. Copper alloys, stainless steels, and titanium are used for condenser tubing, and copper alloys and carbon and stainless steels are used for feedwater heater tubing. A higher proportion of stainless steels and superalloys is used in nuclear cycles. Table 1 gives a list of typical materials used in steam generating cycles.

The most important criterion for the selection of materials is the reliability of steam cycle components during a typical 30-year design life. This is important because of the

high cost of replacement power or lost production in industrial steam generation.

Strength to weight considerations are important in rotating components such as in steam turbines. The cost of material is often a wrong consideration, leading to the selection of the cheapest material and poor component reliability. Typical components where the selection of the least expensive material leads to poor reliability include condensers and feedwater heaters.

Prevention and minimization of corrosion is achieved by a combination of design (steady and vibratory stresses, heat flux, and flow), feedwater and boiler water treatment (control of pH and corrosion potential, and control of impurity concentration), and operation (control of impurity ingress and stress and temperature conditions) (Fig. 3). These corrosion control measures are discussed in Refs 4–6 and 9–19.

### CORROSIVE ENVIRONMENTS

Normal steam cycle environments are not corrosive. They passivate the cycle component surfaces and promote formation of protective oxides such as magnetite, hematite, and spinel. Pure, low-oxygen hot water and steam are good passivating agents, and where impurities are present, alkalizing agents such as ammonia, sodium phosphate, and other water treatment chemicals are added [4,5,11–14].

The large variety of corrosive environments is unique for the steam generation industry. This is because the pressure around the steam cycle changes from vacuum to hundreds of atmospheres (thousands of psi) and the temperature from ambient to over 600°C (1100°F). This changes the aqueous environment from low-temperature water to high-temperature pressurized water, to wet, saturated, and superheated steam. Concentrations of impurities in these

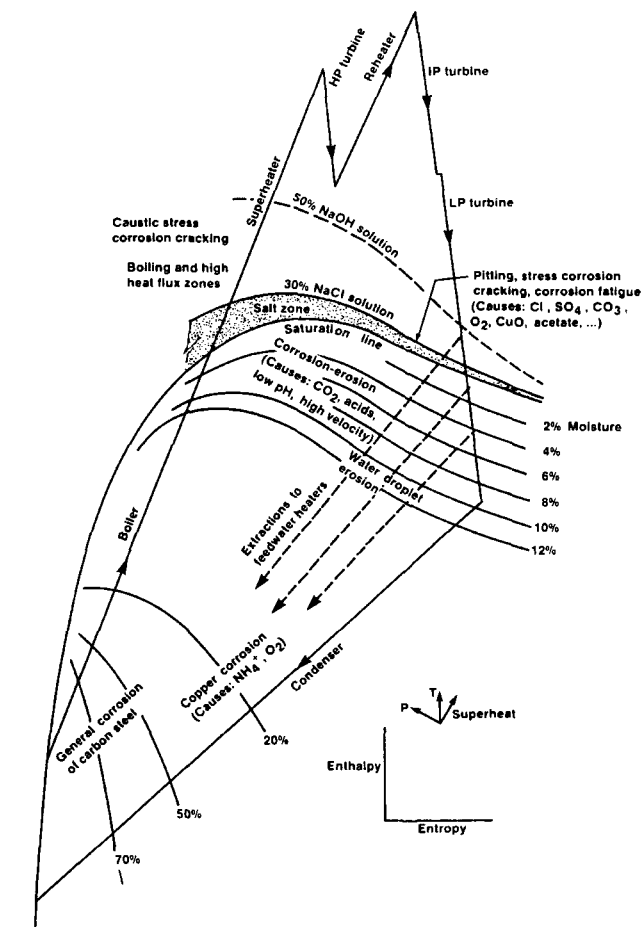

FIG. 2—A Mollier (enthalpy-entropy) diagram combining information on cycle water and steam properties, chemistry, and corrosion [6,10].

aqueous solutions and at component surfaces vary from low ppb to almost 100 %. Over 150 different chemical species have been identified in water, steam, and in deposits on boiler, turbine, and other surfaces [6,11–17]. Typical environments are listed in Table 2 and the sources of chemical impurities and their transport and concentration mechanisms are for a utility drum boiler cycle indicated in Fig. 1.

The cycle components also have to be protected against corrosion during inactive periods such as boiler layup, during which the environments are different from those experienced during operation. The layup protection is typically provided by nitrogen blanketing, or by wet layup with elevated pH and oxygen scavengers in aqueous solutions. Without layup protection, oxygen and CO<sub>2</sub> from air can interact with wet, possibly salt-covered surfaces and cause pitting and other forms of corrosion.

Preservatives, machining and cleaning fluids, dry lubricants (MoS<sub>2</sub> and graphite), and Loctite can also corrosively interact with steam cycle materials.

TABLE 1—Typical materials used in steam-generating units.

Type of Materials (examples)	Applications
Carbon Steels SA106, 212B, 515, 1020, A36, A-302 (0.5 Mo)	Piping, tubing, boiler drums, turbine casing, pressure vessels, turbine rotors, pumps
Low-Alloy Steels NiCrMoV, CrMoV, 0.5Cr-0.5Mo, 0.5Cr-0.5Mo, 1.25Cr, 0.5Mo, 2.25Cr-1Mo, 9Cr-1Mo	Turbine rotors, high-temperature piping and tubing, cast and forged pressure vessels
Austenitic Stainless Steels Types 304, 316, 321, 347, 308, 309 weld metal	High-temperature piping and tubing, nuclear piping, condenser tubing, stationary blades, pumps
Ferritic and Martensitic Stainless Steels AISI403, 422, 630 AL6X-N, Sea-cure	Turbines blades, condenser tubing
Superalloys Inconel 600, 630, Incolloy 800, Pyromet 860, Reactalloy 26, Incolloy 901	PWR steam gen. and other tubes, high-temperature bolts
Stellite (6B)	Erosion shields, valve seats, support keys
Copper Alloys Aluminum bronze, copper-nickel, Admiralty brass, Monel, bronze, muntz metal	Condenser and heater tubing, tube sheets, pump impellers, coolers
Titanium pure, Ti6-4, and other alloys	Condenser tubing, low-pressure turbine blades

A link between the environment and corrosion is provided by the relationship between the “at temperature” pH and corrosion potential (Fig. 4). These relationships are calculated or measured for specific materials, environments, and temperatures. It should be realized that the at temperature pH can be very different from that in a room temperature sample (Fig. 5). This is an important factor for proper simulation of service environments.

The most severe corrosive environments are encountered in the areas where corrosive impurities concentrate. These impurities can concentrate on heat transfer surfaces such as in boiler and steam generator tubes where the surface temperature is above the saturation temperature of the boiling water, and on the surfaces in superheated and saturated steam where the impurities concentrate by precipitation from a steam solution and deposition [4,5,11,14]. Figure 6 shows the gradient of concentration of sodium hydroxide at the surface of a boiler tube.

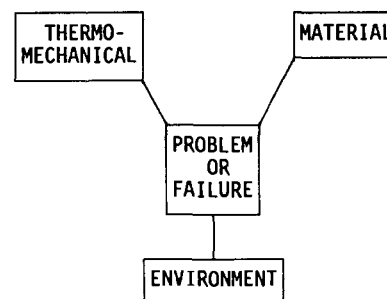

FIG. 3—Three components of corrosion control in steam generating cycles.

TABLE 2—Typical steam cycle environments.

	pH	Conductivity, $\mu\text{S}/\text{cm}$
Noncorrosive		
Pure and treated deaerated feedwater and boiler water	7.0 to 10.5	0.1 to 10
Drum boiler water, phosphate, AVT and NaOH water treatments	9.2 to 12	5 to 5000
Steam: dry, saturated, and wet	7.0 to 9.8	0.1 to 10
Corrosive—Concentrated Solutions		Concentration, %
NaOH on boiler and turbine surfaces	>13	1 to 90
Salts and acids on boiler and turbine surfaces	3 to 8	0.1 to 30
Corrosive—Oxygen and $\text{CO}_2$		Concentration of $\text{O}_2$ , ppb
Condensate and feedwater-aerated	<9	20 to 5000
System fill water		~7000
Corrosive—High Flow Velocity and Turbulence		
Feedwater, condensate, wet steam	5 to 9	$\text{O}_2 < 4$ ppb, reducing environment

In industrial steam cycles, oxygen and  $\text{CO}_2$  from air in return condensate and the chemicals from various industrial processes are the main corrosives. Where organic chemicals leak or are added into the steam cycle, their decomposition products often include organic acids and  $\text{CO}_2$ . Thermal decomposition of organics can occur at temperatures as low as  $150^\circ\text{C}$ .

## CORROSION CONTROL

Corrosion control in steam-generating systems is by a combination of design, material selection, water treatment, and

operation. Marginal design is responsible for most of the corrosion failures in utility equipment. Because most of the corrosion is localized, corrosion cracking and other forms of corrosion in the areas of high heat flux and impurity concentration is often controlled by control of surface stress. Control of flow velocity and heat transfer conditions is also essential. Cycle materials must be compatible with the water treatment chemicals selected for feedwater and boiler water treatments. The combination of copper alloys and ferrous materials in the steam cycle is not recommended because the pH region for the best protection is different for each of these two groups of materials. In general, the cycle materials do not have to be

FIG. 4—Potential-pH diagram for iron in water, providing a link between the chemistry of aqueous environment, material, and corrosion [34].

FIG. 5—Dependence of pH of aqueous solutions on temperature, SB = Strong base.

FIG. 6—Concentration gradient of sodium hydroxide at the surface of a boiler tube; a result of heat transfer which elevates the ID surface temperature above the saturation temperature of pure water.

extremely corrosion-resistant because the maintenance of a protective oxide layer achieved by control of pH and oxygen concentration is sufficient for a long, reliable operation.

With a few exceptions, coatings and linings are not used on the water and steam sides. In an EPRI project, about 50 turbine blade coatings have been evaluated, but none of these are being routinely applied. To reduce steam side oxidation in reheaters and superheaters, chromizing and chromating have been developed but these treatments are also not routinely applied. There is little use of composite materials with the exception of condenser tube sheets, which could be made of explosively clad stainless steel or titanium on carbon steel, and of the surfaces in the primary cycles of nuclear units where carbon or low alloy steels are protected by weld-deposited stainless steels. In pulp mill black liquor recovery boilers, stainless steel clad boiler tubes are often used.

Various types of water treatments, aimed at maintaining low concentrations of impurities and alkaline pH [6,11,12,14] are usually successful in long-time protection against corrosion. The water treatments include removal of dissolved and suspended impurities from makeup and feedwater (external treatment) and feeding alkaline additives, oxygen scavengers, and other chemicals (internal treatment). Water chemistry control also includes deaeration, boiler blowdown, sampling, monitoring, prevention of impurity ingress, and periodic mechanical and chemical cleaning.

## SPECIFIC PROBLEM AREAS

Specific problems associated with the steam generation industry include strong interactions of corrosive environment, heat transfer, and operating and residual stresses. These interactions, in a very large system, can result in unforeseen corrosion and corrosion cracking and component failures. Caustic gouging, hydrogen damage, corrosion fatigue, and pitting of boiler tubes [15], deaerator cracking [21] and pitting, corrosion fatigue and stress corrosion in turbines [17] are the most frequent problems specific to steam generation.

Other major problems include many types of corrosion in PWR steam generators, stress corrosion of austenitic stainless steels in superheaters and feedwater heaters [22], FAC of carbon steel piping [19], corrosion of condenser tubing [23], and steam oxidation of superheaters and reheaters leading to exfoliation and solid particle erosion [24]. Most of these problems are summarized in Ref 5. **The challenge** in corrosion control during operation is that large surface areas (several acres) must be controlled for many years, based on a few water and steam samples analyzed for 10 to 20 chemical parameters (such as pH, conductivity, oxygen, sodium, and chloride).

One of the most dangerous consequences of slow, long-time corrosion is the situation where a *break before leak* occurs. This occasionally happens in pressure vessels and piping. In all instances, the break before leak occurs because the structure, weakened by undetected corrosion, is overloaded by pressure or stress transients beyond its point of resisting to fracture.

A recently recognized generic problem is *corrosion cracking of carbon steel welds* such as in deaerators [21], blow-down flash tanks, steam accumulators, and piping. Also recently recognized is a large number of flow-assisted corrosion failures due to high velocity, low pH, low oxygen, and low chromium contents in carbon steel [19]. The safety related problems are summarized in [25].

The corrosion failure mechanisms specific to the steam generation industry include corrosion fatigue (low-cycle and high-cycle) and SCC. Often, this cracking is preceded by pitting.

The specific component **design problem** is that water chemistry and corrosion are not included in design codes and design practices and often not even understood by mechanical designers. For many steam cycle components, the number of new corrosion design variables, such as  $K_{ISCC}$  (threshold stress intensity for SCC),  $\sigma_{SCC}$  (threshold stress for SCC),  $\Delta K_{th}$  (threshold stress intensity amplitude for corrosion fatigue crack propagation), and stress corrosion, corrosion fatigue, and pit growth rates need to be included in design. Designers should also realize that the traditional approach of selecting higher strength materials for higher stresses can lead to susceptibility to SCC and corrosion fatigue.

## CORROSION TEST METHODS

Almost all known test methods applicable to aqueous solutions [26–30] (see Sections III, IV, and V) have been extensively used for material and design evaluation and in failure analysis of steam cycle materials. Many of these methods have been adapted for field testing. Corrosion variables that need to be known in design and failure analysis are, together with the applicable corrosion test methods, listed in Table 3, Table 3 also lists the corrosion test methods that have been applied for in-service monitoring.

The standard methods used include ASTM [27], ANS, NACE, and numerous other methods [26,28,29]. Many important methods are not yet standardized such as the stress corrosion cracking test method [30], and autoclave testing methods [31,32] Table 3 gives a list of the more common test methods and the tested corrosion parameters.

TABLE 3—Corrosion test methods and tested properties.

Test Method	To Determine
<b>GENERAL CORROSION AND MISCELLANEOUS TESTS</b>	
Coupons, U-bends	Corrosion and pitting rate
Polarization	Corrosion rate, pitting and transition potentials
Crevice	Crevice corrosion
Galvanically Coupled Dissimilar Metal Coupons	Couple potential, crevice corrosion, pitting
Flow Accelerated Corrosion	Effects of pH, O <sub>2</sub> , temp., velocity, and corrosion rate
Radioactive Tracer and Isotope Implantation	Corrosion and erosion rate
<b>STRESS CORROSION</b>	
U-bend, C-rings, Tension, and Bent-beam Specimens	$\sigma_{SCC}$ initiation time
Fracture Mechanics Specimens	$K_{ISCC}$ da/dt, incubation time
Constant Strain Rate	Compare materials and environments
Polarization—Anodic	Transition potential
<b>CORROSION FATIGUE (HIGH AND LOW CYCLE)</b>	
Fatigue—Standard and Ultrasonic Tests	Fatigue limit, cycles to crack initiation
Fracture Mechanics Specimens	$\Delta K_{th}$ da/dN
Fretting	Crack initiation
<b>FIELD TESTS</b>	
All methods listed above and many NDT methods are used for corrosion rate, crack growth rate, and other parameter determination in field tests. Test specimens are in autoclaves or directly inside steam cycle components.	
Corrosion-generated Hydrogen in Steam	Boiler tube, feedwater system, and PWR steam generator support plate corrosion
<i>In situ</i> pH and Corrosion and ORP potentials	Susceptibility to general and localized corrosion
Chemical Analysis of Fe, Cu, Ni, Zn in Feedwater, Condensate, and Boiler Water	Corrosion of tubing and piping (general and flow accelerated corrosion)

## Corrosion Test Approach

A simulation of the actual service environment and stress and temperature conditions is essential for proper representation in corrosion testing for steam cycle applications. The service environments can be estimated theoretically through thermodynamic calculations of the chemistry of solutions at component surfaces [33] and through calculation of the potential-pH diagrams [34]. The advantage of field testing or testing in autoclaves taking water and steam from actual operating cycles is that the environment is very representative of the actual conditions, including the changes during load transients, startups, and shutdowns.

In environmental simulations in laboratory testing, the corrosion potential and pH are the most important variables. The difference between oxidizing and reducing conditions is important for all types of corrosion (in particular for stress corrosion, corrosion fatigue, and flow accelerated corrosion).

## Accelerated Tests

Because of the need to develop reliable data representative of a long-time operation, extrapolation of test results and accelerated tests are often necessary. Corrosion cracking tests are accelerated by the use of higher stress intensity and fatigue stresses and by higher cycling frequencies for corrosion fatigue (ultrasonic fatigue testing). Tests can also be accelerated by using higher test temperature and then extrapolating to lower temperatures. Test environments that can accelerate stress corrosion and corrosion fatigue include dry hydrogen

sulfide and polythionates. It is always controversial how representative are the results of the accelerated testing. Corrosion rates, crack propagation rates, and crack growth incubation times are very difficult to determine with the use of accelerated testing.

## In-Service Monitoring

Because of the complex and changing corrosion environment in many steam cycle components, in-service monitoring is necessary to prevent failures. Corrosion situations can be evaluated through periodic nondestructive testing, water and steam chemistry assessments [11], and field testing of corrosion coupons for general corrosion, pitting, stress corrosion, and corrosion fatigue.

Equipment exists to also monitor the temperature pH, corrosion and redox potentials, and the corrosion hydrogen that is always produced during corrosion by aqueous solutions [35]. Periodic analysis of condensate, feedwater, and boiler water samples for iron and copper gives a good indication of general corrosion and flow accelerated corrosion.

The new technical field of Diagnostic Engineering aimed at an "incipient failure detection" and "predictive and preventive maintenance" is becoming a part of in-service monitoring [36].

## Special Methods

Special nonstandard corrosion specimens have been designed for field and laboratory testing and fracture mechanic

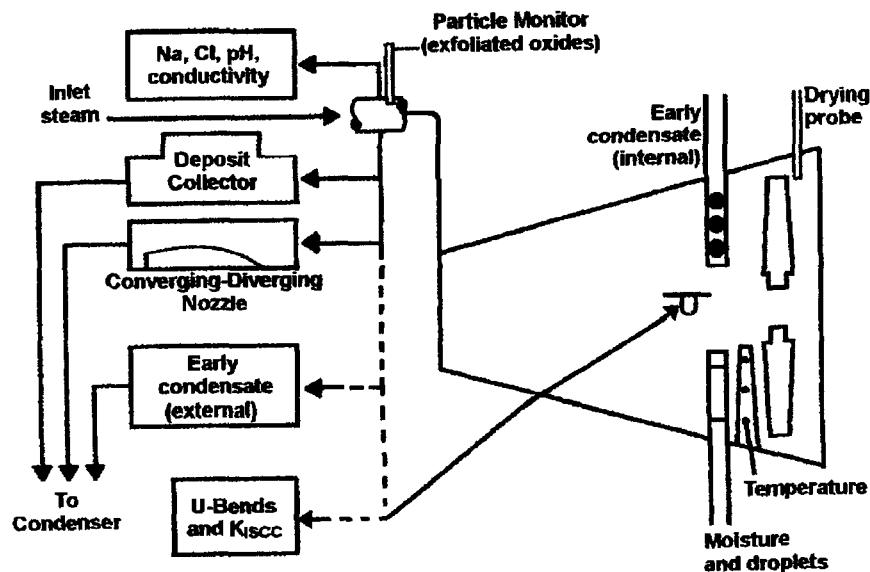

FIG. 7—LP turbine troubleshooting instrumentation that can identify chemical and corrosive conditions.

specimens are often used for stress corrosion and corrosion fatigue crack growth rate testing. For simulation of heat transfer and flow conditions, test methods are often custom-designed. For example, corrosion of PWR steam generator crevices [39] and new types of boilers and steam generators is evaluated by, often long-time, model testing.

### Detection of Corrosion

In corrosion testing, corrosion is detected visually, with optical and electron microscopy, or by electrochemical measurements. In general corrosion and FAC, thickness can be measured ultrasonically or by eddy current probes in tubing. In corrosion cracking tests, crack propagation is measured visually, ultrasonically, by magnetic particle inspection, or by the electric potential method. General corrosion in aqueous solutions can also be measured by monitoring the concentration of corrosion-generated hydrogen.

### Instrumentation

Several diagnostic tools are available for monitoring corrosion, water droplet and solid particle erosion, and for determining deposition rates and deposit composition and morphology in turbines (Fig. 7). The deposits collected with a Steam Turbine Deposit Collector, Converging-Diverging Nozzle for LP turbines, or Converging Nozzle for HP turbines can be analyzed using optical and SEM microscopy, energy dispersive X-ray spectroscopy, X-ray diffraction, and wet chemistry methods [18,37,38]. The results of the deposit analysis can be used to predict deposition and corrosion inside the turbine, and to assess boiler carry-over and the effects of steam and water chemistry upsets.

Several instruments have been developed that can be used to determine the corrosivity of the wet steam environment. One such instrument is the Drying Probe for Wet Steam Stages, which simulates the evaporation of moisture and the

concentration of low volatility impurities on hot surfaces. A Boiler Carry-over Monitor has recently been developed that can be used for the monitoring of high boiler carry-over and the % moisture in process and heating steam and the steam used for oil recovery. Early Condensate Samplers are used to collect samples of steam moisture in turbines. The condensate is collected and withdrawn for analysis while saturated steam is vented into the turbine space.

A Particle Flow Monitor for Exfoliated Oxides is used to determine number and size distributions of oxide particles or water droplets in steam.

### Discussion

It is anticipated that in the near future, important corrosion variables will be included in component design by the component manufacturers and in design codes, including ASME Pressure Vessel Code. For this step, more standard test methods which would be reproducible by different test laboratories are needed.

It is also expected that corrosion considerations will be more emphasized in the steam cycle design and material selection so that all materials of construction of the steam system will be compatible with the water treatment used. In design component integrity monitoring and failure analysis, the combination of the effects of corrosive environment, stress, flow velocity, and thermal conditions must be considered.

# Flue Gas Desulfurization

Harvey S. Rosenberg<sup>1</sup>

Eldon R. Dille<sup>2</sup>

## DESCRIPTION OF MATERIALS OF CONSTRUCTION USED AND SELECTION CRITERIA

A VARIETY OF CONSTRUCTION materials has been used in flue gas desulfurization (FGD) systems on utility boilers. They can all be classified into three major categories: metals, organics, and nonmetallic inorganics.

### Metals

Metals ranging from carbon steel to stainless steels and nickel-based alloys have been used in most components of FGD systems. Unlined carbon steel is used where the flue gas is above the acid dewpoint and/or where alkaline conditions are maintained, such as most of the components of spray dryer FGD systems, inlet ducts upstream of the wet/dry interface of all FGD systems, lime/limestone storage silos, and fresh lime/limestone storage tanks and piping. Under acidic conditions, the carbon steel must be protected by a lining or by other corrosion-control techniques. Alternatively, corrosion-resistant alloys are used under these conditions. Stainless steels (e.g., Type 316L, 317L, 317LMN, 904L, 254 SMO<sup>®</sup>, 25-6MO<sup>®</sup>, and AL6XN<sup>®</sup>) and nickel-based alloys (e.g., G-3, G-30, 625, C-276, C-22<sup>®</sup>, 622, 686, and 59) have been used in FGD system components such as prescrubbers, absorbers, spray nozzles, reheaters, and dampers. In critical locations with more aggressive environments, such as reheaters, outlet dampers, outlet ducts, and gas mixing zones, nickel-based alloys (e.g., alloys 625, G-3, C-276, C-22<sup>®</sup>, 622, 686, and 59) and titanium (grades 2 and 7) have been used.

Because of the relatively high cost of nickel-based and titanium alloys, a significant cost savings can be realized by using thin claddings of these alloys over carbon steel plates, rather than solid alloy plates, for absorbers, dampers, ductwork, and stack liners. Clad plate can be manufactured by hot rolling, explosive bonding, or welding the cladding and base plate together [1,2]. However, these methods are generally applicable only to new FGD systems, because existing systems already have the substrate (e.g., carbon steel) in place. A recently adopted method that is applicable to both new and retrofit construction is called "wallpapering" (NACE RP-0292, Installation of Thin Metallic Wallpaper Lining

in Air Pollution Control Equipment and Other Process Equipment) [3,4]. This method, which has been used in the chemical industry for many years, involves plug welding thin sheets, usually 1.6 mm (1/16 in.) thick, of an alloy such as C-276, C-22<sup>®</sup>, 622, 686, or 59 to the carbon steel substrate. A new practice (NACE International, NACE RP-0199, Installation of Stainless Chromium-Nickel Steel and Nickel-Alloy Roll-Bonded and Explosion-Bonded Clad Plate in Air Pollution Control Equipment) for clad lining is now available [5]. This practice offers guidance for an excellent means of providing protection using thin corrosion-resistant materials.

The most frequently reported failures for alloys in FGD components are pitting and crevice corrosion. General corrosion, erosion-corrosion, or stress corrosion cracking (SCC) also can occur. Many environmental factors are responsible for the failures, but high levels of chloride combined with low pH play a major role [6]. Fluoride also can be a factor, but its role is complex. For example, acid fluorides are especially corrosive to certain alloys such as titanium [7]. However, fluoride forms complex ions with species such as aluminum, magnesium, and silicon, which are typically present in fly ash. However, field corrosion failure analysis studies have shown that the fluoride ion is interacting with the chloride ion in limestone based FGD systems to cause severe crevice and pitting corrosion [8,9]. Elevated temperatures, such as those encountered in prescrubbers and reheaters, are thought to influence SCC susceptibility, while erosive particulates play a role in influencing erosion-corrosion in prescrubbers [10].

### Organics

Organics linings have been used extensively in various FGD components, including prescrubbers, absorbers, tanks, outlet ducts, and stacks. These linings include polyesters, vinyl esters, epoxies, novolac epoxy, novolac phenolic epoxy, fluoroelastomers, and rubber. Organic linings are attractive because they can provide the lowest initial cost for many of these components. The linings are generally applied in liquid form by brushing, rolling, spraying, or troweling. To provide an effective barrier, the organic linings used in FGD systems are often applied in several layers. This decreases the probability of through-thickness pinholes and achieves a greater permeation thickness than typical coatings. Moreover, the polyester, vinyl ester, epoxy, novolac epoxy, and novolac phenolic epoxy linings often contain a mica flake or glass flake filler that further

<sup>1</sup> Research leader, Guild Associates, Hilliard, OH 43026.

<sup>2</sup> Consultant, Specialists in Solutions, Inc., 9401 Wildwood Drive, Highland, IN 46322.

decreases the permeability and provides reinforcement. Mica flake-filled linings are generally not as abrasion-resistant as glass flake-filled linings. In components where high abrasion resistance is required, linings reinforced with glass cloth or inert matting along with abrasion-resistant pigments silicon dioxide, aluminum oxide, tungsten carbide have been used. Although rubber is an organic lining, it is often placed in a separate category because it is applied in sheet rather than liquid form. Three types of sheet rubber have been used for lining absorbers: natural (gum), neoprene, and chlorobutyl. Of these, the rubber industry generally considers chlorobutyl to be the preferred material for this application. Chlorobutyl rubber has low moisture permeability.

Failure of organic linings can occur by blistering, disbonding, and wear from abrasive slurries [11]. Blistering of organic linings immersed in liquids is greatly increased when a thermal gradient is present [12]. Excursions to hot flue gas temperatures can damage or destroy organic linings. Fluoroelastomer linings can withstand excursions up to 260°C (500°F) and are resistant to chemical attack and abrasion. However, they are relatively permeable to moisture and with the use of scrubbed flue gas in the outlet duct, less than desirable coating life has been obtained. In addition, fluoroelastomer coatings are generally more expensive than other types of organic linings. Rubber sheet linings offer excellent resistance to abrasion, but rubber is a flammable material, so care must be taken to prevent ignition of these sheet linings by external sources. It is good practice to label the external surfaces of rubber sheet-lined absorbers indicating the presence of a rubber lining. Close attention to product specification and application is required to prevent short life and inconsistent performance of rubber linings [13].

Fluoroelastomer, fluoropolymer, and fluorinated elastoplastic materials, as well as rubber, are used in expansion joints, typically with fabric reinforcement. The cost of the fluoroelastomer materials may be an order of magnitude higher than that of rubber materials, but longer life expectancy, higher temperature tolerance, and better overall operating performance can easily offset the higher installed cost. Mixing reprocessed fluoroelastomer scrap with virgin fluoroelastomer can reduce the cost of the material, but physical properties critical to the performance of expansion joints are impaired. The causes of failure of fluoroelastomer expansion joints include thermal degradation induced by temperature excursions or thermal cycling, acid attack, and mechanical damage.

Fiberglass-reinforced plastic (FRP, known as glass-reinforced plastic (GRP) in Europe) is used to fabricate mist eliminators, piping and spray headers, and stack liners. Various polymeric resins are used including polyester, vinyl ester, and novolac vinyl ester. The typical operating temperature range of the FRP structures is 82°C (180°F) to 177°C (350°F). FRP also is a flammable material that must be protected against ignition from external sources. The types of FRP failures include mechanical damage, laminate degradation, physical damage, and fire. The causes of failure are inadequate engineering, poor fabrication quality, abrasion, temperature excursions, and, depending on the resin, chemical attack, e.g., acid hydrolysis of polyester.

## Nonmetallic Inorganics

Nonmetallic inorganic materials are used in prescrubbers, spray nozzles, slurry pumps, outlet ducts, and stacks. The materials include prefired bricks and shapes, ceramic tiles, borosilicate foamed-glass blocks, hydraulically-bonded concretes and mortars, and chemically-bonded concretes and mortars, all of which are used as lining materials where temperature resistance, chemical resistance, or abrasion resistance are required. Acid-resistant bricks are commonly used as construction materials for stack liners. A potential failure cause of these bricks is mechanical stress from dimensional changes during service. Also, several free-standing brick flues have been found to lean toward the outer concrete shell. This problem appears to be associated with mixing bypassed gas and scrubbed gas in the stack, thus creating temperature and moisture gradients that cause one side of the flue to expand more than the other side. A free-standing brick flue that is constantly wet with scrubbed FGD gas does not lean [14].

Borosilicate foamed-glass blocks bonded with urethane-modified asphaltic mastic have been used to line outlet ducts and stacks. The combination of these two materials results in a lining that is resistant to permeation by aggressive condensate and can handle continuous temperatures to 205°C (400°F) and excursions to 370°C (700°F). The urethane-modified asphaltic mastic has a temperature limit of 82°C (180°F). However, as the mastic between the bricks is reduced to char by high temperatures, the char provides insulation for the remaining mastic. Moreover, the thermal insulating properties of the glass block and the flexibility of the membrane material contribute to the good performance of the lining. However, the foamed borosilicate glass can be mechanically damaged easily, and failures can occur due to abrasion, puncturing, and cracking. Also, scale that forms on the lining cannot be easily removed. These problems can be minimized by applying a topcoat of chemically bonded mortar over the borosilicate foamed-glass blocks.

Hydraulic-setting, cement-bonded concretes (hydraulic concretes) are used as linings for prescrubbers, outlet ducts, and stacks. These concretes contain aluminate to withstand temperatures of 260°C (500°F) without strength degradation. However, in sulfuric acid solutions (pH < 4), the cement is attacked due to dissolution of the calcium aluminate. This dissolution of the bond results in loosening of the aggregate and erosive wear of the lining [15].

Chemically bonded mortars are commonly used to bond acid-resistant brick stack liners. Chemically bonded concrete mixes can also be used as linings. These materials generally contain siliceous aggregates, a sodium silicate, potassium silicate, or colloidal silica bond phase, and a silicofluoride, phosphate, or organic bond gelling agent. They may also contain potassium fluoride. Since chemically bonded concretes can withstand hot, acidic environments, they offer an abrasion-resistant alternative to organic linings. However, they have a higher permeability than most organic linings and are subject to cracking, so that any condensed acid will reach the substrates to which they are applied. In many cases, an organic membrane is used under a chemically bonded concrete lining to provide additional protection to the carbon steel substrate. While this measure increases the

time for acidic condensate to reach the substrate, it can complicate repair procedures. When the membrane fails due to permeation by acidic species, the concrete must be removed to repair or replace the membrane [16].

### Cost Considerations

The prime objective in selecting construction materials for FGD systems is to choose the most cost-effective or optimum material for each component, i.e., the one meeting the design requirements at the least cost over the life of the facility. A large ratio in the purchase costs of alternative materials may be reduced if installed costs are considered. The reduction can result if the labor costs involved in the installation are significant compared to the difference in the cost of the materials. In addition to installed cost, it is necessary to consider repair and/or replacement cost over the 20- to 30-year design life of the plant when specifying the most economical materials available for the intended service conditions. Certain materials such as organic linings cannot be expected to last the plant lifetime without periodic maintenance touchup, repair, or replacement.

## DESCRIPTION OF CORROSION ENVIRONMENTS ENCOUNTERED

The environment in an FGD system depends upon three factors: temperature, chemistry, and abrasiveness. ASTM has identified three levels of severity, from 1 (mild) to 3 (severe), for classifying these three environmental factors (see Table 1) [17]. Figure 1 is a schematic diagram of environmental severity levels in the major components of a wet FGD system. In all of the three digit codes shown, the first digit represents temperature, the second digit represents chemistry, and the third digit represents abrasiveness. (A code of zero for a given environmental factor denotes that the factor does not exist or is not applicable for a specific operating condition.) For example, the mildest condition encountered can be coded 1-1-1 and represents a temperature below 60°C (140°F), a pH greater than 3 with low concentrations of chloride and fluoride (as defined in Table 1), and low-velocity fluid flow with no direct impingement by particulates. An example of this mild condition is a mist eliminator (see Fig. 1). By contrast, the most severe condition can be coded 3-3-3 and represents a temperature above 93°C (200°F), an acid concentration greater than 15 % with high concentrations of chloride and fluoride, and very high-velocity fluid flow with impingement by entrained particulates.

An example of this severe condition is the inlet of a venturi prescrubber.

Several species in solution have been found to affect the corrosion of alloys in FGD systems. However, most of these species are considered trace elements in scrubbing liquors. Notable exceptions are chlorine and fluorine, both of which are present in coal. Depending on the source, the makeup water can also contribute chlorides and fluorides to the FGD system. When the water balance is tightly closed, dissolved ionic species such as chlorides become highly concentrated. Chloride ions cause both general and localized corrosion in alloys. The corrosion rate for a given alloy is a function of chloride concentration, pH, temperature, and in many instances, the concentrations of trace elements present at levels below 2000 ppm, e.g., aluminum, copper, and iron [18,19]. Uncomplexed fluoride ions can cause localized attack in the heat-affected zone (HAZ) of welded austenitic stainless steels, and can be catastrophic to titanium. In addition to having its own effect on corrosion rates, aluminum, dissolved from fly ash, can react with fluorides to form the complex ions  $AlF_2^{+1}$  and  $AlF^{+2}$ . If there is sufficient aluminum, free fluoride will not be available.

## TECHNIQUES USED FOR CONTROLLING CORROSION AND MATERIALS DEGRADATION

The most important technique for avoiding materials problems is to ensure that the selected material is designed to give satisfactory service in a given environment. The applicability of an alloy in the temperature range of a wet FGD environment is mainly a function of pH and chloride concentration. Because the condensate in an outlet duct or flue can have a pH of 2.5 or lower, a more corrosion-resistant alloy should be used for these components than for an absorber, where the pH of the scrubbing liquor is typically above 5.0. (However, under upset conditions, the pH may drop to 2.0 or lower). The chloride concentration in the scrubbing liquor depends primarily upon the type of coal burned in the boiler. In addition, chlorides are provided by the water balance and the type of makeup water. If there is carryover of scrubbing liquor from the mist eliminator, the chloride concentration in the outlet duct can increase because of evaporation of water during periods of bypass of the absorber. Stainless steel Types 316L, 317LMN, 904L, 254SMO, 25-6MO<sup>®</sup>, and AL6XN<sup>®</sup> have been successfully used in absorber vessels when the chloride concentration is within the applicable range for these alloys. In some FGD reaction tank vessels,

TABLE 1—ASTM classification system for environmental factors in FGD systems.<sup>a</sup>

Level of Severity	Temperature	Chemistry	Abrasiveness
1	Ambient to 60°C (140°F)	pH >3 with <100 ppm F <sup>-</sup> and <1000 ppm Cl <sup>-</sup>	Low velocity fluid flow with no direct impingement of particulates (e.g., duct wall)
2	60° to 93°C (140° to 200°F)	pH 0.1 to 6 with 100 to 1000 ppm F <sup>-</sup> and 1000 to 10 000 ppm Cl <sup>-</sup> , or saturated flue gas	High velocity fluid flow, spray impingement, or strong agitation (e.g., absorber spray zone)
3	Above 93°C (200°F)	Greater than 15 % acid with >1000 ppm F <sup>-</sup> and >10 000 ppm Cl <sup>-</sup> , or intermittent wet/dry zones	Very high velocity fluid flow with impingement of entrained particulates (e.g., venturi throat)

<sup>a</sup>Adapted from Ref 13.

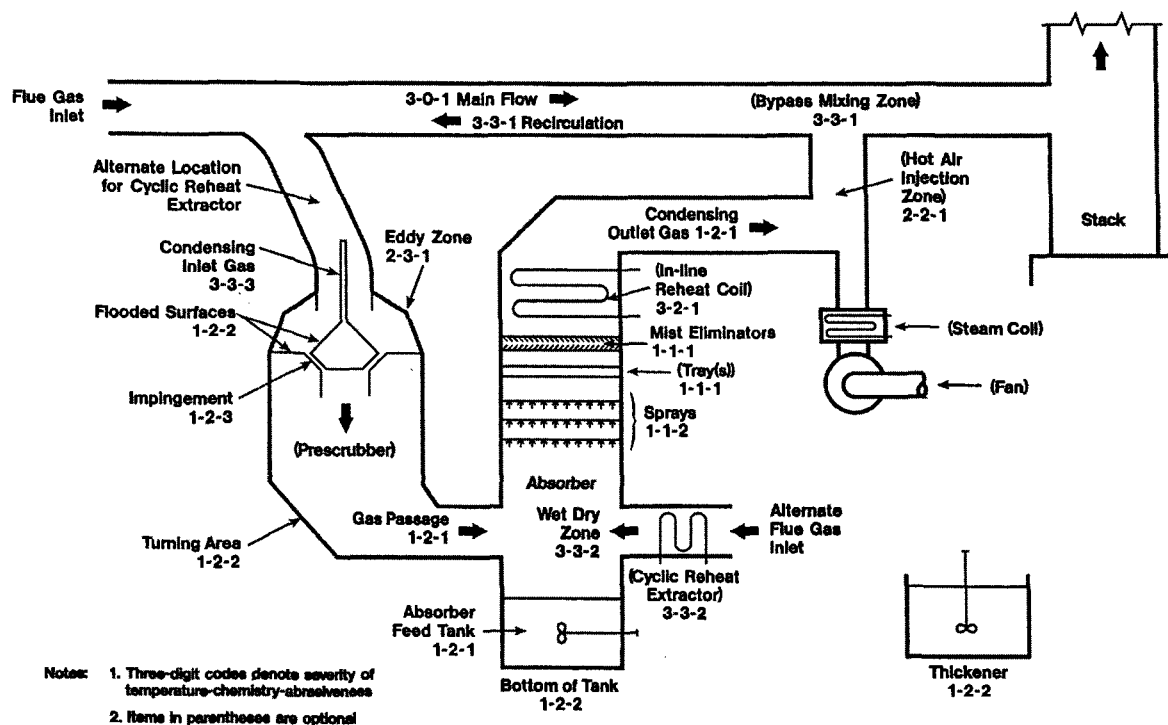

FIG. 1—Schematic diagram of environmental severity levels in wet FGD systems (adapted from Ref 13).

for example, a potential adjustment protection system has been successfully used to control thio-sulfate pitting, chloride/fluoride pitting, crevice corrosion, and general corrosion of all submerged stainless steels Types 317L, 317LMN, and 904L. This combination of stainless steels with the potential adjustment protection system allows the use of an alternative cost effective technique for corrosion control in FGD reaction tanks made of otherwise susceptible materials [20]. In outlet ducts exposed to both scrubbed flue gas and untreated flue gas, the use of a highly corrosion-resistant alloy, such as alloys C-276, C-22®, 622®, 686®, or 59® is generally required to prevent corrosion [21].

In certain cases, it may be possible to modify the environment, i.e., temperature, chemistry, or abrasiveness, to extend the useful life of a material. Temperature modifications in an FGD system can be accomplished only by a limited number of practical methods. These practical methods include: (1) water sprays to protect against thermal excursions, and (2) insulation to reduce thermal gradients. The scrubbed flue gas can be reheated by a variety of methods to prevent, for example, formation of acidic condensate on the floor of the outlet duct or to downstream fans in wet FGD systems. However, most reheat methods increase the capital and operating costs of an FGD system, increase the energy consumption of the system, and create materials problems of their own. Bypass reheat can avoid an increase in energy consumption, but it creates an extremely aggressive environment in the mixing zone of the bypassed gas and the scrubbed gas. Therefore, bypass to the outlet duct or stack for reheat or emergencies should be avoided, if possible.

The process chemistry can be modified by using additives or by minimizing the chloride and fluoride concentrations

in the scrubbing liquor. The use of additives that inhibit oxidation of sulfite to sulfate reduces gypsum deposition, which, in turn, can reduce crevice corrosion that tends to occur under deposits. The use of additives that buffer the pH of the scrubbing liquor may help prevent pH excursions that can cause failure of alloys.

Several methods are available for minimizing the chloride and fluoride concentrations in the scrubbing liquor. These include using a separate quench loop, operating the FGD system with an open water balance, or using sludge stabilization with fly ash and lime so that a considerable amount of water can be purged with the scrubber effluent. A minor reduction of chloride and fluoride concentrations also can be achieved by using river water or well water, rather than cooling tower blowdown, for makeup. Since the chloride and fluoride ions are primarily products of coal combustion, these non-coal related methods for reducing chloride and fluoride only result in minor reductions.

The abrasive effects of fly ash on downstream FGD components also can be minimized by using a separate quench loop, but in conjunction with a venturi prescrubber. Alternatively, a high-efficiency particulate collection device can be used upstream of a wet FGD system.

Aside from the use of linings, other corrosion protection techniques include cathodic protection and corrosion inhibitors. Impressed Current Cathodic Protection (ICCP) technology is attractive because it avoids the use of expensive alloys. The Electric Power Research Institute (EPRI) has developed a system that allows cathodic protection to be applied to duct walls having thin films of condensate, rather than immersed in a liquid [22]. EPRI also has evaluated the performance of several inhibitors on the corrosion behavior

of alloys in a pilot-scale scrubber. The data suggest that the use of corrosion inhibitors in FGD systems is possible, but the results from this particular study were not very encouraging [23].

Another electrochemical technique, potential adjustment protection (PAP), was patented by the Pulp and Paper Research Institute [24]. PAP is an electrochemical corrosion protection technique that is used to protect stainless steel in oxidizing chloride environments. The technique uses a DC current source to move the electrochemical potential of the protected surface in the negative direction. This technique is not cathodic protection (CP) in the traditional sense. Although both CP and PAP move the potential in the electronegative direction, CP requires the set potential to be in the immunity region as depicted by the Pourbaix Diagrams. PAP, on the other hand, takes advantage of the passive film available in stainless steel/oxidizing environment and the set potential is in the passive zone. Some of the economic advantages of PAP versus CP are smaller current source requirements and lower anode consumption. This technique has now been used on 14 FGD stainless steel reaction tanks [25].

Another technique for avoiding corrosion is the use of FRP (GRP in Europe) for FGD components such as absorbers and tanks. FRP vessels as large as 30 m (100 ft) in diameter can be fabricated on site by using a spinning process to produce multiple layers of material [26]. After an initial 3 m (10 ft) high cylindrical section is spun, it is hoisted to the top of the mandrel and another 3 m (10 ft) section is wound, overlapping the first. The overall height of the structure is limited by the mechanical properties of the composite unless external support is provided. A potential problem is abrasion from spray impingement and from highly agitated slurries. The interior surface of a FRP FGD vessel can be lined with an abrasion-resistant lining thus providing additional vessel life.

## SPECIFIC PROBLEM AREAS

### Welding

The quality of the welding is critical in FGD components constructed of stainless steels or nickel-based alloys. Achieving quality control of alloy welding requires stringent specifications, qualified fabricators and installation contractors, and thorough inspection and nondestructive testing of the welds [27]. A great deal of care must be taken to avoid iron contamination during fabrication (e.g., welding by using stainless steel tools and ceramic abrasives). In order to preclude rust blooms, any embedded iron must be removed by an acid pickling treatment. Heat input should be minimized by the use of small diameter welding electrodes and stringer passes to avoid carbide precipitation and hot cracking. Crevice type defects should be avoided or removed by grinding. Assuming that the proper alloy and welding electrodes have been selected for the service environment, the quality of the welds is the next most critical item. Leaking welds can cause discharges of process fluids, which, in turn, can deteriorate external equipment. Corrosion of welds can cause a loss of structural integrity of the welded component, e.g., ductwork, absorbers, and internal supports.

Thin metallic linings require good welding procedures and inspections in order to achieve leak tight welds. Improper welding results in flaws and pinholes in the seal welds between the overlapped alloy sheets. Because of these flaws, liquid can get behind the sheets and cause corrosion of the substrate. Also, during plug welding of the alloy sheets to the substrate, the proper welding material and care must be used to insure that the iron dilution does not adversely affect the corrosion resistance of the weld. One approach is to cover the plug weld with a seal-welded patch of the alloy lining.

### Fire Protection

In cases where combustible linings are used, fire protection should be provided by an automatic water spray system [28]. The system should be designed so that the spray patterns are not obstructed and the lining is completely covered by the spray. The spray nozzles should include corrosion-resistant blowoff caps to prevent plugging. The scrubbing liquor spray nozzles are not suited for fire protection in prescrubbers or absorbers. There have been a few costly fires in FGD systems where the ignition source has been linked to cutting and welding operations during maintenance procedures. Absorbers can contain a large quantity of combustible materials, including plastic mist eliminators and packing, as well as flammable linings. For example, the plastic materials may be as much as 1.2 m (4 ft) in height and 15 m (50 ft) in diameter. The fire hazard is most prevalent when the unit is down for periodic maintenance. Typically, the access hatches are open, allowing a high volume of air movement; the fire loading may be increased due to the presence of combustible scaffolding; and ignition sources may be present because of cutting and welding activities.

The National Fire Protection Association (NFPA), in Report No. NFPA 850, has recognized the fire hazard associated with FGD systems during outage and construction activities [29]. The NFPA committee responsible for this document is considering a revision to enhance guidance. The proposed revision will include identification of hazards for combustible-lined equipment, and will suggest closing the outlet damper during cutting and welding operations to reduce airflow through the equipment [28].

## USE OF TEST METHODS TO EVALUATE CORROSION AND DEGRADATION

Continuous, on-line corrosion monitoring can be used to operate FGD systems at optimal efficiency while avoiding high corrosion rates. Conventional corrosion monitors are designed for use in bulk liquids and do not function satisfactorily in the thin condensate films that form on the surfaces of FGD ducts. Recent EPRI research has made use of an advanced electrochemical method of corrosion surveillance developed by the Corrosion and Protection Centre Industrial Services (CAPCIS) in England [30]. This method allows on-line monitoring of corrosion activity in either thin condensate films or bulk liquids. EPRI introduced the CAPCIS system to the U.S. electric utility industry in 1985, sponsoring several field demonstrations.

An electrochemical monitoring system that tracks the rate and depth of permeation of aggressive chemicals in the walls of FRP or other nonmetallic vessels also is available [31]. The system uses a set of conductivity probes mounted at various depths in the wall of an FRP component. The probes can be attached during fabrication, before final installation, or as a retrofit for equipment already installed.

Methods to evaluate materials performance are used both for materials selection and for failure analysis. Materials selection can be based on field surveys, exposure tests in commercial units, or laboratory test results [21]. Field surveys represent long-term results from actual test environments, but the environmental conditions usually are not well-defined or constant. Exposure tests in commercial units may or may not be realistic, depending upon the test method approach. This point is discussed in the next section. Laboratory tests with simulated flue gas run the risk of missing the effects of trace constituents, which typically are not present in simulated environments. Laboratory tests with selected trace elements may not be indicative of the effect of these elements on materials performance in the field.

Failure analysis involves documentation of environmental conditions, inspection of the failed component, collection of samples of the failed material, any deposits on the material, and any liquids that condensed on or contacted the material, and appropriate laboratory analyses of the collected samples. The laboratory results and the background information are analyzed in an attempt to deduce the failure mechanism and/or the failure cause [32].

### Test Method Approach

Coal has been described as garbage of a previous eon. Thus, because coal contains very many of the elements in the periodic table, it is difficult to simulate the environment in an FGD system. The scrubbed flue gas from coal-fired power plants typically contains nitrogen, carbon dioxide ( $\text{CO}_2$ ), oxygen, water vapor ( $\text{H}_2\text{O}$ ), sulfur dioxide ( $\text{SO}_2$ ), sulfur trioxide ( $\text{SO}_3$ ), nitric oxide ( $\text{NO}$ ), nitrogen dioxide ( $\text{NO}_2$ ), hydrogen chloride ( $\text{HCl}$ ), hydrogen fluoride ( $\text{HF}$ ), trace organics, fly ash, and solids carried over from the absorber slurry. The concentration of species such as  $\text{HCl}$  and  $\text{HF}$  are very low in the scrubbed gas, but can be significant if some flue gas is bypassed for reheat. In one of the early FGD bypass reheated outlet ducts, the scale on the walls of the duct was 10 % potassium fluoride ( $\text{KF}$ ) [8].

If gas cylinders are used to prepare simulated flue gas for exposure testing, many cylinders may be required to run long exposure periods. If a combustion source is used to supply flue gas, it is difficult to match the composition of flue gas from a large pulverized coal-fired boiler. Maintaining the proper ratio of  $\text{NO}$  to  $\text{NO}_2$  is a special problem because  $\text{NO}$  oxidation to  $\text{NO}_2$  is a function of the temperature, the initial  $\text{NO}$  concentration, the oxygen concentration, and the gas residence time in the exposure chamber. The usual procedure is to use simulated flue gas with the same  $\text{SO}_2$  concentration as actual flue gas, but with different concentrations of other species. This procedure can produce erroneous results.

Many species are typically present at various concentrations in FGD outlet duct condensate [15]. Those typically present at concentrations greater than 100 mg/L include aluminum,

calcium, iron, potassium, magnesium, sodium, chlorine, fluorine, sulfate ( $\text{SO}_4^{2-}$ ), borate ( $\text{B}_4\text{O}_7^{2-}$ ), and phosphate ( $\text{PO}_4^{3-}$ ). Species present in the range of 10–100 mg/L include manganese, selenium, silicon, tin, titanium, vanadium, zinc, and nitrate ( $\text{NO}_3^-$ ). Several species, including barium, beryllium, cadmium, lead, and antimony, are present at concentrations less than 10 mg/L. The pH ranges from less than 1.0 to about 2.5, depending on FGD system operating parameters. In preparing solutions for exposure testing, solubility problems need to be considered. If precipitation occurs in a solution the composition changes. Also, if some species typically present in FGD condensate are omitted from the test solution, the results can be erroneous. As previously mentioned, trace elements can affect corrosion rates.

Many of the exposure tests in commercial units have involved the use of spools or racks of different materials placed in various locations inside an FGD system [33]. Although this type of testing can provide comparative data for materials, it may not provide accurate corrosion or degradation rates. By using more corrosion racks, at many locations inside an FGD system, there is a good probability that one or more of the corrosion racks will experience the desired corrosion rates. The environment in the bulk gas stream, in which the specimens are usually placed, is not the same as at a duct wall, where condensation can occur. In some field tests, the specimens were directly mounted on the duct wall so that they experienced the same conditions as the wall [34]. Test coupons were mounted using bolts of the same alloy as the duct wall. To avoid galvanic corrosion of alloy coupons, the coupons were insulated from the bolts and the substrate with fluoropolymer film and washers.

### Methods Used

Laboratory exposure tests are usually conducted in chambers similar to that described in ASTM B 117, Test Method of Salt Spray (Fog) Testing. Because the environment is more corrosive than the salt fog described in ASTM B 117, the variations described in ASTM G 85, Practice for Modified Salt Spray (Fog) Testing, are often used. Some investigators have used a modified procedure in which the test coupons are mounted over holes on the outside wall of the exposure chamber so that they can be subjected to a thermal gradient [35]. Outside mounting of the coupons also affords the opportunity to conduct in situ electrochemical impedance measurements.

Electrochemical impedance spectroscopy (EIS) is an AC technique for determining the components of an analog electric circuit that represents an electrochemical process [36]. Electrochemical impedance is the ratio of the change in potential to the change in current ( $\Delta E/\Delta I$ ) and is determined from the applied potential and the response current as a function of frequency ( $\omega$ ) in an electrochemical cell, when potential and current are linearly related. The impedance,  $Z$ , is a complex number incorporating both the magnitude of  $\Delta E/\Delta I$  and the phase shift between  $E$  and  $I$ . EIS can give extremely valuable mechanistic information for analyzing the corrosion behavior of alloys [37] and for analyzing the performance of coatings [38].

Two ASTM test methods are particularly useful for characterizing organic resin linings and bricks, respectively. These

methods include ASTM D 1653, Test Methods for Water Vapor Transmission of Organic Coating Films; and ASTM C 20, Test Methods for Apparent Porosity, Water Absorption, Apparent Specific Gravity, and Bulk Density of Burned Refractory Brick and Shapes by Boiling Water.

Two additional test methods regarding bricks are worthy of mention. One is a laboratory test in which the moisture expansion that occurred in service is recovered as a shrinkage during heating of a brick sample in a dilatometer [14]. The dilatometer measures thermal expansion as a function of temperature. Shrinkage causes a hysteresis in the thermal expansion curve so that the heating and cooling curves do not coincide. The shrinkage is determined from the difference in the curves at room temperature.

The other method is a field test to document the amount of lean in a free-standing brick flue. A laser beam is used to project a target onto the interior surface of a flue in four compass directions spaced 90° apart. In each direction, the target is tracked at predetermined incremental elevations for the entire height of the stack. The precise position of the target is determined by a triangulation method using two Kern electronic theodolites (precision optical tooling instruments) and a computerized data acquisition system. The data from each compass direction provide a profile of the interior surface of the flue. Opposing wall profiles are used to calculate centerline profiles, which give the amount of lean as a function of height [14].

Standard laboratory techniques are used to characterize samples for a failure analysis. These techniques include metallography, scanning electron microscopy (SEM), electron probe microanalysis (EPMA), X-ray diffraction (XRD), Fourier transform-infrared analysis (FTIR), and analytical chemistry.

## COMMENTS

New materials and innovative applications of existing materials are continually being developed for use in FGD system components. Some of the interesting recent developments include multifunctional epoxy linings with improved environmental resistance, thermal spraying alloy coatings on carbon steel substrates, centrifugal slurry pumps constructed of erosion-resistant cast alloys, solid ceramic ball valves to control slurry flow rates, round and rectangular ductwork constructed of sandwich panels (face sheets welded to a truss core), and structures made of high-strength fabric and sturdy support systems for constructing absorbers, outlet ducts, and stacks or stack liners. Some of these materials or applications may require the development of new testing methods and standards. A test method for continuous monitoring of organic resin lining performance in FGD systems would be very useful if it could be developed.

# Electronics

Robert Baboian<sup>1</sup>

FAILURE IN ELECTRONICS DUE TO corrosion has become a significant factor because of the extremely complex systems (microchips, integrated circuits, computers, etc.) that have been developed and the increasing demand on their reliability. Electronics are now a part of all industries, ranging from transportation industries to medical and consumer products. Technological advances have resulted in the development of sophisticated components with closer spacing so that extremely low levels of corrosive contaminants can cause failure. Testing for this type of behavior is difficult and costly. Further advances in electronics can only be made where corrosion issues are addressed and reliability is maintained. Many publications have appeared in the technical literature on the subject of corrosion in electronics with more and more emphasis on testing [1–10].

## MATERIALS

Electronic materials include a broad range of metals and alloys depending on the specific system, equipment, and components. The system as a whole can include structural materials such as steels, copper, nickel and their alloys, aluminum, and titanium. The system can also include structural materials used for cabinets as well as those used for electronic components. The broadest range of materials used in electronics is in components including integrated circuits, printed circuit boards, contacts, connectors, switches and relays, grounding contacts, and thermal contacts. Table 1 lists various electrical components and includes important materials of construction. Materials used for integrated circuit conductors are aluminum based alloys, often alloyed with silicon and copper, and more recently copper. Conductors and connectors in PC boards are typically made of copper and are soldered with lead-tin alloys or complex additives to these metals. Contacts are fabricated from a range of materials but mainly copper plated with tin, nickel, or gold for added corrosion resistance.

Coupled with the materials used in electronics, the design of electronic devices plays an important role in corrosion behavior. For example, silicon based integrated circuit elements are spaced less than 0.2 microns. Minimum linewidth in state-of-the-art PC boards is less than 100 microns. On hybrid integrated circuits, line spacings may

be less than 5 microns (10). The tolerance for corrosion becomes extremely small with these designs and materials.

## ENVIRONMENTS

Electronics are exposed to a wide range of outdoor and indoor environments generally considered as atmospheric exposure. The corrosion behavior is determined by the actual environment, which can be as benign as a simple low humidity, purified atmosphere, indoor location, to the aggressive environment existing at a pulp and paper mill or on an automobile, which is subjected to road salt splash and spray. The electronics design as well as the nature of the environment are important because failures in printed circuit boards, integrated circuits, and other components have been known to occur even in extremely low levels of moisture and contaminants. Electronics components are mostly indoor or sheltered from direct exposure to liquid splash, spray, rain, snow, etc., and therefore the environment is considered atmospheric exposure.

Materials used in electronics are susceptible to corrosion in a wide range of environments. For example, sulfidation of silver in H<sub>2</sub>S occurs in dry as well as humid air. However, moisture in the form of humidity is generally required for atmospheric corrosion to occur. When the humidity is increased, a moisture film can form on the metallic surface and can yield an increased rate of corrosion. The duration of time at which this occurs is referred to as time of wetness (TOW). However, the humidity at which wetness occurs is dependent on a number of factors including the nature of the material, surface roughness and composition, temperature, and surface contamination including atmospheric pollutants. Since the nature and significance of the moisture film is dependent on very complex and synergistic interactions among a large number of variables, this subject has received a great amount of attention and has resulted in conflicting points of view. This behavior is significant because corrosion tests must be designed properly and include the effects of complex and synergistic reactions. Otherwise, the test environments will not represent those to which electronics are exposed.

In some cases, a critical humidity exists above which significant corrosion occurs. This behavior has been described for steel in SO<sub>2</sub> [11]. However, many of the materials used in electronics do not exhibit this behavior. Copper in SO<sub>2</sub>, for example, corrodes at a steadily increasing rate with

**TABLE 1**—Electrical components.

Component	Design	Materials
Printed Circuit Board	Metallic conductor separated by insulating materials	Copper, copper alloys, copper clad materials, epoxy, resins, ceramics, woven glass fiber, electroplate, solder, tin, lead, conformal coatings
Contacts	Electrical contact maintained by mechanical force	Base Metal—copper alloys, steels (clad) Contact Surface—gold, palladium, silver-palladium, silver, tin, tin-lead, copper
Connectors	Electrical connections between systems or boards	Spring Material—beryllium copper, stainless steels Contact Surface—gold, palladium, silver, silver-palladium, tin, tin-lead
Switches and Relays	Cyclic electrical connection	Copper alloys, steels, stainless steels, electroplate and contact surface materials
Grounding contacts	For shielding	Copper, steels, aluminum, nickel, tin, tin-lead and contact surface materials
Thermal contacts	Heat sinks	Copper, aluminum
Integrated circuits	Small dimension complex systems	Gold, silver, aluminum, Kovar, solder, glass, ceramic, silicon, silicon dioxide, silicon nitride, tungsten

**TABLE 2**—Environmental pollutants causing corrosion.

Pollutant	Sources	Susceptible Metals
Sulfur Dioxide (SO <sub>2</sub> )	Fossil fuel combustion, petrochemical industries, pulp and paper industry, metal producing industry	Most metals
Nitrogen Dioxide (NO <sub>2</sub> )	Auto & truck emissions, fossil fuel combustion, various industries	Copper, brass, synergistic with SO <sub>2</sub>
Hydrogen Sulfide (H <sub>2</sub> S)	Pulp & paper industries, chemical industry, sewage plants, garbage dumps, oil refineries, animal shelters, volcanic activity, swamp areas, marine tidal areas	All copper and silver based metals
Chlorine (Cl <sub>2</sub> ) but most important is chlorine containing gases.	Bleaching plants in industries, metal production, PVC plants, cleaning agents	Most metals synergistic with other pollutants
Ammonia and Its Salts (NH <sub>3</sub> and NH <sub>4</sub> <sup>+</sup> )	Fertilizer, animal and human activity, detergents	All copper based alloys, nickel, silver
Chloride (Cl <sup>-</sup> )	Sea salt mist, road salt areas	Most metals
Soot (Carbon)	Combustion, auto and truck emissions, steel production	Synergistic with other pollutants; provides cathodic sites for most metals
Ozone	Formed in polluted areas, highest concentrations in smog	Strong oxidant to produce acids which attack most metals
Mineral Acids (H <sub>2</sub> SO <sub>4</sub> , HCl, HF, HNO <sub>3</sub> )	Pickling industry, chemical industry, metals production, semiconductor industry	Most metals, glass, ceramics
Organic acids	Wood, packing material, animals, preservatives	Long-term effects on some metals

increasing humidity, while in the absence of pollutants, its corrosion rate is very low, even at 100 % relative humidity. The presence of certain atmospheric pollutants therefore enhances corrosion by reaction on the surface in the presence of moisture to form corrosive species or corrosion products, or both. Their properties are different for each metal and therefore the corrosion behavior will vary. Some pollutants that can cause corrosion in electronics are listed in Table 2, along with their sources and effects on electronic materials. This table does not include the wide range of submicron atmospheric particles including various compounds of sulfate, chloride, nitrate, sodium, ammonium, potassium, magnesium, and calcium [12]. These particles deposit on surfaces and react with moisture to form corrosive electrolytes. Sulfate and ammonium ions are the most common ones found in particulates in outdoor and indoor environments.

Another source of contamination is chemicals from outgassing of organic materials. These vapors from sealants, resins, plastics, coatings, and packing materials can be emitted in closed areas and therefore can reach appreciable concentrations [1]. Examples are: acetic acid from silicone sealants; sulfurous vapors from polysulfide sealants; phenols from phenolic resins; ammonia from molded resins; organic acids from adhesives; amines from epoxy; sulfurous

vapors from paper, cardboard, and insulation; and formic and acetic acids from wood. Rubbers, plastics, and adhesives are also known to have residual acids that can leach out to cause corrosion problems. For example, residual acrylic acid in acrylate adhesives has caused pitting in stainless steel. Many types of rubber outgas sulfur or hydrogen sulfide, or both, which will react with copper and silver alloys. Such rubber can be found in furniture, carpet backing, rubber bands, etc.

Another group of contaminants causing failure in electronics is residual chemicals. These are generally introduced during manufacturing and include fluxes, cleaning compounds, plating solutions, and metal processing fluids. Also included here are chemicals from fingerprints and saliva. Many of these include chlorides, and when these contaminants, such as residual chloride flux, are not removed, corrosive electrolytes are formed.

## CLASSIFICATION OF ENVIRONMENTS

Classification of TOW has been included in ISO 9223, Corrosion of Metals-Classification of the Environment, and has been documented by the Nordic Research Project, as shown in Table 3, which includes six TOW classes where

**TABLE 3**—Classification of time of wetness (TOW).

Category	Time of Wetness		Example of Occurrence
	Hours/Year	% of Year	
$\tau_1$	<10	<0.1	Indoor air with climatic control
$\tau_2$	10–250	0.1–3	Indoor air in normal rooms for living or working conditions
$\tau_3$	250–1000	3–10	Indoor air storage rooms
$\tau_4$	1000–2500	10–30	Indoor air in some production rooms. Outdoor air in cold zone, dry zone, parts of temperate zone
$\tau_5$	2500–5500	30–60	Outdoor air in parts of temperate zone, parts of warm zone. Indoor air in animal houses.
$\tau_6$	>5500	>60	Outdoor air in tropical zone. Indoor air in greenhouse.

Source: Ref 1.

**TABLE 4**—Classification of corrosivity of copper reactivity.

Severity Level	Copper Reactivity (A first month exposure)	Explanation of Severity Level
G1 Mild	<300	Corrosion is not a factor in determining reliability.
G2 Moderate	<1000	The effects of corrosion are measurable and may be a factor in determining equipment reliability.
G3 Harsh	<2000	There is high probability that corrosive attack will occur. Environmental control or specially designed and packaged equipment is recommended.
GX Severe	>2000	Only specially designed and packaged equipment would be expected to survive. Specification of equipment in this class is a matter of negotiation between user and supplier.

Source: ANSI/ISA Standard SP71.

**TABLE 5**—Classification of corrosivity by pollutant level.

Class	Temperature °C	Relative Humidity, %	Pollutant Level, ppb		
			Cl <sub>2</sub>	NO <sub>2</sub>	H <sub>2</sub> S
I	—	—	Negligible	Negligible	Negligible
II	30	70	10 ± 3	200 ± 50	10 ± 5
III	30	75	20 ± 5	200 ± 50	100 ± 20
IV	50	75	50	200	200

Source: Ref 13.

$\tau_1$  to  $\tau_3$  are for indoor conditions and  $\tau_4$  to  $\tau_6$  mainly apply to outdoor environments [1].

Classification of corrosivity has been treated by Abbott in his pioneering work at Battelle [13]. Subsequently, other researchers have made contributions to the development of classification systems and these have been incorporated in standards developed throughout the world [14–16]. Since corrosivity depends on a wide range of factors, including material, physical and chemical properties of the environment, a classification system should be based on these factors. However, the complex interaction of these factors requires that some simplification be made. In general, two systems of classification are used. One is based on corrosion

of copper measured in the environment. The other is based on the levels of relative humidity and pollutants.

Classification according to copper corrosion is used because it is used widely in electronics. Also, copper provides a good representation of how many metals behave in environments. Several reports describe the use of copper where coupons are exposed for at least one month (three to twelve months for low levels of corrosivity) and the amount of corrosion product is determined by weight gain or cathodic reduction, or both [17–20]. Table 4 gives a classification of corrosivity according to copper reactivity as described in ANSI/ISA-SP71.

Classification according to levels of relative humidity and pollutants has gained wide acceptance, especially in combination with copper coupons. One classification of corrosivity is listed in Table 5 with 70–75 % relative humidity, 30–50°C temperature, and the indicated levels of H<sub>2</sub>S, NO<sub>2</sub>, and Cl<sub>2</sub> [21]. These classes of corrosivity are confirmed with copper coupons with no corrosion effect on reliability in a Class I environment, and with corrosion effects above that level. Other pollutants from the list in Table 2 can also be used to classify corrosivity; however, these three are the most commonly used. Since chlorine converts to hydrogen chloride in these tests, some researchers use the end product hydrogen chloride since it is a more exact procedure.

In some cases, the systems of classification are not adequate and can be related to specific factors. For example, behavior of silver contacts in sulfide environments can only be correlated with silver test material. In general, where local conditions vary significantly, correlation may be poor.

## CORROSION MECHANISMS

Corrosion mechanisms in electronic components have been the subject of intense study. Since electronics are largely found indoors and/or within packages or cabinets, the mechanisms leading to corrosion problems are not easily defined. Problems are compounded by the fact that these systems are fabricated by a number of complex processes and consist of a variety of dissimilar materials. Miniaturization and the requirement for high component density has resulted in smaller components, closer spacing, and thinner metallic paths. Thus, the effect of bias potentials and small defects is magnified.

Bias potentials provide corrosion mechanisms due to both anodic reaction and cathodic reaction. These reactions include the formation of acidic or alkaline electrolytes, and ion migration. Pore corrosion and corrosion product creep, galvanic corrosion, and fretting corrosion in connectors are other important mechanisms with electronics. Many of these mechanisms occur due to processing related corrosive residues.

Uniform and localized corrosion mechanisms are all-important in electronic systems and are described elsewhere in this manual. However, some extremely important mechanisms of degradation are unique to this field of interest [22–26]. Pore corrosion is one of these and is frequently associated with noble metal coatings such as gold on copper/nickel [23,24]. Defects in the noble metal coatings give rise to galvanically accelerated pitting of the underlying

base metal. When that process occurs, the corrosion products (for example from copper) can migrate over the surface of the metal coating (such as gold).

Several mechanisms of migration are known to cause problems in electronics and involve metal migration and ion migration [1–4,9,22,23].

Metal migration occurring electrolytically involves: (1) electrodisolution, (2) ion transport, and (3) electrodeposition [25]. The metallic material is oxidized producing ions that are transported through an electrolyte by electrical migration, diffusion, or convection, and then cathodic reduction of the metal ions at dendritic nucleation sites [25]. Failure results due to the resulting conductive path formed across the dielectric between biased electrodes. This behavior has been reported for silver, gold, copper, and tin on devices such as integrated circuits and circuit boards.

Ion migration involves movement of metal ions over a surface away from the source metal [26,27]. The phenomenon is commonly referred to as corrosion product creep. The mechanism is not well understood, but it is known to occur in humid or dry environments depending on the materials. Tarnish films that form on copper in environments containing  $\text{H}_2\text{S}$  and high humidity can creep over adjoining gold surfaces causing increased contact resistance of the gold [26]. Silver iodide, formed when silver is exposed to dry iodine vapor, will creep over tantalum [27]. The latter mechanism involves silver ion migration in silver iodide and electronic conduction in the silver iodide. The driving force in the copper/gold system is thought to involve the local galvanic cell between the dissimilar metals. However, a mechanism involving conductive copper oxide is possible.

One of the most widely investigated effects is the atmospheric sulfidation of silver used in electronics. The mechanisms of silver corrosion in polluted dry and humid atmospheres have been studied [28]. For example, the reaction of silver and  $\text{H}_2\text{S}$  in air can occur directly

or by reaction with oxygen

The latter reaction mechanism is favored by most researchers. The presence of  $\text{NO}_2$  with  $\text{H}_2\text{S}$  greatly enhances silver sulfidation and when high relative humidity is added, the rate of sulfidation is extremely rapid and is limited by gas-phase diffusion even at high flow rates. Therefore, the solid-state transport of silver atoms from the bulk is faster than the interfacial reaction and does not affect the rate.

The silver sulfidation studies serve a very important point to demonstrate the complexity of mechanisms due to synergistic environmental effects. These synergistic effects are not well understood and are difficult to produce during testing unless specific conditions are met. One can easily understand how improper tests can yield results that do not duplicate actual service behavior.

Another phenomenon in electronics degradation is whisker growth, defined as filamentary growth on metallic materials [22–29]. Whiskers can be metallic or inorganic compounds. Although this behavior is still under investigation, it is reported to be a form of induced recrystallization

related to metallurgical imperfections and occurs under the influence of stress. Whiskers grow on tin, zinc, cadmium, and silver and can grow long enough to short out circuitry. Fretting is important in electronics because it can cause loss in electrical continuity in contacts, connectors, and other systems [30]. It occurs under relative motion at a contacting interface in a reactive environment. The relative motion may be produced by vibration, differential thermal expansion, or cyclic contact.

The mechanism of degradation due to the deposition of airborne particles has recently received attention [31]. When the system is exposed to moderately elevated relative humidity (typically 60 %), the critical humidity of the deposited particle is exceeded and the surface absorbs sufficient moisture to form an electrolyte solution. Various corrosion mechanisms including uniform and localized types can therefore occur, leading to failures.

## CORROSION OF COMPONENTS

Structural materials that are directly exposed, such as in cabinets, housings, and heat sinks, are fabricated from materials such as steels, stainless steels, brass, zinc, aluminum, and other metals and alloys with appropriate properties. The types of corrosion encountered in these structures depend on the environment and material as would be expected. Both uniform and localized corrosion can be important when cosmetic corrosion is of concern. In structural applications, crevice corrosion, corrosion fatigue, stress corrosion cracking (SCC), galvanic corrosion, and intergranular corrosion causing reduction in mechanical properties are important.

Printed circuit boards are generally fabricated with copper conductors separated by insulating materials and also incorporate several other metals. These systems are susceptible to corrosion when residual chemicals such as fluxes exist, and outgassing of insulating or adhesive materials such as epoxy or resin occurs. Galvanic corrosion and metal migration due to bias potentials is common under these conditions. Corrosion product creep and metal migration can cause shorting and failure.

Contacts are fabricated with a wide range of materials including gold, silver, and tin. Gold is either clad or electroplated on a substrate metal, usually a conductive material such as copper. When electroplated, a nickel underlayer is used to act as a diffusion barrier. Pore corrosion in the gold electroplate and/or corrosion product creep (usually from copper) can lead to failure. To prevent sticking and erosion, cadmium oxide is incorporated into silver in high current contact applications. With tin, the main cause of failure is fretting. An increase in resistance between contact surfaces is most destructive and is generally a direct result of corrosion reactions.

Connectors are a critical part of an electronic system. Corrosion mechanisms at connector interfaces include pore corrosion, corrosion product creep, fretting, and SCC and general attack. Pore corrosion in connectors is associated with surfaces plated with gold or other precious metals. Corrosion product creep in connectors usually involves copper corrosion products originating from exposed base

metal areas such as at edges with migration distances approaching 8 mm in several months. Fretting is mainly associated with tin in aggressive environments and where relative motion exists in the connector contact surfaces. Precious metals are also affected by fretting under more severe conditions. In some environments, SCC of connector base metals can occur. Copper alloy is susceptible to SCC in ammonia containing atmospheres. Some precious metal surfaces are susceptible to general corrosion in specific environments, which can affect contact resistance. One example is sulfur reacting with silver surfaces.

Switches and relays are also required to maintain conductive contact surfaces as well as thousands or millions of cycles of operation. The same corrosion mechanisms, such as fretting, exist with these devices as observed with connectors and contacts. However, the mechanical requirements can lead to additional wear and erosion corrosion problems.

The requirement to maintain electrical continuity in grounding and electromagnetic interference (EMI) shielding requires that corrosion in the contact areas be avoided. Galvanic corrosion, where dissimilar metals must be bonded, can lead to an increase in electrical resistance and loss in grounding. The same effect can occur with thermal contacts with the additional effect of higher temperatures.

Integrated circuits (IC) are highly intolerant to corrosion due to their small dimensions [5]. One example of a packaged IC consists of a silicon chip mounted on a metal support or frame, small gold wires to attach an aluminum pad on the circuit to external pins, and a plastic, epoxy, or silicone encapsulating material to protect the chip and wire connections. The frame is made from copper, Kovar, alloy 42, or nickel and is selectively plated with gold or silver. This encapsulated package with soldered or plated leads is extremely complex and therefore is susceptible to many corrosion mechanisms. The behavior of the package in a humid environment is highly dependent on the quality of the encapsulation. Moisture permeation, residual deposits such as chlorides, and atmospheric contaminants in contact with the silicon device will contribute to corrosion. Even minimal amounts of these contaminants and the resulting corrosion reactions can cause circuit failure. Examples include corrosion at the gold wire/aluminum pad galvanic

couple and electromigration of silver and, in rare cases, gold causing shorting. The external surface of the IC package is also susceptible to corrosion reactions because of direct exposure to the environment under bias conditions. The IC package leads are generally soldered or plated. Corrosion product creep can short the leads, SCC of the lead (such as alloy 42) can occur, and in some cases tin whiskers can grow with tin plated parts resulting in shorting.

## CORROSION TESTS AND STANDARDS

Accelerated corrosion testing of electronic components differs substantially from traditional accelerated corrosion testing. Most mature accelerated tests have been developed to evaluate the performance of structural materials in rather corrosive environments. Therefore, structural electronic systems such as cabinets, housings, and accessories are tested conventionally. However, electronic components usually function in environments that are comparatively mild where corrosion mechanisms and rates can be unique. The amount of corrosion that can cause failure is quite small when compared to that for other applications. Therefore, results of traditional tests must be evaluated carefully in order to determine if the resulting corrosion mechanisms are those encountered in real life. Also, new and improved tests have been developed specifically for electronic systems. It is of great importance to note that systems that are energized as in service may behave differently because of bias voltages and other effects. Therefore this factor must be taken into account when conducting corrosion tests. Where appropriate, electronic systems and devices should be active/energized during corrosion testing. A list of tests along with their use and standard designation is shown in Table 6. In addition to those listed in Table 6, a number of important standards are used in determining both the susceptibility and the decrease in corrosion protection of various metallic coatings used in electronics applications. Two of these are; ASTM B 765, Guide for the Selection of Porosity Tests for Electrodeposited and Related Metallic Coatings, and, ASTM B 809, Test Method for Porosity in Metallic Coatings by Humid Sulfur Vapor. Other ASTM standards for plated coatings include B 488 (Gold), B 545

TABLE 6—Environmental tests and standards for electronics corrosion.

Test	Standard	Use
Humidity (noncondensing)	IEC 68-2-3	Use and storage at high humidity
Humidity (condensing)	ASTM D 1735, D 2247, DIN 50017	Use and storage at high humidity where condensation occurs
Humidity (cyclic)	IEC 68-2-30, MIL-T-5422	Use and storage at high humidity where condensation occurs
Thermal (cold)	IEC 68-2-1	Use and storage at low temperature, adhesion of plating and coatings, physical distortion
Thermal (hot)	IEC 68-2-2	Use and storage at high temperature, long-term aging of organics and oxidation of metals
Salt Spray (Fog)	ASTM B 117, IEC 68-2-11, ISO 9227	Not recommended but used for coatings and systems
AASS	ASTM G 85, ISO 3769	Not recommended but used for coatings and systems
CASS	ASTM B 368, ISO 3770	Not recommended but used for coatings and systems
Cyclic Salt Spray	ASTM D 2933, SAE J1563	Electronic housings, cabinets, units
Sulfur Dioxide (SO <sub>2</sub> )	ASTM G 87, IEC 68-2-42, DIN 40 046	Noble metal coatings (porosity test)
Hydrogen Sulfide (H <sub>2</sub> S)	IEC 68-2-43, DIN 40 046	Noble metal coatings (porosity test)
Nitric Acid	ASTM B 735, ISO 4524/2	Porosity in gold coatings
Sulfurous Acid/SO <sub>2</sub>	ASTM B 799	Porosity in gold and palladium coatings
Paper Electrography	ASTM B 741	Porosity in gold coatings

(Tin), B 679 (Palladium), B 689 (Nickel), B 700 (Silver) and B 867 (Palladium-Nickel).

## ELECTROCHEMICAL TESTS

Electrochemical tests are powerful tools for determining the corrosion behavior of materials. One of the most important applications of these techniques in electronics is the determination of porosity in precious metal coatings [32]. For example, corrosion potential measurements and controlled potential tests are used to determine porosity in gold electrodeposits on copper/nickel. It is possible to calibrate the techniques so that exposed base metal due to porosity can be estimated. The potential techniques offer advantages of simplicity and high sensitivity at very low levels of porosity. Electrochemical tests are also valuable in evaluating and selecting detergents that are not harmful to electrical components in response to the industry's need to move away from chlorofluorocarbon-based cleaning agents towards aqueous based systems. These electrochemical techniques have been reviewed elsewhere in this manual.

## ENVIRONMENTAL TESTS

Environmental tests for electronics can be divided into two groups based on the information they provide.

The first group includes those tests that do not provide any corrodent other than humidity and oxygen. Such tests are constant humidity exposure, temperature cycling, and temperature/humidity cycling. For these tests, the level of cleanliness of the sample (residual chemicals) is a major variable. The types of questions answered in these tests are: Can a soldering flux be changed without causing corrosion problems? Is there a corrosive agent in organics such as an epoxy that will outgas and lead to corrosion of adjacent electronic components? Is the cleaning operation adequate to remove contaminants? Will corrosion occur during storage, shipping, and handling? Will electrical properties of insulating materials change due to moisture permeation? Will the device remain hermetic?

In running the first group of tests, care must be taken to ensure that the test chambers do not introduce any contaminant other than humidity and oxygen. Very low levels of hydrogen chloride or hydrogen sulfide will introduce corrosion variables that will affect most electronic metals. In general, the noncondensing humidity test is conducted in a chamber at high relative humidity and temperature for a selected period of time. The most common of these for IC packages is the 85°C-85 % relative humidity-bias (THB) test. Higher temperatures have been used in these tests in order to accelerate the effects. However, for general use, the most common condition is 98 % relative humidity at 30–60°C. Condensing humidity tests are commonly conducted in cabinets at 100 % relative humidity and 38°C. Table 6 lists commonly used standards for humidity testing.

Thermal tests, both cold and hot, are conducted to provide information on electronics use or storage at temperature. The performance of materials at low temperature (–40°C) or at elevated temperature is critical in many

applications. Thus, the mechanical properties of plastics, platings, and coatings, the stress relaxation and aging properties of materials, and the heat dissipating properties, can be determined.

Use of cyclic humidity, cyclic temperature, and cyclic bias are common to introduce conditions of condensation, distortions and electrolysis, and determine coating adhesion properties. The combination of physical distortion due to cyclic temperature, humidity producing condensation, and potential bias producing migration is important in determining the resistance and effect of moisture ingress in electronics.

The second group of tests answer questions such as: Are materials selected sensitive to corrosive air pollutants? Do the coatings provide an adequate barrier to corrodents? Are cabinet materials sufficiently corrosion-resistant to protect sensitive components? This group of tests introduces the corrodent and include salt spray (fog) and corrosive gas chamber tests [33]. Cabinet tests using salt fog (Table 6) are the most widely used corrosion tests for electronic systems. Although the salt spray test is not generally recommended for use as a performance test in electronics because corrosion mechanisms are not representative of those observed in service, the aggressive salt mist test is used widely for quality assurance of various systems and components. Other tests include the acetic acid salt spray and the CASS tests, which are also used for quality assurance of coatings. It should be mentioned that cyclic salt spray tests have been developed to incorporate the exposure to ambient atmosphere, hot and cold, and humidity as well as salt spray [33]. These cyclic salt spray tests are more reliable for performance testing, but still must be used with caution.

Several cabinet tests with a single gas environment are used for noble metal coatings in electronics. The most well-known is the Kesternich test and several variations on this test, which uses SO<sub>2</sub> at very high levels (0.1–1 %) at room temperature and 75–100 % relative humidity. A similar group of tests with H<sub>2</sub>S have been used, also with relatively high levels of this pollutant. In general, these single gas tests have been used for porosity in gold and other noble metal coatings, especially on nickel and copper underlayers.

It has been recognized that single gas tests with very high levels of SO<sub>2</sub> or H<sub>2</sub>S do not represent conditions to which electronics systems are exposed. Recent trends in accelerated testing of electronics have centered around environments consisting of flowing gas and low level multi-component gas mixtures, which simulate synergistic environments found in service [13,34–36]. Pollutant formulations usually contain very diluted mixtures of hydrogen sulfide, chlorine, nitrogen dioxide, and sulfur dioxide with continuous flow at 25–30°C and 70–85 % relative humidity. Various combinations and levels (in the ppb range) of these pollutants at specific temperature and relative humidities provide a range of aggressivity as shown in Table 5 [21]. The four classes of environments in Table 5 closely approximate the chemistries found in various service environments and the mechanisms observed in the corrosion of electronic materials. Examples include pore corrosion in noble metal coatings (especially gold), corrosion product creep, and electromigration under bias conditions. The multiplication factor relating the aggressivity of the mixed flowing gas test to

ASTM B 827, ISO 10062	Practice for Conducting Mixed Flowing Gas (MPG) Environmental Tests

field service is determined through the use of copper or silver coupons, or both. The amount of coupon corrosion for a specific time as determined by cathodic reduction or weight gain, or both, is compared to results of coupon exposure in the appropriate field service environment. Table 7 lists some mixed flowing gas test conditions used in laboratories and Fig. 1 shows a diagram of a typical apparatus. Table 8 is a list of standards describing methods for conducting mixed flowing gas tests.

In both groups of tests described here, standard metal coupons should be included in each test to ensure that the test chamber is giving reproducible results. Copper coupons are a good standard because copper is commonly used in electronic devices, it is sensitive to most corrosives, and its oxide thickness is easily measured by coulometric reduction.

Control sample components with well-documented behavior can be used as a comparison. This information is valuable to determine if the chamber is reproducing corrosion effects previously observed.

There are literally thousands of tests used by industrial organizations for specific applications in electronics. Some are very specific, such as the nitric acid test for porosity in gold, (ISO 4524/2), for effects of vibration (IEC 68-2-6), for temperature (IEC 68-2-14), for solder (IEC 68-2-20), and for solderability (IEC 68-2-54). It is very common for laboratories to modify existing standardized tests to suit their specific needs. The technical literature will frequently describe these test conditions.

CHARACTERIZATION OF CORROSION PRODUCTS

The importance of surface and chemical analysis techniques in electronics corrosion testing cannot be overstated. These powerful tools contribute to solving problems and elucidating corrosion mechanisms in simple and complex systems. Chemical analysis techniques include infrared (IR), ultraviolet (UV), and RAMAN spectroscopy; X-ray diffraction; atomic adsorption; emission and mass spectroscopy; gas and liquid chromatography; and optical and transmission electron microscopy. Surface analytical techniques include electron spectroscopy for chemical analysis (ESCA), Auger, secondary ion mass spectroscopy (SIMS), and ion scattering spectroscopy (ISS). These important techniques used in conjunction with corrosion tests are described in another section of this manual.

SUMMARY

Environmental corrosion is having an increasing impact on the reliability of electronics. This chapter has reviewed the nature of the environment to which electronics are exposed and describes the classification of environments as reported in the literature.

Electronics corrosion is a unique subject because it occurs largely indoors or inside packages or cabinets. Therefore, classical corrosion tests do not generally apply. In addition, many failure mechanisms are unique to these systems and therefore are not treatable by classic corrosion kinetic fundamentals. This chapter therefore describes the various corrosion mechanisms important in electronics and lists the various test methods that are used in the industry.

# Telecommunications

*George Schick<sup>1</sup>*

## CORROSIVE ENVIRONMENTS

THE TELECOMMUNICATION CABLE plant is exposed to three basically different environments: aerial, underground, and buried.

Aerial plant is exposed to rain, condensate moisture, manmade pollutants (e.g., acid rain and emissions from chemical plants), and natural corrosives (e.g., airborne salt particles at sea coastal areas).

An underground plant is located in ducts and manholes. These locations may be full or partially full of water and silt. The water may contain soluble salts characteristic of the local environment, de-icing salts, industrial effluents, and microbiological species (such as sulfate-reducing bacteria). The silt may contribute to formation of differential aeration-type corrosion cells. Stray DC currents usually cause the highest rate of corrosion in the underground plant. These currents originate at such places as DC electrified rail transportation systems, mining operations, welding operations, and cathodic protection rectifiers of buried plant (e.g., gas pipelines). In some cities where steam is sent through pipes for heating various buildings, steam leaking from these pipes can ruin nearby communication cables, partially by the high temperatures and partially by water from condensation inside the cable.

A buried plant is directly exposed to local soil, water, contaminants, and stray currents.

## MATERIALS

### Cables and Closures

In the past the copper conductor pairs in telecommunication cables were insulated with paper pulp, and the outer sheath, which serves as an electric shield and provides corrosion-resistant physical protection, was made of a lead alloy containing 1.0 mass% antimony. The connections (splices) between the individual conductors were enclosed either in lead sleeves or in closures consisting of two galvanized half shells of gray cast iron, held together with stainless steel bolts and nuts. Although there is still a considerable amount of lead-sheath cable, lead sleeves, and galvanized cast iron closures, the modern telecommunication cable plant relies heavily on plastics as the material of construction.

The cables in the modern telecommunication plant, which is to a large extent today's plant, contain polyethylene-insulated

copper conductors (PIC). The shielding is accomplished in most cables with corrugated aluminum. The primary function of the shield is to reduce noise due to electric and magnetic fields from transmission and distribution power lines or other interfering sources. The shielding also protects from electrical transients such as power surges and lightning [1]. In some cables the aluminum shield is surrounded with corrugated steel for increased mechanical protection from rodents or stones. Other cables use copper-clad stainless steel for mechanical and corrosion protection. The outer jacket is made of polyethylene, an inexpensive, lightweight material that provides corrosion protection and mechanical protection to the underlying metallic shield(s). It also prevents water from entering the cable core. The connections (splices) are enclosed mainly in plastic closures, although galvanized cast-iron splice closures have been used in the past with polyethylene-jacketed cables.

The modern telecommunication plant increasingly relies on the use of optical fiber cables. The individual fibers inside the cable are coated with an epoxy acrylate polymer. Some of the cables are constructed of totally dielectric materials; others may have a steel strength member in the center in the center of the core. The outer jacket in each case is made of polyethylene. The connections of individual fibers are placed into sealed polymer closures.

The various cable constructions may have some additional components to keep corrosive elements, primarily water, out of the cable core. High-pair-count toll cables with paper-pulp wire insulation are usually pressurized with dry air to keep moisture out of the cable core. PICs may have insulation defects; to avoid corrosion of the positively energized conductors and noise-causing leakage currents at such defect sites, the cores of some cables are filled with cable filling compounds (e.g., wax in mineral oil or rubber in mineral oil) to keep water out. Many of the multipair cable sheath designs use a bituminous compound on the outer surface of the corrugated steel shield to protect against corrosion that could occur if the outer polyethylene jacket is damaged. Filled cables are usually connected with splice closures where the splices are protected with encapsulating compounds. In optical fiber cables the corrugated-steel shield is coated with a thin layer of polymer film to protect against corrosion if the outer polyethylene jacket is damaged.

Submarine optical fiber cables are generally protected by armor to resist mechanical damage and prevent floating of the cable. This armor may consist of helically wound galvanized

<sup>1</sup>Consultant, 9 Sutton Place, Apt. 1, Westwood, NJ 07675.

steel or stainless steel wires, with or without polyethylene jacketing. In some cables, the armor is made of corrugated steel covered with a polyethylene outer jacket. Galvanized steel, and to a lesser extent stainless steel, corrodes in water, and the corrosion process generates hydrogen. Another cause of hydrogen formation is hydrogenase, an enzyme that catalyzes the formation of hydrogen in hydrogen producing bacteria (*clostridium acetobutylicum*) in anaerobic bottom sediments. If fermentable carbohydrates are present (e.g., sugar) these bacteria cause hydrogen production. This hydrogen can enter the fibers and cause signal losses. These signal losses can be quite high in the 1300 nm transmission window. The signal loss increases with water depth because the partial pressure of hydrogen increases with the overall pressure [1].

Hermetically sealed lead, copper, or aluminum can keep hydrogen out of optical fiber cables in excess of the design life of the cable [1].

### Aerial Cable Hardware

The aerial cable plant is located on telephone poles. The support hardware, made of galvanized steel, is attached to the poles and holds in place the galvanized-steel strands that span the space between the poles. The cables themselves are lashed to the strands with galvanized-steel or stainless steel lashing wires. The various splice closures are also attached to the strand with galvanized-steel hardware. Some cables have built-in strands ("Figure 8" cables). Both the cable and the strand are jacketed with polyethylene, and the two jackets are attached to each other with a continuous web of polyethylene. This cable provides corrosion protection to the strand and saves the cost of lashing.

The telephone poles are mechanically secured with galvanized-steel guys, guy rods, and guy anchors. Although the guy anchors are located below grade, their corrosion can affect the aerial plant. Guy anchors may pick up stray currents at one location and transmit these currents to a discharge location where they cause stray-current corrosion. For this reason, in stray-current areas the aboveground guys are isolated with nonmetallic insulating bolts. The corrosion of guy rods and anchors also depends on the corrosiveness of the soil.

Protectors of telecommunication equipment, often mounted on the sides of homes or in basements, which provide electrical protection to the telecommunication equipment user against lightning and power faults, are exposed to environments similar to those of the aerial plant. Some of these protectors, which include a stressed copper alloy cap and cage, are placed in a phenolic housing. Ammonia or ammonium compounds can cause stress-corrosion cracking (SCC) of some of the stressed copper-base alloys, resulting in failure of the protector.

### Manholes

Manholes are located 500–800 ft (152.4–243.8 m) apart in the underground plant. They are mostly reinforced concrete chambers with built-in support hardware. Manholes are the structures where the cables are pulled into the duct system, the cable ends are spliced together, and in some of them,

signal reinforcing and signal equalizing circuits are placed, enclosed in watertight and airtight closures. In the past these closures were made of galvanized steel and galvanized cast iron. The newer types are made of polymers. Even the polymer closures contain some exposed metals, e.g., brass air pressure valves and grounding elements. Because of exposure to lightning and power fault, manholes also contain copper or tin-coated copper bonding ribbons to create equipotential conditions for electric safety.

Electronic Equipment Enclosures (EEEs) (Controlled Environment Vaults (CEVs), Walk-In Cabinets, Cabinets and Huts) are remote telecommunication centers that fulfill some of the functions of central offices (COs) but are located closer to the subscriber loop. EEEs can be constructed of reinforced concrete, steel, or fiberglass. All these locations have their own power and are required to be grounded. Regardless of the material of construction, the grounding electrodes may be stray-current pick up or discharge points; thus, they can corrode or cause corrosion elsewhere. If the material of construction is steel, corrosion problems of this material also have to be taken into account.

## CORROSION CONTROL TECHNIQUES

There are two fundamentally different methods of controlling corrosion in the telecommunication cable plant.

In the design and manufacturing stages, corrosion control is based on the selection of corrosion resistant materials and SCC-resistant alloys, heat treatment (reduced SCC and hydrogen stress cracking susceptibility), jacketing (polymer), coating (paint, bituminous compound, noble or sacrificial metal), and filling compounds (cables, splice closures).

After the plant is in place, local corrosion problems have to be taken into account. These corrosion problems do not exist everywhere, and built-in corrosion control would be prohibitively expensive. The primary corrosion control at this stage is protection against the effects of stray DC currents. Preventing or minimizing the pickup of stray current, draining the stray currents back to their source through low resistance bonds, and applying cathodic protection, can accomplish this. Other corrosion problems of the in-place telecommunication cable plant are discussed below.

An example of galvanic effects is the steel reinforcing bar in concrete in contact with the galvanized steel support hardware. In flooded manholes, the potential of reinforcing bar in concrete is around  $-0.2$  V versus a  $\text{Cu}/\text{CuSO}_4$  reference electrode. The potential of galvanized-steel support hardware against the same reference electrode is around  $-1.0$  V. This galvanic cell can lead to rapid corrosion of the galvanized-steel support hardware. This corrosion can be controlled by intentional insulation between the reinforcing bars and the support hardware.

An example of differential aeration type corrosion is lead-sheathed cable in partially silt-filled ducts. The area of the lead covered with silt is in contact with an environment that has a relatively low concentration of dissolved oxygen, while the area in water is in contact with an environment that has a relatively high concentration of dissolved oxygen. The

potential differences between these areas can be 300–400 mV. The low concentration areas are the corroding anodes, and these differential aeration cells, can lead to localized perforation of the lead cable sheath. This kind of corrosion problem can be resolved with distributed sacrificial duct anodes or replacement with polyethylene-jacketed cable.

Microbiologically induced corrosion can occur in manholes filled or partially filled with stagnant water. Under these anaerobic conditions in the presence of sulfates and some organic materials, sulfate-reducing bacteria (SRB) can proliferate and cause support-hardware failure within a few years. In manholes with high SRB content, the galvanic relationship between copper and steel can change, and copper may become the corroding anode. This condition can lead to bonding-ribbon failures and electrical protection problems. This type of corrosion problem can be resolved with environmental control (e.g., an oxidizing agent sprayed on the SRB-covered areas) or with cathodic protection.

## SPECIFIC PROBLEM AREAS

For electrical safety reasons, the telecommunication cable plant has to be grounded and bonded. This means that some bare metallic components of the plant have to be directly exposed to corrosive environments. Some of these alloys are not particularly corrosion resistant, and at some locations they require corrosion-control measures. An example of such a condition is where the galvanized-steel support hardware is part of the ground in a flooded manhole.

Bonding and grounding can also lead to inadvertent formation of galvanic corrosion cells. Grounding to copper water service pipe, and grounding a telephone cable shield to the multigrounded power cable neutral, can complete the circuit of a galvanic cell where the lead cable sheath is the corroding anode (Fig. 1). Although this problem can be resolved with an insulating joint in the shield of a vertical pole-mounted cable, the cause of the problem is difficult to track down. The reason is that different craft persons may make the grounding to the water pipe and bonding to the power cable neutral at different times.

In the modern optical fiber cable plant, hydrogen permeation into the fiber can cause considerable signal losses. Corrosion of the armor wires on submarine optical fiber

cables is a major cause of hydrogen formation, and without the presence of an effective barrier, hydrogen will enter the fibers. This problem can be resolved only by cable design changes.

## USE OF TEST METHODS TO EVALUATE CORROSION

### Tests for Materials Selection and Performance

Corrosion evaluation of the telecommunication cable plant components is started at the time of earliest availability. At this point, the corrosion test methods are geared toward establishment of corrosion resistance of the exposed bare metallic components in the environment for which they are intended. The test methods are also directed toward evaluation of galvanic compatibility of components made from more than one alloy, and the effectiveness of noble or sacrificial metallic coatings. Test methods are also used to establish susceptibility to SCC and hydrogen stress cracking. Other tests are used to establish whether or not low contact resistance can be maintained between exposed contacting elements (e.g., ground connectors and grounding clamps).

Some of the telecommunication cable plant components are made with metals embedded in polymers, and the metals are exposed to the corrosive environment only at very small areas (e.g., edges or small defect sites on the polymer). Test methods are used to evaluate the penetrability of the metal-to-polymer interface and the ensuing progressive corrosion of the metal.

These corrosion evaluation test methods of new or replacement components often lead to material or design changes to upgrade their performance. An extensive soil burial test program, using 52 different telephone cable shielding systems at six different test locations, was conducted by the USA's Rural Electrification Administration (REA) and the National Bureau of Standards between 1968 and 1974 [3]. The results of this study strongly affected the design of telephone cable shields.

In another program the corrosion resistance of aluminum, copper and copper clad stainless steel has been studied in four different soils for three years [4].

### In-Service Monitoring

The original corrosion test methods used to select the materials for manufacturing the telecommunication plant components cannot prevent all possible corrosion failures. Some corrosion problems may occur due to local conditions (e.g., stray DC currents or heavy industrial pollution). Corrosion of the cable plant is monitored by periodic field-testing and, for areas of prior corrosion failures, by centralized testing. The periodic field tests consist of potential surveys against reference electrodes along the cable routes to establish corrosion areas, potential changes perpendicular to the cables to establish the location of current pickup and discharge points, and current measurements (magnitude and direction) to further find the source of corrosion current. When the source of a corrosive stray current is suspected to be the rectifier of a "foreign plant's" cathodic

FIG. 1—Galvanic cell in the telecommunications cable plant.

protection system (interference) or an HVDC ground electrode, a joint field test is conducted together with the representatives of the "interfering" and the "affected" plants. During these tests, the interference current is periodically turned on and off so that the effect on the other plants can be measured. Other "dynamic" stray-current effects (e.g., stray currents from a DC electrified rail transportation system) on the cable plant can be measured with recording voltmeters. A testing technique that can pinpoint the area of maximum corrosion exposure on the cable, and can determine if a particular stray-current source is the cause of the observed effect is the simultaneous measurements of cable-to-earth potential ( $V_g$ ) and cable-to-interfering plant potential ( $E_1$ ). The measured data are plotted in correlation curves (Fig. 2) [5].

In order to facilitate joint testing, the owners of the affected plants send representatives to periodic meetings to organize and prepare the joint tests. Such voluntarily formed groups are called Corrosion Coordinating Committees.

When corrosion surveys have established the location and source of corrosion problems on a telecommunication cable plant, the next step is to establish mitigation measures. These measures can include placement of insulating joints to limit current pickup by the cable shield in cable entrance facilities (CEFs), some building entrances, vertical riser cables on telephone poles, and, under special conditions, in manholes. Most of these measures consist of placing low-resistance drainage bonds to return stray DC currents to their source without causing corrosion. If the stray current

source is a DC electrified rail transportation system (dynamic stray-current source), a reverse-current switch may have to be installed, in series with the bond, to stop current flow in the wrong direction (from the source to the cable).

Application of either the impressed-current or galvanic-anode type of cathodic protection can counteract the corrosion currents.

Centralized testing monitors the major corrosion areas and their mitigation measures. The potential of a permanent reference electrode, the operation of a cathodic protection rectifier, and the current on a bond wire can be brought to a test desk in a central office via dedicated wire pairs in cables, and they can be monitored at that location.

### Analysis of Simulated Field Failures

Sometimes, despite extensive corrosion testing, some components of the telecommunication cable plant may fail in the field. Often these failures are caused by unforeseen field conditions or by the presence of unexpected corrosives. To establish the source and mechanism of corrosion failure, these components are exposed to simulated field conditions, and the results are compared to the field failures. Some examples of simulated field failures are described below.

Type 410 (UNS S41000) stainless steel bolts, holding together galvanized cast-iron splice closures, failed in flooded manholes after being in service for three to four months. The field failures were simulated using samples assembled with the highest permissible torque, and with and without the use of molybdenum disulfide antiseize compound. To accelerate the failure time, some samples were charged with hydrogen using a power supply and a platinum anode. The results showed failures identical to those that occurred in the field. The cause of the failures was hydrogen, generated by the galvanic cell formed between zinc and stainless steel. The failures were accelerated by the fact that the martensitic (410 type) stainless steel is susceptible to hydrogen stress cracking, and the sulfide of the molybdenum disulfide on the stainless steel surface acted as a catalytic poison for the  $2H \rightarrow H_2$  reaction. The solution to the problem was to change to austenitic stainless steel, eliminate the molybdenum disulfide, and limit the torque.

Galvanized steel manhole support hardware and copper and tin-coated copper bonding ribbons failed in manholes after relatively short exposure times (1–4 years). Examination of these manholes indicated the following: (1) all these manholes smelled of hydrogen sulfide, (2) the hardware and bonding ribbons were coated with black slimy corrosion products, either directly visible or under a rust covering, and (3) when the black slime was wiped away, the metal underneath appeared clean, shiny, and pitted. Microbiological analysis of the water and the black compound indicated the presence of SRB (desulfovibrio desulfuricans). Laboratory tests of small size samples (1 in. by 1 in. (25.4 mm by 25.4 mm) galvanized steel, 3 in. by 0.5 in. (75.2 mm by 12.7 mm) copper and tin-coated copper bonding ribbons) were exposed individually and coupled in 30-L test vessels under anaerobic conditions. This ensured a large corrosive liquid volume to exposed surface area ratio. Potential measurements versus time indicated rapid corrosion of zinc.

FIG. 2—Cable-to-earth vs. cable-to-rail correlation curves (Beta survey).

Mass loss measurements established high rates of corrosion for steel and copper. Potentiodynamic polarization measurements showed that in SRB environment, copper becomes anodic to steel.

In separate laboratory and field experiments, it has been established that spraying 5.25 wt% of sodium hypochlorite (NaOCl) solution on the black corrosion products can provide relief from this type of corrosion problem for one or more years.

## TEST METHOD APPROACH

The test method approach depends on several factors; thus, the test developer has to ask several questions to determine the best approach.

- What constitutes corrosion failure (e.g., loss of strength, perforation, increased contact resistance)?
- How well is the corrosive environment characterized?
- Is there a predominant component of the environment that causes corrosion (e.g., marine, industrial)?
- Can the test be accelerated without rendering it meaningless?
- Is the electrochemistry of the reaction well understood?
- What is the most important failure mode that requires detection (mass loss, loss of tensile strength, local penetration, formation of high resistance film between contacting elements resulting in high contact resistance, cracking)?
- How much time is allocated for testing?

## Environmental Simulation

This approach is useful if the environment is well characterized and a few weeks or months have been allocated for the test; examples include: exposure to salt spray to simulate sea coastal areas, exposure to 3.5 wt% NaCl solution for submarine environment, Kesternich chamber test (humid SO<sub>2</sub> and CO<sub>2</sub> mixture) for industrial environment [6], and mixed flowing gas tests for a range of environments.

## Acceleration

Accelerated corrosion tests are appealing because the allocated time is often very short. Generally, increased temperature, increased concentration of some of the corrosive species, increased or decreased pH, and applied DC current can all increase the rate of corrosion. However, these acceleration factors can be misused for the sake of saving time, and the test may become meaningless.

Some examples where acceleration can be beneficial are as follows:

- Moderately increased temperature to accelerate a reaction that is naturally occurring in the plant.
- Increased concentration of corrosive species in a SCC test (e.g., Mattsson's solution [7]).
- Acidified salt solution exposure to test for the effect of corrosive liquid penetration to a metal-to-polymer interface.
- In all cases it is important to insure that the mechanisms of corrosion are not changed by the acceleration technique.

## Electrochemical Test Methods

Electrochemical test methods evaluate various corrosion characteristics of metals and alloys in a relative short time. Among these characteristics that can be evaluated electrochemically are:

- Corrosion rates, if the corrosion reaction is well defined.
- Galvanic relationships of metals and alloys in various environments.
- Passive range of potentials of active-passive alloys.
- Susceptibility to pitting.

## Detection of Corrosion

Laboratory tests are used to detect corrosion of metals used in various cable plant components. These tests are conducted to establish whether or not a material is suitable for a given component. Corrosion of individual test components can be tested under both laboratory and field conditions. The in-place plant can only be tested under field conditions.

The materials testing may include corrosion studies based on: mass loss, pitting depth, loss of tensile strength, time for SCC or hydrogen stress cracking, and color changes at coating defect sites.

The components can be tested for: SCC to evaluate the effects of applied and residual manufacturing tensile stresses; leakage resistance after salt spray or temperature-humidity cycling tests; and contact resistance after a salt spray test, temperature-humidity cycling, or a hydrogen sulfide exposure test.

The in-service cable plant is tested to establish the presence or absence of stray direct currents, the galvanic corrosion effect of "foreign" plants, the corrosivity of local environmental conditions, and the corrosive effect of "long cells" formed by the changes in the environment. The corrosion of the in-place plant is detected through potential surveys, current tests, soil resistivity tests, redox potential tests, and pH tests.

## Methods Used

The test methods used to evaluate the corrosion of materials and plant components are described in Bellcore Technical Advisories (TAs), Technical References (TRs), and Generic Requirements (GRs). Many of the tests in these documents include and reference ASTM, UL, ANSI/NEMA, and MIL standards. Some of the test methods are specific to the telecommunication industry and can be found only in TAs\*, TRs\*, and GR\*s. Manufacturing and purchase of telecommunication plant components are based on these documents, thus, available to the manufacturers and to companies that sell them. The methods used for in-plant testing are described in Bell System Practices (BSPs)\*\* and licensed Bellcore documents.<sup>2</sup>

<sup>2</sup>Since the writing of this chapter Bell Communications Research became Lucent Technologies and Bell Telephone Laboratories became Lucent Technologies. The \* and \*\* marked documents are available from Lucent Technologies, Morristown, NJ\* and Lucent Technologies, Murray Hill, NJ\*\*.

### Test Methods for Corrosion Evaluation of Materials and Components

ASTM B 117, Test Method of Salt Spray (Fog) Testing, is widely used for testing the effectiveness of telecommunication equipment closures to protect the equipment inside from airborne ionic compounds. The test is also used to evaluate the corrosion resistance of the closure itself under extreme corrosive conditions. The testing time is usually 30 days, and the effectiveness to protect electrical equipment inside the closure is measured by resistances between tip and ring, tip and ground, and ring and ground during and after the test. This test is described in detail in TR-TSY-009 [2]. The salt fog test is also used (four days exposure) to evaluate cable shield bonding clamps. The test and the requirements are described in TA-TSY-001001 [8].

Temperature cycling with humidity is used to test equipment closures to see if condensate (moisture) forms on the inside wall. The condensate moisture may cause electronic noise on the telephone lines, and in combination with DC, electrolytic corrosion. Two different temperature-humidity cycles are used for testing telecommunication equipment. One is described in Fig. 3 and the other in Fig. 4. Temperature-humidity cycling with power is described in military standards MIL 883C [10] and MIL 202F [11].

The rain test is used to evaluate the water tightness of various closures and cabinets. For this test the top and all sides of closures are exposed to continuous water spray for 1 h at an operating pressure of 0.352 kg/cm<sup>2</sup>. The test is described in detail and the pass/fail criteria are given in UL 497 [12].

The dust exposure test is used to evaluate the tightness of closures against wind-blown dust. For this, closures are exposed to a blast of compressed air mixed with dry, Type 1 general-purpose Portland cement using a suction type blast gun. The cement is applied at a rate of 2.27 kg/min. Dust particles, besides causing mechanical damage to equipment, can also act as nucleation sites for condensate moisture. Water-soluble components of dust may form corrosive electrolytes on equipment under DC power. The test is described in detail in ANSI/NEMA 250 [13].

ASTM G 37, Practice for Use of Mattsson's Solution of pH 7.2 to Evaluate the Stress-Corrosion Cracking Susceptibility of Copper-Zinc Alloys [7], is used to evaluate manufacturing and applied stresses in components made of copper-zinc alloys.

FIG. 3—Temperature-humidity cycling for repeater housings in carrier systems.

FIG. 4—Temperature-humidity cycling for cable shield bonding clamps.

The hydrogen sulfide test is used to evaluate bonding and grounding hardware of outdoor telecommunication equipment. This test consists of continuous exposure of bonding and grounding hardware, in contact with conductors, in a test chamber containing 10–15 ppm hydrogen sulfide and 75 % relative humidity at  $25 \pm 2^\circ\text{C}$  for 4, 10, or 21 days. The test is conducted according to IEC 68-2-43 [13]; the contact resistance after the test is measured according to EIA 364-B [15].

Two tests [2] are used to determine the porosity of gold contacts used in outdoor equipment: (1) a nitric acid vapor test (exposure of gold-plated specimens in a desiccator containing 300 mL nitric acid for 1 h at  $24 \pm 3^\circ\text{C}$  and a maximum relative humidity of 60 %); and (2) an alkaline polysulfide test (the specimen is immersed for 60 s in a solution made of sodium sulfide, water, and excess flower of sulfur, filtered and diluted to a specific gravity of 1.142, and made alkaline with sodium hydroxide).

A corrosion test for steam resistant optical fiber cable was developed: 30.2 cm long samples are cut from the cable and 7.6 cm of the outer polyethylene jacket is removed from the middle of the sample. The ends of these cable samples are closed with rubber stoppers. The cable samples are exposed to wet, salty sand in an autoclave for 60 days at  $130^\circ\text{C}$ . The test and the requirements for evaluation of the test results are described in TA-NWT-0011322 [16].

The salt-water corrosion test is used to evaluate submarine splice closures. For this test a splice closure and its outer housing are immersed in aerated 3.5 % sodium chloride solution for 180 days. The test is described in TA-TSY-041 [17]. The same closures are also exposed to a similar test using artificial fresh water (ASTM D 2570, Method for Simulated Service Corrosion Testing of Engine Coolants).

### In-Plant Testing

Table 1 describes the documents used for various in-plant testing.

## SUMMARY

The telecommunication plant is made of a number of metal and non-metal components, exposed to various corrosive environments. Man-made effects, such as DC stray currents, can further accelerate corrosion of the plant.

The metals of construction and some plant components are tested before manufacturing for corrosion resistance in the environments to which they will be exposed. Laboratory tests and field exposures are used for this purpose. The plants are also tested after exposure to the environment to establish the local corrosion effects, especially those caused by DC stray currents.

The metals and plant components are tested by methods described in national standards. Some of the plant components and the in-place plant are tested according to methods and requirements developed by the telecommunication industry.

# Metals Processing

*Terry A. DeBold<sup>1</sup>*

THE SELECTION OF APPROPRIATE tests for materials evaluation requires consideration of pertinent forms of corrosion and details of the environment and methods of fabrication. Mechanical properties, cost, and material availability are also important. This chapter describes the rationale of test selection and supplies background on corrosion testing.

## MATERIAL SELECTION

A wide variety of metals is produced for industries such as automotive, aerospace, marine, energy, chemical processing, etc. Materials include aluminum, titanium, stainless steel, nickel- and cobalt-base alloys, tool steels, and materials for electronic, magnetic, and expansion applications. Regardless of the metal, the same selection process can be used.

### Corrosion Resistance

First, candidate materials must be selected to resist corrosion in the service environment without "overalloying" to increase the cost. All forms of corrosion and effects of fabrication, as discussed below, must be considered.

### Mechanical Properties

Strength is usually the first mechanical property considered, but factors such as hardness, fatigue, impact, and stress-rupture properties are also important for many applications.

### Fabrication

The material chosen must be able to be welded, machined, cold-headed, etc., as necessary without undue cost or difficulty.

### Total Cost

This value analysis of the material includes initial alloy price, installed cost, and the expected life of the finished product. Improved machinability, headability, weldability, or simplified heat treatment may justify higher material cost. A more costly product that provides longer service may be less expensive than lost time for outages to replace a less expensive material.

<sup>1</sup>Specialist, Stainless Alloy R&D, Carpenter Technology Corporation, P.O. Box 14662, Reading, PA 19612-4662.

## Product Availability

The availability, including minimum purchase requirements, is also an important consideration in selecting the most practical and economical material.

## FORMS OF CORROSION

All forms of corrosion must be considered at the beginning of any test program, before discounting attack modes that are not likely to occur. Corrosion types can be divided into general (or uniform) attack and localized corrosion, in which extensive attack can occur in a very small area. Localized corrosion can be more difficult to observe.

Several forms of corrosion are shown following Fig. 1a (no corrosion), as follows: (1b) uniform attack or general corrosion, (dissolution over the entire surface); (1c) galvanic corrosion, (attack of less resistant material in a couple); (1d) erosion corrosion (increased attack due to relative motion of surface and corrosive solution); (1e) fretting (materials under load are subjected to vibration, and slip at the point of contact); (1f) crevice corrosion, (pitting at a gasket or deposit); (1g) pitting; (1h) exfoliation (subsurface attack with a laminated appearance); (1i) selective leaching, (removal of one element from a solid alloy by corrosion); (1j) intergranular (selective attack of grain boundaries); (1k) stress-corrosion cracking (SCC), (cracking in a specific medium in the presence of a tensile stress); (1l) corrosion fatigue (susceptibility to fatigue increased by a corrodent). Also, hydrogen embrittlement is a form of SCC in which hydrogen is produced by local corrosion, e.g., in a crack or pit, and results in crack propagation.

Many materials experience several of the above forms of corrosion. Some forms of attack are more prevalent in certain materials, e.g., exfoliation is well known in aluminum alloys and selective leaching can occur in copper-zinc alloys. A more complete description of corrosion types is found elsewhere in this book and is discussed in the literature [1-3].

## FACTORS THAT INFLUENCE CORROSION RESISTANCE

In addition to the alloy composition, several factors affect corrosion resistance and must be considered in testing programs.

FIG. 1—Several forms of corrosion that occur in metals and metallic alloys [29].

### Effects of the Service Environment and Operation

Tables and isocorrosion charts are available to document experience with general, or uniform, corrosion in relatively pure chemicals at various temperatures and concentrations. An example is shown in Fig. 2. The selection of a material, or the proper test to evaluate a material, often includes more than consideration of uniform attack in pure chemicals. The presence of impurities can accelerate or retard general corrosion, e.g., chlorides (and some other halides) can cause pitting or SCC. Crevices due to the design or adherent deposits can be sites of attack, particularly in the presence of chlorides. Higher velocity of the corrodent can (a) reduce attack if deposits and the resulting crevice attack

are prevented, or (b) increase attack if erosion-corrosion occurs. Both localized and general corrosion can be accelerated by variations in pH; aeration can have different effects depending upon the material/environment system. Also, corrosion may be increased by heat transfer. Examples include: (a) a heat exchanger where steam produces high metal temperatures to heat a corrosive solution, and (b) a cold metal wall where corrosive condensate forms from hot gases.

### Effects of Material Processing and Fabrication

The material condition, fabrication, and finish can also affect its service. Corrosion resistance, particularly SCC, can depend upon whether a material is annealed, hardened, or cold-worked, etc. Welding or stress relieving can affect intergranular or SCC resistance. Smoother surfaces, free of scale and other foreign particles, generally exhibit better resistance. Passivation can be useful for stainless steels to remove free iron contamination, which can cause rusting of resistant materials.

Service life can also be affected by galvanic contact with a dissimilar metal. The less resistant material tends to be dissolved and may experience general corrosion, pitting/crevice corrosion, or SCC. Hydrogen may be liberated at the more resistant metal, making hydrogen embrittlement an issue if the material is susceptible. Stray currents, e.g., from a DC power source, may have the same effect as dissimilar metal contact.

The literature includes additional information regarding the factors affecting corrosion [1-3]. Also, several corrosion data summaries are available to assist in material selection [4-9]. Many of these include consideration of several modes of corrosion and the effects of impurities. All of the above issues must be considered when evaluating a material for service. Testing of an unstressed-annealed material when the material in service will be bent, welded, or stress-relieved may result in a service failure regardless of satisfactory test results.

FIG. 2—Example isocorrosion chart for UNS N08020 in reagent grade sulfuric acid.

## RATIONALE OF TEST SELECTION

The corrosion testing performed in the metals processing industries is generally based on customer need. Corrosion tests may be chosen in order to select the correct material or allow the producer to develop a new alloy. Yet probably the largest volume of testing is conducted on established products for quality control purposes. The following section discusses the reasons for the various types of testing and provides concepts that can be used to design testing programs.

### Quality Control Tests

Quality control tests are frequently standardized and often are designed to detect susceptibility to a specific form of attack rather than simulate service. Standardization provides the opportunity for interlaboratory testing to develop precision (repeatability and reproducibility) and bias (deviation from accepted reference values) information before the test is used. ASTM provides a volume, *Standards on Precision and Bias for Various Applications*, for use in this work [10].

Knowledge of precision and bias is important if acceptance criteria are to be established. Confidence in the values obtained is necessary when a test is used to separate acceptable and unacceptable material. Generally, the establishment of acceptance criteria requires extensive testing of the product forms of interest.

Also, quality control tests are frequently brief and relatively inexpensive. Typically, they must be completed before shipment; delays, or excessive testing costs are not desired by either producer or user.

Discussion of the test objectives by user and producer is essential. Communication facilitates agreement regarding frequency of sampling, specimen location, orientation, and surface finish. Testing must be sufficient to guarantee quality without excessive cost or delay. Tests are often performed on each heat and heat treat lot to verify that the material composition and annealing practice were satisfactory. The specimen location may be chosen to provide a typical sample (generally midradius of a bar) or to evaluate

the area most likely to see service (e.g., the surface). In some cases, specimen location is chosen to restrict the amount of material wasted in cutting. Specimens are generally oriented longitudinally unless the transverse properties or resistance of the cross section is essential to service. In most cases, the equivalent of a 120 grit paper finish is provided, although smoother surfaces are sometimes required.

Perhaps the best-known quality control tests are those contained in the ASTM A 262, *Practices for Detecting Susceptibility to Intergranular Attack in Austenitic Stainless Steels*. These are summarized in Table 1 and discussed further in the testing section below.

### Simulated-Service Tests

Simulated-service tests facilitate specimen observation and control of the test environment versus in-plant tests. Tests for material selection or development generally simulate the service environment, including impurities and possibly factors such as heat transfer and aeration. Communication with the end user is essential to select the optimum tests and accomplish goals with minimum expense. Generally, these tests are not standardized. Fabrication information, such as welding or cold forming, is needed to assure that the material is evaluated in the condition that will see service. ASTM G 58, *Practice for Preparation of Stress-Corrosion Test Specimens for Weldments*, describes procedures for making and using welded stress-corrosion specimens. Also, details of the design and operation of the unit are needed to determine whether the effect of crevices must be evaluated.

Some means of acceleration is necessary to predict years of service using only weeks or months of testing. Several means have been used to accelerate these tests, including (a) use of higher temperatures, lower pH, or increased concentrations of deleterious impurities, (b) use of slow strain rate or electrochemical techniques, (c) use of increased stresses or precracked specimens, and (d) use of metallographic examination or measurement of very small weight losses to detect attack initiation. Examples are provided in the Test Descriptions section below.

TABLE 1—ASTM intergranular corrosion tests.

ASTM Standard	Test Media	Test Duration	Applicable Alloys
A 262-A	Oxalic acid etch	Etch test	Screening for selected alloys in other A 262 practices
A 262-B	$\text{Fe}_2(\text{SO}_4)_3\text{-H}_2\text{SO}_4$	120 h	UNS S30400, S30403, S31600, S31603, S31700, S31703, S32100, S34700, J92500, J92600, J92800, J92900, J92999, J93000
A 262-C	$\text{HNO}_3$ (Huey Test)	240 h <sup>a</sup>	Same as A 262-B <sup>b</sup>
A 262-E	$\text{Cu-CuSO}_4\text{-16 \%H}_2\text{SO}_4$	24 h <sup>c</sup>	UNS S20100, S20200, S30100, S30400, S30403, S30409, S31600, S31603, S31609, S31700, S31703, S32100, S34700
A 262-F	$\text{Cu-CuSO}_4\text{-50 \%H}_2\text{SO}_4$	120 h	UNS J92800, J92900
G 28-A	$\text{Fe}_2(\text{SO}_4)_3\text{-H}_2\text{SO}_4$ (similar to A 262-B)	24/120 h	UNS N10276, N06455, N06007, N06200, N06686, N06985, N08020, N06600, N06625, N08800, N08825, N06022, N06030, N06059, N08367
G 28-B	$\text{H}_2\text{SO}_4 + \text{HCl} + \text{FeCl}_3 + \text{CuCl}_2$	24 h	UNS N10276, N06022, N06059, N06200, N06686
A 763-W	Oxalic acid etch (similar to A 262-A)	Etch test	UNS S44400, S44626, S44660, S43035, XM27
A 763-X	$\text{Fe}_2(\text{SO}_4)_3\text{-H}_2\text{SO}_4$ (similar to A 262-B)	24/120 h	UNS S43000, S44600, S44700, S44800, XM27
A 763-Y	$\text{Cu-CuSO}_4\text{-50 \%H}_2\text{SO}_4$ (similar to A 262-F)	96/120 h	UNS S44600, S44626, S44660, S44735, S44700, S44800, XM27
A 763-Z	$\text{Cu-CuSO}_4\text{-16 \%H}_2\text{SO}_4$ (same as A 262-E)	24 h	UNS S43000, S43400, S43600, S44400, S43035

<sup>a</sup> Shorter duration permitted in some cases.

<sup>b</sup> The nitric acid test has also been applied less frequently to other austenitic, ferritic, and martensitic grades.

<sup>c</sup> Typically 24 h.

### In-Plant and Field Testing

Materials producers frequently supply specimens to users for exposure to plant environments. Comparison of several materials has been facilitated by exposing racks containing plate or sheet coupons along with stressed specimens, as shown in Fig. 3. A concern of both metals producers and users is that the specimens tested be in the condition that will see service. This has resulted in the use of welded U-bend specimens to incorporate the cold-forming and welding effects that may occur in fabrication. The crevice at the restraining bolt provides an evaluation of crevice corrosion resistance. Because crevice geometry and tightness are important variables, a reproducible crevice design is essential.

After testing for as long as possible, the specimens are evaluated by mass loss, visual, and binocular examination and in some cases by metallographic techniques. Generally, these tests can be accelerated only by severe bending or possibly by the application of a tight crevice, and the initiation of corrosion must be detected by careful weighing and examination.

Other plant test specimen designs and evaluation techniques are available. Some fit in restricted spaces and/or monitor electrochemical parameters. Examples of such fixtures, electrode polarization probes, appear in Fig. 4. These allow monitoring of the corrosion process and can detect changes in plant operation that cause excessive attack.

Information regarding field testing is contained in ASTM G 4, Guide for Conducting Corrosion Coupon Tests in Field Applications, while practices for handling samples are found in ASTM G 1, Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens. Related information dealing with field testing in the atmosphere and seawater is found in ASTM G 50, Practice for Conducting Atmospheric Corrosion Tests on Metals and ASTM G 52, Practice for Exposing and Evaluating Metals and Alloys in Surface Seawater. Procedures for field failure analysis are found in ASTM G 161, Standard Guide for Corrosion-Related Failure Analysis.

### TEST DESCRIPTIONS

This section provides comments on the utility of several tests, according to the principles discussed above. A more complete description of corrosion testing appears elsewhere in this manual.

**FIG. 4—Two (top) and three (bottom) electrode polarization probes for exposure in plant environments (photograph courtesy of Metal Samples Co., Inc., Munford, AL).**

### Intergranular Corrosion Tests

The theory and application of intergranular corrosion tests have been discussed in the literature [11]. The tests included in ASTM A 262, as summarized in Table 1, are frequently used for quality control of austenitic stainless steels. These methods detect susceptibility to intergranular corrosion and the test solutions may be quite different than the service environments. These tests are frequently used to evaluate the effectiveness of the heat treatment used prior to shipment of a material. The alloys that may be evaluated by each practice (e.g., Types 304 or 316) are specified as well as the procedure for using the several tests. Comments regarding a few of the tests are useful.

ASTM A 262 Practice A is a rapid procedure in which specimens are electrolytically etched and examined metallographically for attack at the grain boundaries. It has been widely used as a quality control screening test to approve acceptable material. Specimens that fail the oxalic acid test are then evaluated by one of the other tests in ASTM A 262 and are accepted or rejected based on these results. Although the oxalic acid etch test is done quickly, it can be tedious, because examination of all fields is required.

The accelerated Strauss test, ASTM A 262 Practice E (copper-copper sulfate-16 % sulfuric acid test), is also a popular quality control test because it is brief (typically 24 h) and includes an acceptance criterion. After exposure, specimens are bent to expose intergranular attack. Material with attack fails, while unattacked material passes. Experience is important in specimen evaluation to separate "cracks" due to attacked grain boundaries from mechanical cracks that may have occurred in bending. Different laboratories have obtained varying results upon examination of the same set of specimens [12].

Three tests from ASTM A 262 provide corrosion rates: Practices B, C, and F. Practice B requires a 120 h exposure and is generally more popular than Practice C, which requires 240 h of boiling time. Also, Practice C detects susceptibility to attack, which may not affect service in environments other than highly-oxidizing media (such as nitric acid).

Use of these tests requires work and communication between user and producer to establish the maximum acceptable corrosion rate. In one example of this process for austenitic stainless steels, hundreds of specimens representing several product forms were evaluated in ASTM A 262 tests to compare actual corrosion rates with the specified maximum rate [13].

Related standards for determination of intergranular corrosion are ASTM A 763, Practices for Detecting Susceptibility of Intergranular Attack in Ferritic Stainless Steels, and ASTM G 28, Test Methods of Detecting Susceptibility to Intergranular Corrosion in Wrought, Nickel-Rich, Chromium-Bearing Alloys. As seen in Table 1, many of these methods are similar to the ASTM A 262 practices.

### Stress-Corrosion Cracking Tests

SCC behavior often is not as reproducible as intergranular corrosion penetration rates. Initiation and propagation of stress-corrosion cracks can depend upon many factors, including variation in pH and chloride content in crevices, amount of dissolved oxygen, and stress distribution in the material. Because of this, and the longer duration associated with testing, SCC tests have seen limited use as quality control techniques.

Several environments and specimen designs are available for SCC evaluation [14]. ASTM G 36, Practice for Evaluating Stress-Corrosion Cracking Resistance of Metals and Alloys in a Boiling Magnesium Chloride Solution, provides a more severe environment than generally found in service. Resistance in this test depends largely on the nickel content and most austenitic and duplex stainless steels are readily cracked.

Sodium chloride solutions appear to provide environments more representative of service than ASTM G 36. Boiling 25 % sodium chloride, acidified to pH 1.5 with phosphoric acid, provides a less severe environment, which has been used to evaluate stainless steels (see ASTM G 123, Test Method for Evaluating Stress-Corrosion Cracking of Stainless Alloys with Different Nickel Content in a Boiling Acidified Sodium Chloride Solution). Acceleration of cracking in this environment has been accomplished by severely stressing the material using U-bend specimens. See ASTM G 30, Practice for Making and Using U-Bend Stress-Corrosion Test Specimens. Other statically-stressed samples described in ASTM standards include: C-rings (G 38), bend-beams (G 39), and direct tension (G 49).

Several means are available to accelerate SCC tests. Dynamic testing can be an effective method to obtain results rapidly in environments that simulate service. Slow strain rate tension (SSRT) tests are performed by pulling a specimen to failure at strain rates of  $10^{-7}$  to  $10^{-4}$  s<sup>-1</sup> in a corrosive environment [15,16]. See ASTM G 129, Practice for Slow Strain Rate Testing to Evaluate the Susceptibility of Metallic Materials to Environmentally Assisted Cracking. Elongation (or time to fail) and reduction in area are compared to data for specimens pulled in an inert environment. Indications of corrosion susceptibility include the presence of attack on the fracture surface, secondary cracks along the gage section, and reduction in ductility figures (Fig. 5). SSRT methods have been used as acceptance tests for critical materials used in oil field applications and an example of the type of data obtained is shown in Table 2.

Dynamic testing has also been used in the nuclear power industry as a quality control test to identify material that is susceptible to SCC in reactor-water environments. The rising-load test has been performed by loading precracked, Charpy-type specimens in three-point bending using a constant

**FIG. 5—Tested slow strain rate tension specimens showing (a) poor ductility and secondary cracks indicating susceptibility to SCC, and (b) increased ductility versus Fig. 5a and absence of secondary cracking indicating improved resistance.**

extension rate. In this procedure, specimens have been tested in both air and deionized water. The stress intensity at maximum load and the time for the load to drop to one half its maximum value are recorded. Curves for exposures in a test environment and in air are shown in Fig. 6 for a susceptible heat of UNS N07750 and for a more resistant material, UNS N07716. More resistant materials are characterized by (a) higher ratios of the maximum stress intensity in the test environment versus that in an inert air environment, and (b) longer time for the load to decrease to half its maximum value (0.5 P<sub>max</sub>). Although the UNS N07716 was highly resistant, the fluctuation in load during the early part of the curve and the slightly lower maximum stress intensity (c.f. the air test) suggest slight susceptibility to attack. The rising load test is another example of a method that uses dynamic loading and is able to obtain results quickly in an environment that generally simulates long-term exposure.

Design criteria for corrosive environments can be obtained using fracture mechanics specimens. The critical stress intensity for SCC can be determined and is designated K<sub>ISCC</sub>. Frequently, however, the stress intensity after a predetermined test duration is used as a K<sub>f</sub> or final stress intensity rather than monitoring the crack growth to confirm

**TABLE 2**—Example slow strain rate test data for UNS N07716 0.250 in. (0.635 cm) diameter gage with a strain rate of  $4 \times 10^{-6}$ /s.

Environment	% R.A.	Time to Failure, h	R.A. (brine)	TF (brine) <sup>a</sup>	Secondary Cracking	Fracture Surface
			R.A. (inert)	TF (inert)		
Inert	54.8	25.8	...	...	...	...
	55.9	25.9	...	...	...	...
Sour brine	53.9	25.7	0.97	0.99	No	Slight attack
	53.1	26.6	0.96	1.03	No	Slight attack

Inert environment was helium at 177°C (350°F); sour brine was deaerated 100 000 ppm Cl<sup>-</sup>, 150 psi (1.03 MPa) H<sub>2</sub>S, 150 psi CO<sub>2</sub> (added at room temperature) and 10 g/L elemental sulfur; tests at 177°C (350°F).

<sup>a</sup>TF—time to failure.

that crack arrest has occurred. It is obviously important to differentiate between these two types of results.

The double-cantilever beam (DCB) specimen has been used in oil field and other applications [17] and is described in NACE Standard Test Method, Laboratory Testing of Metals for Resistance to Sulfide Stress Cracking in H<sub>2</sub>S Environments (TM0177) (Fig. 7). Thickness of DCB samples used in the oil field has often been restricted by the size of the product form under evaluation. In many applications, thicker samples are preferred as described in ASTM G168, Standard Practice for Making and Using Pre-Cracked Double-Beam Specimen.

Frequently, the DCB specimen is precracked to provide a sharp notch and accelerate hydrogen embrittlement or stress-corrosion processes. Machining and measuring the specimen and deflection as well as precracking parameters

and determination of the crack length require considerable care and expertise. Some material/environment systems allow evaluation in relatively short exposures, e.g., 14 days, based on experience with crack propagation rates (see TM0177). Most materials require a longer evaluation (e.g., one month or more) and the delay is usually objectionable for a quality control test.

The effect of test duration is demonstrated by a method used by the Navy to compare materials for aircraft parts. A single-edge notched (and precracked) cantilever beam specimen is deadweight loaded and exposed to 3 1/2 % NaCl. The time-to-fail at various stress intensities is plotted in Fig. 8. The stress intensity after 1000 h exposure has been used as a measure of resistance, although lower values have been obtained if the specimens are allowed to continue for 10 000 h.

### Pitting and Crevice Corrosion

Pitting and crevice corrosion tests frequently are less reproducible than intergranular corrosion tests. Pit initiation can be influenced by factors such as surface finish, localized differences in the test solution, and nonmetallic inclusions in the microstructure. Crevice corrosion can be dependent upon these variables as well as geometry and tightness of the crevice [18,19]. Propagation of attack in pits and in crevices occurs by a similar mechanism, but depends upon the local pH and chloride content in the attacked area. Additional data regarding pitting corrosion can be found in Ref 20.

Frequent use has been made of ASTM G 48, Test Methods for Pitting and Crevice Corrosion Resistance of Stainless Steels and Related Alloys by the Use of Ferric Chloride Solution. Specimens are immersed in ferric chloride or acidified ferric chloride and are evaluated by visual examination and mass loss. A related document, Guide for Crevice Corrosion Testing of Iron-Base and Nickel-Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environments is found in ASTM G 78.

Ferric chloride has also been used in Test Method C of ASTM A 923, Test Methods for Detecting Detrimental Intermetallic Phase in Wrought Duplex Austenitic/Ferritic

**FIG. 6**—Example of rising load curves in 93°C water and inert air environments for (a) a highly susceptible heat of UNS N07750, and (b) improved resistance demonstrated by UNS N07716.

**FIG. 7**—Double-cantilever beam specimen with side groove.

FIG. 8—SCC results for single-edge notched and precracked cantilever beam specimens of UNS K92580 (52 HRC) in 3.5 % NaCl at room temperature.

Stainless Steels. In this method, ferric chloride has been used to detect the precipitation of harmful intermetallic phases rather than indicate the performance of the steel in other corrosive environments.

Pit or crevice depth and pit density may be determined according to ASTM G 46, Standard Guide for Examination and Evaluation of Pitting Corrosion, but this can be labor-intensive. Results for highly resistant and very susceptible materials can be reproducible, but data for replicates with marginal resistance can be quite variable. Because of this variation these tests are generally difficult to use for quality control purposes.

Determination of the critical pitting or critical crevice temperature is often used as an alternative to comparing the severity of attack on several samples [21–23]. Procedures for this testing are described in Methods C and D of ASTM G 48. Specimens are immersed for a given period (e.g., 72 h) at a temperature that is not expected to cause attack. Fresh specimens are then exposed at 5°C increments for the same duration until the temperature at which attack occurs (critical temperature) is determined. For many materials, the critical temperatures of replicate specimens fall within a  $\pm 5^\circ\text{C}$  variation. Retesting of the same specimen can affect the critical temperature [24]. Testing may be initiated just below the critical temperature, if it can be estimated. If not, this technique can require many specimens and a few weeks to find the critical temperature.

Critical pitting temperature can be rapidly obtained using electrochemical equipment to maintain a preset potential, increase temperature and detect the onset of corrosion by monitoring corrosion current [24]. In ASTM G 150, Test Method for Electrochemical Critical Pitting Temperature Testing of Stainless Steels, a pre-set potential provides consistent conditions and a potential-independent critical pitting temperature. Sensitive detection of attack using the current allows an accelerated evaluation.

Resistance to pitting or crevice corrosion has been estimated by using the composition to calculate a PRE-number, where larger numbers indicate better resistance. A typical equation has been:

$$\text{PRE} = \% \text{Cr} + 3.3(\% \text{Mo}) + 16(\% \text{N}) \quad (1)$$

Actually, the coefficients can vary for comparisons of alloys with widely different molybdenum or nitrogen contents. For example, critical crevice temperatures were determined using ASTM G 48, Method D for several high-nitrogen alloys [25]. These included materials considered for use in medical devices such as BioDur® 108 Alloy (21 %Cr-22 %Mn-1 %Mo-1 %N-Fe) and UNS S20910, a 22 %Cr-13 %Ni-5 %Mn-2 %Mo-0.3 %N-Nb-V-Fe alloy. Both alloys demonstrated good resistance in these tests, but the 1 % nitrogen alloy was superior. While nitrogen was beneficial, regression indicated that its effect was not as strong as indicated in the above equation. Using regression, the equation obtained to compare alloys with nitrogen contents varying over the range of approximately 0.3 % to >1 % was:

$$\text{PRE} = \% \text{Cr} + 3.2(\% \text{Mo}) + 8(\% \text{N}) \quad (2)$$

While the data presented here may not be sufficient to specify nitrogen coefficients, they do demonstrate that care must be taken whenever using such equations to be certain the expression describes the alloys of interest.

### Rusting and Pitting in Corrosive Atmospheres

Automobiles and military equipment frequently are exposed to marine environments and road salt. Beach test sites are available, but simulations in the laboratory are convenient. The ASTM B 117, Method of Salt Spray (Fog) Testing, has been widely used for this purpose to evaluate rusting, pitting, and SCC. Martensitic stainless steels and maraging steels have been exposed to salt spray (and other NaCl environments) to evaluate resistance to SCC prior to use in military equipment and fasteners. Ferritic and austenitic stainless steels have been tested to evaluate resistance to rusting prior to use in automotive applications.

Rusting, pitting, and SCC tests frequently provide results with poor reproducibility. The percent surface rusted after a salt spray test can also be quite variable. The amount of rust covering a specimen after the salt spray test varies if the rust initiates at the top of the coupon and runs down over the test surface or initiates at the bottom and covers only a small portion of the specimen (Fig. 9). Rusting is also dependent upon the surface finish; smoother finishes are usually more resistant. Because of these factors, it is difficult to use the salt spray test for quality control.

Alternative atmospheric cabinet simulation tests are available, including ASTM G 87, Practice for Conducting Moist  $\text{SO}_2$  Tests and ASTM G 85, Practice for Modified Salt Spray Testing. Service in environments where humidity or moisture varies may be simulated by cyclic humidity or alternate immersion tests. See ASTM G 60, Test Method for Conducting Cyclic Humidity Tests and ASTM G 44, Practice for Exposure of Metals and Alloys by Alternate Immersion in Neutral 3.5 % Sodium Chloride Solution.

### Tests to Evaluate Passivation

Alloys with increased chromium content, such as stainless steels, employ a thin, invisible, passive film to provide corrosion

BioDur® Alloy is a trademark of CRS Holdings, Inc. a subsidiary of Carpenter Technology Corporation.

**FIG. 9—Variation in percent rust on 3/4 in. (1.9 cm) diameter conical test surface after ASTM B 117 salt spray exposure due to rust initiation at (a) bottom and (b) top.**

resistance. This film forms rapidly on clean surfaces with exposure to the air. These materials are frequently passivated in acid to optimize corrosion resistance, but for most applications it is likely that the film formed by these treatments is no better than that formed in air. The major purpose of passivation is to remove free iron, i.e., shop dirt containing very small bits of carbon or tool steel. Free iron particles become lodged on the surface of a resistant material and produce rust. Passivation in nitric acid (sometimes with sodium dichromate) or citric acid is performed to remove these free iron particles. Passivation also removes some or all of the sulfides of free-machining stainless steel [26]. Procedures for passivation are found in ASTM A 967, Standard Specification for Chemical Passivation Treatments for Stainless Steel Parts.

It is frequently desirable to test passivated parts to determine if the passivation has effectively removed free iron from machining operations. Both ASTM A 967 and ASTM A 380, Practice for Cleaning and Descaling Stainless Steel Parts, Equipment, and Systems, provide several methods to accomplish this. These include water immersion and high humidity tests which can be completed in as little as one day.

The salt spray test is frequently requested to verify the effectiveness of passivation treatments. This is a more severe environment than necessary to rust iron and frequently it has caused red staining of properly-passivated lower-alloy stainless steels. The salt spray test can, therefore, produce

spurious failures when used to evaluate the passivation of Types 410 and 430 as well as free-machining grades Type 416 and 303. The salt spray test may be useful to evaluate the passivation of more resistant specimens, such as Type 316 and polished Type 304.

ASTM A 380 and A 967 also include the copper sulfate test as a rapid method to provide a gross indication of free iron presence. This test is performed using a copper sulfate-sulfuric acid solution that plates copper when iron is dissolved from the surface. If the test parameters are not carefully controlled, this test can cause undesirable copper plating on properly-passivated material. To avoid spurious failures, the solution and specimen should be at room temperature and specimens should be handled with plastic or stainless tongs and exposed separately, rather than lying together in a basket. According to ASTM A 380, this test is not to be used for martensitic and lower-chromium ferritic stainless steels of the 400 series, because it will show a positive reaction on these materials.

### Electrochemical Tests and Effects

Electrochemical tests provide a means to understand the corrosion process, simulate service conditions, or accelerate evaluation of a material [27]. ASTM G 3, Practice for Conventions Applicable to Electrochemical Measurements in Corrosion Testing; ASTM G 5, Standard Reference Test Method for Making Potentiostatic and Potentiodynamic Polarization Measurements and ASTM G 61, Standard Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-Based Alloys provide background in some of these techniques.

An example of a potentiodynamic curve for Type 430 stainless is found in Fig. 10. Early in the scan at more active potentials, high current indicates a significant amount of corrosion is occurring. At slightly higher potentials, a passive

**FIG. 10—Typical anodic polarization plot for Type 430 stainless steel in 1.0 N sulfuric acid (from ASTM G 3, Practice for Conventions Applicable to Electrochemical Measurements in Corrosion Testing).**

film forms on stainless steels and corrosion (current) is minimum. Still higher potentials cause pitting and increased current results. After exceeding the pitting potential, the scan may be reversed to determine the reduction in potential required for the material to repassivate (not shown). This is indicated by low current, similar to that on the initial scan. Materials with improved resistance repassivate more readily at higher potentials during the return scan.

Electrochemical scanning techniques indicate the ability of a material to resist a given environment or repassivate after corrosion initiates. These tests can compare materials without waiting for pit initiation or for sufficient time to obtain measurable general corrosion rates. Although these tests can be done quickly, relating the results to long-term behavior in mill environments can require extensive expertise.

Other electrochemical techniques have been used for rapid detection of intergranular precipitation. Single- and double-loop electrochemical potentiokinetic reactivation scans are used to detect intergranular precipitation in Types 304 and 304L stainless steels [28]. The single-loop test is described in ASTM G 108, Test Method for Electrochemical Reactivation (EPR) for Detecting Sensitization of AISI Type 304 and 304L Stainless Steel. In single- and double-loop tests, the specimen potential is scanned through the active region, where corrosion at chromium-depleted grain boundaries causes current flow (Fig. 11). Larger current peaks indicate increased susceptibility to intergranular attack. The double-loop test includes an initial scan in the anodic direction to remove any surface condition that could affect resistance during the return scan. Experience has shown that material susceptible to intergranular attack in an EPR test can also be susceptible to intergranular SCC in other environments. Several of these tests can be conducted in one day, making these methods attractive for quality control; however, appropriate electrochemical equipment is required.

Electrochemical techniques have also been used to provide a rapid test in ASTM F 746, Test Method for Pitting or Crevice Corrosion of Metallic Surgical Implant Materials. A specimen is anodically polarized to stimulate pitting and then returned to a less positive preset potential to determine if repassivation will occur. This is repeated at successively higher preset potentials until the final, or critical potential is determined. More resistant materials display higher critical potentials. This relatively brief test does not wait for pits to initiate and reduces variability by maintaining the potential of the specimen.

Galvanic techniques have been used to assess the compatibility of dissimilar metals in an electrolyte. These methods are described in ASTM G 71, Guide for Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes. A galvanic series is one way of predicting the attack of a less-resistant metal due to its contact with a more resistant metal in an electrolyte. See ASTM G 82, Guide for Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance.

Electrochemical data have been used to calculate corrosion rates. It is useful to compare these corrosion rates with those from immersion tests to confirm that similar rates are obtained. Information regarding polarization resistance and determination of corrosion rates from electrochemical data

FIG. 11—Schematic polarization curves for the (a) single-loop and (b) double-loop EPR test methods on Type 304 stainless steel. (Courtesy of the ASTM G01.08 task group on “EPR Testing”.) SCE—saturated calomel electrode;  $I_r$ —maximum current in return scan;  $I_a$ —maximum current in initial, forward scan.

are found in ASTM G 59, Test Method for Conducting Potentiodynamic Polarization Resistance Measurements and ASTM G 102, Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Measurements.

## SAMPLING AND STATISTICAL ANALYSIS

Unfortunately, prolonged test time and increased cost often prevent the development of statistical data in corrosion studies. Frequently, only duplicate specimens are evaluated, although three to five specimens are frequently used in the ASTM B 117 salt spray environment. Triplicate specimens are often suggested for pitting, crevice, and SCC tests. One useful reference is the ASTM G 16, Guide for Applying Statistics to Analysis of Corrosion Data.

## TEST PROCEDURES, RECORDS, AND EQUIPMENT CALIBRATION

In addition to the procedures provided by standards organizations, it is advisable for metals producers to maintain internal procedures manuals. Pertinent information may include details regarding specimen heat treatment or preparation, location and type of equipment and materials to be used, specific user test requirements, report scope and format, along with disposition of records following testing.

ASTM G 107, Guide for Formats for Collection and Compilation of Corrosion Data for Metals for Computerized Database Input, provides an extensive list of parameters that may be recorded to fully describe the test and its results. (Related information is found in ASTM G 135, Standard Guide for Computerized Exchange of Corrosion Data for Metals.) It is generally recommended that gages and all measuring devices be calibrated according to a set schedule and procedure.

## FUTURE TESTING NEEDS AND DIRECTIONS

Continued emphasis may be expected on interlaboratory testing and establishment of precision and bias for standard test methods. Equally necessary for quality control is extensive evaluation of the product forms of interest to establish acceptance criteria that discriminate between satisfactory and unsatisfactory material. While rapid and inexpensive tests will be used for most quality control tests, an increase in more sophisticated techniques such as electrochemical testing and slow strain rate techniques is expected. Additional work is necessary to improve reproducibility of rusting, pitting/crevice, and SCC tests. In some cases, control of the specimen potential may improve test reproducibility.

## To Find What You Need

THE OBJECT OF THIS chapter is to help plant and project engineers understand how corrosion data are generated and used, in order to optimize chemical plant performance and prevent process safety incidents.

To understand *who needs corrosion data*, see:

### Purpose of Corrosion Testing

To understand how to conduct corrosion tests, see:

### Field, Laboratory, and Pilot Plant Testing

#### Coupon Testing

#### Probe Testing

#### Specialized Testing

To understand what value to place on corrosion data, see:

### Confidence in Corrosion Data

### Creation of a Computerized Corrosion Test Database

## INTRODUCTION

Corrosion testing and corrosion monitoring with coupons and corrosion-monitoring probes are used to select materials of construction, determine failure mechanisms, and study corrosion in process environments. Corrosion coupons provide data on the average corrosion response, and corrosion monitoring probes provide data on instantaneous corrosion response. Corrosion testing procedures are required during process research and development, pilot plant operation, plant start-up, and plant operation. ASTM standards [1] provide a wealth of information on corrosion testing, but are not absolute guides.

Even with effective corrosion test programs, many unexpected failures occur in chemical processes. There are several reasons. The corrosion behavior of a material is a combination of the property of the metal (composition and condition) and of the environment. Corrosion can take many forms, from general to localized. An acceptable rate of general corrosion may not translate into successful performance if there is also localized corrosion, such as pitting or stress corrosion cracking. There is no universal corrosion test for all situations, and sometimes a combination of corrosion test techniques may be required to raise one's level of confidence.

<sup>1</sup>Principal Consultant and <sup>2</sup>Senior Research Engineer, Dupont Company, Wilmington, Delaware.

## PURPOSE OF CORROSION TESTING

Corrosion testing is used to select materials of construction, and to monitor the performance of selected materials of construction in service. Availability of the materials should be considered when developing corrosion test programs. Corrosion acceptance testing is performed to ensure that specific corrosion-resistant alloys are manufactured without impairing their corrosion resistance.

## To Select Materials of Construction

The first purpose of corrosion testing is to select materials of construction. The materials of construction to be considered for the test should be the kinds of materials from which process equipment and components are usually fabricated.

### Pressure Containment Equipment

Tanks, heat exchangers, pressure vessels, columns, etc. are usually built of a wide range of materials made to ASME or equivalent codes. If non-code approved alloys are considered, the likelihood of their being approved for fabrication must be weighed.

### Piping and Fittings

Manufacturers of pipe and fittings provide a wide range of wrought materials to ASTM or other standards. Some cast products are also made, e.g., for fittings. Corrosion testing programs may choose from a relatively wide range of alloys.

### Valves and Pumps

Valve and pump bodies are cast in a relatively small range of off-the-shelf materials, and it is difficult to obtain materials outside the range. Cast materials are less homogeneous than wrought materials, and may not exhibit the same corrosion resistance, especially when repair welded and not re-solution annealed. Cast equivalents are not readily available to match every standard wrought composition. For example, manufacturers of valves supply CF3-M (equivalent to wrought alloy 316L) off the shelf, but CF-3 (equivalent to 304L) is more difficult to obtain.

### Engineered Items

Filters, dryers, blenders, etc., are made from standardized off-the-shelf wrought alloys. Equipment manufacturers are familiar with their fabrication techniques. Corrosion testing

should focus on off-the-shelf materials, favored for cost and delivery.

### *Instrumentation*

Pressure transducers, flowmeters, level controls, etc., are also made from a relatively small range of off-the-shelf wrought alloys. Delicate wetted parts of instruments, e.g., rupture discs, may need to be more corrosion resistant than more robust parts.

### *Gaskets and Seals*

Polymers and elastomers are usually specified by proprietary name. Use of ASTM specifications and standard descriptions is not common. When evaluating materials for gaskets and seals, obtain a sample of the actual product to make a test specimen. Do not use a generic material, since the details of composition and manufacture can have a significant impact on performance.

### *Effect of Welding and Forming*

Heat and/or mechanical deformation may lead to loss of corrosion resistance. Welding may cause severe problems for certain materials: for example, sensitization of the base metal in the heat-affected-zone, or molybdenum segregation of weld metal. Welded specimens are often tested to study potential problems. Specimens may be deformed to study the effect of residual stresses from forming or welding. U-bend specimens are often exposed. If space is restricted, a Brinell hardness indentation can be used on a flat specimen to create a region of high residual stress.

### *Corrosion Acceptance Testing*

Certain nickel alloys and stainless steels may develop poor corrosion resistance to some environments if improperly manufactured. The need for corrosion acceptance testing is created because the alloy producer exerts insufficient control of either the final rolling temperature, annealing temperature, or the relationship between thermal treatment and mechanical treatment via forging, rolling, swaging, etc., to create product forms. Corrosion acceptance testing is supplementary standardized corrosion evaluation testing to determine if purchased materials are in the correct condition and exhibit corrosion resistance comparable to baseline standards. Satisfactory performance in a corrosion acceptance test is not necessarily evidence of satisfactory performance for any real world service environment.

Corrosion acceptance testing is covered by ASTM standards A763 (for ferritic stainless steels) [2], A262 (for austenitic stainless steels and nickel alloys) [3], and A923 (for duplex stainless steels) [4]. It is time consuming and increases project costs, because all product forms require testing, such as plate, tube, fittings, etc. With wrought stainless steels, specifying and receiving low carbon grades largely eliminates acceptance testing; it may still be necessary for some aggressive process environments. Duplex stainless steels require corrosion evaluation testing in all instances because of their inherent tendency to form intermetallic compounds that reduce their corrosion resistance. Nickel alloys that precipitate molybdenum-rich phases during thermal and mechanical treating operations may require

corrosion acceptance testing, to verify that their corrosion resistance was not impaired.

A producer who has supplied a specific nickel alloy for many years will have developed the thermal and mechanical processing know-how for the alloy. Experienced producers rely on statistical process control, coupled with sample testing to qualify their alloys. New producers may meet the ASTM compositional specifications for the alloys, but do not necessarily understand the thermal and mechanical processing needed for creating the best metallurgical condition in the alloy. For new producers, corrosion acceptance testing of various product forms made from each heat of the alloy is usually necessary.

## **To Anticipate Process Chemistry Effects**

The second reason for corrosion testing is to understand how the process environment affects materials performance, and also how corrosion impacts the process. This may require ingenuity in devising tests or studies.

### *Metal Ion Contamination*

For some chemical processes, low levels of metal ion contaminants may alter the product and/or chemical reactions. One source of contamination could be the corrosion reaction. Even if a material of construction has an acceptable corrosion rate to meet mechanical integrity requirements, low levels of metal ions introduced into the system by corrosion may not be acceptable.

### *Presence of Water in Process*

Water can influence corrosion significantly. It can react, pass through unreacted, or accumulate in one part of a system. For example, water might accumulate in a distillation column and form a very corrosive second phase. The top of the column might be too cold to allow the water to leave from the top, and the bottom of the column might be too hot to allow the water to leave from the bottom. The column must be fabricated of material resistant to the second phase, instead of lesser materials that would be adequate for other phases.

The applicability of some materials of construction is critically dependent on the presence of water in the process. For example, stainless steels in chlorinated hydrocarbons may be severely attacked if the amount of water increases above a few hundred parts per million (ppm). Titanium, on the other hand, depends on a minimum amount of water to maintain passivity. Corrosion monitoring with probes may be used to signal the start of accelerated corrosion if the required level of water is violated.

### *Nonstandard Operations*

Nonstandard operations hint at the need for supplementary corrosion testing. For example, chemical cleaning operations are sometimes more damaging towards the materials of construction than the process itself. Hydrochloric acid is often used for chemical cleaning because of its low cost and rapid dissolution of metal oxides. Hydrochloric acid affects specific materials of construction, such as stainless steels, by means other than general corrosion.

Hydrochloric acid can result in pitting and stress corrosion cracking. Carbon steels can tolerate a relatively high corrosion rate during hydrochloric acid cleaning, provided an inhibitor is added, because cleaning operations are short and other damage mechanisms are not a factor.

### *Effect of pH*

pH is sometimes a useful indicator of a chemical's corrosiveness: the lower the pH, the greater the amount of free acid present and the more corrosive the solution. A solution of pH 4 contains very little free acid, but nonetheless is quite aggressive towards carbon steel. As a rule of thumb, the minimum pH for using carbon steel is 5. Some metals such as zinc, aluminum, and lead are susceptible to corrosion in highly alkaline solutions. Except for these metals, pH alone is not usually an important indicator of corrosiveness. The pH of organic solvents, in particular, can be difficult to relate to corrosiveness.

### *Utilities*

The quality of cooling water and steam must be considered when selecting materials of construction. The chosen materials may be resistant on the process side, but fail on the utility side. For example, 316 stainless steel may be applicable for vertical heat exchanger tubing that handles a weak organic acid on the process side, but it may fail from chloride stress cracking on the waterside. A duplex stainless steel may be a better choice.

### *Fitness-for-Service Evaluations*

The ability to predict future corrosion is an important aspect of an equipment inspection program. Commonly used guidance documents are API Inspection Codes API 510 (for pressure vessels) [5], API 570 (for piping) [6], and API 653 (for storage tanks) [7]. Knowledge of the amount and type of corrosion expected will affect the scope and type of inspection planned. A complete evaluation of an equipment inspection includes determining the remaining life of equipment and setting an appropriate inspection interval. API 579 "Fitness-For-Service" [8] is a resource document referenced from the API inspection codes for determining the remaining life of equipment subject to corrosion damage. A fitness-for-service assessment requires an estimation of the future corrosion allowance (FCA) for the intended future operating period. This information typically comes from a combination of past inspection data and corrosion rate data for the component material in a substantially similar environment.

## **Institutional Requirements for Corrosion Data**

Corrosion data is used at various stages in the lifecycle of a chemical plant project, principally to assist in development of process flowsheets and select materials and fabrication methods. The required level of depth varies at each stage of the project.

### *Concept Stage*

At the concept stage, process developers review alternative preliminary flow sheets and provide sketchy parameters. The materials engineer looks for showstoppers that indicate the need for an alternative process, such as excessive temperatures

or corrosive environments. The need for exotic materials in one scheme may direct developers to an alternate process.

### *Business Planning Stage*

At the business planning stage, process evaluators assess the profitability of the process and look to the materials engineer for common materials versus exotic materials with significant cost impact.

### *Process Definition Stage*

At the process definition stage, process and project engineers develop an approximate cost for the proposed project, within 25 %. The materials engineer sharpens the pencil on materials selection for the process flow sheet, and arbitrates key decisions that may affect project cost. Materials changes that are made to reduce cost must be carefully considered.

### *Production Design Basis Stage*

At the production design basis stage, all design information is coordinated by process and project engineers into a package for design contractors to bid against. At this stage, materials selection recommendations must be changed into specification information. For example, it is not sufficient to say, "Use 316 for tubing." The applicable ASTM specification and subdetails must be provided.

### *Production Design*

At the production design stage, the project has been approved. Process and project engineers develop the design and specification, and prepare fabrication drawings. Locations for corrosion testing or monitoring are specified at this time. An outside design contractor is often responsible for the details, and must be familiar with the client's requirements and internal standards. Availability of materials also affects the production design stage.

### *Construction and Startup*

Construction forces are contractors, often working in parts of the world unfamiliar to the client. Construction forces must be familiar with client's standards and idiosyncrasies, and good communication is essential. Potential surprises in materials availability, or practices such as quality of test water must be dealt with expeditiously, or costs/delays will increase. Well-developed, complete, and available corrosion data, including performance of back up materials, is invaluable at the construction and startup stage.

### *Plant Operation and Management of Change*

After the plant is started up, operators, technical and maintenance, assume responsibility for day-to-day running of the plant. A startup corrosion test program is often instituted. It provides valuable information when changes are considered. Materials modifications fall under management of change rules imposed by process safety management regulation, such as OSHA 1910.119 [9] in the United States. Management of change is either subtle or discrete. For example, replacement in kind requires no justification, but change of design does.

Examples of replacement in kind, which require no additional corrosion data, are:

- Replacing a flanged section of pipe with a new section of identical material and size, along with new flange gaskets, in accordance with site pipe specifications;
- Replacing internal components of a pump using genuine OEM components, exact duplicate, or rebuilt original components.

Examples of change of design, which require supporting corrosion data, are:

- Increasing temperature, pressure, or flow in a piping system;
- Changing material of construction (such as piping, gaskets, valve packing, fasteners, substituting metals with different hardness, heat treatment, or metallurgy);
- Changing valve trim or materials on a control valve.

## FIELD, LABORATORY, AND PILOT PLANT TESTING

Whenever it is decided that the existing corrosion data sources are inadequate, a decision must be made on how to develop the corrosion data. A corrosion test is designed to provide useful information to meet the end purpose. Corrosion tests may be run in the field, laboratory, or pilot plant. Use of standardized test procedures described in ASTM [10–12] may guarantee success, providing the vagaries and subtleties of the corrosive environment are understood and accommodated in the test.

A chemical process may involve a complex variety of inorganic and organic chemicals. When the process composition is known and invariable, testing to select appropriate materials of construction, or searching the literature, is relatively easy. However, the role of contaminants, and the process parameters of temperature, pressure, velocity, and species concentration must be considered for their effects on corrosion and how they affect the design of a corrosion test. Additionally, changes in process parameters, such as when reactants are blended in, or exothermic reactions, must be considered. Ask the process engineer what contaminants may be present, such as the chloride ion, or species containing sulfur.

When applicable, one must test materials at the actual temperature to which they will be exposed in the process. This is not necessarily the process temperature, and it may require special techniques such as hot-wall testing or cold-finger testing.

A corrosion test requires the following steps:

- Define the type of test needed, including any special safety considerations,
- Run the test by exposing the samples,
- Monitor the solution composition, if necessary,
- Examine the samples after testing for types of attack and quantify the amount of attack.

### Test Location

Simulation of location is the single most important element of a corrosion test. The process flow diagram should be reviewed to identify those locations with the most corrosive

conditions, based on material balance compositions and predicted contaminants. In a field test, the location must be selected to obtain the required type of exposure. For example, condensing conditions where phase separation has occurred may be more corrosive than fully immersed conditions. In a laboratory or specialized test, the conditions at the selected location(s) must be simulated.

Figure 1 is a schematic flow sheet indicating various types of corrosive conditions that may occur at various locations in typical chemical processes. The type of corrosion expected at a process location must be modeled if it is likely to be an issue in successful operation of the plant.

The principal types of test locations are as follows:

*Continuous immersion* is where exposure is to stagnant or flowing liquid. It is usually the easiest location in which to expose samples or to simulate. Continuous immersion is the most important location for developing basic data in stagnant or free-flowing portions of the process. Agitation can influence corrosion test data significantly because it helps maintain a high level of oxygen in solution. Oxygen accelerates corrosion of some metals and retards corrosion of metals that form a passive film. If oxygen is not permitted in the process, a nitrogen pad is usually employed. Slurries and process media that contain solids—these include catalysts, reactants, and products—require special consideration in corrosion testing. Moving slurries can cause erosion-corrosion; stagnant slurries aggravate crevice corrosion.

*Splash zone* is where the exposure is to splashing or spraying liquid. Splash zone is sometimes more corrosive than continuous immersion. For example, chlorides may concentrate through alternate wetting and drying, leading to pitting or stress corrosion cracking in the splash zone. This is more likely to occur when the splash zone is a hot surface.

*Solution line* is the boundary that is formed on a material surface when two phases have a stable interface that remains in one location for an extended time. The exposure alternates between continuous and partial immersion. The solution line level may change due to agitation, or when a vessel or tank is filled by different amounts. Solution line effects cause oxidant levels at the metal surface to fluctuate,

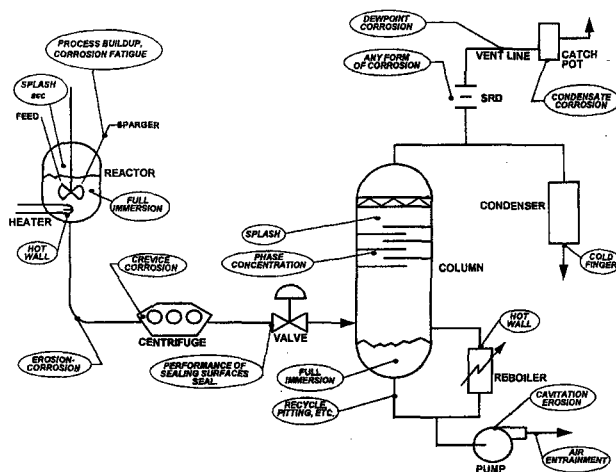

FIG. 1—Various types of corrosion occur in a chemical process.

and can be extremely corrosive to materials like carbon steels. Froth can also create solution line conditions. Solution line exposure is particularly important when evaluating materials for scrubbers, demisters, and columns. Strip-like coupons that completely extend through the susceptible zone may be positioned at the solution line to capture the effect.

*Condensate zone* is where the exposure is to droplets of condensing gases. As with splash zone, the condensate zone may be more corrosive than continuous immersion. Condensate can be extremely corrosive, depending on the distribution of components in a process. The problem may occur in distillation columns or condensers, where aggressive species partition or concentrate. For condensate exposure, one must design the coupon location carefully to ensure the coupon is actually exposed to the condensate.

*Gaseous zone* is where exposure is to vapor in the space above a liquid or to gas phase alone. Under most conditions, the gaseous zone is not usually corrosive until the vapor condenses and forms a corrosive condensate.

## Field Testing

Field corrosion testing consists of coupon testing and probe testing. Coupon exposure times typically range from one to three months. Probes are exposed for as long as a specific condition is under investigation, sometimes for the life of the process.

### *Managing System for Coupon Testing*

Field coupon testing employs small flat and/or U-bend [10,13] samples to average the effects of real world solution contaminants and process transients. Full immersion conditions are easy to reproduce. Splash, waterline, condensing, velocity, and hot wall conditions are more difficult to reproduce. Management of field coupon testing requires effective handoffs between different job functions on the plant site.

In most chemical manufacturing companies, a project, process, maintenance, or reliability engineer makes the initial request. A materials engineer determines coupon selection and exposure time. A planner may requisition the coupons, which are usually mounted on test racks. Maintenance installs the coupons and production alerts when they may be removed. Maintenance removes and decontaminates the coupons, and sends them to a qualified laboratory for analysis. After cleaning, weighing, and examining, the materials engineer calculates corrosion rates and creates a report [10,14], which is communicated to the requestor.

### *Considerations for Electrical and Electrochemical Probe Selection*

Probes consist of electrical resistance (ER) and linear polarization resistance (LPR). They are described in more detail in the section on Probe Testing. The first consideration for probe selection is the conductivity of the process environment. ER probes are the only option for nonconductive processes and for gaseous environments. The desired response time is critical in selecting ER probes. LPR probes provide instantaneous corrosion rate data in conductive environments, but may not be applicable where exposure is

intermittent, such as in spray or splash or solution line zones. ASTM G96 describes probe testing [15].

Probes may be fixed or retractable, and access for removal or replacement of elements is an important consideration. Intrinsic electrical safety requirements must be followed. Probe materials of construction, including sealing compounds used for insulation, must be compatible with the concentrations, temperature, and pressure of species in the chemical process.

In critical locations, consider using more than one probe (redundancy) if it is the primary method of monitoring corrosion.

Roles and responsibilities in procuring, installing, maintaining, and monitoring data from corrosion probes must be defined.

## Laboratory Testing

Laboratory corrosion testing is performed under simulated process conditions, either to help materials selection, or, by isolating specific process variables, to determine corrosion mechanisms. Laboratory testing consists of coupon testing and specialized testing.

Most laboratory testing is performed in glassware at atmospheric pressure, though some testing is carried out in autoclaves. The size of the glassware usually limits coupon exposure locations to liquid and vapor locations, unless a specialized testing, such as the three-position flask, is used. Velocity effects are limited to mild stirring with an agitator or magnetic stirrer.

The simplest type of laboratory test consists of exposing coupons to the liquid phase only. Simple immersion tests are performed using some form of glassware, such as a flask or a resin kettle, and a condenser for refluxing. A typical setup is a 1000-mL flask containing 500 mL of liquid. Laboratory coupon testing is described in ASTM G31 [16].

Factors affecting laboratory testing include the following:

### *Volume of Solution*

The solution volume should be 125 mL/square inch of exposed coupon area at a minimum [16].

### *Exposure Time*

It is usually 100–250 h (about 4–10 days). When relatively high rates of general corrosion are expected, a popular guideline is minimum exposure time (in hours) = 2000/expected corrosion rate in mils per year (mpy). Therefore, if a corrosion rate of 20 mpy is anticipated, one should expose the coupon for about four days (100 h). Certain types of corrosion, such as crevice corrosion, pitting, and stress corrosion cracking, occur only after relatively long incubation periods. If coupon exposure times are too short, they will not be detected during corrosion testing. Examining coupons under a microscope after the test helps reveal whether incipient pitting or crevice corrosion occurred. Incipient corrosion might be an indication of borderline performance. When pitting or crevice corrosion are factors, coupons should be exposed for a minimum of 250 h, and perhaps 1–3 months. Alternatively, electrochemical techniques such as cyclic potentiodynamic polarization might be used to reveal a tendency for crevice corrosion or pitting.

### *Cross Contamination Effects*

During running of the test, check the coupons regularly for signs of excessive corrosion or degradation. If these conditions are found, the test should be concluded, unless it is the purpose of the test. The test solution should also be checked for signs of color changes, which may indicate contamination by corrosion products, or solution degradation. Unless these effects are under investigation, terminate the test. The performance of certain metals is altered when cross contamination from corrosion of other coupons takes place. For example, titanium's corrosion resistance to a reducing acid improves when corrosion of stainless steels puts nickel and chromium ions into solution. Zirconium, on the other hand, may perform worse than expected under these conditions.

### *Stability of Solution*

If the process reaction time is short relative to the required exposure time, two techniques can be used to increase the exposure of coupons to reactants. One technique is to run the reaction repeatedly with fresh reactants until sufficient exposure time is obtained. Another is to use an electrochemical technique such as potentiodynamic polarization.

### *Representative Solution*

When simulating conditions such as concentration or condensation, it is useful to know the exact composition of the condensate. Thermodynamic modeling may be used to calculate the composition of the condensate. Contaminants, such as oxygen or chlorides, also need to be accounted for if they are present in the plant solution.

### *Simulating Location*

Basic laboratory corrosion tests are performed by exposing coupons (to the liquid phase only) at atmospheric pressure. Some testing is performed in autoclaves.

### **Pilot Plant Testing**

Pilot plant corrosion testing offers a few advantages over laboratory testing. For example, more coupons may be exposed at a specific location because the equipment is larger. It may seem that pilot plant testing offers longer exposure times compared with laboratory testing. However, available exposure periods between key process changes may amount to a few batches, so that the accumulated exposure time is relatively short. Effective pilot plant corrosion testing has other challenges.

### *Ease of Access*

Locating coupons where they can be easily installed and removed is a prime consideration, because coupons must be removed whenever there are significant changes to the process parameters. The test locations must not interfere with instrumentation or other items.

### *Frequent Process Parameter/Feedstock Changes*

The explicit purpose of most pilot plant testing is to optimize process parameters, so it is difficult to capture a stable set of conditions under which coupons or probes are exposed. Furthermore, the equipment is not usually designed for optimum location of coupons or probes.

### *Coordination Between Personnel to Optimize Data Quality*

Since most pilot plant test programs have low priority for collecting materials data, the greatest challenge for the materials engineer is in establishing communication and motivation. For examples, component failures are discarded before a qualified person examines them, or coupons are not removed between major campaign changes.

## **COUPON TESTING**

Coupon testing is the most widely used method of gathering corrosion data, on account of its versatility and ease of interpretation. Coupon testing is described in ASTM G4 [11].

### *Coupon Design*

Most corrosion coupons are 1/8-in.-thick flat, rectangular shaped specimens, identified by stamping. This is the least expensive design to manufacture. The U-bend coupon is the most common mechanically stressed coupon, and is used to determine susceptibility to stress cracking [13].

Flat and U-bend coupons may be supplied with an autogenous or butt weld [13]. With a butt weld, the weld profile is retained and not machined off, to duplicate the condition of process equipment, except on U-bend coupons. Autogenous welding (application of a locally melted region on base metal that contains no filler metal) does not always simulate real-world conditions. If welding of the coupon with filler metal is not possible, for example with thin stock, a sensitizing heat treatment may be preferred.

### *Sensitizing*

This is a heat treatment applied to specific stainless steels and nickel alloys to simulate the formation of microscopic compounds that reduce corrosion resistance. Sensitizing may occur in welding, hot forming, or certain types of heat treatments. Although welding is the most common cause of sensitization in process equipment, welded coupons may not sensitize because they contain insufficient weld passes compared with actual process equipment. Thus, the cumulative time spent in the sensitizing temperature range is insufficient for sensitizing to occur. A sensitizing heat treatment is relatively severe compared with the heat input from welding. It is an extreme test to indicate the potential for corrosion susceptibility from welding, or a stress relief heat treatment.

### *Surface Finish*

Coupons are normally 120 grit finished, which is reasonably close to the mill finish found on process equipment. A double disc ground surface is closer to mill finish, and improves reproducibility of results, because it creates a cleaner surface than 120 grit.

### *Electrical Insulation*

Coupons must be electrically isolated from one another with washers and insulating spacers made of TFE. Washers may be flat faced or serrated (with radial grooves). Serrated washers are used when susceptibility to crevice corrosion is to be studied [17], as in the case of a chloride-containing

process. Ceramic washers are used above 200°C, where PTFE is subject to creep.

### Test Rack Design

For field and pilot-plant testing, coupons are mounted on test racks designed to prevent them from detaching during exposure and to protect them from mechanical abuse. Do not weld racks directly to pressure containing parts without a qualified procedure and qualified welder, in accordance with pressure vessel code requirements.

The pipeline insertion rack is the most common design, and is installed at flanges in piping, nozzles, and manways. It can accommodate a useful number of coupons and is easily inserted and removed. It is relatively expensive to fabricate because a significant amount of stock must be discarded. The number of coupons is limited by the internal diameter of the piping, the space in the equipment, the length of the rack, and potential flow restrictions. A flat bar rack is a cheaper design. It is bolted to a tab welded to a blind flange attached to a manway. Pressure vessel code welding requirements may apply. The flat bar rack eliminates the need for additional gaskets, but is harder to install and remove.

Rack material must resist the process environment. Fasteners are susceptible to failure from crevice corrosion underneath the insulating TFE sleeve. Fasteners should have provisions to guard against mechanical loosening (for example, double nutting). They may require upgrading to a more resistant material in severely corrosive environments.

See Fig. 2 for photograph of corrosion test rack.

### Procurement of Coupons and Racks

The items shown in Fig. 3 should be considered when procuring coupons and racks.

### Interpreting Coupon Data

Metal coupon data are relatively easy to use for materials selection purposes from calculation of corrosion rate and observations on the appearance of the coupon. For nonmetallic materials, the problem is to define what constitutes failure. For example, when is color change, flaking, swelling, or tackiness acceptable, and when do they indicate potential failure?

### Interpreting Metal Coupon Corrosion Data

To calculate corrosion rate, one must know coupon dimensions, weight before test, material density, exposure time, and weight after cleaning. For a field test, periods when the process is down are subtracted from the total exposure time to obtain the actual exposure time. ASTM G31 provides a method of calculating corrosion rate [16]. To interpret corrosion rates on metals, use the following guidelines.

- Use 0.2 mpy as the maximum acceptable rate for reactive metals that can embrittle by taking up hydrogen from the corrosion reaction (for example, titanium, zirconium, and tantalum). Hydrogen uptake may occur from self-corrosion or when these metals are the cathodic member of a galvanic couple.

FIG. 2—Corrosion test racks must be designed for easy insertion and removal from equipment and piping.

Rack material	
Fastener material	
Identification of coupons	

FIG. 3—Checklist for corrosion coupon and test rack procurement.

- Use 1 mpy as the acceptable rate for product purity. The acceptable corrosion rate is usually determined by purity requirements. Thus, for greater accuracy, back-calculate the maximum allowable corrosion rate from the maximum amount of metallic ion contamination allowed in the product. Estimate the available area of metal in the process equipment and piping that contributes to corrosion and factor it into the corrosion rate.
- Use 5 mpy as the maximum acceptable rate for clad or relatively expensive metals, such as stainless steel.
- Use 10 mpy as the maximum acceptable rate for carbon steel with a thin film lining. Linings less than 10 mils thick (for example, baked phenolics) contain holidays, which are tiny holes through to the base metal created during curing of the lining. If the corrosion rate of the base metal is excessive, the lining will tend to pop from the surface. A carbon steel coupon should be exposed concurrently when a thin film lining is being evaluated such as in ASTM C868 [18].
- Use 5–25 mpy as the maximum acceptable rate when a corrosion allowance can be incorporated into a relatively inexpensive material of construction, such as carbon steel. Process equipment is generally designed for a service life of 10–20 years, and the design includes a corrosion allowance.

In addition to calculating the corrosion rate, the type and severity of local corrosion on the coupon should be noted by examining the coupon under a binocular microscope. The maximum depth of localized corrosion should be recorded.

Figure 4 shows the effects of localized corrosion in process equipment.

#### *Interpreting Polymer and Elastomer Coupon Data*

Polymer and elastomer coupons are evaluated differently from metallic materials [19]. The testing and evaluation of

polymers and elastomers are more difficult. They are less standardized than metals, and deductions between "generic" types are difficult to make because of the effects of various fillers, additives, and processing variables that must be taken into account.

A rule of thumb for evaluating polymer and elastomer coupons is to measure a key dimension (e.g., thickness), weight, and hardness before testing. After testing, the same measurements are taken immediately, and repeated after the sample has been stored under vacuum for at least 24 h.

Localized Corrosion Type	Potential Effect on Process Equipment
Corrosion fatigue	Catastrophic failure
Crevice corrosion	Loss of surface conformance, e.g. at a gasket surface, or local wall thinning, leading to leakage
Erosion-corrosion	Local thinning, e.g. at an elbow, leading to leakage
Galvanic corrosion	Possible embrittlement of cathodic member of couple, in the case of tantalum, titanium, zirconium. Thinning of anodic member of couple in other cases.
Microstructure-related	Various effects, leading to loss of net structural thickness
Pitting	Pinhole leaks
Stress corrosion cracking	Network of fine cracks, leading to leakage or catastrophic failure

FIG. 4—Effects of localized corrosion are less predictable than general corrosion.

Appearance	Description
Abrasion/Erosion	Wearing away of the surface by the scouring action of the process environment
Blistering	A cavity or sac that deforms the surface of the material, which may have burst and become flattened
Chalking	The formation of a powdery residue on the surface, resulting from degradation
Collapse	The densification of cellular material caused by the breakdown of the structure
Color Change	Alteration of color or surface texture, such as sheen
Cracking	Fractures or separations that extend through the surface layers, which may or may not extend through the thickness of the material
Crazing	Fine cracks at or under the surface
Creep	Dimensional change with time under load
Delamination	Separation of layers of material in the laminate
Dissolution	Solvation of the material
Flaking	Detachment of pieces of material from the substrate or bulk, often preceded by cracking, crazing, or blistering.
Orange Peel	Pitted or uneven texture, visible to the naked eye, resembling an orange peel
Popcorning	The formation of reaction products in the spaces of a sintered material, which causes the material to collapse
Shrinking	Decrease in dimensions
Sintering/Densification	Bonding of adjacent surfaces of particles in the material
Spalling	Cracking or rupture resulting in the detachment of portions of the surface or bulk of the material
Swelling	Increase in dimensions over original, usually by solvent uptake
Tackiness	Sticky or gummy character of the material surface
Warping	Change in the original contour or shape of the material, without swelling

FIG. 5—Polymer and elastomer coupons appearance must be documented.

The idea behind vacuum containment is to permit solvents to evaporate from the coupons. Often, the sample returns to its original condition after vacuum treatment, or after being allowed to stand for a few days in the atmosphere.

Documentation of physical appearance is also required. Figure 5 defines typical physical observations for polymer and elastomer coupons.

Polymer and elastomer coupon data must be used in the context of the application. If the application is structural, such as for an FRP tank, mechanical property data are also required. If the application is fully contained, such as an O-ring, dimensional and hardness change, coupled with visual observations, may provide sufficient information to make a decision. In all cases, it is useful to discuss the results with a qualified person, such as the supplier of the material.

### *Interpreting Lining Coupon Data*

Linings are often evaluated in the type of cell described in ASTM C 868 [18]. In the test cell, two lined panels are exposed simultaneously to test liquid, to study the effect of chemical attack and permeation on the lining system. The tests are often conducted for six months, and visual observations may be conducted during the period. At the end of the test, the lined panels are given a thorough examination, and may also be destructively evaluated for loss of adhesion, substrate corrosion, and hardness change.

### *Glass-lined Steel Coupons*

Glass-lined steel is used in applications requiring cleanliness and high corrosion resistance. Dumbbell-shaped glass-lined coupons may be obtained from the manufacturers of glass-lined equipment to evaluate performance. As with metal coupons, the corrosion rate of glass-lined steel coupons is calculated from surface area, weight loss, glass density, and exposure time.

In equipment designed for severe chemical exposure, glass linings are 40–90 mils thick (nominally 60 mils). The minimum thickness before reglassing is required is 30 mils. The remaining thickness adjacent to the substrate is known as ground coat and has poor corrosion resistance. A vessel with general corrosion should be reglassed when the lining thickness reaches 30 mils. Once the ground coat is exposed, corrosion will proceed at an unacceptable rate. Also, other failure modes such as thermal shock, electrostatic discharge, etc., control glass life. A rule of thumb for the maximum acceptable uniform corrosion rate on a glass-lined steel coupon is 8 mpy.

## **PROBE TESTING**

Probes are used to measure corrosion rate on-line. There are two basic types of probes, electrical resistance (ER) and linear polarization resistance (LPR). Probe testing is described in ASTM G 96 [15]. Probe data may be read on a hand-held meter or downloaded periodically to a computer and/or hand-held meter. These systems require no permanent fields cables.

However, more value is obtained when the output from corrosion probes is connected to transmitters that convert

probe data to a 4–20 mA signal output to the distributed control system (DCS). Thus, it is possible to integrate probe signals to process parameters. Integration with DCS requires cabling, which is more expensive.

In all cases, the need for intrinsic safety barriers must be evaluated. Instrumentation must conform with the electrical classification of the operating area.

### *Electrical Resistance*

The sensing element of an ER probe may be a wire, tube, or cylinder made of the test material. The principle of ER corrosion monitoring is based on measurement of electrical resistance of the sensing element. This is a function of its thickness, which depends on how much corrosion it has experienced. The higher the sensitivity of the probe, the shorter its life. A cylindrical element probe with 25 mils life will take 20 h to detect a corrosion rate of 100 mpy. A tube element probe with 2 mils life will detect a corrosion rate of 100 mpy in 2 h. Thus, the thicker the probe element the less the sensitivity, but the longer the life, and vice versa. However, thicker element probes, such as cylindrical element, are less fragile than thinner element probes, such as wire element. The maximum life of standard ER probes is 25 mils. See Fig. 6 for photo of an ER probe.

ER probes have certain limitations. Resistance is a function of temperature, so that large or rapid temperature swings generate noisy signals. Conductive deposits, such as metal plating out on the probe surface, will decrease resistance, and read a negative corrosion rate. ER probes are not effective in detecting localized corrosion, because the resistance change is not proportional to the local penetration of the corrosion attack.

### *Linear Polarization Resistance*

With LPR, a small electrical potential of approximately 20 mV is applied between two electrodes. The anode is made of the test material. The current response as a result of the applied potential is measured within minutes and converted to corrosion rate. LPR probes are rated to 200–250°C and pressures to 5000 psi. See Fig. 7 for photo of an LPR probe.

**FIG. 6—ER probes may be made of wire, tube, or cylinder.**

FIG. 7—LPR probes are limited to conductive environments.

Corrosion Type	Test	Test Type
Coating degradation	AC impedance	Electrochemical
Condensing surface	Demo flask	Coupon
Condensing surface	Cold finger	Coupon
Erosion corrosion	Rotating electrode	Electrochemical
Erosion corrosion	Velocity test loop	Coupon
Galvanic corrosion	Zero resistance ammetry	Electrochemical
Galvanic corrosion	Potentiodynamic polarization	Electrochemical
General – conducting liquids	Linear polarization resistance	Electrochemical
General – conducting liquids	Tafel extrapolation	Electrochemical
General – nonconducting liquids	AC impedance	Electrochemical
General and localized	Electrochemical noise	Electrochemical
Heated surface	Hot wall	Coupon
Pitting/crevice corrosion	Cyclic potentiodynamic polarization	Electrochemical
Stress corrosion cracking	Slow strain rate	Coupon
Stress corrosion cracking	Siphon	Coupon

FIG. 8—Specialized corrosion tests are usually conducted in the laboratory.

The success of LPR probes is dependent on the conductivity of the process, and the expected corrosion rate. LPR probes are limited to process environments with conductivities greater than 100 microSiemens/cm. The conductivity of tap water may vary between 100 and 1000 microSiemens/cm. Performance is sensitive to fouling, bridging, or short-circuiting.

Attributes of LPR probes are rapid data collection and ability to sense process excursions. These attributes allow them to be used as a process control and for on-line monitoring of corrosion rate.

## SPECIALIZED TESTING

Specialized testing techniques are used to confirm data or simulate corrosion phenomena that are beyond the capabilities of simple laboratory corrosion tests. They are generally performed in the laboratory, and in general require extensive data interpretation. See Fig. 8.

### Coating Degradation—AC Impedance [20,21]

AC impedance measurement offers an advanced electrochemical method of studying degradation processes for organic or nonconductive coatings. Generally, the degradation of coatings in aggressive environments consists of two sub-processes: water or moisture permeation into the coatings, and under-film corrosion when the water approaches the metal substrate. The AC impedance method is mainly used to monitor water permeation and under-film corrosion occurring in coatings during a period of immersion in an electrolyte.

AC impedance relies on the ability to monitor the behavior of a coating that absorbs water by modeling it as a capacitor. By measuring capacitance increase as a function of immersion time, the diffusion coefficient of water and the amount of saturated water within the coating film can be calculated. In addition, any severe under-film corrosion can be monitored by a drastic decrease in the coating resistance and charge transfer resistance.

With improved electronics technology, the measurement of electrochemical impedance over a wide range of frequencies has become fairly straightforward. During the impedance measurement, very small AC signals, which do not significantly disturb the electrode system, are applied. This makes the measurement in situ and nondestructive. Furthermore, the information on the uncompensated solution resistance, electrode polarization resistance, double layer capacitance, as well as resistance of the coating film or passive film on the metal surface, can be obtained in the same measurement.

#### *Condensing Surfaces—Three Position Flask [22]*

A three-position flask (Demo flask) may be used to simulate three exposure locations simultaneously: fully immersed, vapor, and condensate. For the condensate part of the exposure, coupons can be exposed to drips of condensate directly under a condenser, or they can be immersed in a heel of condensate before it is returned to the working container or sent elsewhere. When cross contamination effects are likely, the coupons should be exposed to the drips, not to the heel, and the coupons should be exposed in sequence that minimizes cross contamination effects. See Fig. 9 for sketch of a three-position flask.

#### *Condensing Surfaces—Cold Finger [22]*

The equipment described above is fabricated from glass and operates at essentially atmospheric pressure. For study of processes operated under pressure, the condensing exposure

is achieved by locating a cold finger in the lid of an autoclave. The cooling fluid circulated from a constant temperature bath through the cold finger controls the condensing temperature. As in the atmospheric test apparatus, a helpful addition to the pressure reactor is the ability to collect liquid and condensed vapor samples under operating conditions for analysis. The chemistries are often very different between the liquid and condensed vapor phase samples, and knowing them helps one to correlate the measured corrosion rates to solution chemistry.

#### *Erosion Corrosion—Rotating Electrode [23]*

In this test, a metal sample is rotated in the solution. A rotating cylinder is used to simplify fluid dynamics equations so that corrosion rate can be correlated with shear stress or mass transfer, which in turn can be related to velocity effects in piping and equipment. The same electrochemical techniques used on static samples are applicable to the rotating cylinder electrode. By coupling the samples to electrochemical measuring equipment, one can measure qualitatively the effects of stepped velocity changes in one experiment.

#### *Erosion Corrosion—Velocity Test Loop [23]*

To evaluate the effect of slurries or moving liquids on corrosion, a special test loop may build through which the solid-containing medium or high velocity medium is circulated by means of a pump. Tubular specimens are relatively easy to obtain. They may be exposed in the velocity test loop, and have a nice response to erosion corrosion calculations.

#### *Galvanic Corrosion—Zero Resistance Ammetry [24]*

A zero-resistance ammeter is connected between two metals, and the galvanic current is directly measured as a function of time. At the same time, a reference electrode can also be used to monitor the galvanic couple potential, which can be used to determine the galvanic corrosion if a third metal is to be connected with this couple. Most commercial potentiostats can be used as a zero-resistance ammeter by changing the electrode connections.

#### *Galvanic Corrosion— Potentiodynamic Polarization [24]*

A cathodic polarization curve of the metal with a noble corrosion potential and an anodic polarization curve of the metal with a negative corrosion potential are plotted. The two polarization curves are overlapped. The intersection of two polarization curves is the amount of galvanic current that will be produced when these two metals are in contact with each other. One important point to mention is that, due to the different surface areas of two metals, they receive the same galvanic current (instead of the same current density) during galvanic corrosion. To determine the galvanic current when the two polarization curves are overlapped, they should be modified to use current, not current density, as the x-axis.

#### *General Corrosion in Conducting Liquids— Linear Polarization Resistance [25]*

In linear polarization, the voltage of a test electrode is perturbed 20–30 mV above or below the corrosion potential.

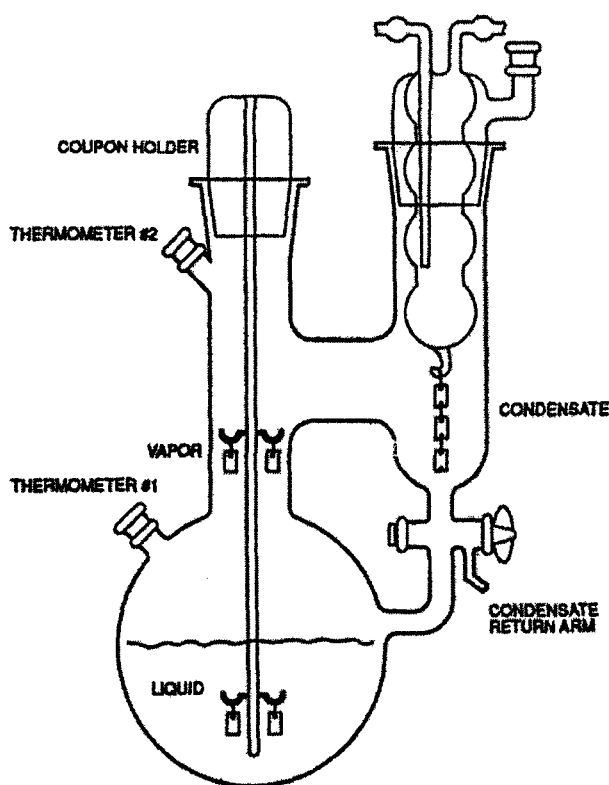

FIG. 9—Three-position flask allows corrosion in three phases to be simulated.

This is called applying a polarization overpotential. When it is small, the polarization overpotential has a linear relationship with polarization current, similar to Ohm's Law. Hence, the relationship (potential divided by current) is called polarization resistance. The corrosion rate is inversely proportional to the polarization resistance.

Linear polarization resistance can be applied to corrosion systems with electrochemical activation control, such as carbon steels and some stainless steels in low concentrations of sulfuric acid. For corrosion systems with a mass transport control or passivating systems, such as carbon steels in water with a pH between 5 and 10, the linear polarization equation is not valid. Additionally, the normal fluctuation of corrosion potential during the measurements can significantly affect the accuracy of the measurements. Under most circumstances, a larger polarization than 10 mV may be used to increase the signal/noise ratio. However, it may put the system out of the linear region, introducing some additional errors in the measurements.

#### General Corrosion in Conducting Liquids— Tafel Extrapolation [25]

A polarization curve is plotted for the metal in the corrosive environment. When the polarization curve is obtained, the anodic and cathodic polarization curves in the Tafel region (region of strong polarization) are extrapolated to the open-circuit, or corrosion potential. The corrosion rate is determined by the intersection between the Tafel straight lines and the horizontal line of corrosion potential. See Fig. 10.

The major error with Tafel extrapolation is the effect of concentration polarization introduced when the applied current is large. The theoretical basis of this method is only valid for the corrosion systems with an electrochemical control. If the applied current is significant, some corrosion systems may come under mass transport control, or at least under mixed electrochemical and mass transport control. This will make it very difficult to define the Tafel region from the polarization curve, introducing errors in the extrapolation process. Tafel extrapolation is not applicable in highly resistive environments: for example, glacial acetic acid.

FIG. 10—Polarization plot for Tafel extrapolation.

#### General Corrosion in Nonconducting Liquids— AC Impedance [26]

Electrochemical polarization, which relies on dc, is limited to highly conducting liquids >100 microSiemens/cm. The ac impedance technique is more suitable for measurements in poorly conducting media, and does not suffer from the same limitation as dc electrochemical techniques. For more details, see Coating Degradation—AC Impedance.

#### General and Localized Corrosion— Electrochemical Noise [27–29]

Electrochemical noise measurement is a relatively new tool compared to other electrochemical methods. It is a sensitive electrochemical method especially for monitoring the localized corrosion, such as pitting and crevice corrosion, although it is also used for monitoring general corrosion as well. Since it was introduced over 20 years ago, the research in seeking the theoretical explanation has lagged far behind its practical applications. The general phenomenal observation is that when corrosion, especially localized corrosion, is initiated on the surface of metals, a spectrum of electrochemical noise is concurrently created, and the characterization of this spectrum of electrochemical noise is an indication of the severity of general corrosion and the form of corrosion.

There are two kinds of electrochemical noise, the electrode potential noise and cell current noise. The potential noise can be measured in two ways. One is by measuring the potential difference between two identical metal electrodes. The advantage of this method is the elimination of the effect of other factors on the electrochemical noise measurement, such as the temperature and fluctuation of environmental conditions. This is because the electrode potential of two identical electrodes should change at the same time when environmental conditions fluctuate. In addition, two identical electrodes configuration is easily made as an electrochemical sensor. The other way for monitoring potential noise is by using a reference electrode, by which the potential difference between the reference electrode and the metal of interest is measured. The current noise is measured by using a zero resistance ammeter, which is connected between two identical electrodes. If it is required, the potential noise of the two identical electrodes can also be monitored at the same time by using an extra reference electrode.

Several parameters can be derived and calculated from the electrochemical noise data obtained, which may be used to determine the severity of general corrosion and the types of corrosion. However, the theoretical explanation of some of the parameters is still under debate. The only generally accepted parameter is the electrochemical noise resistance,  $R_n$ , which is defined as the ratio of the standard deviations of potential noise and current noise ( $R_n = \sigma_v/\sigma_i$ ). This parameter is thought to be equivalent to the polarization resistance  $R_p$ , which can be used to estimate general corrosion rate.

The other parameters include the pitting index, which is defined as the standard deviation of current noise divided by the mean current ( $PI = \sigma_i/I_{mean}$ ), and the power spectral density of a noise, which can be calculated using the MEM (maximum entropy method) and the FFT (fast Fourier

transform). They have been proposed for the identification of localized corrosion. Due to their theoretical limitations, these parameters should be used with precautions.

#### Heated Surface—Hot Wall [22]

For assessing the effects of a heat transfer surface on corrosion, the hot wall tester may be used. One style includes a flat end soldering gun held against the sample on one side, which is sealed at the edges and exposed to a solution on the other side. The solution temperature can be controlled up to boiling, and the heat applied to the sample can be varied by the electrical input to the soldering gun. The combination produces a heat transfer effect across the sample thickness.

#### Pitting and Crevice Corrosion— Cyclic Potentiodynamic Polarization

The basic electrochemical method for evaluating the susceptibility of metals to pitting and crevice corrosion is covered by ASTM G 61 [30]. An anodic polarization curve is measured by a cyclic potentiodynamic polarization method using a specific scanning rate, from which breakdown potential and protection potential can be determined. See Fig. 11.

The evaluation criteria are as follows: the more noble the breakdown potential, obtained at a fixed scan rate, the less susceptible the alloy to the initiation of pitting; and the more noble the protection potential, the less likely is crevice corrosion. When the breakdown potential and protection potential are almost the same value, the possibility for pitting corrosion to occur is almost nonexistent.

Since the values of both breakdown potential and protection potential are significantly affected by the scanning rate, supplementary electrochemical methods are used to overcome this limitation (for example, if by using a supplementary potentiostatic method, the potential of metal may be maintained at a constant value while the corresponding polarization current is recorded as a function of time). If

FIG. 11—Anodic polarization curve for passive corrosion systems.

the recorded current increases with time, the maintained potential should be above the breakdown potential. If the recorded current substantially decreases with time, the maintained potential should be below the protection potential. When using the potentiostatic method in conjunction with cyclic potentiodynamic polarization, the region of each potential is roughly estimated.

#### Stress Corrosion Cracking—Slow Strain Rate

The need to wait three months or longer for results in the U-bend test is often impractical, especially when a material decision for plant equipment may have to be made, sometimes within days. The slow strain rate test offers a rapid way to assess stress corrosion cracking susceptibility. The slow strain rate test is described in ASTM G 129 [31].

The key to the test procedure is that by straining the sample at a selected slow strain rate, the passive film is disrupted. This disruption in the passive film affords an opportunity for a stress corrosion crack to initiate quickly in a susceptible alloy. Results may be obtained in one to five days, depending on the strain rate. By contrast, the U-bend test takes much longer to run, because disruption or breakdown of the passive film with possible crack initiation is generally a very slow process. In the slow strain rate test, the sample is pulled to failure at a preselected strain rate in a tensile machine surrounded by the environment. If stress corrosion cracking is not a problem, the sample will fail by ductile tensile overload with the fracture surface showing the classical dimpled fractured surface under a scanning electron microscope. If stress corrosion cracking occurs, there are many secondary cracks associated with the primary fracture, and there will be a significant reduction in ductility (percent elongation and

Fig. 12—Siphon test allows concentration of aggressive species to be simulated.

percent reduction in area) compared to a similar sample tested in an inert environment.

In some systems (for example, 304 stainless steel in hot water with low levels of chloride), the slow strain rate method gives false negative results. It is because the mechanism of failure requires pitting to be initiated before cracking can occur. Most slow strain rate tests are not run long enough for the slow pitting initiation step to occur. Alternatively, an electrochemical assist can be provided to initiate pitting before the straining occurs.

In general, the slow strain rate test is a conservative test and a useful method for determining whether an alloy is resistant to stress corrosion cracking in a plant solution.

#### *Stress Corrosion Cracking—Siphon Test*

The siphon apparatus can be used with a three-position flask (see Fig. 11) to assess the tendency for chloride stress corrosion cracking to occur on a stressed U-bend exposed to the condensing liquid [22]. The setup provides an alternating wet/dry condition. The condensed liquid fills the cup that empties when full by a siphon action with the liquid flowing across the sample surface. During the filling stage, the liquid film on the U-bend has a chance to flash off, concentrating the chlorides as would occur in a plant situation. See Fig. 12 for sketch showing siphon test arrangement.

## CONFIDENCE IN CORROSION TEST DATA

Corrosion data come from many sources. It is not produced to a common format and displays considerable variation in quality. Understand the source and quality of corrosion data before using it. The reliability of corrosion data sources may be categorized broadly.

#### *Plant Equipment Performance Data from Identical Process*

Plant equipment performance data in an identical process usually provide a high level of confidence. The data may correlate corrosion test exposure information (coupon or probes) with wall thickness monitoring of process equipment and inspection data on type of corrosion.

#### *Field Corrosion Coupon Data from Identical Process*

This also provides high confidence. Field corrosion coupon data provide corrosion rates and localized corrosion information, but may not provide insight into process upsets.

#### *Plant Equipment Performance or Field Coupon Data from a Similar Process*

Even slight differences in temperature, feedstock, impurities, or cooling water source make the data less reliable. However, corrosion data from a similar process provide information to improve the accuracy of a test program.

#### *Pilot Plant Corrosion Data*

Pilot plant corrosion data are often compromised by frequent process parameter and feedstock manipulations during test campaigns. Under these conditions, it is difficult to relate materials performance to process performance,

unless specific test campaigns are dedicated to corrosion data collection. Documentation is often inadequate.

#### *Laboratory Corrosion Data*

Laboratory corrosion tests are designed to simulate the process. Short test times and inability to capture every nuance of the process are limitations. However, laboratory corrosion testing provides important evidence of conditions that might depassivate active-passive alloys, such as increase in temperature or a threshold concentration of an aggressive species.

#### *Thermodynamic and Kinetic Modeling*

Thermodynamic modeling can be extremely useful in understanding the process chemistry and its influence on corrosion and corrosion data, particularly with respect to the speciation of the liquid phase and the potential for solids formation. Software codes for aqueous and nonaqueous systems are available from many sources, but care must be exercised in their use. Special attention should be paid to the source of the thermodynamic data and/or the source of experimental data used to develop the thermodynamic parameters.

Kinetic modeling of corrosion phenomena has made great advances in the past decade, and some software products are capable of predictions for simple systems. The available tools are extremely useful for extrapolation and relative performance if the corrosion mechanism is understood and model parameters have been derived from trusted data. Materials of construction should not be chosen based on predictions from unvalidated kinetic modeling tools. Rather, use the modeling tools to narrow the selection process and minimize the number of corrosion test experiments required.

#### *Corrosion Literature*

The corrosion literature contains gems, but is nonuniform. It requires a specialist to interpret conclusions, because the authors do not have the same goals as the nonspecialist reader, or even objectives similar to other specialists when performing their studies. Keywords included with the literature do little to help the nonspecialist.

#### *Commercial Data Publications*

The weakness of commercial data lies in nonuniform presentation format between different publications. Data are merged from many sources, and smoothed down to the lowest common denominator. Often, the simpler the presentation format, the lower the value of the information. Data from different publications may be in disagreement.

#### *Manufacturers' Data*

Data from materials suppliers is useful and offers insight into the performance of specific materials. What is omitted from materials suppliers' data is sometimes more revealing than what is included. Much of the information is developed under laboratory conditions in pure solutions. Manufacturers are reluctant to supply corrosion data that can be used for direct comparison of their alloys with competing products. ASTM G 157 [32] categorizes 15 test environments that cover a spectrum of processes in the chemical process

industry. It is recommended that new or existing alloys be exposed to these environments. However, manufacturers are reluctant to develop data that allow direct comparison with competing alloys.

### *Process Literature*

Most process literature provides very little information on materials performance.

## **CREATION OF A COMPUTERIZED CORROSION TEST DATABASE**

It is difficult to compare information between sources. On account of the vagaries of chemical process environments, it is important to develop a database that captures essential information on one's proprietary processes. ASTM standard G 107 [33] may be used as a guide. The amount of information it requires may be daunting. A business should decide what minimum essential elements of corrosion data should be captured in its proprietary corrosion test database.

Before deciding what fields require documentation, ask the question, "Will the information collected assist with the design of the plant, or when management of change justification is required during the life of the plant?" A computerized corrosion test database brings together three main types of information, which are materials, corrosion, and performance.

### *Materials Data*

Describe materials from which the test specimens are made with sufficient accuracy to understand the effect of formation, fabrication, heat treatment, or surface finish on performance. With metals, it is relatively easy to use standard descriptions to indicate composition, such as UNS

designation. Most specimens are exposed in the annealed condition. If another heat treatment is used, such as sensitization, it should be included in the documentation.

Polymers and elastomers are not described with the same degree of precision as metals. When describing them in the database, the ASTM generic name or manufacturer's trade-name is not sufficient. Other unique identification features (such as part number, if the specimen is taken from a component) are required for polymer and elastomer samples.

### *Corrosion Data*

Minimum essential data on the corrosive environment are shown in Fig. 13.

### *Performance Data*

Type of information to be recorded depends on the materials from which the test specimens are made. For metals, calculated corrosion rate and type/depth of localized corrosion must be documented. For polymers and elastomers, measured property changes, such as thickness or hardness, are documented, in addition to appearance change. The information for polymers and elastomers is usually recorded immediately after the coupons are removed and after a designated interval, to provide time for them to stabilize. In all cases, performance data may be linked to a photographic record of the coupons.

## **Acknowledgments**

The authors acknowledge contributions from DuPont peers Mike Dorsey, Sherryl Fox, Steve Grise, John Ludman, Tony Pezone, and Brian Saldanha. Sheldon Dean (formerly Air Products and Chemicals Corporation), Srinu Kesavan (FMC Corporation), and Roger Turcotte (FMC Corporation) are acknowledged for enhancing the draft.

Feature	Why Document
Test type	Lab, field, pilot plant are pointers to value of data
Test time	Required to calculate corrosion rate
Exposure	Type of exposure affects decision making
Coupon or probe location	Pinpoints where coupons are in equipment
Site Name	For internal benchmark
Product	Provides alert to vagaries of process
Responsible party	Provides a key contact who knows more
Process step	Provides link to other data sources
Active Corrosives	Important corrosives influence rate of attack
Weight percent or ppm	Quantities of species present influence corrosivity
Temperature - average	Temperature influences corrosivity
Temperature - maximum	Peak temperature attained may influence corrosivity
Pressure	Helps capture all important process parameter elements
Agitation	Relative motion of process environment influences corrosivity
Sparging	Degree of gas entrainment/blanketing influences corrosivity
pH	For some metals, pH influences corrosivity

FIG. 13—Minimum essential documentation of the corrosive environment is required to create an effective computerized test database.

# Pulp and Paper

Angela Wensley<sup>1</sup>

THE SPECTRUM OF CORROSION environments in the pulp and paper industry is perhaps greater than that encountered elsewhere in the chemical process industries [1]. Aqueous environments range from acidic to neutral to basic, and from reducing to oxidizing. High-temperature environments include molten salts and boiler flue gases. Many of these environments are unique to the pulp and paper industry. Figure 1 is a schematic diagram of an integrated pulp and paper mill. Process equipment includes pressure vessels, boilers, kilns, storage tanks, towers, and large machines with rolls that rotate at high speed. This paper reviews the corrosion testing methods used for each of the major pulp and paper process environments.

Pulp and paper process environments are negatively affected by trends to higher production rates and increasingly stringent environmental laws. Higher production can place greater mechanical demands on equipment, as well as increase corrosivity of certain processes (e.g., simply by increasing the temperature). Requirements to discharge less, or even zero, effluent cause the increased recycle of corrosive elements that build up in concentration in process streams [2–4]. Environmental demands are requiring the development of new pulp and paper process technologies [5].

For many years, the pulp and paper industry depended heavily on carbon steels and 300-series austenitic stainless steels as materials of construction. There was heavy reliance on equipment suppliers for materials selection and repair advice. When failures occurred, incremental improvements in materials selection were made; for example, moving from Type 304 to Type 316 to Type 317 stainless steel. Beginning in the mid-1970s, several pulp and paper companies set up their own materials and corrosion laboratories with the aim of solving corrosion problems through proper materials selection, and to assist with materials selection for new process technologies. There has been a trend toward the application of duplex stainless steel for corrosion protection. The use of stainless steels in the pulp and paper industry is the subject of a recent publication jointly sponsored by TAPPI and the Nickel Development Institute [6].

Corrosion researchers working in or for the pulp and paper industry have developed or adapted their own corrosion test methods and standards relevant to the pulp and paper environments, in addition to using published standards. Corrosion test methods used within the pulp and paper industry

include a variety of corrosion coupon exposures and electrochemical procedures, including polarization testing, linear polarization, and corrosion potential monitoring in:

- simulated process environments,
- actual process environments,
- samples of process solutions,
- ASTM, NACE, and TAPPI standard environments.

Davies [7] summarized several of the ASTM standard recommended practices used for corrosion testing in the pulp and paper industry in the 1980s. These included:

- ASTM Standard Recommended Practice G1, Preparing, cleaning, and evaluating corrosion test specimens;
- ASTM Standard Recommended Practice G4, Conducting plant corrosion tests;
- ASTM Standard Recommended Practice G50, Conducting atmospheric corrosion tests of metals;
- ASTM Standard Recommended Practice G48, Pitting and crevice corrosion resistance of stainless steels and related alloys by the use of ferric chloride solution;
- ASTM Standard Recommended Practice G35, Determining the susceptibility of stainless steels and related nickel-chromium-iron alloys to stress corrosion cracking in polythionic acids.

There has been a greater reliance on developing test methods applicable to actual or simulated process solutions, rather than testing in “standard” solutions (e.g., ferric chloride), which are not relevant to pulp and paper processes.

## THE PAPER MACHINE

In a paper machine, a pulp suspension (approximately 2 % pulp in “white water”) is formed into a sheet, dewatered, pressed, and dried into paper. Paper machines operate at higher speeds than pulp machines. Wensley and Moskal have published a review of corrosion in paper machines [8].

## Environments

White waters can vary tremendously in composition among different paper machines, and may contain ions such as thiosulfate, chloride, and sulfate, plus additives to control pH, microbiological activity, drainage/retention, or other product qualities. Thiosulfate is a pitting agent that can be present from hydrosulfite brightening. Chloride is

<sup>1</sup>Pulp and Paper Corrosion Specialist, Angela Wensley Engineering Inc., White Rock, BC, Canada V4B 1K1.

**FIG. 1—A schematic example of an integrated pulp and paper mill.**

present from wood floated in from the ocean, the recycling of other process effluents, and carry-over from the bleach plant. Recycling of process streams in order to minimize effluent has increased both the temperature of the white water and the concentrations of corrosive species. Increased production demands have resulted in higher machine speeds and greater loading of components such as suction roll shells.

Austenitic and duplex stainless steels are the major metallic materials of construction for white water service, particularly for the headbox, piping, and also for suction roll shells. Bronze, once widely used for forming wires and suction roll shells, is used less because of its inherently poor corrosion resistance in modern white water environments. Poor welding quality can undermine the corrosion resistance of stainless steels, especially if the thiosulfate and chloride levels are high. Corrosion under surface deposits including scales, pulp mats, or microbiological growths

can require higher alloy compositions for corrosion resistance. Ultrahigh-strength low-alloy steels and various types of cast iron are used in the less corrosive areas of the paper machine.

Nonmetallic, composite, and ceramic materials are also used in paper machine construction, particularly on the wet forming end where low friction and dimensional stability are critical. Tile linings are used in tanks and wire pits, and corrosion-resistant coatings are used to protect the carbon steel structural beams in paper machines.

Alloy development for suction roll shells has barely kept pace with the ever-increasing performance demands and white water corrosivity in paper machines. Bronze, martensitic stainless steels, early-generation duplex stainless steels, precipitation hardening stainless steels, and later-generation duplex stainless steels have all been used for the manufacture of suction roll shells. Today, the preferred materials for suction roll shells in severe service are duplex

stainless steels with low residual stress and high chromium content to resist pitting. These shells are produced either by centrifugal casting or the by rolling and welding of plate where the final welded assembly is annealed. The history of corrosion studies of suction roll shells has been summarized by Bowers [9].

## Corrosion Testing

Corrosion testing for paper machines has included a variety of electrochemical, pitting, microbiologically influenced corrosion (MIC), corrosion fatigue, and structural coatings tests.

### *Electrochemical Corrosion Testing*

Cyclic anodic polarization procedures based upon ASTM G5 (Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements) have been used to evaluate the localized corrosion resistance of stainless steel alloys in paper machine white waters. The difference between the open circuit or naturally occurring corrosion potential and the pitting breakdown potential of various materials has been reported by many investigators [10–13]. Bowers [14] called the difference between the breakdown potential and the potential of the cathodic/anodic current reversal the “margin of safety.” He also noted the effect of the sulfate to chloride concentration ratio on localized corrosion of Types 304 and 316L stainless steels. These results permitted alternative materials of construction to be ranked and their limits of resistance to be defined.

Variations of the test have been developed by others. In a polarization testing program to compare the localized corrosion resistance of Type 316L stainless steel from different sources, Wensley [13] found that machinable 316L was inferior to conventional 316L at comparable molybdenum contents. She noted that crevice corrosion at the electrode holder can interfere with the measurement of the pitting potential, but that the formation of corrosion crevices can be prevented by using an insulating varnish. A reproducible crevice site was made by means of a Viton O-ring. Bennett and Federowicz [10] used paper rings to simulate crevices under pulp deposits in a study of the effect of chloride on stainless steels.

Castillo and Caudill [15] used both linear polarization resistance and electrochemical noise to study the effect of process changes on the corrosion of Types 316 and 316L stainless steels. Wensley et al. [16] used linear polarization resistance to study the corrosion of bronze in various white water systems in a newsprint mill.

### *Pitting Corrosion Testing*

Theories that corrosion fatigue cracks initiate at corrosion pits have prompted interest in the pitting resistance of suction roll alloys. Reid and Wensley [17] used potentiodynamic pitting scans to evaluate duplex suction roll materials, as did Castillo et al. [18,19]. The pitting resistance of duplex stainless steels was studied extensively by Sriram and Tromans [20]. They conducted potentiodynamic pitting tests in conjunction with electron microscopy, concluding that pitting of the ferrite and austenite phases was dependent on the partitioning of alloy elements and nitrogen enrichment. Yoshitake [21] evaluated a new alloy via pitting tests in 6 % FeCl<sub>3</sub>.

Increased temperature and chloride concentration resulting from closing up the white water system of a mill could result in localized corrosion if the temperature exceeds the critical pitting temperature for the alloy of construction. Conventional electrochemical techniques often result in crevice corrosion, which may be nonreproducible and mask the initiation of pitting. The “Avesta cell” in which the crevice is continuously flushed with distilled water permits an electrochemical determination of the critical pitting temperature. The critical pitting temperature of 316L stainless steel was defined as the temperature at which the breakdown potential dropped about 200 mV as the corrosion reaction changed from transpassive corrosion to pitting [11,12]. Data obtained using the Avesta cell showed that the corrosion resistance of Type 316L stainless steel varied from heat to heat.

Newman et al. [22–24] have aided the understanding of thiosulfate effects on the corrosion of Type 304 stainless steel in paper machine white water. One of their tests was the “scratch method” [24] that was used to investigate pitting at various ratios of thiosulfate to sulfate, with chloride and bisulfite additions in simulated white water further defining the limits of corrosion resistance for stainless steels.

Varjonen et al. [25] studied the pitting corrosion resistance of Type 316 stainless steel in white waters containing thiosulfate using an Avesta Cell, where the pitting breakdown could be studied without interference from crevice corrosion. Salonen et al. [26] and Laitinen et al. [27] used the contact electric resistance (CER) method to study the effect of thiosulfate on the films formed on Type 304 stainless steel. In the CER method, the resistance of the films formed on metal surfaces can be studied as a function of potential. Stable passive films have a high electrical resistance, whereas unstable (or absent) films have a low electrical resistance.

### *Microbiologically Influenced Corrosion Testing*

White water environments are typically 40–60°C and contain dissolved organic nutrients that promote the formation of slimes and biofilms, sulfate ions also provide food for sulfate reducing bacteria. MIC is a particular concern in alkaline papermaking environments. Many mills have converted from acid papermaking (with the addition of alum) to alkaline papermaking in order to produce longer lasting papers. Corrosion considerations in alkaline papermaking have been summarized by Bowers [28]. MIC of austenitic and duplex stainless steels in paper machine environments has been investigated [29]. These investigations included polarization tests of surfaces under biofilms. Carpen et al. [30] simulated the MIC that occurs at splash zone areas of paper machines. NACE has published a book on MIC that is an aid in identifying problems [31].

### *Corrosion Inhibitor Testing*

Magar [32] evaluated inhibitors in white water by means of the linear polarization resistance technique in a search for effective inhibitors to prevent corrosion of bronze suction rolls. A galvanodynamic testing method was used by DeBerry and Ellis [33] in order to study inhibition of corrosion of a duplex stainless steel alloy.

### Corrosion Fatigue Testing

Significant research and testing has been devoted to corrosion fatigue resistance of paper machine suction roll shells [34]. Unfortunately, the results from the various tests used by the various manufacturers have been difficult to compare. Furthermore, their tests do not predict actual performance in the paper machines and cannot be related directly to roll loads or geometries. Experience gained over a long period of time has remained the best guide to selection of suction roll alloys. The tests used are summarized below.

The rotating beam bending test using the RR Moore machine in accordance with TAPPI Technical Information Paper 0402-09 [35] has been the most popular procedure. The fatigue life (number of cycles to failure) is plotted as a function of applied cyclic stress. The mean stress is zero in these tests so the effects of residual stresses are not tested. Unfortunately, most suction shells contain significant residual stresses from casting or weld repairing, and high residual stresses are believed to be responsible for the short service life of some suction shell alloys. Suction shell roll life cannot be predicted from the test results, and the stress fields produced in the test coupons cannot be directly related to those in operating rolls.

Jaske and Castillo [36] used RR Moore rotating beam fatigue machines to study several roll materials with simulated white water solutions dripped onto the test specimen surface. Castillo et al. [19] used rotating bending tests to evaluate the corrosion fatigue resistance of duplex stainless steel suction roll alloys. Yoshitake et al. [21] also used this method.

Glogowski and Castillo [37] used the reverse plate bending test to evaluate cast bronze alloys in paper mill white waters. Rectangular bars with holes drilled to simulate those in suction rolls were tested in accordance with TAPPI Technical Information Paper 0402-08 with simulated white water containing thiosulfate wicked into the holes [38]. This test is better than the rotating beam test as a simulation of the fatigue that occurs at suction roll holes, since it incorporates a drilled hole geometry.

Castillo and Michel [18] used uniaxial fatigue testing to demonstrate the performance of a duplex steel. The axial fatigue tests were done with a Krouse axial mechanical test machine. The mean load was varied to apply a stress to the specimen to simulate the effect of residual tensile stresses in a suction roll, for a number of different stress ratios. The specimens were sprayed with simulated white water during testing. The crack length was measured during their testing via a thin foil crack measuring gage. Log-log plots of the crack growth rate versus the stress intensity range were presented.

Fracture mechanics principles and test methods have been used to determine the corrosion fatigue behavior in well-characterized mechanical conditions. Kelley et al. [39] conducted fatigue tests in a hydraulic fatigue machine using notched compact tension fracture mechanics specimens (ASTM E647, Test Method for Measurement of Fatigue Crack Growth Rates) in a simulated acidic white water. Both crack initiation and propagation were studied. In the crack initiation tests, three holes were drilled in the path of the crack in order to simulate holes in a suction roll.

Yeske [40–42] investigated crack propagation in the corrosion fatigue of suction roll alloys using compact tension

specimens. A correlation with service performance and tensile stresses in the rolls was observed.

Paper machine components other than suction rolls can experience corrosion fatigue cracking. Dorsch et al. [43] used a full size felt roll journal as a laboratory fatigue test specimen in simulated white waters containing thiosulfate ions.

### Structural Coatings Testing

Corrosion resistance of paints for structural steel in paper machine environments has been studied by Bennett and Magar [44,45]. A short-term laboratory testing method was developed to evaluate maintenance coatings. The test method used coupons with one half initially coated and the other half left bare to corrode in the environment, and then later the bare half was coated to simulate a repair coating in the field. Salt fog and Atlas cell immersion tests were also conducted on the paint panels. Rendahl et al. [46] used in-plant exposures of paint test panels.

## THE BLEACH PLANT

Strong oxidizing agents are used in the bleach plant to remove the pulp fiber color produced by chemical pulping, i.e., from dark brown to white. There is widespread consumer demand for white paper. The bleaching operation is accomplished in several stages with various bleaching agents. The stages are identified by the oxidant used, e.g., chlorine (C-stage), chlorine dioxide (D-stage), hypochlorite (H-stage), oxygen (O-stage), peroxide (P-stage), and ozone (Z-stage). Caustic extraction (E-stage) is used between bleaching stages to remove lignin.

Chlorine ( $\text{Cl}_2$ ) and chlorine dioxide ( $\text{ClO}_2$ ) bleaching are carried out in towers (usually carbon steel) lined with non-metallic materials. The bleached pulp is typically washed in a rotary drum washer or diffusion washer after exposure to the bleaching chemicals. For many years, Type 317 stainless steel was the "standard" material of construction for the bleach plant washers. Increased recycle and conversion to  $\text{ClO}_2$  bleaching has resulted in increased corrosivity of bleach plant process streams, requiring stainless steels that contain higher concentrations of molybdenum, nickel-based alloys, or titanium. Bardsley has reviewed the metallurgies required in the new bleaching processes [47].

### Environments

Chlorine-based bleaching created the most corrosive environments in the bleach plant prior to the use of  $\text{ClO}_2$ , with the  $\text{Cl}_2$  providing both high oxidizing potentials and being a source of chloride ions that served as localized (pitting and crevice) corrosion agents. Chlorine bleach washers typically operated under acidic conditions that further promoted localized corrosion of stainless steels in the presence of chloride ions. Chlorine bleaching has been replaced by  $\text{ClO}_2$  because of potential release of organochlorines to the environment. Acidic  $\text{ClO}_2$  bleaching environments are similar to chlorine bleaching environments in their corrosivity to stainless steels. Near-neutral pH  $\text{ClO}_2$  environments have been observed to severely corrode nickel-base alloys. Increased

recycle has led to higher temperatures (60–80°C) that promote localized corrosion.

Alternative bleaching agents using oxygen, ozone, and peroxide have been developed. The environments produced in these stages do not appear to be as corrosive to stainless steels, but peroxide can be highly aggressive to titanium.

## Corrosion Testing

Bleach plant corrosion testing has included corrosion coupon testing, electrochemical testing, electrochemical protection testing, and nonmetallic materials evaluation. Coupon exposure tests have been used to rank candidate materials for these applications. Nonmetallic materials including thermoplastics, thermosets, brick, and tile are widely used in the bleach plant.

### Corrosion Coupon Testing

Members of the TAPPI Corrosion and Materials Engineering Committee conducted cooperative research programs based on field coupon studies in operating bleach plants to evaluate candidate materials for bleach washers [48,49]. Unwelded alloys were tested in Phase 1 and welded alloys were tested in Phase 2 [50,51]. Phase 1 testing [48] used circular test coupons on spool racks, with PTFE spacer washers to allow crevice corrosion to take place under the washers. The multi-crevice Anderson washer was included on the test spools. This washer is described in ASTM STP 576 [52]. In the Phase 2 research program, over 1000 coupons were exposed in a number of bleach washers [53]. Fabricated pipe spools were used in some testing [54,55]. Garner [53] described additional visual and metallographic examination of welded stainless steel bleach plant coupons. Statistical review of the results was performed by Beetham [56].

The pitting resistance of stainless alloys has been ranked using the ferric chloride ( $\text{FeCl}_3$ ) test. This method appears to be appropriate, since it is likely that  $\text{FeCl}_3$  itself may be formed in bleach plant corrosion deposits when ferrous salts are oxidized by  $\text{ClO}_2$ . The  $\text{FeCl}_3$  test establishes a critical temperature above which pitting will occur [57–64]. Pitting resistance is determined in 6 %  $\text{FeCl}_3$ , in accordance with ASTM G 48 (Test Method for Pitting and Crevice Corrosion Resistance of Stainless Steels and Related Alloys by the Use of Ferric Chloride Solution) or in 10 %  $\text{FeCl}_3$  [61,62]. This test provides a conservative limit for the maximum temperature at which a material can be used, and the results are consistent with field experience. Critical crevice corrosion temperatures are measured [59] by means of ASTM G 78 (Guide for Crevice Corrosion Testing of Iron-Base and Nickel-Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environments with Anderson Washers). Wallen [63] evaluated alloys for highly oxidizing bleach plant environments in  $\text{FeCl}_3$  and in other simulated environments. Audouard [64] has used  $\text{FeCl}_3$  testing to evaluate alloys for highly oxidizing bleach plant environments.

Wensley et al. [65–68] conducted tests for several years with duplex stainless steels, highly alloyed austenitic stainless steels, and nickel-base alloys in a  $\text{ClO}_2$  washer using creviced coupons. These tests revealed that in near-neutral D-stage environments all the stainless steels suffered crevice

corrosion and that nickel-base alloys experienced general corrosion due to transpassive dissolution. The crevice washers actually protected the nickel-base alloys from thinning beneath the crevices. All stainless steel alloys experienced crevice corrosion. Test-to-test exposure time variations were normalized by dividing maximum crevice depths for each alloy by the maximum crevice depth observed for a Type 317L standard test corrosion coupon that was exposed in each test.

Many corrosion coupon tests were done in  $\text{Cl}_2$  and mixed  $\text{Cl}_2/\text{ClO}_2$  bleach plant environments in the 1990s to investigate the phenomenon of transpassivation of both nickel-base and iron-base alloys [69–76]. In-plant corrosion coupon testing of stainless alloys has been done in ozone bleaching environments [77]. Both in-plant and laboratory corrosion coupon testing has been done in  $\text{H}_2\text{O}_2$  bleaching environments [78–82].

### Electrochemical Testing

Bleach plant environments are amenable to conventional polarization testing, although the presence of the oxidant prevents measurement of the complete polarization curve. For this reason, polarization testing is normally carried out in simulated solutions without the addition of the oxidant.

To avoid problems with crevice corrosion at the electrode holder, an Avesta cell was used in investigations of the effect of post-weld cleaning on corrosion resistance of austenitic and duplex stainless steels in a simulated  $\text{ClO}_2$  liquor [11,83,84].

Potentiodynamic anodic polarization techniques were used by Bennett [85] in laboratory testing to study Type 316L stainless steel in  $\text{ClO}_2$  bleaching environments. Other researchers used electrochemical testing via an anodic scan with reversal to locate the pitting potential and the repassivation potential [59].

Electrochemical polarization testing has been done to evaluate the corrosion behavior of iron-base and nickel-base alloys in  $\text{ClO}_2$  environments [62,75,86–93], in oxygen bleaching environments [94], in ozone bleaching environments [95–97], in peracetic acid bleaching environments [97], and of titanium and zirconium in  $\text{H}_2\text{O}_2$  bleaching environments [98–100].

### Electrochemical Protection Testing

Electrochemical protection of bleach washers has permitted the continued use of lower alloyed stainless steels, while washing conditions have become more corrosive. Electrochemical protection was applied successfully in an early chlorine dioxide washer [101]. Electrochemical protection at slightly cathodic potentials was commercially applied for C- and D-stage washers [51,102–106]. The effectiveness of electrochemical protection has been assessed by means of coupons [104].

### Nonmetallic Materials Evaluation

The widespread application of fiberglass-reinforced plastic (FRP) composites has prompted comparative testing for resistance to bleaching solutions [107]. Coupons were prepared in accordance with ASTM C 581 (Practice for Determining Chemical Resistance of Thermosetting Resins Used in Glass Fiber-Reinforced Structures Intended for Liquid

Service). Bishop and Cowley [108] have described methods for determining the depth of surface corrosion and the moisture content of resins. They have done considerable in-plant coupon testing in  $\text{ClO}_2$  bleaching environments [109–111].

Bergman [112] described innovative methods for evaluating the performance of fiber-reinforced ester plastics. The techniques include water absorption measurements, mechanical and acoustic emission tests, and light transmission. Using these methods, he has determined failure mechanisms and has compared the performance of alternative materials. Later work has used infrared spectral analysis for both the identification of materials and for estimating the maximum temperature to which the laminate has been exposed; other tests include differential scanning calorimetry and dye staining [113]. These methods revealed the role of water-related damage on FRP performance. Petersson and Bergman [114] have studied the resistance of polymeric materials exposed in the field to various bleaching environments.

## CHEMICAL PULPING

In kraft chemical pulping, wood chips are digested (cooked) using “white liquor” in batch or continuous digesters to produce the pulp. “Black liquor” (spent white liquor containing dissolved lignin) is a by-product of the cooking process. Black liquor is extracted from the digester where it is recovered in flash tanks. Black liquor is also obtained by washing the pulp. The washing is done in brownstock washers. Some black liquor is returned to the digester. Most of the black liquor is subsequently concentrated in evaporators to produce “strong” or “heavy” black liquors that are sent to the recovery boiler to be burned as a fuel. Smelt (a mixture of molten salts that collects in the bottom of the recovery boiler) is dissolved in water to create “green liquor.” The green liquor is recausticized using lime that converts it to the white liquor used for chemical pulping.

Several reviews of corrosion and protection of batch and continuous digesters are available [115,116], as well as for the corrosion of flash tanks [117]. Carbon steel is used extensively for kraft process equipment, including liquor tankage and digesters. Many carbon steel continuous digesters have experienced stress corrosion cracking (SCC) at welds in the impregnation zone at the top of the digester [118,119] where post-weld heat treatment was not mandated by the construction code. The phenomenon of rapid thinning of carbon steel continuous digesters has been increasingly reported through the 1990s [120]. The rapid thinning appears to be related to changes in operation that produce higher temperatures and lower concentrations of NaOH between the wash, extraction, and cooking screens in the digester.

Stainless steel and nickel-base alloys are also used in kraft pulping systems. Some stainless steels can experience SCC, general corrosion thinning, or intergranular attack in alkaline liquors. Piping, tubes (liquor heater and evaporator), tankage, and some process vessels other than digesters have been constructed using Type 304L austenitic stainless steel. Continuous digesters have austenitic stainless steel screens, downcomer piping, and nozzles. Stainless steel composite

plate (typically carbon steel plate roll-bonded using Types 304L, 316, or 321) has been used to construct numerous vessels including many digesters. The current trend is to construct both batch and continuous digesters and ancillary vessels such as flash tanks, level tanks, and steaming vessels from solid duplex stainless steel, particularly Type 2205. Duplex stainless steel and nickel-base alloys have been used for tubes in liquor heaters and for the construction of bottom scrapers in continuous digesters. These applications require strict quality control to ensure optimum performance of the protective coating(s).

Stainless steel or nickel-base alloy weld overlays have been used to extend the life of both continuous and batch digesters. Other corrosion protective measures for digesters include anodic protection and thermal spray coating [116].

## Environments

White liquors, the most concentrated alkaline pulping liquors, are solutions containing the following inorganic compounds: sodium hydroxide ( $\text{NaOH}$ ), sodium sulfide ( $\text{Na}_2\text{S}$ ), sodium thiosulfate ( $\text{Na}_2\text{S}_2\text{O}_3$ ), sodium sulfate ( $\text{Na}_2\text{SO}_4$ ), sodium carbonate ( $\text{Na}_2\text{CO}_3$ ), and sodium chloride ( $\text{NaCl}$ ). A typical white liquor contains 100 g/L  $\text{NaOH}$ , 35 g/L  $\text{Na}_2\text{S}$ , 5 g/L  $\text{Na}_2\text{S}_2\text{O}_3$ , 5 g/L  $\text{Na}_2\text{SO}_4$ , 20 g/L  $\text{Na}_2\text{CO}_3$ , and 1 g/L  $\text{NaCl}$ . White liquor is regarded as being the most corrosive of the alkaline pulping liquors, although higher corrosion rates can be obtained with black liquors at higher temperatures. The strength of white liquors is typically described in terms of the parameter “sulfidity” with higher sulfidity liquors generally having higher concentrations of  $\text{Na}_2\text{S}$ . Green liquor has a comparable inorganic composition, except that it has a lower concentration of  $\text{NaOH}$  than does white liquor. White liquor prior to addition to the digester is typically at 90–100°C. White liquor is usually mixed with black liquor and the chips prior to being added to either batch or continuous digesters. Black liquors have an appreciable organic content. Extractives from some wood species are known to make black liquors much more corrosive. Evaporated black liquors have a higher solids content than do weak black liquors and tend to have relatively high concentrations of both  $\text{NaOH}$  and  $\text{Na}_2\text{S}_2\text{O}_3$ .

The  $\text{NaOH}$  is consumed during either batch or continuous cooking. In a batch digester, the  $\text{NaOH}$  concentration decreases over the duration (approximately 2 h) of a batch cook, and the  $\text{NaOH}$  may eventually be completely depleted. Despite the depletion of  $\text{NaOH}$  in batch cooking, there have been rare occurrences of SCC in batch digesters.

Most of the white liquor is added at the top of a continuous digester, and the  $\text{NaOH}$  concentration is decreased at lower elevations, although there is the possibility of adding white liquor at lower elevations. In some cooking processes, white liquor is added directly at the top and/or to recirculated liquor that is removed from the digester, heated, and then re-introduced into the digester. The caustic concentration in the impregnation zone is high enough to support SCC of carbon steel welds that contain high residual welding stresses. In the wash zone near the bottom, the liquor may be nearly depleted in  $\text{NaOH}$ .

## Corrosion Testing

There has been much corrosion coupon testing in kraft and soda liquors. Electrochemical polarization, linear polarization resistance testing, and contact electrical resistance testing have also been used.

### *Corrosion Coupon Testing*

Wensley and Charlton [121,122] performed coupon studies to determine the effect of liquor composition on general, galvanic, and SCC in white liquors and to determine the effect of steel composition on corrosion rates. Strom [123] tested corrosion coupons of stainless steels in green and black liquors. Wensley and Champagne [124] also did laboratory corrosion coupon testing in white, green, weak black, strong black, and digester extraction (flash tank) liquors to investigate the effect of sulfidity on corrosion of carbon and stainless steels.

Clarke and Stead performed corrosion coupon testing in flash tank liquors [125]. Al-Hassan et al. have done coupon studies in condensed black liquor vapours [126]. Evaporator liquors have been studied recently [127–130]. The evaporator testing included SCC test specimens in the form of U-bends prepared in accordance with ASTM G 30 (Standard Practice for Making and Using U-Bend Stress Corrosion Test Specimens).

Thompson et al. [131] investigated the effects of sand on corrosion and erosion in simulated kraft white liquor using a reciprocating wear tester. Nadezhdin and Cardin [132] studied erosion-corrosion of stainless steels in simulated batch digester cooking liquor using coupons subjected to daily abrasive cleaning. These studies are relevant since sand trapped in the bark of logs moved on the earth can be introduced with the chips in mills where de-barking is not efficient.

Corrosion coupon studies in digesters and in the laboratory using digester liquors have been reported by a number of researchers [133–142]. Some have investigated the effect of organic species—including the addition of catechols—on corrosion in digester liquors using laboratory autoclaves [133,139–141]. Singh et al. [139,140] made liquors using pilot plant digester cooks with various hardwood and softwood species starting with the same white liquor source. They investigated the corrosion of both carbon steel and stainless steel at 170°C. Troselius [141] prepared synthetic liquors to which various inorganic and organic compounds were added to investigate the effects on the corrosion of stainless steel at 170°C. Ramo [142] investigated the influence of sulfur anions on the corrosion of stainless steels in simulated inorganic digester liquors in autoclaves.

### *Electrochemical Polarization Testing in White Liquors*

The earliest study of constituents in white liquor was reported by Ruus and Stockman [143]. Mueller [144,145] was one of the first workers to describe the active/passive corrosion of steel in white liquor. The important effect of polysulfide was explained by Roald [146,147] based on polarization testing and consideration of modern mixed electrode theory. Wensley and Charlton [148] performed potentiodynamic polarization tests to study the effects of various liquor constituents including polysulfide, thiosulfate, and sulfate on the corrosion of carbon steel at 90°C that is relevant to clarifiers

and storage tanks. The effect of passive film composition on stable passivity was studied by Crowe and Yeske [149] who investigated the corrosion of carbon steel in simulated kraft liquor via polarization testing, mass loss, and corrosion potential measurements to determine the effects of liquor components.

Uusitalo [150] analyzed iron sulfides via X-ray analysis to determine their influence on corrosion behavior. Tromans [151] conducted anodic polarization tests and used electron microscopy and including electron diffraction to reveal that sulfide incorporated into the  $\text{Fe}_3\text{O}_4$  film impaired passivation. Honda et al. [152] performed extensive analysis of surface corrosion films in simulated liquor. Clarke and Singbeil [153] completed potentiodynamic polarization scans in white liquor, green liquor, and weak wash liquor at 90°C to investigate the effect of polysulfides on corrosion of carbon and stainless steels.

### *Linear Polarization Resistance Testing*

LPR testing is typically done in accordance with ASTM Standard G 96. Yeske [154] measured the corrosion rates of carbon steels in alkaline sulfide environments using the LPR technique and described the use of the silver/silver sulfide reference electrode. These techniques were developed further by Crowe and Yeske [155] and used with real mill liquors for on-line monitoring of corrosion rates. The corrosion rates were found to be related to liquor composition with a strong flow effect. Crowe [156] also used LPR testing for on-line corrosion monitoring in white liquor clarifiers. Leinonen et al. [157] used the LPR method to monitor corrosion in a batch digester.

### *Contact Electric Resistance Testing*

The contact electric resistance technique has been applied by Ramo et al. [142] to study the corrosion and passivation of stainless steels and of chromium plated stainless steels in alkaline pulping liquors.

### *Hot Plate Boiling Corrosion Testing*

Audouard et al. and Dupouiron [158–160] simulated the performance of stainless steels in batch digesters during filling after a cook. Their studies were conducted under heat transfer conditions where white liquor was sprayed onto metal surfaces heated above the boiling point. They measured corrosion potentials, redox potentials, and polarization resistance and performed polarization tests in white and black liquors and mixtures of both at temperatures up to 170°C.

### *Electrochemical Corrosion Monitoring in Digesters*

Electrochemical corrosion monitoring in batch [157,161] and continuous digesters [162] has been accomplished using reference electrode probes that permit the measurement of the corrosion potential. The corrosion potential of the digester wall has been measured with respect to molybdenum, stainless steel, and silver/silver sulfide reference electrodes. Pawel et al. [163] have used electrochemical noise to monitor corrosion in a continuous digester.

### *Electrochemical Polarization Testing in Autoclaves*

Crowe and Tromans [164,165] performed polarization tests for carbon steel at 150°C in alkaline sulfide solutions

using an autoclave and an external silver/silver sulfide reference electrode. They developed potential-pH diagrams indicating thermodynamically stable compounds at given potentials and pH that were used to interpret the observed corrosion behavior.

Wensley [166–171] conducted extensive potentiostatic polarization studies in continuous digester liquors (mainly extraction liquors) and in batch digester liquors to obtain “corrosion polarization curves” showing the corrosion rate versus potential behavior for numerous materials of construction. “Corrosion polarization curves” show the actual relationship between potential and the anodic process of corrosion without the interference of competing anodic and cathodic reactions that otherwise makes it difficult to distinguish corrosion processes in potentiodynamic polarization curves. The potentiostatic tests were done at individual potentials in the range from –250 to +100 mV versus a molybdenum reference electrode, the range of possible corrosion potentials that materials may be experienced in digester environments. Materials investigated included carbon steels (of both low and high silicon contents), austenitic stainless steels, duplex stainless steels, various weld metal overlays, and thermal spray coatings. Specimens were held for a period of five days at each selected potential, then removed, cleaned, and mass loss corrosion rates were determined. This test method is also well suited to investigating the effects of temperature and NaOH concentration in the liquor and the effects of silicon and chromium contents in carbon steels and stainless steel, respectively [170].

#### *Anodic Protection*

Mueller [172] and then Banks et al. [173] described the anodic protection of batch digesters. These systems maintain the surface potential in the passive range, at more positive potentials to the active/passive transition where corrosion may be substantial and cracking may occur. Banks successfully used a molybdenum oxide reference electrode. Bennett [174] described anodic protection of a continuous soda digester, but molybdenum reference electrodes failed in those tests. Anodic protection has been used in some continuous digesters to mitigate corrosion and SCC [118,175–177]. Yeske et al. described the anodic protection of a white liquor clarifier [178], and Munro described the protection of white and green liquor tankage [179].

Thin layer activation coupons have been used to continuously monitor corrosion rates in continuous digesters, and to verify the effectiveness of anodic protection systems [180]. The surface of a thin layer activation coupon is irradiated to a shallow depth and monitoring is performed with a Geiger counter from outside the digester wall. Subtracting for effects of half-life decay, the corrosion rate can be estimated from the decreased activity of the coupon.

#### *Stress Corrosion Cracking Tests*

The catastrophic failure of a continuous digester by SCC revealed the need to better understand SCC of steels in alkaline sulfide solutions [118]. SCC was subsequently found in many other digesters [181]. SCC rates were measured by examination of double cantilever beam fracture mechanics specimens with various stress intensity factors, which were exposed in the failed digester after repairs were made [118].

Singbeil and Tromans [182–184] investigated the SCC of carbon steel in alkaline sulfide solutions in the laboratory by means of slow strain rate tests (SSRT) and fracture mechanics tests with precracked loaded double cantilever beams. Cracking occurred at active/passive transition potentials. Subsequent research [185–187] showed that there were two active/passive transitions and that cracking was associated with formation of a sulfide containing film. The fast scan/slow scan potentiodynamic techniques did not predict the potential range for SCC. Crack propagation rates, as a function of stress intensity, were investigated via fracture mechanics tests.

Yeske and Guzi [188] published results of SSRT done by using liquor samples continuously drawn through the test cell from a digester impregnation zone. They monitored corrosion potentials over a period of several months and discovered that the corrosion potential entered the cracking zone during digester upsets. Similar monitoring has been conducted by others [189–191]. Crowe [192] described slow strain rate testing, which revealed that the cracking zone varied at different mills and the susceptibility to SCC increased with increasing liquor concentration.

Ring weld tests have been used to evaluate the use of various weld materials to minimize residual stress induced cracking [193]. These were prepared and tested in accordance with ASTM G 58 (Practice for Preparation of Stress Corrosion Test Specimen for Weldments) and ASTM G 31 (Practice for Laboratory Immersion Corrosion Testing of Metals). The ring weld technique was modified for use in evaluating resistance to SCC along with stress relief, shot peening, sealed thermal spray coatings, and weld overlays of Alloy 82 and of Type 309L stainless steel [194].

High-temperature and pressure tests (weight loss, electrochemical measurements, and U-bends) were conducted by Honda et al. [152] with austenitic, ferritic, and duplex stainless steel alloys in alkaline sulfide solutions at 150°C. Dupoirion [160] reported on SCC tests conducted in white liquors using the constant load test.

Kivisäkk [195] used SSRT to study the SCC of carbon and stainless steels in white liquor. Specimens were prepared to ISO Standard 7539-4, Corrosion of Metals and Alloys—Stress Corrosion Testing—Part 4: Preparation and Use of Loaded Tension Specimens. The SSRT was done in accordance with ISO Standard 7539-7, Corrosion of Metals and Alloys—Stress Corrosion Testing—Part 7: Slow Strain Rate Testing.

#### *Sensitization*

Susceptibility of austenitic stainless steels to intergranular attack has been evaluated using ASTM A 262 (Practices for Detecting Susceptibility to Intergranular Attack in Austenitic Stainless Steels) and by ASTM G 108 (Test Method for Electrochemical Reactivation (EPR) for Detecting Sensitization of AISI Type 304 and 304L Stainless Steels). The former method involves electrolytic etching in oxalic acid, while the latter is an electrochemical reactivation test that measures the charge associated with corrosion of the chromium-depleted regions surrounding precipitated carbide particles. Wensley [135] performed sensitization tests using these standard procedures and also measured the rate of intergranular attack of stainless steel specimens in digester liquors. Continuous digester extraction liquors were found

to be an environment that produced severe intergranular attack of stainless steels that had been heat treated in the sensitization temperature range, even when the steels were of low carbon content.

Susceptibility of duplex stainless steels to formation of undesirable intermetallic phases is typically done using ASTM A 923 (Test Methods for Detecting Detrimental Intermetallic Phase in Wrought Duplex Austenitic/Ferritic Stainless Steels). The application of ASTM A 923 to testing of weldments is recommended in TAPPI TIP 0402-29 [196].

#### *Liquor Heater Corrosion*

Austenitic and duplex stainless steels, and nickel-base alloy tubes (both welded and seamless) have been used for digester liquor heater tubes. Stress corrosion and general thinning have been reported. Wensley [197] described methods for acceptance testing of tubing that included microstructural examination and testing of ring samples in boiling magnesium chloride using a procedure similar to ASTM G 36 (Practice for Performing Stress-Corrosion Cracking Tests in a Boiling Magnesium Chloride Solution).

#### *Brownstock and Black Liquor System Corrosion*

Corrosion in brownstock and post-oxygen washers has been investigated by Bennett and Magar [198] using electrochemical procedures. Their results showed that corrosion is affected by pH, chloride concentration, temperature, and aeration. These tests were complemented with instantaneous corrosion rate measurements by linear polarization resistance methods and by weight loss tests.

Corrosion in white liquor has been studied extensively, but there is little information available on black liquor, aside from some work by Mueller [172], Wensley [124], and Singh [139,140]. Mass loss tests in synthetic liquors containing inorganic and organic constituents of black liquors have been done at the University of Virginia [199].

Pepper and Voruganti [200] used ASTM C 581 (Practice for Determining Chemical Resistance of Thermosetting Resins Used in Glass-Fiber-Reinforced Structures Intended for Liquid Service) to investigate several FRP composites for use in brownstock washing environments.

#### *Sulfite Pulping Corrosion*

Sulfite pulping is a process that uses mildly acidic sulfite solutions instead of the very alkaline solutions used in kraft pulping. Murarka et al. [201] published results of corrosion tests in acidic condensates in vapor phase sulfite pulping using a batch type laboratory reactor in which acid was condensed and collected. He devised a means to prevent corrosion due to the acid condensation.

## MECHANICAL PULPING

Mechanically processed pulps are produced by wet grinding wood chips at high temperatures or with chemical additions to enhance the breakup of the wood. Originally, mechanical pulping processes involved the grinding of whole logs against rotating grindstones. Today, most mechanical pulping takes place inside pressurized refiners where wood chips are passed between counter-rotating discs faced with

wear-resistant refiner plates. Refiner plates are made from white cast iron (or hardened steels) or from stainless alloys. Steaming vessels used for mechanical pulping processes may have to be constructed from nickel-base alloys to avoid SCC beneath the deposits and general corrosion due to acidic condensate formation.

## Environments

Mechanical pulping aqueous environments are similar to paper machine white waters. In chemi-thermo mechanical pulping, however, the addition of sulfur ions can increase corrosivity. Pressurized presteaming of wood chips from seaborne logs can result in environments conducive to chloride SCC and also to the evolution of wood acids that can cause corrosion in the vapor phase. Wear is a more significant problem than corrosion in mechanical pulping environments.

## Corrosion Testing

Corrosion in mechanical pulping processes was investigated by Crowe [202] via weight loss tests and potentiodynamic polarization tests. Vapor phase condensate corrosion was more severe than liquid phase corrosion.

#### *Refiner Plate Corrosion and Wear Testing*

The corrosion and wear of refiner plates was studied by Rideout et al. [203] via potentiostatic and potentiodynamic anodic polarization measurements conducted similar to ASTM G 5. An experimental test cell that sealed against the surface of a refiner plate was developed, since coupons were difficult to cut from the hard plates. Thompson and Garner studied wear of refiner plate alloys [204,205] with a device that simulated abrasion under corrosive conditions. The alloy specimens were placed in the wall of a circular test chamber with an impeller at the center of the chamber. Wasikowski [206] evaluated wear with a pin-on-disc type machine, as well as cavitation erosion testing using a vibrating horn device according to ASTM G 32, Test Method for Cavitation Erosion Using Vibratory Apparatus. Thompson [207] used the vibrating horn method to test refiner materials. Reid and Lawn [208] have described inspection techniques for refiner discs. Thompson [209] developed a "clashing wear tester" for studying the wear of refiner plates in the laboratory.

## THE RECOVERY BOILER

Spent pulping chemicals are reduced and recovered in a molten salt (smelt) by combustion in the recovery boiler. The primary fuel is black liquor containing the lignin and myriad other combustible organic compounds, together with the inorganic chemicals from the pulping liquor. The black liquor is concentrated to  $\geq 65\%$  solids by evaporation before being burned in the recovery boiler. Steam generated by the recovery boiler is used for other process applications, including chemical and mechanical pulping, bleach plant mixers, and paper machine dryers. The reduced molten inorganic salts, called smelt, are drained from the bottom of the

boiler into water in the dissolving tank, producing green liquor. TAPPI [210] has summarized recovery boiler operation including corrosion problems. Bruno [211] has also published a review of recovery boiler corrosion.

The boiler has a water-circulating tube wall (waterwall) construction. A layer of smelt freezes on the fireside of the wall due to cooling from the water in the tubes, and this frozen smelt provides a barrier between the tube and the reducing and/or oxidizing gases. Gas composition has been implicated as a major determinant of the corrosion rate on the fireside surfaces. The lower waterwall is the most critical component. Unlike conventional boilers, a waterwall tube leak cannot be tolerated in a recovery boiler, since a smelt-water reaction has the potential for a catastrophic explosion.

As production demands have led to increasingly higher operating temperatures and pressures, protection of carbon steel waterwall tubes has involved studding, application of weld overlay or thermal spray, or the use of composite (stainless-clad carbon steel) or chromized (diffusion-coated carbon steel) tubes to provide resistance to sulfidation and oxidation on the fireside.

The upper furnace is also subject to corrosion in the superheater, the generating section, the economizer, and the precipitator.

## Environments

There are many different high temperature environments in a recovery boiler [210]. On the fireside of the boiler there is the molten smelt and the char bed in the bottom of the boiler. There is an oxidizing environment in the lower furnace where air is injected at up to four elevations for the combustion of the heavy black liquor that is sprayed into the boiler. Waterwall tubes are normally subjected to sulfidation. The use of composite tubes in the lower waterwalls has been successful in resisting sulfidation. The lower waterwall tubes may also have liquor running down them. At primary and secondary air ports, there are local environments that promote preferential corrosion and cracking of composite tubes.

At higher elevations, there is fume and carry-over with the flue gases that cause deposits to form on the superheater, generating bank, and economizer tubes. Deposits may be molten depending on the concentrations of chloride and potassium. Superheater temperatures are usually between 300°C at the steam inlet and 500°C at the outlet. Although there are a variety of materials used in superheaters, ranging from chromium-molybdenum steels to stainless steels and nickel-base alloys, changing materials offers little improvement when superheater deposits are molten.

## Corrosion Testing

Corrosion testing for recovery boilers has involved both laboratory tests in simulated smelt-gas environments and the use of probes inserted directly into recovery boilers.

### *Waterwall Tube Laboratory Testing*

Early research on recovery boiler corrosion conducted in Sweden and Finland was summarized by Moberg [212]. This work involved a field study and some laboratory

investigations in the gas phase and in smelt in a hot gas atmosphere. The effects of alloying elements, temperature, gas composition, and surface treatments were studied. The gas phase testing was completed by thermogravimetric procedures. Tests in synthetic smelt involved periodic dipping of the specimen in the molten phase, followed by exposure to the gas. Field tests were conducted via installation of tube specimens from various materials used in the lower furnace.

Other laboratory smelt tests [213,214] have included placing metal samples into ceramic boats, covering them with salts, and then exposing them in hot gas.

Recovery boiler corrosion fireside testing has been the subject of an extensive research project by the American Forest and Paper Association. Singbeil and Garner [215] published an extensive review of test methods from these studies. The American Forest Products and Paper Association support has produced a standard laboratory test at the Pulp and Paper Research Institute of Canada for the investigation of lower furnace corrosion [216–218] based on sulfidation processes that allow a clearer definition of complex variables.

The Institute of Paper Science and Technology has investigated the corrosion of waterwall materials through laboratory tests in furnaces having a controlled atmosphere, isothermal testing, “single spike” testing, and “double spike” testing [219–222]. The “spikes” were temperature excursions—for example, from a 320°C baseline temperature to 30 min at a maximum temperature of 480°C.

### *Air Port Composite Tube Corrosion*

Local wastage of the stainless steel cladding from composite tubes at ports in the waterwall (particularly primary and secondary air ports) has been attributed to hydroxide condensation [223,224]. The localized corrosion of stainless steel cladding from composite tubes at air ports of recovery boilers has been shown by deposit analysis to be a cyclical mechanism. Laboratory tests in molten salt supported the theory that this corrosion is caused by molten NaOH [225].

Other laboratory tests have confirmed that Type 304L stainless steel is rapidly corroded by molten hydroxide mixtures and that Alloys 600, 625, and 825 have resisted such corrosion [226]. Colwell [227] conducted mass loss experiments in molten NaOH at 320°F and demonstrated that Type 304L stainless steel corrodes more rapidly than carbon steel.

Tran et al. studied the kinetics of carbonation of molten alkali hydroxides [228], the air flow pattern [229], and the corrosion of Type 304L stainless steel by molten hydroxides at air port openings [230]. The presence of oxygen was found to make the corrosion inevitable in the presence of molten hydroxides. Electrochemical testing showed that a galvanic cell is set up between carbon steel and stainless steel with the latter protecting the former.

Falat [231] evaluated alternative primary air port materials in situ and also measured air port temperatures using thermocouples. He came to the conclusion that the corrosion of the stainless steel composite tube cladding could be better explained if the corrodent was molten smelt. Oxidation of molten smelt could produce the thermal spikes that he observed.

Estes et al. [232] used electrodes to study the basicity of molten salt mixtures and performed weight loss tests that

demonstrated that the chromium oxide film that forms on chromium metal can experience very rapid mass loss in molten hydroxides.

### *Composite Tube Corrosion and Cracking*

Many reports of corrosion and cracking in the floor composite tubes in recovery boilers were published in the 1990s [233]. Some cracking was branched like SCC and some cracking was straight, resembling fatigue. This led to several investigations of floor tube corrosion and cracking. Mäkipää [234–236] studied the corrosion of boiler tube materials in experimental melts containing polysulfides. His tests suggested that high nickel composite tube alloys had superior resistance to corrosion. Backman et al. [237] sampled smelts from recovery boiler floors and found that sulfur, chlorine, and potassium were enriched in the bottom layer near the floor. They prepared mixtures of salts and measured their conductivity. Molten deposits could exist at temperatures as low as 320°C when the mixture contained polysulfide.

Swindeman et al. [238] performed isothermal fatigue tests at 600°C on simulated Type 304L stainless steel cladding, using techniques conforming to ASTM E 606. They concluded that the cracking observed in the floor tubes was not due to thermal fatigue alone. Prescott and Singbeil [238] performed SCC testing using U-bends made in accordance with ASTM G 30 and found that SCC can occur in hydrated solutions of sodium sulfide that resemble those that exist during water washing. Tran et al. [240,241] did further investigations into the drying behavior of waterwash solutions by measuring electrical conductivity in a cell that could be heated at a controlled rate. They found that smelt solutions could not be dried out easily at temperatures below 180°C. Hanninen [242] investigated thermal fatigue using a fatigue testing device based on high frequency induction heating that cycled in the range between 300°C and 700°C. He also investigated SCC using U-bends. Hanninen's work suggested SCC was the mechanism of floor tube cracking.

Keiser et al. have reported on the cracking of floor composite tubes [243–247]. They examined samples of cracked floor tubes that had been removed from recovery boilers, measured residual stresses in tubes, and monitored temperature fluctuations using thermocouples. Svensson et al. [248] developed a probe for monitoring resistivity, temperature, and linear polarization resistance in recovery boiler floors.

### *Primary Air Port Composite Tube Corrosion and Cracking*

Closer inspection of recovery boilers that detected cracking of floor composite tubes also led to the discovery of cracking in primary air port composite tubes [249,250]. Some of the primary air port cracking had a branched appearance characteristic of SCC, and some of the cracking was straight, resembling fatigue. Keiser et al. [251] characterized the environments at primary air port openings and found that the cracking occurred in those openings where the temperature was above approximately 350°C and where the temperature fluctuated rapidly.

### *Superheater, Generating Bank, and Economizer Corrosion*

Field tests have been conducted using air-cooled probes fitted with samples of materials [213,252]. Tran et al. [253] used air-cooled probes to collect deposits from the fireside in the superheater and generating section, and then performed lab studies of sodium bisulfate ( $\text{NaHSO}_4$ ) corrosion. Backman et al. [254] used air-cooled probes to obtain samples of superheater deposits for electron microscopy and chemical analysis. Other probes with detachable steel ring samples were used to measure corrosion rates.

Laboratory studies of superheater, generating bank, and economizer corrosion have involved investigations of acidic sulfate deposits. Tran et al. [255–258] performed corrosion tests in a quartz tube furnace having a controlled atmosphere. Klower and White [259] used a chamber furnace to study the corrosion of stainless steels and nickel-base superheater tube alloys in synthetic molten salts. These specimens were repeatedly dip-coated with liquid salt to simulate the periodic formations of molten deposits on superheater tubes. Mäkipää et al. [260,261] studied the scaling of longitudinal tube samples in oxidizing and neutral gas laboratory environments and with air-cooled probes in recovery boilers. The scales were studied using high-temperature contact electric resistance and thermogravimetric analysis. Backman et al. [262] also studied the corrosion of superheater materials in different salt mixtures using a furnace with controlled atmosphere.

### *Near Mud Drum Corrosion*

Generating bank tubes have experienced corrosion adjacent to the mud drum in some recovery boilers. Thompson et al. [263] reported field and laboratory results. First, an in situ conductivity probe was used to determine when corrosive salts formed in the boiler at the mud drum/tube area. Then, erosion testing in the laboratory indicated that removal rates were insufficient to account for the tube wastage. Guzi [264] described an automated ultrasonic inspection procedure for use during boiler outages to detect near mud drum corrosion of generating tubes.

### *Electrostatic Precipitator Corrosion*

Corrosion of the electrostatic precipitator that is used to remove the dust from flue gases that exit the boiler, has been a problem as design and operating techniques have evolved. An intensive research program by Thompson and Yeske [265] has overturned the widely accepted belief that acid condensation was causing the corrosion. In fact, water condensation was found to be the major cause. Flush mounted electrical resistance monitoring probes were used to measure instantaneous corrosion rates. A cooled conductivity probe was used for dewpoint measurement, and weld pad thermocouples were used for temperature measurement.

### *Fluidized Bed Boiler Corrosion*

Corrosion of superheater tubes in fluidized bed boilers is caused by low melting point deposits. Salmenoja et al. [266–268] and Orjala et al. [269] used air-cooled probes to investigate the corrosion of various materials and to sample the deposits.

## DISCUSSION

Corrosion testing in the pulp and paper industry is based both on standards developed for other industries and on methodologies developed by individual researchers in the pulp and paper industry. Relatively few corrosion test standards have been developed for the pulp and paper industry. Corrosion testing has been most often performed either to investigate the performance of alternative materials in existing processes or to assess the effects of process modifications on existing materials of construction. As new processes create new problems, new test procedures will continue to be devised.

Corrosion test methods that are developed must be practical and provide useful results that are understandable to mill personnel. These methods should be embodied in standards to permit comparison of results by different investigators—allowing, for example, the evaluation of the performance of various suppliers' products.

There is a need to focus on chemical analysis of process environments, deposits, and metals in conjunction with the corrosion studies to better describe root cause mechanisms. Corrosion testing prior to equipment purchases will aid in the selection of appropriate materials and educate process engineers about the effects that their decisions have on long-term equipment performance.

The capability for on-line corrosion monitoring of equipment would certainly aid in correlating process changes or upsets with episodes of corrosion of equipment. This would ensure maximum equipment life when process modifications are anticipated that could have negative effects on corrosion resistance.

# Petroleum Production and Refining

*R. N. Tuttle*<sup>1</sup>

THE PETROLEUM INDUSTRY is usually divided into oil and gas production, refining, and oil and gas products. These encompass a wide variety of corrosive environments that must be considered during the process of materials selection and corrosion control management. The corrosive environments include acid gases, such as carbon dioxide (CO<sub>2</sub>) and hydrogen sulfide (H<sub>2</sub>S), and salt water. Refinery operations involve complex chemical systems and many corrosive environments. Management of these systems involves a wide range of activities by the producing, refining, and service companies.

## OIL AND GAS PRODUCTION

Oil and gas production involves the production of oil and gas, along with associated salt water and corrosive acid gases, such as CO<sub>2</sub> and H<sub>2</sub>S. Mineral acids are also often used during producing operations to improve well performance. The producing operations involve wells, piping used for gathering the oil and gas and associated fluids, and facilities for separating and treating the fluids. The wells vary widely in size, depth, and corrosive environments encountered. Temperature may range from roughly 77 to 482°F (25–250°C) and pressures from atmospheric to 25 000 psi (175 MPa). The wells contain a range of carbon steel tubular goods ranging in size from 2- to 24-in. (50- to 600-mm) diameter. Stainless steels and other corrosion resistant alloys (CRAs) are often used for corrosive environments, particularly for deep wells. Liners and FRP pipes are also used for the lower temperature and shallower wells when corrosive environments are encountered.

The produced fluids are separated into three streams: natural gas, liquid hydrocarbon (crude oil or hydrocarbon condensate), and produced water and solids. The liquid hydrocarbon stream is treated to remove the produced water before being shipped to a refinery. The produced water can vary in composition from condensed water to brine. The brine may contain a range of soluble salts at concentrations as high as 25 %. The produced water stream may be treated prior to disposal or re-injection. The gas stream may be further treated in a gas plant to separate the various hydrocarbon fractions and to remove the H<sub>2</sub>S and CO<sub>2</sub>. If the wells produce significant concentrations of H<sub>2</sub>S, it is removed

and converted to sulfur. If the wells produce very high concentrations of CO<sub>2</sub>, it is removed, and when possible re-injected to improve hydrocarbon recovery.

Selection of a material or method to control corrosion often depends on whether the produced fluids are sweet or sour. "Sour" is defined as the presence of sulfur compounds above some arbitrary concentration, and "sweet" is defined as "not sour." A crude oil is typically considered sour if it contains more than approximately 2 % total sulfur; although, the definition of "Sour" crude oil is often determined by the material and process needs of the refining operation.

For gas systems, the definition of sour is considered to be a gas in which the H<sub>2</sub>S partial pressure is greater than 0.05 psi (0.34 kPa). This is based on the NACE Standard MR0175 Sulfide Stress Cracking Resistant Metallic Materials for Oil-field Equipment. Sour multiphase systems (gas, crude oil, water) are treated separately in MR0175. An ISO (International Standards Organization) standard is currently being developed based upon MR0175 and documents prepared by the European Federation of Corrosion (EFC). This document is in FDIS stage as ISO 15156/MR0175.

## Corrosion During Well Drilling

Seamless steel pipe manufactured to API Specification 5D for Drill Pipe is used during the drilling operations. Available grades are E-75, X-95, G-105, and S-135 with specified minimum yield strengths (SMYS) of 75, 95, 105, and 135 ksi (517, 655, 724, 931 MPa), respectively. Drill pipe lengths are connected by tool joints, which involve a threaded pin and a box coupling. The couplings are friction welded to the pipe.

Corrosion fatigue and sulfide stress cracking (SSC) are potential problems during drilling operations. Service stresses and corrosion are the primary factors in drill pipe corrosion fatigue. Inadvertent air entry into the drilling mud system is the prime component of drill pipe corrosion. Internal coatings are often used to reduce general corrosion and to minimize corrosion fatigue. Oxygen scavengers and corrosion inhibitors are often used to minimize drill pipe corrosion.

Drill pipe failures because of SSC may occur when sour gas enters the drill hole during drilling operations. Control of the drilling environment, as outlined in NACE Standard MR0175, reduces the potential for entry of H<sub>2</sub>S into the well. The environmental control methods include use of water-based mud with a pH >10 and addition of sulfide

<sup>1</sup>Tuttle and Associates, Houston, TX.

scavengers. Alternatively, oil-based mud may be used to minimize water wetted steel surfaces.

NACE Publication 1D177 [1] describes corrosion monitoring techniques for drilling operations. Some components of drilling equipment may be fabricated from corrosion resistant alloy (CRA). CRA selection may involve laboratory testing, such as that described below for producing wells.

## Corrosion During Production

Most wells are completed with carbon or low-alloy steel casing, tubing, and liners. These are purchased to API Specification for Casing and Tubing (Spec 5CT). The specified minimum yield strength (SMYS) ranges from 40 to 125 ksi (280 to 860 MPa). Maximum hardness values are specified for those grades commonly used in sour service. Use of CRA in most wells is limited to special wellhead or downhole equipment. However, it is becoming more common to use CRA for tubing and wellheads for wells with corrosive environments.

The composition of produced gas varies widely in both the amount of heavier than methane hydrocarbons and the amount of  $H_2S$  and  $CO_2$  present. A gas condensate well may produce only gas at the bottom of the well, but may produce both gas and hydrocarbon liquids at the surface. The liquids at the surface are a result of condensation because of temperature and pressure changes.

Oil wells generally produce gas in addition to crude oil. Oil wells often require artificial lift as pressures decline. Artificial lift wells use rod pumps, submersible pumps, or gas lift. Injection wells are used in enhanced recovery operations or for disposal of produced water. In enhanced recovery, the injected fluids include steam, water, carbon dioxide, or polymer solutions.

Carbon dioxide in combination with a condensed or produced water phase is the primary cause of corrosion in producing wells. Chlorides present in produced water may increase corrosion. Localized severe corrosion in sweet wells may occur as a result of either high velocity or metallurgical factors. The latter effect, called ringworm corrosion, can be minimized by full-length heat treatment of well tubing.

Presence of hydrogen sulfide has an inhibiting effect on carbon dioxide corrosion, but introduces the possibility of harmful effects such as SSC of high strength carbon steels. Temperature, a major factor in the corrosiveness of produced fluids, can range from about 77°F (25°C) in shallow wells to above 482°F (250°C) in deep wells. Oxygen is generally not a corrosion factor in production wells, since the produced fluids are normally anaerobic (this may not be true for wells that are artificially lifted). The crude oil or hydrocarbon liquids often provide protection from corrosion by forming a water-repelling film on the metal surface, particularly in those wells with a high oil/water ratio.

In enhanced recovery, materials selection and corrosion control measures may significantly differ from those used during the primary production phase. Thus, additional corrosion testing may be required during the selection of corrosion control measures. For example, in some water and steam floods, the produced fluids may change during the well or facility life from sweet to sour because of increased

$H_2S$ . This change may result in potential SSC and other cracking mechanisms. Sulfate-reducing bacteria (SRB) activity in the water phase is the primary cause of the  $H_2S$  increase. As a result, chemical treatment with a biocide may be required.

## Inhibition of Producing Wells

Corrosion inhibitors are often used to control downhole corrosion and related equipment. Inhibitors are organic amine compounds combined with fatty acids. These wet the steel surfaces and form organic films. They are applied either continuously or intermittently. Continuous treatment is commonly done by direct injection into the casing-tubing annulus or by injection into the bottom of the well via small diameter tubing. Inhibitor concentrations in the produced fluids are typically in the range of 5–50 ppm. Intermittent treatments may involve simple batch injections or squeezing an inhibitor concentrate into the producing formation (squeeze method). In many cases, the inhibitor program is managed and conducted by a service company through a joint agreement with the oil company. This service includes inhibition and monitoring. Selection of a specific inhibitor and its treatment schedule is based on field experience supplemented by in-house laboratory testing. Inhibition is generally easier to achieve in sour systems than in sweet systems, because of the lower corrosion rates and the greater attraction of the inhibitors to sulfide surfaces. Inhibition is less attractive for deep wells, because of low inhibitor effectiveness at the high temperatures, and the complications of inhibitor injection.

*Inhibitor Testing*—There are no standardized laboratory tests for evaluating oilfield inhibitors. A number of tests have been described in the literature, but none has been adopted by NACE. The ideal test would determine the inhibitor effectiveness for the specific well fluids, would evaluate any secondary effects (e.g., emulsion problems), and would measure persistence of the inhibitor film.

NACE Publication 1D182 [2] describes a wheel test method that has been used for a number of years to evaluate film persistent inhibitors for oilfield applications. The publication outlines the general features of the method, leaving many details to be standardized by the user. The test involves exposing a steel specimen to a mixture of inhibitor, crude oil, and synthetic brine in a glass bottle that has been purged first with nitrogen to remove oxygen, then with either carbon dioxide or hydrogen sulfide to simulate sweet or sour conditions. The bottle is placed on a wheel and rotated in a controlled temperature cabinet for a specified time. Following this filming treatment, the specimen is transferred to a bottle containing uninhibited oil and brine, and the test repeated. Corrosion rates are measured after one or more exposures to uninhibited fluids. The method can also be used to evaluate inhibitors for continuous treatment by determining the percent protection for a given inhibitor concentration, or by determining the inhibitor concentration necessary to achieve a 90 % reduction in corrosion rate.

NACE Standard Recommendations for Selecting Inhibitors for Use as Sucker Rod Thread Lubricants (MR0174) suggests test methods for evaluating corrosion inhibitors in thread lubricants used to prevent both galling and corrosion of sucker rod threads and box cavities.

Testing inhibitors for application in deep wells is difficult because of the need to evaluate the inhibitor stability and effectiveness at high temperatures and pressures. For example, tests have been made with sour brine at 392°F (200°C) and 19 000 psi (130 MPa) pressure. In addition, flow loops are often used to simulate operating conditions.

#### *Inhibition During Acidizing Treatments*

Acidizing treatments are used to stimulate production by the acidic dissolution of undesirable materials on the walls of the producing formation or by pumping acid into the formation to improve permeability. Hydrochloric acid (HCl) is used for limestone formations. Hydrofluoric acid (HF) is added to the HCl for silicate formations. Inhibitors are added to the acid to protect steel tubing during the short period of exposure to acid during injection, and the following period when partially spent acid is returned to the surface. Suppliers use a variety of nonstandardized tests for acid inhibitor evaluation.

A unique field test for detecting the presence of inhibitor in acid is described in NACE Standard Practice for Handling and Proper Usage of Inhibited Oilfield Acids (RP0273), and in API Recommendations for Proper Usage and Handling of Inhibited Oilfield Acids (Bull. D15). These are designed for detecting the presence of an inhibitor, and not for comparing different inhibitors. The test consists of exposing steel wool to the test acid in a 1-mL-narrow-neck ampoule, placing the ampoule neck-down in a beaker of water that had been heated to boiling temperature, and measuring the time required for the ampoule to float to the surface due to the buoyancy provided by hydrogen generated by corrosion of the steel wool.

#### *Coating and Linings*

Protection of well tubing by organic coatings or linings may be economically attractive. The following standards have been developed to ensure that the coatings selected are adequate for a specific system, or that application of the coating is done in an acceptable manner. These standards are periodically modified and the latest version should be used.

NACE Standard Practice for the Application of Internal Plastic Coatings for Oilfield Tubular Goods and Accessories (RP0191) addresses initial inspection of equipment to be coated, surface preparation, coating application, coupling/connection makeup, and quality control.

NACE Standard Practice for Care, Handling, and Installation of Internal Plastic Coatings for Oilfield Tubular Goods and Accessories (RP0291). This standard addresses the practical aspects in the use of coated tubing.

NACE Test Method for Evaluation of Internal Plastic Coatings for Corrosion Control of Tubular Goods in an Aqueous Flowing Environment (TM0183) compares performance of coatings under identical conditions.

NACE Test Method for Evaluation of Internal Plastic Coatings for Corrosion Control of Tubular Goods by Autoclave Testing (TM0185) complements NACE Standard TM0183.

NACE Test Method for Holiday Detection of Internal Tubular Coatings of Less than 10 Mils (0.25 mm) Dry Film Thickness (TM0384) defines apparatus and procedure for holiday detection in nonconductive coating film.

NACE Test Method for Holiday Detection of Internal Tubular Coatings of 10 to 30 Mils (0.25 to 0.76 mm) Dry Film Thickness (TM0186) complements NACE Standard TM0384.

#### **Materials for Sulfide Stress Cracking (SSC) Resistance**

Sulfide stress cracking (SSC), a form of hydrogen embrittlement, is a serious problem in the oil industry because of the potentially catastrophic nature of a failure of high strength carbon steel casing, tubing, or surface equipment. Inhibition is not a reliable means to prevent SSC because treatment interruptions could lead to failure. Control of SSC is accomplished by careful specification and quality control of equipment for sour wells. Materials that are acceptable for service in sour environments are defined in NACE Standard MR0175. This standard is updated annually.

Of the large number of SSC test methods that have been used to evaluate materials for this service, five have survived: uniaxial load tensile test, Shell bent beam test, C-ring test, double-cantilever-beam test, and slow strain rate test. The first four of these are incorporated in NACE Test Method for Laboratory Testing of Materials for Resistance to Sulfide Stress Cracking in H<sub>2</sub>S Environments (TM0177). Following are comments on these methods [3].

##### *A. SSC of Carbon and Steels—General Test Features*

Tension and beam specimens are cut parallel to the axis of the tubing, since most SSC failures of the tubing have been transverse to the tubing axis. C-ring specimens are used to evaluate effects that have resulted in cases of longitudinal cracking. The test environment was selected to provide hydrogen absorption by the specimen equivalent to that expected in the most severe well environment. This is accomplished by using a solution saturated with H<sub>2</sub>S at atmospheric pressure (15 psia [0.0003 MPa]) at pH 3. This low pH being is obtained by adding 0.5 % acetic acid. Five percent sodium chloride (NaCl) is added to simulate typical produced water. This test solution is commonly called "NACE solution" or "TM0177 solution A."

Other test solutions (e.g., Solution B) are also available to represent mild environments. Test temperature is normally 77°F (25°C), since tests have shown this temperature to be in the most severe range for hydrogen embrittlement effects. Test durations of 21–30 days are consistent with the observed rapid failure of susceptible materials. In testing CRA, the test specimen is commonly coupled to carbon steel to provide a severe hydrogen absorption condition.

##### *B. Acceptability Criteria*

NACE has not adopted acceptability criteria for any of these methods, leaving this decision to the user. In early laboratory tests, all tubular steels tested in a severe test environment failed by cracking if strained to a sufficient degree [4]. However, field experience had shown that primarily only high-strength steels, above approximately 80 ksi (550 MPa) yield strength, were subject to failure. From this fact it was concluded that normal field conditions were such that severe straining did not occur, and that

susceptibility of steels to cracking was related to the strain required for failure. Thus, it became a matter of correlating field experience with laboratory test results to define acceptability criteria.

#### *C. TM0177 Method A (NACE Standard Tensile Test)*

This method uses a smooth tension bar specimen as described in ASTM A 370, Test Methods and Definitions for Mechanical Testing of Steel Products, and ASTM G 49, Practice for Preparation and Use of Direct Tension Stress-Corrosion Test Specimens. The test results in an apparent threshold stress for failure in 30 days, expressed as percent of yield strength. API Spec 5CT requires that the threshold stress for failure in this test be determined for Grades C-90 and T-95 using NACE TM0177, with an acceptance criterion of at least 80 % of the SMYS. An advantage of this test is that it uses a specimen with a well-defined stress state. One drawback is that the presence of nonmetallic inclusions may lead to hydrogen-induced cracking (HIC) related failures in lower strength steels at lower threshold stress values than normally expected for such steels [5].

#### *D. TM0177 Method B (NACE Standard Bent-Beam Test)*

This three-point constant deflection bent-beam test is based on the Shell Sc test that was used extensively in the development of SSC-resistant steels [6]. The Sc test makes use of a small beam with stress raisers in the form of two small holes drilled in the center of the beam. The beam is loaded with a screw at the center point and is supported at each end. Multiple tests are made with measured variations in the beam deflection.

A statistical determination is made of the beam deflection required for a 50 % probability of failure in 21 days. The deflection value is converted to a pseudomaximum stress value in ksi (1000 psi), which is divided by 10 to give the Sc value. The Sc value becomes a number for rank ordering the SSC resistance of the steel being tested. Typically, susceptible steels such as API Grade P-110 (ISO 11960) steel would have Sc values in the 2–5 range. By contrast, resistant steel like API Grade J-55 would have Sc values from 15 to 20.

The critical acceptance criteria ranging from 10 to 12 Sc, depending upon yield strength, was developed by correlating lab data with field experience [4]. An artificial number was used for the test result rather than a stress or strain value for the test result, in an attempt to discourage anyone from assuming that a critical stress or strain value obtained in such an arbitrary test could be used as a design parameter. The 50 % probability of failure concept has an advantage as compared to the threshold stress approach because it is less influenced by an erratic test result.

Other advantages of the Sc test are: (1) Sc values for different materials could include values on both sides of the acceptability criterion, thus providing a tool for research on improved steels since one would have a measure of the nearness to the desired goal; (2) the test evaluates the effect of plastic strain, a critical factor in SSC failures; and (3) the small area of maximum strain allows evaluating SSC susceptibility of localized areas and minimizes inclusion-related hydrogen effects. A major limitation of the Sc test is

that the constant deformation feature de-emphasizes crack growth factors.

#### *E. TM0177 Method C (NACE Standard C-Ring Test)*

This test uses an un-notched C-ring type specimen machined from tubing or bar stock as described in ASTM G 38, Practices for Making and Using C-Ring Stress-Corrosion Test Specimens. A conventional bolt assembly is used to apply the load. Test duration is 30 days. Specimens are exposed at varying levels of outer fiber stress, and an apparent threshold stress for failure is determined. The advantage of this test is that it evaluates the effect of circumferential stress and, thus, serves as an adjunct to the TM0177 tension test when testing tubular goods. Comparison of results from the two tests can be used to detect an anisotropic effect.

#### *F. TM0177 Method D (NACE Standard Double-Cantilever-Beam Test)*

The double-cantilever-beam (DCB) test uses fracture mechanics techniques to evaluate the SSC resistance of tubular steels [7]. It employs a 9.5 by 25 by 100 mm (0.375 by 1.0 by 4.0 in.) specimen with side grooves and loaded with a double taper wedge. In some cases, the specimen is precracked. Typical test duration is 14 days.

The DCB test has the major advantage of providing a critical stress intensity number, which has general engineering acceptance. In contrast to the Sc test, the DCB test emphasizes crack growth and arrest factors rather than crack initiation factors. The fact that the DCB test provides a rank-ordering number rather than a failure/no failure result makes it useful in the development of improved steels and alloys. One disadvantage is the specimen size, which limits its application, although subsize specimens, 4.8-mm (0.188-in.) thick, and curved specimens are acceptable.

#### *G. Slow Strain Rate Test*

The slow strain rate (SSR) test has seen only limited use in testing the SSC resistance of low-alloy steels. One reason may be the difficulty of establishing a criterion for failure in borderline cases. However, SSR tests have been useful in evaluating the effect of environmental variables on SSC of steels, the criterion being changes in either elongation or reduction in area. Also, SSR tests have proved to be valuable in evaluating the stress corrosion cracking (SCC) susceptibility of CRAs.

### **Corrosion Resistance Alloy (CRA) Selection**

Use of CRA is competitive with inhibition in deep, high-pressure wells, particularly in those locations where inhibitor supply may be a space and logistic problem. CRA includes stainless steels (austenitic, ferritic, martensitic, and duplex), nickel-based alloys, cobalt-based alloys, and titanium alloys. Economics is a major factor in alloy selection. The 13 Cr tubing has often been used in gas wells for low H<sub>2</sub>S wells. Tubing materials selection for a deep well could involve price increments between alloys of \$1 to 3 million. High-strength CRA is used to minimize costs. SMYS values of 150 ksi (1000 MPa) are common. The CRA is often cold-worked to achieve the required yield strength.

Corrosion concerns with CRA involve general corrosion, crevice corrosion, hydrogen embrittlement, and stress corrosion cracking (SCC). General corrosion and crevice corrosion data are usually obtained as an adjunct to stress corrosion testing. Evaluation of cracking resistance requires testing for resistance to both hydrogen embrittlement and anodic SCC. Separate tests are required. Hydrogen embrittlement evaluations are obtained in NACE TM0177 tests as described above, with coupling to carbon steel or with an applied potential to ensure a severe cathodic condition. The complexity of testing for SCC resistance is such that no standardized tests have been adopted. The generalized approaches that have been used are discussed in the following paragraphs.

It has been found that many CRAs of interest for downhole tubulars are subject to SCC in the  $H_2S/CO_2$ /chloride system under some conditions of temperature, pH, and chloride content. Presence of small amounts of oxidant in the form of elemental sulfur, resulting either from sulfur present in the produced fluids, or by reaction of  $H_2S$  with oxygen from air contamination, increases markedly the probability of SCC of many alloys. NACE MR0175 provides guidelines for selection of CRA.

#### A. Testing CRAs for SCC Resistance

The mechanistic differences between SSC and SCC (anodic type) have a significant influence on the test methods used. Stated simply, the critical variable in SSC of carbon and low-alloy steels is the stress (strain) required to initiate and sustain cracking in an arbitrarily selected severe environment. In SCC, the critical variables are the electrochemical polarization characteristics of the metal/environment system that control the anodic processes involved in crack initiation and growth. Therefore, alloy SCC susceptibility comparisons are done by determining the critical environmental factors (e.g., temperature,  $H_2S$  partial pressure, chloride concentration) required to cause failure of a severely stressed specimen.

Because of the wide spectrum of potentially severe environments for SCC of CRA, rank ordering of alloy susceptibility has become one of comparing SCC resistance under fixed stress conditions as a function of environmental variables such as temperature, hydrogen sulfide partial pressure, pH, chloride concentration, and the presence or absence of free sulfur. Selection of a CRA for a specific use requires finding SCC-resistant materials whose environmental limits, as defined by this matrix of environmental data, are beyond the expected environmental limits of the specific use.

The favored test methods correspond to TM0177 Method A (smooth tensile test), TM0177 Method C (C-Ring test), and the SSR test. Many test environments have been used. These include TM0177 Solution A and a 25 % sodium chloride (NaCl) solution containing 1 g/L elemental sulfur. Tests are commonly made at temperatures of 194–446°F (90–230°C) in the presence of  $H_2S$  and  $CO_2$  at pressures as high as 5000 psi (35 MPa). Temperature, chlorides, and  $H_2S$  partial pressure are common test variables.

SSR testing is often favored for screening because of the short time required. The test details follow those of conventional methods for SSR testing. Dimensions of the test section

of the uniaxial tension specimen are commonly 3.8-mm (0.150-in.) diameter by 25-mm (1.0-in.) long, with an overall diameter of about 6 mm (0.25 in.). A typical extension rate for such a specimen is  $1 \times 10^{-4}$  mm/s ( $4 \times 10^{-6}$  in./s). Failure is determined primarily by metallographic examination of the fracture. Common practice is to plot failure/no failure data on a  $H_2S$  partial pressure versus temperature graph for tests with common pH, chloride, and free sulfur content. Problems with this method include reproducibility related to surface finish, and failure to detect the effect of some metallurgical changes [8–10].

### Artificial Lift Wells Material Selection

Wells that fail to produce through natural means are usually artificially produced by other means, such as gas lifted by a separate source of gas or by mechanical means such as sucker rod pumps.

#### A. Sucker Rods

One means of producing the wells is through the use of downhole pumps where the energy to operate the pump is provided by the use mechanical rods (sucker rods) that are lifted and lowered by surface operated equipment. Sucker rods are subject to failure by fatigue and corrosion fatigue. Although corrosion fatigue failures can be controlled in part by design and operating factors, and by corrosion inhibition, the corrosion fatigue properties of individual sucker rod materials can be a factor in failure frequency. Laboratory testing has not been a satisfactory means of predicting corrosion fatigue of sucker rods because of the difficulty of reproducing well conditions. This has led to use of a technique for field testing to give reliable data for rod selection.

#### B. Sucker Rod Pumps

NACE Standard for Metallic Materials for Sucker Rod Pumps for Hydrogen Sulfide Environments (MR0176) supplements API Specification for Subsurface Sucker Rod Pumps and Fittings (Spec 11AX). NACE Standard MR0176 provides recommended materials for nine environments with varying degrees of abrasion and hydrogen sulfide corrosion.

### Testing Nonmetallic Materials

The following standards have been developed for testing nonmetallic seal materials used in oilfield equipment:

NACE Standard Worksheet for the Selection of Oilfield Nonmetallic Seal Systems (RP0491) provides information on test conditions, test media, test procedures, equipment, and reports for  $CO_2$  environment testing under pressures greater than atmospheric.

NACE Test Method for Evaluating Elastomeric Materials in Sour Gas Environments (TM0187) measures the ability of elastomeric materials to withstand static exposure to elevated pressure and vapor phase sour gas environments. It is designed for testing O-rings or sheet specimens of elastomeric vulcanites.

NACE Test Method for Evaluating Elastomeric Materials in Carbon Dioxide Decompression Environments (TM0192)

measures the effect of rapid depressurization on elastomeric materials subjected to elevated pressures in dry carbon dioxide environments. It is designed for testing O-rings or other specimens of elastomeric vulcanites.

### Monitoring Downhole Corrosion

Downhole specimens are rarely used for monitoring because of the costs and complications involved. Indirect monitoring of downhole corrosion conditions has been done with specimens or electrical resistance probes installed at the wellhead. These have been used for monitoring inhibition treatments, always with the reservation that such exposure does not accurately simulate downhole conditions.

In some wells, it is possible to obtain an indication of downhole corrosion by analysis of produced fluids for iron. This method is described in NACE Standard Practice for Monitoring Corrosion in Oil and Gas Production with Iron Counts (RP0192). It has been used effectively for monitoring inhibition in wells where corrosion follows a general, nonlocalized pattern, and where the corrosion products are water-soluble (e.g., in sweet wells).

In the case of pumped wells where tubing, rods, and pump are pulled periodically for maintenance, visual inspection is used to evaluate progress of corrosion. These records together with records of corrosion-related failures of downhole equipment serve as a means of monitoring effectiveness of mitigation procedures.

For flowing wells, periodic inspection of tubing by inspection tools, usually mechanical caliper type, are used for monitoring both general corrosion and pitting corrosion. In the latter case, statistical treatment of the pit depth data by extreme value techniques has been used to provide derived data that can provide a time-dependent graph of progress of corrosion (i.e., effectiveness of mitigation procedures). Video cameras are also used to evaluate well conditions.

Monitoring casing for both internal and external corrosion can be done with combinations of mechanical and electromagnetic methods to measure internal and external corrosion damage. For cathodically protected casing, NACE Standard Practice for Application of Cathodic Protection for Well Casings (RP0186) includes a description of a downhole potential survey tool that determines if the protective current from the cathodic protection anodes is reaching the desired depth.

### Water Injection Wells and Facilities

Produced water is usually re-injected into special wells for disposal or to maintain reservoir pressure. Two aspects of water injection corrosion control differ from those involved in producing wells. The first is the need to reduce suspended solids to very low values to avoid plugging the formation at the bottom of the injection well. These solids include steel corrosion products, as well as scales. Sulfide corrosion products are of major concern because of their low solubility. Metal sulfide products can occur because of reactions between metal and the  $H_2S$  from the sour gas or the  $H_2S$  generated by sulfate reducing bacteria.

Secondly, oxygen can result in undesirable corrosion products, and can result in severe pitting in either sweet or

sour systems, which creates the need for close control of oxygen contamination. A common control limit on oxygen contamination of injection water is 20 ppb. Thus, water treatment of injected water may include corrosion inhibition, scale inhibition, bactericides, and oxygen scavengers [11].

#### A. Solids Control

NACE Test Methods for Determining Water Quality for Subsurface Injection Using Membrane Filters (TM0173) describes methods for evaluating water quality of injection water. NACE Test Methods for Laboratory Screening Tests to Determine the Ability of Scale Inhibitors to Prevent the Precipitation of Calcium Sulfate and Calcium Carbonate from Solution (for Oil and Gas Production Systems) (TM0374) is used to rank order scale inhibitors at 158°F (70°C).

#### B. Materials Selection

Extensive use is made of nonmetallic materials and alloys to minimize corrosion effects. This includes plastic and nonmetallic piping and internal coatings (e.g., cement lining, organic coatings). For detailed information on alloys see NACE Standard for Selection of Metallic Materials to be used in All Phases of Water Handling for Injection into Oil-Bearing Formations (RP0475).

#### C. Corrosion Testing

Suppliers usually provide the laboratory evaluation (using conventional test methods) of corrosion inhibitors, scale inhibitors, bactericides, and oxygen scavengers. User companies generally provide evaluation by field monitoring with corrosion specimens. Crevices may be incorporated in specimens to evaluate the possibility of localized corrosion, such as that related to oxygen contamination.

### Surface Piping

Horizontal piping systems used to collect and transport well fluids introduce problems of phase separation resulting in stratified corrosive water and gas phases that complicate inhibition control and monitoring. In addition, there is the possibility of oxygen and bacterial (SRB) contamination that can accelerate corrosion. Control of internal corrosion of steel surface piping generally involves inhibition or plastic lining.

Control of external corrosion of steel piping is generally achieved with coatings plus cathodic protection. Testing related to external environments (soil, seawater) to which oilfield piping may be exposed is handled elsewhere (see Section V of this manual).

#### A. Corrosion Inhibition

Water removal may eliminate the need for inhibition of pipelines. Presence of 1 % or less water in crude oil is not considered sufficient to create a corrosion problem. Corrosion in gas pipelines can be avoided by dehydrating the gas to reduce the water dew point to values below the lowest temperature expected.

In water-containing systems, inhibitor selection is based on considerations and tests described above for downhole inhibition with one added constraint: the need to provide

inhibition for stratified flow conditions that may exist. This requires inhibition systems that can provide protection in the upper vapor phase of pipeline, as well as in the separated water phase at the bottom of the pipe. The latter condition often prevails at low spots in the line. Improved protection can be obtained by periodically pigging the line to distribute inhibitor over the entire internal surface and to remove liquid water.

### *B. Hydrogen Effects*

In sour service piping systems, control of SSC is accomplished by using acceptable materials as defined by NACE Standard MR0175. For example, all grades of steel pipe listed in API Spec 5L (ISO 3183-3) with specified minimum yield strengths of 65 ksi (Grade X-65) or less are listed as acceptable by MR0175. However, weldments in these low-strength pipes, including both seam welds made by the manufacturer and circumferential welds made in the field, are expected to conform to MR0175 requirements for SSC resistant welds, i.e., hardness of 22 HRC maximum. Microhardness surveys of cross sections of typical welds are normally used to evaluate weld susceptibility to SSC.

One additional control factor outside the scope of MR0175 is the need to select steels that are resistant to hydrogen blistering and related cracking phenomena, i.e., HIC and stress orientated hydrogen induced cracking (SOHIC). HIC is sometimes called stepwise cracking. In this discussion, HIC will be the term used to identify the effects of hydrogen-related cracking related to hydrogen blistering.

HIC differs from SSC in two major aspects: (1) HIC is observed with lower strength steels, and (2) HIC is associated with inclusions in the steel or with anomalous structures such as midwall banding. Crack initiation results from formation of molecular hydrogen at inclusions and discontinuities in the steels, and crack growth results from applied and residual stresses aided by the embrittling effect of hydrogen.

These effects have been encountered primarily in steel plate used for vessel construction or for fabrication of welded pipe. The major industry problem has been with welded pipe made from controlled rolled plate. Cases of pipe rupture have been attributed to HIC. Seamless pipe is less subject to these effects, but is not considered to be immune. HIC may be prevented by the manufacturer's control of the inclusion number, size, and shape, particularly sulfide inclusions [12].

### *C. Testing Steels for HIC Resistance*

Evaluation of steels is done via tests that measure the number and size of subsurface cracks following exposure to a standard hydrogen sulfide solution. NACE Test Method Evaluation of Pipeline and Pressure Vessel Steels for Resistance to Hydrogen-Induced Cracking (TM0284) defines a test procedure, but does not set criteria for acceptability. The specimen is cut from a steel pipe or plate in the as-manufactured condition, and exposed for 96 h to H<sub>2</sub>S-saturated synthetic seawater prepared according to ASTM D 1141, Specification for Substitute Ocean Water. The number, location, and dimensions of subsurface cracking are measured. From these data, two factors are calculated: crack length

ratio (CLR) and crack thickness ratio (CTR). Values approaching zero are the desired goals. In the absence of standard criteria, individual users specify CLR and CTR limits. It has been suggested that a lower pH test environment, such as that provided by the TM0177 Solution A, would be more representative of severe pipeline conditions [13].

### *D. Testing CRAs for Pipelines*

Pipeline usage of CRAs introduces an aspect of testing not covered in downhole applications. This is the need to evaluate the corrosion characteristics of weldments. At present, the principal alloys for pipelines are duplex stainless steels, high molybdenum austenitic stainless steels, and some nickel-base alloys. The latter alloys may be used as cladding inside steel piping. Hot-isostatic pressing (HIP) and weld overlaying are used for some equipment items. Corrosion factors introduced by welding include HAZ effects, sensitization, microstructure of weldments, and weld dilution. With appropriate modifications, the test methods described above for downhole applications can be used.

### *E. Monitoring Pipeline Corrosion*

Procedures for monitoring corrosion of pipelines and related surface facilities using retrievable specimens are described in NACE Standard Practice for Preparation and Installation of Corrosion Coupons and Interpretation of Test Data in Oilfield Operations (RP0775). One of the main concerns in the use of such specimens is the problem of location, since corrosion is generally associated with a separate water phase. In some cases, special dropout pots are used to trap a water phase to provide a severe location for specimens. Electric resistance probes can be used in place of specimens. In locations where there is a continuous water phase and fouling is not a problem, polarization type probes can be used [14,15].

Hydrogen probes have been used in sour systems to evaluate the effect of mitigation methods on hydrogen absorption resulting from sulfide-related corrosion. These measurements are of particular value in situations where blistering or HIC is of concern. A hydrogen probe consists of a closed-end steel tube that is inserted in the process stream and equipped with a device (pressure gage or analytical instrument) to measure the rate of hydrogen transmission through the tube wall, thus providing a measure of the effectiveness of inhibition or other means employed to reduce the amount of atomic hydrogen entering the steel. Similar measurements can be made with a hydrogen patch, which is a hydrogen collecting chamber attached to the outer wall of a vessel or pipe [16].

Pipeline corrosion can be monitored by pushing "smart pig" instruments through the line to measure local and general metal loss (by electromagnetic means). Related instruments have been developed that can make ultrasonic measurements of wall thickness. These methods are used to detect the presence of both external corrosion and internal corrosion. In some instances, video camera techniques can be used to evaluate the condition of internal pipe surfaces. Caliper type measurements can be made in those relatively short lines that permit use of a cable to pull the instrument

through the line. Smart pig techniques that do not necessitate shutting down the line are preferred.

### Field Tanks and Vessels

Field production tanks and treating vessels are protected from internal corrosion by coatings with or without added cathodic protection. NACE Standard Practice for Liquid-Applied Internal Protective Linings and Coatings for Oilfield Production Equipment (RP0181) provides guidelines for equipment design, lining selection, application, and inspection. For catalyzed coal tar epoxy linings, NACE Standard Method of Lining Lease Production Tanks with Coal Tar Epoxy (RP0372) applies. Lining selection is generally governed by experience, with new type linings being evaluated by field exposure of suitable test panels. NACE Standard Practice for Design, Installation, Operation, and Maintenance of Internal Cathodic Protection Systems in Oil Treating Vessels (RP0575) is a general cathodic protection guide that includes design criteria, system selection, and monitoring.

### Offshore Structures

The complexity of offshore production platforms and associated pipelines necessitates specialized seawater corrosion control methods. Coatings are used to protect steel components in the atmospheric zone with CRAs used for special items. The splash zone represents a special case, with either special coatings and/or CRAs being used. Control of corrosion of submerged steel equipment is by cathodic protection via either sacrificial anodes or impressed current. Standards covering some of these control measures are listed below:

NACE Standard Practice for Corrosion Control of Steel, Fixed-Offshore Platforms Associated with Petroleum Production (RP0176) gives guidelines for corrosion control by coatings and cathodic protection.

NACE Standard Practice for Metallurgical and Inspection Requirements for Cast Sacrificial Anodes for Offshore Applications (RP0387).

NACE Standard Practice for Metallurgical and Inspection Requirements for Offshore Pipeline Bracelet Anodes (RP0492).

NACE Standard Impressed Current Test Method for Laboratory Testing of Aluminum Anodes (TM0190).

## OIL REFINING

Oil refining involves many processes including distillation, thermal cracking, catalytic cracking, hydrocracking, hydrotreating, catalytic reforming, alkylation, isomerization, and polymerization. Secondary processes include hydrogen production from steam and methane, amine treating of gas streams to remove hydrogen sulfide, sulfur production by oxidation of separated hydrogen sulfide, and sour water stripping to remove hydrogen sulfide and ammonia. Hydroprocesses involve pressures in the range 400–2600 psi (3–18 MPa) and temperatures of the order of 840°F (450°C). A schematic refinery flow diagram is given in Fig. 1. Refining

processes, and related corrosion environments, are subject to change with time resulting from changes in refinery feedstock, changes in market demand for individual products, and process improvements.

Corrosive components in refinery feedstock are sulfur compounds (hydrogen sulfide and organic sulfides), nitrogen compounds, organic acids (principally naphthenic acids), and inorganic salts present in entrained produced water. During the refining process, sulfur compounds are converted to hydrogen sulfide, nitrogen compounds are converted to ammonia and hydrogen cyanide, and inorganic salts may be converted to hydrochloric acid. Treating chemicals include alkanolamines (for removal of hydrogen sulfide and carbon dioxide), sulfuric acid, hydrofluoric acid, and sodium hydroxide.

The two major corrosive environments that occur in oil refining are high-temperature nonaqueous corrosion and aqueous phase corrosion. High-temperature corrosion is either sulfidation, or naphthenic acid corrosion, external oxidation, high-temperature hydrogen attack, or carburization/decarburization reactions. Aqueous phase corrosion results from many complex environments involving combinations of hydrogen sulfide, carbon dioxide, ammonia, hydrogen cyanide, hydrochloric acid, plus treating chemicals (amines, acids, alkalies).

Detailed reviews of oil refining corrosion problems and control methods are given in a book by White and Ehmke [18]. Oil refining corrosion problems are generally solved by making appropriate materials selection based on accumulated industry experience as reflected in published papers plus API and NACE committee reports. Neutralization and inhibition are used in some cases. Monitoring is generally by inspection supplemented by analysis of process streams (e.g., acidity) and by special probes.

### Corrosion Control

#### A. High-Temperature Corrosion

Sulfidation of steel can occur at temperatures above 450°F (230°C), necessitating the use of alloys, generally chromium steels and stainless steels. Alloy selection is influenced by temperature and the sulfur content of the crude oil. In hydroprocesses, temperature and the hydrogen sulfide content of the process stream are the critical factors. In addition, high-temperature hydrogen attack may occur with carbon steels at temperatures above about 430°F (220°C), the latter being dependent on hydrogen partial pressure. Resistance to hydrogen attack is provided by chromium and molybdenum-containing steels selected using the experience summarized in the well-known “Nelson Curves” and in API Recommended Practice 941, Steels for Hydrogen Service at Elevated Temperatures and Pressures in Petroleum Refineries and Petrochemical Plants. This publication is updated periodically.

Some crude oils contain significant concentrations of organic acids, mainly naphthenic acids, which are corrosive to carbon steel at temperatures above about 400°F (200°C), and may require the use of molybdenum-containing austenitic stainless steels (i.e., AISI 316 and 317). Determination of when to use alloys is done by analysis of the crude oil for acid content using ASTM D 974, Test Method for Acid and

5. Hydrogen blistering of steel equipment can occur whenever hydrogen sulfide and water are present. Presence of cyanides may aggravate the effect. Control can be achieved either by selection of resistant steels or by injection of polysulfides. Monitoring of polysulfide treatment is by use of hydrogen probes. Selection of steels resistant to hydrogen blistering and the related stress-oriented hydrogen induced cracking (SOHIC) is accomplished by steel specifications aimed at minimizing sulfide inclusion content and morphology, and confirming the steel quality by tests with NACE Standard TM0284. The latter test method was developed originally for use with piping. It is being adapted to include steel plate as used in refinery vessels.
6. Corrosion of materials in sour water stripping operations involves complex mixtures of sulfides, cyanides, carbonates, and chlorides. Corrosion control is by alloy selection.

## OIL PRODUCTS

Transport of gasoline and other refined products in steel pipelines may result in corrosion products that can create a product contamination problem. Internal corrosion of the pipeline can also have an adverse effect on pipeline capacity. Corrosion results from condensation of a water film on the pipe wall plus dissolved air or SRB in the product. Corrosion control is commonly achieved by adding a corrosion inhibitor. Evaluation of inhibitor performance can be done using NACE Test Method for Antirust Properties of Cargoes in Petroleum Product Pipeline (TM0172). This test method is a modification of ASTM D 665, Test Method for Rust-Preventing Characteristics of Inhibited Mineral Oil in the Presence of Water.

Rust problems during usage of certain refined products, such as steam turbine oils, are controlled by addition of corrosion inhibitors. Evaluation of the performance of these inhibitors is done using ASTM D 665 or ASTM D 3603, Test Method for Rust-Preventing Characteristics of Steam Turbine Oil in the Presence of Water (Horizontal Disk Method).

Presence of small amounts of some sulfur compounds in certain refined products (gas and liquid) can have a corrosion effect on copper alloy components of users' equipment that adversely affects their function. For example, copper corrosion products could cause plugging of metering and pilot valves. Consequently, product specifications may call for the product to pass a copper corrosion test such as ASTM D 1838, Test Method for Copper Strip Corrosion by Liquefied Petroleum (LP) Gases, or ASTM D 130, Test Method for Detection of Copper Corrosion from Petroleum Products by the Copper Strip Tarnish Test, or ASTM D 4048, Test Method for Detection of Copper Corrosion from Lubricating Grease.

Specification restrictions on the total amount of sulfur compounds allowed in commercial natural gas to avoid copper corrosion problems are typically 0.25 grain sulfur per 100 standard cubic feet (SCF) (6 mg S per m<sup>3</sup>). This

restriction for commercial natural gas does not meet the requirements of NACE Standard MR0175, which limits the H<sub>2</sub>S to 0.05 psi partial pressure for resistance to SSC.

## Acknowledgments

The author wishes to thank D. J. Truax and Dick Horvath for their assistance in reviewing the technical content of this chapter.

# Food and Beverage

W. E. Clayton<sup>1</sup> and B. Tholke<sup>1</sup>

## MATERIALS OF CONSTRUCTION USED AND SELECTION CRITERIA

IN THE FOOD AND BEVERAGE INDUSTRY, the workhorse materials are the "300 series" austenitic stainless steels (i.e., S30400, S30403, S31600, and S31603). S30100 and 30200 are used, but less frequently. The 300 series alloys are used because they resist corrosion attack by most environments in the industry, are easily fabricated, do not cause contamination of the products, and are readily sanitized [1–3]. As with any industry, there are many other unique materials that are also used. In neutral or slightly acid environments where chlorides are significant, chloride-resistant stainless steel and/or other high alloy materials are used [4]. Duplex stainless steels are being used more and more frequently [5,6]. In some services like fats and edible oil, copper or copper-containing alloys should be avoided.

Complying materials with FDA/USDA regulations for contact with foods and beverages during manufacture, processing, and handling is a very significant issue. Users should be cautious about generic claims of materials being "FDA approved."

Another unique factor in the food and beverage industry is that the finish and polish of the equipment is often a consideration. There are concerns about microbial sterility on the inside of process equipment [2,7,8]. Of concern are both the type of surface finish on the material and the assurance that fabrication and welding practices prevent cracks or crevices. Surface finish is a valid consideration to cleanability. Eliminating crevices is a very important concern to maintaining cleanliness. Many plants want the outside of the equipment to be "gleaming stainless steel" to give the appearance of purity and high quality to both visitors of the plant and also to plant personnel. Although this is not directly related to process needs, it is a frequent consideration.

Much of the equipment is frequently sterilized and must resist modest cleaning with various kinds of antibacterial solutions [4]. The most common is hot water with a low concentration of hypochlorite. Most of the common stainless steels will handle this type of cleaning without significant problems as long as the cleaning cycle is not too long and there are no serious problems with residue buildup or leaving the cleaning solution in the equipment

afterwards. Steam cleaning is also frequently a part of the cleaning cycle. Quality of cleaning water should properly be maintained to prevent chloride build up and other contaminants. Connolly [3] describes cleaning solutions typically used in wine, brewery, and sugar industries.

There are some environments where the iron contamination of stainless steel during fabrication must be removed prior to operation. This is most often done with nitric acid or nitric-hydrofluoric acid rinsing. The 300 series stainless steels and other high alloys can be a benefit in avoiding loss of flavor, taste, color, or bouquet.

## TYPICAL CORROSIVE ENVIRONMENTS ENCOUNTERED

There is no single or small group of appropriate environments that adequately describes the "food and beverage industry." However, the industry handles aqueous-based solutions that frequently contain acidic chlorides [4]. When the chloride-containing aqueous solutions are modest in temperature, they are typically handled with the S30400/S31600 type stainless steels. However, at higher temperatures more chloride-resistant alloys are needed and must be used. The author's experience is that in most food and beverage services, pitting of S30400/S31600 stainless steel usually occurs only over 60°C and usually the temperature must be over 70°C for stress-corrosion cracking (SCC). However, the temperature to have pitting or SCC can vary widely due to pH, inhibitor effect of other ingredients, or the many other factors well known about chloride corrosion of stainless steel [9]. Pitting and stress corrosion can occur at temperatures much lower than 60 to 70°C [10].

Typical examples of chloride corrosion of stainless steel in the food and beverage industries have been described by Richardson and Godwin [4] and Page [11]. Many food environments are multiphase. Even if the overall chloride level is low, chlorides can be very high in an aqueous phase and highly corrosive.

Other parts of the industry may be based upon fats and edible oils, which typically are not corrosive to even carbon steels as long as the carbon steel equipment can stand the cleaning cycles. The author's experience is that carbon steels are widely used for fats and oils and typically resist corrosive attack well up to 90°C. When fatty acids are present in hot fats and edible oils, stainless steel must be used over 90°C. Also, copper or iron pickup can cause rancidity.

<sup>1</sup>The Procter & Gamble Company, Cincinnati, OH 45224.

S30400 and S31600 are widely used in the brewery and wine industry [12–15] although stress corrosion resistant alloys are needed at high chloride levels [16]. Typical corrosion environments and materials used in the brewery and wine industry are described by Dreyman [17] and Connolly [3].

The 300 stainless series alloys are widely used in dairy [3,18,19] and citrus juice [20] industries. S44400 has been reported [5,13] to be effective in brewery, meat processing, hot water tanks, and similar services where chlorides are present. The 300 series stainless steels are also commonly used for vegetable processing [21].

Some foods require heating to moderately high temperatures during processing in order to sterilize the product. The specific composition of the solution and temperature governs whether or not the environment is highly corrosive [3].

In some food services, wear and abrasion of moving parts and processing equipment can be significant. The wear and abrasion resistance becomes the dominant factor rather than corrosion. Materials often used to eliminate wear and abrasion include hard-faced cobalt or nickel-based alloys for cutting, scraping, conveying, mincing, and atomizing [22]. Electroless nickel plating is sometimes used on carbon steel parts [23]. S44400 has been used for conveyor parts where corrosion resistance similar to S30400 is needed [24]. The author's experience is that precipitation hardenable stainless steel alloys like S17400 are also surprisingly successful for mechanical process equipment when corrosion resistance similar to S30400 is needed but galling must be avoided.

As mentioned above, it is common to clean food processing equipment with sanitizing solutions. For example, in fats and oils processing equipment, there is a need to clean out the equipment with caustic in order to remove organics. Steam cleaning is a common requirement. Almost all equipment is sanitized at some frequency and this often involves chloride environments [4,7]. Clean-in-place systems are usually used.

## TECHNIQUES USED FOR CONTROLLING CORROSION AND MATERIALS DEGRADATION

In the food and beverage industry, the most common approach for controlling corrosion is to use resistant alloys. Because of concerns over contamination of the product, it is not as common to use other approaches for corrosion control. However, linings and coatings are used for shipping by truck, barge, or rail.

Another significant criterion in selecting materials is that they must comply with FDA/USDA regulations for contact with foods and beverages for the specific service [7,8]. Many people do not understand or recognize the process for obtaining such approval. There are two possible methods or directions of approval to consider: (1) external FDA/USDA approval where approval is obtained from the manufacturer/supplier of the material and generally cannot be established or determined by the user company. It is common practice to request that an officer of the company supplying the material of the construction sign a statement on their company letterhead that the material complies with FDA or USDA

regulations for food/beverage contact and include the basis for such approval. Caution should be used when using notes in product catalogues that refer to a material being FDA or USDA approved; and (2) internal FDA/USDA approval where the user needs to evaluate their own manufacturing, processing, or handling process to assure that corrosion products or chemicals leached from organic materials do not contaminate the product. With the extensive use of austenitic stainless steel, FDA/USDA concerns exist mostly with nonmetals.

## SPECIFIC PROBLEM AREAS

Chloride corrosion is the major corrosion problem. The other major specific problem area is assuring that materials used comply with FDA/USDA regulations for contact with foods and/or beverages during manufacture, processing, and handling [2,7].

Material selection and/or processing requirements to assure cleanliness and sterility are critical. For example, welding to assure that crevices are not present at a level that would allow microbial growth in service is a significant consideration. However, some overly zealous people often specify mirror finishes or flush ground welds as a requirement. Usually this extreme is not necessary. Modest surface finishes as well as welds on the inside of equipment that are ground smooth, but not flush, to a 150 silicon carbide grit (30 to 35 rms) finish with fabrication consistent with 3A Dairy Standard [25] are usually adequate in most services. Care should be taken that the grinding and polishing operation does not cause contaminants, usually steel, to be imbedded into the surface. Austenitic stainless steel has been shown to sanitize easily even when the surface has been abraded [2,26].

As mentioned earlier, external appearance of a shiny polished stainless steel is also a frequent consideration.

## THE USE OF TEST METHODS TO EVALUATE CORROSION

Standard corrosion test methods are used. Immersion [27,28], intergranular [29], and electrochemical [30] (for aqueous solution) are the most commonly used ones. Any of the specialized testing methods described by Sprowls [31] might be used for special testing conditions.

## NEW MATERIALS SELECTION

Standard laboratory immersion tests described in the previous section above are used. U-bend stress corrosion [9,32] tests and multiple crevice washer tests for crevice corrosion [33] are used to evaluate localized corrosion.

High-temperature chlorides can require unique chloride resistance testing [9]. In aqueous solutions, it is common to use electrochemical testing to evaluate pitting potential or crevice corrosion. In nonaqueous base solutions, this must usually be evaluated by in-service tests in pilot plants or in existing process equipment.

Wear related or abrasion related problems can only be determined by actually testing hardware in full scale service. Accelerated tests have not proven successful in reflecting most service and performance.

### In-Service Monitoring

In-service monitoring is seldom used in the food and beverage industry except in testing alternatives for known problem areas.

### Failure Analyses

Normal "after the fact" failure analysis is used [34]. There is no standard approach for simulating field failures and lab simulation is infrequently used.

### Test Method Approach

Materials are normally evaluated by using field sample racks in pilot plant or full scale equipment. Electrochemical tests are sometimes used in aqueous solutions to evaluate the likelihood or propensity for localized corrosion due to pitting or crevice corrosion.

### Methods Used

Industry standard field and/or laboratory immersion tests described above are common and adequate for most food and beverage service applications. Single sided tests for linings and coatings [35] are used.

## ADDITIONAL COMMENTS AND DISCUSSION

The problems in the food and beverage industry are typically unique to specific services within those industries. Many of the chloride-resistant stainless steels, duplex stainless steels [5], and high-alloy materials have been used in specific applications with good success [3].

One of the problem areas for food and beverage equipment that is often neglected has to do with the use of jacketed heating and cooling vessels. Sometimes there is a process need to alternately heat a batch process with steam in a jacket and then use cooling water in the same jacket. If chlorides are present in the cooling water, this often can lead to chloride stress-corrosion cracking in the jacketed system. Alternative processing methods or chloride-resistant materials must be used in these cases.

## GENERAL REMARKS

Most food and beverage services are handled with the 300 series stainless steels. The issues relating to complying with FDA/USDA regulations for contact with foods and beverages during manufacture, processing, and handling must be carefully evaluated, especially for nonmetallic materials. However, with few exceptions, most of the problems in the industry relate to FDA/USDA approval, microbes, or to

chloride corrosion. The vast bulk of the equipment used in the industry is S30400, S30403, S31600, and S31603 stainless steel and works very satisfactorily.

# Water Handling Systems

*Bennett P. Boffardi<sup>1</sup>*

CORROSION MONITORING IS an integral part of any water treatment program. It is used to determine treatment effectiveness and to establish the optimum level of chemical treatment that is most cost effective, not necessarily the cheapest per pound.

The purpose of corrosion monitoring is to assess or predict corrosion behavior of the system. Basically, there are two objectives to monitoring: (1) to obtain information on the condition of the operational equipment, and (2) to relate this information to the operating variables (i.e., pH, temperature, water quality, chemical treatment, etc.). Meeting these objectives will provide the following results:

1. Increased life of the plant.
2. Improved quality of the plant's product.
3. Prediction of maintenance needs at the plant.
4. Reduction in plant's operating costs.

Corrosion monitoring is standard practice in the water treatment industry. The plant engineer can use this information to predict equipment life. Monitoring helps the engineer identify significant factors responsible for corrosion problems and assures implementation of solutions.

Corrosion monitoring is a diagnostic tool. It provides information for the solution of corrosion problems. Knowledge of corrosion trends can be very valuable. Frequently, several variables might appear to be significant, and the ability to correlate corrosion rates with a single variable under specific conditions can be vital. As a logical extension of its diagnostic capabilities, corrosion monitoring is used to assess the effectiveness of a solution to a specific water treatment problem.

Corrosion monitoring can be used to provide operational information. If corrosion can be controlled by maintaining a single variable (e.g., temperature, pH, chemical treatment, etc.) within limits previously determined, then that variable can be used to predict changes in corrosion patterns as the limits are exceeded in both a positive and negative direction. An extension of this technique is to use a monitored variable to control chemical addition directly through automatic feed systems.

The particular corrosion monitoring techniques selected depend upon their applicability to the system and the information being sought. Some techniques provide information that is effectively instantaneous. Other techniques provide

a measure of corrosion rate. Others measure total corrosion or the remaining metal thickness, while others provide information on the overall system.

Most corrosion monitoring techniques are best suited to situations where corrosion is of a general nature, but some techniques provide at least some information on localized attack, such as pitting.

No one monitoring technique will provide all the necessary data to properly evaluate the efficacy of the treatment program. More than one technique may be necessary to monitor a particular system.

An overview of the various corrosion monitoring techniques used in cooling water systems is shown in Tables 1–3. The essential information is listed in Table 1, whereas Table 2 lists some of the characteristics of the monitoring techniques. Table 3 is a summary chart of the various monitoring techniques overall.

## CORROSION COUPONS

The most obvious method of assessing the corrosivity of a cooling water system to a specific material is to expose a specimen or coupon made of that material for a given time in the flowing water. Coupons are made from specific alloys, which have been cleaned and preweighed with a known surface area. Coupons vary widely in size and shape. Some commonly used coupons are 12.5 mm (1/2 in.) wide, 75 mm (3 in.) in length, and 1.6 mm (1/16 in.) thick, having an approximately 2155 mm<sup>2</sup> (3.4 in.<sup>2</sup>) surface area. At selected time intervals, the coupons are removed, cleaned, and reweighed to determine the metal loss.

The weight loss is converted to overall thickness loss or average corrosion rate expressed in millimeters per year, mm/y, as follows:

$$\text{mm/y} = 3.65(\Delta W)/[(A)(d)(D)]$$

where

- $\Delta W$  = weight change, mg,
- $A$  = coupon surface area, cm<sup>2</sup>,
- $d$  = metal density, g/cm<sup>3</sup>, and
- $D$  = exposure time, (days).

Conversion to English units, mils per year (mpy), requires the above equation to be multiplied by 39.4.

Corrosion coupons are highly susceptible to initial corrosion because the metal surface is in an "active" state due to surface preparation. Coupons should not be touched during

<sup>1</sup>Consultant, Boffardi and Associates, Inc., Pittsburgh, PA 15102.

TABLE 1—Corrosion monitoring.

Method	Measures	Applications
Coupon Testing	Average corrosion rate expressed as uniform corrosion in mm/y. Weight change over 30 to 90 days duration.	Most suitable for uniform corrosion under steady conditions. Can indicate localized attack, i.e., pitting, underdeposit, galvanic, etc. Coupons made from most engineering alloys.
LPR	Instantaneous corrosion rate is measured by electrochemical polarization of $\pm 10$ mV between two electrode probes. Pitting tendency can be measured.	Suitable for most engineering alloys. Probe must be placed in fluid of sufficient conductivity to provide accurate rate. Alloy multiplier required for materials other than carbon steel.
ER	Metal loss is determined from resistance change of a corroding metal element. Uniform corrosion rates are calculated from resistance reading. Does not measure localized corrosion.	Suitable for measurements in low conductivity environments, either liquid or vapor. Elements made from most engineering alloys. Element design a function of probe life and sensitivity.
Analytical	Concentrations of dissolved or suspended species in fluid systems including pH and conductivity. Does not measure corrosion.	Determines water quality level of chemical treatment, inhibitory and antagonistic species, dissolved and suspended corrosion by-products.
Heat transfer units	Visual observation of corrosion attack on heat transfer surface. Unit can determine corrosion rate from weight loss of heated surface.	Most suitable in simulating conditions in heat exchanger for corrosive attack. Heat transfer tubes can be made from most engineering alloys.
Test Heat Exchanger	Determines the effect of velocity, heat flux, chemical treatment on corrosion, scale, and fouling.	Most suitable in simulating conditions of critical plant heat exchanger. Heat transfer tubes can be made from most engineering alloys.

TABLE 2—Monitoring technique characteristics.

Method	Time Interval for Measurement	Type of Information	Response to Changing Condition	Plant Environment	Type of Corrosion	Ease of Interpretation
Coupon Testing	Long-term duration, 30 to 90 days	Average uniform corrosion rate	Poor	Any	Uniform and localized attack	Simple
LPR	Instantaneous	Corrosion rate, pitting index	Fast	Conductive	Uniform	Simple
ER	Short duration	Integrated corrosion rate	Moderate	Any	Uniform	Simple
Analytical	Fast	Species influencing corrosive attack	Fast	Any	Not applicable	Moderate
Heat Transfer Units	Long-term duration, 30 to 90 days	Corrosion rate, scale, and fouling	Moderate	Any	Uniform and localized attack besides deposition	Difficult

installation and monitoring processes. Use of plastic gloves when handling the coupons is highly recommended. Normally, 30 days is a typical test period for low corrosivity water (under 0.25 mm/y or 10 mpy). Low-corrosivity water usually contains chemical treatments to stifle corrosion attack. Exposure periods less than 30 days can yield misleading results. Frequently, long-term tests are required, up to 90 days' exposure. During this time frame, three sets of coupons are normally placed in a test rack and changed in sequence of 30-, 60-, and 90-day intervals. Normally, the longer the exposure period, the lower the measured average corrosion rate, and the more closely the coupons will approximate conditions in the system. Figure 1 graphically shows the decrease in corrosion rate with exposure time. Steady state is normally achieved in the 60- to 90-day time frame.

Screws and nuts made of nylon or plastic should be used to hold the coupons to the coupon holder. Mixed metallurgy should be avoided. Copper-base screws and nuts should not be used to hold carbon steel or stainless steel coupons. Galvanized screws and nuts should never be used.

Coupons having large amounts of deposits or tuberculation may indicate insufficient chemical treatment, unstable water characteristics, or highly corrosive conditions. Alternatively, deposits may have been transported from elsewhere

in the system. Heavy, uniform deposits will reduce corrosion rates, since they can act as a protective barrier.

General guidelines for acceptable uniform corrosion depend upon the coupon metallurgy. Low-carbon steel (mild steel) corrosion rates less than 0.13 mm/y (5 mpy) are considered good, rates between 0.13 to 0.25 mm/y (5 to 10 mpy) are fair, and rates greater than 0.25 mm/y (10 mpy) are poor. Copper-base alloys, such as admiralty and 90:10 copper nickel, should have rates under 0.013 mm/y (0.5 mpy). Above this value is considered excessive. General classification of corrosion rates is shown in Table 4.

Coupon installation should be placed in a coupon test rack shown in Fig. 2. Note that the broad face of the coupon is vertical to prevent deposits from settling during periods of low flow. It is important that the flow rate through the rack corresponds to heat exchanger flow rate.

Too high a flow rate will keep debris off of the coupons and may initiate erosion attack on copper-base alloys. Low flow rates may result in excessive corrosion and fouling. Normally, flow rates of 1–2 m/s (3 to 5 ft/s) are adequate. The coupon rack should be connected to the return riser to the tower or at the exit of the hottest part of the system using plastic piping or any other material that will not influence coupon corrosion rates. For example, do not use galvanized pipe, copper pipe, or brass valves to connect the

test loop to the riser. Note in Fig. 2 the use of an optional strainer. The strainer should be used in water systems known to have high-suspended solids or assorted foreign matter, or both.

Flow through the coupon rack can be controlled using an orifice control valve, but this valve is subject to plugging. A plugged orifice control valve will have reduced flow or no flow at all, resulting in high coupon corrosion rates. A rotameter valved at the end of the coupon rack will give more flexibility and accuracy in controlling water velocity. A strainer in the system will prevent plugging of the fluid control valve. Cooling water discharge from the rack should go to a sump (drain, tower basin, etc.) and not be plumbed back into the cooling system. The outflow of the rack must be open to the atmosphere.

In a high-rise building the cooling tower is normally placed on the roof and the corrosion rack is in the mechanical room, which are frequently in the basement. In this situation, the corrosion rack is plumbed between the downcomer and the riser. Materials of construction for the corrosion rack should be made of stainless steel to provide rigidity and have minimal influence on the coupons. Use of carbon steel or galvanized steel is not recommended as construction materials. Coupon placement in the rack follows the galvanic series, starting from the active end. That is, aluminum, carbon steel, stainless steel, and then copper-base alloys.

Coupon corrosion studies are simple to perform. This is the most direct method, aside from inspection of the actual

plant equipment, to determine the efficacy of a treatment. Coupon evaluation allows simple comparison between different alloys, which provides visual examination for localized attack, such as pitting, crevice attack, dealloying, or any other form of nonuniform attack. However, there are limitations to coupon evaluation. Coupons provide weight loss determination of corrosion rates. This consists of accumulated loss of material over the period of exposure. Therefore, coupons cannot determine the time or magnitude of corrosion upsets within the exposed time frame. Finally, 30–90 days are needed to allow sufficient weight change to be meaningful. This 30- to 90-day exposure can sometimes indicate differences between short-term and long-term corrosion rates.

## LINEAR POLARIZATION-RESISTANCE METER (LPR)

The linear polarization-resistance (LPR) technique is the only corrosion monitoring method that allows corrosion rates to be measured in real time. Although limited to electrolytically conducting liquids, the response time and data quality of this technique make it superior, where applicable, to all other forms of corrosion monitoring.

LPR is particularly useful as a method to rapidly identify corrosion upsets and, thus, evaluate remedial action, reducing and minimizing unscheduled downtime, thereby prolonging plant life.

Two LPR devices are presently in use, a three-electrode probe (working, counter, and reference electrodes) and a two-electrode probe. In the author's opinion, the three-electrode system is a better-designed corrosion monitor; however, it accounts for a small percentage of LPRs used to monitor corrosion rates in industrial water treatment systems. The two-electrode LPR device is used by most water treatment vendors and industrial plants. It will be the only LPR device discussed.

The basic operation of the LPR instrument uses two electrodes made of the material of interest, i.e., carbon steel, Admiralty, 90:10 copper nickel, etc. One of the electrodes acts as an anode, the other as a cathode. During the operation of the instrument, a very small voltage of 20 mV is applied across the electrodes. In this region, the polarization curves approach linearity, hence the term LPR. The applied potential divided by the measured current  $i_{\text{meas}}$  is a resistance term called Polarization Resistance, or  $R_p$ . The resistance to current flow between the two electrodes of the LPR probe is the sum of polarization resistance values at each electrode and the resistance of the solution between the electrodes ( $R_s$ ).

TABLE 3—Monitoring devices.

Systems	Coupon	LPR	ER	Analytical	Test Heat Exchanger
Once-through Cooling	X	X	X	X	
Closed System Cooling	X	X		X	
Open Recirculating Cooling	X	X		X	X

FIG. 1—Relative carbon steel corrosion rate versus elapsed time.

TABLE 4—Qualitative classification of corrosion rates.

Corrosion Rate (mm/y)		Description
Carbon Steel	Copper-Base Alloys	
<0.03	0 to 0.003	Negligible or excellent
0.03 to 0.08	0.003 to 0.006	Mild or very good
0.08 to 0.13	0.006 to 0.009	Good
0.13 to 0.20	0.009 to 0.0125	Moderate to fair
0.20 to 0.25	0.0125 to 0.03	Poor
>0.25	>0.03	Very poor to severe

$$\Delta E = i_{\text{meas}} (2R_p + R_s)$$

In addition to general or uniform corrosion, localized corrosion (pitting) may occur in a system. A Pitting Index or Imbalance measurement can be obtained from some LPR meters. The electrochemical current generated is a qualitative measurement or index. If the imbalance reading (pitting) is low compared to the corrosion reading, pitting is probably minimal. High imbalance reading compared to a general corrosion rate can indicate that pitting or crevice corrosion will be the main form of attack. When a general corrosion rate reading is about the same as the imbalance index, then some pitting is indicated but the pits will probably be broad and shallow.

The LPR probe should be installed perpendicular to the water flow in a representative water stream which is part of the piping system or at the end of the coupon test rack, as shown in Fig. 2. The probe must be installed such that water flows between the two electrodes in order to avoid fouling of the electrodes. An aligning pin at the male cable connector of the probe indicates the electrode position as shown in Fig. 2. The two electrodes should project into the flowing water, with the probe lead flush with the pipe wall as shown in Fig. 3.

Serious errors in corrosion rate measurements may occur in low-conductivity water due to solution resistivity effects. This situation tends to occur at moderate to high corrosion rates and is manifested by indicating lower corrosion rates than actual. The operating range for various LPR instruments can be obtained from the manufacturer.

The LPR probe alloy multiplier should be used when electrodes are made from materials other than carbon steel. The purpose of the multiplier is to convert the built-in constants that are specific for carbon steel to other alloys. Corrosion rate multipliers account for the specific alloy's anodic reactions, the valency of the anodic reactions, the alloy equivalent weight, and the alloy density. LPR electrodes should be changed periodically and at least annually.

Corrosion rates obtained with LPR instruments provide rate data directly and within a few minutes. This instrument is well suited to applications where upsets or other accelerated corrosive conditions can be detected quickly so that remedial action can be taken. The corrosion rates obtained with the meter assume uniform corrosion with a tendency to predict pitting attack. Deposits on the electrodes can bias the pitting index value. If the index value is high, the probe should be removed and the electrode visually examined for debris. Bridging the electrodes with conductive deposits will affect both the general corrosion value and the pitting index.

The LPR reading may not agree with the coupon corrosion rate. The LPR data are real time and measure the corrosion rate at the time of measurement. Coupon rates are an accumulated average mass loss, taking into account all corrosion that has occurred during its exposure period. Coupon mass losses are a direct measure of corrosion rate, whereas LPR data are generated from electrical currents, which are influenced by other factors. The main advantage of LPR devices is the rapid detection of sudden changes in system operating parameters or chemical levels.

Details on how to calculate corrosion rates from electrochemical measurements can be obtained from ASTM G 102, Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Measurements.

## ELECTRICAL RESISTANCE METER (ER)

The electrical resistance (ER) technique is an online method of monitoring corrosion rates. It is universally applicable to all types of corrosive environments, i.e., conductive to poorly or nonconductive media (such as deionized or potable waters) and vapor phase systems (such as steam).

There are many manufacturers of ER instruments. ER meters measure the change in resistance of a metal element as it corrodes. The metal element or probe is usually in the

FIG. 2—Corrosion test rack installation.

form of a wire, strip, or tube. When it corrodes uniformly, the change in electrical resistance is proportional to corrosion

$$R = K/A$$

where  $R$  is the probe resistance,  $A$  is the cross-sectional area of the metal element, and  $K$  is a constant and a function of probe metallurgy, element length, and resistivity. As the probe element corrodes, its cross-sectional area is reduced, increasing its electrical resistance. Thus, the measurement of electrical resistance is inversely proportional to the remaining metal in the probe. Therefore, increases in the measured resistance signal increase the metal loss to corrosion. The probe is internally temperature compensated for changes in the probe constant, which is temperature dependent.

The advantage of the ER meters is their ability to measure corrosion in liquids, vapor phases, and in inaccessible locations. The liquid does not have to be conductive or have a minimum conductivity as with the LPR systems. However, corrosion rates are not instantaneously determined. The time frame required to determine corrosion rates is a function of probe element and metal loss. Also, the ER probes are suitable only for uniform corrosion. There is no pit index built into the instrument. Any pits developed on the element will cause rapid penetration and indicate excessively high corrosion rates.

Typical probe elements are shown in Fig. 4. Appropriate response time information for any given probe can be obtained from the manufacturer. The corrosion rate is calculated from the change in dial reading on the instrument.

FIG. 3—Installation of LPR probe.

FIG. 4—Electrical resistance element design.

$$\text{Corrosion rate (mm/y)} = \frac{9.3 \times 10^{-3} \times \Delta D \times PF}{T}$$

where  $\Delta D$  is the change in the dial reading,  $PF$  is the probe factor (supplied with each probe), and  $T$  is the elapsed time in days. ER probes must be allowed to corrode for a period of time before accurate corrosion rate measurements can be made. The time duration depends upon the corrosion rate. The higher the rate, the shorter the time period and vice versa.

Probe placement in the fluid should be similar to LPR electrode placement; that is, the probe element should protrude into the fluid. Flow should pass the element. There is no specific orientation for the probe element.

Figure 5 shows a plot of dial setting or metal loss from the ER meter versus time, which can give an indication of corrosion rates. A large change in slope represents an increase in corrosion, whereas a zero slope indicates no significant increase in corrosion.

Generally, LPR is the preferred technology for on-line monitoring of corrosion in highly conductive waters such as those in industrial recirculating cooling water systems. The preference is based on two factors: 1) the relative instantaneous nature of the LPR, and 2) the distortional effect that even a single pit has on the ER measurement and reducing the usable life of the ER probe.

## CHEMICAL ANALYSIS

Water parameters relevant to the corrosion process can be provided through chemical analysis. This monitoring technique does not directly indicate corrosion rate but provides information on factors that can influence the corrosion process. It measures parameters that are known to be associated with acceptable or unacceptable corrosion processes within a system.

A thorough water analysis is not required of every water sample. However, there are core analyses that should be performed to determine the operating state of the system. It is good practice to periodically obtain complete analyses so that seasonal variations in water composition can be tracked.

FIG. 5—Electrical resistance meter dial setting versus time. A is a medium corrosion rate, B is essentially no corrosion, and C is a high corrosion rate.

TABLE 5—Analytical parameters.

Species	Impact on Operating System
pH	Corrosion or scale-forming tendency.
P Reading	Monitor buffering capacity, differentiates $\text{OH}^-$ , $\text{CO}_3^{2-}$ , and $\text{HCO}_3^-$ .
M Reading	Provides data for calculating $\text{CaCO}_3$ potential. Includes all hydrogen titratable species, i.e., $\text{PO}_4^{3-}$ , $\text{SiO}_2$ , polymers. If pH/alkalinity relationship is outside of norm, then additional alkalinity value may be due to other titratable species.
Conductivity	Estimates total dissolved solids.
Suspended Solids	Monitors general water quality or turbidity.
Orthophosphate	Monitors inhibitor concentration and/or reversion.
Polyphosphate	Monitors inhibitor concentration.
Organic Phosphate	Monitors inhibitor concentration.
Total Organic Carbon	Monitors overall water quality.
Calcium, Total	Monitors potential hardness scale deposition.
Calcium, Dissolved	Monitors hardness scale deposition if value is different from calcium, total.
Magnesium, Total	Monitors potential deposition.
Magnesium, Dissolved	Monitors potential silicate or hydroxide deposition if value differs from magnesium, total.
Aluminum, Total	Monitors possible inhibitor adsorption, reducing corrosion protection if concentration $>0.1$ mg/L.
Aluminum, Dissolved	Monitors possible inhibitor adsorption, if concentration $>0.1$ mg/L. Loss of 3.5 mg/L of phosphate per 1 mg/L of aluminum.
Copper, Total	Monitors potential copper corrosion reducing steel corrosion protection if concentration $>0.1$ mg/L.
Copper, Dissolved	Monitors potential copper corrosion. Acceptable level $<0.05$ mg/L.
Zinc, Total	Monitors potential zinc scale deposition and level of treatment needed to inhibit/disperse solids.
Zinc, Dissolved	Monitors background levels and active synergist.

A “well check” analysis is also advisable. This consists of a thorough analysis when the plant is operating properly and corrosion rates are meeting the objectives. The well check can then be used as base line data when corrosion rates are outside the norm and analyses are being performed to determine the cause.

Parameters to be determined for a thorough analysis and their impact on corrosion/deposit are shown in Table 5.

## DISSOLVED OXYGEN MONITORING

Oxygen is the common cathodic reduction species found in water, which is responsible for continued corrosive attack on some engineering materials, such as low carbon steel. However, passive engineering alloys utilize the oxygen to form thin, tenacious, and adherent protective oxide films. Some common alloys with protective films are stainless steels, nickel alloys, copper-base alloys and aluminum alloys. The oxygen concentration at ambient temperatures and atmospheric pressure is approximately 6–8 mg/L. An increase in temperature decreases oxygen solubility, whereas an increase in pressure increases oxygen solubility.

In open cooling water environments, oxygen cannot be economically removed as an antagonistic species. Appropriate cathodic inhibitors control its impact on corrosion.

In boilers, it is a common practice to remove the oxygen from the water, since it is a major corrodent. Removal is through a combination of physical and chemical means. Deaerators physically remove the oxygen by purging the boiler feed water with steam, which heats and degases the water. Oxygen content can be reduced to 5–7  $\mu\text{g/L}$  by this method. Further reduction of oxygen is required and this is achieved through the use of chemical oxygen scavenger. The combination of deaeration and oxygen scavenger can reduce the oxygen content to zero.

Oxygen measurements can be made directly and continuously using online monitors or by wet chemical analysis.

## OXIDATION REDUCTION POTENTIAL (ORP)

Oxygen reduction potential (ORP), or redox potential, is the potential of a reversible oxidation-reduction electrode measured with respect to a reference electrode, corrected to the hydrogen electrode, in an electrolyte. It is an online, real-time measurement. In water treatment, ORP is used to control the addition of oxidizing biocides, such as chlorine, chlorine dioxide, bromine, hydrogen peroxide, ozone, etc. The presence of these chemicals will raise the ORP value. When an ORP probe is placed in the open recirculating cooling water environment in the absence of an oxidant, its value is taken as an initial set point. The addition of an oxidizing biocide increases the ORP value. The actual ORP reading depends upon concentration and activity of the oxidant or biocide, temperature of the system, contaminants and nutrients, pH and other parameters. Usually, at recommended concentrations of oxidizing biocides, the ORP value increases hundreds of millivolts depending upon the above parameters. Maintaining the recirculating water at the higher oxidizing potential assures adequate disinfection.

ORP measurements are similar to pH measurements. A typical ORP cell uses a platinum surface for measuring half of the potential and a silver-silver chloride in potassium chloride as a reference electrode. Maintenance of an ORP system is similar to that of a pH electrode; that is the ORP electrode should remain in the water circuit at all times.

Electrodes are replaced approximately every two years. The electrodes are cleaned in 5 % hydrochloric acid solution to remove any hard-water deposits that may form and interfere with the reference junction.

Quinhydrone is used to calibrate the ORP electrodes. By placing the quinhydrone in a known pH solution, a standard mV reading is achieved. An ORP value of 87 is obtained in a quinhydrone solution at pH 7, and 240 mV at pH 4. Other calibration protocol exists for higher ORP readings in the 600 mV range.

## HEAT TRANSFER SYSTEMS

Fouling and deposit monitors are used primarily to track the buildup of scale or deposits on heat transfer surfaces. The heat transfer tube can also be used as a tubular corrosion coupon to monitor corrosion under heat transfer conditions.

These units are designed to simulate heat exchangers under as near actual operating conditions as possible, taking into account ease of use and simplicity in design. Figure 6 shows a simplified schematic. An electric resistance heating element is used to impose a heat load on the tubular metal surface. The metal test specimen is inside a glass outer jacket in which water flows in the annular space. The glass tube makes it possible to visually examine the metal surface for deposit buildup or corrosion attack.

Heat flux ( $W/m^2$ ), which is the heat transfer rate ( $W$ ) divided by the exposed metal tube surface area ( $m^2$ ), is constant as long as no deposits accumulate on the specimen. However, deposits coming from hardness salts, corrosion by-products, silt, process contamination, biomass, etc., can form on the heated surface, raising the surface temperature. If the surface temperature becomes excessive, there is temperature cutoff switch to protect the device.

It is important to gather as much information about the system using fouling and deposit monitors as possible. Periodic visual inspection of the heat transfer tube is necessary to qualify the buildup of deposit. At the termination of the test, the tube deposit should be collected and chemically analyzed. Photographs of the deposits on the tube can be useful in describing the type of buildup. Also, photographs after the tube has been cleaned can be used to document the type of corrosion attack that has occurred, e.g., uniform, underdeposit, pitting, etc.

After the tube has been cleaned, the corrosion rate of the heat transfer tube should be determined. This rate should be compared with nonheat transfer coupons to determine the impact of heat flux.

## TEST HEAT EXCHANGER

The test heat exchanger is a monitoring tool that evaluates a heat transfer surface for corrosion and deposition. The test heat exchanger is only as good a monitoring or evaluating piece of equipment as its ability to duplicate or represent system conditions. The factors inherent in plant heat exchanger equipment that determine the corrosion and deposition of exchanger surfaces are:

- Product temperature, which determines metal skin temperature.
- Water flow velocity in the tube, which can influence fouling rate. Low velocities of 0–0.6 m/s (0–<2 ft/s) can result in more severe fouling. Average velocities of 1–2 m/s (3–5 ft/s) would correspond to normal rate of deposition. High velocities of 2–4 m/s (6–12 ft/s) will result in less fouling.
- Heat flux, a major influence on scale/deposition rate. Corrosion rates will also be influenced but to a lower degree. Heat flux of 0–6300  $W/m^2$  (0–2000  $BTU/ft^2-h$ ) are considered low. Heat flux of 6300–15 800  $W/m^2$  (2000–5000  $BTU/ft^2-h$ ) are average. Heat flux of 15 800–31 500  $W/m^2$  (5000–10 000  $BTU/ft^2-h$ ) are considered high.
- Cooling water temperature, which accepts heat from the plant exchanger.

FIG. 6—Corrosion deposit test unit.

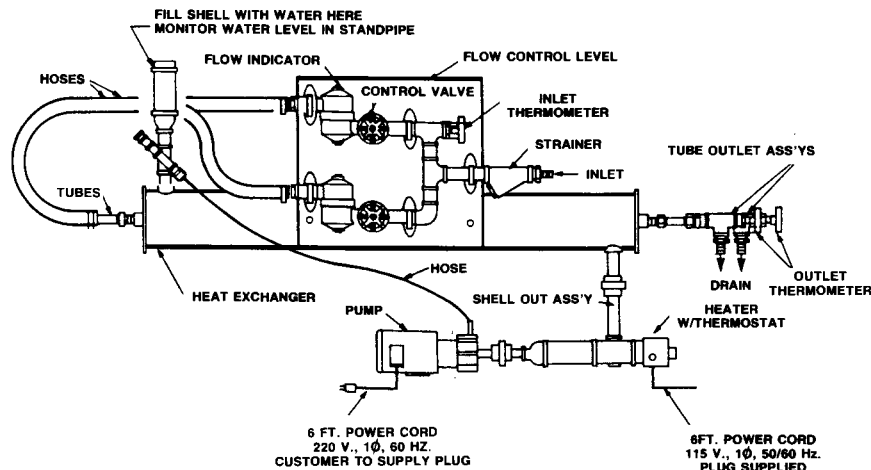

FIG. 7—Field evaluation test heat exchanger.

In order to obtain reliable results from a test heat exchanger, the above factors must be determined from the plant exchanger in the system that is to be duplicated. Once the plant parameters have been determined, they should be duplicated as nearly as possible in the test unit and held constant. Figure 7 is a schematic of a typical two-tube test heat exchanger. It is used to simulate tube side water conditions in a plant exchanger. Heated water or steam on the shell side is used to heat the tubes.

The flow of cooling water to the tubes must be controlled to maintain system velocity. An inlet water strainer is used to eliminate foreign objects, which can restrict flow. A valve ahead of a flow indicator controls flow.

The flow of hot liquid on the shell side is pumped through the exchanger and the temperature controlled by a thermostat. Thermometers on the inlet and outlet waters are used to determine temperature differential  $\Delta T^{\circ}\text{C}$ . Once the operating parameters have been selected and established, they should be checked and recorded on a per day or per shift basis.

The two-tube heat exchanger can be used to compare treatment, metallurgy, and the impact of heat flux on deposition by varying the flow in one of the tubes. At the end of the monitoring test period, which is at least 30 days, the heat transfer tubes should be evaluated for scale deposition, fouling, and corrosion. Analysis usually includes:

1. Cutting the tubes in half for visual inspection on both the heat transfer and nonheat transfer surfaces (tube extension outside the shell).
2. Scraping the deposits from the tube for analysis.
3. Brushing and chemically cleaning the tube to examine tube surface for general and localized corrosion.

These heat exchanger devices require considerable time and expertise to properly operate. They are not commonly used because of manpower commitment and ancillary expenses.

## CONCLUSION

A wide range of corrosion monitoring techniques is used in water treatment to systematically measure the corrosion or degradation of equipment and distribution piping. Corrosion monitoring is a viable tool to assess the performance of any chemical treatment program. There is no one technique that is universally applicable. The wide variety of corrosion monitoring tools can be used in any industry, and, although there are limitations on each technique, they provide a practical means to monitor corrosion behavior. More details on the various monitoring techniques can be found in the technical literature. Selected references include:

# Medical and Dental

*Anna C. Fraker<sup>1</sup>*

MEDICAL AND DENTAL MATERIALS are in the class of materials called biomaterials. Biomaterials are used in the body to replace body components or assist in retaining or restoring body functions. Biomaterials include synthetic materials, modified natural materials, biosynthetic materials, systems engineered materials, and morphological protein molecules that can send signals of direction to cells [1]. Synthetic biomaterials may be metallic, ceramic, polymeric, or a combination of these as needed to meet the needs of intended application.

Materials discussed in this chapter are metals. Some types of corrosion behavior discussed also apply to combinations of metals with ceramics or polymers. Information given in this chapter may serve as a guide for future assessment of metals and alloys considered for use as biomaterials.

Electrochemistry, a science of major importance to the medical and dental materials industry, was applied for the first time to medical materials in the 1930s [2,3]. Today, corrosion testing is conducted by the medical and dental materials industries and other research organizations to determine if materials planned for use in body environments are corrosion-resistant. Corrosion resistance assures that little or no ion release or degradation due to corrosion will occur during use in the body environment. In vitro corrosion test data can be used to screen and characterize the corrosion behavior of the materials, to determine chemical reactions, and to help predict suitability and stability in use. The application of corrosion testing to materials or devices is one of the first steps in developing or improving medical and dental materials and devices. Existing corrosion test methods using potentiostatic/galvanostatic techniques have been refined, ASTM recommended test methods have been developed, and alternating current (AC) impedance tests have been used to address specific problems of the medical and dental materials industry. New approaches to corrosion testing are required for porous coatings, surface layer coatings, and other modifications. Surface analysis techniques, such as Auger spectroscopy and electron spectroscopy for chemical analysis, are coupled with corrosion measurements to give a better understanding of the corrosion reactions and to characterize the interfacial surface of the implant. Scanning electrochemical microscopy (SECM), high-speed scratch testing and step-polarization impedance spectroscopy testing are techniques used to provide information

on surface variability, local electrochemical and mechanical phenomena and electrical properties of surface oxides [4]. A review of corrosion of biomaterials gives the environmental effects and test methods and susceptibility of implants to various types of corrosion [5].

The results of extensive corrosion testing, biocompatibility studies, and clinical evaluation have been used to select the corrosion-resistant metals and alloys that are in use as implants today. In addition, there are new materials being introduced as well as modifications of the currently used ones. Additional information on the biological and chemical reactions at the body/biomaterial interface would be useful in determining short- and long-term effects on the body and in preparing the biomaterial for its intended use.

This chapter provides general information on composition, mechanical properties, and corrosion behavior of some medical and dental metals used at present. References are provided for obtaining detailed information, and regulations and economics are discussed briefly. There is a wealth of information on medical and dental materials research that is not cited here and active investigations are continuing.

## GENERAL AND DESCRIPTIVE INFORMATION ON DEVICES AND MATERIALS

### Implants

The numbers of metallic surgical implants and dental implants in the U.S. are each in the range of 500 000 to 1 000 000 and are expected to increase. Projections of the U.S. Census Department are that the U.S. population over 65 years of age will increase 34 % from 1997–2015. This increase in the over 65 population is large when compared with the increase in population of all ages estimated to be 16 % for the same period. The total cost of a total hip joint may range from \$12 000–\$20 000, with 20 % of this cost being for materials (prosthesis). The total cost of a single dental implant may range from \$1000–\$1500, with the implant cost approximately 20 % of the total cost. Medical devices, equipment, and supplies comprise a \$100 B–\$200 B industry both in the U.S. and in the world [6]. U.S. firms are major suppliers in the worldwide market for medical devices, equipment, and supplies [6]. The World Health Organization (WHO) projects an increase in the over 65 population from 390 million in 1997 to 800 million in 2025.

<sup>1</sup>Retired, formerly Metallurgist, National Institute of Standards and Technology, Gaithersburg, MD 20899.

The success of the artificial hip joint replacement increased in the 1950s and 1960s. Charnley [7] and others introduced a joint that consisted of a metal femoral component articulating against an ultrahigh molecular weight polyethylene acetabular component with both components being inserted using polymethylmethacrylate cement. The success rates today, for periods of up to ten years, exceed 95 %. Current expectations for the life of total hip prostheses are 15–20 years if all aspects of the joint, installation, and patient's activities are optimized. The improved fixation of today using porous implants with and without cement as well as the introduction of new alloys and coatings and other biomaterials may further advance the service life of artificial hips. Biocompatibility increases in importance for porous implants since both surface area and time of implant duration increase. Some aspects of biocompatibility of metals, ceramics, and polymers have been discussed previously [8].

The success rate of dental implants increased dramatically during the 1980s [9]. Improved materials, selection of appropriate materials, and advanced technology have resulted in an improved implant/bone interface attachment that is responsible for the increased success. Success of dental implants is measured by the absence of mobility, no radiolucency between the bone and implant, and no other adverse symptoms or problems. The most successful dental implant today is the endosseous implant where the implant is anchored into the bone and osseointegrated. Success rates can be as high as 95 % over a five-year period [10,11]. Titanium and Ti-6Al-4V are the most widely used materials for the implants. The effects of surface treatment on the surface oxides of titanium have been shown [12,13]. Titanium was the material of choice for Branemark, who correlated the dental implant surface preparation and purity with the histology results of the interfacial bone [14].

The first requirement for an implant material is biocompatibility. The material must not cause any adverse reaction in the body. A second requirement is that the material must be corrosion resistant in the body environment. Corrosion resistance ensures that metal ions will not be released into the body, and the device will retain its integrity and not degrade due to corrosion. A third requirement is that the device must have sufficient mechanical strength and fatigue strength. A fourth requirement is appropriate design for the intended use. Crevices should be avoided to provide good corrosion resistance. A fifth requirement is the appropriate surface treatment. When the device is implanted into the bone, the surface of the device is the part that interfaces and could interact with body fluids and tissue. Surface treatment controls the nature of the surface and is important as a means of improving biocompatibility.

### Development of Surgical Implant Materials

Historical accounts of man's attempts to restore body functions are given in various references [15–23]. After the discovery of aseptic techniques in the 1860s by Joseph Lister [23] and the resulting decrease in infection, it became evident that the metals being used for repairs in the body were a limiting factor. Efforts were made to determine the most appropriate metals. Stainless steels began to be used

in 1926, and the cobalt-based alloys were first used in the mid-1930s [4]. Titanium was determined to be corrosion resistant in the body in the 1950s [24,25] and reported to be biocompatible [26] in 1973. Titanium and the alloy Ti-6Al-4V were not introduced as implants until the 1960s, and were not used much until the 1970s. The 1980s, 1990s, and 2000s saw increased use of titanium and its alloys for surgical and dental implants and for other dental uses.

Other modifications to surgical implants began to occur in the 1970s and continue until the present. Porous coatings were applied by arc plasma spraying [27] and by sintering of spheres [28] and wires [29]. The surface porosity was created for the purpose of providing better attachment of the implant to the tissue, making it possible to attach an implant without the use of polymethylmethacrylate cement. Further efforts to improve bony attachment to the implant involved applying a coating of hydroxyapatite,  $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ , to the porous metal implant [30]. Various aspects of hydroxyapatite coatings are the subjects of numerous papers and studies today.

Another technique that has been investigated for improving the attachment of bone to the device is bone growth stimulation by the application of electrical currents [31,32]. Some bone growth increase was observed in the initial stages, but not in later stages. Recent studies of electrical stimulation on bone growth give results ranging from detrimental and no improvement to improvement initially.

Metallurgical processing played an important role in the improvement of surgical implants in the 1970s and 1980s. This is evidenced by the improved fatigue strength of cobalt-chromium-molybdenum alloys due to annealing, thermomechanical processing, and forging [33–36]. The influence of heat treatment on corrosion-fatigue [37,38] and fatigue strength [39] of Ti-6Al-4V and titanium alloys, and duplex annealing of stainless steels [40] showed the benefits of metallurgical processing. A review article on modern processing of metal implants covers a number of processes that are being used as well as new possibilities for the future, and discusses properties that accompany various processing methods [41]. Surface ion implantation of nitrogen into Ti-6Al-4V has been done to improve the wear resistance [42]. Noble elements have been ion implanted into the surface to improve corrosion resistance [43]. Wear resistance is an important property for both medical and dental devices and materials [44,45].

### Metallic Dental Materials

Dental materials must serve to restore the function of the original biological tooth or part, and the restoration should be aesthetically acceptable if possible. Aesthetics present additional challenges in materials bonding and potential corrosion problems. Tarnish and corrosion of dental alloys [46] and descriptions of dental materials [47] have been discussed previously. Some of the reported earliest uses of synthetic materials in the body were for dental purposes [15,16,18,48,49].

A discussion of some dental uses of synthetic materials and associated repairs follows. Amalgams (based on mixing  $\text{Ag}_3\text{Sn} + \text{Hg}$ ) [50], and (sometimes) gold foil or gold powder are used for direct fillings. Acid assisted consolidation of

precipitated, nanosize silver powder is being studied as a potential process for direct fillings [51]. Cobalt-chromium, nickel-chromium, and titanium-based alloys are used for crowns and partial dentures (fixed and removable), although iron-based and other alloys have been used. Gold, palladium, nickel, and cobalt-based alloys are the predominant systems used for crowns and restorations involving fusing porcelain to metal. Metals used as dental implants and support structures include cobalt-chromium, nickel-chromium, stainless steel, titanium, and titanium alloys. Titanium and Ti-6Al-4V are the most widely used dental implant materials. Stainless steel, cobalt-chromium, nickel-titanium shape-memory alloy, and beta-titanium alloys are used for orthodontic wires. Gold solders, silver solders, and other special solders are used for joining metals.

### Other Uses

Metals are used in the cardiovascular area including heart valves, heart pacemaker leads, and heart pacemaker cases. These metals include titanium, titanium alloys, cobalt-chromium alloys, and cobalt-nickel alloys. Metals used for aneurism clips include cobalt-chromium-molybdenum alloys, cobalt-nickel-chromium-molybdenum alloys, and, previously, stainless steels were used. Metal seeds are used for fractionated hyperthermia treatment of prostate disease, and corrosion analysis showed the alloy, PdCo may be suitable for the seed implants [52].

### CAUTION—Magnetic Resonance Imaging

The use of magnetic resonance imaging (MRI) devices is not recommended for individuals with electrically, magnetically, or mechanically activated implants such as cardiac pacemakers, hearing aids, etc. The magnetic field will interfere with the operation of these devices and could destroy the device. MRI is not recommended for individuals who have aneurysm clips. MRI is not recommended for individuals who have metal clips or other implanted devices that are ferromagnetic, as these devices could be moved out of position. It may be best not to use MRI with individuals who have metallic implants. Sometimes, it is not known what type of metal is implanted and there is the possibility of heat generation by the metals. There is a Federal Register notice [53,54] regarding MRI devices, and some information is available regarding specific metals and devices that do not preclude the use of MRI.

## TYPES OF METALS USED

### Surgical Implant Alloys

Metals and alloys used for surgical implants in the U.S. include 316L stainless steel, cobalt-chromium-molybdenum, cobalt-chromium-tungsten-nickel, cobalt-nickel-chromium-molybdenum, titanium, Ti-6Al-4V, and tantalum. Variations of these alloys, including other alpha-beta titanium alloys, beta titanium alloys, Ti-Ni memory alloy, nitrogenated stainless steel and other cobalt alloys have ASTM-F4 specifications and are being used or considered for surgical implant use. Chemical compositions of selected metals and alloys are given in Table 1. Effects of various elements in alloys can be significant and are discussed in metallurgical texts and handbooks [49]. In some cases, small differences in composition result in alloy phase and microstructural changes that can alter corrosion and mechanical property behavior. There is an ASTM F-4 specification for each variation of the alloys and forms such as wrought, wire, coating powders.

Mechanical property data for selected alloys are given in the specifications of Table 2. One requirement for a load bearing implant is that it be strong enough to support the load. The high modulus of elasticity of these materials and the resulting stiffness can act to shield the bone from the stress necessary to produce new bone growth. Efforts of substituting other materials or composites with a lower modulus of elasticity have not been successful due to lack of strength and fatigue failure. Fatigue fracture is a risk if the materials are too weak, and the avoidance of fatigue is the reason for applying the previously mentioned special thermomechanical processing, forging, and annealing treatments to the alloys.

The compositions and mechanical property data in Tables 1 and 2 are taken from ASTM International Specifications [55]. There are other metals and alloys that have been approved under *market clearance* (510K) for use in the United States by the Food and Drug Administration and other alloys in use in other countries that are not listed here. Chemical and mechanical property data for alloys not in Tables 1 and 2 are available through ASTM specifications.

The composition of 316L stainless steel used for surgical implants is of the austenitic type which has a face centered cubic (fcc) crystal structure and the highest corrosion resistance for this kind of iron alloy. A compositional or processing change that produces a different crystal structure in this

iron alloy is to be avoided. Chromium must be present within the range designated to give adequate corrosion resistance, but chromium is a ferrite former, and ferrite has a body centered cubic (bcc) crystal structure. Molybdenum, another ferrite former, is added in a mass fraction at 2–3 % to increase corrosion resistance (especially pitting resistance). Molybdenum content must not exceed a mass fraction at 3 % as amounts above this could result in ferrite formation and could lower corrosion resistance to oxidizing environments. Nickel is added as an austenitic stabilizer. Since carbon, also an austenite stabilizer, is more soluble in austenite than in ferrite, the nickel addition helps to keep the carbon in solution and prevent formation of martensite. Carbon serves to strengthen the stainless steel, but the carbon must remain in solution. Users and producers should be aware that improper heat-treating causes sensitization to corrosion via chromium carbide formation that depletes grain boundary areas of chromium necessary for corrosion resistance. Sensitization results in intergranular corrosion, and also cracking and pitting. Stainless steel must be in the cold-worked condition to have adequate mechanical properties for a load bearing implant. Nitrogen, another austenitic stabilizer, is added to stainless steel for strengthening, improving mechanical properties, and increasing corrosion resistance. Nitrogen, like carbon, must be in solid solution, or similar precipitated phases as with carbon, can occur. The influence on corrosion of stainless steel is synergistic with elemental additions, heat treatment and/or processing due to changes that occur in the microstructure such as precipitates, phase formation, and solid solution chemistry. Metallurgical aspects of stainless steel, the use stainless steels as implants, and stainless steels without nickel also have been discussed [56].

Titanium alloys undergo phase changes from hexagonal close packed (hcp), alpha phase, to bcc, beta phase, at a temperature near 882°C. The alpha/beta transus temperature and the relative amounts of the two phases are dependent on the composition. Aluminum, oxygen, tin, and zirconium are alpha stabilizers (hcp phase). Chromium, vanadium, molybdenum, niobium, iron, and manganese are beta phase (bcc) stabilizers. Corrosion-fatigue behavior of titanium alloys is directly related to microstructures that result from composition, heat treatment, and cooling procedures. Heat treatment and cooling rates are important aspects of the microstructural formation due to the phase

changes. The use of unalloyed titanium [57] and beta titanium alloys as implants has been described [58,59].

Cobalt-chromium-molybdenum alloys can be strengthened by carbide formation and alloying with refractory metals (such as molybdenum) that go into solution. Further strengthening can be accomplished with forged or hot isostatically pressed (HIP) materials that have microstructures showing twinning and smaller carbide phases [49]. Cooling rates must be controlled carefully to prevent agglomeration of carbides that could reduce the fatigue strength. Microstructures of cast Co-Cr-Mo alloys show large grains with visible carbide phases present where  $\text{Cr}_{23}\text{C}_6$  is the principal carbide formed but  $\text{Cr}_7\text{C}_3$  and the  $\text{M}_6\text{C}$  type, where M is cobalt and molybdenum, also form [35,36,60]. The use of cobalt alloys as implants has been described [61].

## Dental Alloys

Dental alloy properties, compositions, and uses are discussed in detail elsewhere [45,47,62,63,64]. Representative compositions of base metal alloys are given in Table 3. There are four types of gold alloys, and these are represented in Table 4. Other precious metal alloys that are widely used include gold with palladium ranging up to a mass fraction at 50 % plus silver or zinc. High palladium alloys may have up to a mass fraction at 80 % palladium, with platinum, silver, tin, copper, and gallium. High-noble, single-phase alloys have the highest corrosion resistance and would be recommended, but this does not rule out exceptions or considerations on a case-by-case basis [64].

The constituents of alloy powders used with mercury to form amalgams are mass fractions at 66.7–75.5 % silver, 25.3–27.0 % tin, 0–6.0 % copper, and 0–1.9 % zinc. Spherical particles of the Ag-Cu eutectic, mass fractions at 72 % Ag-28 % Cu, are added to conventional alloy powders in a ratio of 1 part Ag-Cu:2 parts conventional powder to produce an improved amalgam. If formation of the  $\text{Sn}_{7-8}\text{Hg}$  phase occurs, increased corrosion will result. Copper additions usually prevent the formation of the  $\text{Sn}_{7-8}\text{Hg}$  phase. Physical property measurements of dental amalgams showed that copper additions resulted in low static creep and high compressive strength and comparable tensile strength and dimensional change when compared with conventional alloys [65]. There are many variations of the composition ranges for the alloy powders.

Solders are composed primarily of gold, silver, or copper with and without tin and zinc. Other metallic materials used for dental fillings in place of amalgams include cold welded silver powder [51] as mentioned earlier.

### Surface Modification

The corrosion resistance of some of the materials, especially stainless steel, can be improved by increasing the thickness of the film through further oxidization. ASTM F 86, Practice for Surface Preparation and Marking of Metallic Surgical Implants, is applicable to the iron alloys and cobalt- and nickel-based alloys. One of the final steps in ASTM F86 is a passivating treatment. Studies [66] showed that passivation treatments in either HNO<sub>3</sub> or oxygenated isotonic sodium chloride had a beneficial effect on the corrosion rate of 316 stainless steel and cobalt-chromium alloys, but had a negligible effect on the corrosion rate of titanium. The use of oxygenated isotonic NaCl was recommended for titanium and titanium alloys over HNO<sub>3</sub>. Other studies recommended the use of isotonic saline for the final washing of titanium and its alloys [14]. Steam and dry heat sterilization produce surface changes that reduce the corrosion rate for stainless steel, have a lesser effect for titanium, and have a negligible effect for Co-Cr alloys [66]. If the thicker oxide formed during passivation is not stable in the

body environment, this oxide provides an avenue for increased metal ion release. Measurements of the open circuit electrode potential over time for these metals exposed to Hanks' solution, a simulated body fluid, show that in vitro potential reaches the same value for these materials regardless of the initial oxide coating [67]. "Natural" oxide films on titanium range in thickness from 0.5-7 nm, depending on alloy composition, environmental exposure, and temperature [68].

Carbon coating of titanium and Ti-6Al-4V [69] and noble metal ion implantation followed by dealloying to enrich the percent of noble element in the surface [70] are examples of other methods used to improve corrosion resistance. Promising treatments such as these need further study, especially regarding corrosion-fatigue, susceptibility to pitting, and long-term behavior. Indications are that the carbon coating on the cobalt-chromium-molybdenum alloy causes a decrease in corrosion resistance due to chromium depletion in the matrix [71].

Hydroxyapatite is the main mineral constituent of bone, and it was expected to accelerate bone formation and to have the added benefit of shielding the bone from the metal. Initially, the accelerated bone growth occurs. Questions regarding hydroxyapatite coatings include the chemical composition of the coating after application, the nature of the metal/coating interface, the strength of the metal/coating

interface bond, and the needed thickness of the coating. The chemistry of hydroxyapatite has been discussed [72]. There are numerous literature references on hydroxyapatite and hydroxyapatite coatings.

## MINIMIZATION OF CORROSION

### Corrosion of Metals and Alloys

Base metals and alloys used in medical and dental devices are corrosion-resistant due to the presence of an oxide film on the surface that is protective [49]. These materials are not corrosion-resistant initially as is evident from their positions in the electromotive force series. The galvanic series, a listing of electrode potentials measured in seawater, indicates the changes in the noble and active tendencies of these materials in practical use for this given environment. Passivity is dependent on environmental factors such as solution pH, temperature, ions, oxygen, etc. Some ways of minimizing corrosion of these materials follow. Others are given in the discussion of the types of corrosion that can occur.

1. The surface preparation procedures described in ASTM F 86 passivate stainless steels and cobalt alloys. Titanium materials do not require this passivation. It is not clear what the ideal surface for the metal implants should be, and this will continue to be an aspect of studies relating to interfaces of these materials with the body. The condition of the surface may influence ion release.
2. Another way to minimize corrosion is to shield the metal from the body by a coating such as the hydroxyapatite coatings, but this procedure presents problems of cracking of the hydroxyapatite coating and integrity of bonding of the hydroxyapatite to the metal.
3. An important consideration for the minimization of corrosion of load bearing implants is to control the microstructure and surface conditions to give the highest corrosion-fatigue strength.

Corrosion of metal implants has been reviewed previously [5,18,49,73], and references are cited to numerous other studies relating to corrosion of implants. In vivo testing is covered in Chapter 42 of this manual. Corrosion occurs initially due to difference in potential of the anodic and cathodic sites and the tendency to establish the most stable system for a metal in an environment. The change in free energy associated with electrochemical reactions is  $\Delta G = -nFE$ , where  $\Delta G$  is the change in free energy,  $n$  is the number of electrons,  $F$  is the Faraday constant, and  $E$  is the cell potential. A negative  $\Delta G$  increases the tendency for corrosion to occur. During corrosion, one equivalent weight of metal ions is released for every 96 500 coulombs (1 Faraday) of electricity passed through the solution. Representative chemical reactions in an aqueous environment are:

- (1) anodic (loss of electrons) (2) cathodic (gain of electrons)

At physiological pH 7.4, the most probable reduction reaction is  $\text{O}_2 + \text{H}_2\text{O} + 4\text{e}^- = 4\text{OH}^-$ . At the corrosion potential,

the open circuit potential of a metal in a given environment, anodic and cathodic reactions occur at equal rates. Extensions of the anodic and cathodic curves result in Evan's diagrams that are used to show which reaction is controlling the corrosion process. One of the reactions, either anodic or cathodic, often dominates the process, and there will be a shift in the slope of the anodic or cathodic line to indicate this control. These reactions occur at cathodic and anodic sites on the metal or these sites can be on dissimilar metals that are electrically connected. The driving force for corrosion reactions to occur is the difference in potential between the anodic and cathodic sites.

ASTM G 3 (Practice for Conventions Applicable to Electrochemical Measurements in Corrosion Testing) [74] and Refs 49, 55, and 73 show the schematics for the apparatus for corrosion measurements and schematic drawings for cathodic and anodic polarization diagrams and polarization plots. ASTM G 5 (Standard Reference Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements) [74] and ASTM F 4 [55] test methods and practices describe the setup and procedures for making potentiostatic and potentiodynamic anodic polarization measurements. A cyclic polarization curve that contains both the cathodic and anodic portions provides data that can be used to describe corrosion behavior in terms of passivity, breakdown, corrosion rate, and susceptibility to pitting.

Pourbaix diagrams [75] are plots that describe the thermodynamically stable chemical species that exist for various pH and potential values for a given metal and set of electrolyte conditions. These diagrams indicate potential/pH ranges of immunity, corrosion, and passivity and are useful as guides to study effects of electrode potential and solution pH.

## TYPES OF CORROSION CONSIDERED

Many of the types of corrosion are localized in nature. These various types of corrosion will be described briefly here and additional information may be found in other references and chapters of this manual. The types of corrosion are pitting, crevice corrosion, fretting, corrosion-fatigue, stress-corrosion cracking (SCC), intergranular corrosion, and galvanic corrosion. In addition to the localized types of corrosion, the chemical dissolution or change of surface films that occurs after implantation is important. Interface reactions and initial reactions of the implant with the body are recognized as factors in implant success.

### Pitting

Pitting is an extreme and severe form of localized corrosion where the anode usually is smaller than the cathode, resulting in a high current density at the pit site and release of significant amounts of metal ions. Pitting causes visible and unknown damage as well as the release of metal ions. Pit initiation can result from a break in the protective film, inclusions or defects in the metal, defects in the film, etc. The first corrosion test method developed by the ASTM Joint F4/G1 Corrosion Section, ASTM F 746, was for screening materials for susceptibility to pitting or crevice corrosion, or both [55,74]. Pitting corrosion also can be assessed

by studying the pit propagation rate [76,77]. Pitting cannot be tolerated for surgical implant materials for a number of reasons, including the release of metal ions and the possibility of serving as a crack initiator in the relatively small piece. The cyclic polarization method of ASTM G 61 (Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-based Alloys) [74] can be used for determining a tendency to pitting. This analysis is based on hysteresis in the return curve compared to the original curve, but interpretation of these cyclic polarization curves is required since other parameters can be responsible for the hysteresis. Pitting resistance of implant metals [78] and of Co-Cr-Mo [79–81] and Co-Ni-Mo alloys [81] has been studied.

### Crevice Corrosion

Crevice corrosion is a localized attack similar to pitting that occurs when an area of the metal is shielded from the environment. This can happen at threaded junctions, screw heads, etc. Metals and alloys not susceptible to pitting can undergo crevice corrosion. Crevice corrosion often can be avoided by design. In vitro tests [79] of Co-Cr-Mo indicated that crevice corrosion possibly could occur. In vivo tests in animals after two years showed no crevice corrosion of Co-Cr-Mo [80,81].

### Corrosion-Fatigue

Corrosion-fatigue occurs as a result of the complementary action of corrosion and mechanical damage. ASTM F 1801-97 is a Standard Practice for Corrosion Fatigue Testing of Metallic Implant Materials [55]. One of the most important requirements for load bearing implants, subjected to cyclic motion, is corrosion-fatigue resistance. Materials that undergo degradation in a corrosive environment do not have a corrosion-fatigue limit in the S/N (stress or applied shear strain amplitude versus number of cycles to failure) curves, below which there is no failure [49]. Fatigue tests of 316L stainless steel [82,83] and Co-Cr-Mo [84] in aqueous solution show a decrease in fatigue strength when compared to the fatigue strength measured in air. Comparison of results [37,85] showed only a slight decrease of fatigue strength for the Ti-6Al-4V alloy when tested in Hanks's solution instead of air. Another aspect of fatigue measurements, cycle frequency, may not significantly affect the fatigue strength when testing in air, but corrosion-fatigue measurements made in a corrosive medium are affected by cycle frequency. High frequencies in corrosion-fatigue testing will result in higher fatigue strengths compared to fatigue strengths from test runs at low frequencies that simulate in vivo loading in walking, such as 1 Hz. A frequency of 1 Hz has been used for many corrosion-fatigue tests. Microstructures and surface conditions influence corrosion-fatigue strength. Corrosion-fatigue measurements of implant metals and effects of heat treating Ti-6Al-4V have been discussed, and it was shown that the corrosion-fatigue life could be increased by heat treating at 900°C and rapid quenching [85]. The rate of quenching is difficult to control. The specification for Ti-6Al-4V, ASTM F 136 (Specification for Wrought Titanium 6Al-4V ELI Alloy for Surgical Implant

Applications) [55] is for the annealed form and contains specific microstructural requirements.

### Stress Corrosion Cracking

Stress corrosion cracking (SCC) is the result of a metal being subjected to a tensile stress in a corroding medium [86]. SCC appears to be complex and more than one mechanism may be involved. One mechanism involves film rupture and dissolution, where preferred anodic dissolution of the crack tip is enhanced due to plastic deformation that occurs at the area exposed by the break in the film. Another postulated mechanism involves the absorption of ions in the strained areas at the crack tip resulting in weakening the bonds within the metal and the film. Another possible explanation is that SCC is a series of brittle fractures. SCC is different from corrosion-fatigue in that the load is static. Fractures resulting from SCC exhibit more branching than those from the more direct paths of corrosion-fatigue fractures. Hydrogen embrittlement is related to SCC and corrosion fatigue, but the difference is that hydrogen embrittlement is caused by the absorption of hydrogen. This hydrogen absorption embrittles the metal and causes cracking. Studies of Co-Cr-Mo alloys in Ringer's solution showed these alloys to be subject to hydrogen embrittlement [87]. SCC generally is not considered to be a problem with surgical implant metals in use at present, and it is mentioned here for information.

### Fretting Corrosion

Fretting, a complementary process of wear and corrosion occurs when a small amplitude relative oscillatory motion between two surfaces that are in contact causes a disruption of the passive film. The passive film is removed by abrasion and other damage, leaving the underlying metal to repassivate by forming another oxide film. Debris produced can serve to accelerate abrasion, and debris can be released into the body. Implant metals require an oxide film for passivity, and will be subject to crevice corrosion. Fretting can occur in articulating devices or at screw plate junctions and in other similar arrangements. When possible, it is best to avoid circumstances or designs in which fretting could occur and to make efforts to prevent it. Wear is an aspect of fretting, and is an important consideration for articulating joints [44] and for dental uses [45].

### Intergranular Corrosion

Grain boundaries or areas adjacent to grain boundaries can become depleted or enriched in elements or compounds. Grain boundaries are regions of crystallographic disorder where contaminants and second phase precipitation are found. This can cause the grain boundary or adjacent area to become either anodic or cathodic to the rest of the grain, and the result is intergranular corrosion.

### Galvanic Corrosion

Galvanic corrosion occurs between dissimilar metals that are in contact and have a difference in potential. The less

noble metal is the anode and the other metal is the cathode. The surface area ratio of the anode to the cathode is important. Reactions at a small anode relative to the cathode will produce high current densities while low current densities result if the ratio is reversed and the anode is large. There are cases where combining dissimilar metals results in improved protection for the less noble alloy. Titanium combined with platinum in acid solutions is an example of this [62,79]. In the case of titanium/platinum, the corrosion potential of the titanium is moved from the active region to the passive region. Combining dissimilar metals for any application, and especially for implants, should not be done without applying corrosion principles and testing. Tests of selected surgical implant metals [88–91] indicate that it would be possible to use coupled or dissimilar metals. Recent analyses of numerous retrieved total hip prostheses made of two of these selected metals [91–93], Co-Cr-Mo head coupled with a Ti-6Al-4V stem for the femoral component, gave conflicting reports. One study [92] included 48 of these coupled metal hip prostheses and concluded that no corrosion had occurred in a period below 9.8 months but corrosion had occurred in all components that had been in place longer than 40 months. Another study, involving analysis of 18 Co-Cr-Mo/Ti-6Al-4V prostheses and eight alumina/Al<sub>2</sub>O<sub>3</sub>/Ti-6Al-4V prostheses that had been implanted for 36–60 months, showed no evidence of corrosion or pitting on either of the metal surfaces. Fretting had occurred in one instance with the Co-Cr-Mo/Ti-6Al-4V prosthesis and in two cases with the alumina/Ti-6Al-4V prosthesis [93]. A report of eight Co-Cr-Mo/Ti-6Al-4V prostheses that had been taken from a larger sample showed no significant alloy corrosion at the interfaces. This report cautioned against usage of the combined materials if any motion could occur at the contact zone [94]. Other laboratory studies indicated that coupling cobalt and titanium alloys did not result in short term corrosion unless fretting occurred [95]. A discussion of possible mechanisms for corrosion of the coupled alloys concluded that controlled laboratory electrochemical testing correlated with retrieval studies is needed [96]. While it is useful to combine the advantages of two different alloys in a single prosthesis, the coupling may cause corrosion problems even when not predicted from corrosion tests that do not consider fretting. The problems may arise from design or reduced tolerances arising from manufacturing or surgical placement that permits micromotion between parts. Micromotion may destroy the passive film and negate conditions that otherwise would have permitted the use of dissimilar metals.

In dentistry, the presence of amalgams and various alloys in the mouth poses potential corrosion problems if an electrical connection occurs. Growing numbers of dental implants increase the possibility for corrosion in the mouth, and consideration should be given to suprastructure metals that are used with implants.

## DESCRIPTION OF CORROSION ENVIRONMENTS

Environments used in vitro testing are saline in nature with various additions. A comparison of in vitro and in vivo

**TABLE 5**—Composition of Hanks' solution.

Solution A
160 g NaCl + 8 g KCl + 4 g MgSO <sub>4</sub> 7H <sub>2</sub> O in 800 mL H <sub>2</sub> O
Solution B
2.8 g CaCl <sub>2</sub> in 100 mL H <sub>2</sub> O
Solution C
A + B + 100 mL H <sub>2</sub> O + 2 mL CHCl <sub>3</sub> (chloroform)
Solution D
1.2 g Na <sub>2</sub> HPO <sub>4</sub> 7H <sub>2</sub> O + 2.0 g KH <sub>2</sub> PO <sub>4</sub> H <sub>2</sub> O + 20.0 g glucose + 2 mL CHCl <sub>3</sub> in 800 mL H <sub>2</sub> O—diluted to 1000 mL
Solution E
1.4% NaHCO <sub>3</sub> = 7 g NaHCO <sub>3</sub> in 500 mL H <sub>2</sub> O
Final Solution
50 mL C + 50 mL D + 24 mL E + 900 mL H <sub>2</sub> O + few drops of chloroform

**TABLE 6**—Composition of Ringer's and modified Krebs-Ringer solutions.

(a) 8.6 g NaCl + 0.30 g KCl + 0.33 g CaCl <sub>2</sub> + water to make 1000 mL
(b) To 900 mL of 0.154 mol/L NaCl, add 20 mL 0.154 mol/L KCl and 20 mL 0.11 mol/L CaCl <sub>2</sub>
(c) Krebs-Ringer—100 parts by volume of 0.154 mol/L NaCl + 4 parts 0.154 mol/L KCl + 3 parts 0.11 mol/L CaCl <sub>2</sub> + 1 part 0.154 mol/L MgSO <sub>4</sub> + 21 parts 0.16 phosphate buffer.

**TABLE 7**—Composition of Fusayama's solution.

0.400 g NaCl + 0.400 g KCl + 0.795 g CaCl <sub>2</sub> 2H <sub>2</sub> O + 0.690 NaH <sub>2</sub> PO <sub>4</sub> H <sub>2</sub> O + Na <sub>2</sub> S 9H <sub>2</sub> O + 1.00 Urea + H <sub>2</sub> O to make 1000 mL.
--

tests recommended isotonic sodium chloride as an appropriate test solution for implant metals [97]. The study showed that the corrosivity of in vivo exposure for stainless steel and the corrosivity of titanium were less in vivo than in isotonic saline. Two common testing solutions relating to simulated body fluids are Hanks' and Ringer's physiological solutions. The compositions of these solutions are given in Tables 5 and 6, respectively. Table 6 gives compositions for (a) Ringer's, (b) Ringer's, and (c) Krebs-Ringer solutions. One of the artificial solutions for simulating conditions in the mouth is Fusayama's solution [98], and the content of this is given in Table 7. Proteins, amino acids, serum, or other substances, as appropriate, may be added as needed to these solutions. Ideally, Hanks's and Ringer's solutions have a pH of 7.4, the normal body pH. Fusayama's solution has a pH of 5.5, similar to the pH found in the mouth. The body pH usually is 7.4, but in cases of a wound or infection, the pH can vary from 5.4 to 7.8 [26]. Environments in in vivo testing are discussed in Chapter 42 of this manual.

## SPECIFIC PROBLEM AREAS

Problem areas include planned or inadvertently occurring coupled metals, localized corrosion such as pitting or corrosion-fatigue, and wear and fretting corrosion. Modified surfaces represent new materials that need characterization for bonding, chemistry, durability, interfaces, and appropriate thickness. Surface characterization and control on increasingly finer scales will be required.

## USE OF TEST METHODS AND PROCEDURES TO EVALUATE CORROSION

Test methods used to evaluate corrosion of medical and dental materials are found in Refs 55 and 74. Useful information and guidance on specimen preparation and testing parameters are available in the literature. The schematic drawing in Fig. 1 from ASTM G 5 [74] shows a setup for exposing a test specimen to a selected environment for corrosion testing. The main components of the test cell are the working electrode (we—specimen), the auxiliary electrode (aux—counter-electrode), and the selected reference electrode (sce—saturated calomel electrode). The reference electrode may be bridged as shown or with an adapter in the same testing container, and the bridge tip should be near the surface of the working electrode. The electrodes in the test cell must be isolated except for the part that is in the testing solution. There should be no solution/air interface at the water line, and shielding, such as glass tubing, should be used. The auxiliary electrode should have a larger surface area than the working electrode, and should be opposite the working electrode area that is being tested. Geometry is important. A surrounding counter-electrode would be best for a round specimen. Surface preparation of specimens should be the same and, for some tests, should be that of the intended use. Selected testing solutions as given in Tables 5 through 7 can be used and kept at a temperature of 37°C, which is the body temperature. The elements of this setup can be used in combined mechanical property/corrosion testing such as corrosion-fatigue, fretting, or SCC.

Potentiostatic and potentiodynamic anodic polarization measurements often are applied to medical and dental materials, and test methods in ASTM G 5 and ASTM F 4 can be used as guides along with published literature. These methods involve applying a potential to the specimen and

measuring the current. Information obtained from these tests includes the corrosion potential, the passive region (in degree and size), and the breakdown potential. ASTM G 61 is a related test method and is for conducting cyclic potentiostatic polarization measurements. This test method provides information on susceptibility to localized corrosion. Setting the applied potential to include the cathodic portion of these curves provides data for determining corrosion rates using the Stern-Geary equation [99]. ASTM G 59 (Practice for Conducting Potentiodynamic Polarization Resistance Measurements) describes a method for conducting potentiodynamic, polarization resistance measurements to determine corrosion rates using the Stern-Geary equation [99]. ASTM F 746 (Test Method for Pitting or Crevice Corrosion of Metallic Surgical Implant Materials) is a recommended practice for determining susceptibility to pitting and crevice corrosion. A standard practice for verification of algorithm and equipment for electrochemical AC impedance measurements is given in ASTM G 106 (Standard Practice for Verification of Algorithm and Equipment for Electrochemical Impedance Measurements). The AC impedance method has been used for measurements of coated surfaces [100].

## REGULATIONS

Medical and dental materials and devices are regulated by the Food and Drug Administration (FDA). The Medical Device Amendments of 1976 amended the Food Drug and Cosmetic Act of 1938 to include medical devices and diagnostic products [101]. This gave the FDA the authority to establish regulations and standards. Devices were defined to be in three classes: I, II, III. Dental materials for many applications such as fillings, crowns and bridges, solders, and restraining wires are in Classes I and II. Many of the dental materials have the approval of the American Dental Association (ADA), but this is not a necessary requirement. Dental implants are controlled by the FDA and are in Class III. The three classes may be described as follows.

Class I, General Controls—a device that is under controls other than standards and premarket approval to assure safety and effectiveness.

Class II, Performance Standards—a device for which controls are not sufficient to assure safety and effectiveness, and performance standards are needed.

Class III, Premarket Approval—a device for which insufficient information exists to assure that general controls and performance standards would provide reasonable assurance of safety and effectiveness. This device is life sustaining, life supporting, or may be implanted in the body, and represents a potentially unreasonable risk of illness or injury. Devices in this category are required to have approved applications for premarket approval.

All of the medical devices and the dental implants discussed in this paper fall in Class III. Devices, including designs and materials that were used prior to 1976 were allowed to continue based on past successful experience. Since 1976, devices could be given market clearance, without clinical testing, if it could be shown that these devices were substantially equivalent to devices used prior to 1976 or to another device that had

FIG. 1—Schematic potentiostatic anodic polarization experimental set-up.

obtained premarket approval. Premarket approval is different from market clearance in that premarket approval requires clinical testing according to a protocol from the FDA and market clearance does not. Congress passed the Safe Medical Device Act of 1990 [102], which went into effect in 1992. The 1990 Act did the following and more:

1. Established mandatory device reporting of failures, provided for post-market surveillance including the authority of the FDA to require additional studies on a device that is already on the market;
2. Gave revised rules for Class II performance standards, labeling guidelines, standards, and Class I general controls.

The 1997 FDA Modernization Reform Act [103] that took effect in February 1998 provides guidance for using FDA recognized consensus standards such as some standards of the ASTM and gives assistance for speeding up FDA approval of some medical devices. The premarket application for market clearance, 510K, may be *special* requiring only a 30 day review and modification, *abbreviated* if FDA approved consensus standards apply, or *traditional* requiring a full review. Some low risk devices are exempted from filing requirements. Experts outside the FDA are permitted to review some intermediate risk devices, and this allows the FDA more time to review devices that are considered high risk. A piece of legislation that helps protect producers of raw materials, The Biomaterials Access Assurance Act, became law in August 1998 [6]. This law exempts suppliers of raw materials from liability in lawsuits involving medical devices if the suppliers met the device manufacturer's requirements and were not negligent in any way.

The United States and the European Union (EU) have entered in Mutual Recognition Agreements (MRA), one of which is for medical devices [6]. The agreement provides for selected medium risk devices for export to the U.S. to be reviewed by the European assessment body based on FDA standards. Devices exported from the U.S. to the EU would be reviewed in the U.S. based on the EU's Medical Device Directive (MDD). While it is not practical to have MRAs throughout the world, the Global Harmonization Task Force (GHTF) composed of the U.S., EU, Canada, Australia, and New Zealand, with some Asian observers, is considering establishing uniform medical device regulations.

## OUTLOOK FOR THE FUTURE

Advances in technology and materials will continue to be studied and used, when possible, by the medical and dental industries to produce improved materials and devices. The Safe Medical Device Act of 1990 mandates reporting of failures, and this will provide data for making improvements. Future improvements also will result from other planned investigations involving retrieval and analysis of medical and dental devices. ASTM F 561, Practice for Analysis of Retrieved Metallic Orthopaedic Implants [55], gives guidelines regarding retrieval and analysis.

ASTM International established the F-4 Committee on Medical and Surgical Materials and Devices in 1964. The ASTM has established a Tissue Engineering Products

Division that will address standards for Tissue Engineering. Information on future developments in biomaterials can be obtained through the ASTM, references given here, and other sources. Corrosion testing will continue to be a part of the analysis of failures and the development of materials and methods.

# Pharmaceutical

David F. Jensen<sup>1</sup>

## GENERAL NATURE OF THE PHARMACEUTICAL INDUSTRY

IN THE PHARMACEUTICAL INDUSTRY, a number of business factors exist that tend to discourage a consistent approach to technical issues such as corrosion testing. Some of the major issues are as follows:

1. In many processes the volumes are small and very expensive, creating an economic justification for testing of all processes that is difficult to support. This leads to equipment that is flexible and can handle varied process conditions and chemistries.
2. Being first on the market with a pharmaceutical product is of major business importance. Because speed is a major issue, many technical issues (i.e., corrosion) are frequently "over engineered" from the standpoint of good engineering practices. This allows flexible equipment to be capable of handling varied conditions and chemistries to support rapid product development. This then limits the need for corrosion testing of all processes.
3. Many reactions are multi-step syntheses, frequently requiring varied chemicals and reaction conditions. Many of the reaction components are proprietary and uncommon to traditional corrosion engineering data sources. Attempting to simulate these varied uncommon chemicals and chemical environments is difficult at best.
4. In many cases the chemistry of the process is still being modified well into development, and some even into production. Successful corrosion control depends on teamwork in which all parties of the project team are aware of process changes being considered and can develop a materials compatibility strategy accordingly.
5. The percentage of products that survive from discovery to production is very small. The time from product decision to production is very small. This also drives the need for flexible equipment, and limits the ability to corrosion testing for a specific process.

Decisions regarding materials of construction are most often made using the knowledge of operating and technical personnel, and the experiences from similar chemistries, rather than testing. Factors, such as the design life of the equipment, future use for the equipment after the process

for which it is being designed is obsolete, etc., are considerations. Most pharmaceutical processes are run as campaigns that may only represent 10 % equipment use. Therefore, most equipment is not dedicated to a given process but is used for several processes. The uncertainty of the ultimate uses of the equipment has led to a fail-safe tendency to overspecifying equipment, particularly regarding the materials of construction.

## TYPES OF EQUIPMENT

In general, equipment used in the pharmaceutical industry can be divided into three categories: processing equipment, ancillary systems, and utility systems. Processing equipment can be defined as equipment used to react, transfer, hold, or in any manner come in contact with the final product or any of the intermediates leading up to the final product. Some examples of processing equipment are stills, reactors, fermentors, receivers, filtration equipment, drying equipment, crystallizers, heat exchangers, sampling systems, blending equipment, and filling equipment.

Ancillary systems are defined as those necessary for production but in which product contact is not an issue. Some examples are solvent and waste storage vessels, scrubbers, neutralization systems, and venting systems.

Utility systems are unique and in part defined as traditional utility systems and in part as processing equipment. Part of the system is supplying noncontact utilities and part of the system is supplying products that contact the final product or intermediates. One example of these dual systems is the water systems. There are the traditional cooling waters for jackets and heat exchangers, but also there are varied "clean" water systems that supply water that are used in processing intermediates or final products, as well as, being used as part of the final product formulation.

## DESCRIPTION OF MATERIALS

Construction materials of choice for processing equipment product contact surfaces are glass-lined, nickel-chromium-molybdenum alloys such as Hastelloy® C-276 (UNS-N10276) or Hastelloy® C-22 (UNS-N06022), and 300 series stainless steels, with the most common being 304L (UNS-S30403) or 316L (UNS-S31603). In addition, some construction materials often used only for product transfer or condenser

<sup>1</sup>David F. Jensen, Engineering Consultant, Eli Lilly and Company, Tippecanoe Labs, TL27, 1650 Lilly Road, Lafayette, IN 47909.

operations are tantalum, Teflon® (PTFE), and graphite. Other materials considered for special applications are titanium, zirconium, and superaustenitic stainless steels containing 6 % molybdenum, such as Allegheny-Ludlum AL-6XN® (UNS-08637) or Avesta 254-SMO® (UNS-S31254).

The effects of corrosion on processing equipment can be a source of contamination. Pitting presents a potential for batch-to-batch or product-to-product contamination, and material removed in the corrosion process becomes a product contaminant.

Materials of construction for ancillary systems are commonly carbon steel, fiberglass-reinforced plastic (FRP), epoxy- or phenolic-lined, stainless steel, and concrete. Many times waste transfer lines will change from a product contact material (near the process equipment) to carbon steel, stainless steel, or polyethylene (near the ancillary equipment). Vent lines are particularly troublesome and require special attention. Smooth surfaces (noncorrugated) with proper sloping to avoid areas for condensation and debris accumulation are essential to minimize corrosion. Smooth and sloping surfaces are also needed to aid in cleaning between campaigns.

Surface finishes are considerations regarding cleanability, particularly in processes where sterility is a major issue. Generally, if the environment is conducive to corrosion, corrosion will occur regardless of the surface finish.

## ENVIRONMENT AND ENVIRONMENTAL FACTORS

Liquid phase is the most common medium in pharmaceuticals. The most common environments include aqueous solutions, and solvents such as acetone, methylene chloride, acetates, and alcohols. Environmental factors include temperature, pH, halogen levels, and oxidizing/reducing atmospheres. Process temperatures typically range from  $-70^{\circ}\text{C}$  to  $+150^{\circ}\text{C}$ . Low temperature is a concern mainly relating to the material's mechanical properties. For example, carbon steel develops brittle characteristics and many of the elastomers, that have high chemical resistance, lose their elastomeric properties below  $-20^{\circ}\text{C}$ . The pH values range from lows of less than 1 and highs of 14. Chloride levels greater than 100 ppm are normally viewed as a corrosion concern, especially at pH values less than neutral. At elevated temperatures and high stress levels even a few ppm of chlorides can promote corrosion. Strong oxidizing environments such as hydrogen peroxide, sodium hypochlorite, and ozone generally

are not major corrosion concerns. Since hydrochloric acid is used and handled in varied concentrations and ways, this is an ongoing challenge.

Most often the chemistry of the process is the driving force for corrosion concerns. Reducing environments are generally not a concern. Erosion from high flow areas such as agitation is not usually a problem or a concern. In the waste handling areas, constant variation in chemistries and conditions are the challenge, making testing more difficult.

## TESTING

The decision to test is usually driven by unusual chemistry such as a new catalyst, reaction components, or reaction conditions. Immersion/mass loss method is primarily used in conjunction with microscopic examination. Process fluids from production or pilot runs are primarily used to best simulate potential corrosion. The test methods are custom designed based, in part, on cost and the ability to obtain sufficient quantities of test fluids, and handle the process conditions. Process conditions are tested outside the process control limits (e.g., temperatures, pH) to better accentuate the corrosion potential. These extremes have to be tempered by the stability of the products in the stream. For wall thicknesses greater than 0.250 in. (6.35 mm), a uniform loss of less than 10 mil/year (0.26 mm/year) is considered structurally acceptable. Significantly lower levels of uniform loss are of concern for product or process contamination issues. Microscopic examination is used to determine potential localized corrosion concerns, such as pitting or stress cracking. Indications of pitting or stress corrosion in stamped areas of the coupon are of particular concern. U-bend tests are rarely used because of insufficient test fluid quantities and availability.

## UNRESOLVED ISSUES IN CORROSION TESTING

More affordable corrosion tests need to be developed with consideration given to the nature of the pharmaceutical industry. The ability to corrosion test in small test volumes (e.g., 50 mL or less), perform accelerated corrosion tests with temperature sensitive products, and perform testing in systems that cannot be run in glass would be a considerable step in promoting corrosion testing.

## ASTM INTERNATIONAL

### Corrosion of Metals

- A 262 Standard Practices for Detecting Susceptibility to Intergranular Attack in Austenitic Stainless Steels  
 A 763 Standard Practices for Detecting Susceptibility to Intergranular Attack in Ferritic Stainless Steels  
 G 1 Standard Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens  
 G 2 Standard Test Method for Corrosion Testing of Products of Zirconium, Hafnium, and their Alloys in Water at 633°K or in Steam at 673°K [Metric]  
 G 4 Standard Guide for Conducting Corrosion Coupon Tests in Field Applications  
 G 15 Standard Terminology Relating to Corrosion and Corrosion Testing  
 G 16 Standard Guide for Applying Statistics to Analysis of Corrosion Data  
 G 28 Standard Test Methods of Detecting Susceptibility to Intergranular Corrosion in Wrought, Nickel-Rich, Chromium-Bearing Alloys

## 852 CORROSION TESTS AND STANDARDS MANUAL

- G 31 Standard Practice for Laboratory Immersion Corrosion Testing of Metals
- G 34 Standard Test Method for Exfoliation Corrosion Susceptibility in 2XXX and 7XXX Series Aluminum Alloys (EXCO Test)
- G 44 Standard Practice for Exposure of Metals and Alloys by Alternate Immersion in Neutral 3.5% Sodium Chloride Solution
- G 46 Standard Guide for Examination and Evaluation of Pitting Corrosion
- G 48 Standard Test Methods for Pitting and Crevice Corrosion Resistance of Stainless Steels and Related Alloys by Use of Ferric Chloride Solution
- G 52 Standard Practice for Exposing and Evaluating Metals and Alloys in Surface Seawater
- G 54 Standard Practice for Simple Static Oxidation Testing
- G 66 Standard Test Method for Visual Assessment of Exfoliation Corrosion Susceptibility of 5XXX Series Aluminum Alloys (ASSET Test)
- G 67 Standard Test Method for Determining the Susceptibility to Intergranular Corrosion of 5XXX Series Aluminum Alloys by Mass Loss After Exposure to Nitric Acid (NAMLT Test)
- G 78 Standard Guide for Crevice Corrosion Testing of Iron-Base and Nickel-Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environments
- G 79 Standard Practice for Evaluation of Metals Exposed to Carburization Environments
- G 107 Standard Guide for Formats for Collection and Compilation of Corrosion Data for Metals for Computerized Database Input
- G 109 Standard Test Method for Determining the Effects of Chemical Admixtures on the Corrosion of Embedded Steel Reinforcement in Concrete
- G 110 Standard Practice for Evaluating Intergranular Corrosion Resistance of Heat Treatable Aluminum Alloys by Immersion in Sodium Chloride + Hydrogen Peroxide Solution
- G 111 Standard Guide for Corrosion Tests in High Temperature or High Pressure Environment, or Both
- G 112 Standard Guide for Conducting Exfoliation Corrosion Tests in Aluminum Alloys
- G 117 Standard Guide for Calculating and Reporting Measures of Precision Using Data from Interlaboratory Wear or Erosion Tests
- G 135 Standard Guide for Computerized Exchange of Corrosion Data for Metals
- G 142 Standard Test Method for Determination of Susceptibility of Metals to Embrittlement in Hydrogen Containing Environments at High Pressure, High Temperature, or Both
- G 146 Standard Practice for Evaluation of Disbonding of Bimetallic Stainless Alloy/Steel Plate for Use in High-Pressure, High-Temperature Refinery Hydrogen Service
- G 157 Standard Guide for Evaluating the Corrosion Properties of Wrought Iron- and Nickel-Based Corrosion Resistant Alloys for the Chemical Process Industries
- G 161 Standard Guide for Corrosion-Related Failure Analysis
- G 170 Standard Guide for Evaluating and Qualifying Oilfield and Refining Corrosion Inhibitors in the Laboratory

### Corrosion of Non-Metals

- G 131 Standard Practice for Cleaning of Materials and Components by Ultrasonic Techniques
- G 166 Standard Guide for Statistical Analysis of Service Life Data

### Corrosion of Pipeline Coatings

- G 6 Standard Test Method for Abrasion Resistance of Pipeline Coatings
- G 8 Standard Test Methods for Cathodic Disbonding of Pipeline Coatings
- G 9 Standard Test Method for Water Penetration into Pipeline Coatings
- G 11 Standard Test Method for Effects of Outdoor Weathering on Pipeline Coatings
- G 12 Standard Test Method for Nondestructive Measurement of Film Thickness of Pipeline Coatings on Steel
- G 17 Standard Test Method for Penetration Resistance of Pipeline Coatings (Blunt Rod)
- G 19 Standard Test Method for Disbonding Characteristics of Pipeline Coatings by Direct Soil Burial
- G 20 Standard Test Method for Chemical Resistance of Pipeline Coatings
- G 42 Standard Test Method for Cathodic Disbonding of Pipeline Coatings Subjected to Elevated Temperatures
- G 62 Standard Test Methods for Holiday Detection in Pipeline Coatings
- G 80 Standard Test Method for Specific Cathodic Disbonding of Pipeline Coatings
- G 95 Standard Test Method for Cathodic Disbondment Test of Pipeline Coatings (Attached Cell Method)

### Atmospheric Corrosion

- B 117 Standard Practice for Operating Salt Spray (Fog) Apparatus
- B 368 Standard Test Method for Copper-Accelerated Acetic Acid-Salt Spray (Fog) Testing (CASS Test)

B 537	Standard Practice for Rating of Electroplated Panels Subjected to Atmospheric Exposure
B 810	Standard Test Method for Calibration of Atmospheric Corrosion Test Chambers by Change in Mass of Copper Coupons
B 827	Practice for Conducting Mixed Flowing Gas (MFG) Environmental Tests
D 2059	Standard Test Method for Resistance of Zippers to Salt Spray (Fog)
D 4585	Standard Practice for Testing Water Resistance of Coatings Using Controlled Condensation
G 7	Standard Practice for Atmospheric Environmental Exposure Testing of Nonmetallic Materials
G 33	Standard Practice for Recording Data from Atmospheric Corrosion Tests of Metallic-Coated Steel Specimens
G 50	Standard Practice for Conducting Atmospheric Corrosion Tests on Metals
G 60	Standard Test Method for Conducting Cyclic Humidity Tests
G 84	Standard Practice for Measurement of Time-of-Wetness on Surfaces Exposed to Wetting Conditions as in Atmospheric Corrosion Testing
G 85	Standard Practice for Modified Salt Spray (Fog) Testing
G 87	Standard Practice for Conducting Moist SO <sub>2</sub> Tests
G 90	Standard Practice for Performing Accelerated Outdoor Weathering of Nonmetallic Materials Using Concentrated Natural Sunlight
G 91	Standard Practice for Monitoring Atmospheric SO <sub>2</sub> Using the Sulfation Plate Technique
G 92	Standard Practice for Characterization of Atmospheric Test Sites
G 101	Standard Guide for Estimating the Atmospheric Corrosion Resistance of Low-Alloy Steels
G 113	Standard Terminology Relating to Natural and Artificial Weathering Tests of Nonmetallic Materials
G 116	Standard Practice for Conducting Wire-on-Bolt Test for Atmospheric Galvanic Corrosion
G 140	Standard Test Method for Determining Atmospheric Chloride Deposition Rate by Wet Candle Method
G 141	Standard Guide for Addressing Variability in Exposure Testing on Nonmetallic Materials
G 147	Standard Practice for Conditioning and Handling of Nonmetallic Materials for Natural and Artificial Weathering Tests
G 149	Standard Practice for Conducting the Washer Test for Atmospheric Galvanic Corrosion
G 156	Standard Practice for Selecting and Characterizing Weathering Reference Materials Used to Monitor Consistency of Conditions in an Exposure Test

### Environmentally Influenced Cracking

A 143	Standard Practice for Safeguarding Against Embrittlement of Hot-Dip Galvanized Structural Steel Products and Procedure for Detecting Embrittlement
B 577	Standard Test Methods for Detection of Cuprous Oxide (Hydrogen Embrittlement Susceptibility) in Copper
B 858	Standard Test Method for Determination of Susceptibility to Stress Corrosion Cracking in Copper Alloys Using an Ammonia Vapor Test
C 692	Standard Test Method for Evaluating the Influence of Thermal Insulations on External Stress Corrosion Cracking Tendency of Austenitic Stainless Steel
F 326	Standard Test Method for Electronic Measurement for Hydrogen Embrittlement from Cadmium-Electroplating Processes
F 519	Standard Test Method for Mechanical Hydrogen Embrittlement Evaluation of Plating Processes and Service Environments
F 945	Standard Test Method for Stress-Corrosion of Titanium Alloys by Aircraft Engine Cleaning Materials
G 30	Standard Practice for Making and Using U-Bend Stress-Corrosion Test Specimens
G 35	Standard Practice for Determining the Susceptibility of Stainless Steels and Related Nickel-Chromium-Iron Alloys to Stress-Corrosion Cracking in Polythionic Acids
G 36	Standard Practice for Evaluating Stress-Corrosion-Cracking Resistance of Metals and Alloys in a Boiling Magnesium Chloride Solution
G 37	Standard Practice for Use of Mattsson's Solution of pH 7.2 to Evaluate the Stress-Corrosion Cracking Susceptibility of Copper-Zinc Alloys
G 38	Standard Practice for Making and Using C-Ring Stress-Corrosion Test Specimens
G 39	Standard Practice for Preparation and Use of Bent-Beam Stress-Corrosion Test Specimens
G 41	Standard Practice for Determining Cracking Susceptibility of Metals Exposed Under Stress to a Hot Salt Environment
G 47	Standard Test Method for Determining Susceptibility to Stress-Corrosion Cracking of 2XXX and 7XXX Aluminum Alloy Products
G 49	Standard Practice for Preparation and Use of Direct Tension Stress-Corrosion Test Specimens
G 58	Standard Practice for Preparation of Stress-Corrosion Test Specimens for Weldments
G 64	Standard Classification of Resistance to Stress-Corrosion Cracking of Heat-Treatable Aluminum Alloys

## 854 CORROSION TESTS AND STANDARDS MANUAL

- G 103 Standard Test Method for Performing Stress-Corrosion Cracking Resistance of Low Copper 7XXX Series Al-Zn-Mg-Cu Alloys in Boiling 6% Sodium Chloride Solution
- G 123 Standard Test Method for Evaluating Stress-Corrosion Cracking of Stainless Alloys with Different Nickel Content in Boiling Acidified Sodium Chloride Solution
- G 129 Standard Practice for Slow Strain Rate Testing to Evaluate the Susceptibility of Metallic Materials to Environmentally Assisted Cracking
- G 139 Standard Test Method for Determining Stress-Corrosion Cracking Resistance of Heat-Treatable Aluminum Alloy Products Using Breaking Load Method
- G 148 Standard Practice for Evaluation of Hydrogen Uptake, Permeation, and Transport in Metals by an Electrochemical Technique
- G 168 Standard Practice for Making and Using Precracked Double Beam Stress Corrosion Specimens

### **Wear and Abrasion**

- D 2809 Standard Test Method for Cavitation Corrosion and Erosion-Corrosion Characteristics of Aluminum Pumps with Engine Coolants
- F 897 Standard Test Method for Measuring Fretting Corrosion of Osteosynthesis Plates and Screws
- G 32 Standard Test Method for Cavitation Erosion Using Vibratory Apparatus
- G 40 Standard Terminology Relating to Wear and Erosion
- G 65 Standard Test Method for Measuring Abrasion Using the Dry Sand/Rubber Wheel Apparatus
- G 73 Standard Practice for Liquid Impingement Erosion Testing
- G 75 Standard Test Method for Determination of Slurry Abrasivity (Miller Number) and Slurry Abrasion Response of Materials (SAR Number)
- G 76 Standard Test Method for Conducting Erosion Tests by Solid Particle Impingement Using Gas Jets
- G 77 Standard Test Method for Ranking Resistance of Materials to Sliding Wear Using Block-on-Ring Wear Test
- G 83 Standard Test Method for Wear Testing with a Crossed-Cylinder Apparatus
- G 98 Standard Test Method for Galling Resistance of Materials
- G 99 Standard Test Method for Wear Testing with a Pin-on-Disk Apparatus
- G 105 Standard Test Method for Conducting Wet Sand/Rubber Wheel Abrasion Tests
- G 118 Standard Guide for Recommended Data Format of Wear Test Data Suitable for Databases
- G 119 Standard Guide for Determining Synergism Between Wear and Corrosion
- G 134 Standard Test Method for Erosion of Solid Materials by a Cavitating Liquid Jet
- G 163 Standard Guide for Digital Data Acquisition in Wear and Friction Measurements

### **Soils**

- G 51 Standard Test Method for Measuring pH of Soil for Use in Corrosion Testing
- G 57 Standard Test Method for Field Measurement of Soil Resistivity Using the Wenner Four-Electrode Method
- G 97 Standard Test Method for Laboratory Evaluation of Magnesium Sacrificial Anode Test Specimens for Underground Applications
- G 158 Standard Guide for Three Methods of Assessing Buried Steel Tanks
- G 160 Standard Practice for Evaluating Microbial Susceptibility of Nonmetallic Materials by Laboratory Soil Burial
- G 162 Standard Practice for Conducting and Evaluating Laboratory Corrosion Tests in Soils
- G 165 Standard Practice for Determining Rail-to-Earth Resistance

### **Electrochemical Testing**

- B 457 Standard Test Method for Measurement of Impedance of Anodic Coatings on Aluminum
- G 3 Standard Practice for Conventions Applicable to Electrochemical Measurements in Corrosion Testing
- G 5 Test Method for Making Potentiostatic and Potentiodynamic Anodic Polarization Measurements
- G 59 Standard Practice for Conducting Potentiodynamic Polarization Resistance Measurements
- G 61 Standard Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of Iron-, Nickel-, or Cobalt-Based Alloys
- G 69 Standard Test Method for Measurement of Corrosion Potentials of Aluminum Alloys
- G 71 Standard Guide for Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes
- G 82 Standard Guide for Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance
- G 96 Standard Guide for On-Line Monitoring of Corrosion in Plant Equipment (Electrical and Electrochemical Methods)

G 100	Standard Test Method for Conducting Cyclic Galvanostaircase Polarization
G 102	Standard Practice for Calculation of Corrosion Rates and Related Information from Electrochemical Measurements
G 106	Standard Practice for Verification of Algorithm and Equipment for Electrochemical Impedance Measurements
G 108	Standard Test Method for Electrochemical Reactivation (EPR) for Detecting Sensitization of AISI Type 304 and 304L Stainless Steels Exposed to Chloride Environments
G 150	Standard Test Method for Electrochemical Critical Pitting Temperature Testing of Stainless Steels

### Electrodeposited Coatings

B 380	Standard Test Method of Corrosion Testing of Decorative Electrodeposited Coatings by the Corrodokote Procedure
B 545	Standard Specification for Electrodeposited Coatings of Tin
B 605	Standard Specification for Electrodeposited Coatings of Tin-Nickel Alloy
B 650	Standard Specification for Electrodeposited Engineering Chromium Coatings on Ferrous Substrates
B 651	Standard Test Method for Measurement of Corrosion Sites in Nickel Plus Chromium or Copper Plus Nickel Plus Chromium Electroplated Surfaces with the Double-Beam Interference Microscope
B 680	Standard Test Method for Seal Quality of Anodic Coatings on Aluminum by Acid Dissolution
B 689	Standard Specification for Electroplated Engineering Nickel Coatings
B 733	Standard Specification for Autocatalytic (Electroless) Nickel-Phosphorus Coatings on Metal
B 734	Standard Specification for Electrodeposited Copper for Engineering Uses
B 735	Standard Test Method for Porosity in Gold Coatings on Metal Substrates by Nitric Acid Vapor
B 741	Standard Test Method for Porosity in Gold Coatings on Metal Substrates by Paper Electrography
B 765	Standard Guide for Selection of Porosity Tests for Electrodeposits and Related Metallic Coatings
B 809	Standard Test Method for Porosity in Metallic Coatings by Humid Sulfur Vapor ("Flowers-of-Sulfur")

### Applications

A 380	Standard Practice for Cleaning, Descaling, and Passivation of Stainless Steel Parts, Equipment, and Systems
B 76	Standard Test Method for Accelerated Life of Nickel-Chromium and Nickel-Chromium-Iron Alloys for Electrical Heating
B 78	Standard Test Method of Accelerated Life of Iron-Chromium-Aluminum Alloys for Electrical Heating
B 154	Standard Test Method for Mercurous Nitrate Test for Copper and Copper Alloys
C 739	Standard Specification for Cellulosic Fiber (Wood-Base) Loose-Fill Thermal Insulation
C 876	Standard Test Method for Half-Cell Potentials of Uncoated Reinforcing Steel in Concrete
D 130	Standard Test Method for Detection of Copper Corrosion from Petroleum Products by the Copper Strip Tarnish Test
D 610	Standard Test Method for Evaluating Degree of Rusting on Painted Steel Surfaces
D 665	Standard Test Method for Rust-Preventing Characteristics of Inhibited Mineral Oil in the Presence of Water
D 849	Standard Test Method for Copper Strip Corrosion by Industrial Aromatic Hydrocarbons
D 876	Standard Test Methods for Nonrigid Vinyl Chloride Polymer Tubing Used for Electrical Insulation
D 1141	Standard Practice for Substitute Ocean Water
D 1193	Standard Specification for Reagent Water
D 1280	Standard Test Method for Total Immersion Corrosion Test for Soak Tank Metal Cleaners
D 1384	Standard Test Method for Corrosion Test for Engine Coolants in Glassware
D 1414	Standard Test Methods for Rubber O-Rings
D 1611	Standard Test Method for Corrosion Produced by Leather in Contact with Metal
D 1654	Standard Test Method for Evaluation of Painted or Coated Specimens Subjected to Corrosive Environments
D 1743	Standard Test Method for Determining Corrosion Preventive Properties of Lubricating Greases
D 1838	Standard Test Method for Copper Strip Corrosion by Liquefied Petroleum (LP) Gases
D 2247	Standard Practice for Testing Water Resistance of Coatings in 100 % Relative Humidity
D 2251	Standard Test Method for Metal Corrosion by Halogenated Organic Solvents and Their Admixtures
D 2570	Standard Test Method for Simulated Service Corrosion Testing of Engine Coolants
D 2649	Standard Test Method for Corrosion Characteristics of Solid Film Lubricants
D 2671	Standard Test Methods for Heat-Shrinkable Tubing for Electrical Use
D 2758	Standard Test Method for Engine Coolants by Engine Dynamometer

## 856 CORROSION TESTS AND STANDARDS MANUAL

D 2803	Standard Guide for Testing Filiform Corrosion Resistance of Organic Coatings on Metal
D 2847	Standard Practice for Testing Engine Coolants in Car and Light Truck Service
D 3263	Standard Test Methods for Corrosivity of Solvent Systems for Removing Water-Formed Deposits
D 3310	Standard Test Method for Determining Corrosivity of Adhesive Materials
D 3316	Standard Test Method for Stability of Perchloroethylene with Copper
D 3482	Standard Test Method for Determining Electrolytic Corrosion of Copper by Adhesives
D 3603	Standard Test Method for Rust-Preventing Characteristics of Steam Turbine Oil in the Presence of Water (Horizontal Disk Method)
D 4048	Standard Test Method for Detection of Copper Corrosion from Lubricating Grease
D 4340	Standard Test Method for Corrosion of Cast Aluminum Alloys in Engine Coolants Under Heat-Rejecting Conditions
D 4627	Standard Test Method for Iron Chip Corrosion for Water-Dilutable Metalworking Fluids
E 712	Standard Practice for Laboratory Screening of Metallic Containment Materials for Use With Liquids in Solar Heating and Cooling Systems
E 745	Standard Practices for Simulated Service Testing for Corrosion of Metallic Containment Materials for Use With Heat-Transfer Fluids in Solar Heating and Cooling Systems
E 937	Standard Test Method for Corrosion of Steel by Sprayed Fire-Resistive Material (SFRM) Applied to Structural Members
F 359	Standard Practice for Static Immersion Testing of Unstressed Materials in Nitrogen Tetroxide (N <sub>2</sub> O <sub>4</sub> )
F 482	Standard Test Method for Corrosion of Aircraft Metals by Total Immersion in Maintenance Chemicals
F 483	Standard Test Method for Total Immersion Corrosion Test for Aircraft Maintenance Chemicals
F 746	Standard Test Method for Pitting or Crevice Corrosion of Metallic Surgical Implant Materials
F 1089	Standard Test Method for Corrosion of Surgical Instruments
F 1110	Standard Test Method for Sandwich Corrosion Test

## INTERNATIONAL ELECTROTECHNICAL COMMISSION (IEC)

60068-2-18	Environmental testing—Part 2 –18: Tests—Test R and guidance: Water
60068-2-43	Environmental testing—Part 2: Tests—Test Kd: Hydrogen sulphide test for contacts and connections
60068-2-60	Environmental testing—Part 2: Tests—Test Ke: Flowing mixed gas corrosion test
60068-2-66	Environmental testing—Part 2: Test methods—Test Cx: Damp heat, steady state (unsaturated pressurized vapour)
60068-2-67	Environmental testing—Part 2: Tests—Test Cy: Damp heat, steady state, accelerated test primarily intended for components
60068-2-74	Environmental testing—Part 2: Test Xc: Fluid contamination
TR 60355	An appraisal of the problems of accelerated testing for atmospheric corrosion
60426	Test methods for determining electrolytic corrosion with insulating materials
60512-11-7	Electrochemical components for electronic equipment—Basic testing procedures and measuring methods—Part 11: Climatic tests—Section 7: Test 11g: Flowing mixed gas corrosion test
60512-11-14	Electromechanical components for electronic equipment—Basic testing procedures and measuring methods—Part 11: Climatic tests—Section 14: Test 11p: Flowing single gas corrosion test
60695-5-1	Fire hazard testing—Part 5: Assessment of potential corrosion damage by fire effluent—Section 1: General guidance
TR1 60695-5-2	Fire hazard testing—Part 5: Assessment of potential corrosion damage by fire effluent—Section 2: Guidance on the selection and use of test methods

## INTERNATIONAL ORGANIZATION FOR STANDARDIZATION (ISO)

### Coatings

1462	Metallic coatings—Coatings other than those anodic to the basis metal—Accelerated corrosion tests—Method for the evaluation of the results
3160-2	Watch cases and accessories—Gold alloy coverings—Part 2: Determination of fineness, thickness, corrosion resistance and adhesion
4536	Metallic and non-organic coatings on metallic substrates—Saline droplets corrosion test (SD test)
4538	Metallic coatings—Thioacetamide corrosion test (TAA test)
4539	Electrodeposited chromium coatings—Electrolytic corrosion testing (EC test)
4540	Metallic coatings—Coatings cathodic to the substrate—Rating of electroplated test specimens subjected to corrosion tests
4541	Metallic and other non-organic coatings—Corrodokote corrosion test (CORR test)
4542	Metallic and other non-organic coatings—General rules for stationary outdoor exposure corrosion tests

4543	Metallic and other non-organic coatings—General rules for corrosion tests applicable for storage conditions
4623	Paints and varnishes—Filiform corrosion test on steel
4623-1	Paints and varnishes—Determination of resistance to filiform corrosion—Part 1: Steel substrates
6988	Metallic and other non-organic coatings—Sulfur dioxide test with general consideration of moisture
TR 8502-1	Preparation of steel substrates before application of paints and related products—Tests for the assessment of surface cleanliness—Part 1: Field test for soluble iron corrosion products
10289	Methods for corrosion testing of metallic and other inorganic coatings on metallic substrates—Rating of test specimens and manufactured articles subjected to corrosion tests
11997-1	Paints and varnishes—Determination of resistance to cyclic corrosion conditions—Part 1: Wet (salt fog)/dry/humidity
11997-2	Paints and varnishes—Determination of resistance to cyclic corrosion conditions—Part 2: Wet (salt fog)/dry/humidity/UV light
12944-1	Paints and varnishes—Corrosion protection of steel structures by protective paint systems—Part 1: General introduction
12944-2	Paints and varnishes—Corrosion protection of steel structures by protective paint systems—Part 2: Classification of environments
12944-3	Paints and varnishes—Corrosion protection of steel structures by protective paint systems—Part 3: Design considerations
12944-4	Paints and varnishes—Corrosion protection of steel structures by protective paint systems—Part 4: Types of surface and surface preparation
12944-5	Paints and varnishes—Corrosion protection of steel structures by protective paint systems—Part 5: Protective paint systems
12944-6	Paints and varnishes—Corrosion protection of steel structures by protective paint systems—Part 6: Laboratory performance test methods
12944-7	Paints and varnishes—Corrosion protection of steel structures by protective paint systems—Part 7: Execution and supervision of paint work
12944-8	Paints and varnishes—Corrosion protection of steel structures by protective paint systems—Part 8: Development of specifications for new work and maintenance

## **Metals and Alloys**

3651-1	Austenitic Stainless Steels—Determination of resistance to intergranular corrosion of stainless steels—Part 1: Austenitic and ferritic-austenitic (duplex) stainless steels—Corrosion test in nitric acid medium by measurement of loss in mass (Huey test)
3651-2	Determination of resistance to intergranular corrosion of stainless steels—Part 2: Ferritic, austenitic and ferritic-austenitic (duplex) stainless steels—Corrosion test in media containing sulfuric acid
6509	Corrosion of metals and alloys—Determination of dezincification resistance of brass
6957	Copper alloys—Ammonia test for stress corrosion resistance
7384	Corrosion tests in artificial atmosphere—General requirements
7441	Corrosion of metals and alloys—Determination of bimetallic corrosion in outdoor exposure corrosion tests
7539-1	Corrosion of metals and alloys—Stress corrosion testing—Part 1: General guidance on testing procedures
7539-2	Corrosion of metals and alloys—Stress corrosion testing—Part 2: Preparation and use of bent-beam specimens
7539-3	Corrosion of metals and alloys—Stress corrosion testing—Part 3: Preparation and use of U-bend specimens
7539-4	Corrosion of metals and alloys—Stress corrosion testing—Part 4: Preparation and use of uniaxially loaded tension specimens
7539-5	Corrosion of metals and alloys—Stress corrosion testing—Part 5: Preparation and use of C-ring specimens
7539-6	Corrosion of metals and alloys—Stress corrosion testing—Part 6: Preparation and use of pre-cracked specimens
7539-7	Corrosion of metals and alloys—Stress corrosion testing—Part 7: Slow strain rate testing
7539-8	Corrosion of metals and alloys—Stress corrosion testing—Part 8: Preparation and use of specimens to evaluate weldments
8044	Corrosion of metals and alloys—Basic terms and definitions
8407	Corrosion of metals and alloys—Removal of corrosion products from corrosion test specimens
8565	Metals and alloys—Atmospheric corrosion testing—General requirements for field tests
8993	Anodized aluminium and aluminium alloys—Rating system for the evaluation of pitting corrosion—Chart method

8994	Anodized aluminium and aluminium alloys—Rating system for the evaluation of pitting corrosion—Grid method
9223	Corrosion of metals and alloys—Corrosivity of atmospheres—Classification
9224	Corrosion of metals and alloys—Corrosivity of atmospheres—Guiding values for the corrosivity categories
9225	Corrosion of metals and alloys—Corrosivity of atmospheres—Measurement of pollution
9226	Corrosion of metals and alloys—Corrosivity of atmospheres—Determination of corrosion rate of standard specimens for the evaluation of corrosivity
9227	Corrosion tests in artificial atmospheres—Salt spray tests
9400	Nickel-based alloys—Determination of resistance to intergranular corrosion
9591	Corrosion of aluminium alloys—Determination of resistance to stress corrosion cracking
10062	Corrosion tests in artificial atmosphere at very low concentrations of polluting gas(es)
10270	Corrosion of metals and alloys—Aqueous corrosion testing of zirconium alloys for use in nuclear power reactors
11130	Corrosion of metals and alloys—Alternate immersion test in salt solution
11303	Corrosion of metals and alloys—Guidelines for selection of protection methods against atmospheric corrosion
11306	Corrosion of metals and alloys—Guidelines for exposing and evaluating metals and alloys in surface sea water
11463	Corrosion of metals and alloys—Evaluation of pitting corrosion
11474	Corrosion of metals and alloys—Corrosion tests in artificial atmosphere—Accelerated outdoor test by intermittent spraying of a salt solution (Scab test)
11782-1	Corrosion of metals and alloys—Corrosion fatigue testing—Part 1: Cycles to failure testing
11782-2	Corrosion of metals and alloys—Corrosion fatigue testing—Part 2: Crack propagation testing using precracked specimens
11845	Corrosion of metals and alloys—General principles for corrosion testing
11846	Corrosion of metals and alloys—Determination of resistance to intergranular corrosion of solution heat-treatable aluminium alloys
11881	Corrosion of metals and alloys—Exfoliation corrosion testing of aluminium alloys
11972	Corrosion-resistant cast steels for general applications
14713	Protection against corrosion of iron and steel in structures—Zinc and aluminium coatings—Guidelines
14993	Corrosion of metals and alloys—Accelerated testing involving cyclic exposure to salt mist, “dry” and “wet” conditions
15324	Corrosion of metals and alloys—Evaluation of stress corrosion cracking by the drop evaporation test
16701	Corrosion of metals and alloys—Corrosion in artificial atmosphere—Accelerated corrosion test involving exposure under controlled conditions of humidity cycling and intermittent spraying of salt solution

## Applications

2160	Petroleum products—Corrosiveness to copper—Copper strip test
4404	Petroleum and related products—Determination of the corrosion resistance of water-containing fire-resistant fluids for hydraulic systems
4952	Structural steels with improved atmospheric corrosion resistance
6251	Liquefied petroleum gases—Corrosiveness to copper—Copper strip test
6315	Road vehicles—Brake linings—Seizure to ferrous mating surface due to corrosion—Test procedure
9455-12	Soft soldering fluxes—Test methods—Part 12: Steel tube corrosion test
9455-15	Soft soldering fluxes—Test methods—Part 15: Copper corrosion test
TR 10129	Plain bearings—Testing of bearing metals—Resistance to corrosion by lubricants under static conditions
TR 10217	Solar energy—Water heating systems—Guide to material selection with regard to internal corrosion
TR 10271	Dentistry—Determination of tarnish and corrosion of metals and alloys
TS 12928	Lubricants, industrial oils and related products (class L)—Family R (Products for temporary protection against corrosion)—Guidelines for establishing specifications
13402	Surgical and dental hand instruments—Determination of resistance against autoclaving, corrosion and thermal exposure (available in English only)
13806	Vitreous and porcelain enamels—Corrosion tests in closed systems

## NACE INTERNATIONAL

### General

RP0197	Standard Format for Computerized Electrochemical Polarization Curve Data Files
RP0198	The Control of Corrosion Under Thermal Insulation and Fireproofing Materials—a Systems Approach

RP0199	Installation of Stainless Chromium—Nickel Alloy Roll-Bonded and Explosion-Bonded Clad Plate in Air Pollution Control Equipment
RP0294	Design, Fabrication, and Inspection of Tanks for the Storage of Concentrated Sulfuric Acid and Oleum at Ambient Temperatures
RP0300	Pilot Scale Evaluation of Corrosion and Scale Control Additives for Open Re-circulating Cooling Water Systems
RP0390	Maintenance and Rehabilitation Considerations for Corrosion Control of Existing Steel-Reinforced Concrete Structures
RP0487	Considerations in the Selection and Evaluation of Rust Preventives and Vapor Corrosion Inhibitors for Interim (Temporary) Corrosion Protection
RP0497	Field Corrosion Evaluation Using Metallic Test Specimens
RP0590	Recommended Practice for Prevention, Detection, and Correction of Deaerator Cracking
RP0690	Standard Format for Collection and Compilation of Data for Computerized Material Corrosion Resistance Database Input
TM0193	Laboratory Corrosion Testing of Metals in Static Chemical Cleaning Solutions at Temperatures Below 93°C(200°F)
TM0299	Corrosion Control and Monitoring in Seawater Injection Systems
TM0397	Screening Tests for Evaluating the Effectiveness of Gypsum Scale Removers
TM0398	Laboratory Corrosion Testing of Metals in Static Cleaning Solutions at Temperatures Above 100°C (212°F)
TM0399	Test Method for Phosphonate in Brine
TM0498	Standard Test Method for Measuring the Carburization of Alloys for Ethylene Cracking Furnace Tubes
TM0499	Immersion Corrosion Testing of Ceramic Materials

### **Cathodic Protection**

RP0169	Control of External Corrosion on Underground or Submerged Metallic Piping Systems
RP0572	Design, Installation, Operation, and Maintenance of Impressed Current Deep Groundbeds
RP0174	Corrosion Control of Electric Underground Residential Distribution Systems
RP0575	Design, Installation, Operation, and Maintenance of Internal Cathodic Protection Systems in Oil Treating Vessels
RP0675	Control of Corrosion on Offshore Steel Pipelines
RP0176	Corrosion Control of Steel, Fixed Offshore Platforms Associated with Petroleum Production
RP0177	Mitigation of Alternating Current and Lightning Effects on Metallic Structures and Corrosion Control Systems
RP0180	Cathodic Protection of Pulp and Paper Mill Effluent Clarifiers
RP0285	Control of External Corrosion on Metallic Buried, Partially Buried, or Submerged Liquid Storage Systems
RP0186	Application of Cathodic Protection for Well Casings
RP0286	The Electrical Isolation of Cathodically Protected Pipelines
RP0387	Metallurgical and Inspection Requirements for Cast Sacrificial Anodes for Offshore Applications
RP0388	Impressed Current Cathodic Protection of Internal Submerged Surfaces of Steel Water Storage Tanks
RP0100	Cathodic Protection of Pre-stressed Concrete Cylinder Pipelines
RP0193	External Cathodic Protection of On-Grade Metallic Storage Tank Bottoms
RP0194	Criteria and Test Methods for Cathodic Protection of Lead Sheath Cable

PS Guide 20.00	Guide for Selecting Painting Systems for Boottoppings
PS Guide 21.00	Guide for Selecting Painting Systems for Topsides
PS Guide 22.00	Guide for Selecting One-Coat Preconstruction or Prefabrication Painting Systems
CS 23.00(I)	Interim Specification for the Application of Thermal Spray Coatings (Metallizing) of Aluminum, Zinc, and Their Alloys and Composites for the Corrosion Protection of Steel
PS 24.00	Latex Painting System for Industrial and Marine Atmospheres, Performance-Based

PS 26.00	Aluminum Pigmented Epoxy Coating System Materials Specification, Performance-Based—Type I, for Use over Blast Cleaned Steel, Type II, for Use over Hand Cleaned Steel
PS 27.00	Alkyd Coating System Materials Specification, Performance-Based

### Paints and Coatings (PAINT)

Paint COM	Commentary on Paint Specifications
Paint 5	Zinc Dust, Zinc Oxide, and Phenolic Varnish Paint
Paint 8	Aluminum Vinyl Paint
Paint 9	White (or Colored) Vinyl Paint
Paint 11	Red Iron Oxide, Zinc Chromate, Raw Linseed Oil, and Alkyd Primer
Paint 12	Cold-Applied Asphalt Mastic (Extra Thick Film)
Paint 15	Steel Joist Shop Primer
Paint 16	Coal Tar Epoxy-Polyamide Black (or Dark Red) Paint
Paint 17	Chlorinated Rubber Inhibitive Primer
Paint 18	Chlorinated Rubber Intermediate Coat Paint
Paint 19	Chlorinated Rubber Topcoat Paint
Paint 20	Zinc-Rich Primers (Type I, Inorganic, and Type II, Organic)
Paint 21	White or Colored Silicone Alkyd Paint
Paint 22	Epoxy-Polyamide Paints (Primer, Intermediate, and Topcoat)
Paint 23	Latex Primer for Steel Surfaces
Paint 24	Latex Semigloss Exterior Topcoat
Paint 25	Zinc Oxide, Alkyd, Linseed Oil Primer for Use Over Hand Cleaned Steel, Type I and Type II
Paint 25.1BCS	Zinc Oxide, Alkyd, Linseed Oil Primer for Use Over Blast Cleaned Steel
Paint 26	Slow Drying Linseed Oil Black Maintenance Primer, (Without Lead and Chromate Pigment)
Paint 27	Basic Zinc Chromate-Vinyl Butyral Wash Primer
Paint 28	Water-Borne Epoxy Primer for Steel Surfaces
Paint 29	Zinc Dust Sacrificial Primer, Performance-Based
Paint 30	Weld-Through Inorganic Zinc Primer
Paint 31	Single-Package Waterborne Alkyd Primer for Steel Surfaces, Performance-Based
Paint 32	Coal Tar Emulsion Coating
Paint 33	Coal Tar Mastic, Cold Applied
Paint 34	Water-Borne Epoxy Topcoat for Steel Surfaces
Paint 35	Medium Oil Alkyd Primer (Air Dry/Low Bake), Type I and Type II
Paint 36	Two-Component Weatherable Aliphatic Polyurethane Topcoat, Performance-Based
Paint 101	Aluminum Alkyd Paint (Type I, Leafing and Type II, Non-Leafing)
Paint 102	Black Alkyd Paint
Paint 103	Black Phenolic Paint
Paint 104	White or Tinted Alkyd Paint
Paint 106	Black Vinyl Paint
Paint 108	High-Build Thixotropic Leafing Aluminum Paint

### Paint Application (PA)

PA COM	Commentary on Paint Application
PA 1	Shop, Field, and Maintenance Painting of Steel
PA 2	Measurement of Dry Coating Thickness with Magnetic Gages
PA Guide 3	A Guide to Safety in Paint Application
PA Guide 4	Guide to Maintenance Repainting with Oil Base or Alkyd Painting Systems
PA Guide 5	Guide to Maintenance Painting Programs

### Qualification Procedures (QP)

QP COM	Commentary on Qualification Procedures
QP 1	Standard Procedure for Evaluating Painting Contractors (Field Application to Complex Industrial Structures)
QP 2	Standard Procedure for the Qualification of Painting Contractors (Field Removal of Hazardous Coatings from Complex Structures)
QP 3	Standard Procedure for Evaluating Qualifications of Shop Painting Applicators
QP 4	Standard Procedure for Evaluating the Qualifications of Contractors Disturbing Hazardous Coatings During Demolition and Repair Work
QP 5	Standard Procedure for Evaluating Qualifications of Coating and Lining Inspection Companies

**Technology Guides (GUIDE)**

Guide 6	Guide for Containing Debris Generated During Paint Removal Operations
Guide 9	Guide for Atmospheric Testing of Coatings in the Field
Guide 10	Guide to Specifying Coatings Conforming to Volatile Organic Compound (VOC) Content Requirements
Guide 11	Guide for Coating Concrete
Guide 13	Guide for the Identification and Use of Industrial Coating Material in Computerized Product Databases
Guide 14	Guide for the Repair of Imperfections in Galvanized or Inorganic Zinc Coated Steel Using Organic Zinc-Rich Coating

**Test Panel Preparation Methods (ME)**

 pressurized corrosion tests, 147–149  
 refreshed and recirculating tests, 148–149  
 safety, 154–155  
 simulation of service environments, 155–156  
 special test conditions, 150–151  
 static tests, 148  
 test conditions, 147  
 test variations, 151–154  
 windowed test vessels, 152  
 High velocity flow testing, seawater, 373  
 Highways, tunnels, and bridges, 706–714  
   coatings, 710  
   corrosive environments, 707–709  
   electrical continuity, 709  
   environmental modification, 709  
   failure analysis, 712–713  
   future, 714  
   in-service monitoring, 711–712  
   inhibitors, 709–710  
   material selection, 709, 711  
   materials of construction, 706–707  
   problem areas, 710–711  
   unresolved issues, 713–714  
 Hot corrosion testing, cobalt-base alloys, 597  
 Hot dip coating, 620  
 Hot plate boiling corrosion testing, chemical pulping, 801  
 Hot wall, 791  
 Humidity tests, 134–135, 355, 359, 545  
 Hydrocarbon gas systems, corrosion testing, 430  
 Hydrochloric acid spray test, 571–572  
 Hydrogen  
   in aluminum and aluminum alloys, 549  
   diffusible concentration, 123–124  
   effects, oil and gas production, 818  
   measurement of concentration, 327  
   nickel and nickel alloys, 581  
   niobium, 618  
   role in titanium, 601  
   tantalum, 617  
   testing, titanium, 607–609  
 Hydrogen damage, 322–339  
   ASTM E 1681, 333–336

   ASTM G 129, 337  
   ASTM G 168, 336  
   cantilever bend tests, 335–336  
   delayed failure, 326–327  
   diffusivity, 322–323  
   ductility effects, 325–326  
   environmental hydrogen embrittlement, 325  
   fracture mechanics testing, 332–339  
   fugacity, 323–324

hydrogen concentration measurement, 327  
 internal hydrogen embrittlement, 325  
 interpretation of test results, 327  
 mechanical testing, 328–331  
 notch effect, 326  
 pipeline, 700  
 potential, 328  
 principles, 322–339  
 process control, 328–329  
 ripple loads, 333  
 solubility, 323  
 stress corrosion cracking, 325  
 temperature and strain rate, 328  
 test selection, 338–339  
 three-point and four-point bend tests, 336–337  
 trapping behavior, 324  
 Hydrogen embrittlement cracking tests, 151, 202, 371  
 Hydrogen induced cracking, 94–95, 818  
 Hydrogen measurements  
   corrosion inhibitors, 488–489  
   high-temperature/high-pressure corrosion testing, 153–154  
 Hydrogen probes, 191

## M

Macrofouling films, seawater, 367

Magnesium and magnesium alloys,  
537-545

compositional effects, 537-539

contaminant tolerance limits, 538

corrosion characteristics, 537-541

corrosion testing, 544-545

elevated temperature, 542

environmental factors, 541-544

galvanic corrosion, 542-544

gravimetric corrosion rates, 544-545

humidity tests, 545

ions/salts, 541

metal fasteners, 543

metal-matrix composites, 644-645

metallurgical treatment effect, 539-540

mill products, 540

organic compounds, 542

painted corrosion performance, 545

protective films, 537

stress-corrosion cracking, 540-541

Magnesium-zinc alloys, 540

Magnetic resonance imaging, cautions with  
medical and dental materials, 836

Maintenance steering group system, 96-98

Manganese, stainless steels, 585

Manholes, telecommunications, 763

Marine atmosphere zone, piers and  
docks, 719

Martensitic stainless steels, 587

Mass change analysis, high-temperature  
gases, 445

Mass loss tests, 109, 206-208

Mass transport overpotential, 110

Mattsson's solution, 570

Mechanical coatings, steel, 621-622

Mechanical damage, pipeline, 700

Mechanical polishing, 68

Mechanical property testing, high-  
temperature/high-pressure  
corrosion testing, 154

Mechanical pulping, 803

Mechanical stress, liquid metals, 470-471

Mechanical treatments, aluminum and  
aluminum alloys, 548-549

Medical and dental materials, 834-843

corrosion environments, 841

corrosion evaluation, 842

corrosion-fatigue, 840

crevice corrosion, 840

dental alloys, 837-838

fretting corrosion, 840

## W

Water  
 chemistry, effect on corrosion, 175–176  
 content, organic liquids, 450, 452  
 copper and copper alloys, 568  
 highways, tunnels, and bridges, 708–709, 712  
 physical properties, 37  
 potable, copper and copper alloys testing, 572  
 presence in chemical processing, 780  
*see also* Industrial waters  
 Water handling systems, 826–833  
 chemical analysis, 830–831  
 corrosion coupons, 826–828  
 dissolved oxygen monitoring, 831  
 electrical resistance meter, 829–830  
 heat transfer systems, 832  
 linear polarization-resistance meter, 828–829  
 oxidation reduction potential, 831  
 test heat exchanger, 832–833  
 Water injection wells and facilities, 817  
 Waterwall tube laboratory testing, 804  
 Wear testing, cobalt-base alloys, 595–597  
 Web, 102  
 Weibull distribution, 85  
 Weight loss corrosion rate measurements, corrosion inhibitors, 487–488  
 Weight loss testing, freshwater, 382  
 Welds, 262, 700, 750, 780  
 Well drilling, 812–813  
 Wenner four-electrode method, 399  
 Wet deposition, 160  
 White liquors, 801  
 Windowed test vessels, 152  
 Wire, steels, 564  
 Wood, 716, 724

## X

X-ray photoelectron spectroscopy, 79–80

## Y

Yttria, effect on stainless steel metal-matrix composites, 647

## Z

Zinc-aluminum coatings, 622  
 Zinc and zinc alloys, 525–529  
 immersion corrosion, 529  
 metal-matrix composites, 649  
 as metallic coatings, 622, 624  
 Zinc-nickel coatings, 622  
 Zirconium, 613–616
