Bibliography—E. L. Lewis, Naval Ship Engineering Center, Philadelphia Div.

In addition to those listed, many other members of Committee E-20 have made substantial contributions to this manual as authors and reviewers. Their help is gratefully acknowledged.

Chapter 1—Introduction

First Edition, 1970

This manual has been prepared by Subcommittee IV of ASTM Committee E-20 on Temperature Measurement. The responsibilities of ASTM Committee E-20 include "Assembling a consolidated source book covering all aspects relating to accuracy, application, and usefulness of thermometric methods." This manual is addressed to the thermocouple portion of this responsibility.

The contents include principles, circuits, standard electromotive force (emf) tables, stability and compatibility data, installation techniques, and other information required to aid both the beginner and the experienced user of thermocouples. While the manual is intended to be comprehensive, the material, however, will not be adequate to solve all the individual problems associated with many applications. To further aid the user in such instances, there are numerous references and an extensive bibliography. In addition to presenting technical information, an attempt is made to properly *orient* a potential user of thermocouples. Thus, it is hoped that the reader of this manual will make fewer mistakes than the nonreader.

Regardless of how many facts are presented herein and regardless of the percentage retained, all will be for naught unless one simple important fact is kept firmly in mind. The thermocouple reports only what it "feels." This may or may not be the temperature of interest. The thermocouple is influenced by its entire environment, and it will tend to attain thermal equilibrium with this environment, not merely part of it. Thus, the environment of each thermocouple installation should be considered unique until proven otherwise. Unless this is done, the designer will likely overlook some unusual, unexpected, influence.

Of all the available temperature transducers, why use a thermocouple in a particular application? There are numerous advantages to consider. Physically, the thermocouple is inherently simple, being only two wires joined together at the measuring end. The thermocouple can be made large or small depending on the life expectancy, drift, and response-time requirements. It may be flexible, rugged, and generally is easy to handle and install. A thermocouple normally covers a wide range of temperatures, and its output is reasonably linear over portions of that range. Unlike many temperature transducers, the thermocouple is not subject to selfheating problems. In practice, thermocouples of the same type are interchangeable within specified limits of error. Also, thermocouple materials are readily available at reasonable cost, the expense in most cases being nominal.

The bulk of the manual is devoted to identifying material characteristics and discussing application techniques. Every section of the manual is essential to an understanding of thermocouple applications. Each section should be studied carefully. Information should not be used out of context. The general philosophy should be—let the user beware.

Second Edition, 1974

In preparing this edition of the manual, the committee has endeavored to include four major changes which greatly affect temperature measurement by means of thermocouples. In 1968, at the time the First Edition was being prepared, the International Practical Temperature Scale was changed. This new scale (IPTS-68) is now the law of the land, and Chapter 8 has been completely rewritten to so reflect this. In 1972–1973, new Thermocouple Reference Tables were issued by the National Bureau of Standards. Accordingly, Chapter 10 has been revised to include the latest tables of temperature versus electromotive force for the thermocouple types most commonly used in industry. Also, along these same lines, the National Bureau of Standards has issued new methods for generating the new Reference Table values for computer applications. These power series relationships, giving emf as a function of temperature, are now included in Chapter 10.3. Finally, there have been several important changes in thermocouple material compositions, and such changes have been noted in the appropriate places throughout the text. The committee has further attempted to correct any gross errors in the First Edition and has provided a more complete bibliography in Chapter 12.

Chapter 2—Principles of Thermoelectric Thermometry

The principles, or theory, underlying thermoelectric effects were not established by one man at one time, but by several scientists working over a span of many years beginning with Alessandro Volta, who concluded in 1800 that the electricity which caused Galvani's frog to twitch was due to a contact of two dissimilar metals. This conclusion was the forerunner of the principle of the thermocouple. Others built on this base; for example, Thomas Johann Seebeck (1821), Jean Charles Althanase Peltier (1834), and William Thomson—later Lord Kelvin—(1848–1854). During this same period, Jean Baptiste Joseph Fourier published his basic heat-conduction equation (1821), Georg Simon Ohm discovered his celebrated equation for electrical conduction (1826), James Prescott Joule found the principle of the first law of thermodynamics and the important I^2R heating effect (1840–1848), and Rudolf Julius Emanuel Clausius announced the principle of the second law of thermodynamics and introduced the concept of entropy (1850).

2.1 Historical Development of Basic Relations

2.1.1 Seebeck

Seebeck discovered the existence of thermoelectric currents while observing electromagnetic effects associated with bismuth-copper and bismuth-antimony circuits. His experiments showed that, when the junctions of two dissimilar metals forming a closed circuit are exposed to different temperatures, a net thermal electromotive force is generated which induces a continuous electric current.

The Seebeck effect concerns the net conversion of thermal energy into electrical energy with the appearance of an electric current. The Seebeck voltage refers to the net thermal electromotive force set up in a thermocouple under zero-current conditions. The direction and magnitude of the Seebeck voltage, E_S, depend upon the temperature of the junctions and upon the materials making up the thermocouple. For a particular combination of materials, A and B, for a small temperature difference

$$dE_S = \alpha_{A,B} dT \tag{1}$$

where $\alpha_{A,B}$ is a coefficient of proportionality called the Seebeck coefficient.

(This commonly is called the thermoelectric power.) The Seebeck coefficient is obtained usually in one of two ways: (1) as an algebraic sum, $\alpha_{A,B}$, of relative Seebeck coefficients, α_{AR} and α_{BR}, where, for a given temperature difference and at given temperature levels, emf's of each of the substances, A and B, making up the thermocouple are obtained with respect to an arbitrary reference material, R; and (2) by numerically differentiating tabulated values of E_S versus T for a given reference temperature, T_R, according to the relation

$$E_S = \int_{TR}^{T} \alpha_{A,B} dT \tag{2}$$

In either case, the Seebeck coefficient represents, for a given material combination, the net change in thermal emf caused by a unit temperature difference; that is,

$$\alpha_{A,B} = \underset{\Delta T \to 0}{\text{limit}} \frac{\Delta E_S}{\Delta T} = \frac{dE_S}{dT} \tag{3}$$

Thus, if $E = aT + 1/2bT^2$ is determined by calibration, then $\alpha = a + bT$. Note that, based on the validity of the experimental relation,

$$E_S = \int_{T2}^{T} \alpha dT = \int_{T1}^{T} \alpha dT - \int_{T1}^{T2} \alpha dT \tag{4}$$

where $T_1 < T_2 < T$, it follows that α is entirely independent of the reference temperature employed. In other words, for a given combination of materials, the Seebeck coefficient is a function of temperature level only.

2.1.2 Peltier

Peltier discovered peculiar thermal effects when he introduced small, external electric currents in Seebeck's bismuth-antimony thermocouple. His experiments show that, when a small electric current is passed across the junction of two dissimilar metals in one direction, the junction is cooled (that is, it acts as a heat sink) and thus absorbs heat from its surroundings. When the direction of the current is reversed, the junction is heated (that is, it acts as a heat source) and thus releases heat to its surroundings.

The Peltier effect concerns the reversible evolution, or absorption, of heat which usually takes place when an electric current crosses a junction between two dissimilar metals. (In certain combinations of metals, at certain temperatures, there are thermoelectric neutral points where no Peltier effect is apparent.) This Peltier effect takes place whether the current is introduced externally or is induced by the thermocouple itself. The Peltier heat was found early to be proportional to the current, and may be written

$$dQ_P = \pi I dt \tag{5}$$

where π is a coefficient of proportionality known as the Peltier coefficient or the Peltier voltage. Note that π represents the reversible heat which is absorbed, or evolved, at the junction when unit current passes across the junction in unit time, and that it has the dimensions of voltage. The direction and magnitude of the Peltier voltage depend upon the temperature of the junction and upon the materials making up the junction; however, π at one junction is independent of the temperature of the other junction.

External heating, or cooling, of the junctions results in the converse of the Peltier effect. Even in the absence of all other thermoelectric effects, when the temperature of one junction (the reference junction) is held constant and when the temperature of the other junction is increased by external heating, a net electric current will be induced in one direction. If the temperature of the latter junction is reduced below the reference-junction temperature by external cooling, the direction of the electric current will be reversed. Thus, the Peltier effect is seen to be related closely to the Seebeck effect. Peltier himself observed that, for a given electric current, the rate of absorption, or liberation, of heat at a thermoelectric junction depends upon the Seebeck coefficient, α, of the two materials.

2.1.3 Thomson

It remained for Thomson (see the Kelvin relations discussed next) to show that α and π are related by the absolute temperature. (We might appropriately mention at this time that the Peltier thermal effects build up a potential difference opposing the thermoelectric current, thus negating the perpetual-motion question.) Thomson came to the remarkable conclusion that an electric current produces different thermal effects, depending upon the direction of its passage from hot to cold or from cold to hot, in the same metal. By applying the (then) new principles of thermodynamics to the thermocouple, and by disregarding (with tongue in cheek) the irreversible I^2R and conduction-heating processes, Thomson reasoned that, if an electric current produces only the reversible Peltier heating effects, then the net Peltier voltage will equal the Seebeck voltage and will be linearly proportional to the temperature difference at the junctions of the thermocouple.

This reasoning led to requirements at variance with observed characteristics (that is, $dE_S/dT \neq$ constant). Therefore, Thomson concluded that the net Peltier voltage is not the only source of emf in a thermocouple circuit, but that the single conductor itself, whenever it is exposed to a longitudinal temperature gradient, must be also a seat of emf. (Becquerel had at that time already discovered a thermoelectric neutral point, that is, $E_S = 0$, for an iron-copper couple at about 280°C. Thomson agreed with Becquerel's conclusion and started his thermodynamic reasoning from there.)

The Thomson effect concerns the reversible evolution, or absorption, of heat occurring whenever an electric current traverses a single homogeneous conductor, across which a temperature gradient is maintained, regardless of external introduction of the current or its induction by the thermocouple itself. The Thomson heat absorbed, or generated, in a unit volume of a conductor is proportional to the temperature difference and to the current, that is,

$$dQ_T = \pm \sigma dTIdt \tag{6}$$

where σ is a coefficient of proportionality called the Thomson coefficient. Thomson refers to this as the specific heat of electricity because of an apparent analogy between σ and the usual specific heat, c, of thermodynamics. Note that σ represents the rate at which heat is absorbed, or evolved, per unit temperature difference per unit current, whereas c represents the heat transfer per unit temperature difference per unit mass. The Thomson coefficient is seen also to represent an emf-per-unit difference in temperature. Thus, the total Thomson voltage set up in a single conductor may be expressed as

$$E_T = \int_{T1}^{T2} \sigma dT \tag{7}$$

where its direction and magnitude depend upon temperature level, temperature difference, and material considered. Note that the Thomson voltage alone cannot sustain a current in a single homogeneous conductor forming a closed circuit, since equal and opposite emf's will be set up in the two paths from heated to cooled parts.

Soon after his heuristic reasoning, Thomson succeeded in demonstrating indirectly the existence of the predicted Thomson emf's. He sent an external electric current through a closed circuit, formed of a single homogeneous conductor which was subjected to a temperature gradient, and found the I^2R heat to be augmented slightly, or diminished, by the reversible Thomson heat in the paths from cold to hot or from hot to cold, depending upon the direction of the current and the material under test.

2.1.4 Interim Summary

In summary, thermoelectric currents may exist whenever the junctions of a circuit formed of at least two dissimilar metals are exposed to different temperatures. This temperature difference always is accompanied by irreversible Fourier heat conduction, while the passage of electric currents always is accompanied by irreversible Joule heating effects. At the same time, the passage of electric currents always is accompanied by reversible Peltier heating or cooling effects at the junctions of the dissimilar metals, while the combined temperature difference and passage of electric current always is accompanied by reversible Thomson heating or cooling effects along the conductors. The two reversible heating-cooling effects are manifestations of four distinct emf's which make up the net Seebeck emf:

$$E_S = \pi_{A,B}\big|_{T2} - \pi_{A,B}\big|_{T1} + \int_{T1}^{T2} \sigma_A dT - \int_{T1}^{T2} \sigma_B dT = \int_{T1}^{T2} \alpha_{A,B} dT \qquad (8)$$

where the three coefficients, α, π, σ, are related by the Kelvin relations.

2.1.5 Kelvin Relations

Assuming that the irreversible I^2R and heat-conduction effects can be disregarded completely (actually, they can be only minimized since, if thermal conductivity is decreased, electrical resistivity usually is increased, and vice versa), then the net rate of absorption of heat required by the thermocouple to maintain equilibrium in the presence of an electric current is

$$q = \frac{Q_{\text{net}}}{t} = \left[\pi_2 - \pi_1 + \int_1^2 (\sigma_A - \sigma_B) dT\right] I = E_S I \qquad (9)$$

This is in accord with the first law of thermodynamics, according to which heat and work are mutually convertible. Thus, the net heat absorbed must equal the electric work accomplished or, in terms of a unit charge of electricity, the Seebeck emf, E_S, which may be expressed in the differential form

$$dE_S = d\pi + (\sigma_A - \sigma_B) dT \qquad (10)$$

The second law of thermodynamics may be applied also to the thermocouple cycle, the unit charge of electricity again being considered, as

$$\Delta S_{\text{rev}} = \sum \frac{\Delta Q}{T_{\text{abs}}} = 0 \qquad (11)$$

where ΔQ implies the various components of the net heat absorbed (that is, the components of E_S), and T_{abs} implies the temperature at which the heat is transferred across the system boundaries. Equation 11 can be expressed in the differential form

$$dS_{\text{rev}} = d\left(\frac{\pi}{T}\right) + \frac{(\sigma_A - \sigma_B)}{T} dT = 0 \qquad (12)$$

Combining the differential expressions for the first and second laws of thermodynamics, we obtain the Kelvin relations:

$$\pi_{A,B} = T_{\text{abs}}\left(\frac{dE_S}{dT}\right) = T_{\text{abs}}\alpha_{A,B} \qquad (13)$$

$$(\sigma_A - \sigma_B) = -T_{\text{abs}}\left(\frac{d^2E_S}{dT^2}\right) \qquad (14)$$

from which we can determine α, π, and $\Delta\sigma$, when E_S is obtained as a function of T. Thus, if

$$E_S = aT + \frac{1}{2}bT^2 + \cdots \tag{15}$$

is taken to represent the thermoelectric characteristics of a thermocouple whose reference junction is maintained at 0°C, and where the coefficients, a and b, are obtained (for example) by the curve fitting of calibration data, then

$$\alpha = (a + bT + \cdots) \tag{16}$$

$$\pi = T_{abs}(a + bT + \cdots) \tag{17}$$

$$\Delta\sigma = -T_{abs}(b + \cdots) \tag{18}$$

Examples of the use of these coefficients are given in Table 1.

TABLE 1—*Determination of various thermoelectric quantities applied to thermocouples.*

Given, the two constants, a and b, as determined with respect to platinum via Eq 15:

Metal	a, $V/°C$	b, $V/(°C)^2$
Iron(Fe)	+16.7	−0.0297
Copper(Cu)	+ 2.7	+0.0079
Constantan(Con)	−34.6	−0.0558

By way of illustration, consider the following combinations of materials: iron-copper and iron-constantan, with their measuring junctions at 200°C and their reference junctions at 0°C:

Iron-copper

$$a_{Fe-Cu} = a_{Fe} - a_{Cu} = 16.7 - 2.7 = 14\mu V/°C$$
$$b_{Fe-Cu} = b_{Fe} - b_{Cu} = -0.0297 - 0.0079$$
$$b_{Fe-Cu} = -0.0376\ \mu V/(°C)^2$$

Iron-constantan

$$a_{Fe-Con} = a_{Fe} - a_{Con} = 16.7 - (-34.6) = 51.3\ \mu V/°C$$
$$b_{Fe-Con} = b_{Fe} - b_{Con} = -0.0297 - (-0.0558)$$
$$b_{Fe-Con} = 0.0261\ \mu V/(°C)^2$$

Since Seebeck voltage $E_s = aT + 1/2bT^2$,

Iron-copper

$$E_s = 14(200) + \frac{1}{2}(-0.0376)(200)^2$$
$$E_s = 2048\ \mu V$$

Iron-constantan

$$E_s = 51.3(200) + \frac{1}{2}(0.0261)(200)^2$$
$$E_s = 10\ 782\ \mu V$$

Note how different combinations of materials give widely different thermal emf's.

Now we proceed to write expressions for α, π, and $\Delta\sigma$, to note how the separate emf's combine to give the (net) Seebeck emf: Since $\alpha_{A,B} = a_{A,B} + b_{A,B}T$ = Seebeck coefficient

Iron-copper

$$\alpha_0 = 14 + (-0.0376)(0) = 14\ \mu V/°C$$
$$\alpha_{200} = 14 + (-0.0376)(200) = 6.48\ \mu V/°C$$

(*Continued*)

TABLE 1—*Continued.*

Iron-constantan

$$\alpha_0 = 51.3 + 0.0261(0) = 51.3\ \mu V/°C$$

$$\alpha_{200} = 51.3 + 0.0261(200) = 56.52\ \mu V/°C$$

Note that it is the great difference in Seebeck coefficients (thermoelectric powers) for the two combinations which accounts for the difference in thermal emf's:

$$E_s = \int_{T_R}^{T} \alpha_{A,B} dT$$

Since $\pi_{A,B} = T_{abs}\alpha_{A,B}$ = Peltier coefficient = Peltier voltage

Iron-copper

$$\pi_0 = 273(14) = 3822\ \mu V$$

$$\pi_{200} = 473(6.48) = 3065\ \mu V$$

Iron-constantan

$$\pi_0 = 273(51.3) = 14\ 005\ \mu V$$

$$\pi_{200} = 473(56.52) = 26\ 734\ \mu V$$

Note that, in the case of the iron-copper (Fe-Cu) couple, $\pi_{cold} > \pi_{hot}$, whereas in the more usual Fe-Con couple, $\pi_{hot} > \pi_{cold}$.

Since $\Delta\sigma_{A,B} = -b_{A,B}T_{abs}$ = Thomson coefficient, and

$$E_T = \int_{T_{Rabs}}^{T_{abs}} \Delta\sigma\ dT = \frac{1}{2} b_{A,B}(T^2_{Rabs} - T^2_{abs}) = \text{Thomson voltage}$$

Iron-copper

$$E_T = \frac{0.0376}{2}(273^2 - 473^2)$$

$$E_T = 2805\ \mu V$$

Iron-constantan

$$E_T = \frac{0.0261}{2}(273^2 - 473^2)$$

$$E_T = -\ 1947\ \mu V$$

We sum the various components

$$E_s = \pi_2 - \pi_1 + \int_1^2 \Delta\sigma\ dT = \text{Seebeck voltage}$$

Iron-copper

$$E_s = 3065 - 3822 + 2805$$

$$E_s = 2048\ \mu V$$

Iron-constantan

$$E_s = 26\ 734 - 14\ 005 - 1947$$

$$E_s = 10\ 782\ \mu V$$

These figures of course, check with the original calculations. Note that, in the Fe-Cu case, the net Thomson emf far outweighs in importance the net Peltier emf, whereas in the Fe-Con case, the converse is true.

2.1.6 Onsager Relations

The historical viewpoint presented thus far has avoided the very real irreversible I^2R and heat conduction in order to arrive at the useful and experimentally confirmed Kelvin relations. We shall now discuss how the present-day, irreversible thermodynamic viewpoint removes this flaw in our reasoning.

Basically, we judge whether a given process is reversible or irreversible by noting the change in entropy accompanying a given change in the thermodynamic state. Thus, if $dS > \delta Q_q/T_{\text{abs}}$, we say the process is irreversible; or, stated in a more useful manner,

$$dS_{\text{system}} = dS_{\substack{\text{across}\\\text{boundary}}} + dS_{\substack{\text{produced}\\\text{inside}}} \tag{19}$$

or

$$dS_s = dS_0 + dS_i = \frac{\delta Q_q}{T_{\text{abs}}} + \frac{\delta F}{T_{\text{abs}}} \tag{20}$$

Hence, only in the absence of entropy within the system boundaries do we have the reversible case, $dS_{\text{rev}} = \delta Q_q/T_{\text{abs}}$, which may be handled adequately by classical thermodynamics in the steady and quasi-steady states. Evidently, the rate of production of entropy per unit volume, ξ, is an important quantity in irreversible thermodynamics, which may be expressed as

$$\xi = \left(\frac{1}{Adx}\right)\frac{dS_i}{dt} = \left(\frac{1}{Adx}\right)\frac{\delta F}{T_{\text{abs}}dt} \tag{21}$$

where Adx is the area times the differential length.

Another significant quantity, the product $T_{\text{abs}}\xi$ (called the dissipation), always can be split into two terms or a sum of two terms; one associated with a flow, J, and the other associated with a force, X. Furthermore, in many simple cases a linear relation is found (by experiment) to exist between the flow and force terms so defined. For example, in the one-dimensional, isothermal, steady flow of electric charges, $\delta Q_e/dt$ across a potential gradient, $-dE/dx$, it may be shown that

$$T_{\text{abs}}\xi = \left(\frac{I}{A}\right)\left(-\frac{dE}{dx}\right) = J_eX_e \tag{22}$$

where J_e and X_e represent the electric flow and force terms, respectively, as defined by the entropy production method. The term J_e represents the electric-current density and the term X_e the electric-field strength or the electromotive force, which of course are related by the linear Ohm's law (that is, $J_e = L_eX_e$, where L_e represents the electrical conductivity). Again, in the one-dimensional, steady flow of thermal charges, dQ_q/dt, across a temperature gradient, $-dT/dx$, it may be shown that

$$T_{\text{abs}}\xi = \left(\frac{Q}{A}\right)\left(\frac{1}{T_{\text{abs}}}\frac{dT}{dx}\right) = J_qX_q \tag{23}$$

where J_q and X_q represent the thermal flow and force, respectively, as defined by the entropy production method. The term J_q represents the thermal current density, and the term X_q represents the thermomotive force, which are, of course, related by the linear Fourier's law (that is, $J_q = L_q X_q$ where L_q represents the product of the thermal conductivity and the absolute temperature). It has been found that, even in complex situations, it always may be stated that

$$T_{\text{abs}}\xi = \sum J_K X_K \tag{24}$$

When several irreversible transport processes occur simultaneously (as, for example, the electric and thermal conduction in a thermocouple), they usually will interfere with each other; therefore, the linear relations must be generalized to include the various possible interaction terms. Thus, for the combined electric and thermal effects we would write

$$J_e = L_{ee}X_e + L_{eq}X_q \tag{25}$$

$$J_q = L_{qe}X_e + L_{qq}X_q \tag{26}$$

or, in general

$$J_i = \sum L_{ij}X_j \tag{27}$$

We have just seen that an entropy production necessarily accompanies both the I^2R and heat conduction effects (that is, they are irreversible); therefore, the Kelvin relations could not follow from reversible thermodynamic theory without certain intuitive assumptions. By reasoning that the electric and thermal currents were independent, Thomson tacitly assumed that $L_{eq} = L_{qe}$ as we shall subsequently show. Experimentally, this reciprocal relationship often was found to be true. The American chemist, Lars Onsager, proved in 1931 from a statistical-mechanics viewpoint that the assumption

$$L_{ij} = L_{ji} \tag{28}$$

is always true when the linear relations between flows, J_k, and forces, X_k, are valid. The Onsager reciprocal relation forms the basis of irreversible thermodynamics. By applying these concepts to the processes involved in the thermocouple, we are led rationally and unambiguously to the Kelvin relations. Thus, whenever the junctions of a thermocouple are maintained at different temperatures, we expect that an electric potential difference, an electric current, and a thermal current will be present. The dissipation for this thermoelectric process is simply the sum of the electric and thermal terms previously given. That is,

$$T_{\text{abs}}\xi = \frac{I}{A}\left(-\frac{dE}{dT}\right) + \frac{Q}{A}\left(\frac{1}{T_{\text{abs}}}\frac{dT}{dx}\right) \tag{29}$$

The generalized linear laws for this case also have been given as

$$J_e = L_{ee}\left(-\frac{dE}{dT}\right) + \frac{L_{eq}}{T_{\text{abs}}}\left(\frac{dT}{dx}\right) \tag{30}$$

$$J_q = L_{qe}\left(-\frac{dE}{dx}\right) + \frac{L_{qq}}{T_{\text{abs}}}\left(\frac{dT}{dx}\right) \tag{31}$$

Recalling that the Seebeck emf is determined under conditions of zero electric current, the Seebeck coefficient, α, may be expressed in terms of the Onsager coefficients as

$$\alpha = \left(\frac{dE_S}{dT}\right)_{I=0} = \frac{L_{eq}}{L_{ee}T_{\text{abs}}} \tag{32}$$

Recalling that the Peltier coefficient, π, represents the heat absorbed, or evolved, with the passage of an electric current across an isothermal junction, this too may be expressed in terms of the Onsager coefficients as

$$\pi = \left(\frac{J_q}{J_e}\right)_{dT=0} = \frac{L_{qe}}{L_{ee}} \tag{33}$$

Finally, we recall that Thomson found experimentally (and expressed in the Kelvin relations) that the Seebeck and Peltier coefficients are related, as shown in Eq 13.

$$\pi = T_{\text{abs}}\left(\frac{dE_S}{dT}\right) \tag{34}$$

In terms of the Onsager coefficients, this requires that

$$\frac{L_{qe}}{L_{ee}} = T_{\text{abs}}\left(\frac{L_{eq}}{L_{ee}T_{\text{abs}}}\right) \tag{35}$$

$$L_{qe} = L_{eq} \tag{36}$$

which indicates that the experimental results agree with those which are predicted by the entropy production-linear law-Onsager reciprocal relation approach; in other words, by irreversible thermodynamics, without using any intuitive assumption. The Kelvin relations, also in accord with experiment, must follow.

2.2 Laws of Thermoelectric Circuits

Numerous investigations of thermoelectric circuits in which accurate measurements were made of the current, resistance, and electromotive force have resulted in the establishment of several basic laws. These laws have been established experimentally beyond a reasonable doubt and may be accepted in spite of any lack of a theoretical development.

2.2.1 Law of Homogeneous Metals

A thermoelectric current cannot be sustained in a circuit of a single homogeneous material, however varying in cross section, by the application of heat alone.

A consequence of this law is that two different materials are required for any thermocouple circuit. Experiments have been reported suggesting that a nonsymmetrical temperature gradient in a homogeneous wire gives rise to a measurable thermoelectric emf. A preponderance of evidence indicates, however, that any emf observed in such a circuit arises from the effects of local inhomogeneities. Furthermore, any current detected in such a circuit when the wire is heated in any way whatever is taken as evidence that the wire is inhomogeneous.

2.2.2 Law of Intermediate Metals

The algebraic sum of the thermoelectromotive forces in a circuit composed of any number of dissimilar materials is zero if all of the circuit is at a uniform temperature.

A consequence of this law is that a third homogeneous material always can be added in a circuit with no effect on the net emf of the circuit so long as its extremities are at the same temperature. Therefore, it is evident that a device for measuring the thermoelectromotive force may be introduced into a circuit at any point without affecting the resultant emf, provided all of the junctions which are added to the circuit by introducing the device are all at the same temperature. It also follows that any junction whose temperature is uniform and which makes a good electrical contact does not affect the emf of the thermoelectric circuit regardless of the method employed in forming the junction (Fig. 1).

Another consequence of this law may be stated as follows. If the thermal emfs of any two metals with respect to a reference metal (such as *C*) are

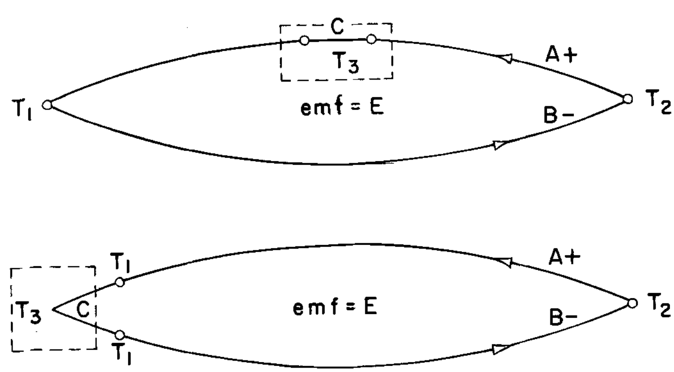

FIG. 1—E *unaffected by third material,* C.

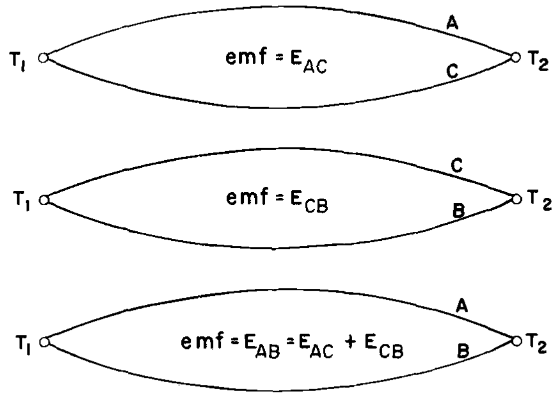

FIG. 2—*Emf's are additive for materials.*

known, then the emf of the combination of the two metals is the algebraic sum of their emfs against the reference metal (Fig. 2).

2.2.3 Law of Successive or Intermediate Temperatures

If two dissimilar homogeneous metals produce a thermal emf of E_1, when the junctions are at temperatures T_1 and T_2, and a thermal emf of E_2, when the junctions are at T_2 and T_3, the emf generated when the junctions are at T_1 and T_3, will be $E_1 + E_2$.

One consequence of this law permits a thermocouple, calibrated for a given reference temperature, to be used with any other reference tempera-

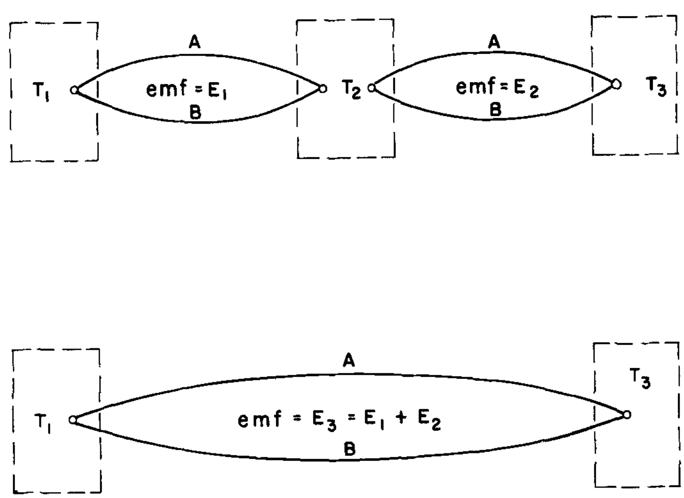

FIG. 3—*Emf's are additive for temperature intervals.*

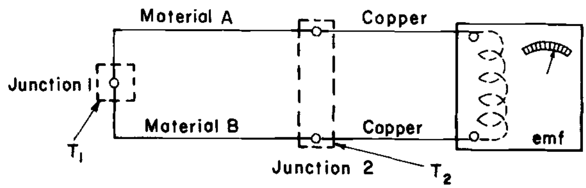
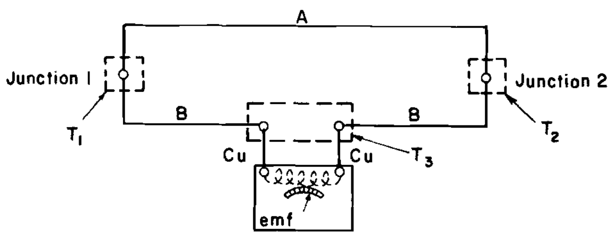


(a) For temperature level (Junction 2 is held at a constant, known reference temperature)



(b) For temperature difference (Junctions 1 and 2 are each exposed to unknown environment temperatures)

FIG. 4—*Several methods for introducing copper extension wires in elementary thermocouple circuits.*

ture through the use of a suitable correction (see Fig. 3 for a schematic example).

Another consequence of this law is that extension wires, having the same thermoelectric characteristics as those of the thermocouple wires, can be introduced in the thermocouple circuit (say from region T_2 to region T_3 in Fig. 3) without affecting the net emf of the thermocouple.

2.3 Elementary Thermoelectric Circuits

Two continuous, dissimilar thermocouple wires extending from the measuring junction to the reference junction, when used together with copper connecting wires and a potentiometer, connected as shown in Fig. 4, make up the basic thermocouple circuit.

An ideal circuit is given in Fig. 5 for use when more than one thermocouple is involved. The usual thermocouple circuit, however, includes: measuring junctions, thermocouple extension wires, reference junctions, copper connecting wires, a selector switch, and potentiometer, as indicated in Fig. 6. Many different circuit arrangements of the above components are also acceptable, depending on given circumstances, and these are discussed in the appropriate sections which follow.

ξ	Entropy production/volume

Chapter 3—Thermocouple Materials

3.1 Common Thermocouple Types

The commonly used thermocouple types are identified by letter designations originally assigned by the Instrument Society of America (ISA) and adopted as an American Standard in ANSI C96.1-1964. This chapter covers general application data on the atmospheres in which each thermocouple type can be used, recommended temperature ranges, limitations, etc. Physical and thermoelectric properties of the thermoelement materials used in each of these thermocouple types are tabulated in Section 3.1.2.

The following thermocouple types are included (these are defined as having the emf-temperature relationship given in the corresponding letter-designated Table in Chapter 10 within the limits of error specified in Table 41 of that chapter):

Type B—Platinum-30 percent rhodium (+) versus platinum-6 percent rhodium (−).

Type E—Nickel-10 percent chromium (+) versus constantan (−).

Type J—Iron (+) versus constantan (−).

Type K—Nickel-10 percent chromium (+) versus Nickel-5 percent (aluminum, silicon) (−) (see note).

Type R—Platinum-13 percent rhodium (+) versus platinum (−).

Type S—Platinum-10 percent rhodium (+) versus platinum (−).

Type T—Copper (+) versus constantan (−).

Temperature limits stated in the text are maximum values. Table 2 gives recommended maximum temperature limits for various gage sizes of wire. Table 3 gives nominal Seebeck coefficients for the various types. Temperature-emf equivalents and commercial limits of error for these common thermocouple types are given in Chapter 10.

3.1.1 General Application Data

Type T—These thermocouples are resistant to corrosion in moist atmospheres and are suitable for subzero temperature measurements. They have an upper temperature limit of 700°F (371°C) and can be used in a vacuum and in oxidizing, reducing, or inert atmospheres. This is the only

NOTE: Silicon, or aluminum and silicon, may be present in combination with other elements.

TABLE 2—*Recommended upper temperature limits for protected thermocouples.*

	Upper Temperature Limit for Various Wire Sizes (awg), °F (°C)				
Thermocouple Type	No. 8 Gage (0.128 in. (3.25 mm))	No. 14 Gage (0.064 in. (1.63 mm))	No. 20 Gage (0.032 in. (0.81 mm))	No. 24 Gage (0.020 in. (0.51 mm))	No. 28 Gage (0.013 in. (0.33 mm))
B				3100 (1705)	
E	1600 (871)	1200 (649)	1000 (538)	800 (427)	800 (427)
J	1400 (760)	1100 (593)	900 (482)	700 (371)	700 (371)
K	2300 (1260)	2000 (1093)	1800 (982)	1600 (871)	1600 (871)
R and S				2700 (1482)	
T		700 (371)	500 (260)	400 (204)	400 (204)

NOTE—This table gives the recommended upper temperature limits for the various thermocouples and wire sizes. These limits apply to protected thermocouples, that is, thermocouples in conventional closed-end protecting tubes. They do not apply to sheathed thermocouples having compacted mineral oxide insulation. In any general recommendation of thermocouple temperature limits, it is not practicable to take into account special cases. In actual operation, there may be instances where the temperature limits recommended can be exceeded. Likewise, there may be applications where satisfactory life will not be obtained at the recommended temperature limits. However, in general, the temperature limits listed are such as to provide satisfactory thermocouple life when the wires are operated continuously at these temperatures.

thermocouple type for which limits of error are established in the subzero temperature range (see note 4 under Table 41, Chapter 10).

Type J—These thermocouples are suitable for use in vacuum and in oxidizing, reducing, or inert atmospheres, at temperatures up to 1400°F (760°C). The rate of oxidation of the iron thermoelement is rapid above 1000°F (538°C), however, and the use of heavy-gage wires is recommended when long life is required at the higher temperatures.

Bare thermocouples should not be used in sulfurous atmospheres above 1000°F (538°C).

This thermocouple is sometimes used for subzero temperatures, but the possible rusting and embrittlement of the iron wire under these conditions makes its use less desirable than Type T for low temperature measurements. Limits of error have not been established for Type J thermocouples at subzero temperatures (see Chapter 10).

Type K—Type K thermocouples are recommended for continuous use in oxidizing or inert atmospheres at temperatures up to 2300°F (1260°C). Because their oxidation resistance characteristics are better than those of other base metal thermocouples, they find widest use at temperatures above 1000°F (538°C). However, this thermocouple is suitable for temperature measurements as low as −420°F (−250°C), although limits of error have been established only for the temperature range 0 to 2300°F (−18 to 1260°C) (see Chapter 10).

3000	...	...	...	7.6	6.5	...	6.5

The Type K thermocouple may be used in hydrogen or cracked ammonia atmospheres if the dewpoint is below −40°F (−40°C). However, they should not be used in:

1. Atmospheres that are reducing or alternately oxidizing and reducing unless suitably protected with protection tubes.
2. Sulfurous atmospheres unless properly protected. Sulfur will attack both thermoelements and will cause rapid embrittlement and breakage of the negative thermoelement wire through intergranular corrosion.
3. Vacuum except for short time periods (preferential vaporization of chromium from the positive element will alter calibration).
4. Atmospheres that promote "green-rot" corrosion of the positive thermoelement. Such corrosion results from preferential oxidation of chromium when the oxygen content of the atmosphere surrounding the thermocouple is low and in a certain range. It can cause large negative errors in calibration and is most serious in the temperature range 1500 to 1900°F (816 to 1038°C).

Green-rot corrosion frequently occurs when thermocouples are used in long unventilated protecting tubes of small diameter. It can be minimized by increasing the oxygen supply through the use of large diameter protecting tubes or ventilated protecting tubes. Another approach is to decrease the oxygen content below that which will promote preferential oxidation by inserting a "getter" to absorb the oxygen in a sealed protection tube.

Type E—Type E thermocouples are recommended for use over the temperature range of −420 to 1600°F (−250 to 871°C) in oxidizing or inert atmospheres. In reducing atmospheres, alternately oxidizing and reducing atmospheres, marginally oxidizing atmospheres, and in vacuum they are subject to the same limitations as Type K thermocouples.

These thermocouples are suitable for subzero temperature measurements since they are not subject to corrosion in atmospheres with high moisture content. However, limits of error for the subzero range have not been established.

Type E thermocouples develop the highest emf per degree of all the commonly used types and are often used primarily because of this feature.

Types R and S—Type R and S thermocouples are recommended for continuous use in oxidizing or inert atmospheres at temperatures up to 2550°F (1399°C); intermittently up to 2700°F (1482°C).

They should not be used in reducing atmospheres, nor those containing metallic or nonmetallic vapors, unless suitably protected with nonmetallic protecting tubes. They never should be inserted directly into a metallic primary protecting tube.

Types R and S thermocouples may be used in a vacuum for short periods of time, but greater stability will be obtained by using Type B thermocouples for such applications.

Continued use of Types R and S thermocouples at high temperatures causes excessive grain growth which can result in mechanical failure of the platinum element. It also renders the platinum susceptible to contamination which causes negative drifts in calibration, that is, a reduction in the emf output of the thermocouple.

Calibration changes also are caused by diffusion of rhodium from the alloy wire into the platinum, or by volatilization of rhodium from the alloy. All of these effects tend to produce negative calibration shifts.

Type B—Type B thermocouples are recommended for continuous use in oxidizing or inert atmospheres at temperatures up to 3100°F (1704°C). They are also suitable for short term use in vacuum to this temperature.

They should not be used in reducing atmospheres, nor those containing metallic or nonmetallic vapors, unless suitably protected with nonmetallic protecting tubes. They should never be inserted directly into a metallic primary protecting tube.

Under corresponding conditions of temperature and environment Type B thermocouples will show less grain growth and less drift in calibration than Type R or S thermocouples.

3.1.2 Properties of Thermoelement Materials

This section indicates in Tables 4 to 10 and in Fig. 7 the physical and electrical properties of thermoelement materials as used for the common letter-designated thermocouple types (Types B, E, J, K, R, S, and T). These are typical data and are listed for information only. They are not intended for use as specifications for ordering thermocouple materials.

Thermoelement materials are designated in the tables by the established American Standard letter symbols JP, JN, etc. The first letter of the symbol designates the type of thermocouple. The second letter, P or N, denotes

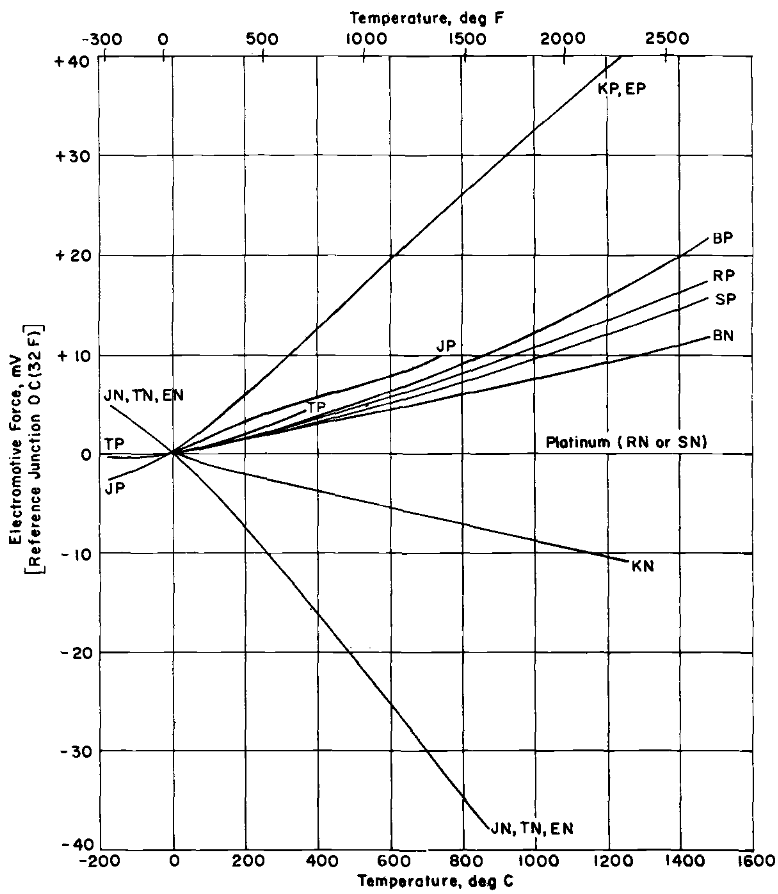

FIG. 7—*Thermal emf of thermoelements relative to platinum.*

the positive or negative thermoelement, respectively. Typical materials to which these letter designations apply are listed next:

BP	Platinum-30 percent rhodium
BN	Platinum-6 percent rhodium
JP	Iron, ThermoKanthal[1] JP
JN, EN, or TN	Constantan, Cupron,[2] Advance,[3] ThermoKanthal JN
TP	Copper
KP or EP	Chromel,[4] Tophel,[2] T-1,[3] ThermoKanthal KP
KN	Alumel,[4] Nial,[2] T-2,[3] ThermoKanthal KN
RP	Platinum-13 percent rhodium
SP	Platinum-10 percent rhodium
RN or SN	Platinum

[1] Trademark—Kanthal Corp.
[2] Trademark—Wilbur B. Driver Co.
[3] Trademark—Driver-Harris Co.
[4] Trademark—Hoskins Manufacturing Co.

Note that JN, EN, and TN thermoelements, as just listed, are composed of the same basic types of material. The typical data contained in the following pages are applicable to any of these thermoelements, but the thermal emf (versus platinum) of the three types may differ significantly depending on the type of thermocouple for which each is intended.

It also should be noted that positive and negative thermoelements for a given type of thermocouple, as supplied by any one manufacturer, will conform to the calibration curve for that thermocouple within specified limits of error. However, because materials used for a given thermoelement by various manufacturers may differ slightly in thermal emf, larger errors may occur if positive and negative thermoelements from different sources are combined. This is particularly true of thermoelements for Types J, R, and S thermocouples.

3.2 Extension Wires

3.2.1 General Information

Extension wires are inserted between the measuring junction and the reference junction and have approximately the same thermoelectric properties as the thermocouple wires with which they are used. Table 11 gives comparative data on extension wires available for thermocouples in common use. Extension wires are normally available as single or duplex, solid or stranded, insulated wires in sizes ranging from 14 to 20 B&S gage. A variety of insulations and protective coverings is available in several combinations to suit the many types of environments encountered in industrial service (see Chapter 4).

Some advantages of using extension wires are:

1. Improvement in mechanical or physical properties of the thermoelectric circuit. For example, the use of stranded construction or smaller

[a] Types JN, TN, and EN thermoelements usually contain small amounts of various elements for control of thermal emf, with corresponding reductions in the nickel or copper content, or both.

[b] Thermoelectric iron (JP) contains small but varying amounts of these elements.

TABLE 6—*Environmental limitations of thermoelements.*

Thermoelement	Environmental Recommendations and Limitations (see notes)
JP	For use in oxidizing, reducing, or inert atmospheres or in vacuum. Oxidizes rapidly above 540°C (1000°F). Will rust in moist atmospheres as in subzero applications. Stable to neutron radiation transmutation. Change in composition is only 0.5 percent (increase in manganese) in 20-year period.
JN, TN, EN	Suitable for use in oxidizing, reducing, and inert atmospheres or in vacuum. Should not be used unprotected in sulfurous atmospheres above 540°C (1000°F). Composition changes under neutron radiation since copper content is converted to nickel and zinc. Nickel content increases 5 percent in 20-year period.
TP	Can be used in vacuum or in oxidizing, reducing or inert atmospheres. Oxidizes rapidly above 370°C (700°F). Preferred to Type JP element for subzero use because of its superior corrosion resistance in moist atmospheres. Radiation transmutation causes significant changes in composition. Nickel and zinc grow into the material in amounts of 10 percent each in a 20-year period.
KP, EP	For use in oxidizing or inert atmospheres. Can be used in hydrogen or cracked ammonia atmospheres if dew point is below −40°C (−40°F). Do not use unprotected in sulfurous atmospheres above 540°C (1000°F).

(Continued)

TABLE 6—*Continued.*

Thermoelement	Environmental Recommendations and Limitations (see notes)
	Not recommended for service in vacuum at high temperatures except for short time periods because preferential vaporization of chromium will alter calibration. Large negative calibration shifts will occur if exposed to marginally oxidizing atmospheres in temperature range 815 to 1040°C (1500 to 1900°F).
	Quite stable to radiation transmutation. Composition change is less than 1 percent in 20-year period.
KN	Can be used in oxidizing or inert atmospheres. Do not use unprotected in sulfurous atmospheres as intergranular corrosion will cause severe embrittlement.
	Relatively stable to radiation transmutation. In 20-year period, iron content will increase approximately 2 percent. The manganese and cobalt contents will decrease slightly.
RP, SP, SN, RN, BP, BN	For use in oxidizing or inert atmospheres. Do not use unprotected in reducing atmospheres in the presence of easily reduced oxides, atmospheres containing metallic vapors such as lead or zinc, or those containing nonmetallic vapors such as arsenic, phosphorus, or sulfur. Do not insert directly into metallic protecting tubes. Not recommended for service in vacuum at high temperatures except for short time periods.
	Type SN elements are relatively stable to radiation transmutation. Types BP, BN, RP, and SP elements are unstable because of the rapid depletion of rhodium. Essentially, all the rhodium will be converted to palladium in a 10-year period.

NOTE 1—Refer to Table 7 for recommended upper temperature limits.

NOTE 2—Stability under neutron radiation refers to chemical composition of thermoelement, not to stability of thermal emf.

NOTE 3—Radiation transmutation rates[a] are based on exposure to a thermal neutron flux of 1×10^{14} neutrons/cm$^2\cdot$s.

diameter solid wire may increase the flexibility of a portion of the circuit. Extension wires also may be selected to adjust the electrical resistance of the circuit.

2. Cost improvement in thermoelectric circuitry. For example, certain base metal extension wires may be substituted for noble metal wires when the reference junction is situated at a distance from a noble metal thermocouple.

Extension wires may be separated into two categories having the following characteristics:

Category 1—Alloys substantially the same as used in the thermocouple. This type of extension wire normally is used with base metal thermocouples.

RP, SP, RN, SN	...	...	...	1482°C (2700°F)	...
BP, BN	...	...	...	1705°C (3100°F)	...

NOTE—This table gives the recommended upper temperature limits for the various thermoelements and wire sizes. These limits apply to protected thermoelements, that is, thermoelements in conventional closed-end protecting tubes. They do not apply to sheathed thermoelements having compacted mineral oxide insulation. In any general recommendation of thermoelement temperature limits, it is not practicable to take into account special cases. In actual operation, there may be instances where the temperature limits recommended can be exceeded. Likewise, there may be applications where satisfactory life will not be obtained at the recommended temperature limits. However, in general, the temperature limits listed are such as to provide satisfactory thermoelement life when the wires are operated continuously at these temperatures.

Category 2—Alloys differing from those used in the thermocouple. This type of extension wire normally is used with noble metal thermocouples and with several of the nonstandardized thermocouples (see Section 3.3).

3.2.2 Sources of Error

Several possible sources of error in temperature measurement accompany the use of extension wires in thermocouple circuits. Most of the errors can be avoided, however, by exercising proper precautions.

One type of error arises from the disparity in thermal emf between thermocouples and nominally identical extension wire components of Category 1. The disparity results from the variations occurring among thermoelements lying within the standard limits of error for each type of thermocouple and extension wire. Thus, for example, it is possible that an error as great as ±8°F could occur in the Type K/KX and J/JX thermocouple-extension wire combinations, where the standard limits of error are ±4°F for the thermocouple and the extension wires treated as separate combinations. Such errors can be eliminated substantially by selecting extension wires whose emf closely matches that of the specific thermocouple, up to the maximum temperature of the thermocouple-extension wire junction.

[a] Extension wires for other thermocouple types will be found in Section 3.3.
[b] M denotes ferro-magnetic alloy: O denotes nonferro-magnetic alloy.
[c] Former (proprietary) designation.

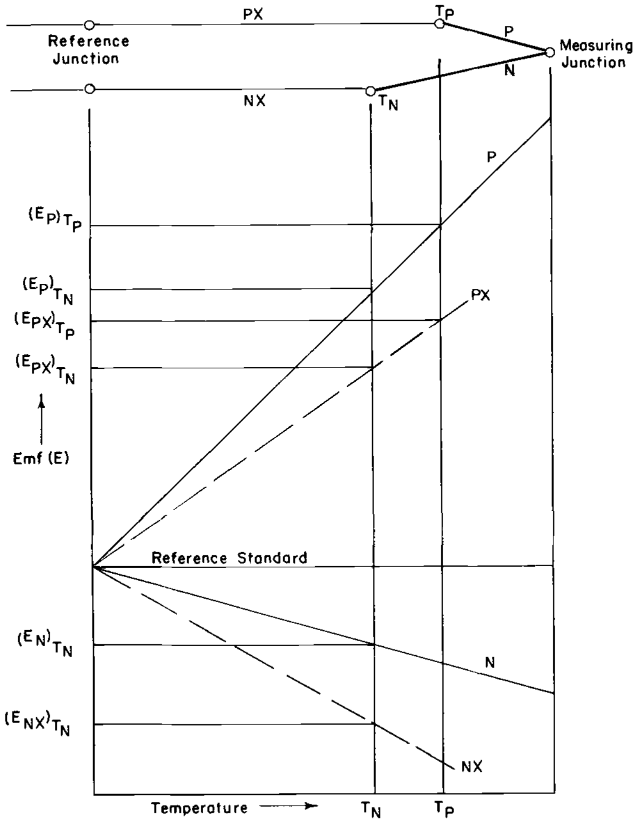

FIG. 8—*Error due to ΔT between the thermocouple-extension wire junctions.*

A second source of error can arise if a temperature difference exists between the two thermoelement-extension wire junctions. Errors of this type are potentially greater in circuits employing extension wires of Category 2, where each extension element may differ significantly in emf from the corresponding thermoelement. Such errors may occur even though the extension pair emf exactly matches the thermocouple emf at each temperature. Referring to Fig. 8, schematically representing emf versus temperature curves for positive and negative thermoelements P and N, and corresponding extension wire elements PX and NX, the following relationships apply at any temperature T within the operating range of the extension wires:

Thermocouple output = extension pair output

that is,

$$E_P - E_N = E_{PX} - E_{NX} \tag{37}$$

Rearranging to

$$E_P - E_{PX} = E_N - E_{NX} \tag{38}$$

If a temperature difference exists between the two junctions such that P joins PX at T_P, and N joins NX at T_N, an unwanted emf will exist across the two junctions, of magnitude

$$\Delta E = (E_P - E_{PX})_{T_P} - (E_N - E_{NX})_{T_N} \tag{39}$$

Rearranging Eq 39 according to Eq 38:

$$\Delta E = (E_P - E_{PX})_{T_P} - (E_P - E_{PX})_{T_N} \tag{40}$$

The sign of ΔE will depend on the relationship of temperature T_P to T_N and the relationship of PX and NX to P and N.

This ΔE will be interpreted as an error in the output of the measuring thermocouple. Such errors do not exceed about one degree at the measuring junction, per degree of ΔT between the thermocouple-extension wire junctions, for any of the thermocouples and extension wires listed in Table 2. These errors can be essentially eliminated by taking steps to equalize the temperatures of the two junctions.

A third source of error lies in the presence of reversed polarity at the thermocouple-extension wire junctions, or at the extension wire-instrument junctions. Although a single reversal of polarity in the assembly would be noticeable, an inadvertent double reversal likewise may produce measurement errors, but could escape immediate detection.

A fourth source of error concerns the use of connectors in the thermocouple assembly. If the connector material has thermal emf characteristics which differ appreciably from those of the thermocouple extension wires, then it is important that a negligible temperature difference be maintained across the connector. This follows directly from the Law of Intermediate Metals (see Section 2.2.2). Thus, in situations where a connector made of a third metal spans a substantial temperature gradient, unwanted emfs are generated between the thermoelectric materials and the extremities of the connector, and they appear as errors in the output of the thermocouple. The magnitude of errors of this type can vary over a wide range depending on the materials involved and the temperature difference spanned by the connector.

If the emf errors arising from the use of extension wires or from other sources are to be expressed as temperature errors, the Seebeck coefficient at the measuring junction temperature must be used.

A useful graphical method of evaluating error sources in thermoelectric circuits is detailed in a paper by Moffat (see Ref *34* on p. 239).

3.3 Nonstandardized Thermocouple Types

Newer thermocouple materials are being evaluated constantly to find combinations which perform special functions more reliably than the common thermocouples. The special functions for which these newer combinations are required frequently involve very high temperatures, but also may include unusual environments such as special atmospheres or areas susceptible to vibration.

Each of the combinations described in this section has been designed to measure temperatures under specific conditions and to perform with a degree of reliability superior to other combinations under these same conditions. The properties of each combination are detailed to allow a quick selection of a combination which is most likely to be suitable for a special condition. Thermocouple compositions are given in weight percent with the positive thermoelement of the thermocouple named first.

The information on newer thermocouple materials is presented using comments, tables, and curves. The comments made for the various thermocouple systems are intended to convey information not easily shown by tables or curves. The information contained in the tables is intended to help the reader to quickly decide if a certain thermocouple system, or a specific thermocouple, is suited to his particular needs. The information given is general and nominal, and cannot be used too literally. For example, the useful maximum temperature of a thermocouple depends in part on wire size, insulation used, method of installation, atmosphere conditions, vibration present, etc. The evaluation of certain properties as good, fair, or poor is subject to wide ranges of interpretation in terms of a particular application; hence, no attempt is made to define these terms. Approximate millivolt-versus-temperature relations for the various thermocouples are shown by curves. The curves are presented to show general temperature ranges for the various thermocouples but are not intended for use in converting emf to temperature. The reader should contact the wire manufacturer for temperature-emf tables.

The thermocouples described here are in use, and sufficient data and experience are available to warrant their inclusion. No attempt is made to include the many other thermocouple materials described in the literature which may have limited uses, or for which there are limited data, or for which there are serious problems of stability, emf reversibility, structural strength, etc.

The best source of information for a specific thermocouple in the "newer material" classification is considered to be the manufacturer of the particular thermocouple under consideration. Other useful information can be found in Ref *1*.[5]

3.3.1 Platinum Types

3.3.1.1 Platinum-Rhodium Versus Platinum-Rhodium Thermocouples—The standard Type R and Type S thermocouples can be used for temperature measurement to the melting point of platinum, 1769°C (3216°F) on a short-term basis, but, for improved service life at temperatures over 1200°C (2192°F), special platinum-rhodium thermocouples are recommended.

[5] The italic numbers in brackets refer to the list of references in this manual.

The platinum-40 percent rhodium versus platinum-20 percent rhodium thermocouple, called the "Land-Jewell" thermocouple, is especially useful for continuous use to 1800°C (3272°F) or occasional use to 1850°C (3362°F). However, it is seldom used where the Type B thermocouple will suffice because of lower output and greater cost.

Other thermocouples suggested for high-temperature measurement have been a platinum-13 percent rhodium versus platinum-1 percent rhodium combination and a platinum-20 percent rhodium versus platinum-5 percent rhodium combination. The former shows slightly less tendency toward mechanical failure or contamination at high temperatures than the standard Type R and Type S thermocouples, while the latter has properties very similar to those of the Type B thermocouple.

Figure 9 and Table 12 show the characteristics of these alloys.

TABLE 12—*Platinum-rhodium versus platinum-rhodium thermocouples.*

	Pt-20Rh Versus Pt-5Rh	Pt-40Rh Versus Pt-20Rh	Pt-13Rh Versus Pt-1Rh
Nominal operating temperature range, in:			
Reducing atmosphere (nonhydrogen)	NR[a]	NR	NR

Stability with thermal cycling	good	good	good
High-temperature tensile properties	good	good	good
Stability under mechanical working	good	fair	good
Ductility (of most brittle thermoelement) after use	good	fair	good
Resistance to handling contamination	fair	fair	fair
Recommended extension wire, 175°C (347°F) max:			
Positive conductor	Cu	Cu	Cu
Negative conductor	Cu	Cu	Cu

[a] NR = not recommended.

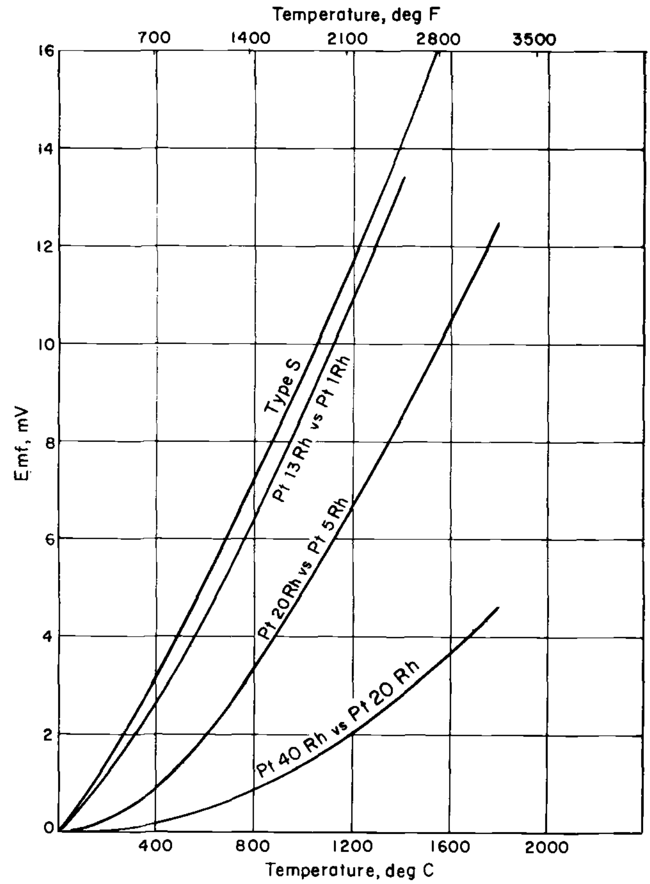

FIG. 9—*Thermal emf of platinum-rhodium versus platinum-rhodium thermocouples.*

All special platinum-rhodium versus platinum-rhodium thermocouples, like the standard Types R, S, and B thermocouples, show improved life at high temperatures when protected by double-bore, full-length insulators of high-purity alumina.

3.3.1.2 Platinum-15 Percent Iridium Versus Palladium Thermocouples—The platinum-15 percent iridium versus palladium combination was developed as a high-output noble-metal thermocouple. It combines the desirable attributes of noble metals with a high emf output at a lower cost than other noble-metal thermocouples.

The output becomes more linear and the Seebeck coefficient (thermoelectric power) increases with increasing temperature. In the absence of vibration, the useful range can probably be extended closer to the melting point of palladium, 1550°C (2826°F).

Figure 10 and Table 13 show the characteristics of these alloys.

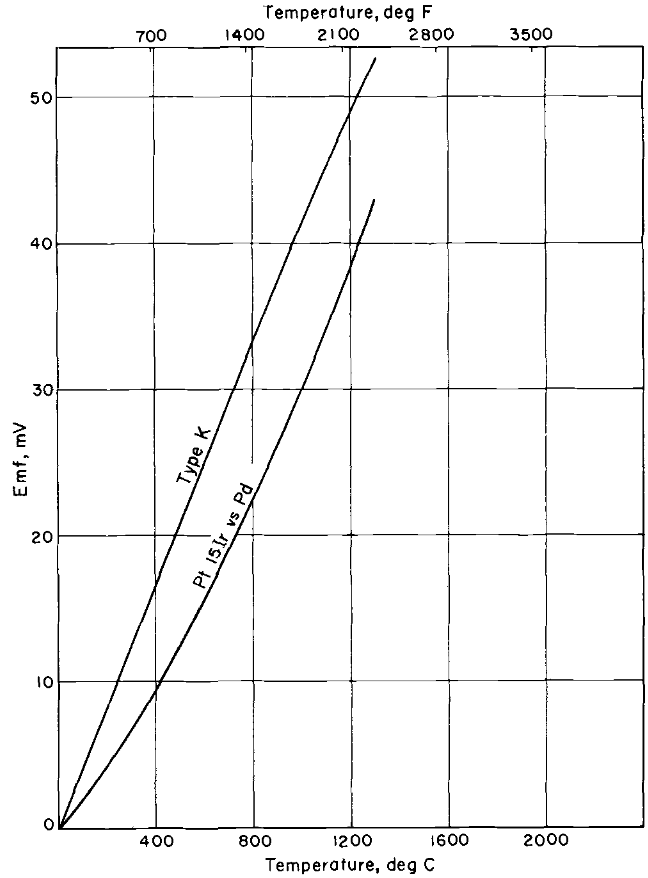

FIG. 10—*Thermal emf of platinum-iridium versus palladium thermocouple.*

Extension wires of base metals have been developed to provide a reasonable match with the thermocouple to about 700°C (1292°F).

Resistance to corrosion of the platinum-15 percent iridium alloy is better than that of the platinum-rhodium alloys in current use. Palladium is slightly less resistant to corrosion than the platinum alloy group. It will superficially oxidize at 700°C (1292°F). The oxide decomposes at about 875°C (1607°F) leaving a bright metal. When subjected to alternating oxidizing and reducing atmospheres, surface blistering may result. As with all noble metals, the catalytic effect of the wires must be considered in combustible atmospheres. Its use may be preferred to base metals, however, for many applications. Both wires are ductile and may be reduced to very small sizes and still be handled with relative ease.

3.3.1.3 Platinum-5 Percent Molybdenum Versus Platinum-0.1 Percent Molybdenum Thermocouple—Platinum alloys containing rhodium are not suit-

TABLE 13—*Platinum-iridium versus palladium thermocouple.*

[b] General Electric Company.

able for use under neutron irradiation since the rhodium changes slowly to palladium. This causes a drift in the calibration of thermocouples containing rhodium. However, a thermocouple of platinum-5 percent molybdenum versus platinum-0.1 percent molybdenum is suitable for use in the helium atmosphere of a gas-cooled atomic reactor. Good stability at temperatures up to 1400°C (2552°F) has been reported. The output of the thermocouple is high and increases in a fairly uniform manner with increasing temperature.

Figure 11 and Table 14 show the characteristics of these alloys.

The thermocouple usually is used in an insulated metallic sheath of platinum-5 percent molybdenum alloy. The sheath may be joined to a Type 321 stainless steel sheath beyond the area of the helium atmosphere. Both the platinum-molybdenum alloy and the Type 321 stainless steel behave well under neutron irradiation and are compatible with graphite which normally is used in the reactor.

Extension wires for this thermocouple can be copper for the positive conductor and copper-1.6 percent nickel for the negative conductor. Using

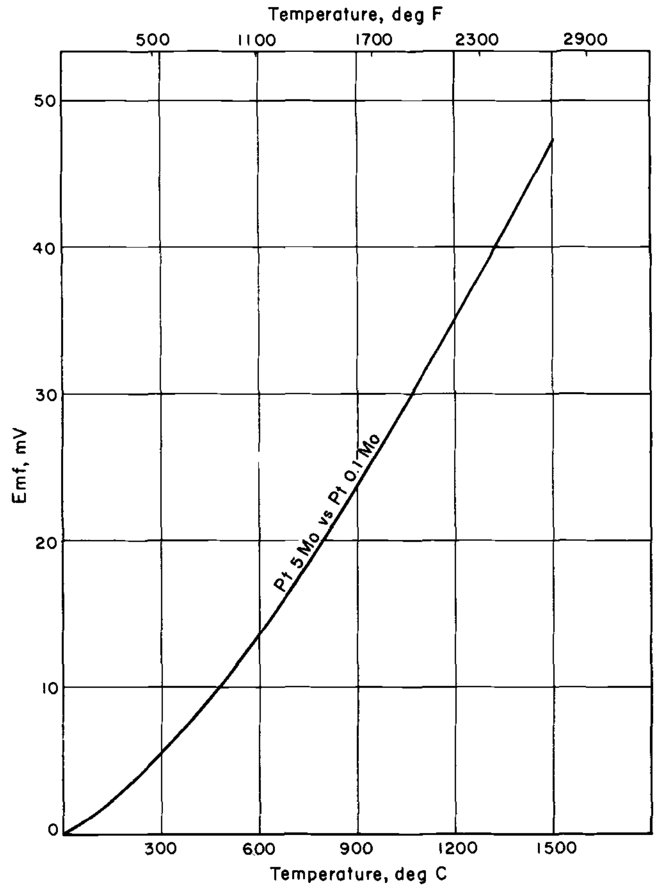

FIG. 11—*Thermal emf of platinum-molybdenum versus platinum-molybdenum thermocouple.*

these materials the junctions between the thermocouple and the extension wires should be maintained below 70°C (158°F).

3.3.2 Iridium-Rhodium Types

3.3.2.1 Iridium-Rhodium Versus Iridium Thermocouples—Iridium-rhodium versus iridium thermocouples are suitable for measuring temperature to approximately 2000°C (3632°F), and generally are used above the range served by platinum-rhodium versus platinum thermocouples. They can be used in inert atmospheres and in vacuum, but not in reducing atmospheres, and they may be used in oxidizing atmospheres with shortened life.

The alloys of principal interest are those containing 40, 50, and 60 percent rhodium. They may be used for short times at maximum temperatures

Negative conductor	Cu-1.6Ni

[a] NR = not recommended.

2180, 2140, and 2090°C (3956, 3884, and 3794°F, respectively), these temperatures being 60°C (140°F) or more below the respective melting points.

Figure 12 and Table 15 show the characteristics of these alloys.

The wires must be handled carefully. They are flexible in the fibrous (as drawn) state, but when annealed are broken easily by repeated bending.

Metals said to be suitable for extension wires are copper for the positive conductor and stainless steel or an aluminum alloy for the negative conductor.

3.3.3 Platinel Types

3.3.3.1 Platinel Thermocouples—Platinel,[6] a noble-metal thermocouple combination, was metallurgically designed for high-temperature indication and control in turbo-prop engines. This combination approximates within reasonable tolerances the Type K thermocouple curve.

Actually, two combinations have been produced and are called Platinel I and Platinel II. The negative thermoelement in both thermocouples is a

[6] Trademark—Engelhard Industries, Inc.

65 percent gold-35 percent palladium alloy (Platinel 1503), but the positive one in Platinel I is composed of 83 percent palladium, 14 percent platinum, and 3 percent gold (Platinel 1786), while that used in Platinel II contains 55 percent palladium, 31 percent platinum, and 14 percent gold (Platinel 1813). Platinel II is the preferred type and has superior mechanical fatigue properties. The thermal emf's of these combinations differ little, as shown in Fig. 13. Other properties are given in Table 16.

From Fig. 13 it is apparent that the emf match with the Type K thermocouple is excellent at high temperatures, but some departure occurs at low temperatures. Generally, the user of Platinel makes the connection between the thermocouple and the extension wire (Type K thermocouple wire) at an elevated temperature (800°C) where the match is good. However, if this is done, care should be taken to ensure that the junctions of both conductors are at the same temperature. If the junction is made at a temperature

where the extension wire/thermocouple emf match is not too close, then corrections should be made. Other base-metal extension wires capable of matching the emf of the Platinels very closely at low temperatures [to 160°C (320°F)] are also available.

It is recommended that precautions usually followed with the use of platinum-rhodium versus platinum thermocouples be observed when the Platinels are employed. Tests have shown that phosphorus, sulfur, and silicon have a deleterious effect on the life of the thermocouples.

3.3.4 Nickel-Chromium Types

3.3.4.1 Nickel-Chromium Alloy Thermocouples—Special nickel-chromium alloys are supplied by various manufacturers as detailed in the following paragraphs. Figure 14 and Table 17 give characteristics of these alloys.

Negative conductor	Type KN	Type KN

[a] High-purity alumina insulators are recommended.
[b] NR = not recommended.

3.3.4.1.1 Geminol—The Geminol[7] thermocouple was developed primarily for improved resistance to deterioration in reducing atmospheres.

The composition of the positive thermoelement has been adjusted specifically to combat in reducing atmospheres the destructive corrosion known as "green rot."

The substitution of an 80 percent nickel-20 percent chromium type alloy for the conventional (Type KP) 90 percent nickel-10 percent chromium alloy positive thermoelement, and a 3 percent silicon in nickel alloy for the conventional (Type KN) manganese-aluminum-silicon in nickel alloy negative thermoelement, results in a more oxidation-resisting thermocouple.

The temperature-emf curve is practically parallel to that of the conventional Type K thermocouple above 760°C (1400°F).

3.3.4.1.2 Thermo-Kanthal special—The Thermo-Kanthal special thermocouple was developed to give improved stability at temperatures between 982°C (1800°F) and 1260°C (2300°F) over that obtained with conventional base-metal thermocouple materials.

[7] Trademark—Driver-Harris Co.

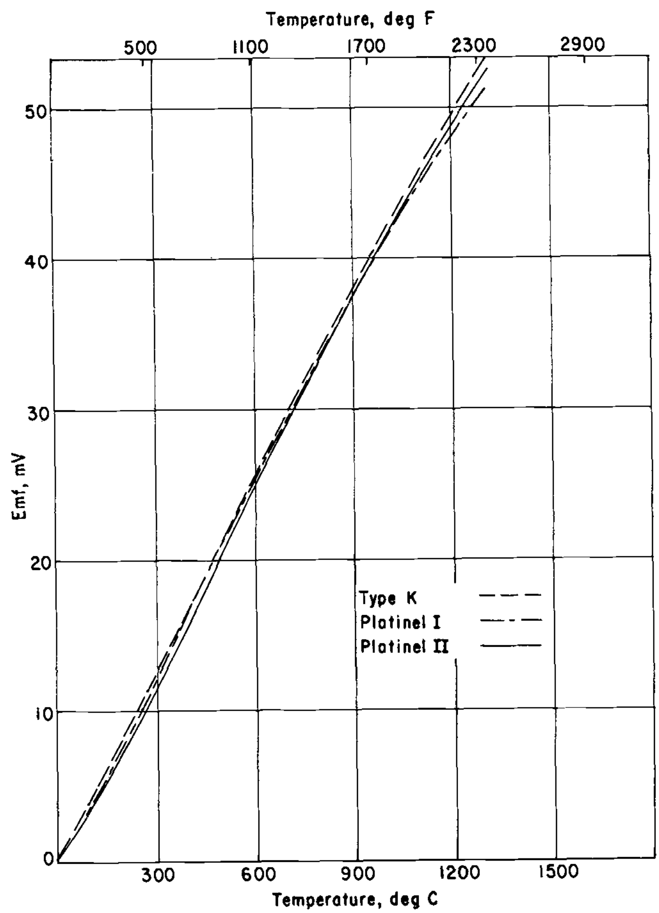

FIG. 13—*Thermal emf of platinel thermocouples.*

3.3.4.1.3 Tophel II-Nial II—

1. The Tophel II-Nial II thermocouple was developed for improved oxidation resistance and emf stability over the conventional Type K thermocouple alloys in both oxidizing and reducing atmospheres at elevated temperatures.

2. Tophel II, which is the positive thermoelement, is a Ni-10Cr base alloy with additions to resist "green rot" attack in reducing atmospheres at elevated temperatures. The emf of Tophel II is within the standard tolerance of the conventional Type K positive thermoelement over the entire temperature range of 32 to 2300°F (0 to 1260°C). Tophel II can be matched with any acceptable Type K negative thermoelement to form a couple which is within the standard tolerance for the Type K thermocouple.

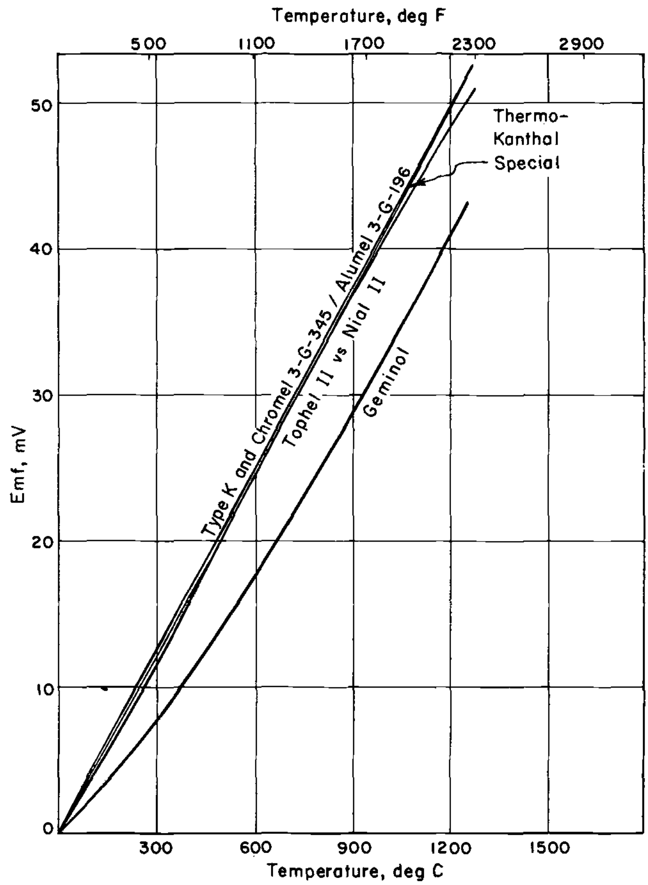

FIG. 14—*Thermal emf of nickel-chromium alloy thermocouples.*

3. Nial II, which is the negative thermoelement, is a Ni-2.5Si base alloy with additions to improve the oxidation resistance and emf stability in an oxidizing atmosphere at elevated temperatures. The emf of Nial II is within the standard tolerance of the conventional Type K thermoelement between the range of 300 to 2300°F (149 to 1260°C). From 32 to 300°F (0 to 149°C), the Nial II is about 0.1 mV less negative than the conventional Type K negative thermoelement with reference to platinum.

4. The Tophel II-Nial II thermocouple meets the emf tolerances designated in ASTM Specification E 230 for the Type K thermocouple from 300 to 2000°F (149 to 1093°C). From 32 to 300°F (0 to 149°C), the Tophel II-Nial II thermocouple generates 0.1 mV (or 5 deg equivalent) less than the standard Type K thermocouple at the same temperature.

5. Tophel II-Nial II thermocouples can be used on existing instruments designed for the Type K thermocouples for temperatures sensing and control within the range of 300 to 2300°F (149 to 1260°C). If extension wire is needed, the negative extension wire should be Nial II, while the positive extension wire could either be Tophel II or any acceptable Type K (+) extension wire.

6. Through the improvements in both oxidation resistance and emf stability, Tophel II-Nial II thermocouples offers longer useful and total service life than conventional Type K thermocouples of the same size. As a corollary benefit, finer size Tophel II-Nial II thermocouples can be used to achieve equivalent or better stability than conventional Type K couples of larger sizes.

3.3.4.1.4 Chromel 3-G-345-Alumel 3-G-196—The Chromel 3-G-345-Alumel 3-G-196 thermocouple is designed to provide improved performance under extreme environmental conditions where the conventional Type K thermocouple is subject to accelerated loss of stability.

More specifically, Chromel 3-G-345 is a Type K positive thermoelement in which the basic 10 percent chromium-nickel alloy is modified to give improved resistance to preferential chromium oxidation ("green rot"). At temperatures from 1600 to 1900°F (871 to 1038°C), conventional Type K positive thermoelements operating in marginally oxidizing environments are subject to embrittlement and loss of output as a result of such attack.

Under those conditions, Type K thermocouples employing Chromel 3-G-345 positive thermoelements offer greater stability than conventional Type K thermocouples. The usual precautions regarding protection of Type K thermocouples in corrosive environments apply to the special thermocouple as well.

The modified Chromel thermoelement meets the accepted curve of emf versus platinum for Type K positive thermoelements, within standard tolerances. It can be combined with either Alumel 3-G-196 or conventional Alumel to form Type K thermocouples meeting standard emf tolerances.

Alumel 3-G-196 is a Type K negative thermoelement of greatly improved oxidation resistance. It is suited to use in both reducing and oxidizing atmospheres, where its stability of output is especially advantageous in fine wire applications at high temperatures. It is nominally 2.5Si-Ni.

Alumel 3-G-196 meets the accepted curve of emf versus platinum for Type K negative thermoelements at all temperatures from 32 to 2300°F (0 to 1260°C). It can be combined with either Chromel 3-G-345 or regular Chromel to form thermocouples meeting standard Type K thermocouple tolerances over the entire range from 32 to 2300°F (0 to 1260°C).

Type K thermocouples employing either or both special thermoelements can be used with conventional extension wires at no sacrifice in guaranteed accuracy of the thermocouple-extension wire combination.

3.3.5 Nickel-Molybdenum Types

3.3.5.1 19 and 20 Alloys[8] *(nickel-nickel molybdenum alloys)*—

1. The 19 Alloy/20 Alloy[7] thermocouple was developed for temperature sensing and control applications at elevated temperatures in hydrogen or other reducing atmospheres. The emf table of the 19 Alloy versus the 20 Alloy does not conform to the Type K or any existing base metal thermocouples designated by ASTM Specification E 230.

2. The 19 Alloy, which is the negative thermoelement, is essentially a Ni-1Co alloy. Its emf versus platinum values are somewhat more negative than those of the Type K negative thermoelement within the range of 32 to 2300°F (0 to 1260°C).

3. The 20 Alloy, which is the positive thermoelement, is essentially a Ni-18Mo alloy. Its emf versus platinum values are less positive within the range of 32 to 500°F (0 to 260°C) than the Type K positive thermoelement, but more positive within the range of 500 to 2300°F (260 to 1260°C). Figure 15 and Table 18 show the characteristics of these alloys.

[8] The 19 Alloy versus 20 Alloy thermocouple was developed by the General Electric Co. Since 1962, the Wilbur B. Driver Co. has been the sole manufacturer of the 19 Alloy and the 20 Alloy.

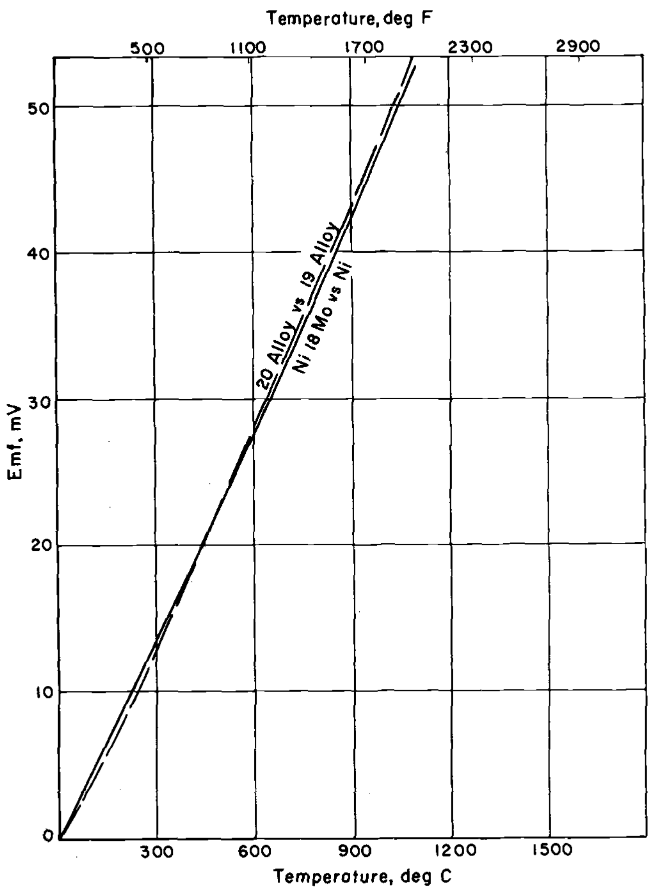

FIG. 15—*Thermal emf of nickel versus nickel-molybdenum alloys.*

4. The 19 Alloy/20 Alloy thermocouple, when properly sealed in a protection tube, offers excellent emf stability at elevated temperatures in hydrogen or other reducing atmospheres.

5. The oxidation resistance of the 19 Alloy/20 Alloy thermocouple is not good. The 19 Alloy/20 Alloy thermocouples are not recommended for use in an oxidizing atmosphere above 1200°F (649°C).

6. 19 Alloy/20 Alloy extension wire should be used in connection with the 19 Alloy/20 Alloy thermocouple.

3.3.6 Tungsten-Rhenium Types

There are three tungsten-rhenium thermocouple systems available—tungsten versus tungsten-26 percent rhenium, doped tungsten-3 percent rhenium versus tungsten-25 percent rhenium and doped tungsten-5 percent rhenium versus tungsten-26 percent rhenium. The price of the first combination has the lowest cost. All have been employed to 2760°C (5000°F), but general use is below 2316°C (4200°F). Applications for these couples have been found in space vehicles, nuclear reactors, and many high-temperature electronic, thermoelectric, industrial heating, and structural projects. However, when employed in a nuclear environment, the effect of transmutation of the thermal emf of the couples should be considered.

The use of tungsten in certain applications as the positive element may pose a problem, since heating tungsten to or above its recrystallization temperature (approximately 1200°C) causes embrittlement resulting in a loss of room-temperature ductility; an effect that is not experienced with the alloy leg containing high rhenium. With proper handling and usage this combination can be employed satisfactorily for long periods. One approach to the brittleness problem is to add rhenium to the tungsten thermoelement. Early research showed that the addition of 10 percent rhenium to the tungsten element did much to retain ductility after recrystallization. This much rhenium, however, greatly reduced the emf response for the thermocouple. Other techniques to retain room-temperature ductility are used by manufacturers; these include special processing and doping with the addition of 5 percent or less rhenium to the tungsten thermoelement.

Doping usually consists of using additives during the process of preparing the tungsten powder and results in a unique microstructure in the finished wire. The additives essentially are eliminated during the subsequent sintering of the tungsten-rhenium powder compact. In fact, presently known analytical techniques do not disclose the presence of the additives above the background level of such substances normally present as impurities in nondoped tungsten or tungsten-rhenium alloys.

The emf response of tungsten-3 percent rhenium and tungsten-5 percent rhenium thermoelements used with thermoelements containing high percentages of rhenium is satisfactory. The thermoelectric power of the tungsten versus tungsten-26 percent rhenium, tungsten-3 percent rhenium versus tungsten-25 percent rhenium, and tungsten-5 percent rhenium versus tungsten-26 percent rhenium is comparable at lower temperatures, but drops off slightly for the latter two as the temperature is increased.

The tungsten thermoelement is not supplied to the user in a stabilized (recrystallized) condition; therefore, a small change in emf is encountered at the operating temperature. In the case of the doped W-3Re, doped W-5Re, W-25Re, and W-26Re thermoelements, these are supplied in a stabilized (recrystallized) condition.

All three thermocouple combinations are supplied as matched pairs guaranteed to meet the emf output of producer developed tables within ±1 percent. In addition, compensating extension wires are available for each of the three combinations with maximum service temperatures as high as 871°C (1600°F) for tungsten-5 percent rhenium versus tungsten-26 percent rhenium.

Important factors controlling the performance at high temperatures are: the diameter of the thermoelements (larger diameters are suitable for higher temperatures), the atmosphere (vacuum, high-purity hydrogen, or high-purity inert atmospheres required), the insulation, and sheath material. Some evidence is at hand, however, which indicates the possibility of selective vaporization of rhenium at temperatures of the order of 1900°C and higher when bare (unsheathed) tungsten-rhenium thermocouples are used in vacuum. For this reason, the vapor pressure of rhenium should be considered when a bare couple is used in a high vacuum at high temperatures. This, of course, is not a problem when these couples are protected with a suitable refractory metal sheath.

Figure 16 and Table 19 show the characteristics of these alloys.

[a] NR = not recommended.
[b] Preferential vaporization of rhenium may occur when bare (unsheathed) couple is used at high temperatures and high vacuum. Check vapor pressure of rhenium at operating temperature and vacuum before using bare couple.

3.4 Compatibility Problems at High Temperatures

In order for thermocouples to have a long life at high temperatures, it is necessary to limit reactions between the metals, the atmosphere, and the ceramic insulation. Such reactions may change the strength or corrosion-resistant properties of the alloys, the electrical output of the thermocouple, or the electrical insulation properties of the ceramic insulant.

[a] Adapted from: *Constitution of Binary Alloys* by Rodney P. Elliot, McGraw-Hill, New York, 1965.

At extremely high temperatures reactions can be expected between almost any two materials. Table 20 has been included to show the temperatures at which such reactions occur between pairs of metallic elements. At lower temperatures, certain reactions do not occur and such as do occur, proceed at a slower rate. Because of potential reactions, it is important to identify the impurities and trace elements as well as the major constituents of the thermocouple components. The "free energy of formation" (Gibbs free energy) for the oxides of each element at the temperatures of interest, can be determined to predict possible oxide reactions. Other reactions may occur and attention should be given to the possible formation of the carbides, nitrides, etc. of the various elements.

Helpful data may be obtained from published reports, but, because of the importance of trace elements and impurities, the sources should be treated with caution. In some cases, the amount and types of impurities in the materials used were unknown.

Certain reactions may be somewhat self-limiting in that the reaction product provides a protective film against further reaction. However, spalling or chipping off of the reaction product may occur because of thermal or physical stress. Thus, the reaction rate and the use of the corrosion product as protection can be ascertained only if tested under the desired operating conditions and times.

The use of oxygen-gettering material should be considered in instances where oxygen is present in limited amounts [2]. This method has been employed with enclosed Type K thermocouples to limit the preferential oxidation of the positive thermoelement. A thin tube (or sliver) of titanium at the hottest location of the thermocouple has been used.

Chapter 4—Thermocouple Hardware and Fabrication

A complete thermocouple temperature sensing assembly, in accordance with the present state of the art, consists of the following:

A. Sensing element assembly including, in its most basic form, two dissimilar wires, supported by an electrical insulator and joined at one end to form a measuring junction. Such assemblies usually fall into one of three categories; those formed from wires have nonceramic insulation, those with hard-fired ceramic insulators, and those made from sheathed, compacted ceramic-insulated wires.

B. Protection tube—ceramic and metal protection tubes, sometimes referred to as thermowells, serve the purpose of protecting the sensing element assembly from the deleterious effects of corrosive or oxidizing or reducing atmospheres. In some cases, two concentrically arranged protection tubes may be used. The one closest to the sensing element assembly is designated the primary protection tube, while the outer tube is termed the secondary protection tube. Combinations such as an aluminum oxide primary tube and silicon carbide secondary tube often are used to obtain the beneficial characteristics of the combination, such as resistance to cutting flame action, and ability to resist thermal shock.

C. Connector—sensing element assembly wire terminations are made to either

- (*a*) Terminals
- (*b*) Connection head
  1. General purpose type
  2. Screw cover type
  3. Open type
- (*c*) Plug and jack quick-disconnect
- (*d*) Military standard (MS) type of connector

D. Miscellaneous hardware such as

- (*a*) Pipe nipple or adapter to join the protection tube to the head
- (*b*) Thermocouple gland—used primarily with sheathed, compacted ceramic-insulated thermocouple assemblies to serve the dual function of mounting and sealing-off pressure in the mounting hole (see Chapter 5).

4.1 Sensing Element Assemblies

Typical thermocouple element assemblies, shown in Fig. 17, A and B, illustrate common methods of forming the measuring junction, A—by twisting and welding and B by butt-welding. C shows an assembly using nonceramic insulation such as, asbestos or fiber glass. D, E, and F show the use of various forms of hard fired ceramic insulators, double bore (D) fish-spine (E) and four-hole (F). Fish-spine provides flexibility, and four-hole provides for two independent sensing elements.

4.2 Nonceramic Insulation

The normal function of thermocouple insulation is to provide electrical insulation for the thermocouple assembly. If this function is not provided or is compromised in any way, the indicated temperature may be in error. Insulation is affected adversely by moisture, abrasion, flexing, temperature extremes, chemical attack, and nuclear radiation. Each type of insulation

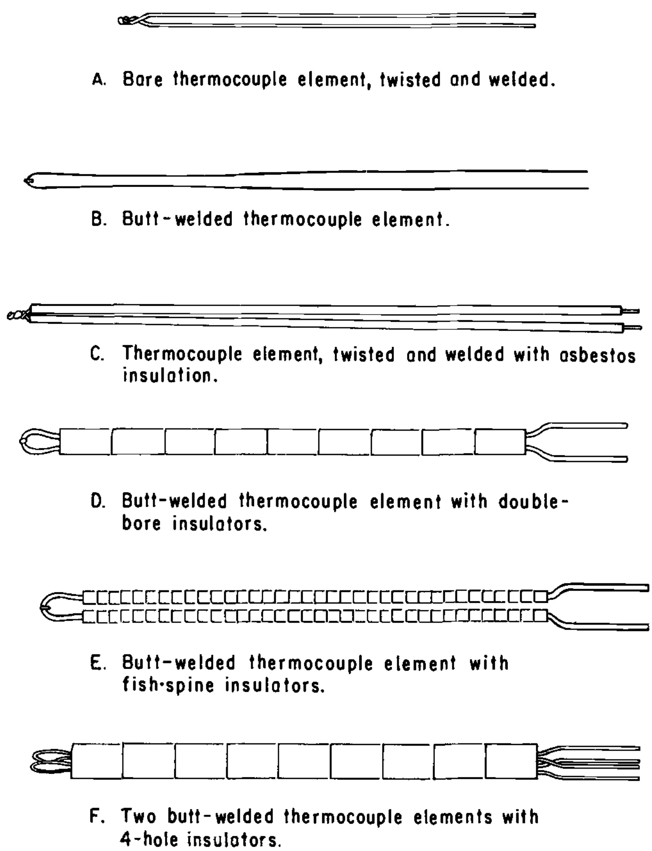

FIG. 17—*Typical thermocouple element assemblies.*

has its own limitations. A knowledge of these limitations is essential if accurate and reliable measurements are to be made.

Some insulations have a natural moisture resistance. Teflon, polyvinyl chloride (PVC), and polyimide are examples of this group. With the fiber type insulations, moisture protection results from inpregnating with substances such as wax, resins, or silicone compounds. Once the impregnating materials have been vaporized off, there is no longer moisture protection. Typically, this occurs once the insulation has been exposed above 400°F (204°C). The moisture penetration problem is not confined to the sensing end of the thermocouple assembly. For example, if the thermocouple passes through hot and cold zones or through an area which is time-wise alternately hot and cold, condensation may produce errors in the indicated temperature, unless adequate moisture resistance is provided.

Protection from abrasion and flexing usually is provided by impregnating materials. However, one cycle over 400°F (204°C) usually results in a deterioration of this protection. After exposure to higher temperature (1100 to 1400°F) (593 to 760°C), whole sections of the insulation can fall off resulting in bare wire and a possible "short." Thermocouples in this condition should not be used if any flexing or abrasion is expected. It is recommended that they be discarded or that the exposed portion of the thermocouple assembly be cut off and another junction formed.

Insulations are rated for a maximum temperature both for continuous usage and for a single exposure. These distinctions should be observed when selecting an insulating material. At elevated temperatures even those insulations which remain physically intact become conductive. Under these conditions, the output of the thermocouple may be a function of the highest temperature to which the insulation is exposed, rather than the temperature of the measuring junction. The change in insulation resistance may be permanent if caused by deterioration of organic insulants or binders which leave a carbon residue. In considering the temperature to which the insulation is exposed, it should not be assumed that this is the temperature of the measuring junction. A thermocouple may be attached to a massive specimen which is exposed to a high temperature source to achieve a rapid heating rate. Parts of the thermocouple wires not in thermal contact with the specimen can be overheated severely while the junction remains within safe temperature limits. With this in mind, high quality insulation should be used when rapid heating rates are expected. Very little factual information is available on actual deterioration rates and magnitudes, but the problem exists so a conservative approach is recommended.

The basic types of elevated temperature insulations are fiber glass, fibrous silica, and asbestos. Of the three mateiials, firbous silica has the best high-temperature electrical properties, although its handling and abrasion characteristics leave something to be desired. The next best high-temperature insulation is asbestos. Because this material has very poor mechanical properties a filler fiber or an impregnating material is added. In some instances, this filler is cotton or another organic compound which leaves a carbon residue after exposure to high temperature, and this results in a breakdown of electrical insulation. Asbestos loses its mechanical strength after exposure to elevated temperatures and tends to drop off even if the thermocouple assembly is not being handled. A more commonly used insulation is fiber glass. It can be impregnated to provide excellent moisture and mechanical characteristics. The main difficulty is that it becomes a conductor above 950°F (510°C). If one is willing to sacrifice the handling characteristics, a nonimpregnated fiber glass insulation is available which is good to 1200°F (649°C).

Chemical deterioration of insulation materials can produce a number of problems. If the environment reacts with the insulation, both the insulation and environment can be affected adversely. The insulation can be removed physically or made electrically conductive, and the process system can become contaminated. For example, some insulation materials are known to produce cracking in austenitic stainless steels.

In summary, an insulation should be selected only after considering possible exposure temperatures and heating rates, the number of temperature cycles, mechanical movement, moisture, routing of the thermocouple wire, and chemical deterioration (see Table 21).

Industry has established insulation color codes for various letter-designated thermocouple and extension wire types, as shown in Table 22.

4.3 Hard-Fired Ceramic Insulators

Hard-fired ceramic insulators most commonly used with bare thermocouple elements are mullite, aluminum-oxide, and steatite, the latter being the most common material where fish-spine insulators are concerned. Single, double, and multibore insulators are available in a wide variety of sizes in both English and metric dimensions.

Lengths in the English dimensional units commonly stocked by many suppliers are 1, 2, 3, 6, 12, 18, 24, and 36 in., with longer lengths to as great as 72 in. being available on special order.

It is usually advisable, especially in the case of precious metal thermocouple element assemblies, to keep the insulator in one piece to minimize contamination from the environment.

Hard-fired ceramic insulators are made in oval as well as circular cross-section examples of which are shown in Fig. 18. Properties of refractory oxides are tabulated in Table 23.

4.4 Protection Tubes

4.4.1 Factors Affecting Choice of Protection Tubes

Thermocouples must be protected from atmospheres that are not compatible with the thermocouple alloys. Protection tubes serve the double

purpose of guarding the thermocouple against mechanical damage and interposing a shield between the thermocouple and its surroundings so as to maintain it as nearly as possible in its best atmosphere.

The agencies that must be excluded are: (*a*) metals (solid, liquid, or vapor) which, coming into contact with the thermocouple, would alter its chemical composition; (*b*) furnace gases and fumes which may attack the thermocouple materials (sulphur and its compounds are particularly deleterious); (*c*) materials such as silica and some of its metallic oxides, which, in contact with the thermocouple in a reducing atmosphere, are reduced, and combine with the thermocouple to attack it; and (*d*) electrolytes which would attack the thermocouple material.

The choice of the proper protection tube is governed by the conditions of use and by the tolerable life of the thermocouple. There may be occasions when the strength of the protection tube may be more important than the long term thermoelectric stability of the thermocouple. On the other hand, gas tightness and resistance to thermal shock may be of paramount importance. In other cases, chemical compatibility of the protection tube with the process may be the deciding factor.

4.4.2 Common Forms of Protection Tubes

4.4.2.1 Metal Tubes—Metal tubes offer adequate mechanical protection for base metal thermocouples at temperatures to 2100°F (1150°C). It must be remembered that all metallic tubes are somewhat porous at temperatures exceeding 1500°F (815°C) so that, in some cases, it may be necessary to provide an inner tube of ceramic material.

[a] Kingery, W. D., "Oxides for High Temperature Applications," *Proceedings of the International Symposium on High Temperature Technology*, McGraw-Hill, New York, 1960.

(*a*) Carbon steels can be used to 1300°F (700°C) usually in oxidizing atmospheres.

(*b*) Austenitic stainless steels (300 series) can be used to 1600°F (870°C), mostly oxidizing although Types 316, 317, and 318 can be used in some reducing atmospheres.

(*c*) Ferritic stainless steels (400 series) can be used from 1800 to 2100°F (975 to 1150°C) in both oxidizing and reducing atmospheres.

(*d*) High nickel alloys, Nichrome, Inconel, etc., can be used to 2100°F (1150°C) in oxidizing atmospheres.

Where the protection tube is subject to high pressure or flow-induced stresses or both a drilled thermowell often is recommended. Although less expensive metal tubes, fabricated by plugging the end of the protection tube, may satisfy application requirements, more stringent specifications usually dictate the choice of gun-drilled bar stock, polished and hydrostatically tested as a precaution against failure.

Examples of drilled thermowells are shown in Fig. 19.

4.4.2.2 Ceramic Tubes—Ceramic tubes are used usually at temperatures beyond the ranges of metal tubes although they are sometimes used at lower temperatures in atmospheres harmful to metal tubes.

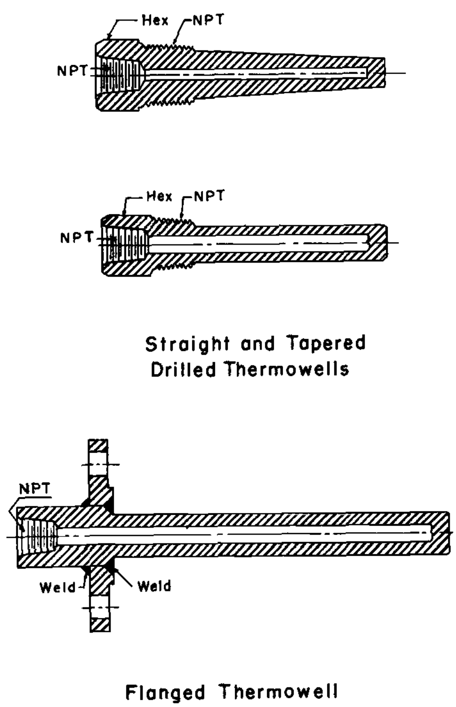

FIG. 19—*Examples of drilled thermowells.*

The ceramic tube most widely used has a Mullite base with certain additives to give the best combination of mechanical and thermal shock properties. Upper temperature limit 3000°F (1650°C).

Silicon carbide tubes are used as secondary protection tubes. This material resists the cutting action of flames. It is not impermeable to gases and, where a dense tube is required, a nitride-bonded type material can be obtained so that the permeability is greatly reduced.

Fused alumina tubes can be used as primary or secondary protection tubes or both where temperatures to 3600°F (1980°C) are expected and when a gas tight tube is essential. Fused alumina tubes and insulators should be used with platinum-rhodium, platinum thermocouples above 2200°F (1200°C) in order to ensure long life and attain maximum accuracy. (The Mullite types contain impurities which can contaminate platinum above 2200°F (1220°C). The alumina tubes are more expensive than the Mullite base tubes but can be obtained impervious to most gases to 3300°F (1815°C).

4.4.2.3 Metal-Ceramic Tubes—"Cermets" are combinations of metals and metallic oxides which, after proper treatment, form dense, high-strength, corrosion-resistant tubes usable to about 2600°F (1425°C) in most atmospheres.

4.5 Circuit Connections

The electrical output of a thermocouple assembly is taken at the end of the extension wires which are most often a separate component of the temperature sensing system. Thermocouples, usually of the sheathed mineral insulated variety, can incorporate a transition fitting inside which the extension wires are welded or brazed to the ends of the thermocouple wires in what usually is referred to as an intermediate junction. Thus the sensing element and extension wires are an integral part of the temperature sensing system.

Where hard-fired ceramic insulators are used, the thermocouple wires usually terminate in a head which is attached firmly to the protection tube in which the insulator is housed—or it may be supported by the insulator itself.

The connection between thermocouple and extension wires is made by means of a screw clamp or binding post to permit easy replacement of the thermocouple. The user should be aware of the need to keep the temperature of the termination below 400°F in the interest of overall accuracy. In any case, the termination should never exceed the temperature limitation of the extension wires.

Highest system accuracy is achieved by running the thermocouple conductors to the reference junction and avoiding the use of extension wires. If circuit connectors are necessary, they should be of thermoelectric materials. Connectors of the quick-disconnect type usually are so designed.

For example, a Chromel-Alumel thermocouple connector incorporates Chromel and Alumel pins or sockets or both.

Industrial types of thermocouple assemblies using heads of the general purpose or screw cover type contain a terminal block assembly consisting of a ceramic block and floating brass terminals. One assumes in using such a component that the temperature of the terminals is uniform and that no temperature gradient exists along their length. In accordance with the law of intermediate metals, no error should result providing this condition results.

Closed and open type heads are generally of cast iron body construction and cast or sheet metal formed covers incorporating an asbestos composition gasket seal. Cast aluminum or zinc alloy die castings are also available. The terminal block assembly may be a phenolic molding which would limit its use to about 170°C (338°F). Higher temperature capability would dictate the use of a ceramic terminal block assembly.

4.6 Complete Assemblies

Figure 20 shows complete assemblies of the components which have been described in the foregoing sections. Many other combinations are possible. Manufacturers' catalogs may be consulted for details.

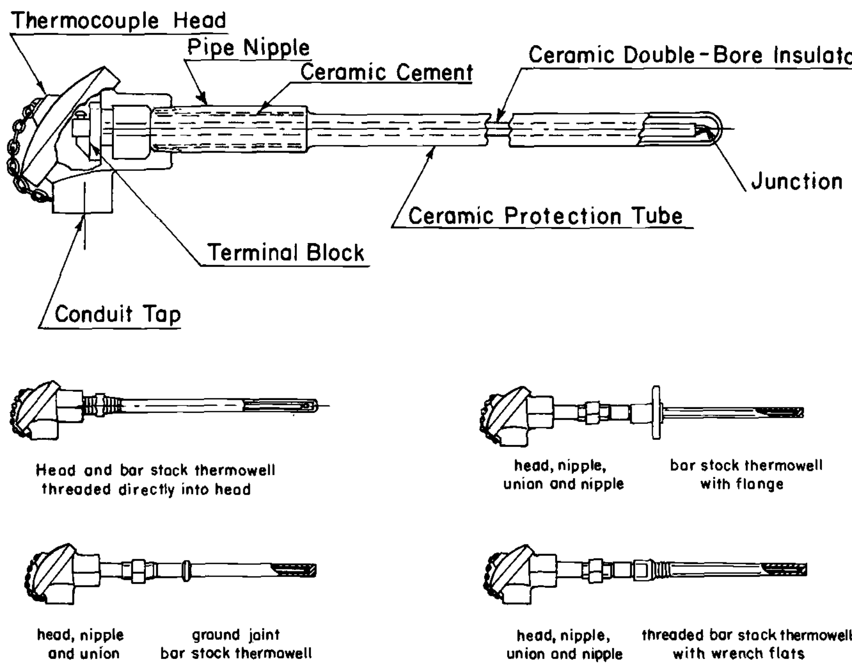

FIG. 20—*Typical examples of hard-fired ceramic-insulated thermocouples.*

4.7 Selection Guide for Protection Tubes

The following information has been extracted from various manufacturer's literature. It is offered as a guide to the selection of protection tubes. Caution should be exercised in applying this information to specific situations.

Application	Protection Tube Material
Heat treating:	
Annealing	
Up to 1300°F (704°C)	wrought iron
Over 1300°F (704°C)	28% chrome iron or Inconel[a]
Carburizing hardening	
Up to 1500°F (816°C)	wrought iron or 28% chrome iron
1500 to 2000°F (1093°C)	28% chrome iron or Inconel
Over 2000°F (1093°C)	ceramic
Nitriding salt baths	28% chrome iron
Cyanide	nickel
Neutral	28% chrome iron
High speed	ceramic
Iron and steel:	
Basic oxygen furnace	quartz
Blast furnaces	
Downcomer	Inconel, 28% chrome iron
Stove Dome	silicon carbide
Hot blast main	Inconel
Stove trunk	Inconel
Stove outlet flue	wrought iron
Open hearth	
Flues and stack	Inconel, 28% chrome iron
Checkers	Inconel, Cermet
Waste heat boiler	28% chrome iron, Inconel
Billet heating slab heating and butt welding	
Up to 2000°F (1093°C)	28% chrome iron, Inconel
Over 2000°F (1093°C)	ceramic, silicon carbide
Bright annealing batch	
Top work temperature	not required (use bare Type J thermocouple)
Bottom work temperature	28% chrome iron
Continuous furnace section	Inconel, ceramic
Forging	silicon carbide, ceramic
Soaking pits	
Up to 2000°F (1093°C)	Inconel
Over 2000°F (1093°C)	ceramic, silicon carbide
Nonferrous metals:	
Aluminum	
Melting	cast iron (white-washed)
Heat treating	wrought iron
Brass or bronze	not required (use dip-type thermocouple)
Lead	28% chrome iron, wrought iron
Magnesium	wrought iron, cast iron
Tin	extra heavy carbon steel
Zinc	extra heavy carbon steel
Pickling tanks	chemical lead

[a] Trademark—International Nickel Co.

(Continued)

Application	Protection Tube Material
Cement:	
Exit flues	Inconel, 28% chrome iron
Kilns—heating zone	Inconel
Ceramic:	
Kilns	ceramic and silicon carbide
Dryers	wrought iron, silicon carbide
Vitreous enameling	Inconel, 28% chrome iron
Glass:	
Fore hearths and feeders	platinum thimble
Lehrs	wrought iron
Tanks	
Roof and wall	ceramic
Flues and checkers	28% chrome iron, Inconel
Paper:	
Digesters	Type 316 stainless steel, 28% chrome iron
Petroleum:	
Dewaxing	Type 304 stainless steel or carbon steel
Towers	Type 304 stainless steel or carbon steel
Transfer lines	Type 304 stainless steel or carbon steel
Factionating column	Type 304 stainless steel or carbon steel
Bridgewall	Type 304 stainless steel or carbon steel
Power:	
Coal-air mixtures	Type 304 stainless steel
Flue gases	wrought iron or 28% chrome iron
Preheaters	wrought iron or 28% chrome iron
Steel lines	Type 347 or 316 stainless steel
Water lines	carbon steel
Boiler tubes	Type 309 or 310 stainless steel
Gas producers:	
Producer gas	28% chrome iron
Water gas	
Carburetor	Inconel, 28% chrome iron
Superheater	Inconel, 28% chrome iron
Tar stills	carbon steel
Incinerators:	
Up to 2000°F (1093°C)	28% chrome iron, Inconel
Over 2000°F (1093°C)	ceramic (primary), silicon carbide (secondary)
Food:	
Baking ovens	wrought iron
Charretort, sugar	wrought iron

Chapter 5—Sheathed, Ceramic-Insulated Thermocouples

5.1 General Considerations

When data were being gathered in 1961 for National Bureau of Standards Monograph 40 [*3*] on Thermocouple Materials, a section was included to cover ceramic packed thermocouple stock "because of the wide use and increasing popularity." New uses continue to be found for this unique heterogeneous materials combination. Compacted ceramic insulated thermocouple material consists of three parts as shown in Fig. 21.
The advantages of this configuration are:

1. It isolates the thermocouple wires from environments that may cause rapid deterioration.
2. It reduces long term calibration drift.
3. It lessens temperature versus wire size problems.
4. It provides an excellent high temperature insulation for thermocouple wires.
5. The sheath can be made of a metal compatible with the process in which it is being used and bears the brunt of the environmental effects.
6. It is easy to use:
   (*a*) Forms easily and retains the bent configuration.
   (*b*) The sheath can be welded without loss of insulation.
   (*c*) Available in a wide variety of sizes and materials.
   (*d*) Readily fabricated into finished thermocouple assemblies with minimum of technique and equipment.
   (*e*) Useful at high pressures or high temperatures or both.
7. It is inexpensive as a finished thermocouple.

5.2 Construction

All compacted types of thermocouples are made by similar processes: they begin with matched thermocouple wires surrounded by noncompacted ceramic insulating material held within a metal tube. By swaging, roll-forming, or other mechanical reduction processes the tube is reduced in diameter, the insulation is compacted around the wires, and the assembly is elongated.

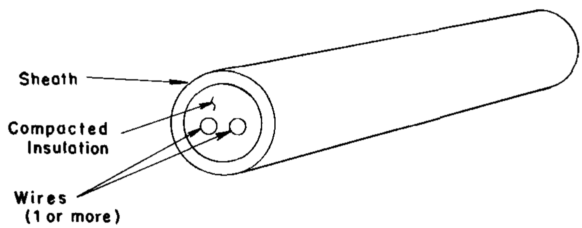

FIG. 21—*Compacted ceramic insulated thermocouple showing its three parts.*

Several options are available to the designer of the sheathed material depending upon the material combinations selected for the temperature measurement application.

Briefly, these are the factors considered in making a design, based on a finished product specification.

1. Type of wire material.
2. Number of wires and their diameter.
3. Type of sheath material.
4. Type of insulation.
5. Length, outside diameter, and wall thickness.

A ductile sheath and refractory (brittle) wire combination requires a design wherein the starting tubing diameter is only slightly larger than the finished size and only large enough on the inside diameter to accommodate a crushable preformed ceramic insulation with the wire(s) strung through the insulator hole(s). This combination then would be reduced to the final diameter by one of the compaction methods usually in a single reduction pass. The design is such that the wire is neither elongated nor reduced in diameter because of its brittle nature at room temperature.

A brittle sheath/brittle wire combination does not lend itself to a compacted insulation design and, therefore, is assembled as a tube-insulator-wire combination without the subsequent sheath reduction.

Ductile wire/ductile sheath combinations cover the widest range of commonly used materials and offer the designer the widest choice of design approaches.

He may elect to make his design using the approach outlined for the ductile sheath/brittle wire combination. He also may choose to use powder loading of the insulating material using a centralizing device and vibration as a variation on the method for making the sheathed wire assembly. Isostatic pressing of the combination is another approach occasionally used; however, by far, the most common technique is to use crushable preformed insulators.

The multiple pass approach as generally described by Siede and Edison [4] lends itself to initial starting material dimensions appreciably larger than the finished diameter of the compacted thermocouple. Since there is a constant volume relationship between the initial compacted tube diameter (D_0) and length (L_0) and the final tube diameter (D_F) and length (L_F), the final lengths achieved are

$$L_F = L_0 \left(\frac{D_0}{D_F}\right)^2$$

and are restricted only by the capabilities of the reduction and annealing facilities available and by the ceramic and metallurgical capabilities of the designer, the design team, or the material suppliers.

The reduction processes, as investigated by Rautio [5], indicate that the sheath diameter, wall, insulation spacing, and wire diameter are all reduced proportionately once the compaction point of the insulation is reached.

For design insight into the reduction effects on the tube diameter and wall thickness, Mohrnheim's [6] paper and its associated references are recommended. LaVan [31] compares the various reduction methods in his paper.

Nominal physical dimensions of sheathed ceramic insulated thermocouples are shown in Fig. 22 [7]. The ratios of sheath outside diameter to wire size and to sheath wall thickness offer a balance between maximum wall thickness (for protection of the sheath compacted insulant) and suitable insulation spacing for effective insulation resistance at elevated temperature.

A decrease in the diameter of the thermoelements could be advantageous in regard to insulation resistance, but it is detrimental structurally according to the work done by Ihnat [8]. Hansen [9] reported when wire diameters were one half of the nominal sizes (Fig. 22) multiple reductions of the sheathed assembly were restricted because of wire fracture.

Ihnat reported on the factors affecting the choice of insulation materials on the basis of resistivity, mechanical strength, resistance to thermal shock, vibration stress, thermal expansion, chemical compatibility, and cost.

Other factors such as relative hardness, compacted density, thermal conductivity, and neutron radiation effects have been reported by Zysk [10].

It is estimated that 90 percent of all sheathed thermocouples produced to date have used magnesium oxide (MgO) as the insulation material. Magnesium oxide is popular as a thermocouple insulator because of its overall compatibility with standard thermoelements and sheathing materials, its relative low cost, and availability.

Aluminum, beryllium, and thorium oxide insulations are also available from suppliers for use with certain wire and sheath combinations. The latter two materials are combined usually with refractory sheath and thermoelements.

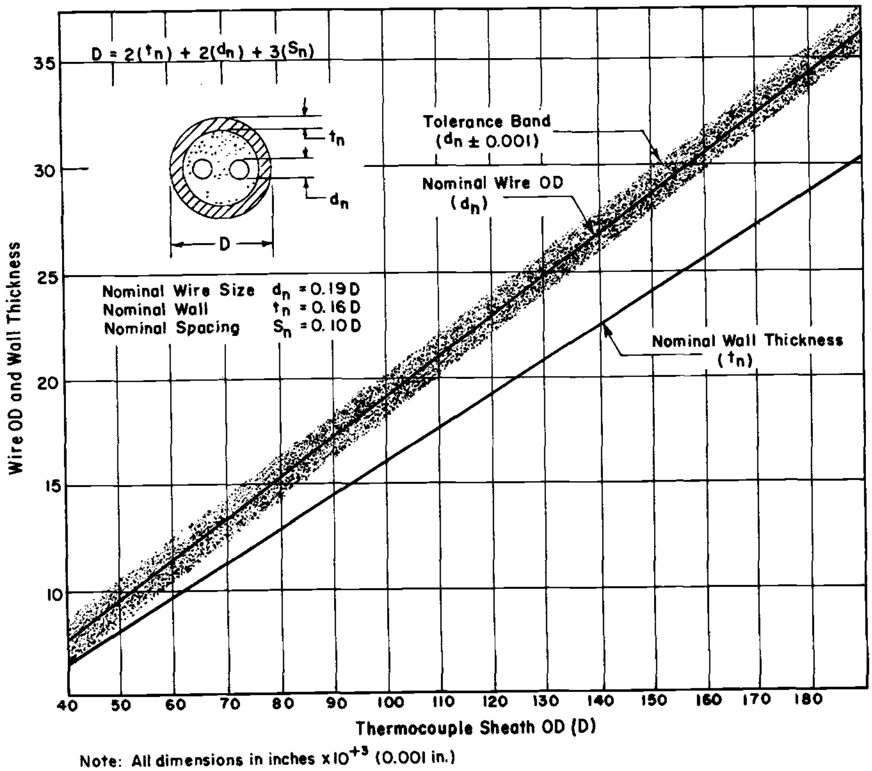

FIG. 22—*Graph showing idealized relationship between thermocouple sheath outside diameter and nominal internal dimensions for reactor grade thermocouples.*

Because many applications of ceramic insulated thermocouples are at temperatures above 400°F, much attention has been given to cleanliness and chemical and metallurgical purity of the components. Bliss [*11*] points up many of the fabrication and application difficulties that can be experienced if extreme care is not exercised by the supplier. A warning heeded by the sailors and frontiersmen of early America can be applied today to the sheathed thermocouple manufacturer: Keep your powder clean and dry!

5.3 Insulation

For most practical purposes the sheathed thermocouple material should have a minimum insulation resistance of 100 megohms at 500 V dc for diameters larger than 1/16 in. outside diameter. This readily is obtained by dry, uncontaminated compacted ceramic. The capture of oil, oil vapors, moisture, perspiration, and lint during manufacture can cause low insulation resistance. The hygroscopic nature of the insulants, especially MgO, and capillary attraction cause rapid absorption of moisture through exposed ends of the sheath. Furthermore, the insulation resistance of all ceramics falls at elevated temperature. Also the insulation resistance of all ceramics, compacted and uncompacted, reduces with an increase in temperature.

For insulation resistance greater than 1000 megohms, special techniques may be required to obtain and maintain these values. It is entirely feasible that 1000 megohms stock laying exposed to 70°F air and a relative humidity above 50 percent will experience a degradation of insulation resistance to less than 0.1 megohm in 15 min. Higher humidity will cause a more rapid degradation. Therefore, the following precautions should be exercised when handling compacted ceramic insulated thermocouples:

1. Do not leave an end exposed for periods longer than 2 or 3 min. Immediately seal ends.
2. Expose ends only in a region of low relative humidity.
3. Store assembly in a warm (above 100°F) and dry (relative humidity less than 25 percent) area.

Some of the characteristics of the more common compacted ceramics are shown in Tables 24 and 25.

TABLE 24—*Characteristics of insulating materials used in ceramic-packed thermocouple stock.*

Insulator	Minimum Purity, %	Melting Point, °F	Approximate Usable Temperature, °F

NOTE—Symbols describing atmospheres are: O = oxidizing; R = reducing; N = neutral; V = vacuum.

[a] Scales readily in oxidizing atmosphere.

[b] Very sensitive to sulfur corrosion.

[c] After exposure to temperature of 100 h except for stainless steels; Haynes 25, W, Mo, Ta, and Cb.

5.4 Wire

The wire is the primary functioning part of the assembly. It is the exposure of the junction of the dissimilar materials to heat that generates a commensurate voltage. From established tables (see Chapter 10) the voltages can be converted into temperature. Deviation from these tables, as given in Chapter 10, are equally applicable to sheathed thermocouples.

Since the wires are contained in a protective sheath and firmly held, small diameter wires can be exposed to high temperatures for long periods of time without serious deterioration.

5.5 Sheath

The sheath material performs several functions in the ceramic-insulated thermocouple system:

1. It holds the oxide in compaction.
2. It shields the oxide and thermoelements from the environment.
3. It furnishes mechanical strength to the assembly.

Since no one sheath material is suitable for all environments a wide variety of different materials are offered. Table 26 shows a group of materials that can be used as sheaths and some of their characteristics.

For maximum life a sheath diameter should be selected that offers the heaviest wall in relationship to the maximum use temperature.

Table 27 illustrates recommended temperatures for various sheath diameters and corresponding wall thicknesses. With the proper selection of sheath material for the environment, the thermocouple can be exposed to temperatures as high as 2000°F for any diameter but at some decrease in life.

TABLE 27—*Recommended maximum long-term service temperature for various sheath dimensions* [27].

Nominal diameter (in.)	0.040	0.062	0.125	0.188	0.250
Nominal wall (in.)	0.007	0.010	0.020	0.025	0.032
Type K (°F)	1 400	1 600	1 600	1 600	1 800
Type J (°F)	1 000	1 200	1 400	1 400	1 600
Type E (°F)	1 200	1 400	1 400	1 600	1 700

5.6 Combinations of Sheath, Insulation, and Wire

Precautions to be observed in selecting combinations are:

1. Be sure the sheath material will survive the environment (see Tables 26 and 27). Do not fail to realize that a thin sheath will deteriorate more rapidly than a thick one.

2. Be sure the assembly of sheath and wire is fully annealed for maximum sheath life and stability of wire calibration.

3. Select a sheath and wire material of similar coefficients of linear expansion. For example: Platinum-rhodium and platinum have about one half the expansion of stainless or Inconel; a grounded hot junction will pull apart unless sufficient expansion loops are allowed in the wire. Insulators often are used for this combination that are hard fired, and either noncompacted or isolated junctions also are used.

4. Select a sheath and wire material of similar annealing characteristics.

5. The combination of Chromel Alumel, iron constantan or Chromel constantan with an aluminum or copper sheath is not desirable. Table 28 indicates the capability of wire and sheath materials.

6. Table 29 gives dimensions of available ceramic-packed stock.

TABLE 28—*Compatibility of wire and sheath material* [13].

Wire \ Sheath	304	310	316	321	347	440	Platinum Alloys	Hastelloy X	Copper	Aluminum	Inconel 600	Inconel 702	Tantalum	Columbium Alloys

2. Easy manufacturing but poor operational compatibility.
3. Difficult manufacturing but good operational compatibility.
4. Difficult manufacturing and poor operational compatibility.

[a] Trademark—Driver-Harris Co.

5.7 Limitations of the Basic Material

1. The sheath can be bent around a mandrel twice the sheath diameter without damage.

2. The life of material having 0.032 in. diameter or less is limited due to grain growth in the sheath wall.

3. Four wires in 0.062 in. sheath diameter and smaller are not practical to handle in the field.

TABLE 29—*Dimensions and wire sizes of available ceramic-packed material.*

0.025	0.006	0.004	...	...

4. Two wires in 0.032 in. sheath diameter and smaller are difficult to handle in the field but are used in laboratory environments.

5. All crushed ceramics are like sponges and tend to capture moisture at the exposed surfaces. The tendency is reduced greatly in air at temperatures of 120°F and greater. If moisture does get into the assembly (as indicated by a reduction of insulation resistance), it can be substantially removed from the ends of the sheath by the following process:

A. Select a point about 6 in. from the exposed end and apply heat until the sheath is dull red.

B. Gradually work this slightly incandescent zone towards the exposed end.

C. When end has cooled below 250°F, apply a sealant, such as:

(*a*) Dow Corning DC 803,

(*b*) General Electric Glyptal,

(*c*) wax, or

(*d*) proprietory sealants.

6. Compacted ceramic material usually is coiled for shipping as shown in Table 30.

TABLE 30—*Compacted ceramic material coiled for shipping.*

Diameter, in.	0.025	0.040	0.062	0.125	0.188	0.250	0.313	0.375
Size of coil, in.	18	18	24	30	48	48	60	60
Weight, lb/100 ft	0.2	0.5	0.8	3.0	6.0	11.0	16.0	24.0

7. Stock material and completed thermocouples usually are supplied to the end user in the fully annealed state with proper metallurgical grain size and no surface corrosion.

8. Therefore, the following precautions should be exercised when specifying or handling compacted ceramic insulated thermocouples:

A. Ensure that the sheath material is annealed fully.

B. If the material is coiled to a diameter which causes a permanent set, subsequent annealing may be required.

C. Avoid repeated bending at same location as this work hardens the sheath and may change the thermocouple calibration.

D. Do not expose the sheath to deleterious temperatures or atmospheres (see Tables 26 and 27).

5.8 Testing

Many tests have been devised to evaluate sheathed ceramic insulated thermocouples. These tests cover the physical and metallurgical properties of the sheath and thermoelements, the isothermal electrical properties of the insulation, and the thermoelectric properties of the thermoelements.

ASTM has issued a specification E 235 [*14*] on sheathed thermocouples for nuclear and other high reliability applications that covers Type K thermoelements in various sheath materials with options available for other sheath materials; alumina or magnesia insulations and alternative thermoelements. In Aerospace Information Report 46 [*15*] the Society of Automotive Engineers has covered the preparation and use of Type K thermoelements for turbojet engines, while the military has issued Mil T 22300 [*16*] (Ships) and Mil T 23234 [*17*] (Ships) for nuclear application of the sheathed thermocouples. In addition many government and commercial laboratories, thermocouple fabricators, and thermocouple users have issued specifications covering specific tests and test procedures for evaluating sheathed thermocouple materials.

Scadron [*18*] outlined some of the tests and tolerances that are applied for the verification of physical, electrical, and thermoelectric integrity of the sheathed thermocouple. Most manufacturer's catalogs cover some aspects of the tests, guarantees, and procedures used to verify product integrity.

Fenton et al [*33*] were concerned with inhomogeneity in bare and sheathed thermoelements and developed procedures and apparatus for testing for drift and inhomogeneity.

National Bureau of Standards Circular 590 [*19*] covers thermocouple testing. While this work was devised for the bare thermoelements it is applicable to the metal sheathed, ceramic insulated stock for evaluation of the electrical characteristics.

Sections 3 and 10 cover thermoelectric characteristics as well as recommendations for upper temperature limits and limits of error for most thermoelement materials. A notable exception for sheathed thermocouples is made in Table 2.

Increased life and accuracy was achieved using sheathed thermocouples by McElroy and Potts [*20*] in their study for the Oak Ridge National Laboratories of drift characteristics of Type K elements. A report from Stroud [*21*] indicates that a sealed sheathed thermocouple with ⅛-in.-diameter Inconel sheath, MgO insulation, and Type J thermoelements was exposed for more than 3500 h at 2000°F (1093°C) in air without falling outside the acceptable calibration error band. This is an example of one of the benefits of the sheathed construction. Zysk [*10*] points up that small dimensions, flexibility, and complete resistance to thermal shock are other advantages of this material.

Table 31 shows various characteristics, tests, and the source of testing procedure which are applicable to sheathed ceramic-insulated thermocouples.

5.9 Measuring Junction

Measuring or "Hot" Junction

Numerous variations in measuring junction construction are possible with this type of material. The application dictates the most desirable method.

1. *Exposed or Bare Wire Junction*—In this type of a junction the sheath and insulating material are removed to expose the thermocouple wires. These wires are joined to form a measuring junction. The junction may be of the twist-and-weld or butt-weld type.
   - (*a*) Fast response (see Table 32).
   - (*b*) Exposed magnesia will pick up moisture.
   - (*c*) Not pressure tight.
   - (*d*) Wires subject to mechanical damage.
   - (*e*) Wires subject to environment and usually will have a very short life.
   - (*f*) Useful life shortened as a result of rapid calibration drift.

TABLE 31—*Various characteristics tests, and the source of testing procedure applicable to sheath ceramic-insulated thermocouples.*

Characteristics	Tests	Procedure	Comments
	PHYSICAL AND METALLURGICAL		
1. OD of sheath	ring gage, micrometer, or met mounts for high precision	good mechanical practice or transverse section per ASTM Method E 3-62	tolerances per Table 29 sample preparation: requires care to prevent smear
2. Roundness of sheath	rotate for total indicated reading	Vee block and dial indicator	important for tube fitting use
3. Sheath surface finish	profilometer or roughness gage	ANSI Standard B46.1	also check clean finish for welding and brazing
4. Sheath wall thickness	thread gage micrometer or metallurgical mount	transverse section per ASTM Method E 3-62	concerns machining, bending, welding, life: can be checked only at ends
5. Insulation spacing	comparator or metallurgical mount	transverse section per ASTM Method E 3-62	see electrical tests
6. Insulation compactness	(A) tap test, (B) helium pressure, (C) dye absorption, (D) compaction density	(A) supplier catalog, (B) MIL-T-22300, (C) and (D) ASTM Method D 2771-69	relative values must be related to application
7. Wire diameter	micrometer or metallurgical mount	visual or transverse section per ASTM Method E 3-62	±1 wire gage size (Table 29)
8. Wire surface and roundness	micrometer and visual	3-point diameter check	10% out of round max showing slight embedment of insulating material into wire
9. Ductility and formability	bend and visual or metallurgical mount	ASTM E 235-73	bend 90 deg only for ease of making metallurgical mount
10. Sheath integrity	(A) water immersion (B) hydrostatic (C) helium leak, (D) dye penetrant	(A) water soak with ends protected [18], (B) ASTM Method E 165-65, (C) ASTM Method E 235-73, (D) ASTM Method E 235-73	(A) may use hydrostatic pressure or steam for some applications: seal weld to protect insulation

(*Continued*)

TABLE 31—*Continued.*

Characteristics	Tests	Procedure	Comments
11. Junction integrity	radiographs	ASTM Method E 235-73	application for junction and 4 in. of sheath
12. Material compatability	thermal cycling	ASTM Method E 235-73	thermal expansion for grounded junction integrity check
13. Metallurgical integrity	metallurgical mount	ASTM Method E 235-73	checks grain size
14. Response time	thermal response test	gas: SAE 46, liquid [24]	assesses thermal mass and welding technique
15. Uniformity of properties	Tests 1, 2, 3, 10, 11, and 13 full length	as noted	use sampling procedure for large runs
16. Stability under service conditions	application experience or life tests	as required	check with other users in same field
CONSTANT TEMPERATURE ELECTRICAL			
17. Insulation resistance	megohm meter between wires and sheath and wires	ASTM Method E 235-73	50 V for OD less than 0.061, 500 V for greater than 0.062
18. Electrical resistance (loop)	Wheatstone bridge	Chapter 3	tolerances ±1 gage size based on wire type, length and dia: also checks continuity
19. High temperature insulation resistance	megohm meter or Wheatstone bridge	immerse full length except for end in temperature chamber: test with ungrounded junction or before junction is made	relative to operational requirement, effective means of testing insulation quality at expected operating temperature of thermocouple
20. Dielectric strength	high potential generator	ac voltage (current limited) applied at room temperature for 1 min 80 V per mil of insulation [32]	seldom used check for contamination and voids in insulation: voltage usually 500 V for 0.062 OD and larger

ISOTHERMAL ELECTRICAL			
21. Capacitance	capacitance bridge		test is usually not applied to thermocouples
22. Uniformity along length	Test 17, 18, 19, 20, 21 for full length	check samples or full lengths coiled if necessary	all tests are seldom necessary for single application
23. Stability under service conditions	application experience or life tests	as required	check for experience by other users
THERMOELECTRIC PROPERTIES			
24. Emf versus temperature	potentiometer and heat or cold source	Chapter 6	test at one or more points up to maximum use temperature
25. Homogeneity	heat source and galvanometer	NBC Circular 590 and Ref *33*	max of $\pm 100\ \mu V$ for J, K, T; $\pm 25\ \mu V$ for B, R, S thermoelements
26. Uniformity full length	Test 24 and 25 for full length	apply sampling procedure for large quantities	random sampling is most economical approach
27. Stability under service conditions	experience or life tests	actual tests	no substitute for actual conditions because of temperature gradients

FIG. 23—*Exposed or bare wire junction.*

2. *Grounded Junction*—A closure is made by welding in an inert atmosphere so that the two thermocouple wires become an integral part of the sheath weld closure. Thus, the wires are "grounded" to the sheath.
   (*a*) Slower response than exposed wire (see Table 32).
   (*b*) Pressure tight to above 100 000 psi.
   (*c*) Wires protected from mechanical damage.
   (*d*) Wires not exposed to environment and will have a longer life.
   (*e*) Coefficient of expansion wire must be close to that of sheath to prevent pulling apart of hot junction. There are proprietary type of hot junctions that permit the use of materials with differing coefficients of expansion.

3. *Ungrounded or Isolated Junction*—This type is similar to the grounded junction except that the thermocouple wires are first made into a junction which is then insulated from the sheath and the sheath closure. The closure is formed by welding without incorporating the thermocouple wires. Thus, the thermocouple is "ungrounded" in relation to the sheath material.
   (*a*) Slower response than grounded hot junction (see Table 32).
   (*b*) Pressure tight to above 100 000 psi.
   (*c*) Wires protected from mechanical damage.
   (*d*) Wires not exposed to environment and will have a longer life.
   (*e*) Strain due to differential expansion between wires and sheath is minimized.
   (*f*) Most expensive.

4. *Reduced Diameter Junction*—
   (*a*) May be either grounded or insulated (2 and 3 mentioned previously).
   (*b*) Applied where fast response is required at junction and heavier sheath or wires are desired for strength, life, or lower circuit resistance over the balance of the unit.

5.10 Terminations

There are numerous ways in which thermocouples of this nature can be treated at the "cold" end. The most common treatments are as follows:

(*a*) *Square Cut and Sealed*—Wire is procured in this manner when the user intends to fabricate his own cold end assembly. The seal inhibits moisture absorption.

(*b*) *Wires, Exposed and Sealed*—Here, the sheath and the insulation is removed leaving the bare thermocouple wires exposed for a specified length. The insulating material is then sealed to inhibit moisture absorption.

(*c*) *Transition Fitting*—The terminal end is provided with a fitting wherein the thermocouple wires are joined to more suitable wires. In this fitting the necessary sealant for the mineral insulant also is provided (Fig. 27).

The terminal in Fig. 27 is:

1. Useful where permanent connections are desired.
2. Least expensive.

(*d*) *Terminals or Connectors*—Various types of fittings are available to facilitate external electrical connections. These include screw terminal heads, open or enclosed, and plug or jack connections (Fig. 28).

5.11 Installation of the Finished Thermocouple

Many types of installation are possible with sheathed thermocouples. Typical installations are shown in Figs. 29, 30, and 31.

Other special flanges and adaptors are available from many thermocouple manufacturers.

5.12 Sheathed Thermocouple Applications

Application information for sheathed thermocouples has been well covered in the literature. Many suggested applications are made in the various suppliers catalogs, and Sannes article [*23*] on the application of the smaller sheath diameters is useful. Section 9.2 of this manual is an excellent reference on surface temperature measurement. A boiler tube application of sheathed thermocouples is discussed in Ref *25*. Gas stream performance is well documented [*26–29*] because of the applications to jet engines and rockets.

Nuclear reactor applications have used sheathed thermocouples extensively for monitoring and control. Johannessen discussed the reliability assurance [*30*] of such applications, and other aspects also are covered in the same reference.

In the event of failure of sheathed thermocouples, Table 33 [*22*] has been included to aid in analyzing the cause.

TABLE 33—*Failure mode and cause analysis.*

Component	Mode of Failure	Possible Causes of Failure
Sheath	longitudinal splits	excessive cold work, improper heat treat, improper drawing speed, or insufficient wall thickness
	rupture at high temperature	excessive vapor pressure due to presence of helium after leak check, moisture in insulation, or insufficient wall thickness
	galling, inclusions and pits	incomplete lubrication, improper reduction method, improper die configuration, contaminated lubrication
	discoloration	improper heat treat atmosphere or temperature, improper cleaning of sheath prior to heat treatment
	brittle material, carbide precipitates, large grain size	improper heat treat time or temperature or quenching or all three
Insulation	low insulation resistance	moisture, contamination or excessive migration of conductors
	corona, arcing or breakdown at dielectric potential	voids, moisture, contamination, conductor decentralization, excessive dielectric potential, loose pack
	loose pack	inadequate sheath reduction, poor initial design, low tensile sheath material, or insufficient sheath wall thickness
	discoloration	inherent contamination, contamination due to reaction with sheath or conductors or both, improper or unclean manufacturing facilities
Conductors	open circuit	excessive elongation, improper initial design, improper heat treatment: defective starting wires
	short circuit (conductor to conductor or conductor to sheath)	loose pack, voids, bend radius too small, improper assembly, conductor decentralization and contaminated insulation
	embrittlement	excessive cold working, improper heat treatment, improper initial condition of conductor
	open circuit-high temperature	nonuniform reduction of area, temperature above wire melting point: defective initial wires (microcracks)

(*Continued*)

TABLE 33—*Continued.*

Component	Mode of Failure	Possible Causes of Failure
Conductors (con't)	out of calibration	improper heat treatment, initial conductor out of calibration, cold work effects not removed, nonhomogeneous section
	poor conductor finish	improper heat treatment on initial conductor, excessive insulation grain size, insulation crushability, insulation grain configuration and hardness, excessive swaging or rolling
	temperature/emf variation with length	nonhomogeneous conductor, nonuniform heat treat or unrelieved cold working
	oblated conductors	worn swaging or rolling dies, or improper die setup
	microscopic conductor fractures	temperature above melting point, excessive cold work and improper heat treat, defective initial wires

Thermocouple Failure Mode	Possible Causes of Failure
Open circuit at room temperature	brittle wires, excessive elongation in manufacture, improper heat treat or excessive cold work: initially defective wires
Open circuit at high temperature or during cycling	brittle wires, nonuniform elongation causing necking of conductors, improper heat treat, excessive temperature for conductors, differential thermal expansion between conductors and sheath: defective initial wires
Short circuit	loose insulation, voids, insulation contamination, conductors twisted, conductor decentralization, moisture
Low insulation resistance	insulation contamination, moisture absorption, improper sealing at ends
High potential breakdown	contamination of insulation conductor decentralization, loose insulation, insufficient sheath wall thickness, voids, excessive potential
Sheath fracture during forming	bend radius too small, brittle sheath material, insufficient sheath wall thickness, inadequate or proper heat treat
Sheath fracture under vibration	support points too far apart, insufficient sheath wall thickness, brittle sheath due to inadequate or improper heat treat, excessive cold work
Sheath burn-through	temperature reaction with atmosphere lowering effective melting point, insufficient sheath wall thickness, improper sheath material for application
Loose insulation material	improper design and insufficient sheath wall thickness

Chapte 6—Emf Measurements

6.1 General Considerations

The basic principle of thermoelectric thermometry is that a thermocouple develops an emf which is a function of the difference in temperature of its measuring junction and reference junction. If the temperature of the reference junction is known, the temperature of the measuring junction can be determined by measuring the emf generated in the circuit. The use of a thermocouple in temperature measurements, therefore, requires the use of an instrument capable of measuring emf.

There are two types of emf measuring instruments in use in industry-deflection meters (millivoltmeters) and potentiometers. The digital voltmeter, which is now being used extensively, is a type of potentiometer. Because of its limitations, the deflection meter is not used for precise measurements.

The deflection meter consists of a galvanometer with a rigid pointer which moves over a scale graduated in millivolts or degrees. The galvanometer indicates by its deflection the magnitude of the current passing through it, and if the circuit in which it is placed includes a thermocouple, it measures the current I generated by the thermocouple in the circuit. If the circuit has a resistance R and the emf is E, by Ohm's law, $E = RI$. If R is kept constant, I is proportional to E, then the scale can be calibrated in terms of millivolts rather than in milli- or microamperes. This calibration holds as long as R remains constant. Any change in R introduces an error in the indicated value of E. Changes in resistance may result from changes in temperature of the thermocouple or its extension wires or of the copper galvanometer coil, from corrosion of the thermocouple wires, from changes in the depth of immersion of the theımocouple, or from changes in contact resistance at switches or binding posts.

In general, the reference junctions of the thermocouple measuring circuit are located near the meter movement. The effect of temperature changes on these junctions is compensated for by a bimetallic spiral attached to one of the control springs of the pointer. This system maintains accurate meter calibration during changes in ambient temperature.

In spite of its limitations, the deflection meter serves a very useful purpose in a great variety of industrial measurements of temperature where the precision required does not demand the use of the potentiometric method of measurement.

Where precision is required in the measurement of thermal emfs, the potentiometer invariably is used. Because of its reliability and freedom from the uncertainties arising from changes in circuit resistance, meter calibration, etc., as well as its much greater openness of scale, it is used in many cases where the precision needed might not seem to justify the higher cost.

Recording potentiometers are used widely for industrial process temperature measurement and control. When reliability and reproducibility are the prime concern, such instruments are satisfactory. However, because of potential inaccuracies in charts caused by printing limitations and humidity effects and practical limits on chart widths and scale lengths resulting in inadequate readability, they are not used where precision is the criteria.

6.2 Potentiometer Theory

Accurate measurement is usually a matter of comparing an unknown quantity against a known quantity or standard—the more direct the comparison, the better. Accurate weighing, for example, often is accomplished by direct comparison against standard weights using a mechanical balance. If the measured weights are too heavy for direct comparison, lever arms may be used to multiply the forces.

The potentiometer, as the term is used here, serves a similar function in the measurement of voltage, and, in fact, may be called a "voltage balance," the standard voltage being furnished by a standard cell, the "lever" being resistance ratios, and the galvanometer serving as the balance indicator. Since no current is drawn from the standard cell or the measured source at balance, the measurement is independent of external circuit resistance, except to the extent that this affects galvanometer or balancing mechanism sensitivity.

6.2.1 Potentiometer Circuits

Figure 32 shows a simple potentiometer circuit which includes a resistor R, a standard cell S, a battery B, a galvanometer G, and a rheostat r. R may be a calibrated slidewire, with a known resistance, and R' a fixed resistor such that R and R' is some simple multiple of the emf of S. If e is taken as 1.019 V, the sum of R and R' may be chosen as 101.9. If the switch K is turned to the standard cell position, the galvanometer, in general, will deflect. The setting of rheostat r, is adjusted until the galvanometer remains at rest when K is closed. Then the drop of potential of the battery current through R and R' is exactly equal to the emf of S, so that if the current in R and R', $T = 1.019/101.9$ A, or 10 mA, through each ohm of R there is then a drop of potential 0.010 V. If R is 20 ohms the total drop through the slidewire is 0.2 V.

Now if K is turned to the "thermocouple" position, a setting may be found for the sliding contact on R at which there will be no deflection of

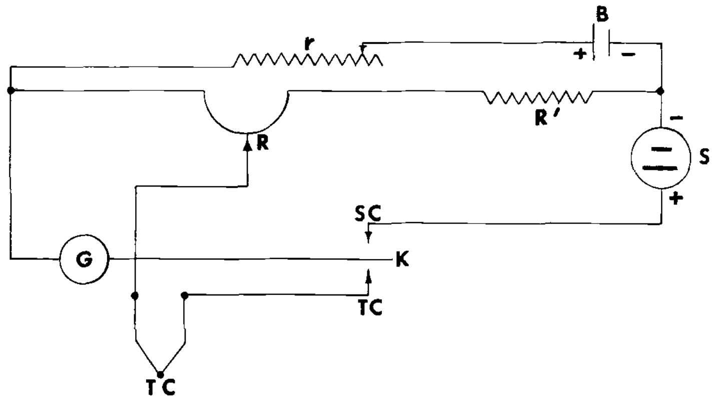

FIG. 32—*A simple potentiometer circuit.*

the galvanometer. At this position, the drop of potential through R of the contact is equal to the emf of the thermocouple. If balance occurs at the 5 ohm point, the emf of the thermocouple is $0.01 \times 5 = 0.05$ V–50 mV.

In this measurement the galvanometer has been used only as a means of detecting the presence of a current, and readings are made only when no perceptible current is passing through it. Therefore, it is not calibrated, and it is only called upon to indicate on balance with sufficient sensitivity to give the desired precision of setting of the sliding contact. An increase in the resistance of the thermocouple circuit can increase only the limits of positions of the contact between which there is no perceptible deflection, but does not affect the position of balance, nor the measured value of the emf. Since the galvanometer is used only to indicate the existence and direction of current, it is necessary to design it to give a linear relationship between current and deflection. Zero stability is not extremely important since it is only necessary to look for departure from any equilibrium position when the key is closed to detect a need for adjustment and the direction in which it should be made. The galvanometer is usually of the suspension type, even in portable potentiometers because of sensitivity required, although electronic null balance detectors are available with similar sensitivities.

The calibration of an instrument of this type is stable since resistors and slidewires can be made with a high degree of stability. The emf of an unsaturated standard cell, as used for potentiometric work, does not change more than about 0.01 percent per year and has a negligible temperature coefficient.

The usefulness of an elementary potentiometer of this sort, having its entire range across the slidewire, is limited by the resolution possible in setting and reading the position of the contact on R.

6.2.2 Standard Cell

While the Zener diode is becoming used more widely as a reference, especially in digital voltmeters, the standard of reference for all voltage measurements is the Weston standard cell. Two types are available—the saturated and the unsaturated.

The saturated cell containing undissolved cadmium sulfate crystals is used in standardizing laboratories such as the National Bureau of Standards to represent the value of the absolute volt. Its emf is 1.01864 absolute volts at 20°C, reproducible within a few microvolts and reasonably constant over long periods of time. From 10 to 40°C its temperature coefficient is negative, the emf decreasing by about 40 μV/°C rise in temperature.

In potentiometric work the unsaturated cell is used. It is more portable than the saturated type, and its temperature coefficient is very near zero. When new, its emf is about 1.019 V. This voltage tends to decrease about 100 mV (0.01 percent) per year, giving a useful life of about ten years.

A standard cell must never be short circuited, nor should its emf be measured with a voltmeter. In precise measurements, the balances should be made with a resistance of at least 10,000 ohms in series with the cell, until the balance is well within range of the detector scale.

Ambient temperatures near the cell should remain between +4°C and +40°C if the cell emf is to remain within ±0.01 percent of its certified value.

6.3 Precision Potentiometry

There are three types of precision-indicating potentiometers presently available; they are (1) laboratory high precision, (2) plant precision, and (3) portable precision. There are three subtypes of the laboratory high precision instruments; (1*a*) six-dial, (1*b*) three-dial automatic balancing, and (1*c*) three-dial manual balancing.

6.3.1 Laboratory High Precision

The six-dial potentiometer meets the most exacting requirements for standardizing, research, and testing laboratories. It is particularly useful for precise temperature measurements in studies of specific heats, melting and boiling points, and for calibrating less precise potentiometers. It also is used for precise measurements such as required in calorimetry cryogenics. It measures emfs in the range of 0 to 1.6 V with 1 μV, or less, limit of error. It is essentially free of thermal emfs, and transients amount to less than 0.1 μV.

The three-dial automatic null balancing potentiometer indicator has a range of 0 to 70.1 mV, is readable to 1 μV, and has a limit of error of 0.02 percent, or 3 μV, whichever is greater. The balancing operation is automatic once the two-dial switches are set manually to place the unknown emf within the scale range. This automatic feature facilitates the rapid measurement of a large number of emfs with a minimum of effort and skill on the part of the operator, and with a high degree of accuracy.

The three-dial, manually operated potentiometer, also is used for precise measurements of voltage. As applied to the measurement of thermal emfs, its characteristics are such as to make it the most generally used of all the potentiometers in this field when accuracy and convenience of measurement are demanded. It is not portable in the sense in which the term is applied to self-contained potentiometers, since to attain the results of which it is capable, some parts of the circuit must be mounted separately. In particular, when highest precision is required, a very sensitive reflecting galvanometer must be mounted in a vibration-free support.

6.3.2 Plant Precision Potentiometer

This potentiometer is a self-contained, two-dial automatic null balancing indicator. It has a range of 0 to 40 mV, is readable to 2.5 μV, and has a limit of error of 0.5 percent below 6 mV and 0.33 percent above 6 mV. The balancing operation is automatic once the dial switch is set manually to place the unknown emf within the scale range.

6.3.3 Portable Precision Potentiometer

This potentiometer is a self-contained, three-dial, manually balancing instrument. It is used for precision checking of thermocouple pyrometers in laboratory and plant and for general temperature measurements. It has two ranges, -10.1 to 0 mV and 0 to 100.1 mV. It is readable to 1 μV. Limits of error are: (*a*) $\pm$(0.05 percent of reading plus 3 μV) without internal reference junction compensation and (*b*) $\pm$ (0.05 percent of reading plus 6 μV) with reference junction compensation.

An example of (*a*) when using an external reference junction (see Chapter 7) is as follows:

> A Type K thermocouple develops 41.269 mV at 1000°C (1832°F). The thermocouple error ($\pm$¾ percent) can be 7.5°C; the instrument error will be $0.0005 \times 41.269 + 0.003 = 0.024$ mV or 0.56°C.

The reference junction compensation (*b*) is provided by an additional slidewire. This slidewire is used to set the reference junction voltage to the value which corresponds to the temperature of the reference junction (obtain millivolt value from reference tables, Chapter 10).

The portable precision potentiometer is designed to measure thermocouple emfs with a precision adequate for all but the more refined laboratory applications. It includes a built-in lamp and scale galvanometer.

6.4 Semiprecision Potentiometry

Potentiometers are available similar to those used for precision potentiometry except for limits of error. They are essentially of the two-dial type with self-contained galvanometer, standard cell, and battery. They are used primarily for general temperature measurements by means of thermocouples, checking thermocouple pyrometers in laboratory and plant, and as a calibrated source of voltage.

One model has two ranges; -10.1 to 0 mV and 0 to 100.1 mV, it is readable to 1 μV. The limit of error is $\pm$(0.05 percent of reading $+20$ μV) without reference junction compensator and $\pm$(0.05 percent of reading $+40$ μV) with reference junction compensator.

Chapter 7—Reference Junctions

7.1 General Considerations

A thermocouple circuit is by its nature a differential measuring device, producing an emf which is a function of the temperatures of its two junctions. One of these junctions is at the temperature which is to be measured and is referred to as the measuring junction. The other junction is maintained at a known temperature and is referred to as the reference junction. (In a practical thermocouple circuit (see Section 2.3) copper wires are often connected to the thermocouple alloy conductors at the reference junction. The term reference junctions will be used to refer to this situation.) If these junctions are both at the same temperature, the presence of the copper "intermediate metal" introduces no change in the thermocouple's emf. If they are not at the same temperature the analysis of the circuit is complicated. Moffat [*34*] gives a helpful analytical method.

The Seebeck coefficient (thermoelectric power) of many common thermocouples is approximately constant from the ice point to the upper temperature limit of the materials (see Section 3.1.1). For such thermocouples, an uncertainty in the temperature of the reference junction will reflect a similar uncertainty in the deduced temperature of the measuring junction. However this situation does not exist for all thermocouple pairs. Notable exceptions occur in the case of the high rhodium-in-platinum alloy thermocouples [*35,36*]. In particular, if the reference junction of a platinum-30 percent rhodium versus platinum-6 percent rhodium (Type B) thermocouple lies within the range 0 to 50°C (32 to 122°F), a 0°C (32°F) reference junction may be assumed, and the error will not exceed 3 μV. This represents about 0.3°C (0.5°F) error in high-temperature measurements. [*37*]

7.2 Reference Junction Techniques

Three basic methods are used to take account of the reference junctions of the thermocouple circuit: (1) the junction is maintained at a fixed temperature, (2) the temperature of the reference junction is allowed to vary, and a compensating emf is introduced into the circuit or accounted for by calculation, (3) the temperature of the reference junction is allowed to vary, and compensation is made by a mechanical adjustment of the readout instrument.

Some variations of these techniques will be described in the following sections. Sources of error which are common to several techniques will be discussed in Section 7.3.

7.2.1 Fixed Reference Temperature

7.2.1.1 Triple Point of Water—A cell can be constructed in which there is an equilibrium between ice, water, and water vapor [*38*]. The temperature of this triple point is 0.01°C on the International Practical Temperature Scale of 1968, and it is reproducible to about 0.0001°C. Williams [*39*] describes a commercially available cell which is not affected by factors such as air saturation and pressure which can cause several millidegrees fluctuation in the temperature of an ice bath. To utilize such precision, extreme attention to immersion error and galvanic error is required, and the measurement system must be of the highest quality.

7.2.1.2 Ice Point—An ice bath consisting of a mixture of melting shaved ice and water forms an easy way of bringing the reference junctions of a thermocouple to 0°C (32°F). If a proper technique is used, the uncertainty in the reference junction temperature can be made negligibly small. With extreme care the ice point can be reproduced to 0.0001°C [*40*].

A recommended form of ice bath is described in Ref *41*, and is illustrated in Fig. 33. Using the recommended construction with maximum diameters of 14 gage B&S for iron or nickel base alloys and 20 gage B&S for copper and noble metals, immersed at least 4½ in. in the water-ice mixture, Caldwell [*42*] found the immersion error to be less than 0.05°C (see Section 7.3.1). Finch [*43*] describes an alternative construction which reduces the immersion error when large conductors must be used.

If improper technique is used, serious errors can be encountered. The largest error which is likely to occur arises due to melting of the ice at the bottom of a bath until the reference junctions are below the ice level and surrounded by water alone. This water may be as much as 4°C above the ice point. While an ice bath is being used excess water should be removed periodically and more ice added, so that the ice level is maintained safely below the reference junctions [*41*].

If the ice used to prepare the bath has been stored in a freezer at a temperature below 0°C, it may freeze the surrounding water and remain at a temperature below 0°C for some time. To avoid this condition the bath should be examined to confirm that a slush of ice shavings in water actually exists.

If appreciable concentrations of salts are present in the water used to make the ice bath, the melting point can be affected. McElroy [*44*] investigated various combinations of tap and distilled water to determine the error introduced. He observed bath temperatures of +0.013°C using distilled water with tap ice and −0.006°C using tap water and tap ice. It is probable that the use of tap water will not introduce significant errors unless accuracies better than 0.01°C are required [*42*].

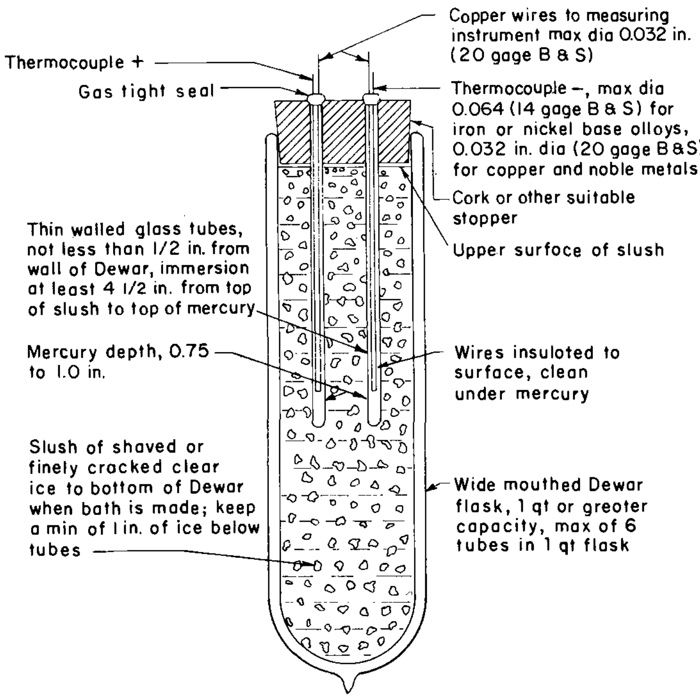

FIG. 33—*Recommended ice bath for reference junction.*

Another possible source of error is galvanic action which is discussed in Section 7.3.2.

Although the ice bath is an easy way of achieving a convenient fixed point for the reference junctions in the laboratory, the need for constant attention makes it unsuitable for industrial application where some form of automatic reference junction is desirable.

7.2.1.3 Automatic Ice Point—The development of the thermoelectric refrigerator (Peltier cooler) has enabled the production of practical devices in which an equilibrium between ice and water is constantly maintained [*45,46*]. Since water expands 9 percent on freezing, the change of volume may be used to control the heat transfer. Substances which undergo a phase change do so without change of temperature. This is an important advantage since the system behaves as if it had an infinite thermal capacity.

This device can provide a reference medium which is maintained at a precise temperature, but careful design is necessary if this precision is to be utilized fully. The system is subject to immersion error (Section 7.3.1) and galvanic error (7.3.2) due to condensation.

Some commercially available devices provide wells into which the user may insert reference junctions formed from his own calibrated wire. Others are provided with many reference junction pairs brought out to terminals which the user may connect into his system. The latter type are subject to the wire matching error (Section 7.3.3).

If the potential errors have been successfully overcome, the error introduced into a system by these devices may be less than 0.1°C.

7.2.1.4 Constant Temperature Ovens—A thermostatically controlled oven provides a way of holding a reference junction at an approximately constant temperature. The major advantage of this method is that one oven can be used with a large number of circuits while maintaining isolation between the circuits without the need for providing separate power supplies for each circuit.

The oven must be maintained at a temperature above the highest anticipated ambient temperature. The need for temperature uniformity within the oven and a precise temperature control system are inherent complications, in addition to the immersion error (Section 7.3.1) and the wire matching error (Section 7.3.2).

Ovens are available with rated accuracies ranging from 0.1 to 0.05°C. A common commercially used junction temperature is 150°F, although other values may be specified.

To use reference junctions held at elevated temperatures with tables or an instrument based on a 0°C reference junction temperature, a constant amount must be added to the thermal emf.

A device using two ovens is available which makes this correction automatically. To generate the necessary emf (for example, 2.662 mV for a Type K system with a 150°F (66°C) reference junction temperature) an additional internal thermocouple is connected in series with the external thermocouple circuit. This internal thermocouple has its reference junction in the first oven and its measuring junction in the second oven. The second oven is maintained at a suitable temperature above that of the first so that the required emf is generated. The external thermocouple circuit then behaves as if its reference junction were at 0°C. The manufacturers' stated accuracies of these devices are similar to those of single oven units.

7.2.2 Electrical Compensation

If the temperature of the reference junction of a thermocouple is allowed to change, the output emf will vary in accordance with the Seebeck coefficient of the couple at the reference temperature. A compensating circuit containing a source of current, a combination of fixed resistors, and a temperature sensitive resistor (TSR) can be designed which will have a similar variation of emf as the temperature of the TSR is varied. If the reference junction of the thermocouple is coupled thermally to the TSR and the compensating circuit is connected in series with the thermocouple so that its temperature-variable emf opposes that caused by the reference junction, the thermocouple behaves as if the reference junction temperature were held constant. In addition, by suitable choice of the fixed resistors, any fixed reference junction temperature may be simulated. Since the TSR is at the temperature of the reference junction, no warm-up or stabilization time is involved. Muth [*47*] has given a more extended description of these circuits.

The disadvantages of this arrangement include the need for a stable power source for each thermocouple circuit, the difficulty of exactly matching the Seebeck coefficient over an extended temperature range, and the addition of series resistance in the thermocouple circuit.

This principle is used in almost all self-balancing recording thermocouple potentiometers. Here the power source already is present as part of the potentiometer circuit. The Seebeck coefficient is matched adequately to allow the accuracy of the entire instrument to be typically 0.25 percent of full scale over a reasonable range of ambient temperatures.

Electric reference junction compensators are also available as small circuit modules with self-contained battery power sources or for connection to a-c power. A typical specification for a battery powered unit is compensation to $\pm 0.5°F$ over an ambient of $+55$ to $+90°F$. Improved specifications are quoted for more elaborate devices.

Some portable manually balanced potentiometers are provided with a thermometer to read the reference junction temperature and an adjustable circuit calibrated in millivolts or temperature. The control must be set manually to add the required emf to simulate an ice-point reference junction temperature.

7.2.2.1 Zone Box—In systems employing many thermocouples an alternative method of dealing with the thermocouple reference junctions is sometimes used. All of the thermocouples are routed to a device called a zone box where each of the thermocouple conductors is joined to a copper wire which is routed to the emf measuring instrument [*48,49*].

Within the zone box all of the reference junctions between the thermocouple conductors and the copper wires are insulated electrically but kept in good mutual thermal contact with each other and with a single transducer which compensates for the temperature within the zone box. This transducer may be a thermocouple of the same type as the measuring thermocouples having any of the types of reference junction described above. In this case its emf may be added to each of the measuring thermocouples in turn as they are switched to the emf measuring instrument. Alternatively the transducer may be a thermistor or resistance temperature detector which needs no reference temperature. In this case, the analyzing instrument determines the necessary correction to the thermal emfs, based on the measured reference junction temperature. Several variations of this technique are described in Ref *49*.

The advantage of this arrangement is the simplicity of the zone box which generally requires no heaters, controls, or power supplies. Since the zone box is approximately at the ambient temperature, the immersion error (Section 7.3.1) can be made easily negligible with a moderate amount of thermal insulation and care to avoid locations having extreme thermal gradients. The wire matching error (Section 7.3.3) should receive attention because the reference junctions are at ambient temperature and the calibration error at this temperature must be accounted for.

7.2.3 Mechanical Reference Compensation

To complete this account of methods used to compensate for the temperature of thermocouple reference junctions, a device used on millivolt pyrometers must be included. The millivolt pyrometer measures the thermal emf of a thermocouple circuit by measuring the current produced in a circuit of fixed and known resistance. The current operates a galvanometer with a rigid pointer which moves over a scale graduated in degrees [*43*]. The reference junction is at the temperature of the instrument, and hence the available thermal emf is a function of the temperature of the instrument. Compensation is often accomplished by attaching one of the hairsprings of the D'Arsonval galvanometer movement to a bimetallic thermometer element so that the electrical zero of the instrument is adjusted to correspond to the temperature of the instrument. This system is subject to the wire matching error (Section 7.3.3), but the precision of the pyrometer seldom justifies making corrections.

7.3 Sources of Error

Several sources of error which may disturb the control or measurement of the reference junction temperature are discussed in this section.

7.3.1 Immersion Error

Whenever reference junctions are being maintained at a temperature which differs from the ambient, heat is transferred between the reference temperature medium (oven, ice bath, etc.) and the ambient via the electrical insulation which separates the junctions from the medium and via the wires which emerge from the reference junctions. Thus the temperature of the junctions always differs from that of the reference medium to a greater or lesser degree. Caldwell [*42*] gives data which allow the error to be estimated for the standard type of ice bath. For other situations the error may be calculated by methods outlined in Refs *50* and *51*, if the coefficients governing heat flow between the medium, the wires, and the ambient can be evaluated.

With careful design the immersion error usually can be made negligible.

7.3.2 Galvanic Error

If water is allowed to contact the thermocouple alloy and copper wires of the reference junction, a galvanic cell may be set up, causing voltage drops which disturb the thermal emfs. If the reference junction is at a temperature below the dew point, the water may appear due to condensation. Insulation on both wires and precautions to avoid the accumulation of water in contact with the wires normally will prevent this error [*42,44*].

7.3.3 Wire Matching Error

Thermocouple wire normally is calibrated with its reference junction at 0°C, and corrections are determined to enable accurate measurements at elevated temperatures. The calibration deviation at ambient temperature is seldom of interest and usually is not determined.

Many reference junction devices are equipped with thermocouple alloy wires, and provision is made for interconnection with the user's thermocouples at ambient temperatures. If the calibration of the wire supplied with the device differs from that of the thermocouples at the ambient temperature, a significant error can result due to the interconnection of the wires. This source of error often is overlooked, since it is assumed that if the interconnection of both wires of a thermocouple pair occurs at the same temperature no error is introduced. The existence of this error is visualized easily if the circuit is analyzed using Moffat's method [*34*].

A simple correction for the wire matching error can be made if the ambient temperature deviation of the wire supplied with the reference junction device is known and the user's thermocouples are calibrated at ambient temperature.

The wire matching error is avoided in those reference junction devices in which the user's wire is used to form the reference junctions.

Chapter 8—Calibration of Thermocouples

The calibration of a thermocouple consists of the determination of its electromotive force (emf) at a sufficient number of known temperatures so that, with some accepted means of interpolation, its emf will be known over the entire temperature range in which it is to be used. The process requires a standard thermometer to indicate temperatures on a standard scale, a means for measuring the emf of the thermocouple, and a controlled environment in which the thermocouple and the standard can be brought to the same temperature. Some of the more commonly used techniques for accomplishing such calibrations will be discussed in this chapter.

Much of this material is based upon National Bureau of Standards Circular 590, *Methods of Testing Thermocouples and Thermocouple Materials*, and the calibration methods appearing in *Temperature Measurement* of the American Society of Mechanical Engineers Performance Test Codes, PTC 19.3 (1973).

8.1 General Considerations

8.1.1 Temperature Scale

The International Practical Temperature Scale of 1968 (IPTS-68) is realized and maintained by the National Bureau of Standards to provide a standard scale of temperature for use by science and industry in the United States. This scale [*52,53*] was adopted by the International Committee of Weights and Measures at its meeting in October 1968 and has general international acceptance. It replaces the International Practical Temperature Scale of 1948 [*54*]. The IPTS-68 distinguishes between the International Practical Kelvin Temperature with the symbol T_{68} and the International Practical Celsius Temperature with the symbol t_{68}; the relation between T_{68} and t_{68} is

$$t_{68} = T_{68} - 273.15 \text{ K}$$

The units of T_{68} and t_{68} are the kelvin, symbol K, and degree Celsius, symbol °C (formerly called centigrade). It is common practice to express values of temperature on the IPTS-68 in Kelvin temperatures below 0°C and in Celsius temperatures above 0°C. Values of Fahrenheit temperature, symbol °F, are obtained from the conversion formula

$$°F = 9/5 \times °C + 32$$

The IPTS-68 is a practical, standard, empirical scale chosen in such a way that temperatures measured on it closely approximate thermodynamic temperatures. It is a practical scale because the value for a given temperature is more easily and reproducibly determined on it than on the thermodynamic scale. The scale is based on eleven reproducible equilibrium states (defining fixed points) to which numerical values are assigned, and on formulas establishing the relationship between values of International Practical Temperature and the indications of standard instruments calibrated at the defining fixed points.

The defining fixed points are established by realizing specified equilibrium states between phases of pure substances. These fixed points and the exact numerical values assigned to them are given in Table 34.

TABLE 34—*Defining fixed points of the IPTS-68.*[a]

Equilibrium State	Assigned Value of International Practical Temperature T_{68}(K)	t_{68}(°C)
Equilibrium between the solid, liquid and vapor phases of equilibrium hydrogen (triple point of equilibrium hydrogen)	13.81	−259.34
Equilibrium between the liquid and vapor phases of equilibrium hydrogen at a pressure of 33 330.6 N/m² (25/76 standard atmosphere)	17.042	−256.108
Equilibrium between the liquid and vapor phases of equilibrium hydrogen (boiling point of equilibrium hydrogen)	20.28	−252.87
Equilibrium between the liquid and vapor phases of neon (boiling point of neon)	27.102	−246.048
Equilibrium between the solid, liquid and vapor phases of oxygen (triple point of oxygen)	54.361	−218.789
Equilibrium between the liquid and vapor phases of oxygen (boiling point of oxygen)	90.188	−182.962
Equilibrium between the solid, liquid and vapor phases of water (triple point of water)[c]	273.16	0.01
Equilibrium between the liquid and vapor phases of water (boiling point of water)[b,c]	373.15	100
Equilibrium between the solid and liquid phases of zinc (freezing point of zinc)	692.73	419.58
Equilibrium between the solid and liquid phases of silver (freezing point of silver)	1 235.08	961.93
Equilibrium between the solid and liquid phases of gold (freezing point of gold)	1 337.58	1 064.43

[a] Except for the triple points and one equilibrium hydrogen point (17.042 K) the assigned values of temperature are for equilibrium states at a pressure p_0 = 1 standard atmosphere (101 325 N/m²). In the realization of the fixed points small departures from the assigned temperatures will occur as a result of the differing immersion depths of thermometers or the failure to realize the required pressure exactly. If due allowance is made for these small temperature differences, they will not affect the accuracy of realization of the Scale. The magnitudes of these differences are given in section III of Ref *52*.

[b] The equilibrium state between the solid and liquid phases of tin (freezing point of tin) has the assigned value of t_{68} = 231.9681°C and may be used as an alternative to the boiling point of water.

[c] The water used should have the isotopic composition of ocean water, see section III,4 of Ref *52*.

The standard instrument used from 13.81 K (−259.34°C) to 630.74°C is the platinum resistance thermometer. The thermometer resistor must be annealed pure platinum that is mounted in a strain-free configuration. The resistance ratio $W(T_{68})$ of the platinum resistance thermometer, defined by

$$W(T_{68}) = R(T_{68})/R(273.15\ \text{K})$$

where $R(T_{68})$ is the resistance at T_{68} and $R(273.15\ \text{K})$ is the resistance at 273.15 K, must not be less than 1.39250 at $T_{68} = 373.15$ K. From 630.74°C to 1064.43°C the standard instrument is the platinum-10 percent rhodium versus platinum thermocouple. Above 1064.43°C, the IPTS-68 is defined by the Planck law of radiation with 1064.43°C as the reference temperature, but the type of standard instrument to be used for the measurement is not specified. However, visual and photoelectric optical pyrometers are the instruments usually used to realize the temperature scale in this region.

The procedures for interpolation lead to a division of the scale into four parts.

(*a*) From 13.81 K to 273.15 K (−259.34 to 0°C) the temperature T_{68} is defined by the formula

$$W(T_{68}) = W_{\text{CCT-68}}(T_{68}) + \Delta W(T_{68})$$

where $W(T_{68})$ is the resistance ratio of the platinum resistance thermometer and $W_{\text{CCT-68}}(T_{68})$ is the resistance ratio given by a reference function [*52,53*]. The deviations $\Delta W(T_{68})$ are calculated from measured values of $W(T_{68})$ at the defining fixed points and the corresponding values of $W_{\text{CCT-68}}(T_{68})$. To obtain $\Delta W(T_{68})$ at intermediate temperatures interpolation formulas are used. For this purpose the range between 13.81 and 273.15 K is divided into four parts; 13.81 to 20.28 K, 20.28 to 54.361 K, 54.361 to 90.188 K, and 90.188 to 273.15 K. In each part $\Delta W(T_{68})$ is given by a polynomial [*52,53*] in T_{68}. The constants in the polynomials are determined from values of $\Delta W(T_{68})$ at the fixed points and the condition that values of $d\,\Delta W(T_{68})/d\,T_{68}$ given by joining polynomials must be equal at the junctions of the temperature ranges.

(*b*) From 0 to 630.74°C t_{68} is defined by

$$t_{68} = t' + 0.045\left(\frac{t'}{100°\text{C}}\right)\left(\frac{t'}{100°\text{C}} - 1\right)\left(\frac{t'}{419.58°\text{C}} - 1\right)\left(\frac{t'}{630.74°\text{C}} - 1\right)°\text{C}$$

where t' is defined by the formula:

$$t' = \frac{1}{\alpha}\left[W(t') - 1\right] + \delta\left(\frac{t'}{100°\text{C}}\right)\left(\frac{t'}{100°\text{C}} - 1\right)$$

where $W(t') = \dfrac{R(t')}{R(0°\text{C})}$. The constants $R(0°\text{C})$, α, and δ are determined by measurement of the resistance of the platinum resistance thermometer at the triple point of water, the boiling point of water (or the freezing point of tin[9]), and the freezing point of zinc. The above formula for t' may also be expressed as

$$W(t') = 1 + At' + Bt'^2$$

where

$$A = \alpha\left(1 + \frac{\delta}{100°\text{C}}\right) \quad \text{and}$$

$$B = -10^{-4}\,\alpha\,\delta\ °\text{C}^{-2}$$

(*c*) From 630.74°C to the gold point (1064.43°C) the temperature t_{68} is defined by the formula

$$E(t_{68}) = \text{a} + bt_{68} + ct_{68}^2$$

where $E(t_{68})$ is the electromotive force of a standard platinum-10 percent rhodium versus platinum thermocouple when one of its junctions is at 0°C and the other is at the temperature t_{68}. The constants a, b, and c are calculated from values of E at 630.74°C ± 0.2°C, as determined by a platinum resistance thermometer, and at the freezing points of silver and gold.

For the foregoing interpolation formula to be valid, the platinum thermoelement of the standard thermocouple must meet certain purity requirements and the values of E at 630.74°C, the silver point and the gold point must also satisfy certain criteria [*52,53*]. Not all Type S thermocouples will meet these requirements, but suitable thermocouples may be obtained commercially.

(*d*) Above the gold point the temperature T_{68} is defined by the formula

$$\frac{L_\lambda(T_{68})}{L_\lambda(T_{68}(\text{Au}))} = \frac{\exp\left[\dfrac{c_2}{\lambda T_{68}(\text{Au})}\right] - 1}{\exp\left[\dfrac{c_2}{\lambda T_{68}}\right] - 1}$$

where $L_\lambda(T_{68})$ and $L_\lambda(T_{68}(\text{Au}))$ are the spectral concentrations at temperature T_{68} and at the freezing point of gold, $T_{68}(\text{Au})$, of the radiance of a blackbody at the wavelength λ; c_2 is defined to be 0.014388 metre kelvin and λ is in metres (exp $[x]$ is defined to be e^x).

In addition to the defining points of the Scale, given in Table 34, certain other points may be useful for calibration purposes. Some of these and their reported temperatures are given in Table 35. Except for the triple point of benzoic acid, each temperature is for a system in equilibrium under a pressure of 1 standard atm.

[9] See note[b], Table 34.

TABLE 35—*Secondary reference points.*
The pressure[a] is 1 standard atm, except for the triple point of benzoic acid.

	°C
Boiling point of normal hydrogen	−252.753
Boiling point of nitrogen	−195.802
Sublimation point of carbon dioxide	−78.476
Freezing point of mercury	−38.832
Freezing point of water	0.00
Triple point of benzoic acid	122.37
Freezing point of indium	156.634
Freezing point of bismuth	271.442
Freezing point of cadmium	321.108
Freezing point of lead	327.502
Freezing point of antimony	630.74
Freezing point of aluminum	660.37
Freezing point of copper	1 084.8
Freezing point of nickel	1 455
Freezing point of palladium	1 554
Freezing point of platinum[b]	1 768

8.1.2 Working Standards

Any one of several types of thermometers, calibrated in terms of the IPTS, may be used as a working standard for the calibration of thermocouples. The choice will depend upon the temperature range covered, whether a laboratory furnace or a stirred liquid bath is used, the accuracy expected of the calibration, or in cases where more than one type will suffice, the convenience or preference of the calibrating laboratory.

8.1.2.1 Resistance Thermometers—The standard platinum resistance thermometer is the most accurate standard for use from approximately −260°C (−436°F) to 630°C (−1166°F). In cases where an uncertainty approaching 0.1°C is necessary at temperatures below −56°C (−69°F) or above about 200°C (392°F) there are few alternatives to the use of resistance thermometers as standards.

8.1.2.2 Liquid-in-Glass Thermometers—This type of thermometer may be used from approximately −183°C (−297°F) to 400°C (752°F), or even higher with special types. Generally, the accuracy of these thermometers is less below −56°C (−69°F) where organic thermometric fluids are used, and above 300°C (572°F) where instability of the bulb glass may require frequent calibration. Specifications for ASTM liquid-in-glass thermometers are given in Ref *56*.

8.1.2.3 Types E and T Thermocouples—Either of these types of thermocouples may be used down to a temperature of −183°C (−297°F) or lower, but the attainable accuracy may be limited by the accuracy of the emf measurements and the inhomogeneity of the wire at low temperatures. The stability of the larger sizes of wire is greater than that of smaller wires under the same conditions. Twenty-four gage wire is a useful compromise between the lesser stability of smaller wire and the greater thermal conduction (greater required depth of immersion) of larger wire. Recommended upper limits are 425°C (797°F) for the Type E and 200°C (392°F) for Type T.

8.1.2.4 Types R and S Thermocouples—Type S or Type R thermocouple is the most satisfactory working standard for use in the range from 630°C (1166°F) up to about 1200°C (2192°F). Its use may be extended down to room temperature if it is desired to use the same standard over a wide range, but its sensitivity falls off appreciably as temperatures below 200°C (392°F) are reached. Twenty-four gage wire most commonly is used for these standards.

8.1.2.5 High Temperature Standards—The IPTS-68 above 1064°C (1947°F) is defined by the Planck law of radiation, and the scale is usually realized by means of an optical pyrometer. The optical pyrometer [*57*], sighted on a blackbody cavity built into the calibration furnace, therefore, can serve as a working standard for all temperatures above 1064°C (1947°F). On the other hand, thermocouples, calibrated on the optical pyrometer scale, can be used themselves as standards. The Type B thermocouple [*58*] is useful up to about 1600°C (2912°F). Tungsten rhenium alloys can be used to higher temperatures, but the optical pyrometer more commonly is used.

8.1.3 Annealing

Practically all base-metal thermocouple wire is annealed or given a "stabilizing heat treatment" by the manufacturer. Such treatment generally is considered sufficient, and seldom is it found advisable to further anneal the wire before testing.

Although new platinum and platinum-rhodium thermocouple wire as sold by some manufacturers already is annealed, it has become regular practice in many laboratories to anneal all Types R, S, and B thermocouples, whether new or previously used, before attempting an accurate calibration. This is accomplished usually by heating the thermocouple electrically in air. The entire thermocouple is supported between two binding posts, which should be close together, so that the tension in the wires and stretching while hot are kept at a minimum. The temperature of the wire is determined most conveniently with an optical pyrometer.[10]

[10] The ordinary portable type of optical pyrometer is very satisfactory for this purpose. As commonly used, the magnification is too low for sighting on an object as small as the wires of noble-metal thermocouples, but this is remedied easily by lengthening the telescope tube or using an objective lens of shorter focal length.

There are some questions as to the optimum temperature and length of time at which such thermocouples should be annealed to produce the most constant characteristics in later use [*59*] and as to whether annealing for more than a few minutes is harmful or beneficial. Most of the mechanical strains are relieved during the first few minutes of heatings at 1400 to 1500°C (2552 to 2732°F), but it has been claimed that the changes in the thermal emf of a couple in later use will be smaller if the wires are heated for several hours before calibration and use. The principal objection to annealing thermocouples for a long time at high temperatures, aside from the changes in emf taking place, is that the wires are weakened mechanically as a result of grain growth. It has been found that annealing at temperatures much above 1500°C (2732°F) produces rapid changes in the emf and leaves the wire very weak mechanically. In addition, rapid cooling [*59*] of the wires following annealing at elevated temperatures should be avoided since it can substantially alter the emf. Except for work of the highest precision, cooling at a rate not exceeding about 400°C/min is satisfactory. The National Bureau of Standards has adopted the procedure of annealing Types R, S, and B thermocouples for 1 h at 1450°C (2642°F), followed by slow cooling.

It has not been demonstrated conclusively that Types R, S, and B thermocouples after contamination can be improved materially in homogeneity by prolonged heating in air, although it is logical to suppose that certain impurities can be driven off or, through oxidation, rendered less detrimental.

8.1.4 Measurement of Emf

One of the factors in the accuracy of the calibration of a thermocouple, is the accuracy of the instrument used to measure the emf. Fortunately in most instances, an instrument is available whose performance is such that the accuracy of the calibration need not be limited by the accuracy of the emf measurements. For work of the highest accuracy it is advisable to use a potentiometer of the type designed by Diesselhorst [*60*], White [*61*], or Wenner [*62*], in which there are no slidewires and in which all the settings are made by means of dial switches. However, for most work, in which an accuracy of 5 μV will suffice, slidewire potentiometers of the laboratory type are sufficiently accurate. Portable potentiometers accurate within 40 to 100 μV also are available. For a more detailed consideration of emf measurements see Chapter 6.

8.1.5 Homogeneity

The emf developed by a thermocouple made from homogeneous wires will be a function of the temperature difference between the measuring and the reference junction. If, however, the wires are not homogeneous, and the inhomogeneity is present in a region where a temperature gradient exists, extraneous emf's will be developed, and the output of the thermocouple will depend upon factors in addition to the temperature difference between the two junctions. The inhomogeneity of the thermocouple wire, therefore, is an important factor in accurate measurements.

Thermocouple wire now being produced is usually sufficiently homogeneous in chemical composition for most purposes. Occasionally inhomogeneity in a thermocouple may be traced to the manufacturer, but such cases are rare. More often it is introduced in the wires during tests or use. It usually is not necessary, therefore, to examine new thermocouples for inhomogeneity, but thermocouples that have been used for some time should be so examined before an accurate calibration is attempted.

While rather simple methods are available for detecting thermoelectric inhomogeneity, no satisfactory method has been devised for quantitatively determining it or the resulting errors in the measurement of temperatures. Abrupt changes in the thermoelectric power may be detected by connecting the two ends of the wire to a sensitive galvanometer and slowly moving a source of heat, such as a bunsen burner or small electric furnace, along the wire. This method is not satisfactory for detecting gradual changes in the thermoelectric power along the length of the wire. Inhomogeneity of this nature may be detected by doubling the wire and inserting it to various depths in a uniformly heated furnace, the two ends of the wire being connected to a galvanometer as before. If, for example, the doubled end of the wire is immersed 10 in. in a furnace with a sharp temperature gradient so that two points on the wire 20 in. apart are in the temperature gradient, the emf determined with the galvanometer is a measure of the difference in the thermoelectric properties of the wire at these two points.

After reasonable homogeneity of one sample of wire has been established, it may be used in testing the homogeneity of similar wires by welding the two together and inserting the junction into a heated furnace. The resulting emf at various depths of immersion may be measured by any convenient method. Other similar methods have been described for detecting inhomogeneity *[63]*.

Tests such as those described above will indicate the uncertainty in temperature measurements due to inhomogeneity in the wires. For example, if a difference in emf of 10 μV is detected along either element of a platinum-rhodium couple by heating various parts of the wire to 600°C (1112°F), measurements made with it are subject to an uncertainty of the order of 1 deg below 500°C, or 2 deg to 1200°C. Similarly, if an emf of 10 μV is detected along an element of a base-metal couple with a source of heat at 100°C, measurements made with it are subject to an uncertainty of the order of 0.2°C at this temperature. The effects of inhomogeneity in both wires may be either additive or subtractive, and, as the emf developed along an inhomogeneous wire depends upon the temperature distribution, it is evident that corrections for inhomogeneity are impracticable if not impossible.

8.1.6 General Calibration Methods

The temperature-emf relation of a homogeneous [*64*] thermocouple is a definite physical property and therefore does not depend upon the details of the apparatus or method employed in determining this relation. Consequently, there are numerous methods of calibrating thermocouples, the choice of which depends upon the type of thermocouple, temperature range, accuracy required, size of wires, apparatus available, and personal preference. However, the emf of a thermocouple with its measuring junction at a specified temperature depends upon the temperature difference between its measuring and reference junctions. Therefore, whatever method of calibration is used, the reference junction must be maintained constant at some known temperature (see Chapter 7), and this temperature must be stated as a necessary part of the calibration results.

Thermocouple calibrations are required with various degrees of accuracy ranging from 0.1 to 5 or 10°C. For an accuracy of 0.1°C, agreement with the IPTS-68 and methods of interpolating between the calibration points become problems of prime importance, but for an accuracy of about 10°C comparatively simple methods of calibration usually will suffice. The most accurate calibrations in the range −260°C (−436°F) to 300°C (572°F) are made by comparing the couples directly with a standard platinum-resistance thermometer in a stirred liquid bath. In the range 300 to 630°C (572 to 1166°F) (and below if a platinum-resistance thermometer and stirred liquid bath is not available) thermocouples are calibrated most accurately at the freezing or boiling points of pure substances. Between 630 and 1064°C (1166 and 1947°F), the Type S thermocouple calibrated at 630.74°C and the freezing points of gold and silver, serves to define the IPTS-68, and other types of thermocouples are calibrated most accurately in this range by direct comparison with the standard thermocouple calibrated as specified. Other thermocouples may be calibrated just as accurately at the fixed points as the Type S thermocouple, but interpolated values at intermediate points may depart slightly from the IPTS-68. Above 1064°C (1947°F), the most basic calibrations are made by observing the emf when one junction of the thermocouple is in a blackbody furnace, the temperature of which is measured with an optical pyrometer. However, the difficulties encountered in bringing a blackbody furnace to a uniform temperature make the direct comparison of these two types of instruments by no means a simple matter.

Although the Type S thermocouple serves to define the IPTS-68 only in the range 630.74 to 1064.43°C, this type of thermocouple calibrated at fixed points is used extensively both above and below this range as a working standard in the calibration of other thermocouples. For most industrial purposes a calibration accurate to 2 or 3°C in the range room temperature to 1200°C (2192°F) is sufficient. Other thermocouples can be calibrated by comparison with such working standards almost as accurately as the calibration of the standard is known. However, it might be pointed up that outside the range 630.74 to 1064.43°C any type of thermocouple suitable for the purpose, and calibrated to agree with the resistance thermometer or optical pyrometer in their respective ranges, has as much claim to yielding temperatures on the IPTS-68 as the Type S thermocouple. In fact, at the lower temperatures certain types of base-metal couples are definitely better adapted for precise measurements.

The calibration of couples then may be divided into two general classes, depending upon the method of determining the temperature of the measuring junction: (1) calibration at fixed points and (2) calibration by comparison with standard instruments such as thermocouples, resistance thermometers, etc.

In order to obtain the high accuracies referred to above and usually associated with calibrations at fixed points, it is necessary to follow certain prescribed methods and to take the special precautions described in detail in the following paragraphs, but for an accuracy of about 5°C the more elaborate apparatus to be described need not be employed.

8.1.7 Calibration Uncertainties

The several factors which contribute to the uncertainties in the emf versus temperature relationship for a particular thermocouple as determined by calibration may be grouped into two kinds; those influencing the observations at calibration points, and those arising from any added uncertainty as a result of interpolation between the calibration points. Errors from either of these sources of uncertainty can be reduced materially, within limits, through use of well designed equipment and careful techniques; hence, the required accuracy should be clearly understood when choosing calibration facilities.

Estimates of the accuracies attainable in the calibration of homogeneous thermocouples by different techniques are given in Tables 36, 37, 38, 39, and 40. The estimates assume that reasonable care is exercised in the work. More or less accurate results are possible using the same methods, depending upon soundness of the techniques used. While excessive care is a waste when relatively crude measurements are sufficient, it should be emphasized that inadequate attention to possible sources of error is more often found to be the practice than the converse. In the following some of the important considerations associated with the various calibration methods are emphasized briefly.

8.1.7.1 Uncertainties Using Fixed Points—The equilibrium temperatures listed in Table 35 (with the possible exception of the sublimation point of carbon dioxide) are sufficiently exact, and the materials are readily available in high enough purity, that accurate work can be done using these

fixed points with no significant error being introduced by accepting the temperatures listed. Using freezing points, however, good designs of freezing point cells and furnaces are important for controlling the freezes and for providing sufficient immersion for the thermocouple, if the full potential of the method is to be realized.

Although uncertainties of the order of ±1°C in the temperatures are assigned to the freezing points (and hence by implication to the melting points) of palladium and platinum, these contribute in only a minor way overall uncertainties of calibrations using freezing point techniques.

8.1.7.2 Uncertainties Using Comparison Methods—The accuracy attained at each calibration point using the comparison method will depend upon the degree to which the standard and the test thermocouple are maintained at the same temperature and the accuracy of the standard used. Comparison measurements made in stirred liquid baths usually present no special problems provided that sufficient immersion is used. Because of the high-thermal conductivity of copper, special attention should be given to the problem of immersion when calibrating Type T thermocouples.

As higher and higher temperatures are used the difficulties of maintaining the test thermocouple and the standard at the same measured temperature are magnified whether a tube furnace, an oven with moderating block, or whatever means is used for maintaining the desired temperature. In addition, at temperatures of about 1500°C (2732°F), and higher, the choice of insulating materials becomes very important (see Chapter 4). Special attention must be paid to possible errors arising from contamination from the insulators or protection tube and from electrical leakage.

When an optical pyrometer is used as the temperature measuring standard, a good blackbody must be used, and the design must be such that the test thermocouple is at the same temperature as the blackbody.

8.2 Calibration Using Fixed Points

The indications of the Type S thermocouple calibrated at 630.74°C and the silver and gold points, as mentioned in Section 8.1.1, define the IPTS-68 between 630.74°C (1167°F) and 1064.43°C (1948°F). If such a thermocouple is calibrated also at the zinc point, a working standard will result which is accurate to about 0.3°C in the range 0 to 1100°C (32 to 2012°F). While the fixed-point calibration is prescribed for defining the IPTS-68, similar methods are also useful in the calibration of other types of thermocouples. Fixed points can be used with various degrees of accuracy, ranging from 0.1 to 5°C, for the calibration of various types of thermocouples in the range −260°C (−436°F) to the melting point of platinum at 1768°C (3214°F). Some of the fixed points for which values have been determined accurately are listed in Section 8.1.1, Table 35. Because of experimental difficulties, fixed points at temperatures higher than the freezing point of copper usually are realized as melting points rather than freezing points, as described later.

8.2.1 Freezing Points

The emf developed by a homogeneous thermocouple at the freezing point of a metal is constant and reproducible if all of the following conditions are fulfilled: (1) the thermocouple is protected from contamination; (2) the thermocouple is immersed in the freezing-point sample sufficiently far to eliminate heating or cooling of the junction by heat flow along the wires and protection tube; (3) the reference junctions are maintained at a constant and reproducible temperature; (4) the freezing-point sample is pure; and (5) the metal is maintained at essentially a uniform temperature during freezing.

Techniques for achieving these conditions are well developed [*63,65,66*]. Many of the metals listed in Table 35 of Section 8.1.1 are available commercially in high purity (99.999 percent or better) and can be used assuming the freezing point temperatures given in the table. It is essential, however, that protection tubes and crucibles be chosen of such material (see Section 4) that the pure metals will not be contaminated. Copper and silver must be protected from oxygen contamination [*63*], and it is also advisable to protect aluminum and antimony; this is done usually by using covered crucibles and covering the freezing point metals with powdered graphite or by sealing the crucible in a glass tube that contains a nonoxidizing gas such as argon or helium. The choice of a suitable furnace is also important. The furnace must provide uniform heating in the region of the freezing point sample, and have adequate controls to bring the sample slowly into its freeze. Complete units consisting of freezing point sample, crucible, and furnace are available commercially. Freezing point standard samples of tin, lead, zinc, aluminum, and copper may be purchased from the National Bureau of Standards.

8.2.2 Melting Points

The emf of a thermocouple at the melting point of a metal may be determined with the same apparatus as that described above for freezing points, but the use of the freeze is usually more satisfactory. Melting points are used to advantage, however, when only a limited amount of material is available or at high temperatures where experimental techniques with freezing points are difficult. To apply this method [*67,68,69,70*], a short length of metal whose melting point is known is joined between the end of the two wires of the thermocouple and placed in an electrically heated furnace the temperature of which is raised slowly. When the melting point of the metal is reached, the emf of the thermocouple remains steady for a few minutes and then drops to zero as the fused metal drops away from the junction. With good technique[11] the method can result in accuracies comparable to those with which the IPTS-68 is realized above 1064°C by optical pyrometry.

8.3 Calibration Using Comparison Methods

The calibration of a thermocouple by comparison with a working standard [*71*] is sufficiently accurate for most purposes and can be done conveniently in most industrial and technical laboratories. The success of this method usually depends upon the ability of the observer to bring the measuring junction of the thermocouple to the same temperature as the actuating element of the standard, such as the measuring junction of a standard

[11] This method is not well adapted to metals that oxidize rapidly, and, if used with materials whose melting temperature is altered by the oxide, the metal should be melted in a neutral atmosphere.

thermocouple or the bulb of a resistance or liquid-in-glass thermometer. The accuracy obtained is further limited by the accuracy of the standard. Of course, the reference junction temperature must be known, but this can be controlled, as described in Chapter 7. The method of bringing the measuring junction of the thermocouple to the same temperature as that of the actuating element of the standard depends upon the type of thermocouple, type of standard, and the method of heating.

8.3.1 Laboratory Furnaces

The calibration procedure consists of measuring the emf of the thermocouple being calibrated at selected calibration points, the temperature of each point being measured with a working standard. The number and choice of calibration points will depend on the type of thermocouple, the temperature range covered, and the accuracy required (see Sections 8.1.6 and 8.4).

8.3.1.1 Platinum-Rhodium Versus Platinum Thermocouples—Thermocouples employing platinum and platinum-rhodium alloys seldom are used for accurate measurements below 300°C (572°F) because the sensitivity of these thermocouples decreases rapidly at low temperatures.

These thermocouples usually are calibrated at temperatures up to 1200°C by comparison with either a Type S or Type R working standard in electrically heated furnaces. Above 1200°C (2192°F) the Type B thermocouple is a preferred working standard because of its greater stability at high temperatures. This thermocouple may be used to 1600°C (2912°F) or higher.

One method for the comparison of two such thermocouples is based upon the simultaneous reading of the emf of the standard and the test thermocouple without waiting for the furnace to stabilize at any given temperature. The measuring junctions are maintained always at close to the same temperature by welding them into a common bead or by wrapping them together with platinum wire or ribbon. A separate potentiometer is used to measure each emf, one connected to each thermocouple, and each potentiometer is provided with a reflecting galvanometer. The two spots of light are reflected into a single scale, the galvanometers being set in such a position that the spots coincide at the zero point on the scale when the circuits are open, and therefore also when the potentiometers are set to balance the emf of each thermocouple. Simultaneous readings are obtained by setting one potentiometer to a desired value and adjusting the other so that both spots of light pass across the zero of the scale together as the temperature of the furnace is raised or lowered.

By making observations first with a rising and then with a falling temperature, the rates of rise and fall being approximately equal, and taking the mean of the results found, several minor errors such as those due to differences in the periods of the galvanometers, etc., are eliminated or greatly reduced.

This method is particularly adapted to the calibration of thermocouples at any number of selected points. For example, if it is desired to determine the temperature of a thermocouple corresponding to 10.0 mV, this emf is set up on the potentiometer connected to the thermocouple, the emf of the standard thermocouple observed as desired above, and the temperature obtained from the emf of the standard. If it is desired to determine the emf of a thermocouple corresponding to 1000°C (1832°F), the emf of the standard corresponding to this temperature is set up on the potentiometer connected to the standard, and the emf of the thermocouple being calibrated is observed directly with the second potentiometer. To reduce the time required to calibrate by this method the furnace should be so constructed that it will heat or cool rapidly. Fast response is obtained in one furnace design which employs a nickel-chromium tube as the heating element [*63*].

A similar furnace using a silicon carbide tube as the heating element can be used to extend the calibration range upward [*58*]. At temperatures above 1064°C (1947°F) the IPTS-68 is defined in terms of ratios of radiation (Section 8.1.1) usually measured with a visual or a photoelectric optical pyrometer. If the test thermocouple is inserted into the back of a blackbody cavity built into the furnace, a pyrometer may be used directly as the working standard. Alternatively, the Type B thermocouple can be used as the working standard after it has been calibrated against a pyrometer.

The thermocouples are insulated and protected by suitable ceramic tubes (Chapter 4). It is essential that good insulation be maintained between the two potentiometers and thermocouple circuits except at the point where the junctions are welded together. The reference junctions are maintained at a known temperature (Chapter 7).

Variations of the two potentiometer method may be used to automate the calibration process when the thermocouple being calibrated and the standard thermocouple are of the same type [*71*]. If the emf of the standard is read with one potentiometer and the emf difference between the standard and the unknown are read with the second potentiometer, the calibration data may be recorded automatically [*72,73*].

If two potentiometers are not available for taking simultaneous readings, the furnace may be brought to essentially a constant temperature, and the emf of each thermocouple read alternately on one instrument [*71*].

When the thermocouples are calibrated by welding or wrapping the junctions together, both would be expected to be close to the same temperature even when the temperature of the furnace is changing. If it is necessary or advisable to calibrate the thermocouples without removing them from the protection tubes, then the junctions of the thermocouple being tested and that of the standard should be brought as close together as possible in a uniformly heated portion of the furnace. In this case it is necessary that the furnace be brought to approximately a constant temperature before taking observations.

There are a number of other methods of heating and of bringing the junctions to approximately the same temperature, for example, inserting the thermocouples properly protected into a bath of molten metal or into holes drilled in a large metal block. The block of metal may be heated in a muffle furnace or, if made of a good thermal conductor such as copper, may be heated electrically. Tin, which has a low melting point, 232°C (450°F), and low volatility, makes a satisfactory bath material. The thermocouples should be immersed to the same depth with the junctions close together. Ceramic tubes are sufficient protection, but to avoid breakage by thermal shock when immersed in molten metal it is preferable to place them inside of secondary tubes of iron, nickel-chromium, graphite, or similar material. In all of these methods, particularly in those cases in which the junctions of the thermocouples are not brought into direct contact, it is important that the depth of immersion be sufficient to eliminate cooling or heating of the junctions by heat flow along the thermocouple and the insulating and protecting tubes. This can be determined by observing the change in the emf of the thermocouple as the depth of immersion is changed slightly. If proper precautions are taken, the accuracy yielded by any method of heating or bringing the junctions to the same temperature may be as great as that obtained by any other method.

8.3.1.2 Base-Metal Thermocouples—The methods of testing base-metal thermocouples above room temperature are generally the same as those just described for testing noble-metal thermocouples with the exception, in some cases, of the methods of bringing the junctions of the standard and the thermocouple being tested to the same temperature and the methods of protecting platinum-rhodium standards from contamination. One arrangement of bringing the junction of a platinum-rhodium standard to the same temperature as that of a large base-metal thermocouple for accurate calibration is to insert the junction of the standard into a small hole (about 0.06 in. in diameter) drilled in the hot junction of the base-metal thermocouple. The platinum-rhodium standard is protected by ceramic tubes to within a few tenths of an inch of the hot junction, and the end of the ceramic tube is sealed to the thermocouple by pyrex glass or by a small amount of kaolin and water-glass cement. This prevents contamination of the standard thermocouple, with the exception of the small length of about 0.1 in., which is necessarily in contact with the base-metal thermocouple. If the furnace is uniformly heated in this region (and it is of little value to make such a test unless it is) contamination at this point will not cause any error. If the wire of the standard becomes brittle at the junction, this part of the wire may be cut off and enough wire drawn through the softened seal to form a new junction. The seal should be examined after each test and remade if it does not appear to be good. More than one base-metal thermocouple may be welded together and the hole drilled in the composite junction. The thermocouples should be clamped in place so that the junctions remain in contact. If two potentiometers are used for taking simultaneous readings, the temperature of the furnace may be changing as much as a few degrees per minute during an observation, but if a single instrument is used for measuring the emf, the furnace temperature should be maintained practically constant during observations. When wires, insulators, and protection tubes are large, tests should be made to ensure that the depth of immersion is sufficient.

8.3.2 Stirred Liquid Baths

At temperatures below 620°C (1148°F) stirred liquid baths provide an efficient medium for bringing a thermocouple and a temperature standard to the same temperature.

Water, petroleum oils, or other organic liquids, depending upon temperature range, are commonly used bath media. Molten salts or liquid tin are used at temperatures higher than are suitable for oil. Baths suitable for this work are described in Ref *74*.

Base-metal thermocouples, either bare wire or insulated, may be calibrated accurately in such baths. Usually no special preparation of the thermocouple will be required other than to insert it to the bottom of a protection tube for immersion in the liquid bath. Borosilicate glass tubing, such as pyrex glass, is convenient for use up to 538°C (1000°F). Vitreous silica or ceramic tubing may be used to 620°C (1148°F). The tube should be closed at the immersed end and of an internal diameter such as to permit easy insertion of the thermocouple or thermocouples to be calibrated but no larger than necessary. Unfavorable heat transfer conditions in an unnecessarily large diameter tube will require a greater depth of immersion in the bath than would a close fitting tube. If a bare wire thermocouple is being calibrated, the wires must be provided with electrical insulation over the length inserted in the protection tube. Sheathed thermocouples may be immersed directly in the bath liquid in cases where the sheath material will not be attacked by the liquid. Salt baths for use at high temperature must be provided with suitable wells into which the thermocouple protection tubes and standard thermometers may be inserted for protection from the molten salt.

The standard thermometer may be a thermocouple standard inserted in the protection tube with the thermocouple being calibrated, or it may be a liquid-in-glass thermometer or resistance thermometer immersed in the bath close to the thermocouple protection tube. The choice of a standard thermometer will be governed principally by the degree of uncertainty which can be tolerated.

8.3.3 Fixed Installations

After thermocouples have been used for some time at high temperatures, it is difficult, if not impossible, to determine how much the calibrations are in error by removing them from an installation and testing in a laboratory furnace. The thermocouples are usually heterogeneous after such use and in such a condition that the emf developed by the thermocouples depends upon the temperature distribution along the wires [75]. If possible, such a thermocouple should be tested under the same conditions and in the same installation in which it is used. Although it is not usually possible to obtain as high a precision by testing the thermocouple in place as is obtained in laboratory tests, the result is far more useful in the sense of being representative of the behavior of the thermocouple [70]. The calibration is accomplished by comparing the thermocouple with a thermocouple standard.

In this case, as in the calibration of any thermocouple by comparison methods, the main objective is to bring the hot junction to the same temperature as that of the thermocouple being tested. One method is to drill a hole in the furnace, flue, etc., at the side of each thermocouple permanently installed, large enough to permit insertion of the checking thermocouples. The hole is kept plugged, except when tests are being made. The standard thermocouple is inserted through this hole to the same depth as the thermocouple being tested with the hot junction ends of the protection tubes as close together as possible. Preferably a potentiometer should be used with the standard thermocouple.

In many installations the base-metal thermocouple and protecting tube are mounted inside another protecting tube of iron, fire clay, carborundum, or some other refractory which is permanently cemented or fastened into the furnace wall. Frequently there is room to insert a small test thermocouple in this outer tube alongside of the fixed thermocouple. A third method, much less satisfactory, is to wait until the furnace, flue, etc., have reached a constant temperature and make observations with the thermocouple being tested, then remove this thermocouple and insert the standard thermocouple to the same depth.

If desired, comparisons can be made, preferably by either of the first or second methods at several temperatures, and a curve obtained for each permanently installed thermocouple showing the necessary corrections to be applied to its readings. Although testing a thermocouple at one temperature yields some information, it is not safe to assume that the changes in the emf of the thermocouple are proportional to the temperature or to the emf. For example, it has been observed that a thermocouple which had changed in use by the equivalent of 9°C at 315°C (16°F at 599°F) had changed only the equivalent of 6°C at 1100°C (11°F at 2012°F).

It may be thought that the method of checking thermocouples under working conditions is unsatisfactory because, in most furnaces used in industrial processes, large temperature gradients exist, and there is no certainty that the standard thermocouple is at the same temperature as the thermocouple being tested. This objection, however, is not serious, because if temperature gradients do exist of such a magnitude as to cause much difference in temperature between two similarly mounted thermocouples located close together, the reading of the standard thermocouple represents the temperature of the fixed thermocouple as closely as the temperature of the latter represents that of the furnace.

Another advantage of checking thermocouples in the same installation in which they are used is that the thermocouple, extension wires, and indicator are tested as a unit and under the conditions of use.

8.4 Interpolation Methods

An experimental thermocouple calibration consists of a series of voltage measurements determined at a finite number of known temperatures. If a test thermocouple were compared with a standard temperature instrument at 100 temperatures within a 10°F range, there would be little need for interpolation between the calibration points. However, if from 4 to 10 calibration points are all that can be afforded in a given range of interest, then what is needed to characterize an individual thermocouple is a continuous relation, by means of which temperatures can be approximated with a minimum uncertainty from voltage measurements at intermediate levels. Efforts to obtain such a continuous relation appear thwarted from the start because of the small number of discrete calibration points available. However, interpolation between the calibration points is possible since the emf changes only slowly and smoothly with temperature.

One can present raw calibration data directly in terms of temperature (T) and voltage (E_{couple}), on a scale so chosen that the information appears well represented by a single curve (see Fig. 34) or by a simple mathematical equation. For example, for the highest accuracy in the range 630 to 1064°C with the Type S thermocouple, the method is that prescribed in Ref *63*, page 13. An equation of the form $e = a + bt + ct^2$, is used where a, b, and c are constants determined by calibration at the freezing points of gold, silver, and antimony. By calibrating the thermocouple also at the freezing point of zinc and using an equation of the form $e = a + bt + ct^2 + dt^3$, the temperature range can be extended down to 400°C without introducing an uncertainty of more than 0.1°C in the range 630 to 1064°C. By calibrating the thermocouple at freezing points of gold, antimony, and zinc and using an equation of the form $e = a + bt + ct^2$, a calibration is obtained for the range 400 to 1100°C, which agrees with IPTS-68 to 0.5°C. However, in general, this practice of directly representing thermocouple characteristics does not yield results within the required limits of uncertainty.

A better method[12] is based on the use of differences between observed values and values obtained from standard reference tables. Such reference tables and the mathematical means for generating them are presented in

[12] Much of the material in this Chapter is based on Ref 77.

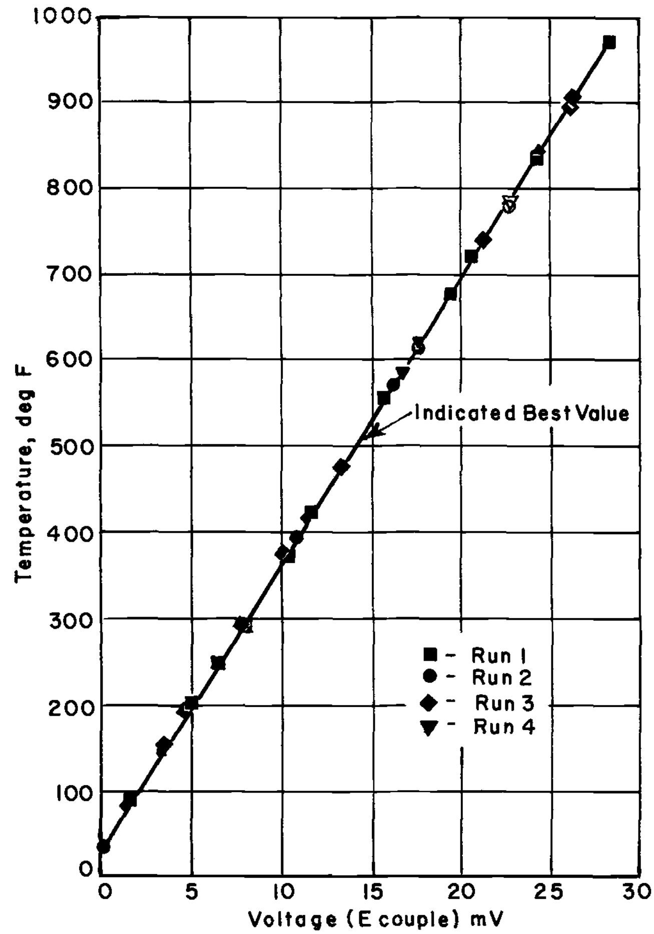

FIG. 34—*Temperature emf plot of raw calibration data for an iron-constantan thermocouple.*

Chapter 10 of this Manual. The data of Fig. 34 are replotted in Fig. 35 in terms of differences from the proper reference table. The maximum spread between points taken at the same level (replication), but obtained in random order with respect to time and level (randomization) is taken as the uncertainty envelope. This information, taken from Fig. 35 is plotted in Fig. 36, and constitutes a vital bit of information about the particular thermocouple and the calibration system. In lieu of an experimental determination of the uncertainty, one must rely on judgment or on the current literature for this information.

Usually, only a single set of calibration points is available. Typical points would be those taken from one run shown in Figs. 34 or 35, and these are shown in Fig. 37 together with four of the many possible methods for representing the thermocouple difference characteristic. Although at first it appears that the most probable relation characterizing a given thermocouple is sensibly indeterminate from a single set of calibration points, it is an important fact that all experimental points must be continued within the uncertainty interval when the uncertainty interval is centered on the most probable interpolation equation.

Making use of this principle, together with the fact that overall experimental uncertainties are minimized by use of the least squares technique, one starts the search for the most probable interpolation equation by passing a least squares equation of the first degree through the experimental data. A check is then made to ascertain whether all experimental points are contained within the uncertainty envelope which is centered on the linear interpolation equation (see Fig. 38). One proceeds, according to the results of the foregoing check, to the next highest degree equation, stopping at the lowest degree least squares equation which satisfies the uncertainty requirements. For the example given here, a third degree interpolation equation is required (see Fig. 39). By obtaining voltage differences from the least squares fit of any set of calibration points, the uncertainty in the thermocouple difference characteristic will be within one half the uncertainty

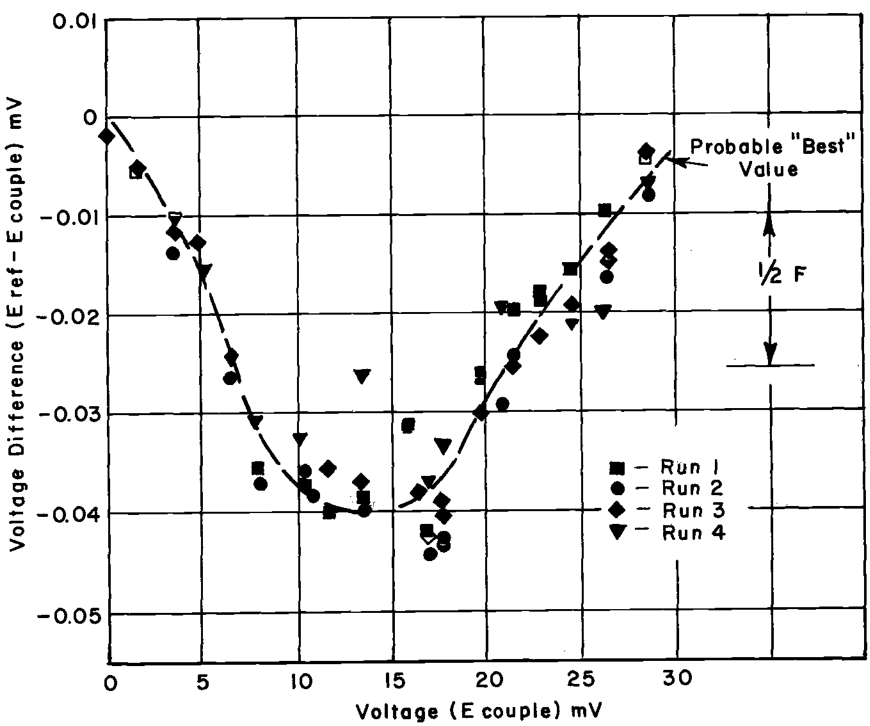

FIG. 35—*Difference plot of raw calibration data for an iron-constantan themocouple.*

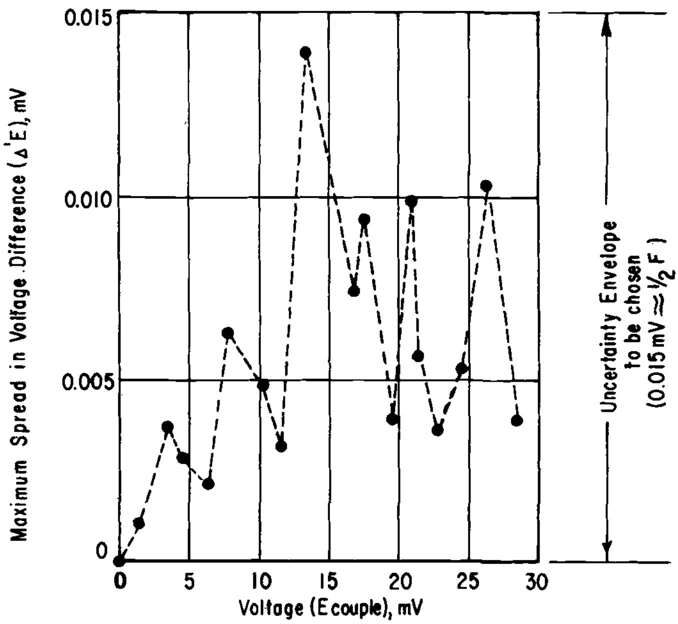

FIG. 36—*Typical determination of uncertainty envelope (from data of Fig. 35).*

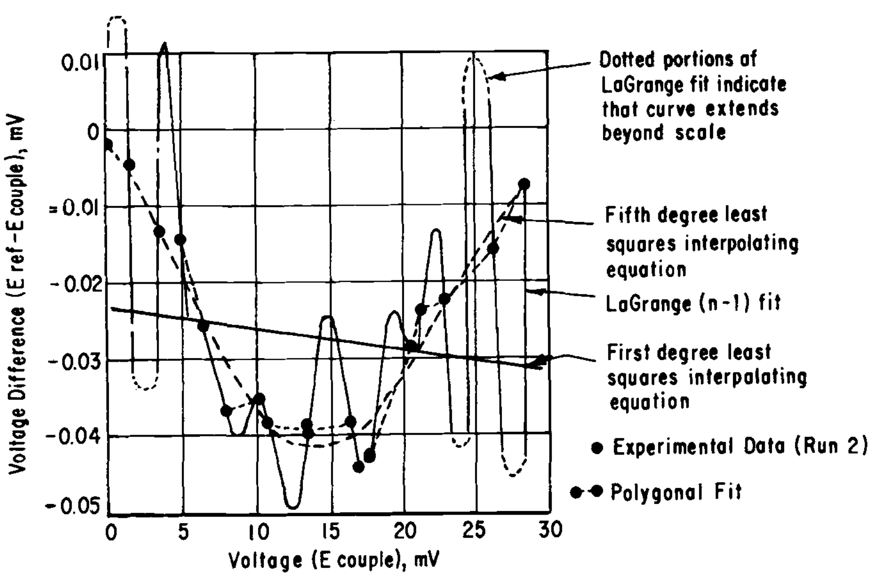

FIG. 37—*Various possible empirical representations of the thermocouple characteristic (based on a single calibration run).*

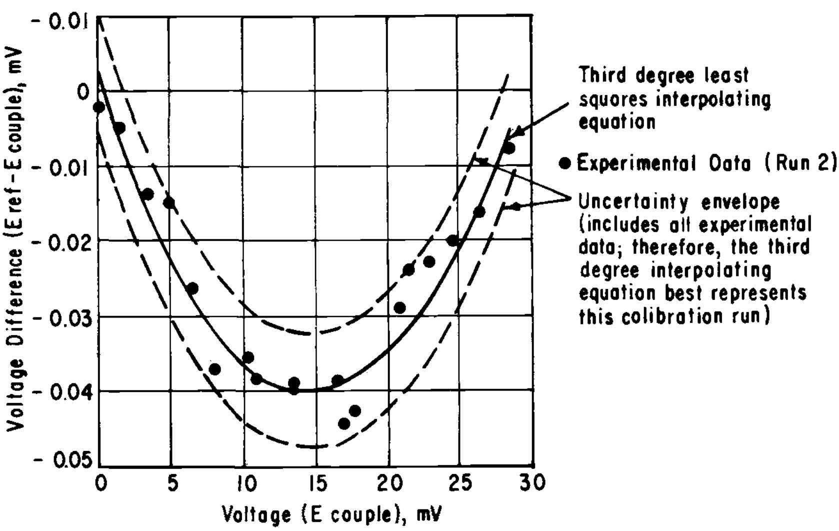

FIG. 39—*Uncertainty envelope method for determining degree of least squares interpolating equation for a single calibration run (cubic).*

interval. Generally, the form of the uncertainty envelope and the degree of the most probable least squares interpolation equation are strongly dependent on the amount of calibration data available and on the temperature range under consideration. It is recommended that the number of distinct calibration points available should be at least 2 (degree +1). The factor two is arrived at from numerical analysis reasoning. A distinct calibration point is defined arbitrarily as one which is separated, temperaturewise, from all other points in the set by as much as one tenth the difference in temperature between the maximum and minimum temperatures of the particular run. The choice of one tenth presupposes a maximum practical degree of four for the least squares interpolation equation, in keeping with the low degree requirement of numerical analysis. Indeed, if the data cannot be represented by a fourth degree interpolation equation, one should increase the uncertainty interval and start the fitting procedure again.

Thus, in general, by using the proper reference table in conjunction with a difference curve, greater precision in temperature determination by means of thermocouples can be obtained from a given number of calibration points than from the use of the calibration data alone.

8.5 Single Thermoelement Materials

The standard method provided by ASTM for evaluating the emf characteristics of single thermoelement materials used in thermocouples for temperature measurement is designated as E 207 and is entitled "Standard Method of Thermal Emf Test of Single Thermoelement Materials by Comparison with a Secondary Standard of Similar Emf-Temperature Properties." The method covers the determination of the thermoelectromotive force of single thermoelement materials (thermoelements), against standard platinum, the cold junction being at the ice point, by comparison to the thermoelectromotive force of a working standard thermoelement of similar emf-temperature properties independently standardized with respect to the same standard platinum.

Summary of Method—The test thermoelements are welded to the working standard to form the test thermocouple. The method involves measuring the small electromotive force developed between the test thermoelement and the secondary working standard having emf-temperature properties similar to the thermoelement being evaluated. The thermoelectromotive force of the test thermoelement then is determined by algebraically adding this measured small emf to the known emf of the secondary working standard referenced to the standard platinum. The testing circuit is shown schematically in Fig. 40. Since the thermal emfs (against any reference material) of the test and standard thermoelements are similar, it is unnecessary to accurately control or measure the junction temperatures because the difference in emf changes insignificantly even for large changes in temperature at the junctions. Actually, the need for the accurate control

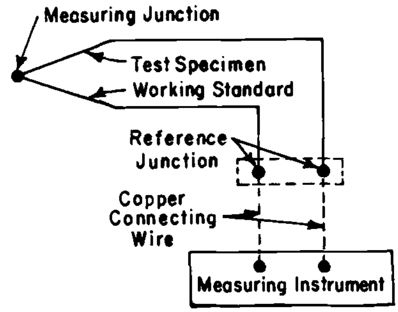

FIG. 40—*Circuit diagram for thermal emf test.*

of the measuring and reference junction temperatures is not eliminated, but merely is shifted to an accurate laboratory method which calibrates the secondary standard against the standard platinum [*71*].

8.5.1 Test Specimen

The test specimen is a length of wire, rod, ribbon, or strip of the coil or spool of the thermoelement material to be evaluated. The length is adequate to prevent the transfer of heat from the measuring junction to the reference junction during the period of test. A length of 2 to 4 ft, depending on the length of the testing medium and the transverse size of the thermoelement, is generally satisfactory. The transverse size of the specimen is limited only by the size of the test medium, the relative convenience of handling the specimens and working standard, and the maintenance of an isothermal test temperature junction.

8.5.2 Working Standard

The working standard is a thermoelement of emf-temperature properties similar to that of the test specimen, and which previously has been standardized thermoelectrically with respect to National Bureau of Standards Platinum No. 67. If a large amount of testing is anticipated, a coil or spool of working standard material is reserved. This working standard lot is selected on the basis of uniformity, and a minimum of three samples taken from the center and the ends of the lot is calibrated against the standard platinum. The working standard and the test specimen may differ in diameter, but it is convenient for their lengths to be about equal.

8.5.3 Reference Junction

The reference junction temperature of the test specimen and of the working standard is controlled during the period of test by maintaining it at the ice point (0°C). The ice-water junction is used because it is recognized as a convenient means for maintaining a constant temperature reference. The description and maintenance of the ice point are given in Chapter 7. A reference temperature other than the ice point may be used. However, the working standard should be calibrated against standard platinum using the alternate reference temperature, or the calibration data adjusted to correspond to the alternate reference temperature.

8.5.4 Measuring Junction

The measuring junction consists of a welded union of the test specimen and working standard. The weldment may be prepared by any method providing a good electrical connection which can be immersed fully in the uniform temperature region of the testing medium. Any number of test specimens and working standards may be welded together provided the resulting assembly does not introduce heat losses which prevent maintaining a uniform temperature region. If separation of the working standard and test specimen cannot be maintained during the test (except where they must make contact at the measuring junction), it is necessary that they be insulated from each other.

8.5.5 Test Temperature Medium

For temperatures up to 550°F (288°C), appropriate liquid baths may be used. For temperatures above 300°F (149°C), electrically heated tube or muffle type furnaces are recommended for comparison testing of base metal or noble metal thermoelement materials of similar emf-temperature properties. For convenience, a separate furnace may be controlled and available for each test temperature. This eliminates lost time in changing furnace temperatures when a large volume of testing is to be done. The length of each furnace is at least 15 in. so as to provide a minimum depth of immersion of 7 in. for the test thermocouple assembly. A constant immersion depth is maintained, whether single or multiple furnaces are used. The inside diameter of the furnace tube is approximately 1 to 3 in., the specific diameter depending upon the size and the number of the specimens to be included in the test thermocouple assembly. The furnace provides a uniform temperature zone extending at least 3 in. back from the measuring junction, or further if required to contain any inhomogeneity in the test thermocouple assembly. The temperature of each furnace is controlled manually or automatically to within ± 20°F (± 11°C) of the desired value which is ample for comparison testing of thermoelements having compositions similar to the secondary working standard.

8.5.6 Emf Indicator

The emf generated by the thermocouple, consisting of the test specimen and the working standard, is measured with instrumentation sensitive to ± 0.001 mV with an accuracy over a 2 mV range of ± 1 percent of the reading plus 0.003 mV. Any millivoltmeter, with circuitry errors taken into account, or potentiometer with a galvanometer or null indicator, providing measurements within these tolerances is acceptable. An indicator with a bidirectional scale (zero center) is convenient, but a unidirectional instrument may be used if a polarity switch is provided in the copper connecting circuit, or if the copper extensions to the instrument are exchanged whenever the polarity between the working standard and test specimen is reversed.

8.5.7 Procedure

For a furnace medium the test thermocouple assembly is inserted into the furnace so that the measuring junction extends at least 3 in. into the uniform temperature zone taking care there is no contact between the wires and the furnace wall. The free ends of the working standard and the test specimens are bent as required so they may be inserted into the mercury-containing glass tubes of the reference junction. If a horizontal furnace is used, the joined thermocouple assembly may be bent midway or towards the free ends in the form of an inverted "L." Care is exercised to minimize distorting the wires prior to testing because of the effect of cold work on emf output. After bringing the test temperature to the specified value, sufficient time is provided for the test assembly to reach steady state conditions before recording the emf generated between the test specimen and the working standard.

In a similar manner the emf generated between all other test specimens in the assembly is measured with respect to the working standard. Then the test temperature is raised to the next higher specified value, or the test assembly is advanced to the next furnace or bath having the next higher specified temperature if multiple furnaces or baths are used. A second set of readings is taken at the new temperature, and the procedure is repeated with readings taken at all specified temperatures. In all cases the readings are taken in sequence from the lowest to the highest temperature to minimize test variations between producer and consumer if any of the alloys are affected by differences in short time heating cycles. A working standard is used for one series of temperature changes only. However, if a portion considerably exceeding the region previously exposed to the uniform heating zone is discarded, the remainder of a base metal standard may be used for another test assembly. For noble metals and their alloys, the amount of reuse depends on the known stability of the material involved.

The polarity of the test thermoelement with respect to the working standard is determined as follows:

(1) If the test specimen is connected to the positive (+) terminal of an unidirectional potentiometer and balance can be achieved, the specimen is positive to the working standard.

(2) If the connections must be reversed to achieve balance, that is, the working standard must be connected to the positive terminal, the specimen is negative to the working standard.

(3) If an indicating potentiometer with a bidirectional scale is used, the specimen to the positive (+) terminal and the working standard to the negative (−) terminal are connected. The polarity of the specimen with respect to the working standard then will be indicated by the direction of balance of the instrument scale.

The emf of the test specimen with respect to Pt-67 is then reported for each test temperature after algebraically adding the measured emf between the test specimen and the standard, and the known emf between the standard and Pt-67.

Chapter 9—Installation Effects

9.1 Temperature Measurement in Fluids

Fluids are divided readily into two types, compressible and incompressible, or more simply into gases and liquids. However, many concepts involved in the measurement of temperatures in fluids are common to both types, and these are discussed first.

9.1.1 Response

No instrument responds instantly to a change in its environment. Thus in a region where temperature is changing, a thermocouple will not be at the temperature of its environment and, hence, cannot indicate the true temperature. The simplified temperature changes considered here are the step change and the ramp change. In the step change, the temperature of the environment shifts instantaneously from T_1 to T_2. In the ramp change, the environment temperature shifts linearly with time from T_1 to T_2.

It is common practice to characterize the response of a temperature sensor by a first order thermal time constant τ which is defined as:

$$\tau = \frac{w\mathbf{V}c}{hA} \tag{41}$$

where w is specific weight, $\mathbf{V}$ is volume, and c is specific heat, all of the sensor; while h is the heat transfer coefficient, and A is the area of the fluid film surrounding the sensor.

A solution of the first order, first degree, linear, differential equation [*78,79*] resulting from a heat balance between the fluid film surrounding the sensor and the sensor itself is

$$T = Ce^{-t/\tau} + \frac{1}{\tau} e^{-t/\tau} \int_0^t T_e e^{t/\tau} dt \tag{42}$$

where T is the sensor temperature, and T_e is the environment temperature, both at time t, and C is a constant of integration.

For a ramp change in temperature (as is found in a furnace being heated at a uniform rate) Eq 42 reduces to

$$(T_e - T) = R\tau \tag{43}$$

Equation 43 states that if an element is immersed for a long time in an environment whose temperature is rising at a constant rate $R = dT_e/dt$, then τ is the interval between the time when the environment reaches a given temperature and the time when the element indicates this temperature.

For a step change in temperature (as when a thermocouple is plunged into a constant temperature bath), Eq 42 reduces to

$$(T_e - T) = (T_e - T_1)e^{-t/\tau} \tag{44}$$

Equation 44 states that if an element is plunged into a constant-temperature environment, τ is the time required for the temperature difference between the environment and the element to be reduced to $1/e$ of the initial difference. Note that for practical purposes the sensor will reach the new temperature after approximately 5 time constants. See Fig. 41 for a graphical presentation of these equations.

Below a Mach number of 0.4, the time constant hardly is affected by the fluid velocity. The size of the temperature change affects τ because physical properties are not necessarily linear functions of temperature. Wormser [*80*] considers these effects in greater detail. Scadron and Warshawsky [*81*] present convenient nomographs for determining the time constant in the presence of heat transfer. Fluid turbulence tends to reduce the time constant by increasing the film coefficient.

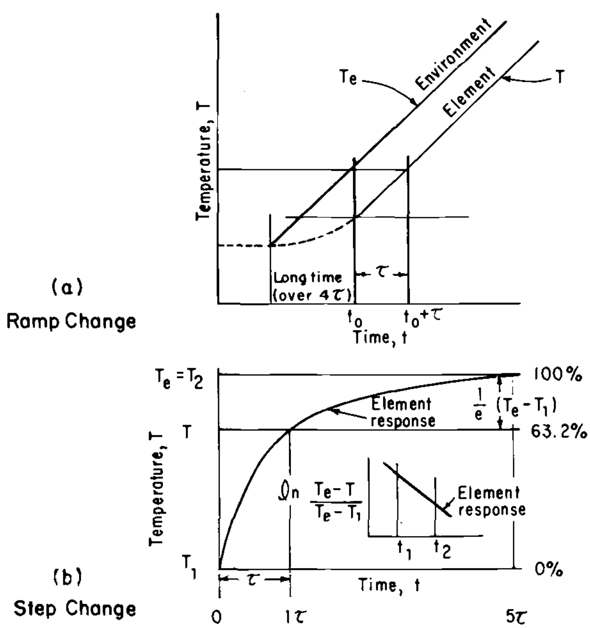

FIG. 41—*Graphical presentation of ramp and step changes.*

If the sensor is contained in a thermowell the response time is increased because of the extra mass and the additional heat transfer coefficient involved. It may be necessary to consider the response as a second order function in which case a dead time is observed before the sensor responds to a step temperature change. However, Coon and Looney [*82,83*] state that the time constant usually is represented adequately by the first order time constant τ.

To achieve the best time constant, the measuring junction should be in intimate contact with the well tip. Spring loading is sometimes used to accomplish this.

The response time usually is measured in liquids by plunging the thermocouple assembly into a well-stirred bath held at constant temperature. If the response time is of the same order as the immersion time, the velocity of immersion or depth of immersion or both become important parameters in the measurement. Reference *84* indicates a method for standardizing the liquid baths used in this determination.

For the response time in gases, the literature should be consulted [*85,86*]. Manufacturers sometimes can supply this information for simple conditions.

Multijunctions [*87*] and electrical networks [*88*] have been used successfully to improve the response of a thermocouple.

9.1.2 Recovery

Whenever a gas moves with an appreciable velocity, in addition to the thermal energy in the form of random translational kinetic energy of the molecules, some of its thermal energy is in the form of directed kinetic energy of fluid flow. The static temperature is a measure of the random kinetic energy, while the dynamic temperature is a measure of the directed kinetic energy. The total temperature is a concept (not a measurement) which sums the static and the dynamic temperatures. Such a total temperature would be sensed by an adiabatic probe which completely stagnates an ideal gas. Thus

$$T_{\mathrm{adi,ideal}} = T_t = T + \frac{V^2}{2Jgc_p} = T + T_V \tag{45}$$

where:

T_t = total temperature,
T = static temperature,
T_V = dynamic temperature,
V = directed fluid velocity,
J = mechanical equivalent of heat,
g = acceleration of gravity, and
c_p = specific heat at constant pressure.

In real fluids, an adiabatic recovery factor (α) generally is defined such that

$$T_{\mathrm{adi}} = T + \alpha T_V \tag{46}$$

where α may be more or less than one depending on the relative importance of thermal conductance and thermal capacitance in the boundary layers surrounding the sensor. Since the Prandtl number is the ratio of these two effects, it is common to express recoveries in terms of the Prandtl number. See Refs *89*, *90*, *91*, and *92* for more information on the recovery factor.

A real sensor immersed in a real fluid tends to radiate to its surroundings. Also there is a tendency for a conductive heat transfer along the probe stem. These two effects are balanced by a convective heat transfer between the probe and the fluid. In addition, real probes do not always stagnate a moving fluid effectively. To account for these realities in temperature measurement in moving fluids, a dynamic correction factor (K) is defined as

$$T_{\mathrm{probe}} = T + KT_V \tag{47}$$

where K corrects for impact, viscosity, and conductivity effects in the fluid, and radiation and conduction effects in the probe. K may take on any value depending on the relative importance of these effects. Variations of K between ± 35 cannot be ruled out. Therefore, the factor KT_V can far outweigh all other factors such as calibration deviations.

9.1.3 Thermowells

Protection tubes or thermowells or both often are used to separate the measuring junction of a thermocouple from the fluid whose temperature is of interest. Such devices are used to avoid contamination of the thermoelements, to provide safety in case of high pressure installations, to provide strength in the case of significant fluid bending forces in the thermocouple, etc. Thermocouples installed in wells can be withdrawn for inspection, calibration, and replacement. A thermocouple in a well responds more slowly to changes in fluid temperature. Typical wells and their strength requirements are defined in Ref *93*.

The depth of immersion in the fluid is an important consideration. One method of checking for adequacy of immersion is to increase the depth of immersion of the thermocouple well assembly in a constant temperature bath until the thermocouple output becomes constant. A minimum immersion depth of ten times the well outside diameter is a rule of thumb often used.

9.1.4 Thermal Analysis of an Installation

A thermocouple installation may give an indication which differs from the fluid temperature which is to be measured because:

1. The boundary walls are at a temperature different from that of the fluid.

2. There may be a temperature gradient along the well.
3. The fluid may be flowing with an appreciable velocity.
4. The thermocouple may be improperly calibrated.

Item 4 has been covered in Chapter 8 and will not be considered further here.

Basically, the thermocouple temperature is the result of a heat balance between the various modes of heat transfer.

$$q_c = q_r + q_k \tag{48}$$

where q indicates rate of heat transfer and the subscripts c, r, and k signify respectively convection, radiation, and conduction. An equation has been developed to describe this heat balance mathematically [*94*] as

$$\frac{d^2T}{dx^2} + a_1(x)\frac{dT_x}{dx} - a_2(x, y)T_x = -a_2a_3(x, y) \tag{49}$$

where $a_1(x) = dA_k/A_kdx$ which indicates the effect of a change in cross-sectional area of the well; $a_2(x, y) = dA_c(h_r + h_c)/kA_kdx$ which indicates the effect of radiation coefficient (h_r), convection coefficient (h_c), conductivity (k), surface area for convection (A_c) and cross-sectional area for conduction (A_k); $a_3(x, y) = (h_cT_{\text{adi}} + h_rT_w)/(h_c + h_r)$ which relates the heat transfer coefficients to the adiabatic fluid temperature (T_{adi}) and the surrounding wall temperature (T_w).

Various solutions are possible for Eq 49 depending on the assumptions one is willing to make. Three simplified solutions are:

1. *Overall Linearization*—When the radiation coefficient is based on an average well temperature, the result is

$$\frac{T_x - a_3}{T_w - a_3} = \frac{e^{mx}}{1 + e^{2mL}} + \frac{e^{-mx}}{1 + e^{-2mL}} \tag{50}$$

where

$$m = \left(\frac{4D(h_r + h_c)}{k(D^2 - d^2)}\right)^{1/2}.$$

Typical values for h_r, h_c, and k are given in Ref *94*. This approach leads to quick, approximate answers whenever the fluid can be considered transparent to radiation.

2. *Tip Solution*—When conduction effects are neglected along the well or protection tube, Eq 49 reduces to

$$T_{\text{tip}} = a_3 \tag{51}$$

which can be solved at once since h_r and h_c are available in the literature (see Ref *94*). This approximation normally would give tip temperatures which are too high since conduction tends to reduce T_{tip}.

3. *Stepwise Linearization*—This is the usual solution to Eq 49. Detailed equations are beyond the scope of this manual, but briefly one divides the well, lengthwise, into a number of elements. The temperature at the center of each element is taken to represent the temperature of that entire element. The heat balance equation is applied successively to one element after another until a match between tip and base temperatures is achieved. Each installation is different. Each must be evaluated carefully to determine if the installation is capable of yielding temperatures within the allowable uncertainties.

9.2 Surface Temperature Measurement

9.2.1 General Remarks

There is no easy method of attaching a thermocouple to a surface so that it can be guaranteed to indicate the true surface temperature. To do this, it would be necessary to mount the measuring junction so that it could attain but not affect the surface temperature. In most cases, the presence of the thermocouple (or any alternative transducer) will cause a perturbation of the temperature distribution at the point of attachment, and thus it only will indicate the perturbed temperature.

9.2.1.1 Measurement Error—In many cases, a significant difference will exist between the indicated temperature and the "true" surface temperature, that is, the temperature that the surface would reach if no thermocouple were present. This difference is normally termed a "measurement error," but it should not be confused with calibration or extension wire errors which are common to all thermocouple measurements. The relationship between the indicated and true surface temperature is often defined by the equation:

$$Z = \frac{T_s - T_i}{T_s - T_a}$$

where:

Z = installation factor,
T_s = true surface temperature,
T_i = indicated surface temperature, and
T_a = temperature of the surroundings or coolant.

This equation expresses the measurement error $T_s - T_i$ as a fraction of the difference between the surface and ambient temperatures.

The value of Z for a particular installation may be calculated or found by experiment; however, as several simplifying assumptions normally are made in any theoretical derivation, experimental verification is necessary if an accurate value of Z is required.

9.2.1.2 Installation Types—There are two basic types of surface thermocouple installation: the permanent, which is used to give a continuous history of the surface temperature, and the temporary, normally made with a sensing probe in mechanical contact with the surface to obtain spot readings. The basic principles for accurate measurement are similar for both types, but the probe type of sensors are more susceptible to measurement errors and generally have a lower accuracy.

9.2.2 Installation Methods

The method of attaching the thermocouple to the surface is governed by considerations of the metallurgical and thermal properties of the materials, their relative sizes, and the modes of heat transfer at the surface. Common methods are shown in Fig. 42.

9.2.2.1 Permanent Installations—For thin materials, the thermocouple junction is attached either directly to the surface (Fig. 42*a*) or is mounted in a heat collecting pad (Fig. 42*b*). It may be welded, brazed, cemented, or clamped to the surface. Good mechanical support of the leads is necessary so that no stresses are applied to the junction.

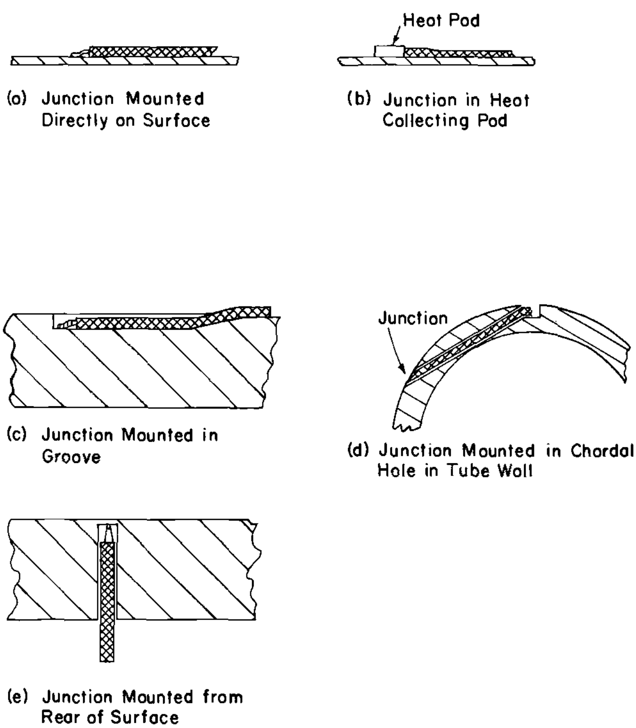

FIG. 42—*Common attachment methods.*

For thicker materials, the thermocouple junction may be peened into the surface or installed in a groove (Fig. 42*c*). The groove may be filled so that the surface is restored to its original profile. A thermocouple in a groove normally will have its junction below the surface and will indicate the subsurface temperature. A similar technique used with tubes is shown in Fig. 42*d*.

The configuration shown in Fig. 42*e* may be used where rapid response is required, as the junction can be made very thin by electroplating or mechanical polishing techniques [*95–99*].

Several installation methods are illustrated in the literature cited, particularly in Refs *100* and *101*.

Metal sheathed thermocouples are suited particularly to surface measurements, especially for severe environments. They combine good strength and small size, and the measuring junction may be reduced in diameter or flattened to achieve good response with small errors.

9.2.2.2 Measuring Junctions—The measuring junction may be formed in several ways, each having its own advantages and disadvantages.

The bead junction commonly is used. The temperature indicated is a function of the temperatures where the wires leave the bead [*102,103*] so that the bead should be small, and the wires should leave the bead as close to the surface as possible. This may be accomplished by using a flattened bead. Good thermal contact between the bead and the surface is essential, especially if there are temperature gradients. If the surface is a material of poor thermal conductivity, it may be advantageous to mount the measuring junction in a heat collecting pad, or button, which has a good conductivity [*104*].

The simplest junction is shown in Fig. 43, in which a single wire is brought to the surface which acts as the second thermoelement. The circuit is completed with a wire of the same material as the surface. This technique usually involves calibration of the wire/surface-material thermocouple. This

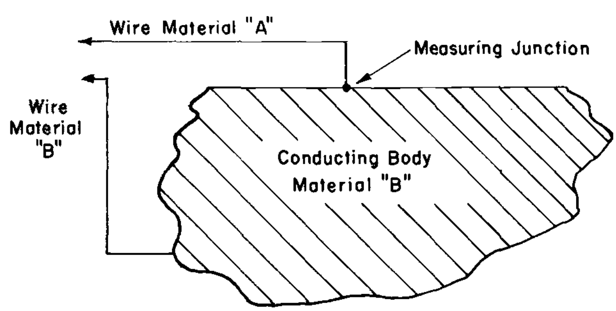

FIG. 43—"*Single wire*" *thermocouple.*

calibration may not be very reproducible since the surface material is probably not an alloy with controlled thermoelectric properties. It, however, does provide a junction exactly at the surface, and the perturbation errors (see Section 9.2.3) can be reduced to a very low value [*95,105,106*].

A common variation is the separated junction in which each wire is joined separately to the surface (which must be an electrical conductor). This type, which is really two series junctions, has the advantage that the two junctions form a part of the surface. The output of such a thermocouple is a weighted mean of the two individual junction temperatures, of the form

$$e_0 = e_m + (b_1 - b_2)\frac{(T_1 - T_2)}{2}$$

where:

T_1 and T_2 = junction temperatures,

e_0 = measured output,

e_m = output which would be measured if both junctions were at the mean temperature $(T_1 + T_2)/2$, and

b_1 and b_2 = Seebeck coefficients of the two thermocouple wires versus the surface material.

Moffat [*34*] gives a graphical method of analysis.

Thus, the output will be greater or less than the mean depending upon which wire is at the higher temperature. The output generally cannot be calculated, as neither T_1, T_2, nor the relationship between each wire and the surface will be known. There will be, therefore, an uncertainty in the measured temperature if temperature gradients exist. This error is minimized if the wires are bonded to the surface as close together as possible, to reduce $(T_1 - T_2)$. This type of junction has been shown to be more accurate than a bead junction [*107,108*].

9.2.2.3 Probes—It is often desirable to know the temperature distribution over a surface or to make a spot check at one particular point. These measurements are made with a probe containing a thermocouple junction which is held in mechanical contact with the surface. The configuration of the junction is based on the intended application, and several types are commercially available. The probes are in most cases held normal to the surface, and for ease in use should be spring-loaded, which also reduces the error.

Probes are subject to the same errors as permanent installations, but the designer has no control over the conditions of use, and so the errors associated with this type of measurement may be significant. Since the probe provides a heat conducting path from the surface, thermal resistance due to oxide or dirt causes an additional error.

Correction factors [*109*] for several types of junctions range from 0.013 to 0.168, but in general must be determined for specific conditions.

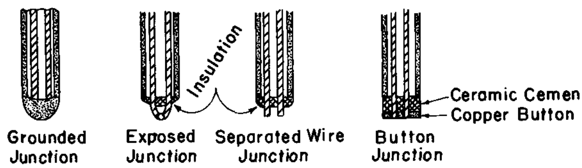

FIG. 44—*Types of junction using metal sheathed thermocouples.*

The size of the junction should be as small as possible. Several types of junction are illustrated in Fig. 44. The junction types in order of decreasing measurement error are: grounded, exposed, button, and separated.

In order to reduce measurement errors, probes with an auxiliary heater have been used [*110,111*]. The probe thermocouple is heated to the surface temperature so that no temperature gradients are set up when the probe is applied to the surface. One form of probe uses two thermocouples (Fig. 45). Equality of the auxiliary and surface junction temperatures indicates that no heat is being transferred along the probe and that the surface junction is at the surface temperature. With this type of probe, the two junctions must be very close, and the response to a change in heater power must be fast or an error can occur in transient measurements. A probe which is controlled automatically has been described recently [*112,113*]. It is claimed to have an accuracy of 3/8 percent and can be used to 1000°F (538°C) on a variety of materials, with a measurement time of less than one second. Sasaki and Kamanda [*114*] used a different approach and eliminated the auxiliary junction. The surface junction was arranged to contact the surface at two second intervals only. The heater input was modulated over a twenty second period and adjusted so that the maxima and minima were above

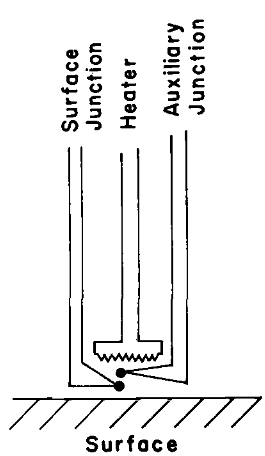

FIG. 45—*Thermocouple probe with auxiliary heater, diagramatic arrangement.*

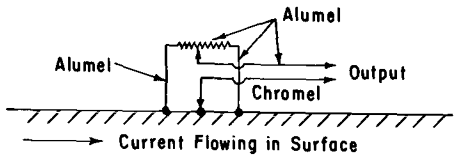

FIG. 46—*Three wire thermocouple to compensate for voltage drop induced by surface current.*

and below the surface temperature. At contact the surface junction temperature changed due to heat exchange unless the two temperatures were equal. With this method the surface temperature of glass bulbs was determined with an accuracy of 0.5°F.

9.2.2.4 Moving Surfaces—Surface temperatures of moving bodies are measured by several methods. A junction mounted in a probe may be held against the body [*115*], but this method results in errors caused by friction. In metal cutting investigations, the metal body and the cutting tool are used as the thermocouple materials. The output of this type of junction has been investigated extensively and has been analyzed by Shu et al [*116*]. Slip-rings to rotating members, intermittent and sliding contacts have been used also. A general review of such installations is given in Ref *101*.

9.2.2.5 Current Carrying Surfaces—A technique of eliminating errors caused by voltage drop in surfaces heated by the passage of d-c current has been described by Dutton and Lee [*117*]. A three-wire thermocouple forming two junctions is used (Fig. 46), and the emf's due to the voltage drop in the surface are balanced out during successive reversals of current. When the balance is correct, the thermocouple output is constant regardless of the direction of the heating current.

This technique is also useful for surfaces carrying large alternating currents. In other cases, filters will suffice to attenuate the a-c component. Self-balancing potentiometers usually are affected adversely if the a-c pickup level is high. D-c indicating instruments and portable potentiometers are normally insensitive to a-c and present no problem unless the current is high enough to damage the coils. If the thermocouple junction is not isolated from the surface, voltages appearing between the surface and the instrument ground (common-mode voltages) cause an error with some instruments.

9.2.3 Sources of Error

When a thermocouple is attached to a surface, its presence alters the heat transfer characteristics of the surface and normally will change the temperature distribution. This causes an error which will be referred to as perturbation error.

9.2.3.1—The causes of perturbation error can be broken down into the following:

The heat transfer characteristics of the surface are changed by the installation, that is, the surface emissivity or effective thermal conductivity will be altered or the wires may act as fins providing additional heat transfer paths.

Thermal contact resistance between the junction and the surface will cause a temperature gradient which will prevent the measuring junction from attaining the correct temperature if heat is being exchanged between the surface and its surroundings.

If temperature gradients exist, there will be an error due to uncertainty in the exact position of the junction or junctions relative to the surface [*102,103*].

The response time of the thermocouple installation introduces errors during transient conditions [*118,119*] (see also Section 9.1.1). The response time will be that of the surface installation and not of the thermocouple alone.

Although not discussed in this chapter, the errors associated with any thermocouple measurement, such as deviations from standard emf and lead wire errors, must be taken also into consideration [*120,121*].

9.2.4 Error Determination

The perturbation error must be determined if the surface temperature must be known with a high degree of accuracy. The installation should be designed to minimize this error, but in many cases materials and size make compromises necessary, so that an ideal design cannot be achieved. The error, and hence the correction factor, can be determined by the following methods.

9.2.4.1 Steady State Conditions—The direct calculation of the error involves solving the heat flow equation for the measuring junction and surface geometry. Normally simplifying assumptions are made, and the results must be interpreted in relation to them. The calculations show clearly the major sources of error and indicate means of reducing errors to a minimum [*122,123,124,125,126*].

Analog methods of solving the heat transfer equations using resistance or resistance-capacitance networks indicate the overall temperature distribution and show the perturbation effect of the thermocouple clearly. They are however difficult to make flexible, and so a number of analog models are required if a range of heat transfer conditions is to be studied [*125,126,127,128*].

Relaxation methods of solving the heat transfer equations have been used to calculate the temperature distribution; this method is attractive if a computer is available to perform the considerable amount of arithmetic required.

Direct experimental measurement on the installation is often the only satisfactory way to accurately determine the error. Care must be taken to simulate the service conditions exactly as a change in a variable can significantly affect the error. The major problem is to determine the true surface temperature. This is discussed extensively in the literature [*96,128,129,130,131,132,133*].

9.2.4.2 Transient Conditions—If surface temperatures are changing, the response of the thermocouple attachment may cause a significant error. The response time of the thermocouple alone will have little significance for surface measurements if the heat transfer path between the surface and the measuring junction is poor or adds thermal mass.

The time required to change the measuring junction temperature causes the thermocouple output to lag the surface temperature in time and decreases its amplitude [*108,118,119*]. The time constant may be determined experimentally from the response to step or ramp functions of surface temperature change.

A. *Insulated Thermocouple Normal to an Electrically Heated Surface*—For surfaces with changing temperatures a bead thermocouple attached normal to an electrically heated surface and insulated from the ambient has been analyzed by Quant and Fink [*134*] and Green and Hunt [*135*].

The analysis showed that in order to obtain a rapid response with a small, steady-state error, it is necessary to use a small junction bead with good surface contact, small diameter wires, and good insulation between the wires and the surroundings.

B. *Surface Heated by Radiation*—Thermocouples mounted on a surface subject to radiant heating at temperature-rise rates up to 30°F per s were investigated by White [*107*]. His results showed that a separated-junction thermocouple produced the least error.

The thermocouple errors increased with increasing plate thickness and with increasing rates of temperature rise. Furthermore, the amount of bare thermocouple wire between the junction and the insulation should be a minimum.

Kovacs and Mesler [*136*] investigated the response of very fast surface thermocouples subject to radiant heating as a function of size and type of junction. Junctions were formed by electroplating or mechanical abrasion. Very thin junctions were subject to an overshoot error for high rates of temperature rise, as heat could not be transmitted back through the thermocouple to subsurface layers fast enough. On the other hand, too thick a junction corresponded to a junction beneath the surface. The junction thickness should be of the same order of magnitude as the distance between the two thermocouple wires to avoid overshooting.

C. *Surface Subject to Aerodynamic Heating*—An analysis and design of a thermocouple installation which can be mounted in a thin-metal skin subjected to aerodynamic heating is given in Ref *137*. A finite difference calculation of the distorted temperature field indicated that errors due to insulation resistance at high temperatures were of the same order of magnitude as those due to the uncertainty of the exact junction location.

9.2.5 Procedures for Minimizing Error

The examples quoted in the preceding section have been treated separately. It is generally impossible to extrapolate from one set of conditions to another unless the installation is identical. The analyses show procedures that should be followed to reduce measurement errors. These are:

A. Use the smallest possible installation to avoid perturbation errors.

B. Bring the thermocouple wires away from the junction along an isotherm for at least 20 wire-diameters to reduce conduction errors. The use of thermocouple materials with low thermal conductivity also will reduce this error.

C. Locate the measuring junction as close to the surface as possible rather than above or below it.

D. Design the installation so that it causes a minimum disturbance of any fluid flow or change in the emissivity of the surface, to avoid changes in convective or radiative heat transfer.

E. Design the installation so that the total response is fast enough to cause negligible lag for the transients expected in service.

F. Reduce the thermal resistance between the measuring junction and the surface to as low a value as possible. If the surface has a low thermal conductivity, a heat collecting pad may be used.

9.2.6 Commercial Surface Thermocouples

Many surface installations are custom engineered, but industry does offer several standard surface thermocouples intended for specific applications [*115,138*].

9.2.6.1 Surface Types—Figure 47 shows several types which are mounted on the surface. Type *a* is a gasket thermocouple which normally is mounted on a stud and Type *b* is a rivet head. The clamp attachment, Type *c*, is used on pipelines and will be reasonably accurate if the pipe is lagged thermally. The weldable pad attachment, Type *d*, is used on boiler or superheater tubes and uses a metal sheathed thermocouple with a grounded junction. The sheath and pad materials are chosen to be compatible with the boiler environment. An accuracy of ± 2 percent is claimed for these thermocouples (± 1 percent if a correction factor supplied by the manufacturer is used).

For installations where it is possible to mount the thermocouples in the surface, stud- or rivet-mounted plugs similar to Type *e* are offered by several manufacturers. Variations of this type have been used extensively for heat transfer measurements [*122,139*] and for applications requiring very rapid response such as the measurement of surface temperatures in gun barrels

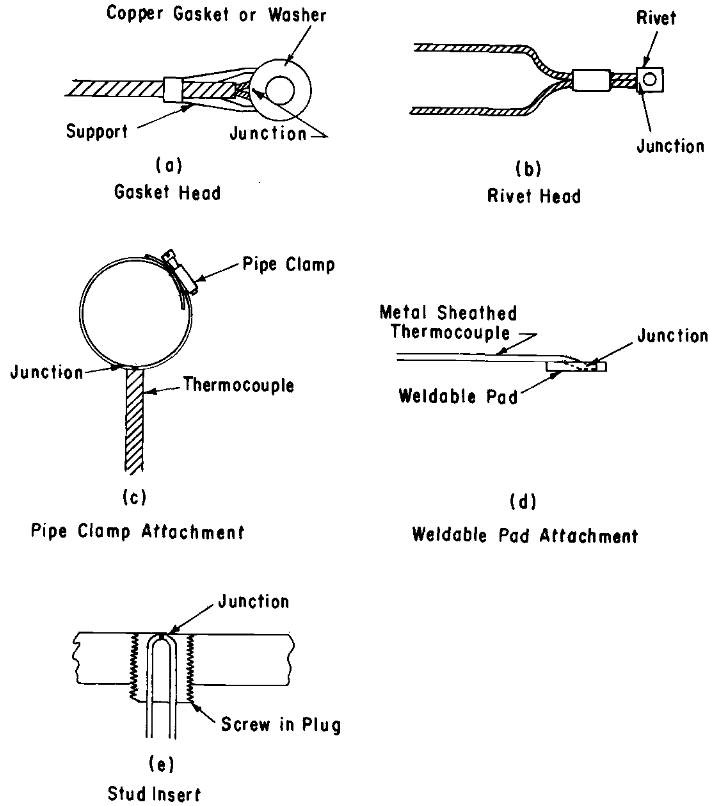

FIG. 47—*Commercially available types of surface thermocouples.*

and rocket exhaust chambers. The material of the plug must match the material of the surface, otherwise significant errors can be introduced [*140*], especially for materials with low thermal conductivity.

9.2.6.2 Probe Types—Probe type thermocouples for temporary or spot readings are offered usually as a complete package consisting of a thermocouple head which contains the measuring junction, a hand probe, and an indicating milliammeter calibrated in degrees. The measuring junctions are normally interchangeable so that one instrument can be used with a variety of heads. The type of head will depend on the surface characteristics. Common types are shown in Fig. 48.

The separated-junction probe is used on electrically conducting surfaces only. Dirt or oxide layers will introduce a thermal resistance error or even prevent the completion of the circuit. For greatest convenience, the two wires should be separately spring-loaded against the surface. The button type of junction must be held carefully as any deviation from the normal will cause a change in the height of the junction above the surface, and the

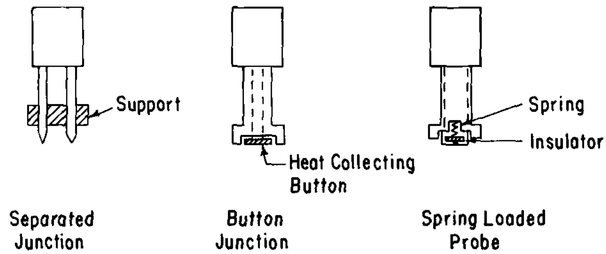

FIG. 48—*Commercial probe thermocouple junctions.*

readings will be inconsistent. The spring-loaded type of junction is available in several forms and has been adapted for measurements on moving surfaces [*115*].

The accuracy obtainable with these probes is not high. However, the errors can be reduced to 2 or 3 percent for good conducting surfaces in still air cooled by natural convection. If the surface is a poor thermal conductor or the rate of heat transfer is high, the error will be considerably higher than this.

For rotating or moving surfaces, probe instruments utilizing a junction spring-loaded against the surface are used. Heat generated by friction causes an error which can be significant. (Bowden and Ridler [*141*] have shown that the temperatures may reach the melting point of one of the metals.)

A heated thermocouple probe instrument for measuring the temperature of wires or filaments is described by Bensen and Horne [*142*], and a wire temperature meter [*143*] has been marketed recently.

Chapter 10—Reference Tables for Thermocouples

The practical use of thermocouples in industrial and laboratory applications requires that the thermocouple conform to an established temperature —electromotive-force relationship within acceptable limits of error. Since the thermocouple in a thermoelectric thermometer system is usually expendable, conformance to established temperature-emf relationships is necessary in order to permit interchangeability.

Section 10.2 consists of reference tables that give temperature-emf relationships for the thermocouple types most commonly used in industry. These are identified as thermocouple Types B, E, J, K, R, S, and T, as defined in ANSI Standard C96.1.

Data in these tables are based upon absolute electrical units and the International Practical Temperature Scale of 1968. All temperature emf data contained in Section 10.2 have been extracted from ASTM Standard E 230-72.

Reference tables giving temperature emf relationships for single leg thermoelements referenced to platinum (NBS Pt 67) are not included in this manual but are contained in ASTM Standard E 230-72.

10.1 Thermocouple Types and Limits of Error

10.1.1 Thermocouple Types

The letter symbols identifying each reference table are those defined in ANSI Standard C96.1. These symbols which are used in common throughout industry, identify the following thermocouple calibrations:

Type B—Platinum-30 percent rhodium (+) versus platinum 6 percent rhodium (−).
Type E—Nickel-10 percent chromium (+) versus constantan (−).
Type J—Iron (+) versus constantan (−).
Type K—Nickel-10 percent chromium (+) versus nickel-5 percent (aluminum, silicon) (−).[13]
Type R—Platinum-13 percent rhodium (+) versus platinum (−).
Type S—Platinum-10 percent rhodium (+) versus platinum (−).
Type T—Copper (+) versus constantan (−).

[13] Silicon, or aluminum and silicon, may be present in combination with other elements.

Detailed information covering the advantages and limitations of each of these thermocouple types, their recommended temperature ranges, and detailed physical properties of the thermoelements comprising them are contained in Section 3.1 of this manual.

10.1.2 Limits of Error

The limits of error for the common letter designated thermocouple types, as listed in Table 41, are taken from ANSI Standard C96.1. Most manufacturers supply thermocouples and thermocouple wire to these limits of error or better.

TABLE 41—*Limits of error for thermocouples.*

			Limits of Error			
	Temperature Range		Standard		Special	
Type	°F	°C	°F	°C (Note 2)	°F	°C (Note 2)
B	1600 to 3100	871 to 1705	±½ percent			
E	32 to 600	0 to 316	±3°F		±2¼°F	
	600 to 1600	316 to 871	±½ percent		±⅜ percent	
J	32 to 530	0 to 277	±4°F		±2°F	
	530 to 1400	277 to 760	±¾ percent		±⅜ percent	
K	32 to 530	0 to 277	±4°F		±2°F	
	530 to 2300	277 to 1260	±¾ percent		±⅜ percent	
R or S	32 to 1000	0 to 538	±2½°F			
	1000 to 2700	538 to 1482	±¼ percent			
T	−300 to −150	−184 to −101			±1 percent	
	−150 to −75	−101 to −59	±2 percent		±1 percent	
	−75 to 200	−59 to 93	±1½°F		±¾°F	
	200 to 700	93 to 371	±¾ percent		±⅜ percent	

NOTE 1—In this table the limits of error for each type of thermocouple apply only over the temperature range for which the wire size in question is recommended (see Table 2). These limits of error should be applied only to standard wire sizes. The same limits may not be obtainable in special sizes.

NOTE 2—Where limits of error are given in percent, the percentage applies to the temperature being measured when expressed in degrees Fahrenheit. To determine the limit of error in degrees Celsius, multiply the limit of error in degrees Fahrenheit by 5/9.

NOTE 3—Limits of error apply to thermocouples as supplied by the manufacturer. The calibration of a thermocouple may change during use. The magnitude of the change depends upon such factors as temperature, the length of time, and the conditions under which it was used.

NOTE 4—Type T wire cannot be expected to meet the limits of error at temperatures below the ice point unless so specified at time of purchase. Selection is usually required.

10.2 Thermocouples Reference Tables

Following is a list of the reference tables included in this section:

Table Number	Thermocouple Type	Temperature Range
42	B	0 to +3308°F
43	B	0 to +1820°C
44	E	−454 to +1832°F
45	E	−270 to +1000°C
46	J	−350 to +2192°F
47	J	−210 to +1200°C
48	K	−454 to +2500°F
49	K	−270 to +1372°C
50	R	−58 to +3214°F
51	R	−50 to +1768°C
52	S	−58 to +3214°F
53	S	−50 to +1768°C
54	T	−454 to +752°F
55	T	−270 to +400°C

10.3 Generation of Smooth Temperature-Emf Relationships

10.3.1 Need for Smooth Temperature-Emf Relationship

A table of reference values for use with thermocouples should be capable of easy and unique generation to facilitate its use in computer and similar applications. Furthermore, the reference values should agree closely with the characteristics of the thermocouple type under study, so that differences will change only slowly and smoothly with temperature level.

Reference Tables 42 to 55 (Section 10.2) give values to three decimal places only, and this roundoff in table values results in inherent discontinuities in the temperature-emf relationship as represented by the tables.

This section provides means for generating smooth, continuous temperature-emf relationships, to as many decimal places as have any useful significance, for the thermocouple types included in this standard. These data will be useful in all applications where discontinuities in the established reference values are objectionable, or where storage of complete tables is impractical.

10.3.2 Methods of Generation

The values of each of the seven thermocouple types given in Tables 42 to 55 are generated by power series equations according to Ref *144*. The coefficients of these equations for the appropriate ranges are given in Tables 56 to 62. Note that these coefficients yield values of emf in microvolts.

TABLE 46—*Type J thermocouples.*

NOTE—The maximum recommended temperature limit for Type J thermocouples is 1400 F (760 C) as specified in Table 2. Extension of the Type J tables beyond 1400 F gives temperature-electromotive force data to 2192 F (1200 C). This extension is a mathematical extrapolation based on limited calibration data and caution should be exercised in its use. The basis for the extended curve is discussed in *NBS Monograph 125*.

TABLE 47—*Type J thermocouples.*

NOTE—The maximum recommended temperature limit for Type J thermocouples is 1400 F (760 C) as specified in Table 2. Extension of the Type J tables beyond 1400 F gives temperature - electromotive force data to 2192 F (1200 C). This extension is a mathematical extrapolation based on limited calibration data and caution should be exercised in its use. The basis for the extended curve is discussed in *NBS Monograph 125*.

This method permits easy generation of the temperature-emf values by a digital computer. It provides a smooth, continuous relationship, and the values will round off to the established temperature-emf values given in Tables 42 to 55 [*145*].

Alternative generation schemes for temperature-emf relationships are described in Refs *146* and *147*.

Chapter 11—Cryogenics

11.1 General Remarks

Although there is some variation in the defined temperature range involved, cryogenics (krī-ō-jen-iks) usually indicates concern with temperatures in the liquid oxygen range (about 90°K or −183°C) or lower. This temperature range will be discussed primarily in this chapter. Since a triple point (of water) or ice bath reference junction often is used, additional comments and values will be given for the entire subzero (0°C) range.

Most aspects of cryogenic thermometry are similar to those applicable at room or high temperatures. In particular, the measurement systems and thermoelectric theory are nearly identical. However, there are significant differences with respect to some materials, techniques or assembly and fabrication, calibration schemes, and methods of practical usage. Fortunately the added difficulties with some details are offset by the removal of a few problems peculiar to high-temperature thermometry: chemical transformations are insignificant; oxidation, reduction, and impurity migration do not occur because of the low temperatures. Annealing of physical imperfections is also absent for the same reasons. Maintenance of fixed points and techniques of calibration are usually considerably easier and sometimes much more accurate. Thermal radiation is usually not important, at least if simple precautions are taken to account for it.

Several books have been written on thermometry and on the experimental techniques necessary for cryogenic research by Scott [*148*] on cryogenic engineering, and by White [*149*] and by Rose-Innes [*150*] on smaller, scientific systems.

11.2 Materials

Many thermocouple materials developed for high-temperature usage have too low a sensitivity at low temperatures to be practical; others have a reasonable sensitivity, but are very erratic with large inhomogeneities and lot-to-lot variations. Only three of the letter-designated type thermocouples have proven themselves for cryogenic use: Types E, T, and K. Type E is definitely recommended as the most valuable for general low temperature use. It is better because of its higher sensitivity (coupled with only average inhomogeneity voltages) and lower thermal conductivity of both thermocouple materials. The latter property is particularly important for obtaining good thermal tempering of measuring junctions. Tables for the total voltage and Seebeck coefficient are given in Section 11.3 for each of the thermocouples just mentioned. These tables were taken from Ref *151*.

There are other, but uncommon, materials that have a higher sensitivity at very low temperatures, below 50°K: *gold*-cobalt and *gold*-iron. Both are negative thermoelectric materials and should be matched with KP or EP "normal" silver, or less preferably, TP, to obtain a thermocouple pair. The older material, *gold*-cobalt (2.1 atomic percent cobalt) has been found to have significant instabilities caused by room temperature annealing of the metastable solution of cobalt in gold. Because of those problems *gold*-cobalt should not be used any more in the future. The alloy *gold*-0.07 atomic percent iron has replaced *gold*-cobalt: it does not have alloying instabilities, it is more homogeneous, and it has a larger Seebeck coefficient.

A table giving the total voltage and Seebeck coefficient of KP or EP versus *gold*-0.07 atomic percent iron is given also in Section 11.3. This table is taken from data published by the National Bureau of Standards [*152*]. Reference tables for several other material combinations that are used as thermocouples in the cryogenic range are also given in this reference.

Figure 49 compares various Seebeck coefficients for materials used in the cryogenic range. Type K is not shown, but would be slightly above Type T.

Chapter 12—Bibliography

12.1 Introduction

The material contained herein was collected from two general sources: (1) scientific, technical, and trade journals and (2) reports of investigations sponsored or conducted by various governmental agencies. The material is an addition to the references and bibliographies appended to the other sections of the manual, the National Bureau of Standards' papers edited by Swindells, and the National Bureau of Standards' bibliography edited by Freeze and Parker, both of which are listed herein. The entries are generally for the period 1963 to 1967, with a few earlier and later items that were brought to our attention. Because of the rapid expansion of the technology, the list does not claim to be exhaustive. Not all of the items are necessarily of current interest, since a few years have made obsolete many that can now be considered only source material of historic interest.

While reasonable coverage was intended, it is inevitable that oversights and other unintentional omissions have occurred; however, references to the volumes of the series "Temperature, Its Measurement and Control in Science and Industry" except the latest Vol. IV have been deliberately omitted because the many references to the series throughout the manual are sufficient to assure reference to the series.

The method used to identify the periodicals follows that used in ASTM Data Series DS 23B, 1970 and DS 2313-S1, 1972, *Coden for Periodical Titles*. For the convenience of the reader who may not have access to these publications, the Coden used in this bibliography are identified in Section 12.3. Numbers prefixed by the letters AD refer to report numbers in the U. S. Government Technical Abstract Bulletin; those by N63, etc., are identifying numbers in the Scientific and Technical Aerospace Reports.

Chapter 13—Definitions

adjusting device (liquid-in-glass thermometer), *n.*—a device to adjust the liquid in the bulb and main capillary to that needed for the intended temperature interval.

bulb (liquid-in-glass thermometer), *n.*—the reservoir for the thermometer liquid.

bulb length (liquid-in-glass thermometer), *n.*—the distance from the bottom of the bulb to the point where the internal bulb diameter begins to decrease as the bulb merges into the stem.

calibrate, *v.*: 1. *general*—to determine the indication or output of a measuring device with respect to that of a standard.

2. *liquid-in-glass thermometer*—to determine the indication of the thermometer with respect to temperature established by a standard.

3. *thermocouple*—to determine the emf developed by a thermocouple with respect to temperature established by a standard.

calibration point, *n.*: 1. *general*—a specific value, established by a standard, at which the indication or output of a measuring device is determined.

2. *liquid-in-glass thermometer*—a temperature, established by a standard, at which the indication of the thermometer is determined.

3. *thermocouple*—a temperature, established by a standard, at which the emf developed by a thermocouple is determined.

Celsius, *n.*—the designation of the degree on the International Practical Temperature Scale. Also used for the name of the Scale, as "Celsius temperature scale." Formerly (prior to 1948) called "centigrade."

centigrade, *n.*—the designation of the degree on the International Temperature Scale prior to 1948. (See *Celsius.*)

coaxial thermocouple element, *n.*—a thermocouple element consisting of a thermoelement in wire form, within a thermoelement in tube form with the two thermoelements insulated from each other and from the tube except at the measuring junction.

complete immersion thermometer, *n.*—a liquid-in-glass thermometer designed to indicate temperatures correctly when the entire thermometer is exposed to the temperature being measured. (Compare *total immersion thermometer.*)

connecting wire (metal-sheathed heater), *n.*—a conductor used to connect the heater resistance wire to the power supply terminals.

connection head, *n.*—a housing enclosing a terminal block for an electrical temperature-sensing device and usually provided with threaded openings for attachment to a protecting tube and for attachment of conduit.

contraction chamber (liquid-in-glass thermometer), *n.*—an enlargement of the bore of the stem which serves to reduce its length, or to prevent contraction of the liquid column into the bulb.

defining fixed points, *n.*—the reproducible temperatures upon which the International Practical Temperature Scale is based.

degree, *n.*—the unit of a temperature scale.

diameter, (liquid-in-glass thermometer), *n.*—the diameter as measured with a ring gage.

electromotive force (emf), *n.*—the electrical potential difference which produces or tends to produce an electric current.

expansion chamber (liquid-in-glass thermometer), *n.*—an enlargement at the top of the capillary to provide protection in case of overheating.

extension wire, *n.*—a pair of wires having such temperature-emf characteristics relative to the thermocouple with which the wires are intended to be used that, when properly connected to the thermocouple, the reference junction is transferred to the other end of the wires.

Fahrenheit, *n.*—the designation of the degree and the temperature scale used commonly in public life and engineering circles in English-speaking countries. Related to the International Practical Temperature Scale by means of the equation:

$$t_F = 9/5\, t_C + 32$$

fixed point, *n.*—a reproducible temperature of equilibrium between different phases of a material. (See *defining fixed points* and *secondary reference points.*)

freezing point, *n.*—the fixed point between the solid and liquid phases of a material when approached from the liquid phase under a pressure of 1 standard atm (101325 N/m^2). For a pure material this is also the melting point.

heater, metal sheathed, electrical resistance, *n.*—one consisting of resistance wire or wires, with or without connecting wires, embedded in ceramic insulation compacted within a metal protecting tube.

ice point, *n.*—the fixed point between ice and air-saturated water under a pressure of 1 standard atm (101325 N/m^2). This temperature is 0°C on the International Practical Temperature Scale.

International Practical Temperature Scale of 1948 (IPTS-48), *n.*—the temperature scale adopted by the 11th General Conference on Weights and Measures in 1960. Replaced in 1968 by the International Practical Temperature Scale of 1968.

International Practical Temperature Scale of 1968 (IPTS-68), *n.*—the temperature scale, which through adoption by the 13th General Conference on Weights and Measures in 1968, is defined in terms of fixed and reproducible equilibrium temperatures (defining fixed points) to which numerical values have been assigned, and equations establishing the relation between temperature and the indications of sensin instruments calibrated by means of the values assigned to the defining fixed points.

kelvin, *n.*—the designation of the thermodynamic temperature scale and the degree on this scale. This kelvin scale was defined by the Tenth General Conference on Weights and Measures in 1954 by assigning the temperature of 273.16°K to the triple point of water. Also the degree on the International Practical Kelvin Temperature Scale.

liquid-in-glass thermometer, *n.*—a temperature-measuring instrument whose indications are based on the temperature coefficient of expansion of a liquid relative to that of its containing glass envelope.

lower range-value, *n.*—the lowest quantity that an instrument is adjusted to measure.

measuring junction, *n.*—that junction of a thermocouple which is subjected to the temperature to be measured.

melting point, *n.*—the fixed point between the solid and liquid phases of a material when approached from the solid phase under a pressure of 1 standard atm (101325 N/m^2). For a pure material this is also the freezing point.

partial immersion thermometer, *n.*—a liquid-in-glass thermometer designed to indicate temperatures correctly when the bulb and a specified part of the stem are exposed to the temperature being measured.

Peltier coefficient, *n.*—the reversible heat which is absorbed or evolved at a thermocouple junction when unit current passes in unit time. Synonymous with *Peltier emf.*

Peltier emf, *n.*—synonymous with *Peltier coefficient.*

platinum 27, *n.*—the platinum standard to which the National Bureau of Standards referred thermoelectric measurements prior to 1973.

platinum 67, *n.*—the platinum standard used by the National Bureau of Standards after 1972 as the reference to which thermoelectric measurements are referred.

potentiometer, Group A, *n.*—a laboratory high-precision type potentiometer having limits of error of approximately 0.2 μV at 1000 μV, and 5 μV or less at 50 000 μV.

potentiometer, Group B, *n.*—a laboratory precision type potentiometer having limits of error of approximately 1 μV at 1000 μV and 12 μV or less at 50 000 μV.

primary standard resistance thermometer, *n.*—a resistance thermometer that has had its temperature-resistance relationship determined in accordance with methods described in the text establishing the International Practical Temperature Scale.

primary standard thermocouple, *n.*—a thermocouple that has had its temperature-emf relationship determined in accordance with methods described in the text establishing the International Practical Temperature Scale.

protecting tube, *n.*—a tube designed to enclose a temperature-sensing device and protect it from the deleterious effects of the environment. It may provide for attachment to a connection head but is not primarily designed for pressure-tight attachment to a vessel.

range, *n.*—the region between the limits within which a quantity is measured. It is expressed by stating the lower and upper range-values.

reference junction, *n.*—that junction of a thermocouple which is at a known temperature.

reference point (liquid-in-glass thermometer), *n.*—a temperature at which a thermometer is checked for changes in bulb volume.

refractory metal thermocouple, *n.*—a thermocouple whose thermoelements have melting points above that of 60 percent platinum, 40 percent rhodium, 1935°C (3515°F).

resistance, insulation (sheathed thermocouple wire), *n.*—the measured resistance between wires or between wires and sheath multiplied by the length of the wire expressed in megohms (or ohms) per foot (or meter) of length. (NOTE: The resistance varies inversely with the length.)

saddle (liquid-in-glass thermometer), *n.*—the bottom support of the enclosed scale of an enclosed-scale thermometer.

secondary reference points, *n.*—reproducible temperatures (other than the *defining fixed points*) listed in the text establishing the International Practical Temperature Scale as being useful for calibration purposes.

secondary standard thermocouple, *n.*—a thermocouple that has had its temperature-emf relationship determined by reference to a primary standard of temperature.

Seebeck coefficient, *n.*—the rate of change of thermal emf with temperature at a given temperature. Normally expressed as emf per unit of temperature. Synonymous with *thermoelectric power.*

Seebeck emf, *n.*—the net emf set up in a thermocouple under condition of zero current. It represents the algebraic sum of the Peltier and Thomson emf. Synonymous with *thermal emf.*

setting temperature (liquid-in-glass thermometer), *n.*—the temperature which causes a reading of zero on the main scale of an adjustable-range thermometer.

sheath (enclosed-scale thermometer), *n.*—the cylindrical glass envelope which encloses the scale and capillary tube.

sheathed thermocouple, *n.*—a thermocouple having its thermoelements, and sometimes its measuring junction, embedded in ceramic insulation compacted within a metal protecting tube.

sheathed thermocouple material, *n.*—one or more pairs of thermoelements (without measuring junction(s)) embedded in ceramic insulation compacted within a metal protecting tube.

sheathed thermoelement, *n.*—a thermoelement embedded in ceramic insulation compacted within a metal protecting tube.

span, *n.*—the algebraic difference between the upper and lower range-values.

standard thermoelement, *n.*—a thermoelement that has been calibrated with reference to platinum 27 or platinum 67.

stem (liquid-in-glass thermometer), *n.*—the capillary tube through which the meniscus of the liquid moves with change of temperature.

temperature interval (liquid-in-glass thermometer), *n.*—a specified portion of the range of a thermometer.

test thermocouple, *n.*—a thermocouple that is to have its temperature-emf relationship determined by reference to a temperature standard.

test thermoelement, *n.*—a thermoelement that is to be calibrated with reference to platinum 27 or platinum 67 by comparing its thermal emf with that of a standard thermoelement.

thermal electromotive force (thermal emf), *n.*—the net emf set up in a thermocouple under conditions of zero current. Synonymous with *Seebeck emf.*

thermocouple, *n.*—two dissimilar thermoelements so joined as to produce a thermal emf when the junctions are at different temperatures.

thermocouple assembly, *n.*—an assembly consisting of a thermocouple element and one or more associated parts such as terminal block, connection head, and protecting tube.

thermocouple element, *n.*—a pair of bare or insulated thermoelements joined at one end to form a measuring junction and intended for use as a thermocouple or as part of a thermocouple assembly.

thermocouple, Type E, B, J, K, R, S, or T, *n.*—a thermocouple having an emf-temperature relationship corresponding to the appropriate letter-designated table in ASTM Standard E 230, Temperature-Electromotive Force (EMF) Tables for Thermocouples, within the limits of error specified in that Standard.

thermoelectric power, *n.*—the rate of change of thermal emf with temperature at a given temperature. Synonymous with *Seebeck coefficient.* Normally expressed as emf per unit of temperature.

thermoelectric pyrometer, *n.*—an instrument that senses the output of a thermocouple and converts it to equivalent temperature units.

thermoelement, *n.*—one of the two dissimilar electrical conductors comprising a thermocouple.

thermopile, *n.*—a number of thermocouples connected in series, arranged so that alternate junctions are at the reference temperature and at the measured temperature, to increase the output for a given temperature difference between reference and measuring junctions.

thermowell, *n.*—a closed end reentrant tube designed for the insertion of a temperature-sensing element, and provided with means for pressure-tight attachment to a vessel.

Thomson coefficient, *n.*—the rate at which heat is absorbed or evolved reversibly in a thermoelement, per unit temperature difference per unit current.

Thomson emf, *n.*—the product of the Thomson coefficient and the temperature difference across a thermoelement.

total immersion thermometer, *n.*—a liquid-in-glass thermometer designed to indicate temperatures correctly when just that portion of the thermometer containing the liquid is exposed to the temperature being measured. (Compare *complete immersion thermometer*).

total length (liquid-in-glass thermometer), *n.*—the overall length including any special finish at the top.

triple point (water), *n.*—the temperature of equilibrium between ice, water, and water vapor. This temperature is +0.01°C on the International Practical Temperature Scale of 1948.

upper range-value, *n.*—the highest quantity that an instrument is adjusted to measure.

verification (liquid-in-glass thermometer), *n.*—the process of testing a thermometer for compliance with specifications.

verification temperatures (liquid-in-glass thermometer), *n.*—the specified temperatures at which thermometers are tested for compliance with scale error limits.

working standard thermocouple, *n.*—a thermocouple that has had its temperature-emf relationship determined by reference to a secondary standard of temperature.
